A recent addition for the cultivation of yeast from clinical specimens is the selective and differential medium called CHROMagar *Candida* (CHROMagar Company, Paris, France). This medium uses a chromogenic mixture for the detection and differentiation of major *Candida* spp. by colony color: *C. albicans*, green; *Candida glabrata*, velvet; *Candida krusei*, rose; and *Candida tropicalis*, steel blue. Numerous reports have shown this medium to be useful for the isolation and presumptive identification of yeasts and to optimize detection of mixed cultures in clinical specimens (Perry, 2007; Ozcan, 2009; Raut, 2009).

Inoculation and Incubation

Processing of clinical specimens for fungal detection requires careful handling because some processes commonly used to prepare specimens for bacterial culture may be too disruptive for the fungal organism (e.g., grinding in a homogenizer). Inoculation of scrapings or curettings onto and into the agar at multiple points on the agar surface is a reliable technique for culture. Tissue should be teased or minced, after which the fragments are similarly inoculated.

Plates or tubes should be incubated in ambient air at 25°–30° C. A controlled temperature incubator is essential. Although it is not necessary to incubate parallel plates or tubes at 37° C for recovery of the yeast phase of dimorphic fungi, in cases where strong suspicion of endemic fungi occurs, incubation at this temperature should be considered. Most fungi grow within a 2-week incubation period, and among commonly isolated fungi, only the dimorphic fungi such as *H. capsulatum* and *B. dermatitidis* are frequently detected after 14 days of incubation. General recommendations for incubation times are as follows: 7 days to detect the presence of yeast in mouth, throat, or vaginal specimens; 21 days to detect fungal pathogens in tissues and sterile body fluids other than blood; and up to 28 days for respiratory, bone marrow, and blood pathogens, and for specimens in which a dimorphic fungus is suspected. In general, all other specimens should be incubated for up to 14 days. Plates should be examined at least twice during the first week, when rapidly growing isolates may appear, and at least weekly thereafter.

Blood Cultures

Recovery of fungi from blood requires special attention and can be accomplished by inoculating broth media by using a biphasic broth-agar system or by using the lysis centrifugation technique (Isolator System; Wampole, Cranbury, N.J.). The lysis centrifugation method consists of a tube containing a solution that lyses erythrocytes and leukocytes (Cockerill, 1996; Reimer, 1997). After the blood is drawn into the vacutainer tube, the lysed contents, including any microbes, are centrifuged into a pellet, which is removed and plated onto the surface of agar plates. Although the Isolator System is considered a sensitive method for detection of fungemia, this system is also more susceptible to contamination through handling of the tube or by airborne spores that settle onto the agar plates during processing (Reimer, 1997). Because a high percentage of fungemias are caused by yeast, continuous-read-automated-culture methods have become the mainstay for fungal detection. Two systems commonly used are the BACTEC system (Becton Dickinson Diagnostic Systems, Sparks, Md.) and the BacT-Alert system (Organon Teknika, Durham, N.C.). Because yeasts are aerobic organisms, aerobic culture bottles are used for detection. Two systems in combination (i.e., BACTEC MYCO/F Lytic blood culture bottles and the Isolator System) have been shown to optimize the recovery of fungi from blood (Vetter, 2001).

GROWTH RATE

The rate of growth of fungal isolates provides a useful clue to diagnostic possibilities. In general, the pathogenic dimorphic and dematiaceous fungi grow slower, requiring a week or longer for colonies to appear. Rapidly growing mould colonies that appear after prolonged incubation on mycologic media should be questioned as possible contaminants. However, many exceptions to this generalization have been noted, and laboratorians need to be aware that fungi such as the *Coccidioides* spp. may grow quickly on nonfungal medium. Protocols on how to handle fungal growth on bacterial cultures are needed to prevent unnecessary exposure of laboratory personnel to highly infectious fungal pathogens that may be encountered.

GROWTH TEMPERATURE

Most moulds grow best at 25°–30° C. Most yeasts, however, grow well at 35°–37° C and are often recovered first on enriched blood agar plates in the bacteriology laboratory. In some cases, growth of a fungus at elevated temperatures is useful for differentiation of species.

MORPHOLOGIC IDENTIFICATION

Some of the morphologic studies necessary for the identification of fungal isolates can be accomplished with colonies from the original isolation plates. However, it is often necessary to transfer portions of colonies to new or different media (subculture) to demonstrate diagnostic structures. Table 61-3 describes some of the media commonly used for the identification of fungal species. One of the media more commonly used is cornmeal agar supplemented with Tween 80 (CM-T80) for the visualization of yeast morphology. Recognition of pseudohyphae with chlamydoconidia on this medium is considered confirmatory for *C. albicans/dubliniensis*. Other morphologic features can help to categorize yeasts into groups to facilitate separation into species. Although biochemical tests are important for identifying yeast isolates, complementation of these with a morphologic examination provides an important check on the biochemical information, especially if a commercial identification system has been used.

Figure 61-16 Germ tubes have extended from the yeast cells of *Candida albicans*. No constriction is seen at the junction of yeast cell and germ tube. The walls of the germ tube are parallel. The yeast was incubated for 2 hours at 37° C in serum. (Gram stain, ×400.)

TABLE 61-7
Serum Germ Tube Test

1. Aseptically transfer several colonies of yeast to a 12 × 75-mm test tube containing approximately 0.5 mL of serum (human, fetal calf, bovine, or rabbit).
2. Incubate the tube at 35° C for up to 3 hours.
3. Place one drop of the mixture on a clean glass slide and coverslip.
4. Examine under high dry (400×) magnification and reduced light for the presence of germ tubes.

TABLE 61-8
Yeast Morphology Test

1. Streak a light inoculum of yeast onto a section of a cornmeal agar containing Tween 80.
2. Coverslip the area inoculated.
3. Incubate at 25°–30° C for 24–72 hours.
4. Observe under 100× and 400× magnification using reduced light for morphologic structures.

Yeast Morphology

The germ tube test is an important initial step in the identification of yeast isolates. Germ tubes, which are elongated, finger-like extensions from a yeast cell, represent the beginnings of a true hypha (Fig. 61-16). This structure can be differentiated from pseudohyphae by the lack of a constriction at the junction of germ tube and yeast cell and by the parallel cell walls in the germ tube. True germ tubes are formed by both *C. albicans* and *Candida dubliniensis* after growth in serum at 37° C for no longer than 4 hours. In many laboratories with well-trained staff, the germ tube in combination with results of morphology on CM-T80 agar is considered confirmatory for the identification of *C. albicans/dubliniensis*.

The traditional germ tube test involves inoculation of a tube of serum (Table 61-7). After observation of the isolate for germ tubes at 37° C, incubation is continued for subsequent study of hyphal morphology and chlamydoconidia formation at 25°–30° C. Thus, all the information necessary for rapid identification can be collected in one procedure. The CM-T80 agar may be substituted, but regardless of the medium used, incubation conditions must be carefully controlled and the test monitored with controls to achieve good results. The traditional Dalmau technique for demonstration of chlamydoconidia on cornmeal agar is detailed in Table 61-8 (McGinnis, 1980).

Mould Morphology

The simplest method for examination of moulds is the cellophane tape mount, using clear tape and staining with lactophenol cotton (aniline) blue

TABLE 61-9
Rapid Testing for Presumptive Identification of Yeast Following Colonial Formation

Urease production	<i>Cryptococcus neoformans</i>
Germ tube production	<i>Candida albicans/dubliniensis</i>
Pseudohyphae present	<i>Candida</i> species
Chlamydoconidia present	<i>Candida albicans/dubliniensis</i>
Lipid growth requirement	<i>Malassezia furfur</i> species complex
Red colonial pigmentation	<i>Rhodotorula</i> species
Ascospore formation	<i>Saccharomyces cerevisiae</i>
Trehalose assimilation	<i>Candida glabrata</i>

(LPCB) stain. If diagnostic structures are not observed, incubation can be continued and the process repeated. The traditional method used in observing mould morphology is to tease the mycelium apart with inoculating needles and examine the teased hyphae with LPCB stain.

Occasionally, a slide culture may be necessary to preserve easily disrupted conidial structures in their original relationships. The classic approach involves cutting a square of an appropriate agar medium (usually Sabouraud dextrose or potato dextrose agar), which is suspended on a glass slide and overlaid with a coverslip. The slide is supported by glass rods in a Petri dish, to which sterile water is added for maintenance of humidity. The coverslip subsequently can be removed after a few days' incubation, placed in a drop of LPCB, and observed for undisturbed reproductive structures.

When a mould isolate is suspected of being a dimorphic fungus (e.g., growth on cycloheximide-containing medium), a slide culture should not be performed, and a cellophane tape test or teased preparation should be examined only after the preparation has been sealed in a biosafety cabinet certified for use. Lactophenol cotton blue is fungicidal, but sealing the coverslip with nail polish before observation provides additional protection. Alternatively, the culture may be flooded with 10% formalin (4% formaldehyde solution) and incubated at room temperature overnight before the mould is manipulated.

BIOCHEMICAL IDENTIFICATION

Biochemical tests are at the heart of identification schemes for yeast and occasionally are useful for identification of moulds. A number of rapid tests for the presumptive identification of yeasts are described in Table 61-9.

Biochemical characterization of yeasts may be accomplished by study of fermentation or assimilation patterns. Assimilation testing, which is used more extensively in the laboratory, assesses the ability of an isolate to use a carbohydrate as the sole source of carbon needed for growth, or of nitrate as the sole source of nitrogen. Numerous commercial identification systems with varying incubation times from 4–72 hours are available and have become the mainstay for yeast identification. These systems include the API 20C AUX system and the VITEK 2 System (both from bio-Mérieux, Hazelwood, Mo.), the MicroScan system (Siemens Healthcare Diagnostics, West Sacramento, Calif.), the UniYeastTek system (Remel Laboratories, Lenexa, Kan.), and the RapID Yeast Plus System (Innovative Diagnostics Systems, Norcross, Ga.). All of these systems perform well, as judged by reports in the literature and by proficiency testing surveys of the College of American Pathologists (Fenn, 1994; Riddle, 1994; Crist, 1996; Bernal, 1998; Espinel-Ingroff, 1998; Ramani, 1998; Hata, 2007). However, because no one system is known to be 100% accurate for identification of yeast species, a combination of methods should be considered, especially when rare species are recognized (Pincus, 2007).

In addition to fermentation and assimilation studies, stimulation of growth by biochemical compounds is a secondary test used in the differentiation of certain *Trichophyton* spp. (Weitzman, 1983). Inclusion of inositol and thiamine in various combinations into agar media (*Trichophyton* agars) allows assessment of growth-stimulating properties. The endpoint of the test, relative growth in comparison with a basal medium, is subjective, and both positive and negative controls should be included.

The test for urease production in cryptococci is of general utility in the clinical laboratory to differentiate these species from *Candida* spp., particularly in respiratory specimens (Canteros, 1996). *C. neoformans* is a pulmonary and systemic pathogen, whereas *Candida* spp. are frequent inhabitants of the upper airways but uncommon causes of primary pneumonia. Urease, however, may be produced by other nonpathogenic species of *Cryptococcus*, by *Rhodotorula* spp., and by some isolates of *Trichosporon* spp. and *C. krusei*.

Urease production can be tested by inoculation of the yeast isolate onto a slant of Christensen urea agar or into urea broth. Alkalinization of the medium after production of NH_3 by urea-splitting organisms is detected by inclusion of a pH indicator in the system. Colonies that have macroscopically visible pseudohyphae (feet) or that grow on cycloheximide-containing agar need not be tested, because *Cryptococcus* does not produce pseudohyphae in vitro and does not grow in the presence of cycloheximide.

Production of urease also is useful to differentiate the mould *Trichophyton mentagrophytes* (urease positive) from *T. rubrum* (urease negative). The isolate should be subcultured to a slant of Christensen urea agar and incubated at 25°–30° C for at least 3 days.

Although commercial biochemical tests are fairly reliable for the identification of yeast, confirmation of the identification by examination of yeast morphology on agar media should also be considered. Using morphologic observation as a check can save embarrassing mistakes that would be made if automated or packaged systems were trusted implicitly.

SEROLOGIC IDENTIFICATION

Immunologic tests are available for detection of both antigens and antibodies to selected fungal pathogens; these assays have been shown to be of value for diagnosing infection and for monitoring therapeutic response (Wheat, 2006; Lau, 2009). Although antibody testing for fungal pathogens has historically been used in some instances for diagnostics, these tests are no longer widely accepted owing to low sensitivity and specificity. In addition, the benefit of antibody detection remains unclear if patients are under immune suppression or are heavily colonized but not infected (Einsele, 2008).

Tests to detect fungal antigens or metabolic byproducts in serum or other body fluids on the other hand have been shown to be more useful for the diagnosis and management of fungal disease. Multiple antigen detection methods are used for the specific diagnosis of a variety of diseases, including aspergillosis, cryptococcosis, histoplasmosis, blastomycosis, paracoccidioidomycosis, and penicilliosis caused by *Penicillium marneffii*. One of the more widely used antigen detection tests is the cryptococcal antigen test for the diagnosis of cryptococcal infection (Huston, 2009). The polysaccharide capsule of *C. neoformans* becomes dissolved in the serum and cerebrospinal fluid and can be detected by the latex-based agglutination test or the enzyme immunoassay. Although these tests have limitations, they have been shown to be helpful in monitoring therapy over time through quantitative measure of the titer of *Cryptococcus* polysaccharide in cerebrospinal fluid (Babady, 2009).

Antigen detection for the diagnosis of histoplasmosis has also proved useful when serum, urine, or bronchoalveolar lavage fluid is tested (Wheat, 2007, 2009b). As a screening test, detection of *Histoplasma* antigen plays a special role in the diagnosis of disseminated and diffuse acute pulmonary histoplasmosis. Studies have shown that *H. capsulatum*-specific antigen can be detected in the urine of 90% of patients with disseminated infection and 80% of patients with acute histoplasmosis (Wheat, 2003b). Detection of antigen in bronchoalveolar lavage has also proved useful for the diagnosis of histoplasmosis, especially when the results of testing are combined with those obtained from cytopathology (Hage, 2009).

A Food and Drug Administration (FDA)-approved enzyme-linked immunosorbent assay (ELISA; Platelia *Aspergillus* ELISA; Bio-Rad, Marnes-la-Coquette, France) is now available for the detection of galactomannan antigenemia for the rapid diagnosis of invasive aspergillosis (Del Bono, 2008; Leeflang, 2008; Wheat, 2008). This test has been shown to be more sensitive than culture when multiple serum samples from high-risk patients are tested; however, limitations of the assay need to be considered. For instance, treatment with piperacillin-tazobactam or amoxicillin-clavulanate has been noted to cause false-positive results, which are reported more commonly in children than in adults. A recent study showed that a biweekly serum galactomannan ELISA was a highly specific diagnostic tool for the detection of invasive aspergillosis in patients undergoing a hematopoietic stem cell transplant (Foy, 2007). Others have shown that when a lower threshold of sensitivity is used, the test has a higher level of performance and the numbers of patients who are unnecessarily treated or referred for additional follow-up are decreased (Del Bono, 2008; Leeflang, 2008). The usefulness of this test for the detection of *Aspergillus* galactomannan antigen in bronchoalveolar lavage fluid in transplant patients has also been shown (Clancy, 2007; Husain, 2007).

A commercial test to detect (1-3)-beta-D-glucan (BG) has become available for the diagnosis of invasive fungal infection (Fungitell Assay;

Associates of Cape Cod, Inc., East Falmouth, Mass.) (Pickering, 2005). This antigen is present in the cell walls of most pathogenic fungi (including *P. jirovecii*) with some notable exceptions such as *C. neoformans* and the Zygomycetes. Published studies have shown that BG may be useful as a screening tool for surveillance of invasive aspergillosis, as well as other invasive fungal diseases in populations at risk (Marty, 2009). Although false-positive results appear to limit the use of this test, additional studies are needed to further define its diagnostic utility (Senn, 2008).

Skin tests have been used for the epidemiologic study of some infections, but they have limited utility for diagnostic purposes.

MOLECULAR IDENTIFICATION

Recent advances in molecular testing for the identification of fungal pathogens have had a significant impact on the diagnosis of fungal infections (Balajee, 2007b; Borman, 2008; Kuba, 2008; Lau, 2009). Numerous reviews have addressed these changes, and the general consensus is that approaches to species identification of many fungi today should include both morphologic and molecular testing methods (Balajee, 2007b).

One of the greatest needs for clinical medicine is the development of a rapid and reliable detection method that can identify fungal pathogens directly from clinical specimens. This need reflects not only the inability of current laboratory tests to provide a timely result, but also the fact that fungal infections in immunocompromised patients usually appear suddenly, progress rapidly, and are often fatal unless treatment is started earlier in the course of infection.

Numerous molecular assays using both probe-based and amplification-based technologies have been developed for the identification of fungal pathogens. With any of these approaches, an initial goal has been to define the genetic loci within the genome for use as the molecular target. Although multiple areas within the fungal genome have been evaluated, the targeted areas most commonly used are those found within the ribosomal DNA (rDNA) gene complex (Table 61-10) (Iwen, 2002). This section of the genome includes variable nucleotide sequence areas within the 18S gene and the 28S gene, as well as DNA sequence areas of the intervening internal transcribed spacer (ITS) regions called ITS1 and ITS2. Sequence homology within the rDNA genes and differences within the spacer regions are used as the genetic basis for the organization of fungi into taxonomic groups (Bastola, 2004). Recently, the ITS regions have been proposed as the prime fungal barcode for fungal species identification by the International Subcommission on Fungal Barcoding (<http://www.allfungi.com/its-barcode.php>).

Probe-based assays are commercially available and are commonly used in the mycology laboratory for the identification of *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides* spp. from culture (Accuprobe, San Diego). Another probe-based method called the peptide nucleic acid fluorescence in situ hybridization (PNA-FISH) assay was recently developed and has become commercially available for the qualitative identification of *C. albicans* in blood cultures (Wilson, 2005; Forrest, 2006). This assay uses

TABLE 61-10

Genetic Targets Utilized for the Detection and Identification of Fungal Pathogens

Gene target	Fungal species
Actin	<i>Candida albicans</i>
β-Tubulin	<i>Aspergillus</i> species
Calmodulin	<i>Aspergillus</i> species, <i>Fusarium</i> species
Chitin synthetase	Dermatophyte species
Cytochrome b	<i>Candida albicans</i>
Dihydrofolate reductase	<i>Pneumocystis jirovecii</i> (carinii)
EF-1	<i>Fusarium</i> species
Mitochondrial rRNA	<i>Pneumocystis jirovecii</i>
rDNA complex (5S gene)	<i>Candida albicans</i> , <i>Pneumocystis jirovecii</i>
rDNA complex (18S gene)	Multiple
rDNA complex (28S gene)	<i>Aspergillus</i> species, <i>Candida</i> species
rDNA complex (IGS regions)	<i>Aspergillus fumigatus</i>
rDNA complex (ITS regions)	Multiple

IGS, Intergenic spacer region; ITS, internal transcribed spacer region; rDNA, ribosomal deoxyribonucleic acid.

a fluorescent-labeled peptide nucleic acid probe that targets the species-specific ribosomal RNA of *C. albicans*. The sensitivity and specificity of this test have been shown to be >99%, and the impact of rapid identification of *C. albicans* in the blood can be seen in the significant reduction in the empirical use of antifungals (Alexander, 2006; Forrest, 2007). Incorporating the *C. albicans* PNA-FISH test as part of the initial identification algorithm for yeast recovered from blood can result in substantial savings for hospitals. Major drawbacks to this assay include the high costs of reagents and the changes in work flow required to incorporate testing in the laboratory.

Numerous amplification methods using both non-sequenced-based and sequence-based approaches for analysis have been applied in identification of fungi. Most of the sequence-based analysis methods have used conventional polymerase chain reaction (PCR) with universal primers to target sequences within the 28S rDNA gene, the 18S rDNA gene, or the ITS1-5.8S-ITS2 target areas. Additionally, Vollmer (2008) used a real-time PCR approach with sequencing as the analysis method.

The availability of a nucleotide-based sequence database that has the breadth of phylogenetics and the taxonomic accuracy needed to identify fungal species is desirable for sequence analysis alignment. The largest database currently used for sequence-based identification is the publicly available GenBank database (National Center for Biotechnology Information, Washington, DC). Unfortunately, because this is an open source database, reports suggest that up to 20% of the sequenced entries listed for fungi are associated with erroneously identified species (Balajee, 2007b). Additionally, there is a need for sequences from a variety of genomic targets in the database that is phylogenetically represented with accurate species identification. Although multiple locus sequencing and alignment comparisons have been done using a variety of fungal species, additional studies using sequence comparison analysis are needed to determine the optimal target or targets for fungal identification. Multiple target evaluations for the identification of aspergilli and fusaria have been done and show this approach to be valid for identification purposes (O'Donnell, 2007; Peterson, 2008).

Non-sequenced-based approaches have also been applied as a means to decrease the time needed for detection of fungi in clinical material. Real-time PCR using the 28S rDNA target and the cytochrome b target have been done and show promise in direct testing applications (Hata, 2008; Kasai, 2008; Vollmer, 2008). More recent molecular technologies that do not require sequencing to evaluate fungal species have included application of PCR to microarray analysis and to other hybridization-based probe technologies. A sensitive and specific DNA microarray combining multiplex PCR and consecutive DNA chip hybridization to detect fungal genomic DNA in clinical samples has shown promise (Spiess, 2007). This assay involved primer sets and probes used to amplify and detect 14 clinically relevant fungal species. This proof-of-concept evaluation showed that fungal pathogens could be detected and identified from clinical samples, which ultimately would improve the diagnosis of invasive fungal infections. The Luminex xMAP hybridization technology for species-specific identification of a wide range of clinically relevant fungal pathogens has also been shown to be applicable to the identification of fungal species both from culture and from clinical material (Landlinger, 2009).

SUSCEPTIBILITY TESTING

For many years, few antifungal chemotherapeutic agents were available, with amphotericin B virtually the only agent effective against most systemic fungal pathogens. Although this potent antifungal agent was frequently toxic, resistance to therapy was rare. With the recent introduction of new antifungal agents and with the widespread use of antifungal prophylaxis, the epidemiology of invasive fungal infections has changed, with non-*albicans* *Candida*, non-*fumigatus* *Aspergillus*, and moulds other than *Aspergillus* becoming more common as causes of invasive disease (Lai, 2008; Rodriguez-Tudela, 2008; Baddley, 2009; Naggie, 2009). These emerging fungi are resistant to or less susceptible than other fungi to standard antifungal agents and thus become more difficult to treat. Furthermore, although the predictability of innate resistance frequently means that species identification is often sufficient to alert the clinician to the likelihood of in vitro and often associated in vivo resistance, the emergence of resistance in a previously susceptible strain during the course of treatment has become more problematic (Arikan, 2007; Johnson, 2008).

The Clinical and Laboratory Standards Institute (CLSI; formerly called the National Committee for Clinical Laboratory Standards) has developed reference macrodilution and microdilution broth methods for

antifungal susceptibility testing of yeasts (CLSI document M27-A3) and moulds (CLSI document M38-A2) (Clinical and Laboratory Standards Institute, 2008b, 2008c). It has also developed a method for antifungal disk diffusion susceptibility testing of yeasts (CLSI document M44-A2) and a method for antifungal disk diffusion susceptibility testing of nondermatophyte filamentous fungi (CLSI M51-A) (Clinical and Laboratory Standards Institute, 2010, 2009b).

The CLSI M27-A3 document has been approved for the testing of *Candida* spp. and *C. neoformans*. Interpretive breakpoints are available for amphotericin B, fluconazole, 5-flucytosine, itraconazole, voriconazole, posaconazole, and the echinocandins, although breakpoints are based largely on historical data and partially on drug pharmacokinetics. Additionally, no data currently exist to indicate a correlation between minimum inhibitory concentration (MIC) and outcomes of treatment with various agents; thus, the results of testing should be considered with caution.

The CLSI M38-A2 method has been developed for in vitro susceptibility testing of the more common rapidly growing filamentous fungi that can cause invasive disease. Organisms included in this document for evaluation are *Aspergillus* spp., *Fusarium* spp., *Rhizopus oryzae* (*R. arrhizus*), *Pseudallescheria boydii*, *Scedosporium prolificans*, and the mycelial form of *Sporothrix schenckii*, as well as the dermatophytes (*Epidermophyton*, *Microsporum*, and *Trichophyton*). This document is a reference standard developed through a consensus process to facilitate agreement among laboratorians in measuring the susceptibility of moulds to antifungal agents. The clinical relevance of testing filamentous fungi remains uncertain, and breakpoints with proven relevance have yet to be identified or approved by CLSI or any regulatory agency.

Because both reference methods are time consuming to perform, simplified alternatives to these methods have been assessed to include the disk diffusion method, the Etest agar-gradient MIC method (bioMérieux, Inc., Durham, NC), the Sensititre YeastOne method (TREK Diagnostic Systems, Inc., Cleveland, Ohio), and the VITEK 2 method (bioMérieux, Durham, N.C.; Pfaller, 2007b). The disk diffusion method has only recently been approved for the testing of yeast, and studies have shown that results obtained from testing using this method are comparable with results obtained with the CLSI microdilution broth method (Diekema, 2007; Messer, 2007; Pfaller, 2007, 2009).

The Etest uses a plastic strip that contains a predefined stable gradient of 15 antifungal concentrations to determine the on-scale MIC of the antifungal agent tested. These strips are commercially available for amphotericin B, anidulafungin, caspofungin, fluconazole, 5-flucytosine, itraconazole, ketoconazole, posaconazole, and voriconazole. Studies have shown the Etest strips to be as reliable as the CLSI standard for in vitro susceptibility testing of both moulds and yeast (Pfaller, 2003; Alexander, 2007).

The YeastOne method uses a dried colorimetric microdilution panel in a microtiter format for antifungal testing. This method is the only FDA-approved kit method for in vitro diagnostic use in testing yeast susceptibility to fluconazole, itraconazole, 5-flucytosine, and voriconazole. Panels are also available for research use only in testing antifungal susceptibility to amphotericin B, anidulafungin, caspofungin, micafungin, and posaconazole. This testing platform has been shown to be dependable for the testing of both moulds and yeast (Castro, 2004; Pfaller, 2008). A modification of this method demonstrated that direct antifungal susceptibility testing of positive *Candida* blood cultures by the YeastOne assay produced an accurate antifungal MIC determination and saved on average 24 hours to the availability of results compared with the time required for the standard procedures traditionally used (Avolio, 2009).

Although the key elements involved in selecting an appropriate antifungal agent include the type of patient (e.g., solid organ or stem cell transplant), the severity of immunosuppression, a history of prolonged exposure to antifungal drugs, and knowledge of the genera and species of the infecting pathogen, susceptibility testing may be warranted in some circumstances, including the following: (1) as part of periodic surveys that establish antibiograms for isolates in an institution; (2) to help in the management of refractory oropharyngeal candidiasis in patients with apparent therapeutic failure; and (3) to aid in the management of invasive candidiasis when the use of azole antifungal agents is uncertain (Cornely, 2008). Also, scant data are available regarding the clinical implications of in vitro susceptibility testing in many cases, and the refractile nature of many fungal pathogens to antifungal therapy makes susceptibility testing an option that needs to be considered. For instance, reports now show that resistance has emerged during treatment of *Aspergillus* infections, thus highlighting the potential need for in vitro susceptibility testing under this circumstance (Lass-Florl, 2008).

CANDIDIASIS, CRYPTOCOCCOSIS, AND OTHER INFECTIONS CAUSED BY YEAST

THE GENUS *CANDIDA*

Candida spp. are the most commonly recognized yeast pathogens; with increased use of immunosuppressive therapies, use of broad-spectrum antibiotics, and the aging of the population, they have assumed a prominent place among nosocomial pathogens (Pfaller, 2007; Guery, 2009; Horn, 2009). These species are currently the fourth most common cause of hospital-acquired bloodstream infection in the United States and rank third among causes of bloodstream infection in the intensive care unit (Mean, 2008; Lewis, 2009). Although *C. albicans* accounts for about 50% of invasive infections caused by *Candida* spp., the non-*albicans* *Candida* spp. have emerged as more common causes of disease (Lewis, 2009; Rueping, 2009). In a recent multicenter evaluation of patients with candidemia (Prospective Antifungal Therapy Alliance database), *C. albicans* accounted for 45.6% of cases, followed by *Candida glabrata* (26.0%), *Candida parapsilosis* (15.7%), *Candida tropicalis* (8.1%), *Candida krusei* (2.5%), and *Candida lusitanae* (0.8%) (Horn, 2009).

Risk Factors

Candida infections are limited in extent and severity, depending on the immune status of the host. Because *Candida* spp. are a part of the normal flora in the gastrointestinal (GI) tract, mucous membranes, and skin, infections generally occur as the result of an opportunity. For instance, the use of broad-spectrum antibacterial therapy upsets the balance of colonizing flora on the mucous membranes of the oral cavity and the GI tract by eliminating the predominant competing bacterial flora, thus allowing overgrowth of yeast (Pfaller, 2007; Lewis, 2009).

Invasive disease by *Candida* spp. develops when host defenses are compromised. Diabetes, immunosuppressive disease or therapy, and neutropenia as a result of disease (e.g., AIDS) or treatment with high-dose chemotherapy are common risk factors. Bloodstream infections, including fungal endocarditis, are fostered by the use of indwelling vascular lines, which is common practice in the management of hospitalized patients (Kojic, 2004).

Clinical Diseases

Although *C. albicans* is the most common pathogen within the genus *Candida*, the frequency of the non-*albicans* species has been noted within the recent past (Pfaller, 2007; Lewis, 2009). Numerous reports describe invasive infections caused by *C. tropicalis* (Garcia-Effron, 2008; Pasquale, 2008), *C. parapsilosis* (Trofa, 2008; van Asbeck, 2009), *C. glabrata* (Li, 2007), *C. krusei* (Krcmery, 1999; Pelletier, 2005), and *C. lusitanae* (Hawkins, 2003).

Resistance to antifungal agents has emerged as a problem with the introduction of newer agents. This resistance is especially problematic within the non-*albicans* *Candida* spp. Resistance has been most notable within *C. glabrata* (resistance to the imidazoles [fluconazole, itraconazole, posaconazole, and voriconazole]) and within *C. krusei* (resistance to itraconazole). Antifungal intrinsic resistance is also present in *C. krusei* and in *C. lusitanae* to fluconazole and amphotericin B, respectively. The Infectious Diseases Society of America has updated its clinical practice guidelines for the management of patients with invasive candidiasis and mucosal candidiasis to reflect changes noted with the addition of the new antifungals (Pappas, 2009).

Cutaneous Disease

Cutaneous disease is the most frequent infection caused by the *Candida* spp.; it presents topically as an erythematous lesion of the skin, sometimes accompanied by a creamy white exudate or scaling (Vazquez, 2002). Moist conditions, such as diaper rash in infants and infection of skin folds (intertrigo) in adults, are precursors to infection. Common sites are those in the groin, between fingers and toes, under the female breast, and in the axilla. Workers who immerse their hands in water for long periods of time are also at risk for infection of the skin of the hands, the nails (onychomycosis), or the nail bed (paronychia) (Jayatilake, 2009). Moreover, chronic cutaneous disease (referred to as chronic cutaneous candidiasis) is an uncommon manifestation of *Candida* infection in patients with defective cellular immunity (Lilic, 2002).

Oral Candidiasis

Oral candidiasis usually manifests as the appearance of creamy white patches overlying erythematous buccal mucosa (thrush) (Akpan, 2002). Although symptoms are usually minimal, dysphagia may result from heavy

infection. Fissuring at the corners of the mouth is common and may be the primary complaint. Oral candidiasis is a common initial infection in patients with HIV and frequently is a marker of immune failure in these patients (Egusa, 2008).

Gastrointestinal Candidiasis

Gastrointestinal candidiasis occurs most frequently as esophagitis and less commonly as gastritis (Bonacini, 2001). Erosive lesions of the distal esophagus and stomach result in substernal pain, which is aggravated by swallowing. White plaques overlie the lesions when viewed by endoscopy. The differential diagnosis includes infection with herpes simplex virus, although these two processes may coexist. Esophageal candidiasis was previously described as a frequent opportunistic infection in persons infected with HIV; however, the use of highly active antiretroviral therapy has led to a striking decline in the prevalence of this disease (Raufman, 2005). Even though *Candida* species are seen frequently as flora of the lower GI tract, the significance of finding yeast in stool is uncertain. True invasive infection of the lower GI tract is less common than disease of the upper tract, although overgrowth of *Candida* spp. in the stool may accompany antimicrobial therapy.

Vaginal Candidiasis

Vaginal candidiasis afflicts postpubertal women; diabetes mellitus, utilization of antimicrobial therapy, pregnancy, and sexual activity are predisposing conditions (Soong, 2009). Vaginal burning and itching, dyspareunia, and a discharge that is classically curd-like are associated with an infection that may be acute or chronic and difficult to eradicate.

Urinary Tract Infection

Urinary tract infection caused by *Candida* spp. is difficult to diagnose because these yeasts are frequently recovered from the urine as a result of vaginal contamination or colonization of the bladder in patients with indwelling catheters, especially when systemic antibiotics have been administered (Lundstrom, 2001; Bukhary, 2008). Severe infection of the upper urinary tract, including necrosis of the renal papillae, is a serious complication that occurs particularly in patients who have obstructive uropathy. Quantitative cultures do not appear useful for assessing the significance of *Candida* spp. in the urinary tract.

Invasive Candidiasis

Invasive candidiasis often involves sources other than the skin or mucous membranes. A vast majority of invasive infections caused by *Candida* spp. result in bloodstream invasion and hematogenous spread of the organism (Mavor, 2005; Pfaller, 2007). Candidemia is defined as the isolation of *Candida* spp. from at least one blood culture specimen with hematogenous spread of the yeast to one or more organs. Nonhematogenous *Candida* infection of a single deep organ (also called disseminated or deep-seated candidiasis) is not common and often is suspected as hematogenous spread to a single organ in which the manifestations of disease are seen. Primary localized invasive infections occur normally after abdominal surgery and following perforation of the gut leading to contamination of the peritoneal cavity with *Candida*. Other forms of deep-seated infection include endophthalmitis, meningitis, pneumonia, osteomyelitis, and hepatitis. Fungal endocarditis resulting from a bloodstream infection is uncommon, but when present is commonly caused by a *Candida* spp. Risk factors for this infection include prosthetic valve surgery, preexisting valvular heart disease, use of intravenous catheters or broad-spectrum antibiotics, intravenous drug abuse, and immunosuppression.

Pathology of *Candida* Infection

The tissue response to *Candida* is regularly purulent, resembling lesions of bacterial infection with abscess formation present. On occasion, the response to *Candida* infection is granulomatous. Budding yeasts, pseudohyphae, and true hyphae may be present in tissue, and when pseudohyphae or true hyphae predominate, yeasts must be differentiated from invasive mould pathogens such as *Aspergillus*. Vascular invasion, as occurs with *Aspergillus* or the Zygomycetes, is uncommon in yeast infection. Yeast can often be demonstrated with an H&E stain but may be more easily recognized in sections stained with GMS or PAS. Studies have also shown that a finding of *Candida* organisms on a Papanicolaou (PAP) smear is a reliable indicator of vaginitis (Heller, 2008).

Laboratory Diagnosis

Specimens for culture should be taken from affected organs and from lesions in which they can be visualized. Modern continuous-monitoring

Figure 61-17 Chlamydoconidia produced by *Candida albicans*. These thick-walled asexual reproductive structures that occur most commonly at the ends of pseudohyphae are characteristic for this species and for *Candida dubliniensis*. (Cornmeal agar plate, $\times 400$.)

blood culture systems detect most clinically significant yeast isolates (Reimer, 1997). Tissue specimens, scrapings, and swabs from the mouth or vagina should be inoculated onto primary fungal isolation media with and without cycloheximide. The presence of filamentous extensions from the edges of the colony (feet) is a macroscopic indication that pseudohyphae are being produced (see Fig. 61-1). *C. glabrata* (formerly *Torulopsis glabrata*) and *Cryptococcus* spp. do not form pseudohyphae in vitro, and some other *Candida* spp., such as *C. lusitanae* and *Candida guilliermondii*, also may not form pseudohyphae.

The extent of the mycologic evaluation depends on the clinical setting and the specimen type. *Candida* spp. are frequently isolated from the respiratory and urinary tracts; however, interpretation of a finding of *Candida* spp. in these areas is difficult. Complete identification of isolates from these sites should be accomplished only selectively after consultation with the responsible clinician.

A preliminary report of *C. albicans/dubliniensis* may be issued if the germ tube test is positive (see Fig. 61-16). Additional study of yeast morphology using cornmeal agar to confirm the presence of chlamydoconidia can facilitate identification of *C. albicans/dubliniensis* within 24–48 hours (Fig. 61-17). Because both *C. albicans* and *C. dubliniensis* are germ tube positive, and because they have a high degree of phenotypic similarity, distinguishing between these two species has been difficult. However, strict adherence to detail when it comes to growth at 42° C, the production of abundant chlamydoconidia, and the sugar assimilation pattern can be used to differentiate between them (Campanha, 2005; Ells, 2009).

When germ tubes and chlamydoconidia are not demonstrated, a preliminary or presumptive identification of *Candida* spp. can be made only if pseudohyphae are present and arthroconidia are absent. Although confirmed species identification under this circumstance requires the use of assimilation tests, ancillary morphologic observations can be used to speed up the identification process (see Table 61-10). For instance, a rapid assimilation trehalose test procedure has been suggested by the CLSI (document M35-A2) for the identification of *C. glabrata*, a species that has emerged as a common cause of invasive disease with known resistance to standard antifungal therapy (Clinical Laboratory Standard Institute, 2008a).

THE GENUS *CRYPTOCOCCUS*

The *Cryptococcus* spp. complex consists of two species: *C. neoformans* and *Cryptococcus gattii* (formerly called *C. neoformans* var. *gattii*). These species are known to cause systemic infection in both immunocompetent and immunocompromised individuals (Bovers, 2008; Ma, 2009). The environmental reservoir for *C. neoformans* (teleomorph, *Filobasidiella neoformans*) is primarily pigeon guano, and infections caused by this organism occur worldwide. *C. gattii* on the other hand is found predominantly in tropical and subtropical areas, especially those associated with eucalyptus trees, and infection appears to be limited in distribution, primarily to northern Australia and Papua New Guinea (Huston, 2009). However, recent infections have been noted in Vancouver Island and surrounding areas, and a high rate of mortality has been associated with these infections (Kidd, 2007; MacDougall, 2007; Bartlett, 2008; Dixit, 2009). Because both species are

classified within the phylum Basidiomycota, they are capable of producing basidiospores under the right circumstances. This teleomorphic (sexual) stage of cryptococci occurs only when appropriate mating types are crossed; thus this stage is not generally recognized in the laboratory. Sexual reproduction in the genera *Cryptococcus*, however, leads to increasing genetic diversity with the potential to produce strains that are hyper-virulent and show increased antifungal resistance (Huston, 2009).

Risk Factors

Immunosuppressive therapy or disease is a risk factor for cryptococcosis (Huston, 2009). Before the appearance of HIV infection, 30%–50% of patients with cryptococcal infection were immunologically normal, as measured by available parameters. Risk factors for these patients include neoplasia, diabetes mellitus, immunosuppressive therapy, and immunologic disease. The introduction of the HIV-infected patient dramatically increased the number of cases of cryptococcosis, and although advances have been made in antiretroviral therapy, in antifungal treatment, and in intracranial pressure management in these patients, *Cryptococcus* continues to have a high rate of mortality (Sajadi, 2009). An estimate of the global burden of cryptococcal meningitis finds the numbers of cases and deaths to be very high within areas of sub-Saharan Africa, where there is a high incidence of HIV-infected people (Park, 2009). Cryptococcosis also remains a significant opportunistic infection in solid organ transplant recipients (Singh, 2008).

Clinical Disease

Primary cryptococcal disease generally occurs in the lungs following inhalation of the fungus from the environment. This disease can remain localized or can disseminate by hematogenous spread to other tissues, most frequently the central nervous system. The severity of the disease is dependent on the host's immune response, with severe disease most frequent in immunologically compromised patients. Practical guidelines for the management of cryptococcal diseases was recently published by the Infectious Diseases Society of America (Perfect, 2010).

Respiratory Tract

Cryptococcal infection of the respiratory tract exhibits a wide variety of presentations (Jarvis, 2008; Shirley, 2009). Immunologically competent patients may exhibit no symptoms despite the presence of cryptococci in the lower respiratory tract, and the infection may be diffuse or localized, to include the formation of coin lesions that usually do not calcify. Immunocompromised patients on the other hand may have extensive infection that often is accompanied by other infectious agents, particularly *Pneumocystis (carinii) jiroveci* or cytomegalovirus. Extrapulmonary disease may appear weeks after a pulmonary infection has been documented.

Skin Lesions

Skin lesions usually result from hematogenous dissemination from the respiratory tract in immunocompromised patients (Christianson, 2003). These lesions present as single or multiple papules, which enlarge and ulcerate, producing a thin exudate that contains the yeast. Primary cutaneous manifestations of the disease are rare but may also be reported in immunocompetent individuals (Revenga, 2002).

Bone and Joint Infection

Bone and joint infection may occur usually as a result of dissemination from the respiratory tract (Liu, 1998). Osteolytic lesions are produced, with abscesses formed in adjacent soft tissue that contain a thin exudate with large numbers of cryptococci. Less commonly, joint spaces are involved.

Central Nervous System Infection

Cryptococcal meningitis is the most frequent and most serious focus of disseminated cryptococcal infection (Satishchandra, 2007; Dorneanu, 2008; Patel, 2009). Onset of this disease may be acute, or presentation may be insidious and progression torpid. Headache and changes in mental status and personality often dominate the clinical picture. Basilar meningitis, involvement of the cranial nerves, and invasion of the underlying cortex result in hydrocephalus and decreased visual acuity. Fever, if present, usually is of low grade, and typical signs of acute meningeal irritation, such as stiff neck and Kernig's and Brudzinski's signs, are often absent.

Pathology of Cryptococcal Infection

The histologic response depends on the degree of encapsulation of the infecting cryptococcal strain. Most commonly, little or no inflammatory

Figure 61-18 Colonies of *Cryptococcus neoformans* usually appear mucoid when first isolated. Some strains are poorly encapsulated and lack the mucoid appearance. (Sabouraud dextrose agar.)

response is seen, and the cells of normal tissue are separated by large numbers of encapsulated cryptococci. Poorly encapsulated strains of *C. neoformans* elicit a granulomatous inflammatory response, and yeasts are found predominantly in the cytoplasm of macrophages. When cerebrospinal fluid is examined, the only cells present may be the yeasts, which may be misinterpreted as mononuclear host cells if infection is not suspected clinically. Large capsules usually are demonstrated in positive India ink preparations; however, they are not always evident, and the cells may be confused with those of *B. dermatitidis* or even immature spherules of *Coccidioides* spp.

Differentiation in tissue sections can be accomplished by staining of cryptococcal mucopolysaccharide with mucin stains or demonstration of melanin pigment with the Fontana-Masson stain. Mayer's mucicarmine stain and the GMS stain have been shown to be important for the diagnosis of cryptococcosis when atypical forms were present in an uncommon location (Gazzoni, 2009). The variable size (3–10 µm) and the decidedly round nature of the yeast *in vivo* are clues to its correct identification, regardless of the degree of encapsulation and the histologic response.

Laboratory Diagnosis

Possible cryptococci should always be identified as to the species complex level. Clues to the presence of this fungus include good growth on blood agar plates incubated in the bacteriology laboratory at 35°–37° C, a mucoid appearance of the colonies (Fig. 61-18), a round appearance of the yeast cells without pseudohyphae in microscopic wet preps or stained preparations, and lack of growth on media that contain cycloheximide. Presumptive identification can be performed rapidly by examining an India ink preparation for capsules (see Fig. 61-14) and/or conducting a rapid urease test. Capsules may be diminished even in heavily encapsulated strains once they have been isolated on agar media; however, subcultures of isolates may restore the mucoid capsule. Definitive identification of the species complex is accomplished by biochemical testing.

Differentiating *C. gattii* from *C. neoformans* using standard phenotypic methods is difficult and usually is needed only for epidemiologic investigations. The incorporation of glycine into specialized medium (L-canavanine-glycine-bromthymol blue medium) has been shown to be reliable for differentiation of these species in that *C. gattii* readily assimilates glycine and *C. neoformans* does not (Klein, 2009). In instances where differentiation is needed, molecular sequencing of the D1/D2 region of the 28S rDNA gene or the ITS regions of the rRNA genes is known to be reliable in separating these two species (Georgi, 2009).

The polysaccharide antigen of the *C. neoformans* spp. complex can be detected in cerebrospinal fluid and serum, most commonly by the latex agglutination test. Although the sensitivity of this test exceeds 90%, considerable variability in performance has been noted among different commercial kits. The frequency of erroneous results can be diminished by treatment of serum specimens with pronase. False-positive reactions appear to be less common in patients infected with HIV, perhaps because of the large numbers of organisms present. Titration of positive results has been done traditionally to assess prognosis and to obtain a baseline for use in following the effects of treatment. Large amounts of antigen and

persistence of antigen following therapy are poor prognostic signs in patients. Measurement of serum antigen appears to be a more sensitive test than testing of cerebrospinal fluid in HIV-infected patients. However, both serum and cerebrospinal fluid should be tested for optimal sensitivity. A negative India ink test on cerebrospinal fluid is a good prognostic sign in non-HIV-infected patients but does not have the same implication for patients with AIDS.

THE GENUS *MALASSEZIA*

The history of the nomenclature used for the genus *Malassezia* is complicated. Currently, this genus is composed of one non-lipid-dependent species (*Malassezia pachydermatis*) and 12 lipid-dependent species (Guillot, 2008). *Malassezia furfur* is considered the most common pathogen in this group among humans. Because differentiation of the *Malassezia* spp. requires molecular sequencing, most clinical laboratories prefer to report results as “*Malassezia furfur* species complex” or “*Malassezia* species.”

Risk Factors

Malassezia yeasts are commensals of the normal skin, and cutaneous disease may occur in normal hosts. Systemic infection occurs primarily in neonates and is associated with intravenous hyperalimentation with lipid solutions (Devlin, 2006). Although *Malassezia* spp. are not ordinarily present on the skin of healthy infants, the yeasts have been recovered from the skin of as many as 37% of infants who were in intensive care units.

Clinical Diseases

Infection caused by *Malassezia* spp. can range from an asymptomatic lesion on the epidermis of normal individuals to systemic disease in the immunocompromised host.

Cutaneous Infection

Malassezia spp. are known causes of pityriasis (tinea) versicolor and seborrheic dermatitis, and evidence is accumulating that they play a significant role in atopic eczema/dermatitis syndrome (formerly called atopic dermatitis) (Ashbee, 2007; Zisova, 2009).

Pityriasis versicolor is a common infection of the epidermis in immunologically normal patients, resulting in hyperpigmentation or hypopigmentation of the skin, commonly on the trunk and upper arms. Fawn-colored macules are the most common presentation, but depigmenting lesions are more obvious in dark-skinned persons and may be accentuated by a suntan in light-skinned individuals. The ill effects are purely cosmetic but may be considerably troublesome. Hypopigmented lesions must be differentiated from vitiligo. Therapy consists of topical application of fungicidal creams or rinses.

Seborrheic dermatitis is a multifactor disease that requires both endogenous and exogenous predisposing factors for its development (Zisova, 2009). An inflammatory reaction against the yeast is considered the basis for the development of this disease.

Systemic Infection

Systemic infection occurs almost invariably in infants who have received intravascular infusions of lipid (the disease is also called *Malassezia* catheter-associated sepsis) (Devlin, 2006). Diluted lipid solution supports the growth of lipid-dependent *Malassezia* spp. by supplying long-chain fatty acids that are also found on the skin and must be supplied in the laboratory for isolation of the yeast. Infected infants are often asymptomatic, but fever, leukocytosis, and thrombocytopenia may be present. Pneumonia is a common systemic manifestation of disease, probably resulting from emboli received from infected intravenous catheters. Removing the infected catheter is therapeutic.

Pathology of *Malassezia* Infection

The diagnosis of pityriasis versicolor usually is made clinically or by demonstrating yeast and short hyphal forms (similar in appearance to spaghetti and meatballs) in KOH preparations of skin scrapings (Fig. 61-19). The addition of Calcofluor white or another fungal stain enhances detection because the fungal cells are small and difficult to visualize when unstained. When biopsied, hyperkeratosis, acanthosis, and dermal mononuclear infiltrates may be seen. Little is known of the pathology of systemic infection with *Malassezia* spp. because biopsies are performed infrequently and lethal infection is uncommon. In rare fatal cases, vasculitis, septic infarcts, and granulomatous inflammation have been described in many organs, including the lung, liver, and kidney.

Figure 61-19 Skin scrapings from a lesion of pityriasis versicolor. The yeast and short hyphal forms (spaghetti and meatballs appearance) are characteristic of *Malassezia furfur*. (Lactophenol cotton blue stain, $\times 400$.)

Figure 61-21 Gram stain from culture demonstrating gram-positive yeast cells of *Malassezia* spp. showing the characteristic collarette (bud scar). (Gram stain, $\times 1000$.)

Figure 61-20 Abundant growth of *Malassezia furfur* is evident on a plate that was overlaid with oil before the inoculum was applied. No growth is seen on a companion plate without oil. (Sabouraud dextrose agar.)

Figure 61-22 An aerial mycelium arises from the yeast-like colony of *Geotrichum candidum*. (Sabouraud dextrose agar.)

Laboratory Diagnosis

Culture for *Malassezia* spp. is rarely requested in cutaneous disease, and direct observation of yeast in KOH preparations usually is done in the physician's office. This yeast should be sought in cultures of blood and intravenous catheter tips from neonates. Before inoculation, a drop of sterile olive oil is added to the surface of a suitable agar medium, such as Sabouraud dextrose agar or sheep blood agar. Within 2–3 days, colonies appear light brown and often have a very dry appearance in the oil overlay. An initial clue to this pathogen is lack of growth in the absence of oil or stimulation of growth by the presence of oil overlay (Fig. 61-20). In contrast, *M. pachydermatis* is not dependent on long-chain fatty acids for growth.

Identification of the genus can be suspected by microscopic examination of the yeast cells, which measure 3–7 μm . The budding process in *Malassezia* is unusual because it occurs as an enteroblastic process with the formation of phialides. The bud is broad based, and the collarettes of the phialides may be observed with the light microscope as a distinct dark ring separating the mother and daughter cells (Fig. 61-21). Species identification can be confirmed using molecular techniques that target regions within the rDNA complex (Affes, 2009; Gaitanis, 2009).

OTHER YEAST AND YEAST-LIKE PATHOGENS

Blastoschizomyces capitatus (formerly called *Trichosporon capitatum*) has caused rare cases of disseminated infection that resemble candidiasis; however, this species characteristically is resistant to most antifungal agents (Bouza, 2004; Martino, 2004). *Trichosporon* spp. constitute another group of yeasts that are widely distributed in nature and occasionally are associated with disseminated infection in humans (Chagas-Neto, 2009; Lacasse, 2009).

The old taxon *Trichosporon beigelii* has undergone molecular analysis, leading to six new species, with *Trichosporon asahii* the most common species recovered from blood cultures (Chagas-Neto, 2008). A morphologically similar fungus, *Geotrichum candidum*, is also a rare cause of pulmonary or disseminated disease, especially in those patients suffering from acute leukemia (Girmenia, 2005; Henrich, 2009). Both *Geotrichum* and *Trichosporon* spp. produce smooth, yeast-like colonies that later develop aerial mycelium, like new hair growth on a bald head (Fig. 61-22). Other saprophytic yeasts such as *Saccharomyces cerevisiae*, *Rhodotorula* spp. (Tuon, 2008), and *Hansenula* spp. (Ma, 2000) may also produce infection on rare occasions.

Demonstration of these yeasts in tissues or isolation from multiple specimens, even from sterile sites, is required to document the role of the unusual yeast in an infectious process.

MYCOSES CAUSED BY DIMORPHIC FUNGI

Thermally dimorphic fungi are the most pathogenic organisms encountered in a clinical mycology laboratory. In the United States, the most important dimorphic pathogens are *Histoplasma capsulatum* var. *capsulatum*, *Blastomyces dermatitidis*, *Coccidioides immitis*, *Coccidioides posadasii*, and *Sporothrix schenckii*. *Sporothrix* is widely distributed throughout the world, and the other organisms are found predominantly in North America, where they have distinct geographic distributions (Fig. 61-23). Epidemic disease is most common with *Histoplasma* and *Coccidioides* and less common with *Sporothrix* and *Blastomyces*. These endemic mycoses share several characteristics, including (1) the ability to cause disease in a healthy host,

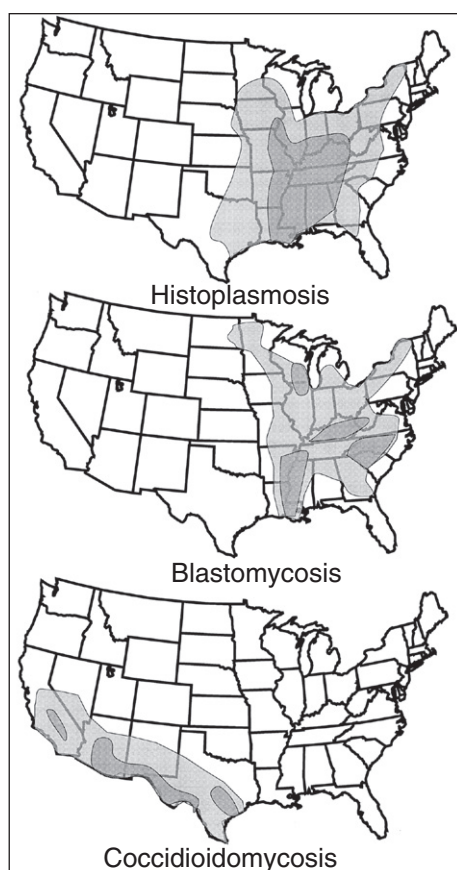

Figure 61-23 Geographic distribution of dimorphic fungal infections in the United States. Areas of greatest endemicity (dark shading) and lesser endemicity (light shading) are illustrated. Sporadic cases may also occur in other areas outside of the endemic zones.

- (2) association with a specific ecologic niche in the environment, and
- (3) demonstration of temperature dimorphism (mould in the environment at a temperature of 25°–30° C and yeast or spherules in the environment [in the case of *Coccidioides*] at body temperature).

THE GENUS *HISTOPLASMA*

H. capsulatum is subdivided into two varieties: *H. capsulatum* var. *capsulatum* (hereafter referred to as *H. capsulatum*) and *H. capsulatum* var. *duboisii*. Both of these fungal pathogens are geographically restricted, and acquisition of infection does not overlap in most cases. *H. capsulatum* var. *capsulatum* is found primarily along the Ohio, Mississippi, and St. Lawrence Rivers but may have worldwide distribution. *H. capsulatum* var. *duboisii*, on the other hand, is limited to equatorial Africa and is believed to cause a disease referred to as African histoplasmosis. Distinguishing characteristics of the tissue phase can be observed to differentiate between these two pathogens; however, lack of travel to the endemic area in Africa generally can be used to rule out infection with the var. *duboisii*.

Risk Factors

The primary risk factor for acquiring histoplasmosis is living in endemic regions of the United States. In some areas, more than 90% of the population reacts positively to histoplasmin skin testing. Growth of *H. capsulatum* in the soil is stimulated by bird guano, although the fungus does not infect the bird. Once growing in the soil, the fungus sporulates and produces conidia, which, during activities that generate aerosols, can be inhaled into the lungs. Occupationally acquired acute histoplasmosis has been reported, leading the U.S. Department of Health and Human Services (2004) to issue a document outlining measures for protecting workers at risk.

Epidemic acute disease has occurred in individuals vacationing to areas endemic for this fungus. A Centers for Disease Control and Prevention (CDC; 2001a) report described 221 cases of histoplasmosis among students representing 37 colleges in 18 states who had vacationed in Acapulco, Mexico, in March of 2001. Most infected individuals had visited a common source point, thus leading to spore exposure. The CDC also described an

outbreak of histoplasmosis among 14 healthy adventure travelers from the United States, who had visited a bat-infected cave in Nicaragua (Weinberg, 2003). Occupationally, a CDC report described an outbreak of histoplasmosis wherein at least 25 workers at an agricultural processing plant in Nebraska developed disease following exposure to a spoil pile known to be contaminated with *H. capsulatum* (Centers for Disease Control and Prevention, 2004).

Clinical Diseases

The magnitude of the exposure and the immune status of the host influence the clinical manifestations of disease, which can range from an asymptomatic infectious process to disseminated life-threatening disease (Kauffman, 2007). Exposure to low concentrations of spores from the environment in a normal host is typically asymptomatic. Therefore most adults living in an endemic area are seropositive and show immunologic evidence of infection; however, they remain asymptomatic to disease. Disseminated disease is usually reserved for individuals who are immunosuppressed.

Acute Pulmonary Infection

Individuals who are exposed to large numbers of conidia may develop a flu-like syndrome with high fever, chills, fatigue, cough, and pleuritic or retrosternal chest pain. More severely affected individuals may be sick for several weeks, but resolution usually is complete without antifungal therapy in the normal host. If focal granulomatous inflammation has occurred, calcification of the focus typically leaves a well-circumscribed coin lesion, which may be seen on the chest radiograph.

Granulomatous and Fibrosing Mediastinitis

These types of manifestations involve the lymph nodes in the mediastinum (Hammoud, 2009). Granulomatous disease is characterized by enlarged lymph nodes, which may obstruct the airways, pulmonary vessels, or esophagus. Fistulas can form within the lymph nodes and adjacent mediastinal structures. Fibrosing disease is a reaction that occurs in the mediastinum among individuals predisposed to an excessive response to *Histoplasma* antigens. Obstructions may form that involve the superior vena cava, the airways, the pulmonary arteries or veins, or the esophagus. Both granulomatous and fibrosing diseases are thought to progress independently.

Chronic Pulmonary Histoplasmosis

This debilitating disease occurs primarily in patients with chronic obstructive pulmonary disease (COPD), most of whom are middle-aged men (Kennedy, 2007). However, studies have shown that this disease is becoming more commonly recognized among females, and that females exhibited fewer cavities and presented with decreased numbers of smokers and reduced extent of smoking exposure, along with absence of COPD (Kennedy, 2007). In this disease, calcification and cavitations may occur, which may mimic chronic pulmonary tuberculosis and pulmonary neoplasia.

Disseminated Histoplasmosis

Dissemination of yeast through the reticuloendothelial system may occur as part of acute pulmonary histoplasmosis, resulting in healed granulomas that often calcify, especially in the spleen. Clinically disseminated infection occurs in two classes of patients. The first group consists of individuals at the extremes of age who do not have a recognized immunosuppressive condition but may have an immune system that is incompletely developed or is diminished by age in ways that are incompletely understood. The second group comprises patients with recognized immunosuppressive diseases or therapies. Before the 1980s, these diseases were predominantly hematologic neoplasms; however, in recent years, HIV infection has dominated the risk factors (McKinsey, 1998). Progression of disease may be rapid or insidious.

Compromised patients may develop an infection of the reticuloendothelial system, resulting in lymphadenopathy, hepatosplenomegaly, or thrombocytopenia (Wheat, 2003b). Destruction of the adrenal cortex by the granulomatous process may be sufficiently extensive to cause hormonal insufficiency. Central nervous system infection may be manifested as chronic meningitis, intracerebral granulomas, or both. Endovascular infection includes endocarditis with large, bulky vegetations. Any part of the GI tract may be affected, and ulcerating lesions may suggest a neoplasm macroscopically. The hallmark of disease is an oropharyngeal ulcer, which may cause hoarseness, dysphagia, or a painful lesion on the tongue or gingiva (Pseudos, 2008).

Figure 61-24 Yeast cells of *Histoplasma capsulatum* in macrophages. The presence of intracellular small, round to oval yeast-like cells in tissue is a characteristic pathologic finding in histoplasmosis. (Hematoxylin and eosin stain, $\times 1000$.)

Figure 61-25 Tuberculate macroconidia with microconidia of *Histoplasma capsulatum* in culture. These structures are characteristic of the environmental mould form of this dimorphic fungus. (Lactophenol cotton blue stain, $\times 400$.) (Courtesy CDC Public Health Image Library.)

Pathology of Histoplasmosis

As a facultative intracellular pathogen, *H. capsulatum* is found predominantly in macrophages. Pathologic lesions consist of collections of infected macrophages, noncaseating granulomas, or caseating granulomas. Histopathologic lesions are similar to those produced by *Mycobacterium tuberculosis*, and these two pathogens should be considered at the same time in the patient workup differential. Intracellular yeasts are often well demonstrated by H&E staining (Fig. 61-24). However, PAS and GMS stains are more sensitive, with the silver stain essential for demonstration of old yeast cells in healed granulomas. This yeast, presumably no longer viable, may be enlarged and distorted in morphology, making diagnosis difficult. Differential diagnosis of yeast forms includes small forms of *B. dermatitidis*, *P. marneffei*, *Leishmania* spp., or *Candida* spp., especially *C. glabrata*. The yeasts of *H. capsulatum* in caseating granulomas are sufficiently distinctive to provide a presumptive diagnosis, but unusual granulomatous presentations of *P. carinii* or *Jiroveci* must be differentiated. As is true with all endemic fungal infections, culture is necessary to make a confirmed diagnosis of disease.

Laboratory Diagnosis

The yeast form in tissue may be demonstrated histologically or in preparations of respiratory secretions, fluids, peripheral blood, bone marrow, or tissue imprints. Wet preparations and Calcofluor white may be used, but the morphology of tissue and yeast cells is best seen with Giemsa staining because the details of nuclear morphology can be assessed. The yeast cells measure 3–5 μm in diameter, have a single nucleus, and bud with a narrow neck.

If disseminated infection is suspected, blood cultures for *Histoplasma* should be performed. The Isolator technique is a sensitive technique for recovering the yeast phase from blood, although other blood culture detection systems can also be used to detect this fungus. Other clinical specimens should be inoculated to an enriched agar, such as brain-heart infusion agar supplemented with sheep blood, which is incubated at 25–30°C.

Colonies of *H. capsulatum* usually appear after incubation for 10–14 days but occasionally require incubation for up to 4 weeks. They are fluffy and vary from white to buff-brown. Diagnostic asexual forms include microconidia and macroconidia. Microconidia, which are produced first, are similar to the structures produced by *B. dermatitidis*. The more characteristic macroconidia have roughened projections from the periphery of the conidia, a configuration referred to as tuberculate (Fig. 61-25). The macroconidia of the saprophyte, *Sepedonium*, may be confused with *Histoplasma*, so differentiation of these two fungi is important. The macroscopic appearance of the colonies, the rate of growth, the growth of *H. capsulatum* on media containing cycloheximide, the presence of yeast forms in tissue, and the clinical history usually are sufficient to diagnose histoplasmosis. Final confirmation most often is provided by nucleic acid hybridization probe testing from the culture isolate. Conversion of the mould to the yeast phase also confirms identification, but this is often difficult and has been supplanted in most clinical laboratories by the molecular probe technique (AccuProbe). However, false-positive probe results have been

reported, and other factors need to be considered before a diagnosis of histoplasmosis can be confirmed (Brandt, 2005).

Serologic tests for the detection of anti-*Histoplasma* antibodies (i.e., immunodiffusion and complement fixation) have several limitations that need to be considered, making these tests marginal for the diagnosis of histoplasmosis. A 2–6-week delay after exposure is required for the production of antibodies, reducing the value of this testing for the diagnosis of acute disease. Once patients are infected with *H. capsulatum*, antibody levels remain detectable for many years. Antibodies to *H. capsulatum* and *B. dermatitidis* also may cross-react. Additionally, patients with immune dysfunction may not produce detectable levels of antibodies, and patients with previous exposure might have elevated levels of antibodies (Wheat, 2003a).

Antigen detection, on the other hand, has been shown to be useful for the diagnosis and management of histoplasmosis (Brandt, 2005; Wheat, 2007, 2009b). The sensitivity of urine antigen detection for diagnosis is greatest in patients with disseminated disease (up to 92%) or acute pulmonary histoplasmosis (75%–80%) (Wheat, 2002). Antigen detection is also useful for following the effects of therapy on fungal burden; when antigen concentrations in urine or serum fall during therapy, treatment failure is suggested. Moreover, increased antigen levels in a previously infected individual suggest a relapse of infection. Use of the antigen assay to detect *Histoplasma* antigen in bronchoalveolar fluid has been shown to complement antigen detection in serum and urine as an objective diagnostic test (Hage, 2009).

The histoplasmin skin test antigen has been useful for epidemiologic studies but should not be used for diagnosis. Not only does the high frequency of positive tests in endemic areas cloud interpretation, but the skin test can cause an individual to seroconvert to positive, further confusing the issue.

THE GENUS BLASTOMYCES

B. dermatitidis is the only species within the genus *Blastomyces* (Gueho, 1997). Endemic areas for this pathogen in the soil include the eastern part of the United States, mainly areas adjacent to the Mississippi and Ohio River basins; areas northwest of the Great Lakes in Canada; and areas within Africa (Bradsher, 2008). However, later reports suggest that the endemic area for blastomycosis may be larger than originally described, and reports have described disease in patients from previously nonendemic areas in Colorado and Nebraska (Centers for Disease Control and Prevention, 1999; Veligandla, 2002).

Risk Factors

Most cases of blastomycosis (also referred to as North American blastomycosis) are sporadic, and an environmental source is not often found. Small outbreaks do occur, and the fungus has been isolated from soil at outbreak sites (McKinnell, 2009). No specific risk factors for blastomycosis are known, although severe, disseminated infection has been described in immunocompromised patients. HIV-infected patients who reside in endemic areas are particularly at risk for serious infection (Pappas, 2002).

Figure 61-26 *Blastomyces dermatitidis* in tissue showing characteristic large, broad-based, budding yeast cells with a thick refractile (double-contoured) wall. (Hematoxylin and eosin stain, $\times 400$.)

Clinical Diseases

As is true with most other endemic dimorphic fungi, the portal of entry is the respiratory tract, where the infection may be asymptomatic, transient, or insidiously progressive (Bradsher, 2008). Chronic pulmonary blastomycosis with low-grade fever, weight loss, and localized pulmonary infiltrates may suggest neoplastic disease, for which diagnostic studies, including bronchoalveolar lavage, fine-needle aspiration of the lung, or surgical lung biopsy, may be undertaken (Lemos, 2002). Dissemination of yeast from the lung most commonly results in cutaneous or skeletal infection (Mason, 2008). The central nervous and genitourinary systems are involved less frequently. Cutaneous lesions often are hypertrophic or ulcerative and may be locally destructive. The lesions may be mistaken for squamous cell carcinoma of the skin. Secondary involvement of the skin over bony lesions also occurs. A delay in diagnosis is not uncommon, especially when patients have no history of exposure to an endemic area (Veligandla, 2002).

Pathology of Blastomycosis

The characteristic histologic response to *B. dermatitidis* is a mixture of acute inflammation with microabscess formation and granulomatous inflammation. In cutaneous lesions, pseudoepitheliomatous hyperplasia of the epidermis overlying the inflammation is characteristic. Yeast cells are most often found in the microabscesses or within multinucleated giant cells. The characteristic yeast can frequently be demonstrated in tissue sections stained with H&E, but the organism may be more readily visible when stained with PAS or GMS. The thick-walled yeast cells measure 8–15 μm in diameter and maintain a broad base during the budding process (Fig. 61-26). An artifactual separation of the cytoplasm from the cell wall in formalin-fixed preparations may give the appearance of a double wall. Although nonbudding yeast cells must be differentiated from yeast cells of *Cryptococcus* spp. and from developing spherules of *Coccidioides* spp., the diagnosis of blastomycosis can generally be proposed by observation of characteristic yeast forms in tissues by an experienced pathologist (Bradsher, 2003).

Surgical pathology and cytopathology have been reported as the primary means of diagnosis because positive culture may not always be recovered. However, microbiology culture and conventional morphologic assessment of routine samples have redundant utility in diagnosis and generally are required to make a confirmed disease diagnosis (Taxy, 2007).

Laboratory Identification

Direct demonstration of the yeast cells may be accomplished in tissue sections or in wet preparations of aspirated fluids and imprints of tissues. Calcofluor white staining may enhance detection of the yeast. Growth is somewhat more rapid than that of *Histoplasma* and fluffy white to buff colonies, which often cannot be distinguished from *H. capsulatum* and usually appear within 1–2 weeks. The microconidia resemble those of

Figure 61-27 Mould form of *Blastomyces dermatitidis* in culture. The lollipop appearance of the conidium on a conidiophore is characteristic of the environmental mould form for this dimorphic fungus. (Lactophenol cotton blue stain, $\times 400$.)

Figure 61-28 Budding yeast cells of *Blastomyces dermatitidis* in culture. When cultures are incubated at 37° C, large, broad-based budding yeasts with a double-contoured wall are detected that are characteristic of the yeast phase of this dimorphic fungus. (Lactophenol cotton blue stain, $\times 400$.)

H. capsulatum (Fig. 61-27), but macroconidia are not formed. A saprophytic mould, *Chrysosporium* resembles *Blastomyces* but does not develop a yeast phase and does not grow on media that contain cycloheximide. Conversion to the yeast phase may occur on routine media incubated at 37° C with hemoglobin and cysteine containing agar used specifically for this purpose (Fig. 61-28). Once again, demonstration of the yeast form in tissue serves as a reasonable substitute for demonstration of dimorphism in the laboratory. The nucleic acid probe hybridization test (AccuProbe) from culture material is the preferred method for confirmation of isolates in most laboratories, although false-positive results have been reported (Iwen, 2000).

Although the complement fixation test has been used as a serologic test for the diagnosis of blastomycosis, this test has considerable limitations and should be used only as an adjunct to culture of the fungus. A *Blastomyces* antigen test similar to the *Histoplasma* antigen test also is available in a reference laboratory; however, data regarding utility and reliability are lacking.

THE GENUS COCCIDIODES

Coccidioides immitis was considered until recently the sole etiologic agent of coccidioidomycosis (Valley fever). Phylogenetic studies now show the existence of two genetically distinct *C. immitis* clades: one called the California clade (*C. immitis*) and the other called the non-California clade (*C. posadasii*) (Fisher, 2002). Although a strong difference in genotype has been noted between these two species, the phenotypic differences are minimal, thus making it difficult for most laboratories to distinguish between them (Saubolle, 2007; Ampel, 2009).

The coccidioidal organisms are soil-dwelling fungi found in the southern portions of California and in other areas of southwestern United States (especially southern regions of Arizona, Utah, Nevada, and New Mexico,

as well as western Texas), northern Mexico, and Central and South America (especially Venezuela) (Talamantes, 2007). Arizona has seen a dramatic increase in cases over the years, with a disproportionate rate of infection occurring in people over the age of 65 years and in those with HIV infection (Centers for Disease Control and Prevention, 2003; Blair, 2008; Kim, 2009). The numbers of reported cases and hospitalizations for coccidioidomycosis in California increased each year from 2000 to 2006 before decreasing in 2007, with the highest incidence seen in Kern County (150 cases per 100,000 population) (Centers for Disease Control and Prevention, 2009).

Another interesting issue with these agents is the recent classification of *C. immitis* and *C. posadasii* by the U.S. Department of Health and Human Services as select agents of bioterrorism (Department of Health and Human Services, 2005; Warnock, 2007). This designation suggests that these pathogens could be used as potential bioweapons and establishes strict federal regulations to be followed by individuals who possess and transport these agents and by those who report confirmed infections (Deresinski, 2003). Individuals have questioned the rationale and justification for classifying the *Coccidioides* as select agents because of the burden placed on diagnostic laboratories for reporting of cases and for deposition of specimens and culture material (Fierer, 2002). Current law requires that the list of select agents undergo a biennial review in 2010. Discussions to reconsider the inclusion of *Coccidioides* as a select agent have been included in this review.

Risk Factors

Residence in an endemic area is the primary risk factor for the development of infection because the arthroconidia of the mould phase are in the soil and are easily disseminated through the air (Parish, 2008). A classic example of epidemic coccidioidomycosis occurred in a group of archeology workers in a dig at the Dinosaur National Monument in northeastern Utah in 2001. Ten workers within this group were recognized to have pulmonary coccidioidomycosis during an excavation, and eight of these individuals required hospitalization (Petersen, 2004). Another outbreak of disease occurred in individuals attending the World Championship of Model Airplane Flying in Kern County, California, in October 2001. This outbreak illustrated the importance of cooperation within the international community for epidemiologic evaluation, because competing teams from more than 30 countries were potentially involved in the outbreak (Centers for Disease Control and Prevention, 2001b). The locations of military bases in the southwestern United States have also shown coccidioidomycosis to have a profound effect on military personnel training in these areas (Crum-Cianflone, 2007). The development of an effective vaccine for Valley fever to protect both military members and civilians residing or training in endemic areas has been a suggested prevention strategy to avoid acquiring the disease (Hector, 2007).

Genetic factors have been suggested to influence the frequency of severe and disseminated infection, but the nature of this association is not completely known (Cox, 2004). Disseminated infection is reportedly more common in blacks and Filipinos than in whites. Asians, Native Americans, and Mexicans also appear to be at increased risk for the disease.

Immunosuppressive infection or disease is a known risk factor for disseminated infection, with HIV-infected patients at particular risk for disseminated disease (Woods, 2000). Transplant recipients who travel to or reside part-time or full-time in endemic areas are also at risk for both primary and reactivation coccidioidomycosis (Vikram, 2009). Clinicians in nonendemic areas should be aware of the potential for this disease, and should know that early diagnosis followed by prompt antifungal therapy could be lifesaving in these patients.

Clinical Diseases

Primary coccidioidomycosis is most frequently asymptomatic, as indicated by the high prevalence of positive skin tests for coccidioidal antigens in endemic areas. Symptomatic disease usually is manifested as fever with cough or chest pain, or both, and may mimic bacterial pneumonia clinically (Parish, 2008). Erythema nodosum and erythema multiforme, which may accompany the primary infection, are good prognostic signs of disease (DiCaudo, 2006). Solitary pulmonary nodules may persist as consequences of the primary pulmonary infection, also similar in appearance to a neoplasm or to tuberculosis.

Disseminated infection most commonly affects the skin, the skeletal system, and the meninges. Skin lesions include papules, ulcers, draining sinuses, and subcutaneous abscesses. Arthritis most often results from involvement of adjacent bones. Meningitis may be acute but is more commonly indolent and chronic.

Figure 61-29 Spherules of *Coccidioides* spp. in tissue. Observation of these large structures in tissue is a presumptive diagnosis for coccidioidomycosis. (Hematoxylin and eosin stain, $\times 100$.)

Figure 61-30 Spherules of *Coccidioides* spp. in tissue showing release of endospores. At maturity, the spherule ruptures and releases endospores, which, in turn, mature to become spherules. When seen in tissue, these immature endospores may be confused with other smaller yeasts. (Gomori's methenamine silver stain, $\times 1000$.)

Pathology of Coccidioidomycosis

The tissue response to *Coccidioides* spp. is granulomatous, with and without caseation. Developing spherules are typically found in macrophages and multinucleated giant cells (Fig. 61-29). Endospores within the spherules measure 2–5 μm in size (Fig. 61-30). The spherules measure up to 250 μm in diameter, and developing spherules have a large range of sizes. The differential diagnosis of developing spherules primarily includes non-budding forms of *B. dermatitidis* or *C. neoformans*. The spherules must be differentiated from the fungal forms in adiaspiromycosis and rhinosporidiosis, both of which are uncommon infections in the United States. In early disease stages, spherules may not be readily observed, and the presence of only endospores may make the diagnosis of coccidioidomycosis difficult.

Laboratory Diagnosis

The diagnosis of coccidioidomycosis can involve a variety of direct microscopic methods (i.e., Calcofluor white stain of respiratory specimen and histopathology of tissue), as well as culture with specific molecular probes for identification (Saubolle, 2007). Spherules may be demonstrated in sputum or, more commonly, in bronchoalveolar lavage fluid, but the sensitivity of direct examination for these structures is generally low. Calcofluor white staining following digestion of the specimen with KOH may increase the sensitivity of testing. If cavitory disease is present, hyphae may be present in clinical specimens, although this is a rare finding. In contrast to the other dimorphic pathogens, the possibility of communicability of arthroconidia directly from the specimen to medical personnel exists under this circumstance.

Coccidioides spp. grow rapidly (within 1 week) and can appear on standard bacteriology media such as blood agar in the laboratory.

Unfortunately, the arthroconidia of the *Coccidioides* are highly infectious and are easily transmitted by aerosolization. Infection of laboratory workers is a major concern, so inoculated cultures should be handled with great care in a biosafety cabinet (Sutton, 2007). The National Institutes of Health has classified both *C. immitis* and *C. posadasii*, along with *H. capsulatum*, as risk group 3 biological agents, that is, agents that are associated with serious or lethal human disease for which preventive or therapeutic interventions may not be available (Department of Health and Human Services, 2009). Biosafety level 3 containment is suggested when specimens known or likely to contain this organism are handled (Department of Health and Human Services, 2007). In a survey of laboratory-acquired infections, coccidioidomycosis was included on a list of the ten most frequently reported infections (Singh, 2009).

Colonies of *Coccidioides* spp. are extremely variable in appearance, ranging from velvety or cottony to granular or powdery. The colonial morphology may change as the colony and arthroconidia develop. Most isolates are white, but a variety of colors may be observed, and a diffusible pigment may be produced by some strains. Cultures often become gray with age. If a *Coccidioides* spp. is suspected, some mycologists prefer to sterilize the culture before examination of the colonies by flooding the container with 10% formalin, followed by overnight incubation. In cases where specimens are suspected to contain *Coccidioides*, screw-capped slants should be used instead of plates. The mould form is not routinely converted to the tissue form because specialized synthetic broth is generally required for this to occur. Separation of species into *C. immitis* and *C. posadasii* is best achieved by specialized molecular techniques, which normally are not available in routine clinical laboratories (Saubolle, 2007). Generally, laboratories will report the results as "*Coccidioides immitis/posadasii*" or as a "*Coccidioides* species."

Alternating barrel-shaped arthroconidia with empty disjuncture cells upon microscopic examination of culture material are distinctive (see Fig. 61-9) but must be differentiated from other organisms that produce arthroconidia, such as *Trichosporon*, *Geotrichum*, and some members of the family Gymnoascaceae. A presumptive identification is generally adequate to make a diagnosis of coccidioidomycosis in an individual who has been in an endemic area and in whom spherules with endospores have been detected in clinical material. A molecular-based genus-specific genetic probe (AccuProbe) is the method of choice for identification of the fungus into the genus level from culture.

In contrast to histoplasmosis and blastomycosis, serologic analysis with the complement fixation test is useful for assessing the extent and prognosis of coccidioidomycosis (Pappagianis, 1990). Of the serologic techniques available, complement fixation has been studied most extensively. Antibodies are detected approximately 2–6 weeks after infection. The height of the titer is an indication of the likelihood of disseminated disease, and a rising titer bodes a poor outcome. Skin testing does not confound the diagnosis by producing a seroconversion, as in histoplasmosis, but the high prevalence of skin test positivity decreases the usefulness of the test. Patients with disseminated infection may demonstrate anergy to the skin test antigen.

THE GENUS *SPOROTHRIX*

Historically, the only known species responsible for sporotrichosis was *Sporothrix schenckii*. However, molecular studies now demonstrate that *S. schenckii* is a complex of at least five putative phylogenetically distinct species (*S. schenckii*, *S. albicans*, *S. brasiliensis*, *S. globosa*, and *S. mexicana*) (Marimon, 2007). Although methods for distinction among these species have been developed, most laboratories do not have the expertise to identify specific species and still refer to *S. schenckii* as the sole cause of sporotrichosis. More appropriately, laboratory reports should now consider identification as a complex of multiple species and should report results as "*Sporothrix schenckii* species complex."

Sporothrix spp. are dimorphic fungi present worldwide in soil, plants, and decaying vegetation. Although considered endemic dimorphic fungi, this complex of species exhibit epidemiologic differences that separate them from the other classic endemic dimorphic fungi (De Araujo, 2001). The mode of entry for these fungi is usually traumatic implantation (vs. inhalation), the disease produced is usually a localized systemic infection (vs. pulmonary), and the incidence of systemic infection is rare (da Rosa, 2005).

Risk Factors

Although *Sporothrix* spp. are common in vegetation throughout the world, they do not appear to be plant pathogens; however, epidemics have been

caused by exposure to plant products (Hay, 2008). One major outbreak occurred among florists and nursery and forestry workers who handled contaminated sphagnum moss grown in Wisconsin (Centers for Disease Control and Prevention, 1988). Another recent major outbreak involved infected cats in Rio de Janeiro, Brazil, where 759 human cases of cat-transmitted sporotrichosis were reported (Schubach, 2008; Reis, 2009). An unusual epidemic occurred among members of a college fraternity in Florida who were building a wall with bricks packed in contaminated straw while consuming copious amounts of beer (Sanders, 1971). The only predisposing factor that was identified with any frequency was consumption of alcohol. It is interesting that the stereotype of the patient at risk for sporotrichosis is the "alcoholic rose gardener."

Clinical Diseases

The overwhelming predominant clinical form of sporotrichosis is involvement of cutaneous and subcutaneous tissues. A papule at the portal of entry may ulcerate and spread the pathogen through regional lymphatics, resulting in a series of lesions progressing up the affected limb (referred to as lymphocutaneous sporotrichosis). Dissemination to osteoarticular structures and viscera is uncommon and appears to occur more often in patients who have a history of alcohol abuse or immunosuppression, especially in patients with AIDS (Kauffman, 2000).

Pathology of Sporotrichosis

Histologic responses to *Sporothrix* and *Blastomyces* are similar. Granulomatous inflammation may be accompanied by small collections of polymorphonuclear neutrophils. In the skin, pseudoeplitheliomatous hyperplasia of the epidermis is common. The yeast cells of *Sporothrix* are pleomorphic and round or elongated, resembling cigars, but they are rarely seen in tissue. A tissue reaction to the fungus may result in radiating eosinophilic material up to 10 μ m in thickness around the yeast cell, known as the Splendore-Hoeppli phenomenon (asteroid bodies) (Hussein, 2008). This distinctive tissue reaction is uncommon, although the reaction is not specific for the diagnosis of sporotrichosis. The differential diagnosis of the skin lesions is primarily mycobacterial infection, especially *Mycobacterium marinum* (swimming pool granuloma) in the United States and cutaneous leishmaniasis in the tropics.

Laboratory Diagnosis

The preferred specimen is an aspirate, curetting, or biopsy of the skin lesion. *S. schenckii* grows well on primary isolation media with cycloheximide incubated at 25°–30° C. The colonies, which may be moist or smooth (glabrous), are often light colored initially and may turn darker with increasing age. This organism produces two types of conidia: thin-walled hyaline conidia arranged as a rosette around the apex of a conidiophore, and thick-walled, dark, sessile conidia attached directly to the hyphae. The thin-walled microconidia are borne on conidiophores that arise at right angles from the hyphae. They may be arranged sympodially around an expanded vesicle at the tip of the conidiophore, producing an arrangement that has been described as a floret (Fig. 61-31). Similar structures are produced by *Acremonium* spp., which have rarely been reported as a cause of human disease. This mould is differentiated from *Sporothrix* by the

Figure 61-31 Sympodial conidia of *Sporothrix schenckii* are borne in clusters at the tips of lateral conidiophores. (Lactophenol cotton blue stain, $\times 400$.)

absence of growth on cycloheximide agar and by the absence of a yeast phase. Conversion of the mould phase to yeast is accomplished by incubation of the isolate at 37° C in an atmosphere of 5% carbon dioxide on an enriched medium, such as brain-heart infusion agar supplemented with sheep blood or on chocolate agar. Phenotypic characteristics such as the morphology of sessile pigmented conidia; growth at 30° C, 35° C, and 37° C; and the assimilation of sucrose, raffinose, and ribitol have been used successfully to distinguish among species (Marimon, 2007). Molecular sequencing using the calmodulin gene target has also proved reliable in differentiating among *Sporothrix* spp. (Marimon, 2006).

OTHER DIMORPHIC FUNGI

H. capsulatum var. *duboisii* causes cutaneous and systemic diseases in Africa. The yeast is larger than that of *H. capsulatum* var. *capsulatum*, and the walls are thicker, resembling the cells of *B. dermatitidis*, but without the broad-based buds. This organism has been considered an emerging infectious agent in HIV-infected patients in Africa (Loulergue, 2007).

Paracoccidioidomycosis (formerly known as South American blastomycosis), a relatively common disease in Brazil, Venezuela, Columbia, Ecuador, and Argentina, is caused by the dimorphic fungus called *Paracoccidioides brasiliensis* (Ramos, 2008). This organism mainly affects the skin, lymph nodes, lung, and oral, nasal, and GI mucosal membranes (Restrepo, 2008). The characteristic tissue phase yeast cells of *Paracoccidioides* have multiple peripheral buds, producing an appearance that has been compared with a mariner's wheel.

Penicillium marneffei is a common cause of disease in HIV-positive patients in Southeast Asia. This agent has also been found to be associated with the bamboo rat (*Rhizomys sinensis*), which is thought to be the natural environmental reservoir for this fungus (Vanittanakom, 2006). The species is unique among the penicillia in being dimorphic by growing as a mould form at 30° C and thus producing reproductive structures typical of *Penicillium* spp., and producing in tissue yeast-like cells that are oval or cylindrical and may have cross-walls (Cooper, 2000).

DERMATOPHYTOSES

Dermatophytic fungi are common and important causes of human morbidity (Andrews, 2008; Havlickova, 2008; Seebacher, 2008; Vermout, 2008). Generally the infections are mild, and rarely do the fungi associated with these infections cause invasive disease. Three genera are recognized as causes of dermatophytosis: *Microsporum*, *Trichophyton*, and *Epidermophyton*. As a group, the dermatophytic fungi are distributed worldwide, but individual species may have a more restricted geographic distribution. Dermatophytes may also be found in strict association with humans (anthropophilic), with animals (zoophilic), and with soil (geophilic).

RISK FACTORS

Dermatophytic infections result from contact with the relevant source of the fungus, which may also provide a clue to the diagnosis. For instance, infection of the face in farmers who have contact with cows as they milk the animals is characteristically caused by *Trichophyton verrucosum*, a zoophilic dermatophyte found in cattle. Geographic variation in dermatophytic pathogens is illustrated by a study of an epidemic of cutaneous fungal infection among American troops during the Vietnam War (Allen, 1973). Most infections were caused by a heavily sporulating variant of *T. mentagrophytes* that had not been recognized in the United States. Skin disorders caused by dermatophytic fungi are now recognized more often in sports in which there is direct contact between athletes, such as wrestling (Adams, 2002; Nenoff, 2002; Field, 2008).

CLINICAL DISEASES

Dermatophytes produce infection of the epidermis, hair, and nails (Seebacher, 2008). Infection is often referred to as ringworm (or tinea), a name derived from the advancing, serpiginous nature of the lesions (especially evident on the skin). Clinical terminology uses the Latin name "tinea" followed by the body part involved, such as tinea capitis (scalp), tinea barbae (beard), tinea corporis (trunk and limbs), tinea pedis (foot), tinea cruris (groin), and tinea unguium (nail, also called onychomycosis). With occasional exceptions, *Epidermophyton floccosum* infects primarily the skin, *Microsporum* spp. infect the scalp and skin, and *Trichophyton* spp. infect the skin, scalp, and nails. *Trichophyton tonsurans* is the most common cause of tinea capitis in the United States, with *M. canis* a common cause of scalp

infection, particularly in children. When deep infection of hair follicles occurs, a boggy inflammatory process called a kerion results. *T. mentagrophytes* and *T. verrucosum* are particularly associated with kerion formation. *T. mentagrophytes*, *T. rubrum*, and *M. canis* are commonly found to cause tinea corporis and tinea pedis, and *E. floccosum* is a common cause of tinea cruris.

Considerable intercontinental and intracontinental variability in the global incidence of dermatophytic infection has been noted (Havlickova, 2008). Local socioeconomic conditions and cultural practices can influence the prevalence of a particular infection in a given area. For instance, tinea pedis has been shown to be more prevalent in developed countries than in emerging economies and is likely to be caused by the anthropophilic agent *T. rubrum*. In poorer countries, scalp infection (tinea capitis) caused by *Trichophyton soudanense* or *Microsporum audouinii* is more prevalent.

LABORATORY DIAGNOSIS

Diagnosis of a dermatophyte infection generally involves both microscopic examination and culture, although treatment of dermatophyte infection is not directed by the specific identification of the isolate (Robert, 2008). Demonstration of hyphae in skin scrapings (using a KOH preparation) is frequently the only diagnostic technique performed before therapy is initiated (Fig. 61-32). The size and morphology of hyphae suggest the involvement of dermatophytes in the infection. Verification of the species is useful for confirming that the hyphae did in fact belong to a dermatophytic fungus, for assessing the probable source of the infection, and for assessing the increased likelihood of chronic, relapsing infections (especially when *T. rubrum* is identified) (Robert, 2008). Skin scrapings, nails, and hair can be examined in KOH preparations, which may incorporate Calcofluor white to facilitate the detection of hyphae. Care must be taken when reading this type of preparation in that tissue fragments, fibers, and cholesterol crystals may be mistaken for hyphae by the inexperienced observer.

Fungi such as *M. audouinii*, *M. canis*, and *Microsporum ferrugineum* are associated with hair infection and cause the hairs to fluoresce with a long-wavelength ultraviolet light (Wood's lamp). In the United States, tinea capitis due to a fluorescing fungus is most likely caused by *M. canis* because the other two species are not common in this geographic area. Microscopic examination of infected hair by an experienced observer may suggest the etiologic agent, based on the appearance and location of the arthroconidia. In ectothrix colonization, as occurs with *M. canis* and *M. audouinii* infection, arthroconidia are external to the hair shaft. Endothrix invasion, as seen in infection with *T. tonsurans*, is characterized by arthroconidia within the hair shaft. In favic infection, hyphae, air bubbles, or tunnels and fat droplets are present in the intrapilar area.

Infected hairs, nail scrapings, or scrapings of the edges of skin lesions should be submitted to the laboratory in a clean, dry container or placed on the surface of primary isolation medium supplied by the laboratory. Sabouraud dextrose agar was designed for recovery of dermatophytic fungi and is also effective for isolating *Candida* spp., especially *C. albicans*, which may produce similar infections of the skin and nails. Dermatophytes are not inhibited by cycloheximide, which will inhibit many saprophytic fungi. All dermatophytic fungi have septate, hyaline hyphae and produce

Figure 61-32 Hyphae of a dermatophyte are demonstrated in a scraping from the edge of a tinea lesion. The presence of thin-segmented hyphae in this clinical setting establishes the diagnosis of dermatomycosis but does not define the specific cause. (Potassium hydroxide preparation, ×400.)

Figure 61-33 The obverse of a *Microsporium canis* colony (left) showing the characteristic lemon yellow pigment, which also may be seen on the reverse of the colony (right). (Sabouraud dextrose agar with cycloheximide.)

Figure 61-34 Thick-walled, roughened, tapered, spindle-shaped macroconidia of *Microsporium canis* with thin, septate hyphae. (Lactophenol cotton blue stain, $\times 400$.)

macroconidia and/or microconidia in various combinations. Arthroconidia and chlamydoconidia may also be produced, but the morphology of the macroconidia and especially of the microconidia is more important for identification. Sexual stages of the dermatophytes have been identified, but they are not encountered in the clinical laboratory. The combination of micromorphologic features with some phenotypic testing is used to differentiate the dermatophytes (Caddell, 2002).

Microsporium spp. produce characteristic macroconidia, which are the key diagnostic structures. In some cases, microconidia, which are not as useful diagnostically, are produced. *M. canis*, the most frequently isolated zoonotic species of this genus, produces a characteristic lemon yellow pigment in culture (Fig. 61-33), which is intensified by growth on potato flake agar. The macroconidia of this species are illustrated in Figure 61-34.

The genus *Trichophyton* includes the important dermatophytic fungi *T. rubrum* (Fig. 61-35), *T. verrucosum*, *T. mentagrophytes* spp. complex (see Fig. 61-11), and *T. tonsurans* (Fig. 61-36). The colonies may have a fluffy, granular, or, less commonly, glabrous appearance. Macroconidia, which are useful for identification, may be produced by this genus, especially in strains that produce powdery colonies, but unfortunately they usually are absent. Microconidia are formed more commonly. When present, the macroconidia are thin-walled and smooth and contain variable numbers of septa. Interpretation of the microscopic morphology in some isolates can be difficult because overlap occurs frequently. Phenotypic testing using the *Trichophyton* agars is helpful in the characterization of nutritional requirements among members of the genus. Seven media have been described; however, four of these seem to be the most useful for identification purposes. These media include T1, basal medium agar (for a control to compare with other supplemented media); T2, basal medium with inositol (growth stimulated by inositol); T3, basal medium with

Figure 61-35 Fluffy white colonies of *Trichophyton rubrum* with diffusible red pigment, which may also be seen on the reverse of the colony. (Potato dextrose agar.)

Figure 61-36 A flat colony showing pale yellow coloration with a reddish-brown pigmentation at the periphery characteristic of *Trichophyton tonsurans*. Radial furrowing of the thallus as seen is also common. (Sabouraud dextrose agar with cycloheximide.)

inositol plus thiamine (growth stimulated by the addition of both inositol and thiamine); and T4, basal medium with thiamine (growth stimulated by thiamine only). In combination, these media allow assessment of dependency on inositol, thiamine, or both compounds together for growth.

Differentiation of *T. mentagrophytes* and *T. rubrum* is facilitated by several nonmorphologic tests as well (Ates, 2008). A diffusible pigment may be produced by both species, but the intensely red pigment of *T. rubrum* is encouraged by culture on potato dextrose agar or cornmeal agar with 1% dextrose. Production of urease within 3–5 days by *T. mentagrophytes* but not by *T. rubrum* also helps differentiate these two species. Finally, the hair penetration test can be used as a differential test wherein *T. mentagrophytes* produces wedge-shaped defects in hairs in vitro, whereas *T. rubrum* grows on the outside of the hair without penetration. Use of both morphologic and nonmorphologic approaches provides the most accurate identification of isolates.

The only pathogen within the genus *Epidermophyton* is *E. floccosum*, an anthropophilic fungus that is an important cause of tinea cruris and, less commonly, tinea pedis. Colonies, which are initially brownish yellow, gray, or khaki brown, become velvety and folded as they mature (Fig. 61-37). *E. floccosum* produces no microconidia, but distinctive macroconidia provide clues to identification (see Fig. 61-10). These structures have smooth external walls, with up to four cross walls and a club shape, and they tend to “flocculate,” hence the epithet name.

To differentiate among closely related dermatophytes, molecular assays have been developed. Species identification for dermatophytes is time consuming and requires knowledge and technical expertise because of morphologic similarity, variability, and polymorphism within dermatophytes (Abdel-Rahman, 2008; Kanbe, 2008; Bontems, 2009). Molecular phylogenetic analysis of multiple dermatophytic species involved in

Figure 61-37 The suede-like texture and yellowish green color of the mould colonies are characteristic of *Epidermophyton floccosum*. (Sabouraud dextrose agar with cycloheximide.)

infection has suggested that although profound differences in morphology and pattern of infection among species are noted, there does not appear to be a distinct species difference on modern molecular analysis (Graser, 2008). This observation suggests that a polyphasic approach to identification may need to be considered.

MYCOSES CAUSED BY DEMATIACEOUS MOULDS

The dematiaceous moulds (also called the black moulds) are a fascinating and complex group of fungi characterized by the formation of a dark pigment due to production of melanin in the cell walls of hyphae or conidia or both (Revankar, 2007). Although these fungi are soil and plant saprophytes and historically are considered rare causes of disease in humans, they appear to be emerging as more common fungal pathogens (Silveira, 2001).

CLINICAL DISEASES

The clinical syndromes are typically distinguished on the basis of histologic findings into eumycotic mycetoma (also called eumycetoma), chromoblastomycosis (also called chromomycosis), and phaeohyphomycosis (Garnica, 2009). These diseases are frequently diagnosed by a unique histologic picture in tissue followed by isolation of the fungus in culture and morphologic evaluation of the reproductive structures. The classification of black moulds has undergone numerous changes over the years, which adds difficulty to recognition of the etiologic agent.

Mycetoma

Mycetoma is a localized, chronic granulomatous infection characterized by the formation of a painless subcutaneous mass of chronic onset, with multiple sinuses draining pus and grains (also called granules) with extension to the bone (Garnica, 2009). The disease is most often confined to the hands or feet (also called “Madura foot”) in immunocompetent individuals such as farmers, field hands, and others in contact with contaminated soil-laden materials. This disease can be caused by bacteria (actinomycotic mycetoma) or by fungi (eumycotic mycetoma) that are dark pigmented (dematiaceous), or rarely by nonpigmented and filamentous fungi (haline) (Lichon, 2006; Welsh, 2007). A mycetoma occurs after a traumatic injury with a contaminated object such as a splinter, a thorn, or any other penetrating item. Although more than 25 mould species have been known to cause eumycotic mycetoma, the most common cause is *Madurella mycetomatis*, followed by a variety of other dematiaceous and hyaline fungi. *Scedosporium apiospermum* (teleomorph, *Pseudallescheria boydii*), a hyaline fungus, is considered the most common cause of this disease in the United States.

A noninvasive disease involving the paranasal sinus has been described as a fungal mycetoma (also called a fungus ball) (Grosjean, 2007; Pagella, 2007; Robey, 2009). This condition involves the accumulation of dense fungal concretions in the sinus cavities, most often the maxillary sinus, and is associated with a variety of moulds, including dematiaceous fungi.

Figure 61-38 Image showing granules of various sizes (black grains) of the fungus *Madurella grisea* composed of black masses of hyphae. (Courtesy CDC Public Health Image Library.)

Figure 61-39 Histologic appearance of “black grain mycetoma” due to *Madurella mycetomatis*. (Gridley stain, $\times 1000$.) (Courtesy Dr. Libero Ajello, CDC Public Health Image Library.)

Although some categorize this infection as a mycetoma, others prefer to describe it as a fungal rhinosinusitis because this infection does not specifically fit the description of a mycetoma presented here (an absence of granule formation). Controversies on the categorization and definition of fungal rhinosinusitis occur because of the wide spectrum of immune and pathologic responses associated with this disease. Attempts are being made to develop a consensus on the terminology and disease classification for this condition (Chakrabarti, 2009).

A definitive diagnosis of a mycetoma can be achieved by the demonstration of grains (or granules) in a tissue biopsy, in draining exudates from a sinus tract, or in material aspirated from an unopened lesion (Fig. 61-38). These grains are microscopically composed of broad, interwoven, septate hyphae 2–5 μm in diameter (Fig. 61-39). For dematiaceous fungi, these grains are associated with a dark pigment and generally are called “black grains”; with fungi that are nondematiaceous and produce nonpigmented hyphae, these are called “white grains.” Identification of the etiologic agent requires culture on standard fungal media such as Sabouraud dextrose agar, which may take 4 weeks or longer to grow (Fig. 61-40). Once isolated, the fungal species is identified using gross colony morphology and pigmentation, along with close observation of the micromorphologic characteristics of reproductive structures following sporulation (Fig. 61-41). In cases where sporulation does not occur, physiologic tests such as carbohydrate and nitrate utilization may aid in identification. Molecular assays using targets within the rDNA complex have been shown to be reliable for identification of dematiaceous fungi (van de Sande, 2005; Borman, 2008).

Chromoblastomycosis

Chromoblastomycosis (chromomycosis) is a chronic infection of the skin and soft tissue characterized by the presence of muriform fungal structures

Figure 61-40 Close-up of a dematiaceous fungus growing on Sabouraud dextrose agar.

Figure 61-41 Image showing phialides with terminal conidia of the *Madurella mycetomatis* fungus. (Lactophenol cotton blue stain, $\times 400$.) (Courtesy Lucille George, CDC Public Health Image Library.)

called sclerotic bodies within the infected tissues. The disease affects immunocompetent individuals who most often live in tropical and subtropical areas and is distinguished by the formation of a painless verrucous plaque or nodule at the site of inoculation following a penetrating trauma, with healing areas of the lesion evident along with the formation of scar materials (Queiroz-Telles, 2009). The most common etiologic agents are the black moulds *Fonsecaea pedrosi* and *Cladophialophora carrionii*, although numerous other species may also be involved (Baddley, 2003a). The distinguishing feature is the presence of round, nonhyphal, brown cells (sclerotic bodies) in tissues (Fig. 61-42). These structures, which divide by producing a septal plane, are diagnostic of the entity but do not provide a clue as to species identification of the mould. Culture and recognition of morphologic features of the isolate are needed to identify the infecting species.

Phaeohyphomycosis

Phaeohyphomycosis (from the Greek word “phaeo,” meaning “dark”) was a term originally proposed by Ajello (1974) as a histopathologic entity to cover all infections “caused by fungi that develop in tissue in the form of dark-walled dematiaceous septate mycelial elements.” Over the years, phaeohyphomycosis has become more recognized as a cause of subcutaneous and systemic diseases characterized by the formation of pigmented septate hyphae in tissue. Although both chromoblastomycosis and eumycotic mycetoma are caused by dematiaceous fungi, they are distinguished from phaeohyphomycosis by the appearance in tissue of sclerotic bodies and mycotic granules, respectively.

Figure 61-42 Sclerotic cells observed in tissue that is characteristic of the etiologic agents of chromoblastomycosis. (Hematoxylin and eosin stain, $\times 400$.)

Phaeohyphomycosis ranges from an indolent subcutaneous lesion, probably resulting from direct inoculation of fungi at the site, to a devastating, destructive infection that is almost always fatal in the immunosuppressed patient. The subcutaneous form of the disease is characterized by the formation of a solitary asymptomatic subcutaneous nodule or cyst usually in an immunocompetent individual, but disseminated disease may also occur in the immunocompromised patient (Naggie, 2009). The most common dematiaceous fungi associated with the cutaneous condition are *Exophiala jeanselmei*, *Wangiella dermatitidis*, and *Biopolaris* spp. (Garnica, 2009). Systemic infection reportedly has been associated with these and a variety of other dematiaceous fungi. For instance, numerous reports have shown *Cladophialophora bantiana* to be a cause of fungal brain abscess in the compromised patient (Garzoni, 2008). In another report described by the CDC, five cases of meningitis caused by *E. dermatitidis* resulted from the injection of contaminated steroids prepared by a compounding pharmacy (Centers for Disease Control and Prevention, 2002).

In most cases of phaeohyphomycosis, diagnosis may be difficult because many etiologic agents are often considered contaminants when isolated from culture. In tissue, the presence of irregular, swollen, septate hyphal forms with yeast-like structures that stain with a melanin-specific Masson-Fontana stain is presumptive for the diagnosis of phaeohyphomycosis.

Sick Building Syndrome

Dematiaceous moulds have also been associated with the condition known as “sick building syndrome.” The mould most commonly associated with this condition is *Stachybotrys chartarum*, although the causative association of mould contamination within a building with disease has been questioned. Others have suggested that toxins associated with moulds such as *S. chartarum* are associated with health problems following exposure (Miller, 2003; Straus, 2009; Terr, 2009). To offer credit to this suggestion, the U.S. Environmental Protection Agency has provided a document that presents a comprehensive review on mould remediation in commercial buildings and schools as a means of disease prevention (Environmental Protection Agency, 2001).

ZYGOMYCOSIS

The Zygomycetes are important causes of invasive fungal infection in compromised hosts, and diseases caused by these moulds are referred to as zygomycosis (Freifeld, 2004; Roden, 2005; Almyroutidis, 2006). This disease is also called mucormycosis and phycomycosis, although zygomycosis is now more frequently used because this name is a more precise term that relates disease to the taxonomic classification (Freifeld, 2004). *Rhizopus* spp. are the organisms most commonly isolated from patients with zygomycosis, and *R. (oryzae) arrhizus* and *R. microsporus* are recognized as causing a majority of cases (Ribes, 2000; Alvarez, 2009). Other less common species include *Lichtheimia (Absidia) corymbifera*, *Apophysomyces elegans*, *Cunninghamella bertholletiae*, *Mucor circinelloides*, and *Rhizomucor (Mucor) pusillus*.

RISK FACTORS

Uncontrolled diabetes, steroid use, neutropenia, infant prematurity, stem cell or solid organ transplantation, and the use of deferoxamine are all well-described risk factors for the development of zygomycosis (Freifeld, 2004; Roden, 2005). In general, most of these conditions are associated with impairment of normal leukocyte immune function. Diabetic ketoacidosis is the most common recognized underlying condition for the development of zygomycosis in humans. Ketoacidotic serum has been shown to stimulate the growth of *Rhizopus* in vitro (Artis, 1982). However, recognition of no underlying condition following penetrating trauma, surgery, and burns has also been seen at the time of infection (Roden, 2005).

CLINICAL DISEASES

The two major clinical presentations for zygomycosis are sinus infection with or without cerebral or orbital involvement and localized pulmonary infection that may lead to disseminated disease. Another, more rare condition is a localized cutaneous infection that occurs following trauma. Risk factors for the two major presentations are somewhat different (Mantadakis, 2009).

An invasive infection that begins in the paranasal sinuses is known as rhinosinus, rhinocerebral, sinus-orbital, or craniofacial zygomycosis, depending on how far the infection has spread. The infection begins as an undifferentiated sinusitis, but the hyphae may rapidly break through the thin walls of the sinus and extend up into the orbit, forward into the skin of the face, and back up into the cranial cavity. Rhinocerebral disease may progress rapidly, and death often results. Thrombosis of the carotid artery or cavernous sinus may occur following invasion of deep tissue.

The second major presentation of zygomycosis is pulmonary disease, which may be followed by hematogenous dissemination. Infection begins as an undifferentiated pneumonia, which may be complicated by hemoptysis and cavitation. Risk factors for pulmonary infection include neutropenia and immunosuppression, particularly by hematologic malignancy; disseminated infection is common and the outcome is almost uniformly fatal (Pagano, 2004).

A less common presentation of zygomycosis is infection of skin and soft tissues (Alsuwaida, 2002; Oh, 2002). Hyphae may reach the skin by the hematogenous route, by direct extension from a deep focus, or by introduction from the outside. Contaminated adhesive tape has been reported as a source of primary cutaneous disease in the compromised patient (Alsuwaida, 2002). Other rare cases of zygomycosis include primary involvement of the GI tract, the heart, the brain, or the kidneys (Roden, 2005).

PATHOLOGY

The diagnosis of zygomycosis is made most frequently on the basis of characteristic histopathologic findings in tissue. The tissue response is dominated by necrosis, regardless of the site of infection. The propensity for these moulds to invade through the walls of arteries and veins, producing acute thrombosis, leads to extensive coagulative necrosis (Chandler, 1987b). The hyphae appear as ribbons of broad hyphae that are often twisted and collapsed with a variable width from 5–20 μm (see Fig. 61-3). Septa are sparse and usually are not observed in tissue, but an overlay of the exterior walls of collapsed hyphae may be mistaken for septa. Swollen segments of hyphae and hyphae cut in cross-section may be incorrectly interpreted as yeast cells. Branching tends to occur at right angles in a haphazard pattern. These hyphal characteristics along with the angioinvasive property of these fungi are highly suggestive of a Zygomycete-caused infection. Comparison of the histologic features of Zygomycetes versus those of other nonpigmented hyphae in tissue is described in Table 61-11. The hyphae of these moulds often stain better with the H&E stain than with the GMS method.

LABORATORY DIAGNOSIS

Zygomycetes often are considered common contaminants within the mycology laboratory, and the potential clinical implications of isolates should be carefully investigated before they are dismissed as saprophytes. Collaboration between the pathologist and the laboratory is important because demonstration of hyphae in tissue provides important evidence that an isolated mould was present in vivo and was not an environmental contaminant. Broad, sparsely septate hyphae may be demonstrated in tissue sections or in imprint smears of tissue, using the Calcofluor white stain.

TABLE 61-11

Histopathologic Features of the Zygomycetes in Comparison With Other Fungi That Occur as Nonpigmented Hyphae in Tissue*

Characteristic	Zygomycetes [†]	<i>Aspergillus</i> [‡]	<i>Fusarium</i>
Hyphal characteristics			
Width (μm)	Variable (5–10)	Consistent (3–6)	Consistent (3–8)
Branching pattern	Haphazard	Dichotomous	Right angle
Septation frequency	Rare	High	High
Reproductive structures in tissue	Absent	May be present where infected area communicates with air	Chlamydoconidia sometimes present
Angioinvasiveness	Yes	Yes	Yes

Modified with permission from Freifeld AG, Iwen PC. Zygomycosis. *Semin Respir Crit Care Med* 2004;25:221–31.

*In all cases, a definitive diagnosis of the species requires isolation and identification of the fungus on synthetic media.

[†]Entomophthorales are included in this group with the hyphal fragments in tissue generally coated by anophous eosinophilic Splencore-Hoepple material and lack of angioinvasiveness noted.

[‡]Because of hyphal degeneration or host immune response or both, the hyphae of the *Aspergillus* species may exhibit atypical morphologic forms that may cause problems in the differential diagnosis.

Figure 61-43 A fluffy gray colony of *Rhizopus* spp. fills the space within the Petri dish (lid lifter). (Sabouraud dextrose agar.)

Most Zygomycetes grow well on standard fungal medium. Unfortunately, recovery of a Zygomycetes from tissue is difficult when negative culture results are common, although histologic evidence of a Zygomycetes is present (Roden, 2005). Aggressive processing of a specimen is thought to damage the organism so it is no longer viable; therefore, tissue should be minced or teased, rather than homogenized, after which it is inoculated onto the surface of a primary isolation agar (Ribes, 2000). Zygomycetes are inhibited by cycloheximide, so nonselective fungal medium should be included when fungal cultures are performed. Isolates grow rapidly (within 48–72 hours) and produce abundant aerial hyphae that rapidly reach the lid of the Petri dish, colloquially referred to as “lid lifters” (Fig. 61-43). The hyphae are characterized as woolly and initially white, turning gray to black as spores develop.

Rhizopus spp. produce unbranched sporangioophores that support sporangia (60–350 μm) with an ellipsoidal columella containing sporangiospores. The sporangiospores are oval and frequently have a brown pigment (see Fig. 61-6). An important diagnostic feature for *Rhizopus* is the presence of hyaline to brown root-like structures called rhizoids, which develop at the point where the sporangioophores arise. In contrast to *Rhizopus*, the rhizoids of *Lichtheimia* (*Absidia*) spp. arise from the stolons between conidiophores. The sporangioophores are pear-shaped rather than round, and a

collarlette is visible around the columella when the sporangium disintegrates.

Mucor spp. on the other hand do not produce rhizoids; the conidiophores usually are more branched than other Zygomycetes and growth does not occur above 37° C. *Rhizomucor*, which is morphologically intermediate between *Rhizopus* and *Mucor*, has rudimentary rhizoids and branched conidiophores and grows at temperatures as high as 58° C. *Mucor* spp. were commonly thought to be the second most recognized causes of zygomycosis; however, they now have been described as a rare cause of human disease (Iwen, 2005). This is due to the fact that *Mucor corymbifera* has been reassigned to the genus *Lichtbeimia* (*Absidia*) as *L. corymbifera*, and *M. pusillus* has been reclassified in the genus *Rhizomucor* as *R. pusillus* (Ribes, 2000).

Although genera of the Zygomycetes can be readily recognized in the mycology laboratory, few laboratories have the expertise needed to identify specific species. One method used to accurately identify the Zygomycetes has been the observation of zygospores following mating studies because of the heterothallic nature of this group of organisms (Weitzman, 1995). Although this method is used successfully, mating studies do not always yield a positive result. Additionally, the need to maintain a library of testing strains needed to perform mating does not make this method realistic for most clinical laboratories (Iwen, 2005, 2007).

Numerous molecular methods have been described for species identification of the Zygomycetes using a variety of molecular targets. Nucleotide sequence comparisons using the ITS regions of the rDNA complex and the variable D1/D2 region of the 28S gene have been shown to have the highest discriminatory capability for the identification of most Zygomycetes species (Hall, 2004; Schwarz, 2006; Alvarez, 2009; Balajee, 2009a).

ASPERGILLOSIS, FUSARIOSIS, AND OTHER MYCOSES CAUSED BY HYALINE FUNGI

This large group of saprophytic fungi is frequently encountered in the clinical laboratory and contains some of the most important pathogenic moulds. These moulds are collectively classified as hyaline because they produce nonpigmented hyphae, and the disease is frequently called hyalohyphomycosis. The number of species within this group that are capable of causing human disease is large and continues to expand as immunosuppressive therapies become more common methods for the management of patients. By far the most recognized hyaline moulds causing human disease are classified in the Eurotiales (*Aspergillus*, *Paecilomyces*, and *Penicillium*), the Microascales (*Scedosporium* and *Scopulariopsis*), and the Hypocreales (*Cylindrocarpon*, *Fusarium*, and *Trichoderma*). In this section, detailed consideration will be given to *Aspergillus* spp. and *Fusarium* spp., the hyaline moulds most commonly believed to cause invasive human disease.

THE GENUS *ASPERGILLUS*

Invasive aspergillosis is the most common life-threatening opportunistic invasive mycosis in immunosuppressed patients (Leefflang, 2008). The term aspergillosis is used to describe these infections, which are caused by species within the genus *Aspergillus*. This group of organisms has the ability to produce a wide spectrum of infections, which include mycotoxicosis, allergic manifestations, and superficial infection in the normal host; localized noninvasive infection in hosts with tissue damage or foreign body obstruction; and invasive infection in the compromised host (Bodey, 1989). Although they are not discussed further here, numerous reviews are recommended for additional information on intoxication by ingestion of *Aspergillus* toxin (Etzel, 2002; Hedayati, 2007) and allergic manifestations associated with *Aspergillus* spore exposure (Agarwal, 2009; Schubert, 2009; Thia, 2009).

The number of new *Aspergillus* spp. associated with human disease has continued to expand with the utilization of genomic methods for identification (Balajee, 2007a, 2009a, 2009b; Geiser, 2007, 2009). Many species now described are known to be cryptic species associated with species commonly identified in the past (Geiser, 2007). Because these species cannot be easily differentiated in the laboratory, the laboratory now more accurately reports the phenotypic identification as a complex of species such as "*Aspergillus fumigatus* species complex." This concept of reporting is not fully utilized within the clinical laboratory, and the old method of reporting using common species names is still used most often (Samson, 2007).

Aspergillus fumigatus is considered the most common species associated with invasive aspergillosis, followed by *Aspergillus flavus* and *Aspergillus terreus* (Dagenais, 2009; Krishnan, 2009). However, in some studies, *A. flavus* has emerged as a predominant pathogen, especially when those patients with fungal sinusitis and fungal keratitis were evaluated in several institutions worldwide (Krishnan, 2009). Suggestions are that the bigger size of the *A. flavus* spores, in comparison with the spores of *A. fumigatus*, may favor their deposit in the upper respiratory tract and eye (Pasqualotto, 2009).

Aspergillus terreus as the third most common species recognized is often refractory to therapy with the antifungal amphotericin B and has the propensity to disseminate (Balajee, 2009; Lass-Flörl, 2009). Multiple other species of *Aspergillus* have rarely been recognized as causing invasive disease (Marr, 2002a; Balajee, 2009b; Florescu, 2009).

Risk Factors

The aspergilli are ubiquitous fungi to which all people are exposed on a regular basis. These fungi reside in vegetation of all types and are ubiquitous in the environment. Nosocomial infections, although uncommon, have been linked to numerous cases associated with hospital construction in the literature (Warnock, 2001; Vonberg, 2006). Engineering infection control through facility design to prevent high-risk patients from spore exposure has been done to provide a safer environment for patients (Noskin, 2001).

The most important risk factors for invasive aspergillosis are immunosuppressive disease, high-dose chemotherapy with or without transplantation, and solid organ transplantation (Maschmeyer, 2007; Ben-Ami, 2009; Zilberberg, 2009). Neutropenia is a prominent predisposing factor for disease; however, serious invasive disease may rarely occur in individuals who are not immunosuppressed by chemotherapy or malignancy (Denning, 2004). For instance, wound infection has been a problem in patients with extensive burn wounds and in individuals exposed to materials contaminated with conidia—a situation reminiscent of the Zygomycetes (Holzheimer, 2002). A fungus ball may also occur in the lung of patients with chronic obstructive lung disease, bronchiectasis, and an old cavity caused by tuberculosis (Riscili, 2009).

Clinical Diseases

The spectrum of invasive disease caused by *Aspergillus* species is broad. Although these fungi have a low pathogenicity in humans and rarely cause disease in the immunologically competent individual, immunocompromised patients are at risk for invasive disease. Those patients especially at risk are those with prolonged granulocytopenia or graft-versus-host disease and those undergoing immunosuppressive therapy or receiving corticosteroid treatment (Kontoyiannis, 2002). Because *Aspergillus* spores are normally present in the environment, the most common primary sites of infection are the lower respiratory tract and, to a lesser extent, the paranasal sinuses.

Ocular Infections

Keratomycosis usually follows trauma to the eye, especially in patients who have been treated with topical steroids. Pain and blurring of vision follow the traumatic episode, and if not treated, the infection may extend into the anterior chamber. Enucleation of the eye may be necessary if the process is not halted. The most common underlying disease recognized in a study of 15 patients with orbital invasive aspergillosis was diabetes mellitus, with all patients having a primary paranasal sinus infection (Choi, 2008). Ocular symptoms of this disease in the immunosuppressed patient include visual disturbances, periorbital swelling, and periorbital pain.

Otic Infections

Otomycosis is an infection of the external ear that is usually caused by *Aspergillus niger* or *A. fumigatus*. Pain, decreased hearing, and a discharge are accompanied by a fluffy green or black growth in the ear canal. Extension beyond the external ear is rare but may occur in immunosuppressed patients (Vennewald, 2003).

Sinus Infection

Invasive fungal sinusitis can be classified as an acute fulminant invasive disease or as a chronic indolent invasive disease (Morpeth, 1996). Spread of the fungus from the sinus into adjacent tissues is frequently dependent on the host immunologic response and on whether metabolic ketoacidosis is present, although invasive infection has also been reported in apparently healthy individuals (Parikh, 2004; Sivak-Callcott, 2004).

Cutaneous Infection

Aspergillus spp. may infect the skin after dissemination from another site, usually pulmonary, or the infection may be a primary infection after direct cutaneous exposure to a contaminated environmental source (Arikan, 1998; van Burik, 1998; Thomas, 2008). Recognized risk factors include immunosuppression, but local factors that abrogate defense mechanisms of the skin are also important such as may occur with burn wounds and surgical wounds, especially if occlusive dressings are present. Dissemination to the skin from another primary source in the suppressed patient is difficult to treat and generally results in death. This condition is usually recognized by multiple lesions appearing over different areas of the body.

Primary Pulmonary Infection

Primary pulmonary aspergillosis is the most common invasive mould infection in immunocompromised patients, especially in those patients with hematologic malignancies who are undergoing intensive chemotherapy (Vonberg, 2006). Even though the disease is usually associated with severely immunocompromised persons, less invasive and noninvasive diseases that affect the lungs such as aspergilloma (fungus ball), chronic necrotizing pulmonary aspergillosis, semi-invasive aspergillosis, chronic invasive pulmonary aspergillosis, symptomatic pulmonary aspergillosis, and *Aspergillus* pseudotuberculosis may also occur (Denning, 2003). The predilection of aspergilli to invade blood vessels leads to infarction and hemorrhage in the lungs and may involve hematogenous spread to other organs (Zmeili, 2007; Thompson, 2008).

Disseminated Infection

Dissemination from the lung or any other primary site of infection may affect any other organ system within the body. The propensity of hyphae to invade vascular structures and cause thrombosis leads to infarcts and abscesses in multiple organs. Single or multiple organs, including the brain, skin, kidneys, pleura, heart, esophagus, liver, or any other site, may be involved (Denning, 1998a).

Pathology of Aspergillosis

The histologic appearance of the aspergilli in tissue is similar to that observed with the other hyaline moulds, and differentiation among genera and species usually is not possible, except in unusual cases where sporulation within the tissue cavity has occurred. The tissue reaction may be granulomatous but is more commonly dominated by polymorphonuclear neutrophils unless the patient is severely neutropenic. Vascular invasion, thrombosis, and infarction often are prominent features. The hyphae are thin (2–5 µm) and septate and branch at acute angles (dichotomous) (see Fig. 61-4). The H&E stain often colors the hyphae, but the morphology may be demonstrated to advantage with the PAS or GMS technique. The histologic appearance of aspergilli in tissue and Zygomycetes can be differentiated on the basis of size, hyphal characteristics, and the presence of septations (see Table 61-11).

When the pathologic process is a fungus ball, the hyphae may stain poorly using histopathologic stains. A cavity that is in contact with air, as in the lung or sinuses, may develop fruiting heads, an event that permits identification in the genera and possibly to the species (Fig. 61-44). The conidiophores, which are not septate and may be wider than the vegetative hyphae, should not be confused with the Zygomycetes. Thick-walled Hülle cells and cleistothecia have also been described in vivo. When the patient is immunocompetent and the histologic response is granulomatous, the hyphae may be fragmented and confined to the cytoplasm of macrophages and multinucleated giant cells. The granulomatous response to *Aspergillus* in the lung may be mistaken for bronchocentric granulomatosis in patients who have allergic disease (Nagata, 1990).

Laboratory Diagnosis

Aspergilli are saprophytic fungi that should never be dismissed as contaminants without consultation with the attending physician. Isolation from a sterile site or repeated isolation from respiratory specimens suggests clinical significance. Hyphae may be demonstrated directly in clinical specimens in imprint preparations or wet preparations. Calcofluor white staining is useful for demonstrating the mould in specimens. Obtaining tissue, fluid, scrapings, or curettings for examination is important. Tissue should be teased or minced and inoculated directly onto the surface of the isolation medium. *Aspergillus* spp. grow rapidly, but most are inhibited or are partially inhibited by cycloheximide. The colonies of many of these moulds teem with conidia. To prevent contamination of the worker and other cultures, the colonies should be manipulated carefully in a biological safety cabinet, after which the surfaces of the safety cabinet should be

Figure 61-44 A fruiting head of *Aspergillus* is demonstrated within a pulmonary mycetoma (fungus ball). The phialides and conidia are well demonstrated. Although the hyphae of *Aspergillus* are not etiologically diagnostic, demonstration of the fruiting head documents the presence of this genus. (Gomori's methenamine silver stain, $\times 400$.)

Figure 61-45 Fluffy colonies with granular areas produced by fruiting heads of *Aspergillus flavus*. The development of yellow or green coloration within the white colonies is characteristic. (Sabouraud dextrose agar.)

thoroughly wiped with a fungicidal solution. Maintenance of isolated moulds in plastic bags with continuing incubation also reduces the probability of contaminating other cultures.

Specific identification of *Aspergillus* spp. is made by study of the reproductive structures and the macroscopic appearance of the culture. Careful attention to details of the conidial head is needed for species identification (Klich, 2002). *A. fumigatus* grows rapidly, producing colonies with a fluffy appearance and a blue-green appearance to the colony (see Fig. 61-2). Examination of the colony with a dissecting microscope reveals the conidiophores with their expanded vesicles as small globes projecting above the vegetative mycelium. The conidiophore is smooth, relatively short (300–500 µm), and expanded into a flask-shaped vesicle. The phialides develop in a single row (uniseriate), most commonly on only the upper two thirds of the vesicle, parallel to the axis of the conidiophore (see Fig. 61-8). The conidia are roughened (echinulate) and are round to oval.

Colonies of *A. flavus* have a velvety yellow to green appearance once fruiting heads develop (Fig. 61-45). The conidiophore is long (400–700 µm), ending in a vesicle that may be elliptical or round. The conidiophore is rough and stubby. A single or double (biseriate) row of phialides occurs over the whole vesicle or the upper three quarters (Fig. 61-46). Round to oval conidia appear yellow-green en masse and measure 3–4.5 µm. *Aspergillus terreus* can be differentiated from other species by the production of a cinnamon brown colony with microscopic characteristics that include short conidiophores (<250 µm) and biseriate phialides.

Although the gold standard for making a diagnosis of invasive aspergillosis is to obtain a positive culture from sterile tissue with histologic evidence of mycelial invasion, the need for invasive techniques to obtain the

Figure 61-46 The fruiting head of *Aspergillus flavus* is uniseriate and biseriate. The phialides extend around much of the vesicle with a roughened (spiny) appearance of the conidiophore. (Lactophenol cotton blue stain, $\times 400$.)

specimen, the delayed time required for culture, and the rapidity by which the aspergilli can spread make diagnosis problematic. Serologic tests are available for the detection of galactomannan to rapidly diagnose invasive aspergillosis (Aquino, 2007; Foy, 2007; Del Bono, 2008; Husain, 2008; Leeftang, 2008; Wheat, 2008) and for the detection of (1-3)-beta-D-glucan for nonspecific diagnosis of an invasive fungal infection (Senn, 2008; Marty, 2009). All of these tests have shown utility in the management of patients with invasive aspergillosis; however, limitations of the various assays need to be understood (Wheat, 2009a).

Although molecular methods have led to dramatic changes in the taxonomy of the *Aspergillus* species, they will continue to be evaluated as methods for the rapid diagnosis of fungal infection from clinical material. Multiple molecular targets for the identification of *Aspergillus* spp. have been evaluated, and targets showing greatest promise for identification appear to be the partial β -tubulin and calmodulin genomic areas (Geiser, 2007, 2009). The general consensus at the present time is that a combination of phenotypic and molecular testing needs to be considered for the accurate identification of *Aspergillus* spp..

Multiple platforms for direct detection of *Aspergillus* DNA in clinical specimens have been evaluated with varying degrees of success (Balajee, 2007a; Hummel, 2007, 2009; Klingspor, 2009; Logotheti, 2009; Wengenack, 2009). A recent systemic review and meta-analysis done on the use of PCR tests for the diagnosis of invasive aspergillosis directly from blood, plasma, and serum samples concluded that a single PCR-negative result was sufficient to exclude a diagnosis of proven or probable aspergillosis (Mengoli, 2009). However, two or more positive tests were required to confirm the diagnosis because of increased specificity after testing of multiple samples. With advances in molecular testing, a formal evaluation of PCR needs to be considered to assess its use in patients most likely to benefit from testing.

THE GENUS *FUSARIUM*

Fusarium spp. have been implicated in a number of infectious diseases, including keratomycosis, burn wounds, and invasive disease in immunocompromised patients (Jossi, 2009). Fusaria are now considered the second most common pathogenic moulds causing invasive disease (Dignani, 2004). Although still considered a rare cause of human disease, a major outbreak of *Fusarium* keratitis was recently reported wherein 130 cases of eye infection were confirmed (Centers for Disease Control and Prevention, 2006; O'Donnell, 2007). An epidemiologic investigation showed that most infected patients wore contact lenses that had been cleaned with a lens solution obtained from one manufacturer. This investigation led to the voluntary recall and permanent removal of the associated contact lens solution from the worldwide market.

The histopathologic picture for fusariosis is essentially identical to that observed with invasive aspergillosis (angioinvasive and acute branching septate hyphae). A differentiating feature from invasive aspergillosis is that fungemia is more commonly described in fusariosis. *Fusarium*-positive blood cultures are frequently detected during disseminated disease; however even in documented disseminated disease, detection of aspergilli in the blood is rare (Lionakis, 2004).

Figure 61-47 Canoe-shaped conidia of *Fusarium* spp. The conidia are often septate. (Lactophenol cotton blue stain, $\times 400$.)

In culture, *Fusarium* colonies develop rapidly, producing a fluffy aerial mycelium, which often has a pink, lavender, or salmon color. Diffusible pigments may be seen in the surrounding agar. Simple or branched phialides develop directly from the hypha without a separate conidiophore. Short oval microconidia may be produced, but the distinctive structure is a canoe-shaped or crescent-shaped macroconidium, which may have one or more septa (Fig. 61-47). Identification of species in the mycology laboratory is difficult, usually requiring a reference laboratory with experience in recognition of subtle microscopic details related to the reproductive structures.

The taxonomy of *Fusarium* species has undergone extensive evaluation using molecular sequence analysis of multiple genomic targets (O'Donnell, 2008, 2009a). Although most fusaria pathogenic to humans are nested within the *Fusarium solani* or the *Fusarium oxysporum* species complex, it continues to be traditional taxonomic practice to refer to members of these complexes as single species (i.e., *F. solani* and *F. oxysporum*). These recent molecular phylogenetic studies, however, have begun to clarify species boundaries within evolutionary lineages of *Fusarium* that contain human pathogens. Currently however, recognition of the species, although important for epidemiologic purposes, does not have an impact on therapeutic decisions; thus many laboratories continue to report these as "*Fusarium* species." The recommended molecular target for identifying species within the two major complexes is now the partial EF-1 α gene (Balajee, 2009a; O'Donnell, 2009b).

THE GENUS *SCEDOSPORIUM*

Medically important species within the genus are *Scedosporium apiospermum* (teleomorph *Pseudallescheria boydii*, previously known as *Allescheria boydii* and *Petriellidium boydii*) and *Scedosporium (inflatum) prolificans* (Cortez, 2008). These fungi are ubiquitous saprophytic fungi found in the soil and in decaying vegetation. *S. prolificans* has been reported as a rare cause of disseminated infection, whereas *S. apiospermum*, although most often associated with a subcutaneous infection (eumycotic mycetoma), is the most common species associated with invasive disease in the immunocompromised patient. A distinctive clinical syndrome of sinopulmonary and central nervous system infections in immunocompetent individuals has been associated with near drowning in polluted waters, with *P. boydii* as the etiologic agent (Gilgado, 2009).

S. apiospermum (*P. boydii*) grows rapidly on isolation medium at 25° C, producing a fluffy colony, which develops a brownish gray to dark gray ("mousy") color after incubation for several days. The culture darkens still further with continued incubation (Fig. 61-48). The asexual phase is characterized by single or small clusters of annelloconidia on a straight or branched conidiophore that may develop terminally or laterally from the vegetative hyphae. The conidia are light brown and have an oval, sperm-like morphology (Fig. 61-49). In the sexual phase (*P. boydii*), brown cleistothecia are produced that contain ascospores (see Fig. 61-13). The cleistothecia (100–300 μ m in diameter), which are found most readily at the edges of the colony, develop best on nutritionally deficient media, such as cornmeal agar, V-8 juice agar, or potato dextrose (potato flake) agar. Because this fungus is homothallic, recognition of brown cleistothecia in

Figure 61-48 A developing colony of *Scedosporium apiospermum* with the characteristic mousy gray coloration. (Sabouraud dextrose agar.)

Figure 61-49 Tadpole- or sperm-shaped microconidia of *Scedosporium apiospermum* are representative of this organism. (Lactophenol cotton blue stain, $\times 400$.)

the clinical laboratory is common. Strictly speaking, when the cleistothecia are demonstrated, the isolate should be reported as *P. boydii*, and it should be reported as *S. apiospermum* if the asexual conidia are the only diagnostic structures observed.

Although both macroscopic and microscopic characteristics can be used to separate species within the genus *Scedosporium*, molecular studies now suggest that *P. boydii* is a complex of multiple species (Gilgado, 2005, 2008).

OTHER SEPTATE HYALINE MOULDS

A long list of hyaline moulds are environmental saprophytes of low virulence and usually are not associated with clinical disease when isolated in the mycology laboratory (Walsh, 2004b). As mentioned earlier, any of these moulds may be pathogenic under the right conditions. In most cases, the host defenses of the patient are compromised in some way, or the fungus is introduced into the body by trauma or medical manipulation. Increasing numbers of case reports document saprophytic fungi producing infection of deep tissue and systemic organs (Rodriguez-Villalobos, 2003; Schinabeck, 2003; Sanchez, 2007; Van Schooneveld, 2008; Salmon, 2009). Demonstration of hyphae in tissue is extremely important for documenting the pathogenicity of these isolates, with culture necessary for species recognition. Molecular methods with sequence comparison analysis are becoming the standard for identification of these unusual pathogens (Balajee, 2007b).

PNEUMOCYSTIS PNEUMONIA

The taxonomic position of *P. (carinii) jiroveci* has undergone numerous changes over the years. This organism was originally described as a protozoan with the morphologic forms identified as trophozoites, cysts, and

sporozoites. This protozoan hypothesis remained predominant until DNA analysis showed this organism to be more closely related to the fungi (Edman, 1988). More recently, molecular information showed that the organism had differing DNA sequences when identified from diverse mammal hosts. To address this issue, the *Pneumocystis* Working Group in 1994 proposed the name *P. carinii* f. sp. *hominis* as a special form (*formae specialis*) of the organism causing *P. carinii* pneumonia (PCP) in humans (Pneumocystis Working Group, 1994). Subsequently, those attending the International Workshop on Opportunistic Protists in 2001 began the process to rename the species to *P. jiroveci* (pronounced “yee row vet zee”) (Frenkel, 1999; Stringer, 2002). Although initially controversial (Hughes, 2003), the name has now become widely accepted as the “microbe that causes PCP in humans,” with the acronym PCP now standing for “*Pneumocystis* pneumonia.”

RISK FACTORS

P. jiroveci (human-derived *Pneumocystis*) is a pathogen capable of causing a broad spectrum of clinical presentation. This organism was first recognized in outbreaks of pulmonary disease among malnourished infants in Eastern Europe during and after World War II (called “interstitial plasma cell pneumonia”) (Cushion, 2003). More recently, *Pneumocystis* became a major cause of life-threatening pneumonia in 60%–80% of HIV-infected adults in America and Western Europe, and it subsequently became known as one of the AIDS-defining illnesses (Centers for Disease Control and Prevention, 1999b; Travis, 2009). Although still a serious problem within this patient population, the incidence of disease in people with AIDS has decreased to less than 10% of patients owing to the availability of HAART, the increasing use of anti-PCP prophylaxis, and improved awareness of the infection (D’Avignon, 2008). This disease should also be considered in any immunosuppressed patient who presents with fever, respiratory symptoms, or infiltrate on chest radiograph (Dei-Cas, 2000). Initially, clinical disease was thought to be due to reactivation of childhood latent infection in immunosuppressed cases, but studies now show that the organism can be transmitted between humans by the airborne route (Nevez, 2003; Totet, 2003). In individuals with compromised immune systems (e.g., HIV infection, chemotherapeutic regimens, organ transplantation), a potentially severe and fatal pneumonia can occur. Disseminated disease may also occur via spread through lymphatic and blood routes, but this is uncommon. Although rare, infection has been documented in patients without a predisposing illness (Al Soub, 2004).

CLINICAL DISEASES

Pneumonia is the most common manifestation of *P. jiroveci* infection (D’Avignon, 2008; Krajicek, 2009). Although the onset may be acute or insidious, symptomatic adults frequently present with dyspnea, a nonproductive cough, an inability to breathe deeply, chest tightness, and night sweats. The classic radiologic feature of PCP is fine, bilateral, perihilar interstitial shadowing; however, other radiographic pictures may be present (Barry, 2001). Often, radiographic infiltrates are much more extensive than would be suggested by the degree of symptoms. Concurrent infection with other agents, particularly cytomegalovirus and *C. neoformans*, is common. The most common extrapulmonary sites of infection are the thyroid, liver, bone marrow, lymph nodes, and spleen (Wazir, 2004).

PATHOLOGY

The definitive diagnosis of PCP requires the demonstration of cysts or trophozoites within clinical specimens (Fig. 61-50). Historically, this required an open thorax lung biopsy because of the low number of organisms present in other respiratory specimens and the lack of sensitive diagnostic tests. Although open lung biopsy is still considered one of the most sensitive tests for the detection of this disease, other specimens such as induced sputum and bronchoalveolar lavage have proved to be reliable sources for diagnosis. Classic histopathologic findings of PCP in sections of lung stained with H&E include widening of the alveolar septa with an infiltrate of mononuclear cells and foamy exudate within the alveolar spaces (sometime referred to as honeycombed exudates) (Woods, 2003). This exudate consists of aggregated cysts and trophozoites. The cyst form of *P. jiroveci* can be illustrated in tissue using the GMS stain. These cysts, which are 5–6 μ m in diameter, stain brown to black and have the characteristic cup-shaped or crescent-shaped morphology. *Pneumocystis* cysts do not bud; this feature can be used to distinguish this organism from other fungi found in tissue.

LABORATORY DIAGNOSIS

P. jiroveci has been cultivated in cell cultures, but serial maintenance of subcultures has not been accomplished. The standard for diagnosis is staining bronchoalveolar lavage fluid with an immunofluorescent monoclonal antibody directed against surface epitopes for *Pneumocystis* cysts and trophozoites (Cushion, 2003). The life cycle of *P. jiroveci* involves development of sporozoites within a cyst, after which the sporozoites are released. In patients with HIV infection, sufficient numbers of organisms are produced that sputum induced with saline by a skilled respiratory therapist may provide the diagnosis. Experience with sputum has varied among centers, however, and the yield is very low in patients who have underlying disease other than HIV. Use of fluorescein-conjugated monoclonal antibodies to detect *P. jiroveci* in clinical specimens has proved to be a specific and sensitive method for identification (Fig. 61-51) (Kovacs, 2001). The immunofluorescence technique has been more sensitive in histochemical stains in some reports, but the skill and care of the observers undoubtedly play a role in the comparative sensitivity of the techniques (Cushion, 2003). Cysts of *P. jiroveci* occasionally may also be encountered in Gram-stained preparations, although this technique is not a sensitive method for detection.

Various PCR amplification strategies have been described for detecting *P. jiroveci* in clinical specimens (Robberts, 2007; Gupta, 2009). In an evaluation of nine different molecular assays, the mitochondrial large subunit rRNA target using a nested PCR platform was shown to be the most sensitive assay, with the highest degree of concordance seen with findings of histologic examination (Robberts, 2007). Additional studies have shown this assay to be useful in identifying patients who are in the early stages of infection (Gupta, 2009).

Figure 61-52 Histopathologic changes in protothecosis of the skin and mucous membrane of the nose due to *Prototheca wickerhamii*. Septation of the algal cells leads to multiple intracellular bodies and structures known as morula. (Courtesy Dr. William Kaplan, CDC Public Health Image Library.)

Figure 61-53 Colonies of *Prototheca wickerhamii* are yeast-like in appearance. (Sabouraud dextrose agar.)

PROTOTHECOSIS

Protothecosis is an infection caused by achlorophyllic algae of the genus *Prototheca* (Leimann, 2004; Lass-Flörl, 2007). Most human infections are caused by *Prototheca wickerhamii*; however, rare cases have also been caused by *Prototheca zopfii*. Although these species are classified as algae, they are included in this chapter because of the resemblance of the infections to fungal disease. *Prototheca* are found in fresh and marine waters and probably gain entrance to the body through superficial wounds. Some patients are immunocompetent, but serious underlying diseases, such as diabetes mellitus, or immunosuppressive therapies often predispose patients to infection with these pathogens. Other patients have received injections of corticosteroids at the site of infection or have had musculoskeletal infection, particularly involving the tendons. Infections commonly involve the skin and subcutaneous tissue, with subsequent involvement of underlying tendons.

Prototheca form large, nonbudding cells that can readily be seen in tissue. The appearance is a spheroid or ovoid cell with a prominent wall and a "morula-like" structure containing thick-walled autospores (Lass-Flörl, 2007). Although *Prototheca* species are not readily apparent in H&E-stained smears, they can be observed with GMS or PAS stain. However, these structures must be differentiated from the dimorphic fungi (Fig. 61-52). Algae grow readily on fungal isolation media that do not contain cycloheximide, and the colonies resemble those of *Candida* spp. (Fig. 61-53). *Prototheca* species can be identified to the species level by using commercial yeast identification systems, such as the API 20C System and the VITEK 2 system (bioMérieux).

PARASITIC INFECTIONS AND THE IMMUNOCOMPROMISED HOST, 1236

SELECTED REFERENCES, 1238

KEY POINTS

- Accurate diagnosis of parasitic infection usually depends on macroscopic or microscopic examination of specimens that have been appropriately collected and preserved. Thick and thin blood smears are useful for detecting and characterizing organisms found in the blood. Fecal specimens may be fresh or may be placed into fixatives such as formalin and polyvinyl alcohol.
- Immunodiagnostic methods for parasitology include detection of both antibodies and antigens. Established enzyme immunoassays include antigen tests for *Plasmodium* spp. in blood or serum; *Giardia lamblia*, *Cryptosporidium* spp., and *Entamoeba histolytica* in feces; and *Trichomonas vaginalis* in vaginal swabs. Direct fluorescent assays are also useful for identifying organisms in primary specimens. Serologic testing is an important adjunct in recognizing parasitic infections that reside in deep tissues, organs, and body spaces not readily amenable to routine morphologic testing methods.
- Molecular diagnostic methods now emerging are based on amplification techniques that offer high levels of sensitivity and specificity for both diagnosis and monitoring of parasitic disease.
- The diagnosis of malaria should be considered in the differential diagnosis of unexplained fever with the history of travel in endemic geographic regions. Thick and thin blood smears are complementary for detecting and identifying infecting *Plasmodium* spp. based on varieties of developmental stages, presence of malarial pigment, and stippling seen in infected erythrocytes.
- Other protozoal infections include babesiosis and trypanosomiasis found in blood, leishmaniasis (causing cutaneous, mucocutaneous, and visceral forms of disease), and toxoplasmosis, often affecting the central nervous system following congenital infection and in patients with acquired immunodeficiency syndrome (AIDS).
- Amebae are ingested as cysts, resulting in infection of the colon and passage of both cysts and trophozoites in the feces. Resulting diseases include amebic dysentery, amebic colitis, and liver abscess. Diagnosis is made by microscopic examination of stool and by serologic testing for antibodies in serum.
- Flagellates include *Giardia lamblia*, which causes diarrhea from ingestion of contaminated water and is diagnosed by the finding of trophozoites or cysts in feces. *Trichomonas vaginalis* is acquired by sexual transmission and is detected in vaginal wet mounts by its characteristic motion.
- Coccidia (*Cystoisospora*, *Cryptosporidium*, and *Cyclospora*) and microsporidia can cause protracted diarrhea in immunosuppressed individuals such as those with AIDS.
- Intestinal helminths include nematodes (roundworms), cestodes (tapeworms), and trematodes (flukes). These organisms reside as adults in the gastrointestinal tract or in other locations (liver, lung, blood). Knowledge of their life cycles and zoogeography with intermediate hosts is critical for establishing the parasitic stage in presumed infection. Eggs, larvae, or adult forms (from 1 mm to >10 m in length, depending upon the species) can be recovered from stool, urine, or sputum.
- Tissue helminths include filaria (larvae found in blood and also on skin biopsy), *Trichinella* (in muscle), *Strongyloides* (disseminated infection), and hydatidosis (large cystic lesions in the liver or lungs), among others.
- Arthropods cause disease through direct tissue invasion, envenomation, vesication, blood loss, transmission of infectious agents, hypersensitivity reactions, and psychological manifestations. Characteristics necessary for identification can be maintained by preserving the organisms in alcohol (ticks, mites, fleas, lice), by drying them (winged forms) after killing them with fumes of organic solvents, or by killing them with hot water (maggots) and subsequently storing them in alcohol.

The study of parasitology has gained renewed importance in a world made smaller by the rapid movement of people, especially travelers to and migrants from areas endemic for parasitic disease, and by the appearance of emerging and reemerging pathogens in individuals immunocompromised for a variety of reasons. Parasitic diseases of humans and domestic animals place a tremendous burden on limited healthcare resources and

adversely affect economic and societal development in many countries around the world. Although the types of organisms classified as parasites constitute a large group, those that infect humans are limited in number and are composed mostly of protozoa, helminths, and arthropods (Table 62-1).

Clinicians in the United States and elsewhere are increasingly being confronted with unusual diagnostic problems associated with parasitic infection. Likewise, laboratorians have been challenged with the development of new technologies to accurately and rapidly diagnose such parasites as *Cryptosporidium parvum*, *Cryptosporidium hominis*, *Cyclospora cayetanensis*, *Toxoplasma gondii*, as well as microsporidia in both immunocompetent and immunocompromised hosts. The worldwide resurgence of malaria and other parasitic diseases has required laboratorians to strengthen their expertise in identification of the usual blood, intestinal, and tissue protozoa and helminths.

Once these diseases have been diagnosed, additional problems may be encountered in their management owing to lack of effective therapies and the emergence of resistance to traditional therapy. Many parasites require arthropod vectors for their transmission, and the irregular application of vector control efforts has, in some instances, resulted in the emergence of insecticide resistance. Malaria has made a tremendous resurgence in many areas because of relaxed control efforts and the emergence of drug-resistant parasites and insecticide-resistant mosquitoes. Schistosomiasis has spread into many new areas because of increased irrigation associated with population growth and the need to expand agricultural production.

Because of the chronic nature and the generally long prepatent periods (i.e., time between infection and appearance of diagnostic stages) of many parasitic diseases, physicians may not consider them in a differential diagnosis unless the patient voluntarily offers information, or specific inquiry is made about travel history or other possible exposure. Malaria is one parasitic disease that often presents as an acute, febrile illness and may have lethal consequences unless it is considered in the differential diagnosis and a history of travel to an endemic area is elicited.

Various estimates have been put forth for the prevalence and related mortality figures of parasitic infections on a worldwide basis (Table 62-2). The actual incidence of parasitic infections in the United States is unknown, however, because most infections are not reported to public health officials. *Giardia lamblia*, other intestinal protozoa, and intestinal roundworms are reported most frequently (7.2%, 10%, and 3.5%, respectively) by state laboratories, but other parasites, including *Cryptosporidium*, *Cyclospora*, and microsporidia, probably occur more frequently and are underdiagnosed (Kappus, 1994; Garcia, 2007).

This chapter provides an overview of the general approach used by laboratorians to recover and identify parasitic protozoa and helminths from human specimens. Discussion of individual species of parasites focuses on essential clinical and biological information necessary to assist in diagnosis and management. For more extensive coverage of specific parasites, a number of excellent texts are available (Beaver, 1984; Warren, 1990; Lane, 1993; Guerrant, 1999; Garcia, 2007, 2009; Markell, 1999; Strickland, 2000; Cook, 2002; Mullen, 2002; among others). Some of these references are older and may be less accessible; however, they discuss classic disease presentations and historic perspectives in a way that is sometimes lacking in newer literature. Parasitology atlases are also important resources for any laboratorian performing parasitology examinations and should be readily available (Spencer, 1982; Brooke, 1984; Ash, 1987, 2007; Sun, 1988; Peters, 1989; Garcia, 2010; Murray, 2007). Several texts specifically address the pathologic aspects of parasitic infections (Marcial-Rojas, 1971; Binford, 1976; Sun, 1982; Von Lichtenberg, 1991; Woods, 1993; Orihel, 1995; Connor, 1997; Gutierrez, 2000). Parasitic infections that are problematic in immunocompromised patients also have been reviewed (Walzer, 1989).

LABORATORY METHODS

Numerous methods have been described for the recovery and identification of parasites in clinical specimens, some of which are useful for detection of a variety of species, whereas others detect only a particular species. It is preferable for the laboratory to offer a limited number of procedures competently performed than a larger variety of infrequently performed tests that may prove problematic. Analyses of blood and fecal specimens account for the largest share of clinician requests for parasitologic evaluation. A variety of additional specimens are submitted to the laboratory less frequently, including urogenital specimens, sputum, aspirates, and biopsy material. As newer information becomes available on certain of the

TABLE 62-1

A Summary of the More Commonly Found Human Parasites and Their Primary Sites of Infection

Subkingdom Protozoa	Subkingdom Metazoa
Phylum Sarcomastigophora	Phylum Platyhelminthes
Subphylum Sarcodina (amebae)	(flatworms)
<i>Entamoeba histolytica</i> (I)*	Class Cestoidea (tapeworms)
<i>E. dispar</i> (I)	<i>Diphyllobothrium</i> spp. (I)*
<i>E. hartmanni</i> (I)	<i>Dipylidium caninum</i> (I)*
<i>E. coli</i> (I)	<i>Echinococcus granulosus</i> (H)*
<i>E. polecki</i> (I)	<i>E. multilocularis</i> (H)*
<i>Iodamoeba bütschlii</i> (I)	<i>Hymenolepis nana</i> (I)*
<i>Endolimax nana</i> (I)	<i>H. diminuta</i> (I)*
<i>Naegleria fowleri</i> (T, C)*	<i>Taenia saginata</i> (I)*
<i>Acanthamoeba</i> spp. (T, C, E)*	<i>T. solium</i> (I, T)*
<i>Balamuthia mandrillaris</i> (T, C)*	Class Trematoda (flukes)
<i>Sappinia diploidea</i> (T, C)	<i>Clonorchis sinensis</i> (H)
<i>Blastocystis hominis</i> (I)	<i>Fasciola hepatica</i> (H)*
Subphylum Mastigophora	<i>Fasciolopsis buski</i> (I)
(flagellates)	<i>Heterophyes heterophyes</i> (I)
<i>Giardia lamblia</i> (I)*	<i>Metagonimus yokagawai</i> (I)
<i>Dientamoeba fragilis</i> (I)*	<i>Nanophyetus salmincola</i> (I)*
<i>Chilomastix mesnili</i> (I)	<i>Opisthorchis viverrini</i> (H)
<i>Retortamonas intestinalis</i> (I)	<i>Paragonimus</i> spp. (L)*
<i>Enteromonas hominis</i> (I)	<i>Schistosoma haematobium</i> (B)
<i>Pentatrichomonas hominis</i> (I)	<i>S. japonicum</i> (B)
<i>Trichomonas vaginalis</i> (V)*	<i>S. mekongi</i> (B)
<i>T. tenax</i> (M)	<i>S. mansoni</i> (B)

TABLE 62-2

Estimated Prevalence of Parasitic Infections Worldwide

Disease	Estimated population involved	Annual number of deaths
Protozoan		
Amebiasis	Up to 10% of world population	40,000–110,000
African trypanosomiasis	100,000 new cases/year	5000
American trypanosomiasis	24 million	60,000
Giardiasis	200 million	
Leishmaniasis	1.2 million	
Malaria	400–490 million	2.2–2.5 million
Helminthic		
Ascariasis	1.3 billion	1550
Cestodiasis	65 million	
Clonorchiasis/opisthorchiasis	13.5 million	
Dracunculiasis	<100,000	
Fasciolopsiasis	10 million	
Lymphatic filariasis	128 million	
Hookworm	1.3 billion	
Onchocerciasis	17.7 million	
Paragonimiasis	2.1 million	
Schistosomiasis	150 million	500,000–1 million
Strongyloidiasis	35 million	
Trichostrongyliasis	5.5 million	
Trichuriasis	900 million

so-called emerging parasites, the laboratory may need to develop and use additional, highly specific test methods or to find competent referral laboratories where such tests are performed.

The types of specimens collected for laboratory evaluation depend on the species and stage of the parasite suspected. Knowledge of the life cycle of the parasite aids in determining the type, number, and frequency of specimens required for diagnosis. Immunologic and molecular methods for the diagnosis of parasitic diseases also are useful in many instances, and may be the only methods available in certain circumstances. Complete descriptions of general and esoteric laboratory procedures for the recovery and identification of parasites referred to here may be found in a variety of sources to which the reader is referred (Beaver, 1984; Ash, 1987; Balows, 1988; Price, 1994; Garcia, 2003, 2007, 2009, 2010; Murray, 2007).

Familiarity with calibration and use of the ocular micrometer is necessary for any laboratory performing parasitologic examination (Clinical and Laboratory Standards Institute, 2005). Measurement of the size of protozoal trophozoites and cysts and of helminth eggs and larvae is often required to make an accurate identification. Pathogenic and nonpathogenic amebae (specifically *Entamoeba histolytica* and *Entamoeba hartmanni*) can be differentiated with assurance only by taking careful size measurements. Similarly, eggs of *Diphyllobothrium* spp., *Paragonimus westermani*, and *Fasciola/Fasciolopsis* may be readily differentiated on the basis of accurate measurements (Smith, 1979; Clinical and Laboratory Standards Institute, 2005).

EXAMINATION OF BLOOD

Parasites that may be detected in blood specimens include the agents of malaria (*Plasmodium* spp.), babesiosis (*Babesia* spp.), trypanosomiasis (*Trypanosoma* spp.), leishmaniasis (*Leishmania donovani*), and filariasis (*Wuchereria bancrofti*, *Brugia malayi*, *Loa loa*, and *Mansonella* spp.). The most important techniques to be performed in the clinical laboratory to assist in the diagnosis of blood parasites include preparation, staining, and examination of thick and thin blood films. Other techniques used less frequently include the buffy coat smear and various concentration techniques reserved for recovery of microfilariae (National Committee for Clinical Laboratory Standards, 2000).

Thick and Thin Blood Films

Examination of permanently stained blood films is required to identify most blood parasites. Thin films are prepared in the same manner as for hematologic differential evaluation; blood is spread over the slide in a thin layer, yielding intact, nonoverlapping cellular elements. Integrity of the blood cell membranes is important for determining the intracellular or extracellular nature of the infection. In the thick film, blood is concentrated in a small area that is many cell layers deep. During staining, erythrocytes are dehemoglobinized and only leukocyte nuclei, platelets, and parasites (if present) are visible. The thick film is preferred for diagnosis because it contains 16–30 times more blood per microscopic field than does the thin film, thus increasing the chances of detecting light parasitemia and decreasing the time needed for reliable examination. The amount of blood examined in a thick film in 5 minutes using the 100× oil immersion objective would require at least 30 minutes when examined in a thin film. Although thick films increase the likelihood of detecting an infection, species identifications are usually performed by examination of thin films because morphology is often more definitive, especially for malarial parasites. For routine examination, both thick and thin films should be prepared.

Preparation of Slides

Blood for examination may be obtained by fingerstick, earlobe puncture, or venipuncture. Fingerstick blood should flow freely to prevent dilution with tissue fluid, and it should not be contaminated with the alcohol disinfectant, which should be allowed to dry first. If obtained by venipuncture, the first drop of blood (anticoagulant-free) from the needle is used to prepare the films at the bedside. Use of anticoagulants is discouraged when malaria is suspected because they may cause distortion of the parasites and interfere with staining. In practice, however, blood usually is submitted to the laboratory in an anticoagulant, which may be the only practical method to ensure that high-quality smears can be prepared. Ethylenediaminetetraacetic acid (EDTA)-anticoagulated blood is preferred in such cases and should be transported to the laboratory within the hour to prevent deterioration of organism morphology. Anticoagulants do not interfere with the staining of microfilariae.

Both thin and thick films should be prepared on clean, grease-free slides. Thick films are prepared by puddling several small drops of blood into an area the size of a dime (1.5 cm) and allowing the blood to dry flat at room temperature, usually overnight. A proper thick film should be thin enough that newspaper print may be read through it. If it is too thick, the film may peel from the slide. Excess heat may fix erythrocytes and may prevent dehemoglobinization.

Staining

Blood begins to lose its affinity for stain in about 3 days, and older thick films do not dehemoglobinize well. Best staining results are achieved when using Giemsa stain because host cell and parasite chromatin stains vividly but the hemoglobin in erythrocytes is only a pale red, and this is the only stain that allows visualization of the erythrocyte stippling that occurs with infection by certain malarial parasites. Wright's stain may be used for thin films, but it stains parasites less well than Giemsa and it stains erythrocytes, producing a busier background. Because Wright's stain incorporates alcohol as its fixative, thick films must be lysed in water before staining.

The Giemsa staining procedure requires somewhat more attention to preparation of reagents and staining protocol than does the Wright's staining procedure, which is often automated. Generally, fresh Giemsa stain must be made each day of use by diluting stock solution into phosphate-buffered water. To achieve appropriate staining reactions, including the appearance of Schüffner's stippling, buffered water must be maintained at pH 6.8–7.2. Each new lot of stock Giemsa stain must be checked to determine optimal staining time and dilution because some variation is seen from lot to lot (National Committee for Clinical Laboratory Standards, 2000).

Examination of Smears

Both thick and thin smears are examined in their entirety under the low-power (10×) objective to detect microfilariae, which rarely occur in large numbers. In particular, the feathered edge of thin smears should be examined, as microfilariae are often carried there during preparation of the smear. Examination using a 50× oil immersion objective may subsequently be used to screen blood films for protozoa, although thorough examination using the 100× oil immersion objective still is necessary to detect the smallest parasites such as *Plasmodium* spp., *Babesia* spp., and leishmanias.

Again, examination of the feathered edge is important because erythrocytes are drawn out into a single layer of cells, allowing thorough evaluation of their morphology and the presence of intracellular protozoa. An experienced microscopist should examine at least 100 oil immersion fields (requiring about 5 minutes) on the thick blood film and 200 fields (requiring at least 15 minutes) on the thin film using the 100× objective before issuing a negative report (Ash, 1987).

Concentration Techniques

A variety of special techniques have been described for the concentration of blood parasites, specifically leishmanias, trypanosomes, and microfilariae, details of which may be found elsewhere (Beaver, 1984; Ash, 1987; Garcia, 1999, 2001, 2010; National Committee for Clinical Laboratory Standards, 2000).

Preparation of buffy coat smears, which most clinical laboratories can perform with existing resources, is helpful in the detection of *L. donovani*, trypanosomes, and microfilariae. Following centrifugation of an anticoagulated blood sample, the layer of cells between plasma and packed erythrocytes is drawn off and is used to prepare blood films for staining or for preparation of a wet mount to detect motile organisms (Ash, 1987; Strickland, 2000).

For detection of microfilariae, Knott's concentration or membrane filtration is helpful, particularly when the density of microfilariae in peripheral blood is very low. With the Knott technique, anticoagulated blood is lysed with 2% formalin and centrifuged to concentrate the microfilariae in the sediment, which then may be examined as a wet preparation or stained with Giemsa or hematoxylin stain. In the membrane filtration procedure, blood is lysed and passed through a 5-μm membrane filter, which is subsequently stained with hematoxylin to reveal any microfilariae (Ash, 1987; National Committee for Clinical Laboratory Standards, 2000).

Use of the fluorochrome acridine orange in a microhematocrit centrifuge format (QBC blood parasite detection method; QBC Diagnostics, Philipsburg, Pa.) allows detection of blood parasites and appears to be more sensitive than traditional thick and thin smears. Laboratories that encounter malaria infrequently may experience difficulty in interpreting results by this method, however, and are encouraged to retain expertise in performance of traditional blood film techniques (National Committee for Clinical Laboratory Standards, 2000).

EXAMINATION OF FECAL SPECIMENS

The presence of intestinal parasites is primarily identified through the direct examination of stool using wet mounts, concentration techniques, permanently stained smears, and, less frequently, culture. Newer immunoassay methods using species-specific antibody reagents to detect antigens of *G. lamblia*, *Cryptosporidium* spp., and *E. histolytica* have become popular. Stages of helminths commonly recovered include eggs and larvae, although intact worms or portions thereof may occasionally be seen. Intestinal protozoan infections are diagnosed by detection of trophozoites, cysts, or oocysts. Routine methods for the identification of ova and parasites (O&P examination) should include procedures that permit recovery of both protozoa and helminths, with use of special procedures limited to specific requests. At a minimum, laboratories performing parasitologic examination should be capable of performing direct wet mount examination of fresh stool, a concentration procedure, and a permanent stain method. Many protozoan infections will be missed unless permanent stains are examined (Garcia, 1979, 1997, 2003, 2010; Price, 1994; Clinical and Laboratory Standards Institute, 2005).

Specimen Collection, Handling, and Preservation

Recovery and subsequent identification of parasites in fecal specimens requires proper collection and handling. Old, poorly preserved, or contaminated specimens are of little value. Specimens should not be collected for 1 week after the patient has ingested any materials that leave a crystalline residue, such as nonabsorbable antidiarrheal compounds, antacids, bismuth, barium, or antimalarial agents. Oily laxatives such as mineral oil may also interfere with examination. Use of antibiotics or contrast media may decrease the numbers of organisms, especially protozoa, in the intestinal tract for several weeks (Ash, 1987; Garcia, 2007).

Specimens may be submitted to the laboratory fresh or in appropriate preservatives. All fresh specimens should be examined within 1 hour of passage, and liquid specimens should be examined within 30 minutes or placed immediately in preservatives to maintain the best yield. This method ensures that fragile protozoal trophozoites are not inadvertently destroyed. Specimens that cannot be processed immediately should be left at room temperature or refrigerated and should not be placed in an incubator because this only speeds disintegration of parasites.

Specimens may be passed directly into clean, dry paper cartons, or a portion may be transferred to a container after the patient squats over wax paper. Diarrheic specimens may also be collected in clean bedpans. Containers should have tight-fitting lids and should be placed in plastic bags before transport to the laboratory. Inadvertent introduction of urine or toilet water with the specimen may readily destroy protozoal trophozoites and should be avoided. Also, contamination with water or soil may accidentally introduce free-living organisms that may prove difficult to differentiate from parasitic ones.

Kits consisting of vials of preservatives appropriate for performing direct examinations, concentration procedures, and preparation of stained smears are available from a number of commercial sources at low cost. Aliquots of freshly passed stool should be immediately placed into these vials and mixed thoroughly. These kits are especially helpful for those patients who are unable to bring in a fresh sample in timely fashion, or for those who will be collecting several specimens over the course of several days. With the two-vial technique, one portion of specimen is fixed in three parts of 5%–10% buffered formalin and another portion in three parts of polyvinyl alcohol (PVA) fixative. Other available preservation systems include merthiolate-iodine-formalin (MIF) and sodium acetate-formalin (SAF) (Table 62-3). SAF has an advantage in that it can be used for permanent stains as well as for direct mounts and concentration procedures, and it does not contain mercury, which is present in Schaudinn's and PVA fixatives. In addition to being poisonous, mercury presents disposal problems in an increasing number of states. However, the quality of permanent stains when SAF is used is not as good as when Schaudinn's or PVA fixative is used. Zinc sulfate-based PVA and other newer commercial products are gaining popularity, and their use may be indicated when mercury chloride-based compounds cannot be used (Garcia, 1993, 1997, 2007, 2010; Clinical and Laboratory Standards Institute, 2005).

Examination of three specimens collected every other day is considered the minimum necessary to perform an adequate O&P evaluation (Garcia, 2003; Clinical and Laboratory Standards Institute, 2005). This procedure ensures an optimum interval for recovery of those parasites known to shed diagnostic forms intermittently, especially *G. lamblia* and *Strongyloides stercoralis*. Additional sensitivity may be achieved in detecting these parasites, as well as *E. histolytica*, using purgation. The laboratory must be notified prior to initiation of purgation, however, to have staff available for processing. Specimens should be collected in separate containers and submitted to the laboratory within minutes of collection. Saline purgatives such as sodium sulfate or buffered phosphosoda are recommended.

TABLE 62-3

Commonly Used Stool Fixatives and Examination Techniques

Fixative	EXAMINATION TECHNIQUE		
	Direct wet mount	Concentration procedure	Permanent stained smear
None (fresh stool)	Yes	Yes	Yes
10% formalin	Yes	Yes	No
Schaudinn's fluid	No	No	Yes
Polyvinyl alcohol (PVA)	No	No*	Yes
Modified PVA†	No	No*	Yes
Merthiolate-iodine-formalin (MIF)	Yes	Yes	No‡
Sodium acetate-formalin (SAF)	Yes	Yes	Yes

*Although concentration techniques using PVA have been described, they are not widely used because of problems with recovery of some organisms.

†Copper sulfate or zinc sulfate replaces the mercuric chloride.

‡Smears prepared from MIF-preserved specimens may be stained with polychrome IV stain.

Macroscopic Examination

Fecal specimens should be examined grossly for consistency (formed, soft, loose, or watery) and for the presence of mucus, blood, larval or adult worms, and proglottids. Protozoan trophozoites are more likely to be found in watery or loose specimens, whereas cysts predominate in formed or soft specimens. Helminths or their eggs may be found in any type of fecal specimen. Most parasites are uniformly distributed in the stool as a result of the mixing action of the cecum, although some eggs (especially schistosomes) may enter the fecal stream in the lower colon and rectum and be unevenly distributed, as may pinworm and *Taenia* spp. eggs. Protozoal trophozoites may be more numerous in the last portion of stool evacuated and should be specifically sought in mucus (Garcia, 2003).

Microscopic Examination

Specimens may be examined microscopically by direct wet mounts of fresh or preserved material, wet mounts of concentrates, or permanent stains. Each procedure has specific advantages and limitations. Direct saline wet mounts of fresh feces allow detection and observation of motile protozoan trophozoites and helminth larvae. Direct mounts of preserved feces may allow detection of parasites that do not concentrate well. Concentration procedures increase the examiner's ability to detect protozoan cysts and helminth eggs and larvae but are unsatisfactory for detecting protozoan trophozoites. Permanent stains are useful for detection and morphologic examination of protozoan trophozoites and cysts.

The circumstances under which each procedure is performed vary depending on the type of specimen (formed, soft, loose, or watery) submitted. Generally, a fresh soft, loose, or watery specimen should have all three procedures performed (Garcia, 2003, 2007). Watery specimens may be concentrated by simple centrifugation rather than by flotation or formalin-ethyl acetate concentration. The direct wet mount may be omitted if the specimen is submitted in preservatives (Clinical and Laboratory Standards Institute, 2005). At a minimum, formed specimens should be examined by a concentration procedure, although improved yield has been demonstrated when a permanent stain is added to the workup (Garcia, 1979, 2007).

Direct Wet Mount

The direct wet mount is one of the most easily performed parasitologic tests, although proper interpretation requires careful examination and experience in using the microscope to full advantage. The test is most useful when fresh specimens, especially liquid stools or duodenal aspirates, are examined for motile trophozoites or helminth larvae. A small amount of stool is mixed with a drop of 0.85% saline and covered with a coverslip. The preparation should be dense enough that newspaper print can just be read through it.

Examination of the entire coverslip is performed systematically under the low-power (10×) objective, with the microscope diaphragm closed down to increase contrast. Suspicious objects and those that are refractile, such as protozoal cysts, should then be examined with the high-power (40×) objective. Detection of motility of slow-moving amebae requires that an object be examined for at least 15 seconds. In the absence of suspicious objects, up to a third of the preparation should be examined using the 40× objective. The oil immersion objective usually is not used unless the coverslip has been sealed with nail polish or vaspar (a 50:50 mixture of petroleum jelly and paraffin).

A second preparation may be made in identical fashion, except that a drop of a 1:5 dilution of Lugol's iodine or an equivalent preparation is added in place of the saline. Use of straight Lugol's or Gram's iodine causes clumping of material and is not recommended. Iodine is helpful in enhancing the visibility of nuclear structures in protozoal cysts and in detecting glycogen inclusions. Limitations, however, include loss of trophozoite motility and cyst refractility, as well as difficulty in recognizing chromatoid bodies.

Concentration Techniques

Concentration procedures, which may be performed on fresh or preserved specimens (see Table 62-3), are more sensitive than direct wet mount examination for detection of protozoan cysts and helminth eggs and larvae because they decrease the amount of background material in the preparations and, in most circumstances, actually concentrate the organisms. Although a variety of methods and modifications have been described, some are useful only for specific parasites (Melvin, 1982; Ash, 1987; Clinical and Laboratory Standards Institute, 2005; Garcia, 2007). For routine use, a method should be selected that allows reliable detection of both

protozoan cysts and helminth eggs. Concentration methods are based on sedimentation or flotation principles. In sedimentation, the heavier parasites settle to the bottom as a result of gravity or centrifugation. In flotation, the lighter parasite cysts and eggs rise to the surface of a solution of high specific gravity. The two most widely used concentration procedures in the United States are the zinc sulfate centrifugal flotation technique of Faust and the formalin ether sedimentation method of Ritchie (or their modifications). In practice, ethyl acetate has replaced ether in the latter method because of the dangers associated with handling ether, and comparable results are achieved (Truant, 1981).

Formalin–ethyl acetate concentration is a biphasic sedimentation technique that is efficient in recovering most protozoan cysts and helminth eggs and larvae, including operculate eggs, and is moderately effective for schistosome eggs. Less distortion of protozoal cysts occurs with this technique than with zinc sulfate flotation. Eggs of *Hymenolepis nana* may be missed, however, and concentrations of *G. lamblia* and *Iodamoeba bütschlii* cysts may not be very good. For proper concentration of coccidian oocysts and spores of microsporidia, attention must be paid to the recommended speed and time of centrifugation (Clinical and Laboratory Standards Institute, 2005; Garcia, 2010). Despite these problems, the technique is used widely for both its simplicity and its suitability in most laboratory situations.

With the zinc sulfate flotation method, fresh stool is processed using zinc sulfate with a specific gravity of 1.18 and formalinized stool is processed with a solution of specific gravity of 1.20. Parasitic elements are recovered from the surface film of the solution following centrifugation. This method yields a cleaner preparation than is provided by formalin–ethyl acetate concentration, but it is unreliable for the recovery of nematode larvae, infertile eggs of *Ascaris*, and the eggs of most trematodes and large tapeworms. Problems with recovery also occur with stool specimens containing excessive amounts of fats. Use of formalinized stool specimens rather than fresh stool helps clear the specimen and prevents popping of opercula and distortion of the parasites (Bartlett, 1978).

Permanent Stains

Use of stained slide preparations provides a permanent record of a patient's specimen and allows review by consultants should difficulties arise in identification. Of the methods described for studying fecal specimens, only the permanent stain is designed for analysis using the oil immersion objective (100×). The permanent stain is most useful for detection of protozoal trophozoites and cysts, which may be recognized when direct and concentrated preparations are negative. Although they generally are not useful for detecting helminth eggs or larvae, permanent stains are inherently more sensitive for detecting protozoal infections, and their use has been recommended for every stool sample submitted for O&P examination (Clinical and Laboratory Standards Institute, 2005).

A variety of staining techniques and modifications and their advantages and disadvantages have been described. The Wheatley trichrome stain and iron hematoxylin stain are all-purpose methods that allow detection of amebae and flagellates. Unfortunately, detection of most human-infecting coccidia and microsporidia requires the use of special stains. Technical problems may arise in the performance of any staining procedure; most are related to the age of the specimen, proper smear preparation and fixation, and the quality of the reagents. Positive control slides of known staining quality should be run with each batch of slides stained. This is especially true in the performance of more specific stains for coccidia and microsporidia. Less commonly used stains, such as polychrome IV stain for use with MIF-preserved specimens and chlorazol black E stain for use with fresh specimens, are not reviewed here, but details may be found elsewhere (Clinical and Laboratory Standards Institute, 2005; Garcia, 2007).

Wheatley's Trichrome Stain

In the United States, the Wheatley modification of the trichrome method continues to find widespread acceptance because of its simplicity, reliability, and cost-effectiveness. Details of the procedure are available from a number of sources (Melvin, 1982; Price, 1994; Clinical and Laboratory Standards Institute, 2005; Garcia, 2010). Appropriate specimens include those that have been fixed in Schaudinn's fixative or PVA fixative; SAF- or MIF-preserved specimens may be stained with trichrome, but results are less satisfactory.

Iron Hematoxylin Stain

Iron hematoxylin stains are technically more difficult to perform than the trichrome stain, but results generally are superior owing to enhanced

definition of key nuclear and cytoplasmic characteristics (Price, 1994). A modified iron hematoxylin stain that may prove useful incorporates carbol fuchsin, allowing concurrent staining of acid-fast organisms such as *Cryptosporidium*, *Cyclospora*, and *Cystoisospora* (Palmer, 1991; Clinical and Laboratory Standards Institute, 2005). Specimens fixed in Schaudinn's, PVA, or SAF fixative may be stained with iron hematoxylin stains (the preferred stain for SAF).

Modified Acid-Fast Stains

Oocysts of *Cryptosporidium*, *Cyclospora*, and *Cystoisospora* are difficult to recognize on trichrome- or iron hematoxylin-stained smears, but their presence may be detected by using an acid-fast staining technique such as the modified Kinyoun method, modified acid-fast dimethyl sulfoxide, or auramine-O (Ma, 1983; Bronsdon, 1984; Current, 1991; Clinical and Laboratory Standards Institute, 2005). Acid-fast stains are sensitive and cost-effective for detection of these protozoa, but they lack specificity. Close attention must be paid to defined morphologic criteria when these stains are used, and the use of positive control material is mandatory. For laboratories in which *Cryptosporidium* is rarely encountered, use of the highly specific and sensitive commercially available immunoassay reagents is recommended. Stool, sputa, biliary tract, and other appropriate specimens that are fresh, formalin-fixed, or SAF-fixed may be used with acid-fast stains.

Stains for Microsporidia

Microsporidia (specifically *Enterocytozoon bienersi* and *Encephalitozoon intestinalis*, along with a number of other species) have been implicated as common agents of diarrheal disease, especially in immunocompromised patients, although their detection has been problematic. Although biopsy and electron microscopy have been mainstays in their diagnosis, staining procedures that may be performed in the clinical laboratory have been described. A modified trichrome stain using an increased (10-fold) concentration of chromotrope 2R combined with an increase in staining time has gained acceptance as a specific test for the identification of microsporidial spores (Weber, 1992, 1994; Murray, 2007). Fluorescent staining methods using optical whitening agents such as Uvitek-2B and Calcofluor white are also useful for rapid and sensitive screening of stool and other clinical specimens for such spores (van Gool, 1993; DeGirolami, 1995; Didier, 1995; Luna, 1995). The small size (1.5–3 µm) of these organisms makes their detection difficult, and such studies should not be undertaken without appropriate control materials for comparison.

Additional Techniques for Examination of Enteric Parasites

Cellulose Tape Technique for Pinworms

The female pinworm, *Enterobius vermicularis*, migrates from the cecum to the perianal skin, where she deposits typical eggs that are fully embryonated. The eggs or, occasionally, adult worms may be detected on examination of clear, adhesive cellophane tape or commercial collection kits that have been pressed on to the perianal skin. Eggs or adults are rarely found in stool, which is considered to be an inappropriate specimen for detection of this parasite. Specimens should be collected late at night, when the worms are most active, or first thing in the morning before bathing or defecation. Several specimens taken on different days should be examined before infection is ruled out.

Egg Studies

Estimation of worm burden occasionally is requested to assist in the evaluation of therapeutic efficacy or in following rates of reinfection with intestinal nematodes (*Ascaris*, *Trichuris*, and hookworms) or, occasionally, schistosomes. Procedures include the direct smear method of Beaver, the Stoll dilution egg count, Kato's thick smear, and various modifications (Beaver, 1984; Ash, 1987; Clinical and Laboratory Standards Institute, 2005). Large variations in results are inherent when these tests are performed, and levels of egg counts indicating clinical significance vary, depending on the infecting species and the person's age and nutritional status (Beaver, 1984).

Egg hatching methods have been used in the analysis of schistosomiasis to detect presence of eggs in light infections and to determine their viability. Schistosome eggs, which are fully embryonated when passed, contain a miracidium that hatches within several hours when eggs are placed in dechlorinated water. In practice, urine or stool is mixed in about 10 volumes of water, which is then placed in a sidearm or Erlenmeyer flask. All but the sidearm or the top of the flask is covered with foil wrap, and

the unit is placed under a desk lamp. Hatched miracidia are positively phototropic and congregate near the light. Eggs, if available, may be examined directly for viability by examining for movement of cilia within flame (excretory) cells (Clinical and Laboratory Standards Institute, 2005).

Nematode Culture and Recovery Techniques

Several culture techniques (coproculture) assist in the detection and identification of certain nematode infections, including the Harada-Mori filter paper strip culture, filter paper/slant culture, and charcoal culture (Beaver, 1984; Ash, 1987; Clinical and Laboratory Standards Institute, 2005; Garcia, 2007). Differentiation of hookworms and trichostrongyles on the basis of egg morphology is difficult, whereas infective stage larvae are more readily identified. Such culture techniques may also prove useful in recovery of *Strongyloides* larvae, which may be few in number, and in differentiating them from those of hookworms. With all culture methods, feces are incubated in a humid environment to encourage egg hatching. With the Harada-Mori and filter paper/slant techniques, larvae migrate from the feces into a water phase, where they may be readily detected. In the charcoal culture, larvae first migrate into a dampened gauze pad, which is then placed in water, allowing the larvae to settle out.

The Baermann funnel technique is a sensitive and reliable method for recovery of *Strongyloides* and other nematode larvae from a stool specimen. In this assay, feces are placed on several layers of gauze on top of a wire screen that is suspended in a funnel. The bottom of the funnel is clamped off, and water is added to the level of the gauze. Larvae actively migrate through the gauze and settle to the bottom of the funnel, where they may be drawn off for examination. Larval recovery may be improved over that of culture techniques because a larger quantity of feces is examined. In latent *Strongyloides* infection, in which few larvae are being shed, several examinations over a week's time may be required to detect the infection (Ash, 1987; Garcia, 2007).

Objects Resembling Enteric Parasites

A large variety of objects that closely resemble various parasite life cycle stages may be seen in feces and other specimens sent for O&P examination. Careful differentiation of these objects from real parasites is necessary to prevent inappropriate or unnecessary treatment. White blood cells, macrophages, and squamous and columnar epithelial cells may resemble amebae; yeasts and starch granules may resemble protozoal cysts; pollen and fungal conidia may resemble helminth eggs; plant fibers may resemble nematode larvae; and pieces of vegetables or vegetable skins may resemble adult worms or proglottids (Table 62-4). Examples of artifacts and pseudoparasites have been reviewed elsewhere (Ash, 2007; Clinical and Laboratory Standards Institute, 2005; Garcia, 2007, 2010).

EXAMINATION OF UROGENITAL AND OTHER SPECIMENS (SPUTA, ASPIRATES, BIOPSIES)

Vaginal and urethral discharges, prostatic secretions, or urine may be submitted to the laboratory for detection of *Trichomonas vaginalis*. The most rapid and cost-effective method is the preparation of several wet mounts using a drop of specimen (urine should be centrifuged) diluted with a drop of saline, which is then covered with a coverslip. The slide is examined under the low-power (10x) objective using reduced lighting conditions for motile trophozoites, which display a jerky movement. High-power examination may reveal the beating flagella and the undulating membrane characteristic of the species. Use of culture, fluorescent antibody reagents, or a commercial DNA probe technique improves sensitivity, if needed (Briselden, 1994). Demonstration of imidazole drug resistance requires culture of the organism (Meri, 2000).

A number of protozoal and helminthic parasites may be detected in sputa, and the appropriate examination technique depends on the suspected organism. Generally, the technique required to detect a parasite from its usual site of infection is applied to sputum and most commonly involves a wet mount. When amebae are suspected, permanent stains should be performed. Acid-fast or specific antibody-based stains are appropriate for *Cryptosporidium*, whereas modified trichrome or fluorochrome stains should be used for detection of spores of microsporidia. Identification techniques for *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) are described elsewhere.

Examination of aspirates requires the use of stains as appropriate for the implicated organism. In addition to the methods used for sputum,

TABLE 62-4 Objects Recoverable from Stool That Resemble Enteric Parasites	
Type of artifact	Resemblance
Neutrophils	<i>Entamoeba histolytica</i> cysts
Macrophages	<i>Entamoeba histolytica</i> trophozoites
Columnar epithelial cells	Amebic trophozoites
Squamous epithelial cells	Amebic trophozoites
Yeasts	Protozoan cysts (especially <i>Endolimax nana</i>)
Fungal conidia	Helminth eggs
Mushroom spores	Helminth eggs
Plant cells	Protozoan cysts, helminth eggs
Plant hairs	Nematode larvae
Pollen grains	Helminth eggs (<i>Ascaris</i> or <i>Taenia</i>)
Diatoms	Helminth eggs
Starch granules, fat globules, air bubbles, mucus	Protozoan cysts
Ingested mite eggs	Helminth eggs
Ingested plant nematode eggs	Helminth eggs
Ingested plant nematode larvae	Nematode larvae

Adapted from Garcia LS, editor. Clinical microbiology procedures handbook. Vols. 1, 2, and 3, 3rd ed. Washington, DC: American Society for Microbiology; 2010.

Giemsa staining is often appropriate when examining for protozoa, especially the hemoflagellates. Biopsy material should be submitted for routine histology after imprint smears are prepared for staining with Giemsa or other appropriate permanent stain. Culture for leishmanias and trypanosomiasis also can be performed on tissues and may be important for demonstrating those infections. Skin biopsies sent for *Onchocerca* or *Mansonella* examination should be teased apart in saline and the saline examined after 30–60 minutes for microfilariae. Muscle biopsy specimens for *Trichinella spiralis* larvae may be examined by compressing the fresh specimen between two glass slides or by submitting it for routine histology. Likewise, rectal or bladder biopsies may be examined for schistosome eggs.

PARASITE CULTURE TECHNIQUES

Culture methods have been described for a wide variety of protozoan parasites, but few clinical laboratories undertake the task because of infrequent requests and lack of familiarity with methods. When culture requests are made, they are usually for *T. vaginalis*, *Leishmania* spp., *Trypanosoma cruzi*, *E. histolytica*, *Acanthamoeba* spp., or *Naegleria fowleri*. In addition, virology laboratories are occasionally asked to culture for *T. gondii*. Methods are reviewed elsewhere (Ash, 1987; Fritzsche, 1989a; Clinical and Laboratory Standards Institute, 2005; Garcia, 2007, 2010; Murray, 2007).

IMMUNODIAGNOSTIC METHODS

Several immunodiagnostic methods are available to identify the parasitic antigen or the antibody that is produced in response to the parasitic infection. Some signals are amplified, and others are direct detection methods. In general, laboratory methods employed are enzyme immunoassay (EIA), indirect immunofluorescence assay (IFA), direct fluorescence antibody assay (DFA), Western blot, radioimmunoassay, and immunodiffusion, among others.

Antigen Detection

Antigen detection methods are commercially available for several parasitic diseases, including amebiasis, cryptosporidiosis, giardiasis, malaria, and trichomoniasis (Table 62-5); these methods may be useful for initial testing or in those instances in which traditional tests are negative, yet a high index of clinical suspicion remains. These tests offer the advantage of detecting current infection and can often be performed by someone other than an experienced morphologist (Wilson, 1995; Garcia, 2010).

Antigen detection in stool samples is usually performed using fecal immunoassays. A number of published studies have suggested that these assays have good sensitivity and specificity when compared with routine

ova and parasite examination (Aldeen, 1995; Kehl, 1995; Zimmerman, 1995; Maraha, 2000; Hanson, 2001; Garcia, 2007). These immunoassays are easy to use and rapid, permit batch processing, and do not require experienced microscopists. Given the current shortage of medical technologists and individuals with specialized training in parasitology, use of immunoassays appears to be an attractive alternative. However, laboratories that use rapid immunoassays should be aware of potential problems with false-positive results and should closely monitor test performance. Currently, fecal immunoassays are marketed for *G. lamblia*, *C. parvum*/*C. hominis*, the *E. histolytica*/*E. dispar* group, and *E. histolytica*. Antigen detection tests using blood or serum are also available for *Plasmodium* spp. and *W. bancrofti*. A latex agglutination test for *T. vaginalis* antigen detection in vaginal swabs has also been introduced. Additional commercially manufactured kits are under development for detection of *Dientamoeba fragilis* and the microsporidia. Immunoassays are usually available in three formats: EIA, DFA, and lateral flow (immunochromatography) cartridges. Fresh or preserved stool samples are appropriate for most antigen detection kits (Fedorko, 2000). Although each kit has unique operating characteristics, most are generally comparable in performance (Garcia, 2000, 2007; Katanik, 2001).

Rapid antigen detection methods developed for malaria may detect histidine-rich protein II (HRP-II), parasite lactate dehydrogenase (pLDH),

or both, in peripheral blood. HRP-II tests are specific for *Plasmodium falciparum*, and pLDH tests detect all four *Plasmodium* spp. Sensitivities of these assays are comparable with, or lower than, traditional microscopic examination, but sensitivities greater than 90% have been reported. One of these tests is currently approved by the Food and Drug Administration for clinical diagnosis of malaria in the United States (Murray, 2009).

T. vaginalis antigens from vaginal samples may also be detected using rapid antigen tests. These tests can be used for rapid detection of *T. vaginalis* infection in the clinic setting and may replace wet mount examinations, which generally have lower sensitivities, depending on the proficiency of the personnel performing the microscopic examination. Miller and colleagues demonstrated that the *T. vaginalis* rapid antigen test had sensitivities comparable with those of culture (Miller, 2003).

Most EIAs are available in microwell format. Antigens from frozen, fresh, or 10% formalin-preserved stool samples are suitable for testing by this method. Concentrated or PVA samples are not suitable for testing with EIA kits. Parasite antigen is captured by immobilized antibodies coated on microwells and is detected by an enzyme-conjugated secondary antibody that is capable of producing a colored reaction following the addition of substrate. Although the colored wells can be read visually or with the use of a spectrometer, the latter seems to be the preferred

option because of occasional ambiguous results obtained with some kits (Kehl, 1995). In general, EIA tests have good sensitivities and specificities. Garcia and colleagues evaluated nine immunoassay kits for detection of *G. lamblia* and *Cryptosporidium* spp. in comparison with a reference DFA test that visualizes the parasite directly in the sample; investigators found that all kits had high sensitivities, ranging from 94% to 99%, and 100% specificities (Garcia, 1997, 2007). However, published reports have suggested that occasional problems are found with some EIA kits that may produce false-positive results; these problems have led to their recall (Doing, 1999). Hence, a strong quality control (QC) program and participation in proficiency test programs are required to ensure high-quality test results. Local epidemiology of the parasitic infection can help to determine whether additional confirmatory testing is required; consultation with local public health authorities may prove useful in characterizing which infections are being seen locally. Additionally for some diseases such as giardiasis, examination of two specimens by EIA or microscopy may be necessary to achieve diagnostic sensitivity greater than 90% (Hanson, 2001).

Lateral flow cartridges are a popular format of immunoassay because of their ease of use and the minimal performance time required. These kits can be stored conveniently at room temperature and may be used in single or batch processing. The parasite antigen in the sample migrates through the membrane and binds to specific capture antibodies; use of a secondary reagent results in development of a colored reaction. These kits also have an internal control to ensure that the colloidal dye conjugates used in the assay are intact and that proper capillary flow has occurred. To ensure complete migration of the specimen, only the supernatant of a well-mixed stool sample is used, and some samples may be diluted to a liquid state before testing. Any color visible at the reagent test zone (usually a band) is interpreted as positive. Some studies have demonstrated that cartridge assays are somewhat less sensitive than a microwell EIA plate assay (Pillai, 1999; Johnston, 2003). When lack of sensitivity is a concern, it may be necessary to perform alternative O&P studies if patients' symptoms persist.

DFA testing allows direct visualization of the parasites in stool specimens using antibodies conjugated to fluorescent dyes. These assays are easy to perform and to interpret, permitting rapid screening of slides when compared with some of the traditional stains used in parasitology (Zimmerman, 1995; Garcia, 2007). A fluorescence microscope is necessary for this procedure, and this is a limiting factor in some laboratories. Currently, kits are available for detection of cysts of *G. lamblia* and oocysts of *Cryptosporidium* spp. Fixed stool specimens may be used for this procedure (10% formalin, SAF, or one of the mercury- or formalin-free products; Fedorko, 2000). Although fresh stool samples can be tested directly, the sensitivity of the assay can be improved by performing the test on centrifuged stool (500 *g* for 10 minutes). Occasionally, fluorescing bacteria and yeasts may be seen, but these are readily distinguished from *Giardia* and *Cryptosporidium* on the basis of their size and shape. The edges of the wells should be carefully examined to avoid missing the rare parasite in light infections. Given the recent recognition of additional *Cryptosporidium* spp. that may infect humans, studies related to specificity of the various immunoassays are needed to determine actual sensitivity in detecting any *Cryptosporidium* infection (Graczyk, 1996; Coupe, 2005).

Serologic Diagnosis

Tests that are available from public health, hospital, or commercial laboratories to detect immunologic reactivity to parasitic diseases are summarized in Table 62-6. Historically, serologic procedures for parasitic diseases have been plagued by low sensitivity and specificity, primarily owing to the complex antigenic nature of parasites and the possibilities for cross-reactions from related species. The introduction of newer test methods combined with the use of more highly defined antigenic components is providing more accurate results with greater predictive values. Many of the newer tests use the EIA or immunoblot (Western blot) format, although IFA, indirect hemagglutination (IHA), complement fixation (CF), and bentonite flocculation (BF) methods remain popular.

Serologic diagnosis of parasitic infection is used as an adjunct to the usual diagnostic modalities or in special situations where identification of the parasite itself or its antigen or nucleic acid from host tissue or excreta is not possible. Parasitic infections such as toxoplasmosis and toxocariasis reside in deep tissues and cannot be readily diagnosed by morphologic means; others such as cysticercosis and echinococcosis develop in organs, where invasive studies that may be required are not recommended in the initial patient evaluation. Other conditions such as filariasis,

TABLE 62-6

Examples of Serologic Assays for Parasites Available from Reference Laboratories

Disease	Organism	Specimen type	Assay
Amebiasis	<i>Entamoeba histolytica</i>	Serum	EIA, ID, IHA

schistosomiasis, and strongyloidiasis may remain subclinical because of light infections, or because the clinical evaluation occurred during the prepatent period. Other circumstances where serologic evaluation may prove useful include diagnoses of extraintestinal amebiasis and trichinellosis. Chronic stages of trypanosomiasis are preferably diagnosed by serology. Serologic studies also help in the diagnosis of occult infections such as visceral larva migrans, cysticercosis, and filariasis. Last, serologic studies serve as a powerful tool in enhancing our understanding of the epidemiology of diseases such as schistosomiasis, toxoplasmosis, amebiasis, Chagas' disease, malaria, and babesiosis. High antibody levels are useful for diagnostic purposes if they occur in a patient with no previous exposure to the parasite and no recent history of travel to an endemic area. Unfortunately, positive antibody levels in persons living in endemic areas do not often help in the clinical diagnosis. Detection of antibodies, especially immunoglobulin (Ig)G, provides evidence of infection but may not be able to differentiate active from past exposure. In some parasitic diseases, levels of antibodies may decline slowly following successful therapy or self-cure. Serologic tests for parasitic diseases generally evaluate IgG levels, with the exception of toxoplasmosis and babesiosis, in which IgM- and IgA-specific antibodies may be helpful for determining the age of infection (National Committee for Clinical Laboratory Standards, 2004).

Because serologic tests for parasitic diseases are infrequently requested, specimens generally are submitted to public (Centers for Disease Control and Prevention [CDC]) or private reference laboratories. Some of the more commonly requested tests, especially those that are obtained as commercial kits, are often available locally, including those for toxoplasmosis, amebiasis, and trichinosis.

Many of these assays are developed in-house and hence lack correlation with universal standards. Interpretive criteria are established by reagent manufacturers or by the center performing the test, and these criteria often vary from institution to institution. Individuals requesting such tests should inquire about the performance characteristics, including sensitivity and specificity, and should be aware that cross-reactions may occur. For example, antibody tests for Chagas' disease are known to cross-react with antibodies produced in response to *Leishmania* infections. However, reactivity to homologous antigen is greater, and this test is useful in diagnosing chronic stages of the disease when parasitemia is generally low. Usually serology for chronic Chagas' disease correlates well with molecular diagnostic methods (Weinberg, 2001). Helminthic parasites are well known to cross-react in serologic assays that use crude antigen preparations because of phylogenetic, hence antigenic, similarities.

Several factors that may influence the test performance of serologic assays include disease manifestation, test format, reagents used, and

TABLE 62-7

Examples of Real-Time PCR Assays for Parasites

parasite viability, to name a few. The sensitivity of the test is increased in patients with invasive amebiasis but may be weak in intestinal amebiasis with minimal tissue invasion, and absent for asymptomatic carriers. The type of serologic assay format may also determine the sensitivity, as in the diagnosis of toxoplasmosis (National Committee for Clinical Laboratory Standards, 2004). The double-sandwich IgM enzyme-linked immunosorbent assay (ELISA) is known to be more sensitive and specific than IgM immunofluorescence for detecting recently acquired and congenital toxoplasmosis. IHA has been the primary test for serodiagnosis of amebiasis. The sensitivity of the assay is also dependent on the type or stage of parasite antigen used, for example, the sensitivity of cutaneous leishmaniasis can be improved by using amastigote antigens in place of promastigote antigens in the IFA test. Serologic assays are also affected by parasite viability; hydatid cysts occurring in the lung and dead or calcified cysts are less frequently detected than active cysts in the liver.

MOLECULAR DIAGNOSTIC METHODS

Diagnostic methods using DNA amplification and nucleic acid probe techniques have been described for most of the common parasitic diseases and offer high levels of sensitivity and specificity (Weiss, 1995; Wilson, 1995). For more complete details on this topic, the reader is referred to a recent publication (Persing, 2011; Espy, 2006). Molecular methods offer some unique advantages such as rapid (automated) results, high sensitivity and specificity, and ability to detect and differentiate species variants—all independent of the patient's underlying immune status, which is a potentially limiting feature of serologic assays. Molecular techniques are prone to cross-contamination, however, if proper processing precautions are not strictly enforced.

Although most of these applications have remained as tools for research laboratories and are not routinely available, several polymerase chain reaction (PCR) assays have been developed for parasites such as *Plasmodium* spp., *Babesia* spp., *T. gondii*, *Leishmania* spp., *Trypanosoma* spp., *G. lamblia*, *Cryptosporidium* spp., and *T. vaginalis* (Table 62-7). Some of these assays are available in real-time format, wherein the kinetics of the nucleic acid amplification reaction is recorded and analyzed by computer algorithms to allow detection of amplicons. Over the past decade, several laboratory developed real-time PCR methods have been described for clinical diagnosis of some of these parasitic diseases (see Table 62-7). The introduction of this technology has allowed rapid detection and has avoided the fear of cross-contamination due to steps involved in postamplification analysis. PCR also presents the opportunity to monitor the success of antiparasitic therapy (Lee, 2002; Bossolasco, 2003) or to detect reactivation following therapy (Costa, 2000). Because the innate nature of molecular methods is genotypic, PCR assays have the ability to accurately detect to the species level, depending on the gene being targeted (Vallejo, 1999; Mahboudi, 2002). To date, the equipment and other resources needed, including personnel trained in molecular biology, have remained out of reach for most diagnostic laboratories because of fiscal limitations. Although a variety of commercial diagnostic kits are available for detection of viral and bacterial pathogens, only one kit has received approval for a parasite—the kit for *T. vaginalis* (Briselden, 1994). Molecular methods may prove to have great importance in the identification of parasite-harboring vectors and may contribute to disease prevention through control programs targeted to such vectors (Weiss, 1995).

QUALITY ASSURANCE, QUALITY IMPROVEMENT, AND SAFETY

A quality assurance program for the parasitology section of the laboratory is similar to that for the other laboratory sections and covers all essential aspects of the operation, including, among others, a well-written and complete procedure manual that is reviewed annually, guidelines for maintaining all specimen and test result records, a complete QC program with appropriate technical supervision and review, and participation in an approved proficiency testing program. Laboratories also need to focus on customer satisfaction, using a variety of available measures, and to participate in the team approach to identifying problems and generating solutions as part of a continuous quality improvement process (Garcia, 2007, 2010).

The performance of individuals responsible for the parasitology section should be monitored periodically with both internal and external unknown specimens, and competency assessments should be up to date, especially for those laboratories that encounter positive specimens infrequently. A variety of reference materials should be readily available for use at the laboratory bench, including positive slides and fecal specimens, printed atlases, and slide atlases.

Unpreserved specimens for parasitologic examination should be considered potentially infectious, and all blood and body fluids should be handled according to Universal Precautions as defined by the Final Rule on Blood-borne Pathogens by the Occupational Safety and Health Administration, as published in the *Federal Register*. In addition to blood-borne viral pathogens, malarial parasites and hemoflagellates may remain infective. A variety of parasites may remain infective in fresh stool specimens, including cysts of enteric protozoa; eggs of *Taenia solium*, *E. vermicularis*, and *H. nana*; and larvae of *S. stercoralis*. *Trichuris trichiura*, *Ascaris lumbricoides*, and hookworm eggs may remain infective in older specimens, and *Ascaris* eggs can survive and embryonate while in 5% formalin. Fecal specimens also may contain pathogens such as *Salmonella*, *Shigella*, or viruses. Strict observance of proper specimen handling techniques and disposal is essential. Personal attention to hand washing is also necessary. Use of ethyl acetate in place of ether in the performance of concentration techniques is strongly recommended to guard against the possibility of explosion (Truant, 1981; Clinical and Laboratory Standards Institute, 2005; Garcia, 2007, 2010).

BLOOD AND TISSUE PROTOZOA

MALARIA

Malaria (from the Italian “mal’ aria,” meaning “bad air”) is an acute and sometimes chronic infection of the bloodstream characterized clinically by fever, anemia, and splenomegaly, and is caused by apicomplexan parasites of the genus *Plasmodium*. The defining clinical features of a malarial attack or paroxysm consist of, in order, shaking chills, fever (up to 40° C or higher), and generalized diaphoresis, followed by resolution of fever. The paroxysm occurs over 6–10 hours and is initiated by the synchronous rupture of erythrocytes with the release of new infectious blood stage forms known as merozoites. The disease generally occurs between 45° N and 40° S (World Health Organization, 1987) and is spread exclusively by female anopheline mosquitoes. The four species of plasmodia causing human malaria are *Plasmodium vivax*, *P. falciparum*, *Plasmodium malariae*, and *Plasmodium ovale*. *P. falciparum* infection occurs principally in tropical areas worldwide, whereas *P. vivax* infections occur in both tropical and temperate zones. *P. malariae* also occurs worldwide but to a much lesser extent than *P. falciparum* or *P. vivax*. *P. ovale* is the least frequent of the malarias, with most cases being acquired in western Africa, India, or South America. Recently, human infection with *P. knowlesi*, a malarial parasite of Old World monkeys, has been described in the Malay Peninsula and Borneo. These infections are potentially life threatening but are difficult to distinguish from *P. malariae* microscopically, leading to misidentification. Use of PCR has been required to make the correct differentiation (Cox-Singh, 2008).

Because infection with falciparum malaria is potentially life threatening, its presence must be considered in the differential diagnosis of unexplained fever, and history of travel in endemic geographic areas should always be sought. In an era of increasing world travel, the risk of acquiring malaria is not insignificant, and the rapid spread of drug-resistant strains poses particular problems when appropriate prophylaxis or therapy is considered.

Laboratory evaluation of patients suspected of having malaria continues to rely on timely examination of thick and thin blood films to

demonstrate the intraerythrocytic parasites. Although they are straightforward in their approach, performance of these techniques may be problematic. Reliable identification of organisms requires continuous training to maintain expertise; therefore, those laboratories that rarely see positive specimens may choose to refer specimens to reference laboratories, provided that processing and reporting are timely.

More advanced laboratory methods, including acridine orange staining (see earlier under **Laboratory Methods**) and detection of parasite-specific DNA (Lanar, 1989; Weiss, 1995; Clinical and Laboratory Standards Institute, 2005), provide enhanced sensitivity and specificity but generally are not appropriate or available for smaller laboratories. Immunocapture assays developed for the detection of *Plasmodium*-specific lactate dehydrogenase or HRP-II appear to provide a high degree of sensitivity and specificity in the diagnosis of malaria. Several versions of these tests, configured as “dipstick” methods, are especially promising in situations where ease of

performance is critical and usual laboratory facilities are lacking (Palmer, 1998; Piper, 1999; Marx, 2005; Murray, 2009).

Life Cycle

Malarial parasites undergo a sexual phase (sporogony) in *Anopheles* mosquitoes that results in the production of infectious sporozoites, as well as an asexual stage (schizogony) in humans that results in the production of schizonts and merozoites (Fig. 62-1). In the bloodstream, some merozoites eventually differentiate into gametocytes (gametogony), which, when ingested by female anopheline mosquitoes, mature into male microgametes and female macrogametes. Fusion of a microgamete and a macrogamete results in the formation of the motile ookinete, which migrates to the outside of the stomach wall and forms an oocyst. Within the oocyst, numerous spindle-shaped sporozoites are formed. The mature oocyst ruptures into the body cavity, releasing sporozoites, which then migrate

Figure 62-1 Life cycle of malarial parasites. (Courtesy the Centers for Disease Control and Prevention, Parasitology Training Branch, Atlanta).

through the tissues to the salivary glands, from which they are injected into the vertebrate host as the mosquito feeds. The time required for development in the mosquito ranges from 8–21 days.

Sporozoites injected into the vertebrate host reach the hepatic parenchymal cells within minutes and initiate the proliferative phase known as exoerythrocytic schizogony. Release of merozoites from ruptured hepatic schizonts initiates the bloodstream infection or erythrocytic schizogony and, eventually, the clinical symptoms of malaria. *P. vivax* and *P. ovale* differ from *P. falciparum* and *P. malariae* in that true disease relapses of the former species may occur weeks to months following subsidence of previous attacks. This occurs as a result of renewed exoerythrocytic and, eventually, erythrocytic schizogony from latent hepatic sporozoites, which are known as hypnozoites (Krotoski, 1982). Recurrences of disease due to *P. falciparum* or *P. malariae*, called recrudescences, arise from increased numbers of persisting blood stage forms to clinically detectable levels, not from persisting liver stage forms. Liver cells are infected only by sporozoites from the mosquito; thus, transfusion-acquired *P. vivax* or *P. ovale* infection does not relapse.

Merozoites released from infected hepatocytes subsequently infect erythrocytes. Following amplification of parasites in the bloodstream for a period of time and the development of synchrony in their appearance, clinical attacks of malaria occur. *P. vivax* and *P. ovale* parasites primarily infect young erythrocytes, whereas *P. malariae* infects older erythrocytes and *P. falciparum* infects erythrocytes of all ages.

Morphologic stages seen in erythrocytes include trophozoites (growing forms), schizonts (dividing forms), and gametocytes (sexual forms) (Figs. 62-2 through 62-5). The youngest trophozoites have a globose shape with a central vacuole, a red chromatin mass, and blue cytoplasm. On stained blood films, early trophozoites resemble signet rings and generally are referred to as rings or ring forms. Growing trophozoites beyond the ring stage retain a single chromatin mass but have more abundant cytoplasm, which may appear compact or may be ameboid (irregular). Mature trophozoites still have only one chromatin mass but an increased amount of cytoplasm that partially fills the erythrocyte. Hemozoin (hematin) pigment, a breakdown product of hemoglobin, is characteristic of all erythrocytes containing mature stages of malarial parasites but is not evident in ring forms. Immature schizonts have two or more chromatin masses and undivided cytoplasm, whereas mature schizonts have both cytoplasm and chromatin completely divided, so that individual merozoites are evident. The mature schizont ruptures the erythrocyte, releasing merozoites and initiating a new cycle of infection. The erythrocytic cycle takes approximately 48 hours (tertian periodicity) for *P. falciparum*, *P. ovale*, and *P. vivax* infections, and 72 hours (quartan periodicity) for *P. malariae* infection. At some point during the infection, a subpopulation of merozoites develops into gametocytes. Those of *P. vivax*, *P. malariae*, and *P. ovale* are rounded, whereas those of *P. falciparum* are elongate (sausage-shaped). Macrogametocytes (female) characteristically have a compact chromatin mass, whereas microgametocytes (male) have chromatin that is more dispersed. Developing gametocytes are more compact than growing trophozoites.

Epidemiology

Endemic transmission of malaria requires a reservoir of infection, an appropriate mosquito vector, and a susceptible host. Control of malaria is directed at elimination of mosquito hosts, treatment of active cases, and prophylaxis of susceptible persons. However, emergence of mosquitoes resistant to insecticides, development of resistance to prophylaxis and therapy by *P. falciparum* and, more recently, *P. vivax* (Murphy, 1993; Garcia, 2007), and lack of adequate funding have made control difficult in many areas.

Individuals with sickle cell trait are less susceptible to *P. falciparum* malaria, and persons who lack certain Duffy blood group determinants are protected against *P. vivax* infection (Miller, 1976). Glucose-6-phosphate dehydrogenase (G6PD) deficiency has been associated with protection from malaria, but evidence is less striking than with these other genetic abnormalities.

Transfusion-induced malaria may occur when blood donors have subclinical malaria and may prove fatal for the recipient. Similarly, congenital malaria may occur in infants born to mothers from endemic areas. The infant acquires the infection at birth as a result of rupture of placental blood vessels with maternal–fetal transfusion. Neither transfusion nor congenital malaria is expected to relapse because exoerythrocytic schizogony does not occur. The number of civilian cases of malaria reported in the United States increased from 151 in 1970 to 1838 in 1980 but dropped to 1411 in 1993 (Centers for Disease Control and Prevention, 1988, 1993). Species causing infection in 1987 were *P. vivax* (44%), *P. falciparum* (43%),

P. malariae (4%), *P. ovale* (3%), and undetermined (6%). The interval between arrival in the United States and onset of illness was less than 1 month for 25% of *P. vivax* and 80% of *P. falciparum* cases. Only 3% of patients became ill more than 1 year after arrival. U.S. citizens acquired the infection in Africa (63%), Asia (18%), the Western Hemisphere (14%), or Oceania (4%).

Clinical Disease

Most patients who develop *P. falciparum* infection become symptomatic within 1 month of exposure, whereas a delay of up to 6 months or more may be seen with the other *Plasmodium* species. Common presenting symptoms of malaria include chills and fever, which often are associated with splenomegaly. In the early stages of the disease, febrile episodes occur irregularly but eventually become more synchronous, assuming the usual tertian (*P. vivax*, *P. falciparum*, and *P. ovale*) or quartan (*P. malariae*) periodicity. Patients with malaria may develop anemia and may have other manifestations, including diarrhea, abdominal pain, headache, and muscle aches and pains. *P. falciparum* malaria can result in high rates (50%) of parasitemia, which can lead to severe hemolysis with hemoglobinuria and profound anemia. Erythrocytes infected with growing trophozoites and schizonts of *P. falciparum* become sequestered in small vessels of the body, and this may lead to occlusion of these vessels, causing symptoms related to capillary obstruction and tissue anoxia. Involvement of the brain is known as cerebral malaria, in which the patient becomes disoriented, progressing to delirium, coma, and often death. Exchange transfusion may be lifesaving in severe cases of *P. falciparum* infection (Nielson, 1979; Powell, 2002).

The course of untreated malaria depends on the species. Most fatal cases of malaria are due to *P. falciparum*. In nonfatal cases, the febrile paroxysms become less severe with time and the disease gradually subsides. Patients with *P. vivax* or *P. ovale* infection may have relapses after many months or, occasionally, years. Persons with *P. falciparum* and *P. malariae* infection may have symptom-free periods but suffer from sporadic recrudescences owing to persisting low-grade parasitemia. Relapses and recrudescences may be associated with changes in the host's defense mechanisms or possibly with antigenic changes in the infecting organisms.

Peripheral smears may show leukocytes that contain malaria pigment. Increased reticulocyte counts occur commonly and are associated with rapid erythrocyte turnover. The presence of greatly enlarged platelets may be noted on peripheral blood films and may occur as a result of their rapid turnover secondary to splenic sequestration. Malarial infection may interfere with certain serologic tests, producing false-positive results, especially those for syphilis.

Therapy and prophylaxis of malaria have become highly complex topics because of the widespread appearance of resistance by *P. falciparum* to chloroquine and other antimalarials and, to a lesser extent, resistance by *P. vivax* to chloroquine. Also, persons who have acquired *P. vivax* or *P. ovale* malaria, or who have spent extended time in areas highly endemic for these parasites, require treatment with primaquine to eradicate hepatic hypnozoites and to prevent relapse. Use of primaquine may be dangerous in patients who have G6PD deficiency, and screening of at-risk patients before therapy is initiated may be necessary.

Diagnosis

Malaria should be included in the differential diagnosis of fever in patients who have a history of travel to or residence in endemic areas, drug addiction, or blood transfusion. Diagnosis usually is established by demonstrating parasites in thick and thin blood films. Blood specimens ideally are collected just before the next anticipated fever spike or at the onset of fever. Specimens drawn several hours apart sometimes may be required to demonstrate infection or to diagnose the species, because the number and morphologic stage of parasites vary during the cycle. Careful examination of thick films should reveal the presence of the parasites in almost all patients with clinically apparent malaria.

Identification of malarial parasites on thin blood films requires a systematic approach. Three major factors should be considered: appearance of infected erythrocytes, appearance of parasites, and stages found. Table 62-8 summarizes diagnostic characteristics of the species, which are illustrated in Figures 62-2 to 62-5. Erythrocytes infected by *P. vivax* or *P. ovale* parasites often appear enlarged compared with adjacent, uninfected cells, whereas *P. malariae* and *P. falciparum* parasites are usually found in erythrocytes of normal size. In all, 20% or more of erythrocytes infected with *P. ovale* are often oval or fimbriated (having irregular projections of the cell margins), whereas less than 6% of erythrocytes infected with *P. vivax* are oval. Schüffner's stippling, noted as numerous small uniform pink granules

TABLE 62-8

Comparison of *Plasmodium* Species Affecting Humans

Species	Appearance of erythrocyte size	Schüffner's stippling	Parasite cytoplasm	Appearance of parasite pigment	Number of merozoites	Stages found in circulating blood
<i>Plasmodium vivax</i>	Enlarged; maximum size (attained with mature trophozoites and schizonts) may be 1–2 times normal erythrocyte diameter	+	Irregular, ameboid in trophozoites; has "spread out" appearance	Golden brown, inconspicuous	12–24; average is 16	All stages; wide range of stages may be seen on any given film
<i>Plasmodium malariae</i>	Normal	– (Ziemann's dots rarely seen)	Rounded, compact trophozoites with dense cytoplasm; band-form trophozoites occasionally seen	Dark brown, coarse, conspicuous	6–12; average is 8; "rosette" schizonts occasionally seen	All stages; wide variety of stages usually not seen; relatively few rings or gametocytes generally present
<i>Plasmodium ovale</i>	Enlarged; maximum size may be $1\frac{1}{4}$ – $1\frac{1}{2}$ times normal red blood cell diameter; approximately 20% or more of infected red blood cells are oval and/or fimbriated (border has irregular projections)	+	Rounded, compact trophozoites; occasionally slightly ameboid; growing trophozoites have large chromatin mass	Dark brown, conspicuous	6–14; average is 8	All stages
<i>Plasmodium falciparum</i>	Normal; multiply infected red blood cells are common	– (Maurer's dots occasionally seen)	Young rings are small, delicate, often with double chromatin dots; gametocytes are crescent or elongate	Black; coarse and conspicuous in gametocytes	6–32; average is 20–24	Rings and/or gametocytes; other stages develop in blood vessels of internal organs but are not seen in peripheral blood except in severe infection

With permission from Smith JW, Melvin DM, Orihel TC, et al. Diagnostic parasitology—blood and tissue parasites. Chicago: American Society of Clinical Pathologists; 1976.

in the erythrocyte, is usually seen in cells infected with *P. vivax* and *P. ovale*, although it may not be evident in cells infected with early ring forms or on slides that have not been stained at the appropriate pH (see earlier under [Laboratory Methods](#)). The presence of Schüffner's stippling is helpful because it is not seen in *P. malariae* or *P. falciparum* infection.

As trophozoites grow in the infected cells, the amount of hemoglobin in the erythrocyte decreases and hemozoin pigment accumulates. The amount and appearance of the pigment vary among species. Ring forms of all parasites may have a similar appearance, and if only occasional ring forms are found, the species may not be identifiable. Young rings of *P. falciparum* are smaller than those of the other species (one-sixth the diameter of the red blood cell, compared with one-third the diameter of the red blood cell for the other species). Rings of *P. falciparum* that have grown are similar in size to those of the other species. Trophozoites that appear to be lying on the surface of the erythrocyte or protruding from it are called appliqué or accolé forms, and are most often seen in *P. falciparum* infection. Doubly infected cells and double chromatin dots in ring trophozoites occur most commonly in *P. falciparum* infection but can occur with the other species as well.

Growing trophozoites of *P. vivax* have irregular shapes and are termed ameboid. Those of *P. malariae* and *P. ovale* remain compact. Mature trophozoites and schizonts of *P. falciparum* are usually sequestered in capillary beds secondary to cytoadherence to endothelial cells and are not seen in the peripheral blood except in very severe cases of infection. When schizonts are identified in the peripheral blood, determining the number of merozoites is helpful in identifying the various species. Gametocytes of *P. falciparum* are readily identified by their characteristic sausage shape. Gametocytes of *P. vivax*, *P. malariae*, and *P. ovale* have a similar shape and so are difficult to differentiate, although characteristics of infected red cells can aid identification.

The varieties of developmental stages in the peripheral blood aid in diagnosis. In *P. falciparum* infection, ring forms predominate, and finding numerous ring forms without more mature stages serves as evidence for *P. falciparum* infection. In *P. vivax*, *P. malariae*, and *P. ovale* infections, various stages of parasites are found with some predominance of one stage depending on the phase of the cycle.

Thick films are preferred for detecting malaria infections because a greater quantity of blood is examined (see earlier under [Laboratory Methods](#)). Ring forms often have the appearance of punctuation marks rather than complete rings, and the presence of red chromatin and blue cytoplasm should be required to identify them as parasites. Schüffner's stippling still may be a helpful identifying characteristic, and it may be recognized around growing trophozoites as a pink halo rather than as distinct granules seen in thin films. The ameboid character of *P. vivax* trophozoites is not as evident in thick films, but the number of merozoites in mature schizonts is helpful. Macrogametocytes and microgametocytes cannot usually be differentiated. The distinctive sausage shape of *P. falciparum* gametocytes is still evident, although they may appear stubbier than in thin films. Gametocytes of the other species can be detected and are easily differentiated from host cell nuclei by the presence of refractile hemozoin pigment.

Mixed infections occur occasionally (about 5% of the time), but caution should be used in making such a diagnosis unless definite evidence reveals two separate populations of parasites. The most common mixed infections are *P. falciparum* and *P. vivax*. Finding gametocytes of *P. falciparum* in a person obviously infected with *P. vivax* is diagnostic.

Multiple artifacts may be confused with malarial parasites on thick and thin films. The most common artifacts on thin films are blood platelets superimposed on red blood cells. These platelets should be readily identified because they do not have a true ring form, do not show differentiation of the chromatin and cytoplasm, and do not contain pigment. Clumps of bacteria or platelets may be confused with schizonts. At times, masses of fused platelets may resemble gametocytes of *P. falciparum* but do not show the differential staining or the pigment. Precipitated stain and contaminating bacteria, fungi, or spores may also be confused with these parasites.

Species-specific serologic tests for malaria are particularly useful for epidemiologic surveys and for detection of infected blood donors. Such tests do not reliably differentiate current from past infection, however. Sensitive and specific IFA tests using antigens from the four human species are available from the CDC (Wilson, 1995). Assays for the direct detection of malarial antigens in blood are especially useful (see [Laboratory Methods](#); Murray, 2009).

Figure 62-6 **A**, Human infection with *Babesia microti*; note high parasitemia and multiple infected red cells (oil immersion). **B**, *Trypanosoma* sp. in stained blood film; note nucleus, kinetoplast, and undulating membrane (oil immersion). **C**, *Leishmania mexicana* amastigotes in impression smear of thigh lesion (Giemsa stain; oil immersion). **D**, Pseudocyst of *Toxoplasma gondii* in brain tissue (hematoxylin and eosin [H&E]; oil immersion). **E**, Cutaneous rosette of *T. gondii* tachyzoites in an immunocompromised patient (H&E; oil immersion). **F**, Tachyzoites of *T. gondii* recovered from a bronchoalveolar lavage specimen from an individual infected with the human immunodeficiency virus (Giemsa stain; oil immersion).

BABESIOSIS

Similar to malarial parasites, etiologic agents of babesiosis or piroplasmosis are apicomplexan protozoa found worldwide that infect erythrocytes, often producing febrile illness of variable severity. Unlike malaria, babesiosis is transmitted by ticks and is found in a variety of animal species that serve as reservoirs (Krause, 2002).

Human infection in the United States occurs predominantly in the northeastern and midwestern states, where the rodent parasite *Babesia microti* is responsible for infection (Homer, 2000). *Ixodes scapularis* is the usual tick vector. Recent studies have implicated another, as yet unnamed, *Babesia* spp. (tentatively known as WA1) as being responsible for disease in the western United States. This parasite, associated with disease in Washington State and California, is thought to be transmitted by the Western black-legged tick, *Ixodes pacificus* (Quick, 1993; Persing, 1995). In Europe, the canine parasite *Babesia divergens*, transmitted by *Ixodes ricinus*, infects humans, and a recent report of *B. divergens*-like infection in Washington State expands the range of known human cases (Herwaldt, 2004).

The spectrum of babesiosis varies from latent, subclinical infection to fulminant, hemolytic disease. Fatalities have been reported, especially in splenectomized or immunocompromised individuals. Immunocompetent persons may experience symptoms similar to those of malaria, including fever, chills, malaise, and anemia, although without recognizable periodicity. Investigation of an outbreak caused by *B. microti* on Nantucket Island in New England showed that some symptomatic patients harbored the parasite for months and others showed serologic evidence of infection without a history of clinical disease (Ruebush, 1980). Other evidence indicates that chronic subclinical infections may not be uncommon (Persing, 1995).

Babesia parasites multiply in erythrocytes by schizogony but do not produce gametocytes. Although trophozoites of many species appear pear-shaped at some point in their development, those of *B. microti* usually appear as delicate ring forms that may be easily confused with those of malarial parasites, especially *P. falciparum* (Fig. 62-6, A) (Healy, 1980; Homer, 2000). *Babesia* trophozoites can be differentiated from those of malarial parasites by the presence of multiple rings in one cell that may form a tetrad (Maltese cross) and the absence of large, growing trophozoites and gametocytes; extracellular trophozoites may be seen in heavy infections. Also, *Babesia*-infected cells lack hemozoin pigment, which is present in *Plasmodium*-infected cells. History of residence in or travel to endemic areas, or of a recent tick bite, might suggest *Babesia* infection. Serologic tests (e.g., IFA) for both *B. microti* and WA1 are available from the CDC on referral from state health departments and from some

commercial laboratories. Serology tests for malaria are negative in babesiosis, although patients with malaria may cross-react in the *Babesia* serologies (Wilson, 1995).

HEMOFLAGELLATES

The hemoflagellates of humans and animals are members of the order Kinetoplastida and are characterized by the presence of a large mitochondrion known as a kinetoplast, which contains enough DNA to be seen by light microscopy when treated with Giemsa stain. Two genera important in human disease are *Trypanosoma* and *Leishmania*. Members of both genera are transmitted by arthropod vectors and have animal hosts that serve as reservoirs.

Kinetoplastida assume different morphologic forms depending on their presence in vertebrate hosts, including humans, or in their insect vectors (Fig. 62-7). The amastigote stage is spherical, is 2–5 μm in diameter, and displays a nucleus and kinetoplast. By definition, an external flagellum is lacking, although an axoneme (the intracellular portion of the flagellum) is apparent at the ultrastructural level. Amastigotes may be found in human or animal hosts infected with *T. cruzi* or *Leishmania* spp., where they multiply exclusively within cells. The promastigote is an elongated and slender organism with a central nucleus, an anteriorly located kinetoplast and axoneme, and a free flagellum extending from the anterior end. This stage occurs in the insect vectors of *Leishmania* and is the stage detected in culture. The epimastigote is similar to the promastigote, but the kinetoplast is found closer to the nucleus and has a small undulating membrane that becomes a free flagellum. All species of *Trypanosoma* that infect humans assume an epimastigote stage in the insect vector or in culture. In the trypomastigote, the kinetoplast is found at the posterior end and the flagellum forms an undulating membrane that extends the length of the cell, emerging as a free flagellum at the anterior end. Trypomastigote forms occur predominantly in the bloodstream of mammalian hosts infected with various *Trypanosoma* spp. Infectious stages found in appropriate insect vectors following transformation from the epimastigote form are known as metacyclic trypomastigotes.

Trypanosoma

Infections with trypanosomes include those caused by *Trypanosoma brucei* (African or Old World trypanosomiasis) and *T. cruzi* (American or New World trypanosomiasis, or Chagas' disease). Both are of great importance in endemic areas but are rarely seen in the United States. A third species, *Trypanosoma rangeli*, has been described in humans in the Americas but does not cause clinical illness. Bloodstream trypomastigotes of the *T. brucei*

Figure 62-7 Morphology of hemoflagellates.

group (see Fig. 62-6, B) are up to 30 μm long with graceful curves and a small kinetoplast. Those of *T. cruzi* are shorter (20 μm), assume S and C shapes on stained blood films, and display a larger kinetoplast.

In equatorial Africa, parasites of the *T. brucei* group infect both animals and humans and are transmitted by the bite of tsetse flies in the genus *Glossina*. Multiplication of organisms at the bite site often produces a transient chancre. East African trypanosomiasis is caused by *T. brucei rhodesiense*, which has a number of animal reservoir hosts. The disease is characterized by a rapidly progressive acute febrile illness with lymphadenopathy. Patients die before central nervous system (CNS) involvement is prominent.

The infection in western Africa is caused by *T. brucei gambiense*, which is responsible for classic African sleeping sickness. The disease has a more chronic course that begins with intermittent fevers, night sweats, and malaise. Lymphadenopathy, especially of the cervical lymph nodes (Winterbottom's sign), may be pronounced. Involvement of the CNS becomes prominent with time. Somnolence, confusion, and fatigue progress, leading to stupor, coma, and eventual death. Humans are the primary reservoir for this disease (World Health Organization, 1986; Garcia, 2007).

The diagnosis is suspected on the basis of geographic history and clinical findings. Patients show high total IgM levels in blood and cerebrospinal fluid (CSF). Pleocytosis occurs with 50–500 mononuclear cells per microliter in CSF. The diagnosis is established by demonstrating the parasites on thick and thin films of peripheral blood, buffy coat preparations, or aspirates of lymph nodes or bone marrow, or in spun CSF that is stained with Giemsa (Van Meirvenne, 1985; Cattand, 1988; National Committee for Clinical Laboratory Standards, 2000). Culture or animal inoculation may be helpful, if it is available; a number of molecular methods have also been described.

American trypanosomiasis, or Chagas' disease, is caused by *T. cruzi*. In its sylvatic form, the parasite occurs in the United States, Central America, and most of South America. Human infections are common in parts of Mexico and Central and South America, where they are transmitted by kissing bugs of the family Reduviidae. Genera and species involved in transmission vary from one country to another and among different ecologic niches. Some reduviids are responsible for maintaining the sylvatic cycle in animal reservoirs, whereas others are adapted to a domiciliary life in which they infest poorly constructed houses, usually in rural areas. At the time of feeding, the reduviid bug defecates. The bug feces contain infective trypomastigotes that, as a result of scratching or rubbing, enter the body at the bite site or through intact mucosa of the mouth or conjunctiva. Infective forms actively enter nearby tissue cells, where they transform into dividing amastigotes. When the infected cell is filled with amastigotes, transformation to trypomastigotes occurs, followed by cell

rupture. Trypomastigotes are released into the peripheral blood and reach distant tissues, where they can start the reproductive cycle de novo.

Chagas' disease may cause acute or chronic infection. Acute disease is most common in children younger than 5 years of age and is characterized by malaise, chills, fever, hepatosplenomegaly, and myocarditis. Swelling of the tissues around the eye (Romaña's sign) may be present if inoculation of the organisms occurs on the face. Swelling of tissues at other locations following the bite of an infected reduviid is called a chagoma. In older individuals, the acute course is milder and often asymptomatic, and the patient remains infected for life. Chronic manifestations of the infection, including megaesophagus, megacolon, and alterations in the conduction system of the heart, are related to destruction of the effector cells of the parasympathetic system by autoantibodies. Infection can be transmitted by blood transfusion, and quiescent infections may be exacerbated by immunosuppression.

Diagnosis in the acute stage is established by demonstrating the parasite on thick and thin blood films, in buffy coat smears, or in aspirates of chagomas or enlarged lymph nodes. Aspirates, blood, and biopsy specimens can also be cultured using Novy-MacNeal-Nicolle medium (Ash, 1987; National Committee for Clinical Laboratory Standards, 2000; Garcia, 2007; Visvesvara, 2010b). In endemic areas, xenodiagnosis (examination of the gut contents of laboratory-raised reduviids that have been allowed to feed on a patient) may be used. In the chronic stage, serodiagnosis is the method of choice. EIA, IFA, and CF tests are available, although they cannot differentiate between acute and chronic disease, and cross-reactions may occur in patients with leishmaniasis.

Leishmania

Leishmaniasis is a disease of the reticuloendothelial system caused by kinetoplastid protozoa of the genus *Leishmania*. All species that infect humans have animal reservoirs and are transmitted by sandflies belonging to the genera *Phlebotomus* in the Old World and *Lutzomyia* in the New World. The parasites assume the amastigote form in mammalian hosts and the promastigote form in insect vectors. Species of *Leishmania* cannot be differentiated by examination of amastigotes or promastigotes. Leishmaniasis may assume many different clinical forms; cutaneous, mucocutaneous, and visceral diseases are best known. The form and severity of disease vary with the infecting species, the particular host's immune status, and prior exposure (Peters, 1987; Cook, 2002).

Cutaneous Leishmaniasis

Old World cutaneous leishmaniasis (oriental sore) occurs in southern Europe, northern and eastern Africa, the Middle East, Iran, Afghanistan, India, and southern Russia. Infections are caused by *Leishmania tropica*,

Leishmania major, and *Leishmania aethiopica*, although *L. donovani* and *Leishmania infantum* may also produce cutaneous lesions. *L. tropica* produces the urban or dry ulcer, which is more long lived than the rural or wet ulcer of *L. major*. Ulcers caused by these species usually develop on an exposed area of the body and heal spontaneously. Infection produces long-lasting immunity. *L. tropica* may become viscerotropic, as was demonstrated recently in military personnel who participated in Operation Desert Storm (Magill, 1993). *L. aethiopica* causes a more aggressive cutaneous infection, which in some individuals metastasizes to produce mucosal lesions or diffuse cutaneous leishmaniasis, the latter of which is characterized by multiple skin nodules resembling lepromatous leprosy.

Cutaneous leishmaniasis of the New World is caused by many species, including *Leishmania mexicana*, *Leishmania braziliensis*, *Leishmania amazonensis*, *Leishmania venezuelensis*, *Leishmania garnhami*, *Leishmania pifanoi*, *Leishmania peruviana*, *Leishmania panamensis*, and *Leishmania guyanensis*, among others (Garcia, 2007). Lesions produced by *L. mexicana* often involve the earlobe (chiclero ulcer), are self-limiting, and are not known to metastasize to the mucosa. However, *L. mexicana* and *L. amazonensis* may produce diffuse cutaneous lesions similar to those produced by *L. aethiopica*. A focus of cutaneous leishmaniasis exists in the southern part of Texas, where infections are caused by one or more species (Gustafson, 1985). *L. peruviana*, which has been found on the western slopes of the Peruvian Andes, causes an infection called uta, a benign cutaneous lesion that occurs predominantly in children. *L. peruviana* is acquired in the home, where the main reservoirs are domestic dogs. This epidemiologic situation contrasts with other cutaneous leishmaniasis, which usually are acquired in forests and have wild animals as reservoir hosts.

Mucocutaneous Leishmaniasis

Mucocutaneous leishmaniasis (espundia) is caused primarily by *L. braziliensis* and related species, which produce typical cutaneous lesions that generally are more aggressive, last longer, and often disseminate to mucous membranes, especially in the nasal, oral, or pharyngeal areas. In these locations, they may produce disfiguring lesions secondary to erosion of soft tissues and cartilage. *L. braziliensis* is distributed in Mexico and Central and South America.

Visceral Leishmaniasis

Visceral leishmaniasis of the Old World occurs sporadically over a wide geographic area and is caused by *L. donovani* or by *L. infantum*. *L. donovani* predominates in Africa, India, and Asia, and *L. infantum* predominates in the Mediterranean region and the Middle East, although overlapping ranges occur. New World visceral leishmaniasis is caused by *L. chagasi* and occurs sporadically throughout Central and South America. On occasion, some species that cause cutaneous disease have been responsible for visceral disease, as demonstrated recently in some troops who participated in Operation Desert Storm (Magill, 1993). In some areas, humans may serve as the disease reservoir, although a variety of animals, including dogs and cats, usually assume this role.

The infection is usually benign and often subclinical, although some individuals, especially young children and malnourished individuals, have marked involvement of the viscera, especially liver, spleen, bone marrow, and lymph nodes. In some cases, death occurs after months to years unless it is treated appropriately. The infection is called kala-azar in India, in reference to the darkening of the skin. Visceral leishmaniasis also is an opportunistic infection in individuals with concurrent human immunodeficiency virus (HIV), and the condition responds poorly to therapy in such circumstances (Medrano, 1992; Strickland, 2000; Garcia, 2007).

Diagnosis of Leishmaniasis

The diagnosis usually is established by visualization of amastigotes in smears, imprints, or biopsies, or by growth of promastigotes in culture. In integumentary leishmaniasis, the border of the most active lesion should be biopsied, and the fresh biopsy should be used to make imprints. A smear should be prepared by making a 2–3-mm incision at the border of the ulcer and recovering small amounts of tissue from the cut surfaces with the scalpel blade. Both the imprint and the smear should be treated with Giemsa stain. Specimens that may be submitted when visceral leishmaniasis is suspected include buffy coat preparations, lymph node and bone marrow aspirates, and spleen and liver biopsies (Garcia, 2007).

A culture is desirable because it is more sensitive and allows determination of the species or subspecies, a practice that may help in clinical management of the patient. Biopsy or aspirate specimens collected aseptically are cultured in Novy-MacNeal-Nicolle medium or in Schneider's *Drosophila* medium supplemented with fetal calf serum (Visvesvara, 2010b).

Cultures usually begin to show promastigotes in 2–5 days but should be held for 4 weeks.

Amastigotes found in imprints, smears, and tissue sections are recognized by their size (2–4 µm) and the presence of delicate cytoplasm, a nucleus, and a kinetoplast (see Fig. 62-6, C). In tissue sections, they may appear smaller because of shrinkage during fixation. Amastigotes must be differentiated from other intracellular organisms, including yeast cells of *Histoplasma capsulatum* and trophozoites of *T. gondii*. *Leishmania* spp. have a kinetoplast and do not have a cell wall. In contrast, *Histoplasma* lack the kinetoplast, and the cell wall stains with periodic acid-Schiff (PAS) and methenamine silver stains. According to one study (Weigle, 1987), the sensitivity of histologic sections stained with hematoxylin and eosin (H&E) is 14%; imprints, 19%; cultures, 58%; and all methods combined, 67%.

Toxoplasma gondii

T. gondii is a protozoan parasite of the phylum Apicomplexa that has a worldwide distribution in humans and in domestic and wild animals, especially carnivores. Infection in immunocompetent persons is generally asymptomatic or mild, but immunocompromised patients may experience serious complications. Infection in utero may result in serious congenital infection with sequelae or stillbirth (Remington, 2005).

The sexual stage in the life cycle of this coccidian parasite is completed in the intestinal epithelium of cats and other felines, which serve exclusively as definitive hosts. During this enteroepithelial cycle, asexual schizogony and sexual gametogony occur, leading to the development of immature oocysts that are passed in the feces. Oocysts mature to the infective stage (which contain two sporocysts with four sporozoites each) in the environment in 2–21 days. Ingestion of infective oocysts may lead to infection of a wide variety of susceptible vertebrate hosts in which actively growing trophozoites (tachyzoites) may infect any nucleated cells. Proliferation of tachyzoites results in cell death and injury to the host during acute infection. Once immunity has developed, the organisms form tissue cysts that may eventually contain hundreds or thousands of slowly growing bradyzoites. The presence of tissue cysts is characteristic of chronic infection. All stages of the life cycle occur in felines, but only trophozoite and cyst stages occur in humans and other intermediate hosts.

Humans acquire infection with *T. gondii* by ingestion of inadequately cooked meat, especially lamb or pork, that contains tissue cysts or by ingestion of infective oocysts from material contaminated by cat feces. Outbreaks have occurred from inhaling contaminated dust in an indoor riding stable (Teutsch, 1979) and from drinking contaminated water or unpasteurized goat's milk (Benenson, 1982; Sacks, 1982; Bowie, 1997). Transmission via blood transfusion and through organ transplantation also can occur.

Most acute infections are asymptomatic or mimic other infectious diseases in which fever and lymphadenopathy are prominent. Congenital infection may occur when the mother develops acute infection during gestation. Risk of infection to the neonate is unrelated to the presence or absence of symptoms in the mother, but severity of infection depends on the stage of gestation at which it is acquired. Intrauterine death, microcephaly, or hydrocephaly with intracranial calcifications may develop if infection is acquired in the first half of pregnancy. Infections in the second half of pregnancy are usually asymptomatic at birth, although fever, hepatosplenomegaly, and jaundice may appear. Chorioretinitis, psychomotor retardation, and convulsive disorders may appear months or years later (Remington, 2005; Wilson, 2007).

In immunosuppressed individuals, especially those with AIDS, infection with *T. gondii* usually presents with CNS involvement (Luft, 1988). Other possible clinical and pathologic manifestations include pneumonitis, myocarditis, retinitis, pancreatitis, or orchitis (Luft, 1989; Schnapp, 1992). Toxoplasmosis may be difficult to diagnose clinically and is often discovered at autopsy (Gutierrez, 2000). These infections usually result from reactivation of a latent infection, acquired months or years before, but occasionally result from a primary infection.

Diagnosis of toxoplasmosis may be established by examination of tissues, blood, or body fluids (Wilson, 2007). Demonstration of tachyzoites or tissue cysts is definitive but may prove difficult to demonstrate in H&E-stained sections; fluorescent or immunoperoxidase stains, if available, are useful. Giemsa is good for staining smears of body fluids and tissue imprints. Organisms may be demonstrated by inoculating appropriate material into tissue culture or uninfected mice. Recovery in routine viral cultures also has been described but requires extended incubation (Shepp, 1985). Isolation of organisms from blood or body fluid serves as evidence

Figure 62-8 **A**, *Naegleria fowleri* trophozoites in primary amebic meningoencephalitis (H&E; oil immersion). **B**, *Acanthamoeba* sp. culture showing trails left by motile trophozoites on a lawn of *Escherichia coli* (phase contrast microscopy; $\times 100$). **C**, *Acanthamoeba* sp. trophozoites within a cutaneous lesion in an individual infected with the human immunodeficiency virus (Giemsa stain; oil immersion). **D**, *Acanthamoeba* sp. trophozoite and cyst (differential interference contrast microscopy; $\times 400$). **E**, Double-walled cysts of *Acanthamoeba* sp. within corneal stroma (H&E; oil immersion). **F**, Cysts of *Acanthamoeba* sp. stained with Calcofluor white (epifluorescence microscopy; $\times 400$).

of acute infection, whereas recovery from tissues may reflect chronic infection. In smears, tachyzoites are crescent-shaped or oval, measuring approximately $3 \times 7 \mu\text{m}$; cysts measure up to $30 \mu\text{m}$ in diameter and are usually spherical, except in muscle fibers, where they appear elongate (see Fig. 62-6, *D* through *F*).

Use of PCR technology is highly sensitive and specific in detecting toxoplasmic encephalitis, disseminated disease, and intrauterine infection; testing is available from a small number of commercial and research laboratories (Grover, 1990; Cazenave, 1991; Parmley, 1992; Weiss, 1995; Wilson, 2007).

Serology remains the primary approach in establishing a diagnosis of toxoplasmosis (National Committee for Clinical Laboratory Standards, 2004; Wilson, 2007). The Sabin-Feldman dye test and the IFA test are standards against which other methods are compared, although the former is performed in only a few centers. EIA tests are commercially available and generally provide results similar to those of IFA. Antibodies appear in 1–2 weeks, and titers peak at 6–8 weeks. Tests for IgM-specific antibodies are especially useful for diagnosis of congenital and acute infection, but knowledge of test limitations, specifically the occurrence of false-positive reactions, is extremely important. The persistence of IgM-specific antibodies, sometimes for a year or longer, also is problematic and must be interpreted in conjunction with IgG antibody results. Because many persons have had asymptomatic infection, low IgG titers have little significance. Titers in patients with chronic ocular infection may also be low. Immunocompromised patients such as those with AIDS who have active *Toxoplasma* infection almost always have preexisting specific IgG antibodies, although titers may be low, and IgM antibodies are infrequently detected. Interpretation of IgG and IgM antibody titers varies by test method and by manufacturer. The laboratory performing the test should provide the necessary interpretive criteria (National Committee for Clinical Laboratory Standards, 2004).

OPPORTUNISTIC FREE-LIVING AMEBAE

Amebae of the genera *Naegleria*, *Acanthamoeba*, *Balamuthia*, and *Sappinia* are inhabitants of soil, water, and other environmental substrates, where they feed on other microscopic organisms, especially bacteria and yeasts. All four genera have been associated with opportunistic infection of the CNS, and *Acanthamoeba* causes keratitis (Martinez, 1985; Marciano-Cabral, 1988; Ubelaker, 1991; Kilvington, 1994; Visvesvara, 2007; Qvarnstrom, 2009).

Primary amebic meningoencephalitis, caused by the ameboflagellate *Naegleria fowleri*, typically affects children and young adults who have been swimming or diving in warm, freshwater lakes or pools. The

ameboflagellate enters the brain via the cribriform plate and olfactory bulbs and reaches the frontal lobes, where it produces an acute hemorrhagic meningoencephalitis that is usually fatal within 1 week of onset of symptoms. The disease has an extremely poor prognosis, despite vigorous therapeutic intervention. Diagnosis is usually established at autopsy examination by the finding of trophozoites (cysts are rarely seen) in tissue sections (Fig. 62-8, *A*). Antemortem diagnosis is made occasionally by identifying typical trophozoites in CSF on direct wet mounts, in stained preparations, or in culture. Trophozoites measure $10\text{--}35 \mu\text{m}$; have large, round, central karyosomes; and if exposed to warm distilled water, convert to flagellated forms in 1–2 hours. Cysts are spherical, measuring $7\text{--}15 \mu\text{m}$ in diameter. Culture usually is performed on nonnutrient agar plates (1.5% agar, 0.5% sodium chloride, pH 6.6–7.0) seeded with a lawn of heat-killed or living *Escherichia coli* (Visvesvara, 2010c). Amebae ingest the bacteria, leaving tracks in the bacterial lawn, which may be seen under low-power magnification using reduced light (Fig. 62-8, *B*).

Granulomatous amebic meningoencephalitis (GAE) may be caused by several species of *Acanthamoeba*, including *Acanthamoeba castellanii*, *Acanthamoeba culbertsoni*, *Acanthamoeba polyphaga*, and *Acanthamoeba astronyxis*, among others (Marciano-Cabral, 2003). It is usually a subacute or chronic opportunistic infection of chronically ill, debilitated, and immunosuppressed individuals, leading to death weeks to months following onset of symptoms. Infection is thought to spread hematogenously from primary foci in skin, pharynx, or the respiratory tract. Systemic infections occur in individuals with AIDS and may present as ulcerative skin lesions, subcutaneous abscesses, or erythematous nodules (Fig. 62-8, *C*) (Tan, 1993). Exposure to fresh water is not necessary because cysts of *Acanthamoeba* readily become airborne and may be recovered from the throat and nasal passages (Wang, 1967; Lawande, 1979). The pathologic reaction in tissues is granulomatous, with trophozoites predominating in viable tissue, and cysts predominating in areas of necrosis. Diagnosis usually is established at autopsy, but organisms may be recognized in brain biopsies or recovered using the culture technique described for *Naegleria*. *Acanthamoeba* trophozoites are somewhat larger than *Naegleria*, measuring $15\text{--}45 \mu\text{m}$, and display needle-like filamentous projections from the cell known as acanthopodia. Cysts measure $10\text{--}25 \mu\text{m}$ and are double-walled, displaying a wrinkled outer wall (ectocyst) and a polygonal, stellate, or round inner wall (endocyst) (Fig. 62-8, *D*). Identification to the species level is problematic and reflects uncertainty as to the validity of the 18 or more described species. Currently, genotyping is the preferred approach used in differentiating types of *Acanthamoeba* (Marciano-Cabral, 2003). Immunofluorescence and immunoperoxidase techniques may prove useful in identifying and differentiating species and are available from the CDC (Visvesvara, 2007).

Figure 62-9 Size ranges of intestinal protozoa. (*Balantidium coli* trophozoites may measure up to 200 µm.)

GAE may also be caused by leptomycid amebae, specifically *Balamuthia mandrillaris* (Visvesvara, 1993). Morphologically, *Balamuthia* cannot be differentiated from *Acanthamoeba* by routine histology, although differences may be detected at the ultrastructural level. These organisms are antigenically distinct and may be identified using specific monoclonal or polyclonal antisera in DFA or immunoperoxidase assays (Visvesvara, 2007). *Balamuthia* do not grow on agar plates used for *Naegleria* and *Acanthamoeba*, but they have been recovered in tissue culture using mammalian cell lines. A single case of encephalitis caused by *Sappinia* (*S. pedata*), another free-living ameba, was recently described and identified by a real-time PCR assay (Qvarnstrom, 2009).

Acanthamoeba keratitis is an increasingly recognized painful infection of the cornea that is most likely to occur in persons who use daily-wear or extended-wear soft contact lenses or who have experienced trauma to the cornea (Anuran, 1987; Kilvington, 1994; Marciano-Cabral, 2003). Incomplete or infrequent disinfection and use of homemade saline and multi-purpose solutions are known risk factors for acquiring the infection (Stehr-Green, 1990; Verani, 2009). The disease is characterized by development of a paracentral ring infiltrate of the corneal stroma, which progresses to ulceration and possible perforation, with loss of the eye. The infection may be confused with fungal, bacterial, or herpetic keratitis but is characteristically refractory to commonly used antimicrobials. Keratoplasty has been used routinely in management of this disease, although recent advances in medical therapy have been reported (Varga, 1993; Dart, 2009). Diagnosis usually is established by demonstrating amebic trophozoites or cysts in corneal scrapings or biopsies (Fig. 62-8, E). A variety of permanent stains can be used, including Giemsa, PAS, and trichrome. Use of the fluorochrome Calcofluor white is especially helpful in recognizing amebic cysts (Fig. 62-8, F) (Marines, 1987; Garcia, 2010). While cultures (described earlier) provide increased sensitivity over staining methods and are often available from clinical laboratories, the sensitivity achieved by PCR may equal or exceed that of culture (Boggild, 2009).

INTESTINAL AND UROGENITAL PROTOZOA

Protozoal groups inhabiting the intestinal tract of humans include amebae, flagellates, ciliates, coccidia, and microsporidia, not all of which are pathogens. In a review of fecal specimens submitted to state health department laboratories, *G. lamblia* was present in 7.2%, *E. histolytica* in 0.9%, *D. fragilis* in 0.5%, and *Cryptosporidium* spp. in 0.2% of specimens. Nonpathogenic protozoa were found in approximately 10.7% of specimens (Kappus,

1994). Most intestinal infections are acquired by fecal–oral contamination directly from food handlers, or indirectly via contaminated water.

For most laboratorians, identification of intestinal protozoa is one of the more difficult aspects of parasitology. Protozoal parasites are small, and pathogenic species must be differentiated from nonpathogenic species and from inflammatory cells, epithelial cells, yeasts, pollen, and other confusing objects. Numerous characteristics assist in identifying intestinal protozoa. Size is helpful (Fig. 62-9), and a properly calibrated ocular micrometer must be available. Differentiation of amebae from flagellates in wet mounts of fresh material is relatively easy because of the typical pseudopod extension seen with amebae, whereas flagellates move more rapidly and in a so-called falling leaf, darting, or tumbling fashion.

Number and size of nuclei and pattern of chromatin distribution, best seen in permanent stained preparations, are also useful. Cytoplasmic characteristics include fibrils and other special structures typical of flagellates, ingested materials in amebic trophozoites, and glycogen masses and chromatoid bodies in amebic cysts. Flagellates generally are elongated and tapered, with a nucleus or nuclei at one end.

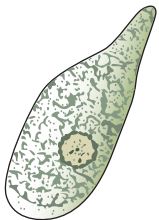

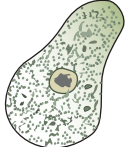

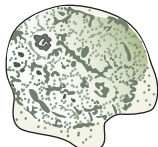

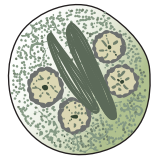

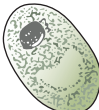

During examination by any method, both nuclear and cytoplasmic characteristics should be assessed from a number of individual organisms to complete the identification. When reporting the presence of two or more species in a sample, the observer should be able to define distinct populations of organisms to prevent confusion with an occasional organism with an atypical appearance.

Trophozoites predominate in liquid stool but degenerate within an hour after passage unless they are placed into preservatives. Cysts predominate in formed stool and are more resistant to degeneration. Both forms may be seen in direct wet mounts prepared from fresh feces. Formalin does not preserve trophozoites well, and they may be missed unless permanent stained smears are prepared. Definitive identification should be made on examination of permanent stained slides.

AMEBAE AND *Blastocystis hominis*

Three genera of amebae may inhabit the intestinal tract of humans: *Entamoeba*, *Endolimax*, and *Iodamoeba*. Cysts are ingested and excyst in the small intestine. Resulting trophozoites proliferate by binary fission in the lumen of the colon. Both cysts and trophozoites may be passed in feces, but only mature cysts are infective. *E. histolytica* is the only amebic species capable of invading tissues and causing disease.

The genus *Entamoeba*, characterized by the presence of chromatin on the nuclear membrane, includes *E. histolytica*, the etiologic agent of amebiasis; *E. dispar*, a nonpathogenic species morphologically identical to

E. histolytica, *E. hartmanni*, and *Entamoeba coli*, which are commonly found commensal species; and *Entamoeba polecki*, which is occasionally found in people who have contact with pigs (Fig. 62-10) (Levin, 1970; Gay, 1985). *Entamoeba gingivalis*, which does not have a known cyst stage, may inhabit the oral cavity of people with poor oral hygiene (Dao, 1983). *E. polecki* and *E. gingivalis* are seen infrequently and are not described further. *Endolimax nana* and *I. bütschlii* are nonpathogenic species. *Dientamoeba fragilis* now is recognized as a flagellate, although it lacks external flagella, and is discussed with the flagellates in the text but may be found with amebae in tables and figures because it is morphologically similar to them (Garcia, 2007).

Entamoeba histolytica

E. histolytica may cause various clinical diseases, most commonly amebic dysentery, amebic colitis, and liver abscesses (Beaver 1984; Ravdin, 1988; Strickland, 2000). General host defense mechanisms, previous contact with the parasite, diet, and the strain of *E. histolytica* influence the severity of infection. Analysis of isoenzyme patterns (zymodemes) has shown that only certain strains can cause invasive disease and that most infections remain undetected (Bruckner, 1992; Murray, 2007). Genetic and biochemical differences between invasive and noninvasive strains have been identified, and it has been proposed that nonpathogenic strains should be named *Entamoeba dispar* (Diamond, 1993).

Amebic dysentery, which occurs infrequently in the United States, is an acute disease characterized by bloody diarrhea with abdominal cramping. Invasion of the intestinal mucosa occurs, producing ulceration that may lead to perforation and peritonitis. The more common form of disease seen in this country is amebic colitis, which may mimic ulcerative colitis and other forms of inflammatory bowel disease. Symptoms generally are less severe than in amebic dysentery but may include nonbloody diarrhea, constipation, abdominal cramping, and weight loss. Small, pinpoint mucosal ulcerations may develop and expand within the submucosa to form flask-shaped ulcers. All of the colon may be involved or only a portion, most commonly the cecum, rectosigmoid, or ascending colon.

Amebic liver abscess is the most common form of extraintestinal amebiasis, occurring in approximately 5% of patients with a history of intestinal amebiasis. Symptoms include fever and right upper quadrant pain. These liver abscesses are usually diagnosed by radiographic scans, ultrasound, and serologic tests. Amebae are present in the stool in less than half of patients at the time liver abscess is manifest. Amebic hepatitis, characterized by an enlarged, tender liver in someone with intestinal amebiasis, may

occur in some cases. Its pathogenesis is poorly understood. Rarely, amebic abscesses appear in other organs, such as the lung, brain, or skin, by hematogenous spread from the intestine or by contiguous spread from a liver abscess. Masses of granulomatous tissue, known as amebomas, may form in response to the presence of amebae, which in the intestine may cause a so-called napkin ring lesion that could be mistaken for a carcinoma.

Epidemiology

Most infections with *E. histolytica* are acquired by ingestion of contaminated food or water, although one outbreak was caused by a contaminated colonic irrigation machine (Istre, 1982). Pseudo-outbreaks of amebiasis result from laboratory misidentification of inflammatory cells, other amebae, and fecal debris as *E. histolytica* (Krogstad, 1978; Centers for Disease Control and Prevention, 1985). Although *E. histolytica* is an endemic parasite in the United States, many citizens acquire infection while traveling through or residing in foreign countries.

Diagnosis

Examination of a series of stool specimens should be sufficient for diagnosis of intestinal amebiasis in most cases. If the patient has been given antibiotics or contrast media, the amebic infection may be masked for a period of time. Aspirated material from liver abscesses can be examined microscopically to detect trophozoites. The last material aspirated is most likely to contain trophozoites and may be examined by direct microscopic examination or permanently stained slides. If tissue is available, sections may show organisms that stain prominently with PAS (Fig. 62-11, C).

Culture procedures (Diamond, 1988; Clinical and Laboratory Standards Institute, 2005; Visvesvara, 2010a) are not widely used for diagnosis but are useful for research and are essential for determining pathogenicity based on zymodemes. EIA antigen detection tests that are specific, sensitive, and able to differentiate *E. histolytica* from *E. dispar* are commercially available (see Table 62-5) (Clinical and Laboratory Standards Institute, 2005; Garcia, 2007). Use of PCR amplification techniques and DNA probes is also useful for differentiating *E. histolytica* from *E. dispar* (Samuelson, 1989; Bendall, 1993; Weiss, 1995), but none are commercially available at this time.

Serologic tests (see Table 62-6) are most useful for diagnosis of extraintestinal infection because approximately 95% of patients with amebic liver abscess are seropositive. This decreases to 70% for patients with active intestinal infection and to 10% in asymptomatic carriers. Detectable titers

Figure 62-11 Intestinal protozoa, trichrome stain, oil immersion, except as noted. **A**, Trophozoite of *Entamoeba histolytica*. **B**, Quadri-nucleate cyst of *E. histolytica* with rounded chromatoid bars. (Photograph courtesy David Bergeron.) **C**, *E. histolytica* trophozoites with ingested red blood cells from a colonic lesion (H&E). **D**, Trophozoite of *E. hartmanni*. **E**, Trophozoite and binucleate cyst of *E. coli*. **F**, Multinucleate cyst of *E. coli*. **G**, Cyst of *Iodamoeba bütschlii* with characteristic glycogen vacuole. **H**, Binucleate trophozoites typical for *Dientamoeba fragilis*.

may persist for months or years after successful treatment (Rosenblatt, 1995; Wilson, 1995).

Trophozoites of *E. histolytica* vary from 10–60 μm in diameter, with the commensal forms usually 15–20 μm and the invasive forms greater than 20 μm in greatest dimension (Table 62-9; Figs. 62-9 through 62-12). In direct wet mounts, trophozoites show progressive motility via rapidly formed hyaline pseudopodia that demonstrate a sharp demarcation between endoplasm and ectoplasm; unstained nuclei are not visible. In invasive disease, some trophozoites contain ingested erythrocytes (see Fig. 62-11, **C**), a feature diagnostic of *E. histolytica* infection. In stained preparations, the peripheral nuclear chromatin is evenly distributed along the nuclear membrane as fine granules. The karyosome is small and is often centrally located, with fine fibrils, which generally are not visible, attaching it to the nuclear membrane. Variations in nuclear structure occur, with some karyosomes located eccentrically and peripheral chromatin irregularly distributed. The only characteristic that is pathognomonic for *E. histolytica* is phagocytosis of erythrocytes, which very rarely occurs with other species. The cytoplasm is finely granular, and in invasive organisms, no inclusions or only erythrocyte inclusions are seen. Noninvasive organisms may contain ingested bacteria. In degenerating organisms, the cytoplasm may become vacuolated and nuclei may show abnormal chromatin clumping.

Cysts of *E. histolytica* are spherical and measure 10–20 μm (usually 12–15 μm) in diameter (Table 62-10; see Figs. 62-9, 62-10, and 62-12). The rounded precyst stage has a single nucleus but does not have a refractile cyst wall. As it matures, the cyst develops four nuclei, each approximately one-sixth the diameter of the cyst. Cyst nuclei appear similar to those of trophozoites, but their smaller size makes them less useful as differentiating features. The cyst cytoplasm may contain glycogen vacuoles and chromatoid bodies with blunted or rounded ends. The number and size of nuclei and the appearance of chromatoid bodies are important diagnostic criteria for identifying cysts.

Those laboratories that do not use one of the immunologic or molecular methods to differentiate *E. histolytica* from *E. dispar*, and that rely exclusively on morphologic analysis, must use a reporting format that takes the differing technologies into consideration. Thus, a report of “*E. histolytica*/*E. dispar*” would be most appropriate in the latter circumstance.

Nonpathogenic Amebae

Laboratory personnel must be able to differentiate nonpathogenic or commensal intestinal amebae from *E. histolytica*/*E. dispar* and *D. fragilis* (a flagellate), which are potential pathogens. Identification characteristics, best visualized in permanent stained sections, are summarized in Tables 62-9 and 62-10 and in Figures 62-9, 62-10, and 62-12. Identification of trophozoites is based on size and nuclear and cytoplasmic characteristics; identification of cysts is based on size, number and characteristics of nuclei, and presence and character of chromatoid bodies and glycogen masses.

E. hartmanni has morphologic characteristics similar to those of *E. histolytica*, except trophozoites have a maximum diameter of 12 μm and cysts have a maximum diameter of 10 μm , and cysts often have a single nucleus. Historically, *E. hartmanni* has been called the small race of *E. histolytica*. Differentiation requires careful measurement of a representative sample of organisms with a properly calibrated ocular micrometer.

Entamoeba coli, a common lumen-dwelling ameba, may be difficult to differentiate from *E. histolytica*. The cytoplasm stains somewhat more darkly than the cytoplasm of *E. histolytica* and is more vacuolated, containing numerous ingested bacteria, yeasts, and other materials. Although nuclear characteristics differ from those of *E. histolytica* (see Fig. 62-12), significant overlap may occur, especially in specimens that have not been promptly preserved. Mature cysts of *E. coli* contain eight nuclei, although occasional cysts contain 16 or more. Immature cysts, which are not common, have four nuclei that are larger (one-fourth the diameter of the cyst) than nuclei of *E. histolytica* (one-sixth the diameter of the cyst) and

TABLE 62-9

Morphology of Trophozoites of Intestinal Amebae

Species	Size (in diameter or length)	Motility	Nucleus numbers*	Peripheral chromatin	Karyosomal chromatin	Cytoplasm appearance	Inclusions
<i>Entamoeba histolytica</i> / <i>E. dispar</i>	10–60 μm ; usual range, 15–20 μm commensal form [†] ; over 20 μm for invasive form [‡]	Progressive, with hyaline, finger-like pseudopods	1 Not visible in unstained preparations	Fine granules; usually evenly distributed and uniform in size	Small, discrete; usually central but occasionally eccentric	Finely granular	Erythrocytes occasionally in invasive forms; noninvasive, contain bacteria
<i>Entamoeba hartmanni</i>	5–12 μm ; usual range, 8–10 μm	Usually nonprogressive but may be progressive occasionally	1 Not visible in unstained preparations	Similar to <i>E. histolytica</i>	Small, discrete, often eccentric	Finely granular	Bacteria
<i>Entamoeba coli</i>	15–50 μm ; usual range, 20–25 μm	Sluggish, nonprogressive with blunt pseudopods	1 Often visible in unstained preparation	Coarse granules, irregular in size and distribution	Large, discrete, usually eccentric	Coarse, often vacuolated	Bacteria, yeasts, other materials
<i>Endolimax nana</i>	6–12 μm ; usual range, 8–10 μm	Sluggish, usually nonprogressive with blunt pseudopods	1 Visible occasionally in unstained preparations	None	Large, irregularly shaped	Granular, vacuolated	Bacteria
<i>Iodamoeba bütschlii</i>	8–20 μm ; usual range, 12–15 μm	Sluggish, usually nonprogressive	1 Not usually visible in unstained preparations	None	Large, usually central; surrounded by refractile, achromatic granules; these granules often are not distinct even in stained slides	Coarsely granular, vacuolated	Bacteria, yeasts, or other materials
<i>Dientamoeba fragilis</i> [§]	5–15 μm ; usual range, 9–12 μm	Pseudopods are angular, serrated, or broad lobed, and hyaline is almost transparent	2 (In approximately 20% of organisms, only 1 nucleus is present) Nuclei invisible in unstained preparations	None	Large cluster of 4–8 granules	Finely granular, vacuolated	Bacteria

*Visibility is for unfixed material. Nuclei sometimes may be visible in fixed material.

[†]Usually found in asymptomatic or chronic cases; may contain bacteria.

[‡]Usually found in acute cases; often contain red blood cells.

[§]A flagellate (see text).

Figure 62-12 Nuclei of amebae. This drawing shows some of the various appearances of amebic nuclei in stained preparations. (*Dientamoeba fragilis* is a flagellate; see text.)

TABLE 62-10

Morphology of Cysts of Intestinal Amebae

Species	Size	Shape	Nucleus number	Peripheral chromatin	Karyosomal chromatin	Cytoplasm chromatoid bodies	Glycogen
<i>Entamoeba histolytica</i> / <i>E. dispar</i>	10–20 μm ; usual range, 12–15 μm	Usually spherical	4 in mature cyst; immature cysts with 1 or 2 occasionally seen	Peripheral chromatin present; fine, uniform granules, evenly distributed	Small, discrete, usually central	Present; elongate bars with bluntly rounded ends	Usually diffuse; concentrated mass often present in young cysts; stains reddish brown with iodine
<i>Entamoeba hartmanni</i>	5–10 μm ; usual range, 6–8 μm	Usually spherical	4 in mature cyst; Immature cysts with 1 or 2 often seen	Similar to <i>E.</i> <i>histolytica</i>	Similar to <i>E. histolytica</i>	Present; elongate bars with bluntly rounded ends	Similar to <i>E. histolytica</i>
<i>Entamoeba coli</i>	10–35 μm ; usual range, 15–25 μm	Usually spherical; occasionally oval, triangular, or of another shape	8 in mature cyst; occasionally supernucleate cysts with 16 or more are seen; immature cysts with 2 or more occasionally seen	Peripheral chromatin present; coarse granules irregular in size and distribution, but often appear more uniform than in trophozoites	Large, discrete, usually eccentric, but occasionally central	Present; usually splinter-like with pointed ends	Usually diffuse, but occasionally well-defined mass in immature cysts; stains reddish brown with iodine
<i>Endolimax nana</i>	5–10 μm ; usual range, 6–8 μm	Spherical, ovoid, or ellipsoidal	4 in mature cysts; immature cysts with fewer than 4 rarely seen	None	Large, usually centrally located	Occasionally, granules or small oval masses seen, but bodies as seen in <i>Entamoeba</i> species are not present	Usually diffuse; concentrated mass seen occasionally in young cysts; stains reddish brown with iodine
<i>Iodamoeba bütschlii</i>	5–20 μm ; usual range, 10–12 μm	Ovoid, ellipsoidal, triangular, or of another shape	1 in mature cyst	None	Large, usually eccentric; refractile, achromatic granules on one side of karyosome	Granules occasionally present, but bodies as seen in <i>Entamoeba</i> species are not present	Compact, well-defined mass; stains dark brown with iodine

Adapted from Brooke MM, Melvin DM. Morphology of diagnostic stages of intestinal parasites of man. PHS Publication No. 1966. Bethesda, Md.: U.S. Department of Health Education and Welfare; 1969.

may contain glycogen. Distribution of peripheral chromatin and karyosomes should not be given great emphasis in identification of *Entamoeba* cysts. Chromatoid bodies, when present, are irregular in shape with splintered or pointed ends, rather than the rounded ends seen in *E. histolytica*.

Endolimax nana is the smallest ameba to infect humans. Trophozoites often have atypical nuclei that contain a triangular chromatin mass, a band of chromatin across the nucleus, or two discrete masses of chromatin on opposite sides of the nuclear membrane (see Fig. 62-12). A clear halo or karyolymph space surrounds the karyosome and extends to the nuclear membrane. Atypical nuclear forms may be helpful in differentiating *E. nana* from *I. bütschlii*, which is similar in appearance but larger. Cysts of *Endolimax* usually contain four nuclei, although smaller numbers may be seen. Glycogen, when present, occurs diffusely in the cytoplasm rather than as a discrete mass. Cysts are easily differentiated from those of other amebae but may be confused with *Blastocystis hominis* organisms. The nuclei of *B. hominis*, however, lack the halos that are typically seen with *E. nana* cysts.

The nuclei of *I. bütschlii* trophozoites and cysts have a large, centrally located karyosome frequently surrounded by achromatic granules that may not be distinct but appear only as a muddy karyolymph space or halo. In some nuclei, the halo is clear without evident achromatic granules, making the organism indistinguishable from *E. nana*. Cysts of *I. bütschlii* contain a single nucleus, in which the karyosome is often eccentric with a nearby crescent of achromatic granules (see Figs. 62-9, 62-10, and 62-12). The cyst is characterized by a prominent vacuole of glycogen that stains reddish brown in iodine-stained wet mounts, thus the name of the organism.

Glycogen is dissolved by aqueous fixatives and may not be demonstrable in material that has been stored.

Blastocystis hominis

Blastocystis hominis inhabits the large bowel and is frequently found in stool specimens of asymptomatic individuals. While appearing in stains as an amoeba-like protozoan, the phylogenetic affinities of this parasite remain uncertain. Some studies have linked heavy infection to symptomatic intestinal disease, although this remains controversial (Markell, 1986; Sheehan, 1986; Miller, 1988; Zierdt, 1991; Stenzel, 1996; Garcia, 2007). *Blastocystis* may assume one of three forms: vacuolated (seen most commonly), ameboid, or granular. The vacuolated form, also known as the central vacuolar form, usually is spherical and variable in size (5–20 μm) and has a central clear area and two to four peripheral nuclei (Figs. 62-13, A, and 62-14, G). Ameboid forms with bizarre shapes may predominate in heavy infections. The presence of *Blastocystis* should be reported, especially when they are numerous (five or more per 400 \times field) (Sheehan, 1986; Stenzel, 1996).

FLAGELLATES

Dientamoeba fragilis

Dientamoeba fragilis is an ameboid pathogen that infects the colon and has been associated with diarrheal disease, especially in young children (Yang, 1977; Spencer 1979; Turner, 1985; Preiss, 1991; Johnson, 2004). Although

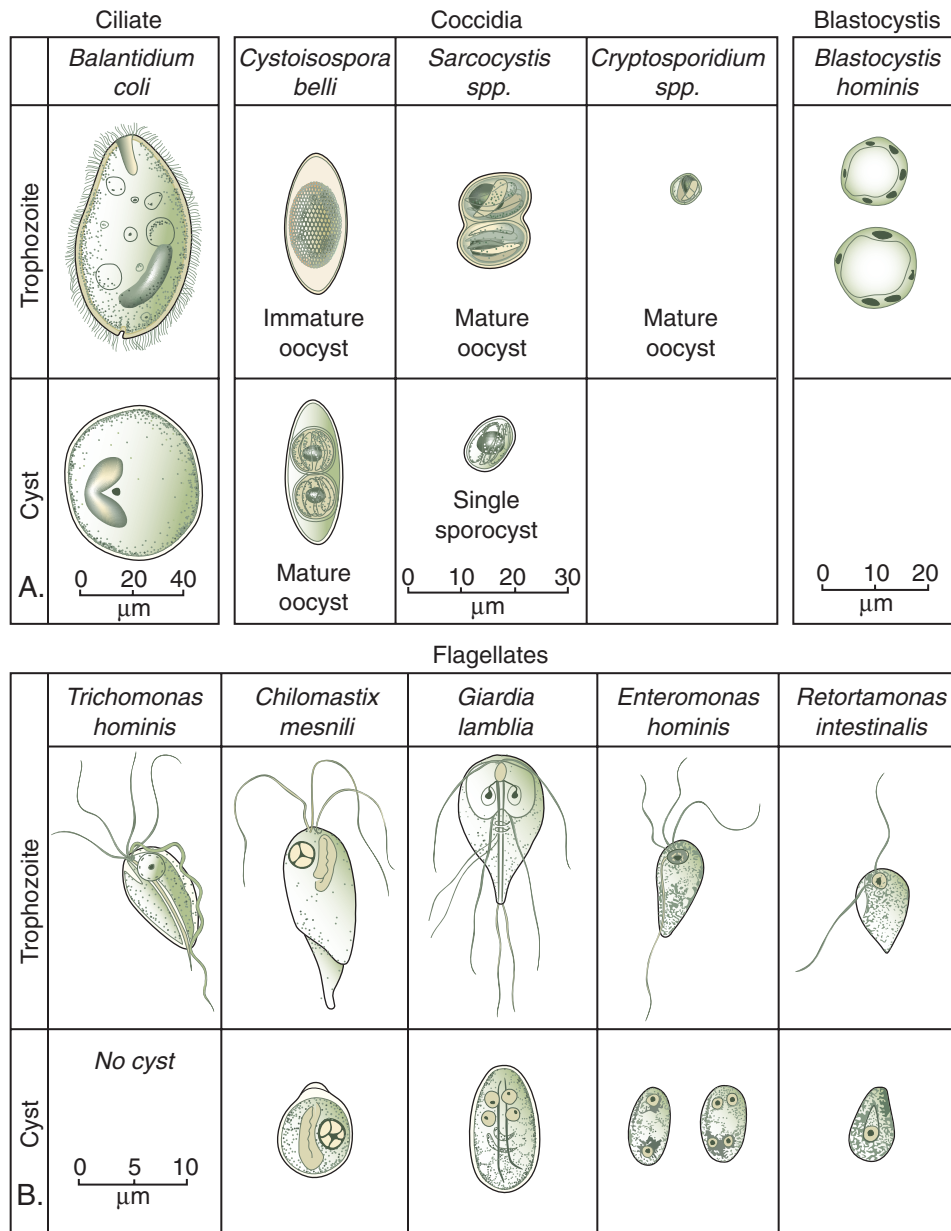

Figure 62-13 **A**, Ciliate, Coccidia, and *Blastocystis hominis* spp. found in stool specimens of humans. **B**, Flagellates found in stool specimens of humans. (Adapted from Brooke MM, Melvin DM. Morphology of diagnostic stages of intestinal parasites of man. Publication No. [CDC] 848116. Washington, DC: U.S. Department of Health and Human Services; 1984.)

similar in appearance to amebae, *Dientamoeba* has been reclassified as a flagellate on the basis of ultrastructural details and antigenic similarities. Also, no cyst stage has been described. Because of the similarity of *Dientamoeba* to amebae at the light microscope level, this species has traditionally been included in tables and figures for amebae (see Table 62-9 and Figs. 62-9, 62-10, 62-11, H, and 62-12).

Symptoms of *D. fragilis* infection include diarrhea and abdominal distention. Recent evidence suggests that dientamebiasis is a more frequent cause of diarrhea than previously thought: 4.3% of patients in one study harbored this organism (Spencer, 1979; Murray, 2007). Approximately 25% of persons infected with this parasite have symptomatic disease. In contrast to amebiasis, this infection usually is not associated with other fecal protozoa but does show a 10–20 times greater than expected association with enterobiasis (pinworm infection, discussed later). This association and some experimental evidence suggest that *D. fragilis* infection may be spread by ingestion of pinworm eggs infected with *D. fragilis* (Burrows, 1956; Johnson, 2004). *D. fragilis* infection will be overlooked unless permanently stained slides are examined. Multiple specimens may need to be submitted because shedding varies from day to day. When smears are prepared, the last portion of the stool evacuated should be examined because the number of parasites found there tends to be greater. Two thirds to four fifths of the organisms contain two nuclei that consist of a cluster

of four to eight karyosomal granules, which may appear as one large irregular karyosome (see Fig. 62-12). Uninucleate *D. fragilis* may be confused with trophozoites of *E. nana* or *I. bütschlii*. The cytoplasm is finely granular and often contains ingested bacteria. Trophozoites are delicate and may be easily overlooked, so stained slides must be carefully examined. An immunofluorescence method has been described that may help in the detection of this parasite, but it is not commercially available (Chan, 1993).

Giardia lamblia

Giardia lamblia is a pathogenic intestinal protozoan that causes both endemic and epidemic disease worldwide; in the United States, it is especially problematic for travelers, campers, children attending day care, and homosexual men (Wolfe, 1992). It frequently causes disease in individuals drinking contaminated water, and a number of large water-borne outbreaks have been described from places such as Aspen, Colorado; Leningrad, Russia; and Rome, New York (Craun, 1986). Pathogenic protozoa are not killed by the usual concentrations of chlorine in municipal water supplies; therefore, unless the water supply is filtered, it may serve as a source of infection, as it did in the Rome, New York, outbreak.

G. lamblia trophozoites multiply in the small bowel and attach to the mucosa by a ventral concave sucking disk. Infection may be asymptomatic or may cause disease ranging from mild diarrhea with vague abdominal

Figure 62-14 Intestinal protozoa, trichrome stain, oil immersion, except as noted. **A**, Trophozoite of *Endolimax nana*. **B**, Quadrinucleate cysts of *E. nana*. **C**, Trophozoite of *Giardia lamblia* displaying prominent nuclei, median bodies, flagella, and a tapered posterior end. **D**, Cysts of *G. lamblia* with nuclei and fibrils. **E**, Duodenal biopsy demonstrating a *G. lamblia* trophozoite (H&E). **F**, A lemon-shaped cyst of *Chilomastix mesnili* with visible nucleus and hyaline cap. **G**, Multiple central vacuolar forms of *Blastocystis hominis*. **H**, Trophozoite of *Balantidium coli* in wet mount; note cilia covering the cell, cytostome, and macronucleus.

complaints to a malabsorption syndrome with diarrhea and steatorrhea, similar to that of sprue. The pathogenesis is not fully understood, although disruption of the integrity of the brush border with resulting disaccharidase deficiency may occur from direct or indirect effects of the organism's presence (Wolfe, 1992). Giardiasis should be considered in any patient presenting with diarrhea of longer than 10 days' duration.

Diagnosis is established by demonstration of *Giardia* trophozoites or cysts, or both, in fecal specimens. Trophozoites predominate in diarrheic stool, whereas infectious cysts are more likely to be found in formed stool. The passage of organisms varies from day to day; therefore, examination of multiple specimens, collected on different days, may be necessary. Direct wet mounts are particularly helpful for demonstrating trophozoites, with their so-called falling leaf motility, in a diarrheic or aspirate specimen. Cysts can be seen in direct wet mount and concentration techniques, and both trophozoites and cysts may be demonstrated on permanently stained slides. In some cases, the organisms cannot be demonstrated in fecal specimens, and small bowel aspirates or so-called string test specimens may be required. In such instances, the laboratory should be advised in advance, so personnel will be available to perform a direct wet mount examination immediately on receipt of the specimen (Garcia, 2007).

Many antigen detection methods based on IFA or EIA are commercially available (Clinical and Laboratory Standards Institute, 2005; Garcia, 2007, 2010). They appear to have good sensitivity and specificity and may detect some infections not found by morphologic examination of stools. They also can be particularly helpful in epidemiologic investigations but cannot replace the need for traditional morphologic examination of the specimen to detect other pathogenic parasites.

When viewed in their broadest dimension, *Giardia* trophozoites are pear-shaped with a tapered posterior end, and have two nuclei that give the appearance of a smiling face with prominent eyes (Table 62-11; see Figs. 62-13, B, and 62-14, C through E). When viewed from the side, the anterior end of the organism is thicker and tapers posteriorly; the anterior

half to three quarters consists of the sucking disk on the ventral surface. The four lateral, two ventral, and two caudal flagella usually are not evident in wet mounts or in stained preparations. Cysts are oval and usually quadrinucleate. Below the nuclei are dark-staining median bodies that cross longitudinal fibrils, providing distinctive internal characteristics. The cytoplasm often is retracted from the cyst wall.

Chilomastix mesnili

Chilomastix mesnili (see Table 62-11, Figs. 62-13, B, and 62-14, F) is a nonpathogenic lumen-dwelling flagellate of humans that must be differentiated from trophozoites of amebae and *Giardia* in stained smears. The consistent location of the single nucleus at one end of the organism and the tapering of the end opposite the nucleus are helpful. If multiple organisms are examined, the cytostome and the spiral groove are visible in some. The three external flagella usually are not visible in stained or formalin-fixed preparations. The lemon-shaped cysts contain various curved cytoplasmic fibers with a safety pin-like appearance.

Pentatrichomonas hominis

Pentatrichomonas hominis, known previously as *Trichomonas hominis* (see Table 62-11 and Fig. 62-13, B), is an infrequently seen nonpathogenic intestinal flagellate that may be confused with *E. bartmanni* or small *E. histolytica* trophozoites. Organisms do not stain particularly well and often are distorted in permanent smears. Several organisms may have to be examined in stained preparations to demonstrate the single *Entamoeba*-like nucleus, undulating membrane and associated costa, and flagella. A prominent rod-like object, the axostyle, runs through the organism and protrudes from the posterior end. No cyst stage has been described.

Trichomonas vaginalis

Trichomonas vaginalis is a common cause of vaginitis, characterized by inflammation, itching, vaginal discharge, and, occasionally, dysuria. The

TABLE 62-11

Morphology of Intestinal Flagellates

Species	Size (length)	Shape	Motility	Number of nuclei	Number of flagella*	Other features
Trophozoites						
<i>Pentatrichomonas hominis</i> [†]	8–20 μm; usual range, 11–12 μm	Pear-shaped	Rapid, jerking	1 Not visible in unstained mounts	3–5 anterior; 1 posterior	Undulating membrane extending length of body
<i>Chilomastix mesnili</i>	6–24 μm; usual range, 10–15 μm	Pear-shaped	Stiff, rotary	1 Not visible in unstained mounts	3 anterior; 1 in cytostome	Prominent cytostome extending $\frac{1}{3}$ – $\frac{1}{2}$; spiral groove across ventral surface
<i>Giardia lamblia</i>	10–20 μm; usual range, 12–15 μm	Pear-shaped	Falling leaf	2 Not visible in unstained mounts	4 lateral; 2 ventral; 3 caudal	Sucking disk occupying $\frac{1}{2}$ – $\frac{3}{4}$ of ventral surface
<i>Enteromonas hominis</i>	4–10 μm; usual range, 8–9 μm	Oval	Jerking	1 Not visible in unstained mounts	3 anterior; 1 posterior	One side of body flattened; posterior flagellum extending free, posteriorly or laterally
<i>Retortamonas intestinalis</i>	4–9 μm; usual range, 6–7 μm	Pear-shaped or oval	Jerking	1 Not visible in unstained mounts	1 anterior; 1 posterior	Prominent cytostome extending approximately $\frac{1}{2}$ length of body
Species	Size	Shape	Number of nuclei	Other features		
Cysts						
<i>Chilomastix mesnili</i>	6–10 μm; usual range, 8–9 μm	Lemon-shaped, with anterior hyaline knob or “nipple”	1 Not visible in unstained preparations	Cytostome with supporting fibrils. Usually visible in stained preparations.		
<i>Giardia lamblia</i>	8–13 μm; usual range, 11–12 μm	Oval or ellipsoidal	Usually 4; not distinct in unstained preparations; usually located at one end	Fibrils or flagella longitudinally in cyst. Cytoplasm often retracts from a portion of cell wall.		
<i>Enteromonas hominis</i>	4–10 μm; usual range, 6–8 μm	Elongate or oval	1–4, usually 2 lying at opposite ends of cyst; not visible in unstained mounts	Resembles <i>E. nana</i> cyst. Fibrils or flagella usually are not seen.		
<i>Retortamonas intestinalis</i>	4–9 μm; usual range, 4–7 μm	Pear-shaped or slightly lemon-shaped	1 Not visible in unstained mounts	Resembles <i>Chilomastix</i> cyst. Shadow outline of cytostome with supporting fibrils extends above nucleus.

*Not a practical feature for identification of species in routine fecal examinations.

[†]*Pentatrichomonas hominis* does not have a cyst form.

infection usually is spread by sexual intercourse, often by males who have an asymptomatic infection. Occasionally, males may have symptomatic prostatitis or urethritis. *T. vaginalis* infections usually are diagnosed in the physician's office by direct wet mount examination of vaginal fluid, prostatic fluid, or sediments of freshly passed urine. Morphologically, *T. vaginalis* resembles *P. hominis* but is larger (up to 23 µm), and the undulating membrane extends only half the length of the body. Because of the difference in habitat, it generally is not necessary to differentiate these trichomonads morphologically.

Direct wet mount examination may be insensitive, and the use of culture or commercially available immunoassay techniques is recommended when infection is not readily diagnosed (Garcia, 2007; Murray, 2007). Cultures, including use of a convenient “pouch” system, have a sensitivity of about 90% (Krieger, 1988; Schmid, 1989; Beal, 1992; Levi, 1997), as do DFA and EIA techniques that use monoclonal antibodies (Krieger, 1988; Lisi, 1988; Wilson, 1995). Papanicolaou-stained gynecologic smears may reveal *T. vaginalis* on occasion but have poor sensitivity and specificity.

Other Flagellates

Enteromonas hominis and *Retortamonas intestinalis* are small, nonpathogenic, intestinal flagellates that are seen infrequently but, when present, may occur in large numbers. Morphologic characteristics are reviewed in Table 62-11 (see also Fig. 62-13, B). *Trichomonas tenax* is a trichomonad that occasionally is recovered from the oral cavity but does not cause disease.

CILIATES

Balantidium coli

The ciliate *Balantidium coli* (see Figs. 62-13, A, and 62-14, H) may cause a dysentery-like syndrome with colonic ulcerations similar to that of amebiasis, but it does not produce liver abscesses or other systemic lesions. Human infection, rare in the United States, is usually acquired from hogs, which are commonly infected. *B. coli* is the largest protozoan to infect humans. Trophozoites are between 40 µm and more than 200 µm in greatest dimension (most measure 50–100 µm) and are uniformly covered with

Figure 62-15 **A**, Schizont of *Cystoisospora belli* containing numerous merozoites developing within gallbladder epithelium (H&E; oil immersion). **B**, Oocyst of *C. belli* in feces (wet mount; oil immersion). **C**, Small-bowel biopsy demonstrating development of *Cryptosporidium parvum* oocysts within the brush border of enterocytes (H&E; $\times 400$). **D**, Modified acid-fast stain of a fecal smear demonstrating an oocyst of *Cyclospora cayentanensis* (oil immersion). **E**, Modified acid-fast stain of a fecal smear demonstrating an oocyst of *Cyclospora cayentanensis* (oil immersion). **F**, Small-bowel biopsy demonstrating development of microsporidial spores within enterocytes (epoxy-embedded section stained with toluidine blue; oil immersion). **G**, Microsporidial spores seen in liver parenchyma in an individual infected with the human immunodeficiency virus (Brown and Brenn stain; oil immersion). **H**, Numerous microsporidial spores in feces stained with the modified trichrome stain (oil immersion).

cilia that are slightly longer at the anterior end adjacent to the cytostome. A large macronucleus is readily seen in stained preparations, and a smaller micronucleus is infrequently visible. Numerous food vacuoles and contractile vacuoles are present in the cytoplasm. Cysts are rounded, measuring 50–70 μm in length. Cilia may be seen within younger cysts, and nuclear characteristics are similar to those of trophozoites. Stool specimens that have been contaminated with stagnant water may contain free-living ciliates, which usually can be distinguished from *B. coli* by differences in their ciliary pattern.

COCCIDIA

The coccidia comprise a large group of apicomplexan parasites that have a sexual stage in the intestinal tract of invertebrate and vertebrate animals. Some species also develop asexually in extraintestinal sites in host tissues. Genera infecting the intestine of humans, such as *Isospora*, *Sarcocystis*, *Cryptosporidium*, and *Cyclospora*, generally produce self-limited diarrheal disease in immunocompetent persons. Severe protracted diarrhea may develop in immunocompromised hosts following infection with *Isospora*, *Cryptosporidium*, and *Cyclospora*.

Cystoisospora belli

Cystoisospora belli (formerly known as *Isospora belli*) undergoes both asexual and sexual development in the cytoplasm of small intestine epithelial cells (Fig. 62-15, A). Sexual development results in the production of oocysts, which are passed in the stool and mature to the infective stage in the environment. Human infections cause diarrhea and malabsorption but generally are self-limited. In patients with AIDS or other immunosuppressive disorders, disease may persist for months or years, and may contribute to death (DeHovitz, 1986; Mannheimer, 1994; Murray, 2007). Diagnosis

is established by finding the unsporulated oocysts measuring $12 \times 30 \mu\text{m}$ in fecal specimens, usually in direct wet mounts or concentration preparations (Fig. 62-15, B). If the unfixated specimen is left at room temperature for 24–48 hours, sporulation occurs. The infectious oocyst contains two sporocysts, each with four sporozoites (see Fig. 62-13, A). These oocysts are similar to those of *Cryptosporidium* in that they stain acid-fast.

Sarcocystis spp.

Sarcocystis spp. are typical two-host coccidia in which the sexual phase develops in the intestinal mucosa of carnivorous animals, and the asexual, extraintestinal phase occurs in the muscles and tissues of various intermediate hosts. Humans may serve as definitive or intermediate hosts, depending on the species of *Sarcocystis*. Intestinal infection with *Sarcocystis hominis* and *Sarcocystis suibominis* is acquired by ingestion of raw or incompletely cooked beef or pork, respectively, which contains tissue cysts (sarcocysts). Infection usually is asymptomatic, but occasional patients have transient diarrhea, abdominal pain, or anorexia. Intestinal infection is self-limited because asexual multiplication occurs in the intermediate host and is not repeated in the definitive host. Oocyst production is limited by the number of organisms ingested in the form of sarcocysts. The diagnosis is established by detection of sporulated $25 \times 33 \mu\text{m}$ sporocysts in the stools (see Fig. 62-13, A). Each mature sporocyst contains four sporozoites. The oocyst wall is thin and often is not detectable, or has already ruptured, releasing the two sporocysts. These forms, best seen in wet mounts or in acid-fast-stained smears, appear larger than oocysts of *Cryptosporidium*. Trichrome stains are of little value in detecting these parasites. Humans also may serve as intermediate hosts for several unnamed animal species of *Sarcocystis* (known collectively as *Sarcocystis lindemanni*), in which case cysts are found in skeletal and cardiac muscles (Beaver, 1979; Strickland, 2000).

Cryptosporidium spp.

Cryptosporidium spp. use a single host in their life cycle but may infect humans (predominantly *C. hominis* and *C. parvum*) and a wide variety of animals, including cattle and sheep (Coupe, 2005). Parasites develop in the brush border of epithelial cells of the small and large intestine and occasionally spread to other sites such as the gallbladder, the pancreas, and the respiratory tract (see Figs. 62-13, A, and 62-15, C and D). *Cryptosporidium* is a common cause of acute, self-limited diarrhea in normal persons, especially in children who attend day care. The epidemiology of cryptosporidiosis is similar to that of giardiasis. One of the largest known outbreaks of water-transmitted infection occurred in Milwaukee, Wisconsin, in 1993. In that outbreak, an estimated 400,000 individuals became ill from tap water contaminated with farm runoff following heavy rains (MacKenzie, 1994). Similar to cysts of *Giardia*, *Cryptosporidium* oocysts are refractory to usual chlorination levels of drinking water, and unless a community's water supply from a surface source is filtered, epidemics may occur. In patients with AIDS, *Cryptosporidium* may cause chronic secretory diarrhea that can last for months to years and may contribute to death. The incubation period is about 8 days, and in previously healthy persons, the illness lasts 9–23 days. Patients may have malaise, fever, anorexia, abdominal cramps, and diarrhea (Current, 1991; Mannheimer, 1994).

Diagnosis usually is established by stool examination. Various concentration methods, including formalin–ethyl acetate sedimentation and Sheather's sugar flotation, work well (Clinical and Laboratory Standards Institute, 2005; Garcia, 2007). The availability of the formalin–ethyl acetate method makes this technique attractive, although centrifugation speed and times must be increased to maximize recovery (Clinical and Laboratory Standards Institute, 2005; Garcia, 2010). A smear is prepared from the sediment and stained with an acid-fast stain or immunofluorescent reagents. Several acid-fast staining methods, including auramine-O, have been evaluated, but a modified cold Kinyoun method is used most widely. Spherical oocysts measure 4–6 μm in diameter and, when stained by the modified Kinyoun procedure, appear a deep fuchsia, although some unevenness of staining intensity is noted, along with variability in the percentage of cysts that stain positive. Positive control slides must be used with every run.

Commercial DFA and EIA reagents, which provide good sensitivity and specificity (Clinical and Laboratory Standards Institute, 2005; Garcia, 2007; Murray, 2007), are especially good for laboratories where *Cryptosporidium* is infrequently encountered, and where there is difficulty in maintaining expertise in the interpretation of acid-fast stains.

The need to examine stool specimens for *Cryptosporidium* depends on the populations served and the goals, interests, and abilities of the individual laboratory. Some laboratories perform examination for *Cryptosporidium* only on specific request; others evaluate all specimens from immunocompromised patients.

Cyclospora cayetanensis

Cyclospora cayetanensis is a recently described coccidian parasite responsible for diarrheal disease in immunocompetent and immunocompromised individuals (Ortega, 1994; Murray, 2007). The parasite has been recovered from patients in several countries, including the United States, and was initially described as a blue-green alga, a cyanobacterium-like body, or a coccidian-like body, among others (Ortega, 1993; Shields, 2003). Infection causes a flu-like illness with nausea, vomiting, weight loss, and explosive watery diarrhea lasting 1–3 weeks. Oocysts, passed unsporulated, appear as nonrefractile spheres 8–10 μm in diameter that contain a cluster of refractile globules enclosed within a membrane when viewed by light microscopy. A total of 1–2 weeks is required for sporulation, after which the mature oocyst contains two sporocysts, each with two sporozoites. In trichrome-stained smears, the oocysts appear as clear, round, and somewhat wrinkled objects. Oocysts autofluoresce bright green to intense blue under ultraviolet epifluorescence; they stain acid-fast when modified acid-fast or auramine-O staining techniques are used. They must be differentiated from oocysts of *Cryptosporidium*, which stain in an identical fashion but are smaller (4–6 μm) (Fig. 62-15, E).

MICROSPORIDIA

Microsporidia are obligate intracellular, spore-forming protozoan parasites in the phylum Microspora that infect a variety of animals, including humans (Shadduck, 1989; Franzen, 1999). They are serious pathogens in immunocompromised hosts, especially those with AIDS, in whom they are responsible for a large percentage (up to 30% in some studies) of otherwise unexplained diarrheal disease (Curry, 1993). *Enterocytozoon bieneusi* and

Encephalitozoon intestinalis, the two species implicated most commonly in human intestinal infection, may cause protracted diarrhea and weight loss in AIDS patients similar to that caused by *Cryptosporidium*. *E. intestinalis* may also cause disseminated disease (Cali, 1993; Willson, 1995; Murray, 2007).

The organisms multiply intracellularly (merogony) and form resistant spores (sporogony) that eventually rupture the host cell and infect adjacent cells or are passed out of the body. The spore contains a coiled polar tubule, which is forcefully extruded under appropriate environmental stimuli and penetrates the membrane of the recipient cell. The parasite's sporoplasm is injected through the tubule into the host cell cytoplasm, where multiplication ensues. Reservoir hosts have not been identified. Occasionally, patients have been infected by other genera of microsporidia, including *Encephalitozoon* (hepatitis, ocular infection, CNS disease), *Nosema* (disseminated infection), and *Pleistophora* (myositis) (Shadduck, 1989; Curry, 1993), among others (Franzen, 1999; Garcia, 2007).

Until recently, diagnosis required examination of tissues submitted for routine light (Fig. 62-15, F and G) and electron microscopy. Development of a modified trichrome staining method for examination of stool specimens for spores has been a significant advance in detecting infection (Weber, 1992; Garcia, 2007). With this method, the small (1.5–3 μm), elliptical spores stain red against a faint green background, and some display a characteristic midbody cross-band (Fig. 62-15, H). Modifications of this method have also been described. Fluorochrome stains such as Uvitex 2B and Calcofluor white appear to be more sensitive in detecting spores and may be useful in the initial screening of specimens (van Gool, 1993; DeGirolami, 1995; Luna, 1995). The small size of the spores makes detection by any method a challenge (Clinical and Laboratory Standards Institute, 2005).

INTESTINAL HELMINTHS

Intestinal helminths discussed here include those nematodes (roundworms), cestodes (tapeworms), and trematodes (flukes) that reside as adults in the gastrointestinal tract or live in other locations (liver, lung, or blood) and produce eggs that exit the human body via the intestinal tract. Sizes for adult helminths vary from 1 mm to more than 10 m in length; sizes for eggs range from 25–150 μm (Fig. 62-16).

An understanding of helminth life cycles and zoogeography is critical in knowing which parasite stages may be present in a presumed infection, what organs or tissues may be involved, and when diagnostic stages may be expected to appear following exposure. Although diagnosis usually depends on finding and identifying an appropriate developmental stage (egg, larva, or adult), some parasitic infections may be diagnosed chiefly on clinical grounds or on the basis of serologic evidence, or both.

Certain species have developmental cycles whereby infectious stages may be transmitted directly from person to person (*Enterobius* and *H. nana*). In others (*Trichuris*, *Ascaris*, and *Trichostrongylus*), an additional maturation period outside of the host is required before the parasite egg or larva (in the latter case) is infectious. Ingestion of infective stages may also occur incidentally along with parasite vectors (*Dipylidium*, *Hymenolepis*), plants (*Fasciolopsis*, *Fasciola*), or animal tissues (*Trichinella*, *Taenia*, *Diphyllobothrium*, *Clonorchis*, *Opisthorchis*, *Paragonimus*, *Heterophyes*, *Metagonimus*, and *Nanophyetus*). In some cases, larval parasite stages may directly penetrate the skin (hookworms, *Strongyloides*, and schistosomes).

Recovery and identification of helminth eggs and larvae in stool, urine, or sputum requires a systematic approach and appropriate training of the individuals performing the evaluations. The size of the eggs and larvae is an especially important characteristic, and measurement often requires a properly calibrated ocular micrometer. External characteristics of eggs that should be noted include their shape, their wall thickness, and the presence or absence of a mamillated covering, operculum, opercular shoulders, abopercular knob, polar plugs, or spines. Egg development (embryonated, unembryonated) and the presence or absence of hooklets, which are characteristic of cestodes, should be noted. The examiner also needs to have an appreciation for the large variety of artifacts detected in human feces that may mimic parasite eggs and larvae (see Table 62-4).

NEMATODES

Enterobius vermicularis

Enterobiasis or oxyuriasis is the most common helminthic infection in children of all social strata in the United States. Although it is primarily a parasite of young children, rapid maturation of the egg allows it to be

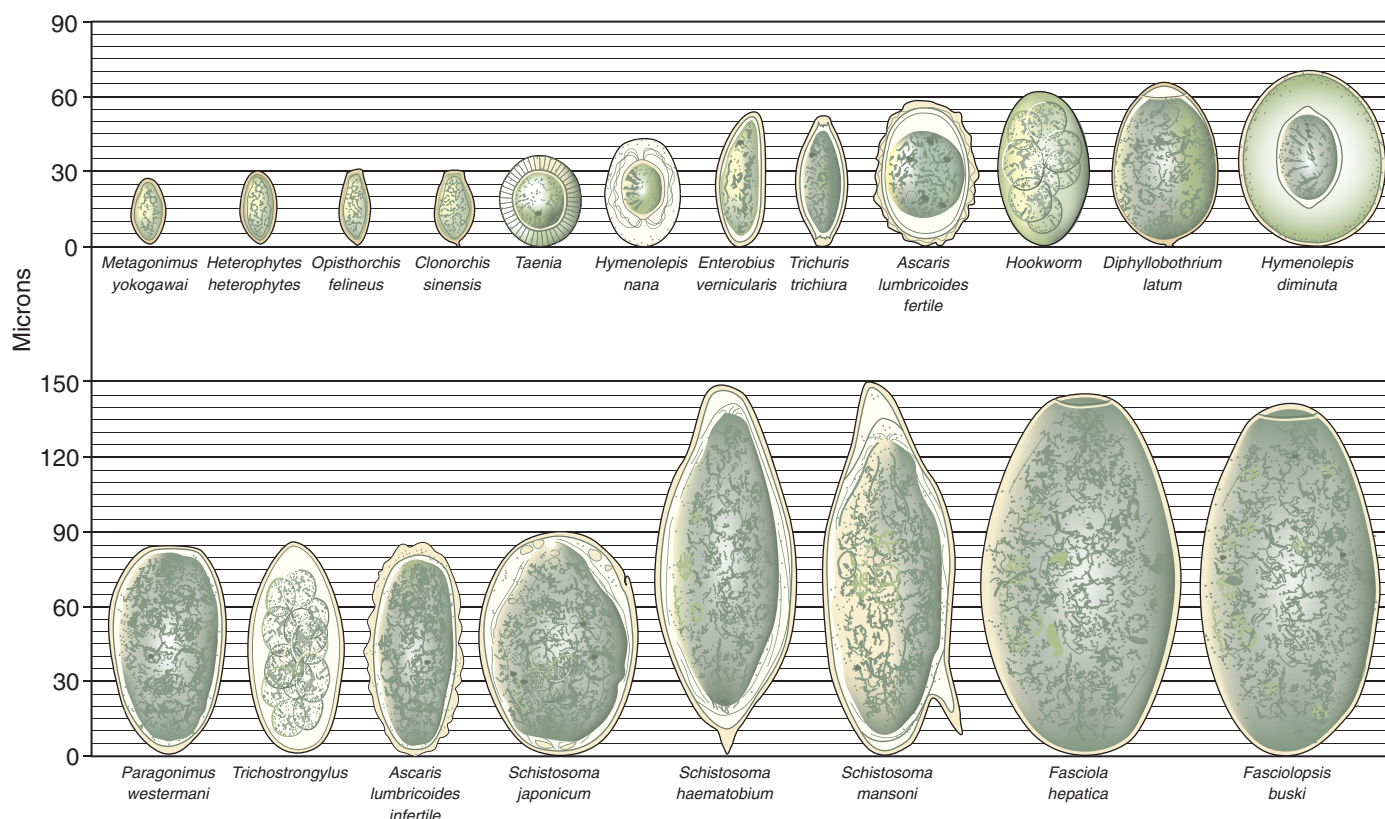

Figure 62-16 Relative sizes of helminth eggs. (Courtesy Centers for Disease Control and Prevention, Parasitology Training Branch, Atlanta.)

readily transmitted from child to child and from child to adult, in both family and institutional settings. Male and female worms reside primarily in the cecum and adjacent areas. Females measure up to 13 mm in length and have a pointed posterior end that gives rise to their common name, the pinworm. Both sexes have prominent lateral alae that are seen in cross-section and a prominent esophageal bulb (Fig. 62-17, *A* through *C*).

Although males are rarely seen, females may be found on the surface of a stool specimen or on the perianal skin, especially at night, where eggs are deposited. Eggs are colorless and ovoid with one side flattened, and measure 20–40 μm wide by 50–60 μm long (see Fig. 62-17, *B*). They are infective within hours and when ingested complete development to the gravid adult stage within 1 month (the prepatent period).

Although infection may be asymptomatic, children often suffer from pruritus ani, irritability, and loss of sleep. Enterobiasis should be ruled out early in the evaluation of enuresis. Adult worms may also migrate to unusual sites such as the vagina, fallopian tubes, or peritoneal cavity. Their ultimate death in these locations may provoke inflammatory, granulomatous reactions (Symmers, 1950; Garcia, 2007).

Recovery of eggs or, less commonly, adults from the perianal skin is usually done using the cellulose tape technique after the child has gone to sleep or first thing in the morning (Ash, 1987; Garcia, 2007). Only 5%–10% of cases are detected using routine stool examination. Diagnosis may require examination of several samples taken on different days before eggs can be detected (Sadun, 1956).

Trichuris trichiura

Trichuriasis is common worldwide in tropical and subtropical regions. Adult worms are found in the large intestine, especially the cecum, but in heavy infection they can be found throughout the colon and rectum. Males and females measure up to 50 mm in length and remain attached to the intestinal mucosa by the long, slender anterior end, while the thicker posterior end hangs free in the lumen. Female worms are elongate, whereas the tails on males are coiled (Fig. 62-17, *D*). *Trichuris* has a direct life cycle in which eggs are passed in stool unembryonated and require several weeks under appropriate soil conditions to mature to the infective stage. When embryonated eggs are ingested, larvae are released and mature into adults in the colon, where they attach and survive up to 10 years.

Light infection usually is asymptomatic, but when larger numbers (>300 worms) are present, diarrhea or symptoms of dysentery may develop in association with dehydration and anemia (Beaver, 1984; Strickland,

2000). Rectal prolapse, a life-threatening complication, may occur in heavily infected children (Cooper, 1988).

Diagnosis is made by finding typical eggs in direct fecal smears or with concentration techniques. The eggs are barrel-shaped with refractile plugs at both ends and usually measure 50–55 μm long by 22–24 μm wide (Fig. 62-17, *E*). Occasionally, humans may become infected with the dog whipworm, *Trichuris vulpis*, which has eggs that are larger, wider, and more barrel-shaped than those of *Trichuris trichiura*. Egg quantitation techniques occasionally may be requested to assess infection intensity, therapeutic efficacy, and reacquisition rates of parasites.

Capillaria philippinensis

This parasite, normally found in fish-eating birds, infects humans who ingest raw or incompletely cooked fish that contain infective larvae in their flesh. Although first described in persons from the Philippines, and later Thailand, occasional cases have been reported in Asia, the Middle East, and South America (Cross, 1992; Murray, 2007). The parasites may cause chronic diarrhea, and infected individuals may pass eggs, larvae, and even adult worms in their feces. Eggs resemble those of *Trichuris*, although they measure 36–45 μm in length by 21 μm in width and have thick, radially striated shells and mucoid plugs, which are inconspicuous.

Ascaris lumbricoides

This is the largest nematode that infects the intestinal tract of humans and is probably the most common of the intestinal roundworms, infecting an estimated 1.3 billion individuals worldwide (Markell, 1999). Infection occurs primarily in areas with little or no sanitation and, as with *Trichuris*, is especially common in children, who are also more likely to harbor heavy infection.

Adult *Ascaris* live primarily in the duodenum and proximal jejunum. Females measure up to 35 cm in length by 6 mm in diameter. The male is somewhat smaller and has a ventrally curved tail, unlike the female (Fig. 62-17, *F*). Both adult and immature worms can be identified by the presence of three prominent lips at the anterior end.

Females produce approximately 200,000 eggs per day, which are unembryonated when passed and require 4–6 weeks in a satisfactory environment to become infective. Following ingestion, eggs hatch in the intestine, and larvae penetrate the mucosa to gain access to the bloodstream. They are carried to the lungs and mature briefly in the alveolar capillary bed before entering the alveoli. Respiratory clearance mechanisms move the

Figure 62-17 All direct examination with brightfield illumination except as noted. **A**, Adult male pinworm, *Enterobius vermicularis*, with curved posterior end; note prominent esophageal bulb ($\times 4$). **B**, Numerous eggs of *E. vermicularis* as seen on a cellophane tape preparation ($\times 400$). **C**, Adult *E. vermicularis* in the appendix; note characteristic lateral alae ($\times 100$). **D**, Adult whipworms, *Trichuris trichiura*; note females with straight tails and males with coiled tails. **E**, Eggs of *T. trichiura* ($\times 400$). **F**, Adult female and male *Ascaris lumbricoides*, the large human roundworm. **G**, Fertile, unembryonated egg of *A. lumbricoides* ($\times 400$). **H**, Infertile and decorticate egg of *A. lumbricoides* ($\times 400$). (**D** and **F** from Zaiman H, editor. A pictorial presentation of parasites: a cooperative collection; http://www.astmh.org/Zaiman_Slides/1271.htm.)

larvae to the epiglottis, where they are swallowed and grow to adulthood in the small bowel. Development from embryonated egg to adult takes approximately 2 months.

Symptoms of ascariasis vary from asymptomatic infection to severe disease. Migration of large numbers of larvae through the lungs can cause *Ascaris* pneumonitis or Löffler syndrome, characterized by bilateral diffuse, mottled pulmonary infiltrates and mild bronchitis associated with peripheral eosinophilia. The syndrome is rare and usually occurs in individuals who have been previously exposed to *Ascaris* antigens.

The presence of a few worms in the intestine is rarely noticed, whereas heavy infection may produce varying degrees of abdominal pain and diarrhea. Intestinal obstruction may also occur with a mass of worms, especially in children. Even a small number of worms is cause for concern because of their ability to invade ectopic sites such as the common bile duct and liver, appendix, and stomach. Fever or drug therapy may stimulate migration. In endemic areas, anthelmintics often are prescribed before anesthetics are used in elective surgery.

Infection is diagnosed by demonstrating eggs in feces or on recovery of an adult that has been passed or vomited. The large number of eggs produced each day makes detection of even a single worm probable. A count of fewer than 20 eggs per slide (2 mg of feces) indicates light infection, and a count of more than 100 eggs per slide indicates heavy infection.

Fertile *Ascaris* eggs are round to slightly oval with a yellow-brown, irregular external mamillated layer and a thick shell. Eggs that have lost their mamillated layer are called decorticate and may superficially resemble hookworm eggs. They are passed unembryonated and measure approximately 55–75 μm long by 35–50 μm wide (Fig. 62-17, **G** and **H**). Single females may produce unfertilized eggs, which are larger and more elongate (up to 90 μm in length) and have a thinner shell with irregular mamillations. These eggs are filled with irregularly sized fat globules.

Trichostrongylus spp.

Human disease caused by *Trichostrongylus* spp. represents a zoonotic infection because these parasites principally infect large herbivores such as sheep, cattle, and goats. Several species may infect humans, including *Trichostrongylus colubriformis*, *Trichostrongylus orientalis*, *Trichostrongylus axei*, and *Trichostrongylus brevis*, all of which are found in many parts of the world. Adult worms inhabit the small bowel and produce eggs that mature outside of the body. Larvae emerge and crawl about on soil and vegetation, where they are available to be ingested by definitive hosts. Unlike hookworms, they do not invade skin directly, nor does the life cycle involve a migratory phase through the lungs. Infection usually is light and asymptomatic, but heavy infection may produce abdominal pain and diarrhea, usually with eosinophilia. Eggs resemble those of hookworms but are longer and narrower, measuring 78–98 μm by 40–50 μm , and are slightly tapered at one end.

Hookworms

Hookworms, which are among the more common helminths known to infect humans, occur in tropical and subtropical regions and some temperate areas. *Necator americanus* is found in the United States and in other areas of the world and frequently overlaps in distribution with *Ancylostoma duodenale*, which does not occur in the United States.

Adult females measure up to 12 mm in length, and the males slightly less. Males are readily distinguished by the fan-shaped copulatory bursa at the posterior end. The anterior end of hookworms is modified into a buccal capsule that contains teeth or cutting plates. Both sexes attach to the mucosa of the small intestine, where they may reside for up to 18 years (Beaver, 1988; Garcia, 2007).

Eggs are passed in feces and develop rapidly, depending on prevailing conditions. Rhabditiform larvae are released and develop into the infective filariform stage in about 7 days. On contact with an appropriate host, the

Figure 62-18 **A**, Hookworm (*Ancylostoma duodenale* or *Necator americanus*) egg ($\times 400$). **B**, Egg of *Heterodera* sp., a group of plant nematodes occasionally found as artifacts in human stool following ingestion of infected vegetables ($\times 400$). **C**, Massive *Strongyloides stercoralis* infection in the duodenal mucosa; note presence of adult female, eggs, and larvae (H&E; $\times 100$). **D**, *S. stercoralis* noninfectious rhabditiform larva (iodine stain; $\times 100$). **E**, *Trichinella spiralis*, cross-section of a larva in gastrocnemius muscle (H&E; $\times 100$). **F**, Multiple *T. spiralis* larvae in bear meat (compressed wet muscle preparation; $\times 100$). **G**, Regurgitated *Pseudoterranova* sp. following fish dinner ($\times 4$). **H**, *Anisakis* sp., cross-section of larva found in small bowel following surgery for acute obstruction (H&E; $\times 400$).

larvae penetrate the skin, gain access to the host's circulation, travel to the lungs, and move up the tracheobronchial tree to be swallowed. On maturation in the small intestine, oviposition begins. Although the life cycles of both species are similar, *Ancylostoma* can mature directly to the adult stage in the intestine if infective larvae are ingested.

Hookworms can produce disease in the skin, at the site of larval penetration. This condition, known as ground itch, is characterized by inflammation, redness, and blister formation, along with intense itching. Migration of large numbers of larvae through the lungs may produce Löfller syndrome, as described earlier for *Ascaris*. Depending on the worm burden, intestinal infection can result in gastroenteritis with abdominal pain, diarrhea, and nausea. Hookworms are best known, however, for their ability to produce chronic blood loss with secondary iron deficiency anemia. The presence of each adult *A. duodenale* can result in the loss of 0.15–0.25 mL of blood per day, compared with 0.03 mL for each *N. americanus*. Development of children can be severely affected by chronic infection. Blood loss and the number of hookworms present correlate with the number of eggs per gram of stool, which may help the clinician determine when to initiate therapy in individuals living in endemic areas (Layrisse, 1964a, 1964b; Cook, 2002).

Diagnosis is made by finding the characteristic thin-shelled eggs in feces. These eggs are partially embryonated when passed and measure 58–76 μm in length by 36–40 μm wide (Fig. 62-18, **A**). Embryonated eggs or free rhabditiform larvae may be found in unpreserved specimens that are not examined promptly. Hookworm rhabditiforms can be differentiated from those of *S. stercoralis* because the former have a longer buccal chamber and inconspicuous genital primordium (Fig. 62-19). Continued maturation of larvae results in the appearance of infective filariforms, which have a pointed posterior end and an esophagus approximately one-fourth the length of the larva. Hookworm eggs may need to be differentiated from those of *Trichostrongylus* spp. (which are longer and more

pointed) and those of plant parasitic nematodes, especially *Heterodera* spp. (which are longer, have blunt ends, and are often asymmetrical) (Fig. 62-18, **B**).

Although adult hookworms can be differentiated on the basis of their mouth parts and the copulatory bursa in males, eggs of human hookworms are indistinguishable. In direct wet mounts, egg counts of fewer than five eggs per coverslip denote light infection that is unlikely to result in anemia, whereas more than 25 eggs per coverslip denotes heavy infection that is likely to be associated with symptoms.

Strongyloides stercoralis

Strongyloidiasis occurs in many areas in the tropics and subtropics, but this infection also is reported in temperate zones and has historically been endemic in areas of southeastern United States. Adult females are 2–3 mm long and live buried in the mucosa of the duodenum, where they reproduce parthenogenetically (Fig. 62-18, **C**). Parasitic males do not occur in the vertebrate phase of the cycle. The eggs hatch primarily in the small bowel, releasing first-stage or rhabditoid larvae, which then are passed in the feces (eggs are almost never found). In this direct cycle, the rhabditoid larvae metamorphose into infective third-stage filariform larvae in the soil. These infective larvae readily penetrate the skin of exposed individuals; they migrate via the circulatory system to the lungs and then move up the bronchial tree and are swallowed. Development to the adult stage is completed in the small intestine. Under appropriate soil conditions of high humidity, an indirect cycle may appear transiently, in which the newly deposited larvae develop into a free-living generation consisting of reproductive males and females. Eggs produced by this generation develop into filariform larvae that again are infective for humans. A third variation in the life cycle of *Strongyloides* involves autoinfection, in which maturation to the filariform stage is completed within the intestinal tract, with subsequent reinvasion of bowel mucosa or perianal skin.

Figure 62-19 Hookworm and *Strongyloides stercoralis* larvae. **A.** *S. stercoralis* rhabditoid larva in human stools. Note the short size of the buccal cavity and the large genital primordium (GP). **B.** Hookworm rhabditoid larva as seen in a few instances in stools left for at least 24 hours at room temperature. The buccal cavity is longer, and the genital primordium is smaller.

Disease presentation is variable and may depend on the strain acquired (Genta, 1989). Early migration of filariform larvae may produce irritation, redness, and pruritus at the site of entry, whereas later migration through the lungs may produce Löfller syndrome (Purtilo, 1974). The presence of intestinal symptoms is related to the intensity of the infection. The affected individual may have symptoms of peptic ulcer, abdominal pain, and diarrhea. A malabsorption syndrome has been reported with chronic infection.

The ability of the parasite to autoinfect may result in persistence of the infection for decades, as was recognized in allied troops who were held as prisoners of war in southeast Asia during World War II (Gill, 1979). In otherwise healthy patients, autoinfection may produce larva currens (linear urticarial lesions). In immunocompromised, alcoholic, or malnourished patients, autoinfection may result in a life-threatening hyperinfection syndrome caused by rapid multiplication of the parasite (Maayen, 1987; Genta, 1992). Severe pneumonia is often a presenting manifestation of hyperinfection, followed by marked diarrhea, enteritis, and septicemia. Patients who have lived in endemic areas should be screened for *Strongyloides* prior to receiving immunosuppressive therapy (Strickland, 2000).

Diagnosis is made on recovery and identification of typical rhabditiform larvae in stool specimens, although the routine O&P examination does not always reveal their presence (Fig. 62-18, D) (Pelletier, 1988; Genta, 1989; Garcia, 2007). *Strongyloides* rhabditiform larvae must be

differentiated from those of hookworms and are characterized as having a short buccal cavity and a prominent genital primordium (see Fig. 62-19). *Strongyloides* filariform larvae have a notched tail and an esophagus approximately half the length of the body. Either stage of larvae is readily seen in fresh saline wet mounts under low power. If infective filariform larvae are detected in a recently passed specimen, the diagnosis of superinfection is warranted (Eveland, 1975; Murray, 2007).

Examination of duodenal aspirates or string test specimens may be helpful in suspicious cases in which routine stool examinations are non-productive. The Baermann funnel concentration method or one of the coproculture techniques (see earlier under **Laboratory Methods**) may also demonstrate the infection (Ash, 1987; Genta, 1989; Clinical and Laboratory Standards Institute, 2005; Garcia, 2007). Larvae may be found in sputum or other pulmonary specimens, especially in the hyperinfection syndrome. Serologic tests are useful when infection is suspected but cannot be demonstrated by other methods. EIA and other tests display good sensitivity and specificity, although cross-reactions may appear with filariasis and some other nematode infections. These tests generally do not differentiate between past and current infection but may be useful in monitoring therapy (Wilson, 1995).

Anisakiasis

See later under **Tissue Helminths**.

CESTODES

Cestodes or tapeworms are ribbon-like platyhelminths that live in the intestinal tract of vertebrates as adults and in the tissues or body cavities of various intermediate hosts as larvae. They attach to intestinal mucosa by means of a scolex, or attachment organ, at the anterior end that may display suckers, grooves (bothria), or a rostellum with hooks, depending on the species. The body of the worm, or strobila, comprises an actively growing neck region and a series of proglottids that undergo sequential development through immature, mature, and, finally, gravid stages at the posterior end. Each proglottid has a complete set of male and female gonads and is capable of producing fertile eggs. Eggs of most cestodes infecting humans (*Diphyllobothrium* being an exception) may be readily differentiated from those of other helminths by the presence in each of a six-hooked embryo. Depending on the species, eggs are released directly into the fecal stream or are passed in intact proglottids. It is not uncommon in some species for long lengths of strobila to be passed intact, or for proglottids to actively migrate out of the anus. Large species of *Taenia* and *Diphyllobothrium* may grow to 25 feet or longer and may live for 20 years.

Cestode larval stages develop to the infective stage in invertebrate or vertebrate hosts, depending on the species, and complete their life cycle when ingested by a definitive host. Larval stages of several species may infect humans, causing cysticercosis, hydatidosis, sparganosis, and coenurosis. These conditions are covered more fully later under **Tissue Helminths**.

Taenia saginata

Humans are the sole definitive host for *Taenia saginata*, the beef tapeworm. Although it is distributed worldwide, the worm is especially common in the Middle East, Africa, Europe, Asia, and Latin America. It occurs rarely and sporadically in the United States. Larval cysticerci (*Cysticercus bovis*) develop in the tissues of cattle that graze on land contaminated by human waste. When humans ingest infected raw or incompletely cooked beef, the cysticercus develops into a reproductive adult in the small intestine in 2–3 months. Symptoms are rare but may include abdominal discomfort and diarrhea. Unlike *T. solium*, the eggs of *T. saginata* are not infectious to humans, and their ingestion does not result in cysticercosis.

Diagnosis is made by finding eggs in the stool, using direct or concentration techniques, or in the perianal folds, using the cellophane tape technique. Eggs are spherical and measure 31–43 μ m in diameter (Fig. 62-20, A). The shell is thick, is radially striated, and contains a six-hooked embryo. Eggs of all *Taenia* species are indistinguishable and should be reported only as *Taenia* eggs.

Species identification may be made on recovery of proglottids or, more rarely, the scolex. Proglottids of taeniids have a characteristic lateral protrusion known as the genital pore. Careful injection of India ink through the genital pore, using a tuberculin needle and syringe, may succeed in outlining the uterus. The gravid uterus of *T. saginata* has 15–20 lateral branches, whereas that of *T. solium* has 7–13 lateral branches (Figs. 62-20, B, and 62-21). Proglottids may also be cleared overnight in glycerol or stained with carmine or hematoxylin using published procedures (Ash,

Figure 62-20 **A**, Eggs of *Taenia saginata* (indistinguishable from those of *Taenia solium*; $\times 400$). **B**, Gravid proglottid of *T. saginata* injected through the genital pore with India ink. **C**, Gravid proglottids of *Hymenolepis nana* stained with acetocarmine ($\times 100$). **D**, Egg of *H. nana*; note presence of hooklets and polar filaments ($\times 400$). **E**, Egg of *Hymenolepis diminuta*; note lack of polar filaments ($\times 400$). **F**, Egg of *Diphylobothrium* sp.; note open operculum and small terminal knob ($\times 400$). **G**, Gravid proglottids of *Diphylobothrium* sp. stained with acetocarmine ($\times 2$). **H**, Egg packet of *Dipylidium caninum* (differential interference contrast microscopy; $\times 400$).

1987). If recovered, the scolex of *T. saginata* can be identified by the presence of four suckers and the absence of hooks on the crown or rostellum.

Taenia solium

T. solium, the pork tapeworm, is most common in Europe, especially in eastern Europe, Latin America, China, Pakistan, and India. It is encountered in the United States on occasion, most often in recent immigrants. Infection with the adult tapeworm is acquired by eating raw or incompletely cooked pork containing cysticerci (*Cysticercus cellulosae*). Symptoms, if present, are identical to those of *T. saginata* infection. More important, accidental ingestion of *T. solium* eggs from one's own adult tapeworm or from contaminated food may result in cysticercosis (Schantz, 1992). Additional details on cysticercosis may be found later under Tissue Helminths.

Procedures used for diagnosis of intestinal *T. solium* infection are identical to those used for *T. saginata* infection, although certain morphologic differences are apparent. The scolex of *T. solium* has four suckers and, unlike *T. saginata*, a rostellum armed with two rows of hooks. Gravid proglottids have 7–13 lateral uterine branches (see Fig. 62-21).

Hymenolepis nana

Hymenolepis nana, known as the dwarf tapeworm, has worldwide distribution and is the most frequently recovered cestode species seen in the United States. It is a common parasite in mice and is the smallest to infect humans, measuring up to 4.0 cm in length. The scolex has an armed rostellum, and the proglottids have all of their genital pores located on the same side of the strobila (Figs. 62-20, C, and 62-21). The life cycle may be direct, through the ingestion of infectious eggs, or indirect, through the ingestion of intermediate hosts (usually grain beetles) containing cysticercoid larvae. In the former instance, eggs may be passed directly from person to person,

usually among children, or may be ingested in food, especially grain products that are contaminated by rodent droppings.

Eggs hatch in the intestine and embryos penetrate the mucosa, where they mature as cysticercoid larvae. They subsequently emerge and reattach to the intestinal wall to complete their development into adult tapeworms in 2–3 weeks. Ingestion of grain beetles containing cysticercoid larvae occurs much less frequently. Internal autoinfection may occur in some individuals in whom eggs hatch shortly after being discharged from the worm and rapidly invade the intestinal wall without leaving the body. Such a mechanism is thought to be responsible for the occasional case of massive infection.

Symptomatic infection, characterized by abdominal pain, diarrhea, anorexia, and irritability, may develop in patients with large numbers of worms. Diagnosis is made by recovery from stool of the oval, thin-shelled, colorless eggs, which measure 30–47 μm in diameter (Fig. 62-20, D). They contain a centrally located, six-hooked embryo (oncosphere), which is separated from the outer shell by a clear space. This embryo displays two polar thickenings from which thin filaments arise and extend into the clear space between embryo and outer shell. Occasionally, intact strobila may be recovered if the stool is closely examined.

Hymenolepis diminuta

The rat tapeworm, *Hymenolepis diminuta*, is cosmopolitan in distribution and occasionally infects humans. Infection is rare, however, because of the obligate need for an arthropod intermediate host, in which the cysticercoid larvae develop. Human infection usually occurs following the accidental ingestion of infected beetles that contaminate grain or cereal products. Adult tapeworms develop in the small intestine, where they may grow to 60 cm in length. Similar to those of *H. nana*, the proglottids all have genital pores on one side, but unlike that species, the scolex lacks an armed rostellum. Infection usually is asymptomatic because of the small number of

Figure 62-21 Gravid proglottids of different human tapeworms.

worms likely to infect a single individual, although intestinal symptoms have been reported. Diagnosis is made by the finding in the feces of moderately thick-shelled, slightly ovoid, yellow-brown eggs measuring 70–85 μm by 60–80 μm (Fig. 62-20, E). The eggs are most easily confused with those of *H. nana* but, unlike in that species, lack polar filaments.

Diphyllobothrium spp.

Humans may be infected by one of several species of the fish tapeworm *Diphyllobothrium*, which normally infect piscivorous mammals and possibly birds (Curtis, 1991; Connor, 1997). These parasites are widely distributed in the temperate zones, especially northern Europe, Scandinavia, the former USSR, and Japan. Infection also occurs in Canada and in the north central states, the Pacific Coast states, and Alaska in the United States. Although *Diphyllobothrium latum* is the most common species known to infect humans, differentiation cannot be made on the basis of egg morphology.

This parasite inhabits the small intestine, where it can reach a length of 10 m or longer and can persist for years. Eggs are passed unembryonated in the feces and must reach a freshwater stream or lake to continue development. Following several weeks of embryonation, a ciliated larval form, the six-hooked coracidium, hatches and is ingested by a copepod, a type of zooplankton. The coracidium develops into a proceroid larva, which is infective for the second intermediate host, a fish. In fish, the proceroid migrates into the tissues and develops into the plerocercoid larva. Plerocercoids may be passed up the food chain unchanged and accumulate in larger fish. Humans acquire these larvae through ingestion of raw or incompletely cooked fish that have spent at least part of their life in fresh water.

Adult worms mature and initiate egg production in approximately 1 month. Infection may be asymptomatic, with passage of a length of strobila being the initial complaint. In others, a variable degree of abdominal discomfort and diarrhea may be present. Rarely, intestinal obstruction occurs. In endemic areas in northern Europe, a small percentage of patients develop vitamin B₁₂ deficiency and associated megaloblastic anemia.

Diagnosis is made by the finding of typical brown, oval, operculate eggs in feces using standard recovery techniques. Eggs measure 58–76 μm by 40–51 μm and, in addition to the operculum, have a small, round, knob-like projection on the abopercular end (Fig. 62-20, F). The presence of the operculum is unique among those cestodes infecting humans, and care must be taken not to confuse these eggs with those of trematodes, especially *Paragonimus* or *Nanophyetus*. Identification to the genus level is possible when a length of strobila or an intact worm is passed. The scolex is elongate and displays a pair of longitudinal grooves known as bothria, which replace the usual suckers. Gravid proglottids are wider than they are long and have their genital pores located midventrally, adjacent to a centrally located rosette-shaped uterus (Figs. 62-20, G, and 62-21).

Dipylidium caninum

Dipylidium caninum is a common tapeworm of dogs and cats in most parts of the world and not infrequently infects humans, especially children. In the usual life cycle, tapeworm eggs are ingested by flea larvae, which infest areas frequented by dogs or cats. The cysticeroid larvae persist as the flea undergoes metamorphosis to the adult stage. Accidental ingestion of the adult flea containing the infectious cysticeroid results in infection. Children are at highest risk for infection because of their close contact with pets. Worms mature in the small intestine and grow up to 70 cm in length.

Infection produces few symptoms and generally causes concern only on detection of the actively moving proglottids.

Detection is based on the finding of characteristic eggs, egg packets, or proglottids in the feces. Spherical eggs, each containing a six-hooked embryo, measure from 24–40 μm in diameter and occur singly or in packets (Fig. 62-20, H). The scolex is somewhat elongate with four suckers and a small, retractable rostellum. Proglottids are barrel-shaped and possess two genital pores, one on each lateral margin, which give rise to the common name double-pored tapeworm (see Fig. 62-21).

TREMATODES

Trematodes, or flukes, are dorsoventrally flattened helminths (platyhelminths) that include both hermaphroditic forms (intestinal, liver, and lung flukes) and those with separate sexes (blood flukes or schistosomes). All species that infect humans are characterized by the presence of an oral sucker, through which the digestive tract opens, and a ventral sucker used for attachment. Adults vary in length from 1 mm (*Metagonimus*) to 70 mm (*Fasciola gigantica*).

Eggs reach the environment by being passed in the feces, sputum, or urine, depending on the species. Hermaphroditic flukes produce operculate eggs, which are not embryonated (*Clonorchis* and *Opisthorchis* being exceptions). Schistosome eggs are not operculated, and each contains a mature larva when passed. Trematode larvae, or miracidia, are ciliated and are capable of penetrating the tissues of a molluscan host. Each species of trematode uses a particular species of snail as the first intermediate host. A complex asexual multiplication process within the snail results in the production of numerous free-swimming larvae called cercariae. Schistosome cercariae are capable of penetrating human skin directly, resulting in the disease schistosomiasis. Those of hermaphroditic flukes encyst on aquatic vegetation or invade the tissues of second intermediate hosts such as fish or crabs, depending on the species. Ingestion of these encysted larval stages, known as metacercariae, results in human infection.

Human trematode infection may occur in many tropical and subtropical regions and involves considerably more species (mostly rare and sporadic intestinal infections) than can be presented here. Its presence depends on lack of sewage treatment, availability of appropriate intermediate hosts, and, in the case of hermaphroditic species, dietary customs associated with ingestion of infective metacercariae. Some of these diseases, especially schistosomiasis, are spreading because of increased use of irrigation in endemic areas. Symptoms vary depending on the number of worms parasitizing the host at a given time, the tissues and organs involved, and host responses. Many infections are asymptomatic.

The diagnosis of trematode infection is made by recovery and identification of the characteristic eggs in stool, sputum, urine, and, occasionally, tissues. Direct mounts and formalin–ethyl acetate concentration methods are most useful for recovery of these eggs, whereas zinc sulfate flotation methods are less satisfactory.

Fasciolopsis buski

This intestinal trematode is the largest species to infect humans, varying from 20–75 mm in length and from 8–20 mm in breadth. It occurs in many parts of China, southeast Asia, and India and is frequently found in pigs, which serve as a natural reservoir. Infection is acquired by ingesting infective metacercariae on aquatic food plants such as water chestnuts and

Figure 62-22 **A**, Egg of *Fasciolopsis buski*, indistinguishable from that of *Fasciola hepatica*, in stool (×400). **B**, Egg of *Heterophyes* sp. in stool (×400). **C**, Adult *Clonorchis sinensis* in bile duct (H&E; ×100). **D**, Egg of *C. sinensis* in stool (×1000). **E**, Pair of adult *Paragonimus* sp. in lung tissue with surrounding inflammatory reaction (H&E; ×10). **F**, Egg of *Paragonimus* sp. in stool; note prominent operculum (×100).

water caltrop. Worms attach to the wall of the duodenum and jejunum, where they mature to egg-laying adults in about 3 months. Symptoms such as diarrhea, epigastric pain, and nausea may develop if enough worms are present to produce ulceration of the superficial mucosa. Eosinophilia may be present, even in those who are asymptomatic.

Diagnosis is made by the finding of large (130–140 μm by 80–85 μm), brown, oval, and thin-shelled eggs (Fig. 62-22, *A*). The operculum may be inconspicuous, and the eggs are passed unembryonated. Differentiation from *Fasciola* eggs generally is not possible, although these infections may be differentiated on the basis of geographic history and symptoms. Eggs of echinostome trematodes, which occasionally infect humans, are similar but smaller (Beaver, 1984).

Heterophyes and *Metagonimus*

These two genera include a number of species of minute (1–3 mm in length) intestinal worms that infect humans. *Heterophyes heterophyes* and *Metagonimus yokogawai* are common parasites in Asia but, along with other species, are found in other parts of the world as well. Infection is acquired by ingestion of metacercariae in raw or incompletely cooked freshwater fish. Although it is of minor medical importance, infection with these worms may produce diarrhea and abdominal pain. Infection is self-limited because the worms have a life span of only a few months.

Diagnosis is established by the finding of embryonated, operculate eggs that measure 20–30 μm in length by 15–17 μm in width (Fig. 62-22, *B*). Differentiation of these eggs from those of *Clonorchis* and *Opisthorchis* is difficult, although the operculum is more deeply seated with *Opisthorchis*. Such differentiation may be important, however, for medical reasons.

Nanophyetus salmincola

Nanophyetus (Trogloremia) salmincola is a small (0.8–1.1 mm) intestinal fluke that has been reported in humans in areas of far eastern Siberia and the Pacific Northwest Coast of the United States (Eastburn, 1987; Fritsche, 1989b). These worms are acquired by ingesting raw, incompletely cooked, or home-smoked salmon or trout that contain infectious metacercariae. Symptoms are related to the number of worms present and may include abdominal pain and diarrhea, with or without eosinophilia. Eggs measuring 60–80 μm by 34–50 μm are broadly ovoid, operculate, and yellowish brown (Eastburn, 1987). Thickening of the shell at the abopercular end should be differentiated from the knob seen on eggs of *Diphylllobothrium*. This fluke is the vector for a rickettsia that produces a highly lethal infection in canines known as “salmon-poisoning” disease.

Fasciola hepatica

Cattle, sheep, and goats in many parts of the world are infected with the liver fluke *Fasciola hepatica* and, less commonly, with the related species *Fasciola gigantica*. Adult parasites live in the biliary tree and lay eggs that

are passed in the feces. Cercariae shed from the snail intermediate host encyst on aquatic vegetation, where infectious metacercariae then are available to herbivorous hosts. Humans usually acquire the infection by eating watercress. Once ingested, the larvae penetrate the intestinal wall and migrate through the peritoneal cavity to the liver. They burrow through the capsule and parenchyma, coming to reside within the bile ducts, where egg laying is initiated in about 2 months. Migration of the larvae through the liver elicits a painful inflammatory reaction both in the tissue and, later, in the bile ducts, which eventually become fibrosed. Clinical manifestations include colic, obstructive jaundice, abdominal pain and tenderness, cholelithiasis, and eosinophilia.

Diagnosis is made by the finding of eggs in the stool. The unembryonated, yellowish brown, operculate eggs, 130–150 μm by 63–90 μm , cannot be distinguished easily from those of *Fasciolopsis* (see Fig. 62-22, *A*). Spurious infection, which occurs by ingesting infected cattle or sheep liver, is diagnosed by obtaining a good history and performing a follow-up stool examination to look for elimination of the eggs.

Clonorchis sinensis and *Opisthorchis viverrini*

Clonorchis sinensis, the Oriental liver fluke, and a closely related species, *Opisthorchis viverrini*, inhabit the biliary system of humans and other piscivorous animals, including cats and dogs. *C. sinensis* occurs mainly in China, Taiwan, Korea, Japan, and Vietnam, whereas *O. viverrini* is found primarily in southeast Asia, especially northern Thailand. Human infection is also known to occur with *Opisthorchis felinus* in Europe and *Amphimerus pseudofelinus* (same as *Opisthorchis guayaquilensis*) in Ecuador.

All these parasites are acquired by the ingestion of infectious metacercariae in raw or uncooked freshwater fish. Larvae migrate up the common duct into the liver bile ducts, where they live up to 20 years and grow up to 25 mm in length (Fig. 62-22, *C*). They produce small eggs that are shed into the bile and subsequently are passed in stools.

Infection is often asymptomatic, although large numbers of flukes and repeated infection may cause inflammation of the bile ducts and subsequent hyperplasia, fibrosis, and hepatic cirrhosis. Development of cholangiocarcinoma has been linked epidemiologically with long-standing infection.

Diagnosis is made by recovering the small brown, embryonated, operculate eggs from stools (Fig. 62-22, *D*). Eggs of *Clonorchis* cannot be readily differentiated from those of *Opisthorchis*. Both measure 25–35 μm by 12–20 μm and have a prominent, seated opercula and a small knob at the abopercular end. These eggs are difficult to differentiate from those of the *Heterophyes*/*Metagonimus* group, although the latter species do not have prominent, seated opercula or a small knob at the abopercular end. When specific identification is not possible, the laboratory report should reflect this (i.e., should state, “*Clonorchis*/*Opisthorchis*/*Heterophyes*/*Metagonimus* eggs”).

Paragonimus spp.

Several species of *Paragonimus* may parasitize the lungs of cats, dogs, and other carnivores, including humans. *Paragonimus westermani* is problematic in many areas of Asia, whereas in Central and South America several species have been implicated, including *Paragonimus mexicanus*, *Paragonimus caliensis*, and *Paragonimus ecuadoriensis*. *Paragonimus kellicotti* has occasionally been implicated in cases from North America, and other species have been described from Africa (Pachucki, 1984; Mariano, 1986; Strickland, 2000; Cook, 2002; Murray, 2007).

Adult worms measure up to 12 mm by 6 mm and often are found in pairs in lung parenchyma, where they reside in a fibrotic capsule produced by the host (Fig. 62-22, E). The capsule communicates with the bronchi, through which eggs pass to be eventually expelled in sputa or feces. Although a specific snail serves as the first intermediate host, freshwater crabs and crayfish serve as second intermediates for infectious metacercariae. Ingestion of uncooked, or marinated, crustacea may result in infection. Larvae are released in the stomach and migrate through the intestinal wall into the peritoneal cavity, eventually reaching the lungs after penetrating the diaphragm. Maturation takes approximately 5–6 weeks, and worms may live for many years.

Symptoms, when present, may be caused by larvae migrating through tissues or by adults established in the lungs. Not infrequently, worms develop in ectopic sites, including the peritoneum, subcutaneous tissues, and brain. The onset of lung infection is usually associated with fever, chills, and the appearance of eosinophilia. Once established, symptoms include chronic coughing with abundant mucous production, along with episodes of hemoptysis. Radiographs may show nodular shadows, calcifications, or patchy infiltrates. Eggs remaining in the lung tissues or in ectopic sites may cause an extensive granulomatous reaction.

Diagnosis is made by the finding of typical eggs in stools, sputum, or, occasionally, tissues. Eggs of the different *Paragonimus* species cannot be readily differentiated, and specific identification may be inferred from the area of origin. Operculate, unembryonated eggs measure 80–120 μm by 45–70 μm and have a moderately thick, yellow-brown shell (Fig. 62-22, F). The operculum is flattened and usually is set off from the rest of the shell by prominent shoulders. The abopercular end is somewhat thickened but does not have a knob. *Paragonimus* eggs may be differentiated from those of *Diphyllotritium* and *Fasciola/Fasciolopsis*, which they superficially resemble, by size.

Schistosoma spp.

Schistosomiasis, or bilharzia, is among the most important parasitic diseases worldwide, afflicting 200–300 million individuals. Adult male and female blood flukes inhabit veins of the mesentery or bladder. The most important species infecting humans are *Schistosoma mansoni*, *Schistosoma japonicum*, *Schistosoma mekongi*, *Schistosoma haematobium*, and *Schistosoma intercalatum*; other species infect humans less frequently.

Adult female schistosomes are slender, measuring up to 26 mm by 0.5 mm. Males, which are slightly shorter, enfold a female using the lateral margins of the body (the gynecophoral canal) to assist in sperm transfer. When examined in situ, schistosomes are often found in copula. In their preferred locations, blood flukes elicit little or no inflammatory response. Eggs are deposited in the smallest venule that can accommodate the female worm, where they elicit a strong granulomatous response that results in extrusion of the egg into the intestinal lumen or the bladder. Pathology is primarily related to the sites of egg deposition, the numbers deposited, and the host reaction to egg antigens.

Eggs are fully embryonated when passed and readily hatch when deposited in fresh water. The miracidia penetrate an appropriate species of snail host, where they undergo transformation and extensive asexual multiplication. After about 4 weeks, large numbers of fork-tailed cercariae emerge from the mollusk. Cercariae swim actively about for hours and readily penetrate the skin of susceptible hosts, including humans. After penetration, the cercariae, now called schistosomules, enter the circulation and pass through the lungs before reaching the mesenteric-portal vessels.

Symptoms of schistosomiasis result primarily from penetration of cercariae (cercarial dermatitis), from initiation of egg laying (acute schistosomiasis or Katayama fever), and as a late-stage complication of tissue proliferation and repair (chronic schistosomiasis). In a matter of hours after cercarial penetration, a papular rash associated with pruritus may develop. This is a sensitization phenomenon resulting from prior exposure to cercarial antigens. The most severe form of dermatitis occurs in individuals who are repeatedly exposed to cercariae of nonhuman (primarily avian) schistosomes. Cercarial dermatitis or swimmer's itch occurs worldwide and is a well-recognized entity in the United States (Hoeffler, 1974).

Initiation of egg laying by mature worms 5–7 weeks after infection may result in acute schistosomiasis, or Katayama fever, a serum sickness-like syndrome that occurs with heavy primary infection, especially that of *S. japonicum*. The antigenic challenge to the host is thought to result in immune complex formation (Boros, 1989).

Chronic infection results in continued deposition of eggs, many of which remain in the body. Granulomas produced around these eggs in the intestine and in the bladder are gradually replaced by collagen, resulting in fibrosis and scarring. Eggs trapped in the liver may induce pipe-stem fibrosis with obstruction to portal blood flow. Occasionally, eggs are deposited in ectopic sites, such as the spinal cord, lungs, or brain (Cook, 2002; Garcia, 2007).

Diagnosis is established by demonstrating eggs in feces or urine by direct wet mount or formalin–ethyl acetate concentration methods. Zinc sulfate concentration is not satisfactory for recovery of heavy schistosome eggs. Eggs also may be detected in biopsies of rectal, bladder, and, occasionally, liver tissues by crush preparation or in histologic section (Fig. 62-23). Use of egg hatching methods may occasionally be requested to determine viability or, less commonly, to detect light infection. Feces mixed with distilled water are placed in a flask that is covered with foil to keep out light, with only the neck or a sidearm exposed to bright light. Miracidia, if present, actively swim to the light and can be detected using a hand lens.

Serologic tests may be helpful in screening persons who have traveled to endemic areas and those with negative urine or stool examination who are at risk for infection, or for monitoring response to therapy. Although not widely available, a limited number of reference laboratories and the CDC provide testing. Generally, serologic testing varies with the antigens used and the test methods employed. The CDC uses the Falcon assay screening test in a kinetic enzyme-linked immunosorbent assay (FAST-ELISA). Sera that are positive by the screening test are further evaluated by immunoblot to improve specificity (Wilson, 1995).

Schistosoma mansoni

Schistosoma mansoni occurs in Africa, especially in the tropical areas and the Nile delta, southern Africa, and Madagascar, Brazil, Venezuela, Surinam, and certain Caribbean islands, including Puerto Rico. Adult *S. mansoni* live primarily in the portal vein and in the distribution of the inferior mesenteric vein. Initial deposition of eggs in the large intestine may produce abdominal pain and dysentery, with abundant blood and mucus in the stool. Eggs may be detected in feces at this time. Chronic infection may result in liver fibrosis and portal hypertension, depending on the number of worms present; eggs may be more difficult to find in feces during this stage.

Eggs, which measure 116–180 μm by 45–58 μm , are oval, with a large distinctive lateral spine that protrudes from the side of the egg near one end (see Fig. 62-23, A and B). If the spine is not visible, the egg may be rotated by gently tapping the coverslip. Movement of the miracidium within the egg may be evident in unfixed material if the larva is viable. Concentration techniques may be required to detect eggs because individuals with limited exposure or with chronic infection may pass few of them.

Schistosoma japonicum

Schistosoma japonicum, which occurs in China, southeast Asia, and the Philippines, causes disease that is clinically similar to that of *S. mansoni* but often more serious because many more (up to 10 times as many) eggs are produced by *S. japonicum*. The disease has been essentially eliminated from Japan, although animal reservoirs still exist. Adult worms live primarily in the distribution of the superior mesenteric vein, and eggs readily reach the liver, inducing fibrosis and portal hypertension as a common complication of chronic infection. The smaller size of the eggs predisposes them to dissemination, especially to the brain and spinal cord. The eggs are broadly oval, measuring 75–90 μm by 60–68 μm , and have an inconspicuous lateral spine, which may be difficult to demonstrate (see Fig. 62-23, C and D).

Schistosoma mekongi

This species occurs in humans and animal reservoirs in countries along the Mekong River, especially Cambodia and Laos (Bruce, 1980). It is similar to *S. japonicum* but is differentiated from that species by several biological characteristics and by smaller eggs (60–70 μm by 52–61 μm), which otherwise are indistinguishable from those of *S. japonicum*.

Schistosoma haematobium

Urinary schistosomiasis occurs in many parts of Africa, the Middle East, and Madagascar. Parasites migrate via the hemorrhoidal veins to the

Figure 62-23 **A**, Egg of *Schistosoma mansoni*; note prominent lateral spine ($\times 400$). **B**, Eggs of *S. mansoni* in an intestinal biopsy; note presence of lateral spine (H&E; $\times 400$). **C**, Egg of *Schistosoma japonicum*; note presence of small lateral spine ($\times 400$). **D**, Eggs of *S. japonicum* in a small-bowel biopsy (H&E; $\times 400$). **E**, Egg of *Schistosoma haematobium* found in urine sediment; note presence of a terminal spine ($\times 400$). **F**, Eggs of *S. haematobium* seen in a vulvar granuloma; note presence of a terminal spine (H&E; $\times 400$).

venous plexuses of the urinary bladder, prostate, uterus, and vagina. One of the earliest and most common symptoms of infection is hematuria, especially at the end of micturition. Chronic infection may cause pelvic pain and bladder colic, with an increased desire to urinate. Accumulation of eggs in the tissues may result in hypertrophy of the urothelium, squamous metaplasia, and marked fibrosis, which may progress to obstruction and, ultimately, renal failure. Urinary schistosomiasis also has been associated with squamous cell carcinoma of the bladder (Badawi, 1992).

Eggs are recovered from the urine by examination of spun sediment. They are elongate, measuring 112–180 μm by 40–70 μm , and have a characteristic terminal spine (see Fig. 62-23, *E* and *F*). Occasionally, they may be detected in feces or in a rectal biopsy.

Schistosoma intercalatum

This species occurs in many parts of central and western Africa and produces intestinal schistosomiasis. Eggs have a terminal spine and so resemble those of *S. haematobium*, but they occur primarily in the feces and are larger (140–240 μm by 50–85 μm).

TISSUE HELMINTHS

NEMATODES

Filaria

Filarial nematodes, also known as threadworms, are common arthropod-transmitted parasites of vertebrate animals. Adult male and female worms are long and slender, measuring up to 100 mm in length, and are known to inhabit a variety of tissues, including subcutaneous tissues, lymphatics, blood vessels, peritoneal and pleural cavities, heart, and brain. All species produce larvae known as microfilariae, which may be recovered from blood or skin, depending on the species. The microfilariae of some species circulate in the blood with a well-defined periodicity (diurnal or nocturnal), whereas others do not. Microfilariae continue their development only in the appropriate arthropod vector, usually a mosquito or fly, where they mature to the infective stage. Such larvae then are deposited in the tissues of a definitive host when the vector takes another blood meal.

The diagnosis of filariasis usually is made by the finding of microfilariae in the blood or skin, because adult stages are often sequestered in the tissues. Use of Giemsa or hematoxylin-stained thick smears of peripheral blood is routine, although more sensitive procedures such as membrane filter, Knott's concentration, or saponin lysis may also be required (National Committee for Clinical Laboratory Standards, 2000). Microfilariae may be seen moving in direct mounts of blood or tissue fluid.

Species identification is important because pathogenicity varies. Principal characteristics used for identification of microfilariae include the presence or absence of a sheath and its staining characteristics, the shape of the tail and the distribution of cell nuclei within, and the size of the cephalic space and the appearance of its nuclear column. Because microfilariae of *Wuchereria* and *Brugia* usually display a nocturnal periodicity, blood from patients suspected to be infected with these filaria should be drawn between the hours of 10 PM and 2 AM. *Loa loa* displays diurnal periodicity, so blood preferably should be drawn around noon. *Mansonella ozzardi* and *Mansonella perstans* are characteristically nonperiodic. Microfilariae of *Mansonella streptocerca* and *Onchocerca volvulus* are present in the skin and are detected by examination of skin snips or punch biopsies.

Serologic tests for the diagnosis of lymphatic filariasis may prove helpful in select patients, especially those who are not native to endemic areas. Such methods are limited in their ability to distinguish between past exposure and current infection, however, and infection with other nematode species may result in the appearance of cross-reacting antibodies. Antigen detection tests also may be of value in the diagnosis of lymphatic filariasis but generally are not available (Wilson, 1995).

Wuchereria bancrofti

This species, responsible for bancroftian filariasis, is the most common filarial species to infect humans. Endemic areas include central and northern Africa, India, southeast Asia, certain South Pacific islands, and portions of Central and South America and the West Indies. Adult worms reside in the lymphatic system, where chronic infection and reinfection result in lymphadenopathy and lymphangitis, which may progress to lymphedema and obstructive fibrosis (Fig. 62-24, *A*). Severe involvement of the lower extremities and genitalia may result in elephantiasis.

In most areas, microfilariae circulate in peripheral blood with a nocturnal periodicity that corresponds with feeding activities of the usual vectors—*Culex*, *Aedes*, and *Anopheles* mosquitoes. Infections originating in the South Pacific are essentially without periodicity. The microfilariae are sheathed, although this may not always be obvious with Giemsa staining. The tail is pointed, and no nuclei are present in the tip. The cephalic space is not as long as it is wide, and the nuclei in the nuclear column are distinct (Figs. 62-24, *B*, and 62-25). Concentration procedures may be necessary for recovery because microfilariae may be present in small numbers.

Brugia malayi

This species produces disease similar to that of *W. bancrofti*, although it is often milder and more frequently involves the lymphatics of the upper extremities. The parasite occurs mainly in India, southeast Asia, Korea, the Philippines, and Japan. Human infection with related zoonotic species is encountered periodically in the United States.

Figure 62-24 **A**, *Wuchereria bancrofti*, cross-section of adult in human lymph node; note extensive inflammatory reaction (H&E; $\times 100$). **B**, Sheathed microfilaria of *W. bancrofti*; cell nuclei do not extend to the tip of the tail (Giemsa stain; $\times 1000$). **C**, Sheathed microfilaria of *Brugia malayi*; two solitary cell nuclei are seen in the tail tip (Giemsa stain; $\times 1000$). **D**, Sheathed microfilaria of *Loa loa*; cell nuclei extend to the tail tip (Giemsa stain; $\times 1000$). **E**, *Onchocerca volvulus*, cross-section of adult in skin nodule (H&E; $\times 100$). **F**, Unsheathed microfilaria of *Mansonella perstans*; cell nuclei extend to the tail tip (Giemsa stain; $\times 1000$).

The microfilariae circulate in the blood and are primarily periodic. Microfilarial sheaths of *Brugia malayi* stain well with Giemsa stain. The tail has a swelling at the tip and has two solitary nuclei located beyond the ends of the nuclear column (termed subterminal and terminal nuclei). The cephalic space may be much longer than it is wide (Figs. 62-24, C, and 62-25). *Brugia timori* is a distinct species occurring in the eastern end of the Indonesian archipelago, especially on the islands of Timor and Flores. Microfilariae are very similar to those of *B. malayi*, although somewhat larger.

Loa loa

Known as the eye worm, *Loa loa* lives in subcutaneous tissues. The nematodes migrate continuously, producing transient (2–3 days) local inflammatory reactions known as Calabar or fugitive swellings. Their occasional appearance in the conjunctiva allows them to be surgically excised. Loiasis occurs primarily in west and central Africa, where deer flies of the genus *Chrysops* serve as vector.

This parasite elicits strong eosinophilia and occasionally has been seen in the United States in people with a history of travel to Africa. The microfilariae, which circulate in the blood with diurnal periodicity, are sheathed, although the sheath does not stain with Giemsa stain. Nuclei in the tail extend to the rounded tip. The nuclear column is distinct, and the cephalic space is short (Figs. 62-24, D, and 62-25) (National Committee for Clinical Laboratory Standards, 2000; Garcia, 2007).

Onchocerca volvulus

Onchocerciasis is a leading cause of blindness in endemic areas, which include central Africa, Central America (Mexico and Guatemala), and northern South America. Vectors are black flies of the genus *Simulium*. Adult worms live in hard, fibrous nodules in subcutaneous and deeper tissues that can grow to be 40 mm in diameter (Fig. 62-24, E). Nodules tend to occur on the upper half of the body in patients from Central America and on the lower half in those from Africa. Adult worms produce microfilariae that migrate continuously throughout the skin. Complications arise from the migratory activities of microfilariae, resulting in several forms of dermatitis. Movement of microfilariae through the surface of the eye may result in keratitis, corneal opacity, and damage to the anterior and posterior chambers and iris, thus leading to blindness with repeated infection over time.

Diagnosis is made by the finding of typical microfilariae in teased skin snips or skin biopsies, preferably taken from over the scapular region or from the iliac crest, when placed in saline. Alternatively, fluids expressed from scarified skin or aspirates of nodules may be examined (Beaver, 1984; Garcia, 2007). Microfilariae in stained preparations lack both a sheath and nuclei in the tail tip (see Fig. 62-25).

Figure 62-25 Anterior and posterior ends of microfilariae most commonly found in humans. All camera lucida drawings.

Mansonella spp.

Several species of *Mansonella* infect humans, but all are generally regarded as causing little pathology. Microfilariae, however, must be differentiated from the truly pathogenic filarial species. *M. ozzardi* is found in Central and South America and in some areas of the Caribbean. Adult parasites reside in subcutaneous tissues. *M. perstans* occurs in many areas of tropical Africa and sporadically in South America. Adults are thought to reside primarily in body cavities and the mesenteries. Microfilariae of both species are unsheathed and circulate in peripheral blood without evidence of periodicity. *M. ozzardi* microfilariae have a thin, pointed tail without nuclei, whereas the tail of *M. perstans* is broad and blunt with nuclei extending to the tip (Figs. 62-24, F and 62-25). *M. streptocerca*, which is found in tropical Africa, may be confused with *Onchocerca volvulus*, because both adult and microfilarial stages occur in skin and subcutaneous tissues. Also, dermatitis may be produced by this species. Microfilariae of this species, which may be recovered in skin snips, are unsheathed and have a crook in the tail with nuclei extending to the tip. All species of *Mansonella* are transmitted by gnats of the genus *Culicoides*.

Zoonotic Filariae

Certain filarial nematodes of the genera *Dirofilaria* and *Brugia* that naturally parasitize wild and domestic mammals sporadically infect humans. *Dirofilaria immitis*, commonly known as the canine heartworm, is widely distributed, and human infection is well documented. The mosquito-transmitted larval stage migrates to the right side of the heart. When the worm dies, it is swept into a small pulmonary artery, producing a granulomatous nodule that appears as a coin lesion on a chest radiograph. Diagnosis usually is made by histologic examination of the nodule.

Other species of *Dirofilaria*, including *Dirofilaria tenuis*, *Dirofilaria repens*, and *Dirofilaria ursi*, commonly cause subcutaneous nodules in humans but fail to produce microfilariae. Such nodules have been reported from many body sites, including the face, conjunctiva, and breast, and usually are removed surgically. Histologic examination often reveals a prominent mixed inflammatory reaction surrounding a dead worm. Criteria for identification of zoonotic filariae in tissue sections may be found elsewhere (MacDougall, 1992; Orihel, 1995; Connor, 1997; Gutierrez, 2000).

Other

Dracunculus medinensis

Adult Guinea worms live in subcutaneous tissues and become clinically evident when the female worm migrates to the skin surface and produces a blister, usually on the lower extremities. When the extremity is immersed in water, the blister ruptures, releasing swarms of motile larvae from the female worm into the water. Specific zooplankton (i.e., copepods) ingest the larvae, which then mature to the infective stage and are transmitted back to humans when copepods are accidentally swallowed in drinking water.

The disease is endemic to areas of Africa, the Middle East, and Asia and may be responsible for disfiguring cutaneous scars and more serious secondary bacterial infection. Extensive control efforts have been made in recent years to eradicate this destructive parasite, and success is thought to be at hand (Centers for Disease Control and Prevention, 1992; Cairncross, 2002; Garcia, 2007).

Diagnosis is made by the finding of the female worm emerging at the skin surface with larvae in the discharge fluid. The worm may be gently extracted over a period of days, but care must be taken not to damage it during removal. Should the worm die in situ, pronounced inflammatory reaction and secondary bacterial infection may disable the affected individual.

Angiostrongylus cantonensis and *Angiostrongylus costaricensis*

Human eosinophilic meningoencephalitis, caused by *Angiostrongylus cantonensis*, occurs both in epidemics and sporadically in many areas of the south Pacific, southeast Asia, and Taiwan. The mature parasite normally is found in the pulmonary arteries of rats. Larvae migrate up the trachea and are passed in the feces. They develop to the infective stage in slugs or land snails and, when eaten by the usual rodent host, migrate through the brain before maturing in the pulmonary arteries. Humans acquire the infection by eating large edible snails; raw or incompletely cooked shrimp or crabs, which may serve as transport hosts; or vegetables contaminated with infected mollusks. In humans, *A. cantonensis* larvae migrate to the CNS,

producing generally nonfatal meningitis with high spinal fluid eosinophilia (Alicata, 1991). Diagnosis is established both clinically and historically, although larvae occasionally have been recovered from spinal fluid (Kubersky, 1979; Strickland, 2000; Cook, 2002; Garcia, 2007).

Angiostrongylus costaricensis occurs widely in Central and South America (Loria-Cortez, 1980). This parasite, which is responsible for the intestinal form of angiostrongyliasis, normally resides in the mesenteric arteries of the ileum and cecum of rodents. Human infection occurs in the same anatomic location but often results in granulomatous inflammation and symptoms of acute abdomen. Diagnosis is made by histologic examination of surgical specimens and the finding of adults or eggs in the tissues (Strickland, 2000).

Trichinella spiralis

Human trichinosis occurs worldwide, although its incidence in the United States has been in steady decline, with fewer than 100 cases reported each year. Humans acquire the infection through ingestion of raw or incompletely cooked pork, pork products, or, less commonly, bear meat that contains infective larvae. Ingested worms mature in the small intestine, where gravid females produce new larvae for 2–3 weeks. During this stage, gastrointestinal symptoms occur, lasting several days. Larvae subsequently enter lymphatics and venules, thus reaching the general circulation. They primarily invade the skeletal musculature, where they undergo further development and encapsulation. During the migratory and encapsulation phases, fever, muscle pain, respiratory difficulties, periorbital edema, and eosinophilia may develop, depending on the inoculating dose. After the parasites have encysted, few symptoms are noted. Encysted larvae may remain viable for several years, although they eventually become calcified.

Diagnosis is usually made on the basis of history and clinical symptoms and is confirmed by the demonstration of trichinella cysts in skeletal muscle biopsy, particularly the gastrocnemius or deltoid muscles (see Fig. 62-18, E and F). Indirect tests include creatine phosphokinase, which is often elevated, and detection of antibodies by bentonite flocculation or EIA. Of these latter tests, creatine phosphokinase is more specific, and EIA is more sensitive (Wilson, 1995).

Larva Migrans

Larva migrans is caused by prolonged wandering through body tissues of larvae of certain hookworms, ascarids, and *Strongyloides* species that normally infect wild or domestic animals. The syndrome varies with the species involved, the number of worms, and the tissues parasitized.

Cutaneous larva migrans, or ground itch, is produced by the cutaneous wanderings of cat or dog hookworms of the genus *Ancylostoma*, which penetrate the skin but cannot mature in the usual pattern. Serpiginous, erythematous, and pruritic tracks are apparent on the skin in areas where there has been contact with the ground. This is particularly problematic in warmer, humid climates, where eggs and larvae of these hookworms survive longer. Some species of *Strongyloides* that parasitize wild animals may cause a similar dermatitis (Beaver, 1984).

Visceral larva migrans (VLM) is produced primarily by the random wanderings of the dog ascarid *Toxocara canis* and, to a lesser degree, by *Toxocara cati* from the domestic cat. Children are usually infected following the accidental or intentional ingestion of soil contaminated with dog or cat feces. After hatching, the larvae are unable to complete their usual cycle and instead begin a prolonged migration through various tissues and organs. Children may present with failure to thrive and may display fever, hepatomegaly, pneumonitis, hypereosinophilia, and hypergammaglobulinemia. An inflammatory reaction in the retina from ocular larva migrans may mimic retinoblastoma, a malignant tumor from which it must be differentiated. Diagnosis of VLM is usually made on clinical grounds because the parasite is rarely recovered. Serologic tests may be helpful in confirming a presumptive diagnosis, and the currently recommended procedure is an EIA that uses larval stage excretory-secretory antigens (Wilson, 1995; Garcia, 2007).

A VLM-like syndrome may also be caused by species of *Gnathostoma* that infect the stomach of various mammals. Human infection is most common in southeast Asia but has been reported in Mexico and Ecuador. These parasites use a copepod for the first intermediate host, and fish and amphibians as secondary hosts. A variety of reptiles, birds, and mammals may serve as paratenic hosts. The larvae may migrate through subcutaneous tissues, causing transient swellings, and to deeper tissues, eventually invading the CNS. The occurrence of migratory lesions and a history of eating raw fish may be helpful in establishing a clinical diagnosis.

Capillaria hepatica

Although normally a parasite common to rodents, this species occasionally causes human disease, especially in children, in whom it may mimic VLM, hepatitis, amebic liver abscess, and other diseases. In the usual rodent host, eggs are ingested and resulting larvae migrate to the liver, where they mature and deposit eggs directly in the parenchyma. When the liver is eaten by a predator, the eggs are passed out in the feces and contaminate soil. Children are at particular risk of acquiring the eggs if they eat dirt. In endemic areas, diagnosis is made by examination of liver biopsies or tissue obtained at autopsy. Eggs are readily recognized in tissue biopsies as having thick, striated walls and plugs at both ends.

Anisakis, Pseudoterranova, and Eustrongyloides spp.

Ingestion of raw fish, although considered by many to be a delicacy, has resulted in an increase in the number of reported cases of fish nematode infections. *Anisakis* and *Pseudoterranova* are common gastrointestinal parasites of marine mammals, and the infective stages are found in various saltwater fish, salmon, and squid intermediate hosts. Small shrimp-like crustaceans (krill) serve as the first intermediate host. When ingested, these larvae may penetrate the wall of the stomach or small bowel, causing acute abdominal pain. Anisakiasis may be presumptively diagnosed based on an appropriate history and clinical findings, and the condition may be confirmed by the recovery of an intact worm at endoscopy or by the presence of an eosinophilic granuloma containing an identifiable nematode in a surgical specimen. Species of *Anisakis* appear to be more prone to produce invasive disease, whereas *Pseudoterranova* spp. tend to be coughed up or vomited intact (see Fig. 62-18, G and H) (Sakanari, 1989). The species level of larval anisakids is difficult to identify (Binford, 1976).

A small number of infections with *Eustrongyloides* spp. have been reported in individuals who had eaten live minnows or home-prepared sushi. These parasites usually infect fish-eating birds, but in humans, the bright red larvae invade the abdominal cavity, requiring surgical removal (Wittner, 1989).

CESTODES

Several species of cestode infect humans in their larval stages and may produce serious disease. The more commonly encountered ones are readily distinguishable from each other and have unique patterns of transmission. When seen in tissue sections, larval and adult stages of cestodes contain basophilic-staining laminated bodies known as calcareous corpuscles, which are an important aid in their recognition.

Cysticercosis

Human infection with the larval stage of the pork tapeworm, *T. solium*, is found worldwide and occurs following unintentional ingestion of the eggs of an adult tapeworm. The disease is especially prevalent in Mexico and the rest of Latin America, Europe, Africa, India, and Asia. Most cases in the United States originate from highly endemic areas, although in recent years, the number of locally acquired cases has increased (Richards, 1985; Carabin, 2005; Murray, 2007).

Eggs may be ingested accidentally with contaminated food or water and subsequently hatch in the gastrointestinal tract. Embryos penetrate the intestinal mucosa and disseminate via the bloodstream to distant sites, especially the skeletal muscle, and also to the heart, brain, or eye, where symptoms of infection and inflammation may become especially apparent. Seizures are a common complication in endemic areas and are often the presenting symptom (Fig. 62-26, A).

The diagnosis is usually made on clinical grounds in endemic areas but may be much more difficult to establish in nonendemic settings. Use of computed tomography (CT) scans is very helpful but generally is not available in most endemic areas. Radiographs are helpful in recognizing the presence of calcified cysts but not in recognizing recent infection. Recovery of an intact cysticercus at the time of surgery confirms the diagnosis. The cysticercus, or bladder worm, is a translucent, fluid-filled, oval sac containing a single inverted scolex that measures 5 mm or more in diameter (Fig. 62-26, B).

Among serologic assays, the glycoprotein immunoblot assay available from the CDC has high sensitivity and specificity, outperforming several EIAs with which it was compared (Diaz, 1992). Unfortunately, these assays do not distinguish between active and inactive infections, and thus are not useful in monitoring response to therapy.

The occurrence of cysticercosis in someone from a nonendemic area and without an appropriate travel history should be investigated for accidental exposure to individuals involved in food preparation, or for the possibility of infection with a different *Taenia* species (Schantz, 1992).

Hydatidosis

Human infection with larval stages of tapeworms of the genus *Echinococcus* may take one of three forms: unilocular hydatid disease caused by *Echinococcus granulosus*, multilocular or alveolar hydatid disease caused by *Echinococcus multilocularis*, or polycystic hydatid disease caused by *Echinococcus vogeli* (Thompson, 1995). Members of the dog family are definitive hosts for these minute tapeworms. What they lack in size they make up for in numbers, with many hundreds or thousands of worms producing large

E, Human infection with a coenurus larva; note thin bladder membrane and numerous developing protoscolices ($\times 10$). (Courtesy Dr. Heike Duebner.) F, Sparganum (larva of *Spirometra* spp.) found in a retro-orbital lesion (Giemsa stain; $\times 100$).

numbers of eggs in one host. Eggs are passed in the stools and are ingested by the intermediate hosts, which include sheep, cattle, pigs, rodents, and other herbivorous animals. Humans, especially children, are infected following accidental ingestion of eggs from the environment.

Eggs hatch in the intestine, and embryos penetrate the intestinal wall and then enter the bloodstream. Although most hydatids develop in the liver, some disseminate to other sites. Development of the cysts is slow, and it may take many years for a cyst measuring 10–15 cm in diameter to form. In the usual secondary hosts, the cysts contain numerous protoscolices, which proliferate from a germinal membrane.

E. granulosus, the most important species producing human disease, is common in many sheep- and cattle-raising areas of the world, including the United States, where dogs are the usual definitive host. Unilocular hydatids develop as single cysts in the liver and secondarily in the lungs or other locations. The cysts are filled with clear fluid and contain brood capsules and numerous protoscolices, which can number in the thousands (Fig. 62-26, C and D). Symptoms in humans include a slowly growing mass lesion, although infection in the CNS becomes apparent earlier than in other sites. The diagnosis is suggested on the basis of clinical presentation and history plus the use of radiography, CT scans, and ultrasonography. Serologic tests are very useful in confirming a diagnosis and usually involve a screening test such as EIA or IHA, followed, if positive, by a confirmatory assay such as immunoblot or gel diffusion (Wilson, 1995). Sensitivity varies from 60%–90%, depending on the characteristics of the case. False-positive reactions may occur with cysticercosis, although disease presentation should prevent confusion. Aspiration of cyst contents is potentially dangerous because spillage of cyst contents may result in dissemination of disease or possibly anaphylactic shock; however, if aspiration is performed, cyst contents usually reveal hydatid sand, a mixture of protoscolices, disintegrating brood capsules, hooklets, and calcareous corpuscles.

E. multilocularis produces multilocular or alveolar hydatid disease in the northern regions of Europe and Russia, and in Alaska, Canada, and the northern tier of states in the United States. Intermediate hosts include several genera of small rodents; foxes, wolves, and dogs are definitive hosts. Human infection occurs in the liver, where the hydatid develops as an invasive cyst that insinuates itself within the tissue in an alveolar pattern. Although the germinal membrane proliferates in the human liver, protoscolices fail to develop. The pathologic picture is reminiscent of hepatic carcinoma. Serologic assays that use *E. granulosus* antigens are useful in the diagnosis of this disease. The differential use of antigens from both parasites shows promise of discrimination between the two diseases (Wilson, 1995).

E. vogeli produces a polycystic hydatid cyst in humans that is invasive but, unlike *E. multilocularis*, produces both brood capsules and protoscolices. The disease is limited to Latin America, where rodents, specifically the paca, and bush dogs complete the life cycle (D'Alessandro, 1979). Polycystic hydatid disease in South America may also be caused by *Echinococcus oligarthus*, a parasite of felids and rodents. This species is similar morphologically to *E. vogeli*, and cases have been misidentified (D'Alessandro, 1995).

Sparganosis

Sparganosis is caused by larval cestodes of the genus *Spirometra*, which are closely related to *Diphyllobothrium* spp. Adult stages commonly parasitize cats and dogs and their relatives in Asia (*Spirometra mansoni*) and North America (*Spirometra mansonoides*). Life cycles are similar to those of *Diphyllobothrium*: Copepods serve as first intermediate hosts for proceroid larvae, and fish serve as second intermediate hosts for plerocercoid larvae. Humans become infected with these larval stages (the sparganum) through ingestion of copepods in drinking water or ingestion of raw or incompletely cooked fish. Use of frogs and snakes as poultices may also result in the transfer of larvae to the human host. Sparganosis usually presents as localized or migratory subcutaneous swellings associated with erythema and pain, although brain infection may occur. Surgical exploration may reveal a delicate, slender, ivory-colored worm varying from a few to many centimeters in length. Cross-sections demonstrate a thick tegument with deep folds and parenchyma with prominent muscle bundles. No body cavity is seen, as in the nematodes, and calcareous corpuscles are numerous (Fig. 62-26, F) (Orihel, 1995; Gutierrez, 2000; Garcia, 2007).

Coenurosis

Intestinal *Taenia* spp. of cats and dogs (primarily *Taenia multiceps* and *Taenia serialis*) produce a larval stage in intermediate hosts known as a coenurus.

This stage consists of a large (up to 10 cm) transparent sac containing numerous scoleces that bud off from a germinal membrane and invaginate into the fluid-filled cyst (Fig. 62-26, E). Sheep are the usual intermediate hosts for *T. multiceps*, and rodents, hares, and rabbits for *T. serialis*, although humans serve in this role through accidental ingestion of eggs originating from domestic cats and dogs. Similar to cysticerci, coenuri may develop in any organ, producing a similar disease. Diagnosis is usually made by examination of the excised cyst or its demonstration in tissue sections. The presence of multiple invaginated scoleces within a single bladder differentiates the coenurus from other larval cestodes.

TREMATODES

All liver-, lung-, and blood-inhabiting trematodes that mature in humans produce eggs that usually exit the body via stool, urine, or sputum. Because of their extraintestinal location, these flukes and their eggs may be found in tissues incidentally or in association with symptoms.

Adult *F. hepatica*, *C. sinensis*, and *O. viverrini* may be found in hepatic and biliary tissues, and occasionally in ectopic locations. The presence of typical eggs free in the tissues or within the uterus of the helminth often provides definitive identification. Adult *Paragonimus* spp. primarily reside in the lung but may be found in ectopic sites such as brain and subcutaneous tissue, where they produce abscesses, often associated with large numbers of eggs. Adult schistosomes reside in blood vessels, primarily in the distribution of the inferior mesenteric vein (*S. mansoni*), the superior mesenteric vein (*S. japonicum* and *S. mekongi*), and the vesical plexus (*S. haematobium*). Although the adult stages are rarely encountered in tissue sections, eggs may be found in large numbers in tissues of the intestine, liver, and bladder (see Fig. 62-23, B, D, and F). Eggs may disseminate via the bloodstream to other sites, including the brain, spinal cord, lungs, heart, kidneys, and spleen. The eggs of *S. japonicum* are especially prone to disseminate because of their smaller size and the large numbers typically produced. Identification of eggs is dependent on recognition of their typical sizes and morphologic characteristics in appropriate tissues.

MEDICALLY IMPORTANT ARTHROPODS

Arthropods comprise a large and diverse group of organisms, few of which have clinical or economic significance. Those that do, however, are important causes of morbidity and mortality in humans and their domestic animals, and are responsible for serious economic losses to agriculture. Although perhaps best known among clinicians for their ability to transmit various infectious agents, including viruses, bacteria (rickettsia, spirochetes, others), protozoa, and certain helminths, arthropods also cause serious disease by direct tissue invasion, envenomation, vesication, blood loss, and allergic reaction. Exaggerated fears of arthropods (entomophobia) and delusions of infestation (delusory parasitosis) are not uncommon neuroses, which may be disabling to some individuals. Species directly or indirectly responsible for human disease include representatives of all the major arthropod classes (Table 62-12).

In this section, an approach that the clinical laboratory may use when evaluating clinical specimens containing arthropods is presented, followed by a brief discussion of each of the arthropod groups of medical importance. A variety of general and specialized texts and guides

TABLE 62-12

Classification of Arthropods of Medical Importance

Class Insecta (insects)	Class Arachnida (arachnids)
Order Anoplura (sucking lice)	Subclass Scorpiones (scorpions)
Order Siphonaptera (fleas)	Subclass Araneae (spiders)
Order Dictyoptera (cockroaches)	Subclass Acari (ticks, mites, chiggers)
Order Hemiptera (bedbugs, kissing bugs)	Class Diplopoda (millipedes)
Order Hymenoptera (ants, wasps, bees)	Class Chilopoda (centipedes)
Order Coleoptera (beetles)	Class Crustacea (crustaceans)
Order Lepidoptera (moths, butterflies, caterpillars)	Order Copepoda (copepods)
Order Diptera (flies, mosquitoes, midges)	Order Decapoda (crabs, crayfish)
	Class Pentastomida (tongue worms)

are available for more complete coverage of the field of medical entomology (National Communicable Disease Center, 1969; Beaver, 1984; Lane, 1993; Strickland, 2000; Mullen, 2002; Garcia, 2007; Goddard, 2007; Murray, 2007).

BIOLOGICAL CHARACTERISTICS

Arthropods are characterized by a bilaterally symmetrical, segmented body; several pairs of jointed appendages; and a rigid chitinous exoskeleton that is molted repeatedly during growth. Development proceeds from egg to adult through gradual (egg, nymph, and adult stages) or complete (egg, larva, pupa, and adult stages) metamorphosis. Bedbugs, kissing bugs, lice, and cockroaches are examples of insects that undergo gradual metamorphosis. Flies and mosquitoes; fleas; ants, bees, and wasps; and beetles undergo complete metamorphosis; worm-like larval forms pupate to emerge as adults. Arachnids undergo developmental changes most similar to the process of gradual metamorphosis. The larval stages of those arthropods that undergo complete metamorphosis often prove to be the most difficult for clinical laboratorians to identify and should be referred to a specialist.

MECHANISMS OF INJURY

Direct Tissue Invasion

Invasion of superficial tissues (referred to as infestation) may occur with a variety of arthropods, of which scabies mites, chigoe fleas, and some dipteran larvae (maggots) are most common. Invasion of deeper body tissues and cavities (referred to as infection) occurs primarily with maggots and rarely with pentastomid larvae. Tissue invasion by dipteran larvae is referred to as myiasis and may occur in living or devitalized tissues, depending on the involved species.

Envenomation

Many arthropods are capable of injecting saliva or venom with their bites or stings. For most individuals, these compounds cause only local tissue reactions, but serious, life-threatening reactions such as anaphylaxis may occur, often as a result of previous sensitization to the particular toxin. Hymenopteran (ants, bees, and wasps) and scorpion stings are among the greatest offenders (Reisman, 1994). The bites of certain arthropods, especially centipedes; mosquitoes, flies, and biting midges; bedbugs, kissing bugs, and assassin bugs; sucking lice; fleas; and ticks and mites may also be toxic, causing local or systemic reactions. Almost all spiders are venomous, but only a few groups (widow spiders, violin spiders, and certain tarantulas) pose significant health risks to humans. Less common but recognized causes of envenomation result from exposure to the urticating hairs of certain caterpillars and beetle larvae.

Vesication

Certain of the larger tropical millipedes are capable of spraying a vesicating (blister-causing) chemical substance from glands located on each body segment. These compounds are especially irritating should they reach the conjunctiva. Blister beetles are so named because of their ability to discharge vesicating fluids (cantharidin, the active ingredient in the aphrodisiac Spanish fly) from their bodies when handled.

Blood Loss

Arthropods responsible for producing significant irritation or blood loss to humans and domestic animals include bedbugs, kissing bugs, lice, fleas, flies, mosquitoes, biting midges, ticks, and mites. Although these activities are rarely life threatening, the concurrent transmission of infectious agents may be.

Transmission of Infectious Agents

Many arthropods play an integral role in the mechanical or biological transmission of infectious disease agents. The common housefly, *Musca domestica*, may be responsible for the mechanical transmission of agents of bacillary dysentery, cholera, typhoid, viral diarrhea, amebic dysentery, and giardiasis, as well as pinworms and tapeworms. Mechanisms involved in the biological transmission of infectious agents vary from simple organism amplification in the arthropod vector to more complex life cycle changes in the involved parasite. Ticks and mites are involved in the transmission of certain bacteria (*Rickettsia*, *Ehrlichia*, *Anaplasma*, spirochetes, others),

protozoa (*Babesia*), and viruses. Among insects, lice are involved in the transmission of bacteria (*Rickettsia*, *Bartonella*, and *Borrelia*); kissing bugs transmit trypanosomes; fleas transmit the agents of plague, typhus, and canine tapeworm; and dipterans transmit arboviruses, malarial parasites, trypanosomes, leishmanias, filarial worms, and bacteria.

Hypersensitivity Reactions

Most serious reactions to arthropod bites and stings result from allergic hypersensitivities. Hymenopteran stings alone are responsible for most arthropod-related deaths and usually result from the development of hypersensitivity following repeated exposure to venom (Reisman, 1994). Allergies may be exacerbated following exposure to the saliva, excrement, or body parts of mites, ticks, lice, bedbugs, caterpillars, moths, and butterflies. Asthma and hay fever may also develop in response to the presence of the large variety of house, dust, and animal mites in the environment (Frazier, 1980).

Psychological Manifestations

Entomophobia refers to an unreasonable or excessive fear of seeing or touching arthropods. Although this fear may occasionally result in disruption of a person's normal activities, it rarely becomes incapacitating. Delusory parasitosis is a more serious emotional disorder in which an individual is convinced that he or she is infected with parasites or arthropods despite objective evidence to the contrary. As the delusion progresses, the individual may report loss of employment, divorce, repeated use of pesticide services, and movement from house to house. Visits to healthcare providers are usually numerous, although unsatisfactory. The problem may originate in the home or workplace and may be transferable from one to the other. The delusion may be so convincing that other family members or friends may believe it or acquire it themselves. The patient may submit to the laboratory numerous specimens such as skin, fabric, lint, hair, and mucus. It is incumbent on laboratory personnel to examine these materials to rule out true infestation. The mysterious onset of irritation and itching may be due to bites from unrecognized scabies mites, lice, fleas, or bedbugs, or from insects and mites questing from an abandoned rodent or bird nest in an area of human habitation. Before such causes are dismissed, they must be looked for and their presence excluded (Lynch, 1993; Goddard, 2007; Murray, 2007).

LABORATORY APPROACHES TO ARTHROPOD IDENTIFICATION

Arthropod specimens are often directed to the clinical laboratory by both clinicians and patients with the expectation that they can be accurately identified, but few laboratory personnel receive more than a cursory exposure to entomology during training. Nonetheless, laboratorians should have access to texts and dichotomous keys, which should allow limited identification of the more commonly encountered medically important groups, especially ectoparasites (fleas, lice, mites, and ticks). Of greater importance is the ability of laboratory personnel to recognize those rare situations in which outside expertise should be sought. This specifically relates to those occasions when significant clinical decisions regarding therapy and prognosis are being made. State or local public health laboratories often have the expertise available or know of individuals trained in medical entomology who can be reached at regional educational institutions, museums, or other public or private agencies, including the CDC.

Specimens submitted to the laboratory are most often intact organisms, skin scrapings, tissues, sputum, urine, or stool. Inanimate objects, including foodstuffs, water, clothing, bedding, and carpeting, among others, may also be submitted. It is not uncommon for patients to submit arthropods recovered from the toilet bowl following urination or a bowel movement. In most cases, the presence of such organisms is coincidental and is not related to infection.

Proper killing and preservation of arthropods is important to preserve those characteristics necessary for identification. Small, nonwinged arthropods, especially ectoparasites (lice, fleas, ticks, and mites), larval forms (maggots, grubs, and caterpillars), spiders, and scorpions, should be placed directly into 70%–80% ethyl alcohol. Large larval forms are best killed in hot (not boiling) water to extend their bodies and prevent contraction before immersion in alcohol. Attached tissue or other debris should be gently removed or washed away prior to preservation. Smaller forms (mites, small ticks, fleas, and sandflies) may be prepared as permanent slide mounts.

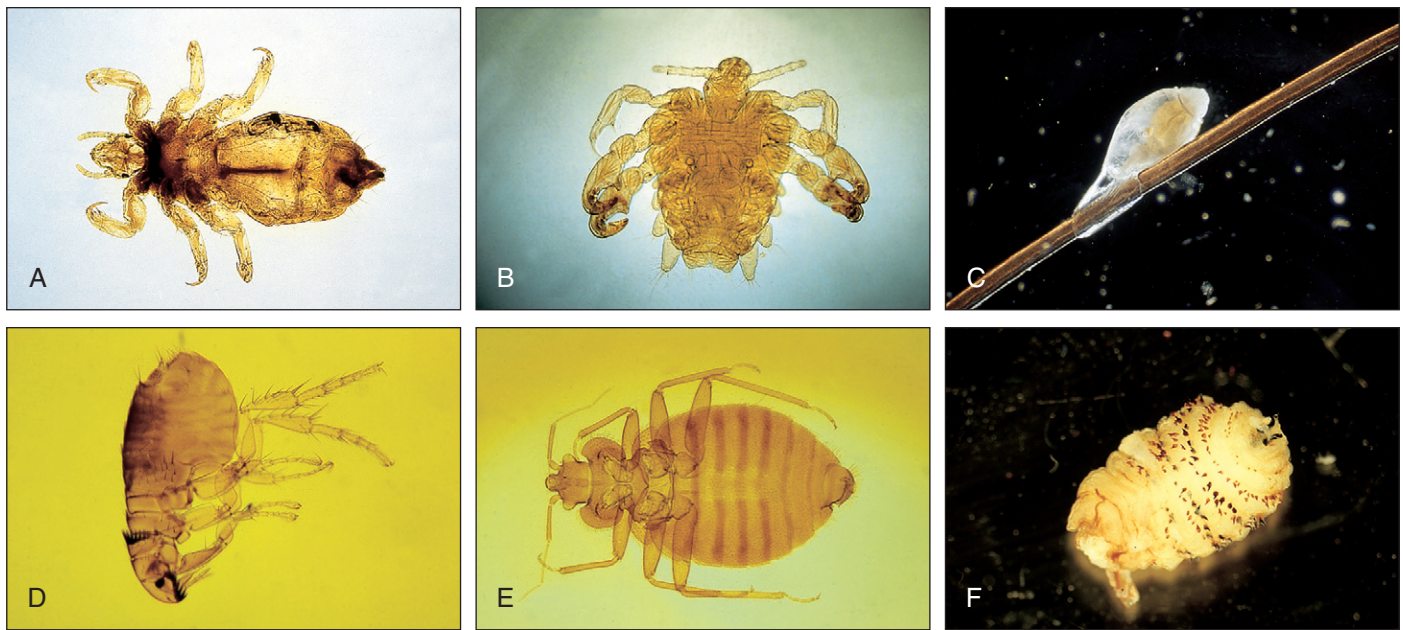

Figure 62-27 Medically important insects. **A**, *Pediculus capitis*, the head louse. **B**, *Phthirus pubis*, the crab louse. **C**, Empty egg case (nit) of *P. capitis*. **D**, *Ctenocephalides canis*, the common dog flea; note powerful hind legs. **E**, *Cimex lectularius*, the common bedbug. **F**, Larva of *Dermatobia hominis*, the human botfly; note the two sclerotized hooks at the anterior end and numerous body spines ($\times 10$). (**A**, **B**, and **E** with permission from Murray PR, Barron EJ, Pfaller MA, et al, editors. *Manual of clinical microbiology*. 6th ed. Washington, DC: ASM Press; 1995.)

Winged insects, especially adult mosquitoes, midges, and flies, should be killed by exposure to the fumes of ethyl acetate or chloroform and preserved dry to retain the taxonomic information contained in the body and wing scales. Such arthropods usually are pinned and dried, followed by storage in tight-fitting boxes protected with naphthalene or dichlorobenzene. Additional details regarding the collection, preservation, and preparation of arthropod specimens for examination are found elsewhere (Beaver, 1984; Steyskal, 1987; Lane, 1993; Garcia, 2007).

INSECTS

Insects account for more than 90% of all described arthropod species, although few are responsible for human disease. Members of this class are distinguished from other arthropods by having a body divided into three parts (head, thorax, abdomen); one pair of antennae; three pairs of legs; and one, two, or no pairs of wings. This is the only arthropod class in which flight has developed.

Sucking Lice

Sucking lice are dorsoventrally flattened, wingless insects that have characteristic claws on the ends of each leg that allow attachment to body hairs or clothing (Fig. 62-27, **A** and **B**). All species suck blood intermittently, which may cause unexplained dermatitis. Eggs, known as nits, are deposited on hair shafts or clothing, depending on the species. Although named for their primary site of attachment, they do not always remain confined to that location. The head louse, *Pediculus capitis*, and the body louse, *Pediculus humanus*, are indistinguishable from the nonspecialist. They are longer than they are wide and grow to about 3 mm in length. Biological differences are apparent; only *P. humanus* transmits the agents of epidemic typhus, trench fever, and relapsing fever (Kim, 1986). Infestations with both species occur among people living in crowded conditions who have little opportunity for bathing and laundering. Children of school age are at particular risk for acquiring head lice through the sharing of caps, clothing, and combs (Orkin, 1985). Nits of head lice are deposited primarily on hair shafts, and those of body lice are deposited on clothing. Because objects such as hair casts, dander, hair spray, and fungal hair infection may mimic nits, differentiation is important. Nits are typically 1 mm long and when unhatched have intact opercula (Fig. 62-27, **C**). Transmission occurs primarily through the sharing of infested clothing and bedding because body lice tend to lay their eggs in clusters, especially along seams or waistbands. The pubic louse, *Phthirus pubis*, is distinctly different from the others; it is rounder (measuring up to 2 mm in diameter), the abdomen is more crab-like, and the first pair of legs is significantly smaller and more slender than the other pairs (see Fig. 62-27, **B**). Pubic lice and their nits

are found primarily on pubic hairs but may extend to the chest, armpit, and facial hair. Transmission occurs primarily during sexual intercourse.

Fleas

Fleas are small (1–2 mm), laterally compressed, wingless ectoparasites capable of sucking blood (Fig. 62-27, **D**). Long, muscular legs are adapted for jumping great distances. Fleas that attack humans are parasites of other mammals or poultry and include both blood-sucking pests (many species) and tissue-penetrating jiggers. Infestations commonly occur with exposure to domestic animals and pets; the most pestiferous species are the dog flea (*Ctenocephalides canis*), the cat flea (*Ctenocephalides felis*), and the human flea (*Pulex irritans*). Some individuals become highly sensitized to flea bites, whereas others are unaffected. Cat and dog fleas are the usual intermediate hosts for the tapeworm *D. caninum* and less frequently for *H. diminuta* and *H. nana*. Because larvae of these species often develop in an animal's bedding, or in carpets and furniture, eradication may require fumigation and cleaning of those articles. The Oriental rat flea, *Xenopsylla cheopis*, is an extremely important species because it transmits the plague bacillus and the agent of murine typhus. Although normally parasitizing several species of rats, this flea readily attacks humans should the rodent host die. The jigger or chigoe flea *Tunga penetrans* is found in both Central and South America and in regions of tropical Africa. The female flea attaches to and embeds itself in the skin, especially between the toes and under the toenails, where it grows to the size of a small pea. After eggs are discharged, the flea dies, prompting an inflammatory response and possible secondary bacterial infection. Tungiasis is diagnosed by identifying the dark portion of the flea's abdomen (displaying the spiracles) protruding from the skin surface of an enlarging lesion (Beaver, 1984; Lane, 1993; Garcia, 2007; Goddard, 2007).

Cockroaches

Cockroaches have closely adapted themselves to human habitation, sharing our food, shelter, and warmth. Although they are primarily nuisance pests, cockroaches are potential carriers of fecal pathogens owing to their ability to move quickly from sewers and drains to food preparation areas. In addition to transmitting pathogenic bacteria, they may spread hepatitis and poliovirus; intestinal protozoa, including *E. histolytica*; and several species of enteric nematode. Allergies and asthma may develop in some individuals following exposure to the excreta, cast skins, or body parts of cockroaches (Goddard, 2007).

Bedbugs and Kissing Bugs

Bedbugs (family Cimicidae) and kissing bugs (family Reduviidae) are blood-sucking insects that have a long, narrow proboscis that is folded

underneath the body when not in use. Bedbugs (*Cimex lectularius* and *Cimex hemipterus*) are reddish brown, dorsoventrally flattened, wingless insects approximately 5 mm in length (Fig. 62-27, E). They are cosmopolitan in distribution and attack most any mammal, feeding primarily at night. During daylight hours, they hide under mattresses, loose wallpaper, and floorboards. Although they are not known to transmit disease, bedbug bites may cause painful weals or bullae, depending on an individual's sensitivity to their saliva.

Kissing bugs (*Triatoma*, *Rhodnius*, *Panstrongylus*) have a cone-shaped head on a narrow neck and an abdomen that is widened in the middle. These insects are black or brown, and some have orange and black markings on the abdomen. They average 1–3 cm in length and, unlike bedbugs, have well-developed wings for flight. Similar to bedbugs, kissing bugs are relatively painless feeders on vertebrates and produce similar skin reactions. In Mexico and Central and South America, they transmit the agent of Chagas' disease, *T. cruzi*, in the feces, which is secondarily inoculated into the skin by the human host while scratching (Lane, 1993; Goddard, 2007).

Bees, Wasps, and Ants

Hymenopterans are social insects that readily defend their nests when disturbed. In nonreproductive females, the ovipositor is modified as a stinger capable of injecting venom for use in the capture of prey or for defense. The venom of bees, wasps, hornets, and yellow jackets causes only transient swelling and discomfort in most individuals but may be responsible for systemic reactions, including anaphylaxis, in others who were previously sensitized (Reisman, 1994). Up to 100 people in the United States die each year from hymenopteran stings. The Africanized honey bee is now present in North America following its introduction into Brazil in 1956. These bees, which are more easily provoked than other honey bees, exhibit massive stinging behavior. Many species of ant are problematic for humans because of their ability to bite, and some groups, such as harvester and fire ants, are capable of giving painful stings.

Beetles

Although beetles are perhaps best known as pests of agricultural crops, some species may give a painful bite, and others, especially blister beetles, may exude vesicating fluids (cantharidin) that cause dermatitis or blister formation. The larvae of certain larder beetles have urticating hairs that may be responsible for dermatitis or, if ingested, irritation of the gastrointestinal tract. Larval and adult larder and grain beetles also may serve as intermediate hosts for the rodent and human tapeworms *H. diminuta* and *H. nana*.

Moths and Butterflies

Certain larvae (caterpillars) of Lepidoptera possess urticating hairs or spines capable of injecting venom when handled. Although most effects of these toxins remain localized to the skin, systemic effects such as shock and paralysis have been reported (Goddard, 2007). Adult tussock and gypsy moths are known to have urticating scales and hairs that may cause dermatitis, eye irritation, or respiratory tract irritation, especially among forestry workers (Shama, 1982).

Flies, Mosquitoes, and Midges

Diptera are characterized by the presence of a single pair of membranous wings. Among all arthropods, they are responsible for the greatest share of human disease through blood-sucking activities, biological or mechanical transmission of infectious agents, and direct tissue invasion by larval forms (myiasis). Bites from a variety of flies, mosquitoes, and biting midges often cause local irritation from sensitivity to the saliva and, in some individuals, systemic reactions. In addition to blood-sucking activities, the repeated attacks themselves may be physically and psychologically damaging. Certain blood-sucking species are also responsible for the transmission of important human pathogens, including malaria, filariasis, and arboviral disease by mosquitoes; onchocerciasis by blackflies; loiasis by deer flies; leishmaniasis and bartonellosis by sand flies; and African trypanosomiasis by tsetse flies. Other viral, bacterial, and parasitic agents are readily transmitted mechanically by nonbiting flies such as house flies, flesh flies, and blow flies, which can easily contaminate human food.

Myiasis may occur in an accidental, facultative, or obligatory fashion. The housefly, *Musca domestica*, has no requirement for developing in mammalian tissue, yet may be found occasionally in dead tissue or under plaster casts. This type of accidental myiasis is not uncommon but rarely is clinically significant. Facultative myiasis is most often caused by blowflies and

flesh flies, which ordinarily feed on dead tissues but may move into adjacent viable tissues. Obligatory myiasis is caused by certain species that develop only in living tissues. Those species that infect humans are all of zoonotic origin. The human botfly, *Dermatobia hominis*, develops in boil-like subcutaneous lesions, with the posterior end of the maggot appearing at the skin surface (Fig. 62-27, F). This species is most commonly found in individuals who have spent time in Central or South America or, less frequently, Africa, and is unusual in that its eggs are mechanically transported to the host by other flying insects, usually mosquitoes. The tumbu fly (*Cordylobia anthropophaga*), found in sub-Saharan Africa, causes a furuncular type of myiasis. Eggs of this species usually are laid on the ground or on hanging laundry, and larvae rapidly penetrate the skin on contact. The most serious obligatory myiasis is caused by the Old World screwworm, *Chrysomya bezziana*, and the New World screwworm, *Cochliomyia hominivorax*. These species lay their eggs directly on their cattle hosts, usually on wounds or near the nostrils. The larvae actively feed on and move through living tissues. Human infection may be particularly destructive if larvae invade the eye, nose, or mouth. Other species may also be responsible for traumatic, obligatory myiasis in humans (Lane, 1993).

ARACHNIDS

Medically important arachnids include scorpions, spiders, ticks, and mites. Scorpions and spiders have two body segments, the cephalothorax and the abdomen, whereas ticks and mites have only one. Members of the group have four pairs of legs as nymphs and adults; larval ticks and mites have three pairs of legs. All lack antennae, mandibles, and wings. Scorpions and spiders are best known for their ability to inject poisonous venom, whereas ticks and mites are best known as vectors for viral, bacterial, and protozoal pathogens.

Scorpions

Unlike other arachnids, scorpions have a pair of forward-directed pincer claws that impart a crab-like appearance and a segmented tail with a bulbous stinging apparatus in the tip (Fig. 62-28, A). They are predatory in nature and paralyze their intended victim with venom from the sting, which may also be used for defensive purposes. Toxicity to humans varies depending on the species; many elicit no more reaction than that of a bee sting, but some are deadly, causing more than 1000 deaths annually. Poisonous species are found in the Western Hemisphere, Europe, Africa, and the Middle East (Beaver, 1984; Goddard, 2007).

Spiders

Spiders lack a tail with an attached stinger but instead have fang-like chelicerae among their mouthparts, through which venom can be expressed. Although most spiders are venomous, few have chelicerae capable of penetrating human skin. Most spider bites cause only transitory irritation and pain. Widow spiders (genus *Lactrodectus*) are one group responsible for systemic arachnidism through the action of a potent neurotoxin capable of producing weakness, myalgia, paralysis, convulsions, and, occasionally, death. Published mortality rates vary from less than 1% to 6%. Five closely related species are found in the United States; the black widow (*Lactrodectus mactans*) is the most widespread. Female black widow spiders are glossy black with a characteristic red or orange hourglass-shaped marking on the underside of the abdomen and have a leg span of 3–4 cm. They live in protected locations such as woodsheds, basements, and outdoor privies (Strickland, 2000).

Violin spiders (genus *Loxosceles*) are responsible for necrotic arachnidism or loxoscelism. In the United States, the brown recluse or fiddleback spider (*Loxosceles reclusa*) is most often involved, although other species are present. This species is 1–2 cm long and tan to dark brown; it has a darkened, violin-shaped marking oriented base forward on the dorsum of the cephalothorax. When present in homes, violin spiders are reclusive in their habits, preferring undisturbed areas such as closets, basements, and under porches. Their bite is painless and often goes unrecognized until several hours later, when the area becomes red, swollen, and painful. The venom is dermonecrotic and hemolytic, producing cutaneous necrosis and sloughing of involved skin over several days. The resulting lesion may be difficult to heal and subject to secondary infection. Systemic reactions such as hemolysis and acute renal failure are rare. Other spider genera have also been implicated in producing necrotic arachnidism (Fisher, 1994).

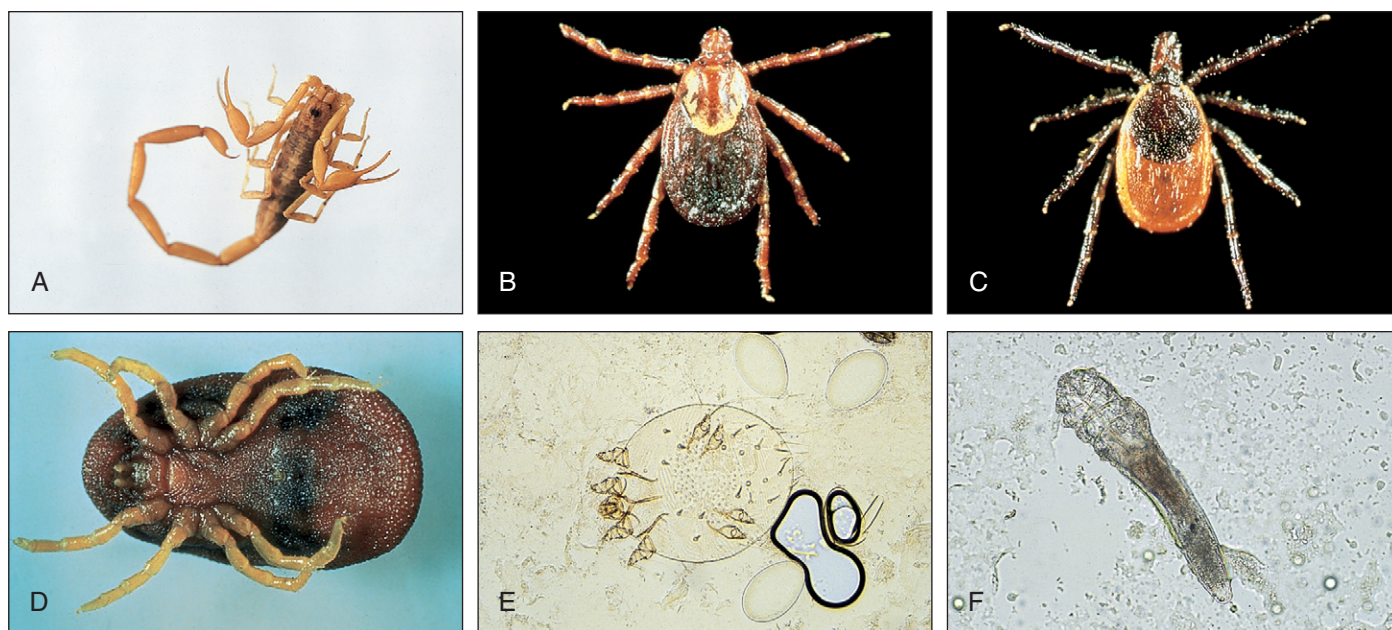

Figure 62-28 Medically important arachnids. **A**, Scorpion; note forward-directed pincher claws and stinger on the tail tip. **B**, *Dermacentor variabilis* (dog tick), nonengorged adult female. **C**, *Ixodes scapularis* (black-legged tick or deer tick), nonengorged adult female. **D**, *Ornithodoros* sp. (soft tick), nonengorged adult, ventral view. **E**, *Sarcoptes scabiei* (itch mite) adult; note presence of adjacent eggs in skin scrapings. **F**, *Demodex folliculorum* (follicle mite) adult. Washington, DC: ASM Press; 1995; **B** and **C**, with permission from Northwest Infectious Disease Consultants; **E**, with permission from Spach DH, Fritsche TR. Norwegian scabies in a patient with AIDS. *N Engl J Med* 1994;331:777.)

Ticks

Unlike spiders and scorpions, ticks have a fused cephalothorax and abdomen, as well as a characteristic toothed hypostome for feeding. Tick development progresses through four stages: egg, larva, nymph, and adult. Following hatching, a blood meal is required for progression to the subsequent stage. Humans usually acquire ticks in grassy or brushy areas in close proximity to the usual animal hosts. All species are obligate blood-sucking ectoparasites and are important vectors of viral, bacterial, and protozoal pathogens to humans and domestic animals. Their feeding activities may produce local tissue damage and blood loss, especially to livestock and wildlife, or tick paralysis, a syndrome caused by a neurotoxin secreted by a tick's salivary glands that produces ascending flaccid paralysis and toxemia. Symptoms may closely mimic those of Guillain-Barré syndrome, poliomyelitis, or botulism. Removal of the attached tick usually results in resolution of symptoms within hours to days.

Species affecting humans include members of the family Ixodidae (hard ticks) and Argasidae (soft ticks). Hard ticks have anteriorly directed mouthparts and a sclerotized plate, or scutum, on the dorsum. The scutum covers the entire dorsum in the male but only the anterior portion in the female, allowing the body to swell when engorged (Fig. 62-28, **B** and **C**). Argasid ticks have a soft leathery body lacking a scutum and ventrally directed mouthparts that are not visible when viewed from above (Fig. 62-28, **D**). Unengorged ticks are generally 2–5 mm long but may enlarge to several times that size following engorgement. Engorged hard ticks may mimic soft ticks, so care must be exercised in their identification (Sonenshine, 1991, 1993).

Most ticks found crawling on or embedded in human skin are hard ticks. Soft ticks tend to feed only briefly and then often at night. Important species of hard ticks in North America include *Dermacentor variabilis* (American dog tick), *Dermacentor andersoni* (Rocky Mountain wood tick), *Amblyomma americanum* (Lone Star tick), *Rhipicephalus sanguineus* (brown dog tick), *Ixodes scapularis* (black-legged or deer tick), and *Ixodes pacificus* (Western black-legged or deer tick). *Dermacentor* and *Amblyomma* ticks are called ornate ticks because of the presence of white markings on their scuta; the other species are inornate ticks.

Dermacentor ticks transmit Rocky Mountain spotted fever and possibly tularemia, Q fever, and Colorado tick fever. *Ixodes* ticks are vectors of Lyme disease, babesiosis, anaplasmosis, and ehrlichiosis, and in other parts of the world, these ticks are responsible for the transmission of certain arboviruses. *Amblyomma* ticks are capable of transmitting Rocky Mountain spotted fever, as well as tularemia and possibly Lyme disease. All these genera are capable of causing tick paralysis. *Rhipicephalus* ticks have been

implicated in the transmission of Rocky Mountain spotted fever and ehrlichiosis in North America, and of boutonneuse fever in the Mediterranean area. Soft ticks of the genus *Ornithodoros* occur in many parts of the world, including the United States, and are important vectors of the relapsing fever spirochetes (*Borrelia recurrentis* and related forms) (Spach, 1993; Murray, 2007; Ismail, 2010).

Mites

Mites are arachnids of microscopic size (usually <1 mm) that are widely distributed in the environment. Medically important species may attack humans directly, serve as vectors for infectious disease, or cause dust allergies. Humans are commonly infested with both *Demodex folliculorum* and *Demodex brevis*, the follicle mites, and *Sarcoptes scabiei*, the itch or mange mite. Follicle mites are minute (0.1–0.4 mm), elongate parasites with stubby legs that can be recovered from hair follicles and sebaceous glands (Fig. 62-28, **F**). They are common incidental findings on histologic skin preparations. Although their presence has been associated with various skin conditions, they are commonly found in healthy individuals as well, which makes their significance difficult to assess (Burns, 1992).

Sarcoptes scabiei mites are of greater medical importance because of their ability to create serpiginous tunnels through the upper layers of the epidermis. Transmitted through personal contact, these mites are found primarily in the interdigital spaces and the flexor surfaces of the wrists and forearms and less commonly in other areas, including the breasts, buttocks, and external genitalia. Inflammation and intense itching result from the tunneling activity and from the deposition of eggs and excreta. Clinical manifestations vary depending on the degree of sensitization to the parasites and their products. Lesions often become secondarily infected. Generalized dermatitis occurring in the presence of thousands of mites, typically in elderly or immunocompromised individuals, is known as crusted or Norwegian scabies.

The diagnosis is made by placing skin scrapings collected from tunneled areas in 20% potassium hydroxide or mineral oil for clearing and examining under the microscope. Detection of eggs, six-legged larvae, and eight-legged nymphs or adults is diagnostic but may be difficult to demonstrate (Figs. 62-28, **E**, and 62-29). The diagnosis of scabies in an institutional or school setting may result in pseudoepidemics, in which numerous individuals develop itching without evidence of disease. Care must be exercised to properly diagnose the disease to identify real cases and differentiate them from cases of delusory parasitosis (Orkin, 1985; Lynch, 1993).

A number of animal mite species may attack humans for a blood meal, either as larval forms or as adults, when normal mammalian or bird hosts

Figure 62-29 *Sarcptes scabiei*. Diagram of a subcutaneous burrow.

are not available. Larval chigger mites (family Trombiculidae) are problematic in many parts of the world because their saliva can produce large weal-and-flare reactions with intense itching. These tiny six-legged larvae are often red and commonly attach to the skin in areas where clothing is restrictive, such as at the ankles, waistline, armpits, and wrists. In parts of Asia and Australia, trombiculid mites are vectors for the transmission of the agent of scrub typhus (Lane, 1993).

Certain nonbiting mites play a role in allergic rhinitis, asthma, and some skin conditions. The secretions, excreta, and body parts of *Dermatophagoides farinae* and *Dermatophagoides pteronyssinus* are potent allergens that may occur in great numbers in the household environment (Frazier, 1980). Routine testing by an allergist may identify the offending agent.

CLASSES OF LESSER MEDICAL IMPORTANCE

Millipedes

Millipedes are worm-like arthropods with numerous apparent body segments, each with two pairs of legs; they are commonly found in and under decaying vegetation. Although they lack mouthparts capable of producing serious bites, many species produce vesicating secretions from glands located on each body segment. When handled roughly, the larger tropical

species are capable of squirting these fluids over a distance of several centimeters. Exposure of the skin or mucous membranes to these fluids may produce a burning sensation and blister formation.

Centipedes

Centipedes are flatter than millipedes, have only one pair of legs per body segment, and display long antennae. They are fast moving and can inflict a painful sting from a pair of forward-directed pincers that are modified from the first pair of legs. Although they are rarely responsible for serious injury to humans, the larger species (26–45 cm) found in the southern United States and in tropical regions are able to penetrate human skin when handled, giving a painful, burning sting with local tissue reaction. Although systemic reactions may occur in individuals who have been previously sensitized, fatalities are rare (Goddard, 2007).

Crustaceans

Crustaceans of medical importance are primarily those species that serve as hosts for larval stages of several different helminths. Several genera of crabs and crayfish are intermediate hosts for the metacercariae of various species of lung fluke (*Paragonimus* spp.) found around the world. Copepods are common microscopic zooplankton, certain species of which serve as first intermediate hosts for the nematodes *D. medinensis* and *Gnathostoma spinigerum* and for cestodes of the genera *Diphyllotrichium* and *Spirometra*.

Pentastomids

Pentastomes, or tongue worms, are arthropods of uncertain affinities owing to lack of morphologic characteristics. Adult stages are worm-like organisms that live in the nasal passages of certain predatory reptiles, birds, and mammals. Larval stages resemble mites and reside in rodents, herbivores, and freshwater fish. Human liver and lung infections with larval stages have been reported from Asia and Africa. Adult stages have been recovered from the nasopharynx of individuals from the Middle East and Africa, where they are responsible for an obstructive condition known as halzoun (Beaver, 1984; Strickland, 2000; Garcia, 2007).

PARASITIC INFECTIONS AND THE IMMUNOCOMPROMISED HOST

Immunocompromised hosts are hosts that have abnormalities in their humoral or cellular immune systems resulting from disease, therapy, or congenital abnormality. Severe malnutrition may also compromise host defenses. In most instances, the predisposing host abnormalities are primarily of the cellular (T cell) immune system and result from AIDS, malignancy, chemotherapy of malignancy, immunosuppression for transplantation, corticosteroid therapy, or a combination of these. The predisposing immune defect for giardiasis is with humoral immunity and for babesiosis it is with splenectomy.

With the worldwide epidemic of HIV infection and AIDS being particularly severe in underdeveloped countries with a high incidence of parasitic infection such as malaria, schistosomiasis, ascariasis, amebiasis, and filariasis, it is fortunate that these infections do not cause particularly severe disease in AIDS patients; however, as comorbidities their contribution to healthcare costs is enormous.

Some parasitic infections such as cryptosporidiosis, toxoplasmosis, and strongyloidiasis are more severe in immunocompromised hosts, but there are differences depending upon the type of immunosuppression. For example, although cryptosporidiosis and toxoplasmosis are particularly problematic in AIDS patients, strongyloidiasis is not a major problem in this population, but it is a problem in transplant recipients and patients receiving antineoplastic chemotherapy.

Table 62-13 lists parasitic infections that are more severe and/or frequent in immunocompromised patients. Clinical manifestations may be different from those seen in the general population, as is noted in the comment section.

TABLE 62-13

Parasitic Infections in Compromised Hosts

Infection	Predisposing host abnormalities	Comments	References
Intestinal Protozoa			
Cryptosporidiosis	AIDS (especially CD4 ⁺ <200/μL), transplantation, antineoplastic chemotherapy	Severe protracted diarrhea (up to 17 L/day). May have extraintestinal involvement, including pancreas, biliary tract, and lungs. Limited therapy available, is not curative.	Wittner, 1993 Thielman, 1998
Cystisporiasis	AIDS, transplantation, antineoplastic chemotherapy	Severe protracted diarrhea. Extraintestinal involvement of regional lymph nodes may be seen. Effective therapy is available.	Wittner, 1993 Thielman, 1998
Cyclosporiasis	AIDS, probably other immunosuppression	Severe protracted diarrhea clinically similar to cryptosporidiosis and isosporiasis. Responds to trimethoprim-sulfamethoxazole.	Wittner, 1993 Thielman, 1998
Microsporidiosis	AIDS, other severe immunosuppression	Various syndromes: 1. Multisystem disease 2. Enteritis with severe diarrhea (most frequent) 3. Ocular infection 4. Hepatobiliary with granulomas, hepatic necrosis, or cholangitis 5. Skeletal muscle disease Examination of urinary sediment with appropriate stain may allow diagnosis of nonenteric syndromes and some cases of enteric disease.	Wittner, 1993 Thielman, 1998
Giardiasis	Common variable immunodeficiency, X-linked agammaglobulinemia	Prolonged diarrhea with malabsorption. AIDS is not a predisposing condition.	Thielman, 1998
Blood and Tissue Protozoa			
Granulomatous amebic encephalitis	AIDS and other immunocompromised states	Usually caused by amebae of the genera <i>Acanthamoeba</i> or <i>Balamuthia</i> . Produces subacute or chronic central nervous system infection but may be acute in severely immunosuppressed hosts with dissemination	Martinez, 1997
Toxoplasmosis	AIDS with CD4 ⁺ usually <100/μL and other immunocompromised states; heart transplant, donor seropositive and recipient seronegative	Usually result of reactivation of cysts from previous infection. Often disseminated disease with multiorgan involvement or multifocal central nervous system lesions. Can cause pneumonitis resembling that caused by <i>Pneumocystis jiroveci</i> . May cause chorioretinitis. Can occur after transplantation of bone marrow but usually mild. Heart transplant with donor serologically positive and recipient serologically negative may lead to severe, often fatal toxoplasmosis.	McCabe, 1993
Leishmaniasis	AIDS, other immunosuppression	Limited influence on cutaneous leishmaniasis. Susceptibility to visceral leishmaniasis increased, but not disease severity. More likely to relapse after treatment.	Herwaldt, 1999
American trypanosomiasis (Chagas' disease)	AIDS, lymphoblastic lymphoma, cardiac transplantation, other immunosuppression	In AIDS, central nervous system often involved, myocarditis, skin lesions.	Mileno, 1998 Markell, 1999
Babesiosis	Splenectomy	Usually subclinical infection in those with intact host defenses. Splenectomized patients usually develop clinically evident disease, which can be fatal.	Mileno, 1998 Markell, 1999
Helminth			
Strongyloidiasis	Immunosuppression for transplantation or by cancer chemotherapy or adrenal corticosteroids or lymphoma. AIDS is not a major predisposing factor	Because of endogenous autoinfection, hyperinfection or disseminated infection can develop and present as pneumonia or severe intestinal disease. Gram-negative sepsis or gram-negative meningitis can result from translocation of intestinal bacteria via invading larvae. Should check for strongyloidiasis before immunosuppressing patient from highly endemic areas.	Mileno, 1998 Markell, 1999
Arthropod			
Scabies	Malignancy, transplant immunosuppression, antineoplastic therapy	AIDS leads to "Norwegian" or crusted scabies with widespread involvement by thick, crusted lesions. Sometimes has severe itching. Patient has numerous mites and is therefore highly contagious. Often less responsive to therapy.	Mileno, 1998 Markell, 1999

AIDS, Acquired immunodeficiency syndrome.

KEY POINTS

- Collect specimens from site of infection before initiating therapy.
- Collect adequate volume of sample for testing required.
- For all cultures, tissue, fluid, or aspirate material is always superior to a swab specimen.
- Use required collection and transport materials to preserve specimen integrity.
- Communicate clear orders and source information.
- Expedite the transport of specimens to the laboratory and do not allow them to sit in collection areas.

Appropriate specimen collection, transport, and processing are crucial preanalytical steps in the accurate diagnosis of infectious diseases. Guidelines for specimen handling are discussed in this chapter. General principles are reviewed first, followed by discussion of the most common types of specimens submitted to the clinical microbiology laboratory for testing.

GENERAL PRINCIPLES

TIMING OF SPECIMEN COLLECTION

For optimal detection of the pathogens responsible for an infectious disease, specimens should be collected at a time when the likelihood of recovering the suspected agent is greatest. For example, the likelihood

of recovering most viruses is greatest in the acute phase of the illness. Specimens for recovery of bacteria should ideally be collected before antimicrobial therapy is started.

SPECIMEN VOLUME

The volume of specimen collected must be adequate for performance of the microbiological studies requested. If insufficient volume is received, the health care worker caring for the patient should be notified; either additional sample can be obtained or the physician must prioritize the requests. If a swab is used to collect the specimen, a polyester-tipped swab on a plastic shaft is acceptable for most organisms. Calcium alginate should be avoided for collection of samples for viral culture, because it could inactivate herpes simplex virus (HSV); cotton may be toxic to *Neisseria gonorrhoeae*; and wooden shafts should be avoided, because the wood may be toxic to *Chlamydia trachomatis*. Swabs are not optimal for detection of anaerobes, mycobacteria, or fungi, and they should not be used when these organisms are suspected. An actual tissue sample or fluid aspirate is always superior to a swab specimen for the recovery of pathogenic organisms.

SPECIMEN COLLECTION

Specimens should be obtained from the site of infection with minimal contamination from adjacent tissues and organ secretions and, with the exception of stool, should be collected in a sterile container. All specimens should be labeled with the name and identification number of the person from whom the specimen was collected, the source of the specimen, and the date and time it was collected.

SPECIMEN TRANSPORT

After collection, specimens should be placed in a biohazard bag and transported to the laboratory as soon as possible. If a delay is unavoidable, urine, sputum and other respiratory specimens, stool, and specimens for detection of *C. trachomatis* or viruses should be refrigerated to prevent overgrowth of normal flora. Cerebrospinal fluid (CSF) and other body fluids, blood, and specimens collected for recovery of *N. gonorrhoeae* should be held at room temperature, because refrigeration adversely affects recovery of potential pathogens from these sources.

UNACCEPTABLE SPECIMENS

Each laboratory director must establish criteria for rejecting specimens unsuitable for culture. Most clinical microbiologists agree that the following specimens should be rejected:

- Any specimen received in formalin
- 24-hour sputum collections
- Specimens in containers from which the sample has leaked
- Specimens that have been inoculated onto agar plates that have dried out or are outdated
- Specimens contaminated with barium, chemical dyes, or oily chemicals
- Foley catheter tips
- Duplicate specimens (except blood cultures) received in a 24-hour period
- Blood catheter tips submitted for patients without concomitant positive blood culture

The following specimens should be rejected for anaerobic culture:

- Gastric washings
- Urine other than suprapubic aspirate
- Stool (except for recovery of *Clostridium difficile* for epidemiologic studies or for diagnosis of bacteria associated with food poisoning)
- Oropharyngeal specimens, except deep tissue samples obtained during a surgical procedure
- Sputum
- Swabs of ileostomy or colostomy sites
- Superficial skin specimens

UNIVERSAL PRECAUTIONS

Universal precautions must be followed when handling all specimens. Appropriate barriers are used to prevent exposure of skin and mucous membranes to the specimen. Gloves and a lab coat must be worn at all

times, and masks, goggles (or working behind a plastic shield), and impermeable gowns or aprons must be worn when there is risk of splashes or droplet formation. Optimally, all specimen containers but, at a minimum, those containing respiratory secretions and those submitted specifically for detection of mycobacteria or fungi should be opened in a biological safety cabinet. Specimens collected for virus isolation should be handled in a biological safety cabinet to prevent contamination of the cell cultures.

REFERRAL TESTING

When specimens or cultures must be shipped to a reference laboratory, they must be packaged according to dangerous goods shipping guidelines (see International Air Transport Association website). Specimens must be limited to no more than 40 mL. Cultures of bacteria and fungi should be grown on solid media in tubes. The cap of the primary container (tube or vial) should be sealed with waterproof tape and inserted into a second container, surrounded by sufficient packing material to absorb the entire volume of the culture or specimen if the primary container were to leak or break. If several primary tubes are placed in a second container, they must be either individually wrapped or separated so as to prevent contact between them and there must be secondary packaging, which must be leakproof. The second container should be capped and placed in a shipping container made of corrugated fiberboard or hard plastic. An itemized list of contents must be enclosed between the secondary and outer packaging. The secondary and outer containers should be of sufficient strength to maintain their integrity at temperature and air pressures to which they will be subjected. If a specimen must be shipped on dry ice (which is considered to be a hazardous material), it must be marked "Dry ice, frozen medical specimen." The dry ice should be placed outside the second container with the packing material in such a way that the container does not become loose inside the outer container as the dry ice evaporates. All infectious shipping packages must be labeled with an official label containing the address and contents as well as the name and telephone number of the person responsible for the shipment.

BLOOD

Detection of blood-borne pathogens is one of the most important functions of the microbiology laboratory. Culture of blood is essential in identifying bacteria responsible for bacteremia, sepsis, infections of native and prosthetic valves, suppurative thrombophlebitis, mycotic aneurysms, and infections of vascular grafts. Blood cultures also are useful in diagnosing invasive or disseminated infections caused by certain fungi, especially species of *Candida*, *Cryptococcus neoformans*, species of *Fusarium*, and *Histoplasma capsulatum*. Parasites are detected in blood by microscopic examination of peripheral smears. In general, blood should be collected for culture before beginning antimicrobial therapy when any one or a combination of the following are present: fever (38° C or greater), hypothermia (36° C or lower), leukocytosis (especially with a left shift), granulocytopenia, or hypotension.

SPECIMEN COLLECTION

Timely detection and accurate identification of organisms in the blood depend on appropriate collection, transport, and processing of the specimen. Germane to the detection of all microorganisms in the blood is the phlebotomy technique. To minimize contamination of blood specimens by skin flora, the venipuncture site should be prepared with a bactericidal agent. The skin first is cleaned with alcohol (70% isopropyl or ethyl alcohol) and then with a 1–2% iodine solution, an iodophor, or chlorhexidine. For maximum antisepsis, the area should dry for 1–2 minutes before venipuncture of the selected peripheral vein.

APPROPRIATE TIMING FOR DETECTION OF BACTEREMIA AND FUNGEMIA

The optimal time to draw blood for cultures when bacteremia or fungemia is suspected is just before a chill but, because this is not predictable, most blood cultures are collected after the onset of fever and chills. Blood is drawn with a needle and syringe and, without changing needles, is injected directly into bottles of culture media or other blood culture system (Krumholz, 1990). The inoculated bottles are immediately inverted several times to ensure mixing, and then they are transported to the laboratory at

room temperature as soon as possible after collection. Blood cultures should never be refrigerated.

SPECIMEN VOLUME

In adults with bacteremia, the number of colony-forming units (CFU) per milliliter of blood is frequently low. Therefore, for adults, collecting 20–30 mL of blood per culture set is strongly recommended (Ilstrup, 1983; Washington, 1986; Towns, 2002; Cockerill, 2004). In infants and children, the concentration of microorganisms in blood is higher, and collection of 1–5 mL of blood per culture is adequate.

SPECIMEN DRAWS

Recommendations concerning the number of blood specimens to collect are based on the nature of the bacteremia: transient, intermittent, or continuous. Transient bacteremia follows manipulation of a focus of infection (e.g., an abscess, a furuncle, or cellulitis), instrumentation of a contaminated mucosal surface (as occurs during dental procedures, cystoscopy, urethral catheterization, suction abortion, or sigmoidoscopy), or a surgical procedure in a contaminated site (e.g., transurethral resection of the prostate, vaginal hysterectomy, colon resection, and debridement of infected burns). Transient bacteremia also occurs early in the course of many systemic and localized infections such as meningitis, pneumonia, pyogenic arthritis, and osteomyelitis. Most intermittent bacteremias are associated with an undrained abscess, whereas continuous bacteremia is the hallmark of intravascular infection, such as bacterial endocarditis, mycotic aneurysm, or an infected intravascular catheter. Continuous bacteremia also occurs during the first few weeks of typhoid fever and brucellosis.

The optimal number of blood cultures for detection of bacteremia in patients without endocarditis is controversial. Most authorities agree that two or three 20-mL blood samples drawn over a 24-hour period and equally distributed into aerobic and anaerobic blood culture bottles is sufficient to detect most bloodstream infections. One investigator demonstrated that a total of four blood cultures drawn within 24 hours increased the yield of potential pathogens by as much as 20% (Cockerill, 2004). The optimal time interval between cultures is unknown, but 30–60 minutes for the first two sets has been suggested, with another one to two sets drawn over the remaining 24 hours if symptoms of septicemia persist (Cockerill, 2004). However, if initiation of antimicrobial therapy is deemed urgent, cultures should be collected before therapy is begun, from separate sites within a few minutes.

Organisms such as the coagulase-negative staphylococci, viridans streptococci, corynebacteria, *Bacillus* species, and *Propionibacterium* species are frequent blood culture contaminants but may also be true pathogens. Collecting two sets of blood cultures per febrile episode helps distinguish probable pathogens from contaminants. The latter are generally present in only one bottle of one set of cultures, whereas pathogens are typically recovered from more than one set.

RECOVERY OF MICROORGANISMS

Host factors such as antibodies, complement, phagocytic white blood cells, and antimicrobial agents may impede recovery of microorganisms from blood; therefore, various approaches have been used to counteract these factors. Diluting the blood specimen in broth medium in a 1:10 ratio provides optimal neutralization of the serum bactericidal activity (Washington, 1986). Incorporating 0.02–0.05% sodium polyanethol sulfonate in the blood culture medium inhibits coagulation, phagocytosis, and complement activation, and inactivates aminoglycosides. Methods that counteract the presence of antimicrobial agents include using antibiotic-adsorbent resins or the lysis–centrifugation system (see later).

BLOOD CULTURE SYSTEMS

Several blood culture systems, each with advantages and disadvantages, are available (Wilson, 1996; Reimer, 1997). Automated detection systems are rapidly replacing manual systems. Both automated and manual systems use nutritionally enriched liquid media, which are capable of supporting growth of most bacteria. Traditionally, two bottles are inoculated, and one is vented to ensure recovery of aerobes. Given the decline in anaerobic bacteremias, this practice of one aerobic and one anaerobic bottle per set has been questioned (Sharp, 1991; Murray, 1992). Routine inoculation of two aerobic media and only selective use of anaerobic blood cultures may allow detection of more bacteremias and fungemias.

Manual Blood Cultures

Two commercial manual blood culture systems are available. One is a biphasic system, consisting of a broth medium in a bottle to which a chamber containing agar media on a paddle is attached. To subculture this system, the bottle is tipped, allowing the blood–broth mixture to enter the chamber and flow over the agar media. Colonies on the agar medium are used for identification and susceptibility testing. For recovery of aerobic and facultative bacteria and yeasts, this system is comparable to or better than other systems (Murray, 1991).

The lysis–centrifugation blood culture system consists of a tube containing reagents that inhibit coagulation and the complement cascade, lyse blood cells, and provide a cushion for the microorganisms during centrifugation. Blood is added to the tube, which is inverted several times to prevent clotting and transported to the laboratory as soon as possible. Ideally, the specimen is processed immediately, but processing can be delayed for up to 8 hours without adversely affecting recovery of microorganisms. To process the culture, the tube is centrifuged for 30 minutes at 3000 g, the supernatant is discarded, and the sediment is mixed on a vortex mixer and plated onto agar media. Smaller tubes for low-volume samples, from infants and young children, are also available. Advantages of lysis–centrifugation include excellent recovery of *Staphylococcus aureus*, some Enterobacteriaceae, and fungi (it is the best system for recovery of *H. capsulatum*), the direct availability of colonies for identification and susceptibility testing, and the ability to carry out quantitative cultures. Moreover, this system is flexible because special media can be inoculated to recover organisms with specific growth requirements, such as species of *Legionella* and mycobacteria. However, the system is labor-intensive, is less likely to recover *Streptococcus pneumoniae*, *Haemophilus influenzae* or anaerobes, and the risk for contamination is increased.

Automated Blood Culture Systems

Several automated continuously monitoring blood culture systems are available commercially (Wilson, 1996). All such systems are much less labor-intensive than the “manual” systems described above. Additionally, with these systems the usual incubation period can be shortened from 7 to 5 days (Woods, 1994; Reisner, 1999). One such system is based on the colorimetric detection of carbon dioxide (CO₂) produced during microbial growth (Thorpe, 1990). A CO₂ sensor is bonded to the bottom of each blood culture bottle and is separated from the broth medium by a membrane that is impermeable to most ions and to components of media and blood but freely permeable to CO₂. Inoculated bottles are placed in cells in the instrument, which provides continuous rocking of both aerobic and anaerobic bottles. If bacteria are present, they generate CO₂, which is released into the broth medium; the pH then decreases, causing the sensor to change color from green to yellow. Color changes are monitored once every 10 minutes by a colorimetric detector. Media available for use with this system include routine aerobic and anaerobic media, which accommodate 5–10 mL of blood; Pedi-BacT, which accommodates 4 mL of blood or less; and fastidious antibiotic neutralization, which enhances recovery of fungi and recovery of bacteria from patients receiving antimicrobial agents.

A second continuous-monitoring system is based on fluorescent technology (Nolte, 1993). Bonded to the base of each vial is a CO₂ sensor that is impermeable to ions, medium components, and blood but freely permeable to CO₂. If organisms are present, they release CO₂ into the medium; it then diffuses into the sensor matrix and generates hydrogen ions. The subsequent decrease in pH increases the fluorescence output of the sensor, changing the signal transmitted to the optical and electronic components of the instrument. The computer generates growth curves, and data are analyzed according to growth algorithms. Inoculated bottles are placed in individual cells of the instrument, in which both aerobic and anaerobic bottles are continuously rocked. Aerobic and anaerobic low-volume (5–7 mL of blood) and high-volume (8 to 10 mL of blood) media, Peds-Plus medium (0.5 to 5 mL of blood), and the Myco F Lytic medium for recovery of fungi and mycobacteria are available (Waite, 1998).

A third system detects growth of organisms in broth by measuring gas consumption and/or gas production (Zwadyk, 1994). Each inoculated vial is fitted with a disposable connector that contains a recessed needle. The needle penetrates the bottle stopper and connects the bottle headspace to the sensor probe. The sensor monitors changes within the headspace in the consumption and/or production of all gases (CO₂, N₂, and H₂) by growing organisms and creates data points internally in the computer. Two basic types of medium are available: aerobic and anaerobic media that contain 80 mL of broth and accommodate 0.1–10 mL of blood, and EZ

Draw (direct draw) aerobic and anaerobic bottles that contain 40 mL of broth and accommodate 0.1–5 mL of blood.

DETECTION OF RARELY ENCOUNTERED BACTERIA

Detection of some bacteria requires prolonged incubation or special media. For example, when brucellosis is suspected, blood should be collected early in the disease and cultures should be incubated for 2–3 weeks, although with the automated systems brucellas often grow in less than 1 week (Bannatyne, 1997). Infections with species of *Borrelia*, except *Borrelia burgdorferi* (the etiologic agent of Lyme disease, most commonly diagnosed serologically), are diagnosed by detecting spirochetes in the peripheral blood during febrile periods. Organisms are visualized in wet preparations made by mixing a drop of blood with a drop of sodium citrate, and examining it with light- or dark-field microscopy, and in thin and thick blood films stained with Wright's or Giemsa stains, examined by light microscopy. To isolate *Leptospira interrogans* from blood, a few drops of fresh or anticoagulated blood collected during the first week of illness are added to each of three to four tubes of leptospiral semisolid culture medium (Fletcher's medium or Ellinghausen–McCullough–Johnson–Harris medium).

Two methods may be used to recover mycobacteria from blood specimens. With the lysis–centrifugation technique, (1) a concentrate is prepared, (2) the sediment is inoculated to solid and/or liquid media, and (3) the cultures are incubated for up to 8 weeks. An alternative and perhaps more rapid approach is direct inoculation of the liquid medium developed by the manufacturer of automated and semiautomated broth culture systems specifically for recovery of mycobacteria.

DETECTION AND NOTIFICATION OF POSITIVE CULTURES

Positive blood cultures containing commonly isolated aerobic organisms are usually detected within 12–36 hours of incubation. The initial report is a Gram stain report only. Identification and susceptibility results can be expected within 24–48 hours after the Gram stain report. Cultures containing anaerobes are usually not detected for 48–72 hours, and identification is not available for 3–4 days after that. Fastidious organisms, such as those found in the HACEK group (*Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, *Kingella*) may not be detected until 3–5 days.

Detection of Viruses

With regard to viruses, blood specimens are most commonly collected to monitor response of infection with human immunodeficiency virus (HIV), hepatitis C virus (HCV), hepatitis B virus (HBV), or cytomegalovirus (CMV) to antiviral therapy by using quantitative polymerase chain reaction (PCR) to measure viral load. Such assays are commercially available for each of these viruses, and in all cases manufacturer's guidelines for specimen collection and transport should be followed. For HIV and HCV, blood specimens also may be collected for genotyping (commercial assays are available), and PCR (qualitative or quantitative PCR) generally is used to confirm an initial positive HCV antibody result. As with viral load, manufacturer's guidelines regarding specimen collection and transport should be followed.

In addition to assessing response to antiviral therapy, measuring viral load in a blood specimen is useful for monitoring for development of disease and for diagnosis of disease in specific situations. In immunocompromised patients, especially transplant recipients but also patients with acquired immunodeficiency syndrome (AIDS), determining the level of CMV deoxyribonucleic acid (DNA) in blood is used to predict those at high risk for development of CMV disease and direct the initiation of preemptive therapy (Herrmann, 2004; Kalpoe, 2004; Meyer-Koenig, 2004; Lugert, 2009). Monitoring the level of Epstein-Barr virus (EBV) DNA in serum or plasma by quantitative PCR is indicated in transplant recipients at high risk for EBV-associated lymphoproliferative disease (Rowe, 2001). Quantitative PCR from whole blood or peripheral blood mononuclear cells is useful for diagnosis of disease due to HHV-6 or HHV-7 in transplant recipients and is the test of choice for diagnosing disease caused by parvovirus B19 in immunosuppressed patients or in the fetus. If a commercial quantitative PCR assay is used, guidelines for specimen collection and transport should be followed. If, on the other hand, an assay developed

TABLE 63-1

Infectious Meningitis Syndromes

Syndrome	Onset/Duration	Probable Pathogens
Acute	<24 hours	Pyogenic bacteria
Subacute	1–7 days	Enteroviruses, pyogenic bacteria
Chronic	Persisting at least 4 weeks	<i>Mycobacterium tuberculosis</i> <i>Treponema pallidum</i> <i>Brucella</i> sp. <i>Leptospira interrogans</i> <i>Borrelia burgdorferi</i> <i>Cryptococcus neoformans</i> <i>Coccidioides immitis</i> <i>Histoplasma capsulatum</i>

and validated in-house is used, guidelines published by that laboratory should be followed.

Detection of Parasites

Blood specimens are useful for diagnosis of malaria, babesiosis, trypanosomiasis, and some filariasis (Rosenblatt, 2009). Specimens should be collected in tubes with anticoagulant and transported promptly to the laboratory. If smears must be sent to a reference laboratory, they should be fixed in absolute alcohol soon after they are made. The techniques used in the laboratory for detecting the aforementioned parasites are the same and are discussed here in order of the simplest to the most complicated.

The simplest technique for detecting parasites in a sample of blood is the direct mount, prepared by placing one drop of blood on a glass slide, covering it with a cover glass, and examining it immediately. Direct mounts are excellent for diagnosis of trypanosomiasis or filariasis because the trypomastigotes and the microfilariae easily can be seen moving, often with low or medium power. The definitive diagnosis is made by staining smears.

The thin smear, made as for hematologic work and stained in a similar manner, is the standard preparation for determining the species of *Plasmodium*, *Babesia*, *Trypanosoma*, and microfilaria found. Thin smears for parasitologic work are fixed and then preferably stained manually with Giemsa stain, but automated hematologic staining is adequate. Smears are first scanned at low power to detect microfilariae, which are large objects (between 100 and 200 μ m) and easily seen, usually at the lateral edges of the smear. After they are located, microfilariae should be studied under oil immersion for identification. Following scanning with low power, the smear is examined with a high dry objective, searching for trypanosomes; and finally under oil immersion, to find and identify *Plasmodium*, *Babesia*, and *Trypanosoma*.

Thick smears are useful for detecting all the parasites mentioned earlier, and are part of the minimum laboratory work-up for their diagnosis. A drop of blood is placed on a clean glass slide and, with the corner of another slide, is gently spread to cover 1 cm square. The preparation is allowed to dry and without fixation is stained with Giemsa stain, allowing for its dehemoglobinization.

BODY FLUIDS

CEREBROSPINAL FLUID

CSF is collected to diagnose meningitis and, less frequently, viral encephalitis. Infectious meningitis, a medical emergency requiring early therapy to prevent death or serious neurologic sequelae, is divided into acute, subacute, and chronic clinical syndromes, based on duration of symptoms. Potential pathogens are listed in Table 63-1. Enteroviruses are the agents most commonly responsible for meningitis, and they should be considered first in the differential diagnosis of meningitis in a child or adolescent during the late summer and early fall. The pyogenic bacteria responsible for meningitis vary with the age of the affected individual (Table 63-2).

Sample Collection and Transport

CSF is usually obtained by lumbar spinal puncture but sometimes it is aspirated from the ventricles or collected from a shunt. As when collecting blood for culture, careful skin antisepsis is essential for collection of CSF, which typically is submitted to the laboratory in three or occasionally four tubes. Suggestions for tests performed on fluid in each tube are as follows: tube 1, protein and glucose; tube 2, preparation of

TABLE 63-2

Common Bacterial Causes of Acute Meningitis by Age

Age	Organisms
Neonates–3 months	Group B streptococcus <i>Escherichia coli</i> <i>Listeria monocytogenes</i> * <i>Streptococcus pneumoniae</i>
4 months–6 years [†]	<i>Streptococcus pneumoniae</i>
6–45 years	<i>Neisseria meningitidis</i>
>45 years	<i>Streptococcus pneumoniae</i> <i>Listeria monocytogenes</i> Group B streptococcus

*May cause meningitis in immunocompromised individuals in all age groups.

[†]Incidence of meningitis due to *Haemophilus influenzae* type b in the United States has declined dramatically as a result of vaccination.

TABLE 63-3

Normal Cerebrospinal Fluid Parameters and Changes in Infectious Meningitis

Condition	WBCs (cells/ μ L)*	Protein (mg/dL)	Glucose (mg/dL)
Normal	5 (lymphocytes)	14–45	45–100 (2/3 serum)
Meningitis			
Acute/subacute bacterial	500–200,000 (PMNs)	↑	↓
Chronic bacterial	200–2,000 (lymphocytes)	↑	↓
Tuberculous, fungal		↑	↓
Enteroviral	200–2,000 (PMNs early; lymphocytes later)	↑	Normal

↑, Increased; ↓, decreased; PMNs, polymorphonuclear leukocytes; WBC, white blood cells.

*Cell type listed usually predominates.

smears to stain with the Gram stain or other stains and for culture; tube 3, cell counts; and, if indicated, tube 4, special tests such as the cryptococcal antigen, serologic test for syphilis, molecular tests or other serologic studies, and cytology. The parameters of normal CSF and the usual changes that occur during meningitis caused by different organisms are listed in Table 63-3.

CSF should be transported promptly to the laboratory and processed as rapidly as possible. If a brief delay in processing is unavoidable, the specimen should be held at room temperature unless viral culture is requested, in which case a portion (preferably 1 mL but no less than 0.5 mL) may be refrigerated for a short time. Specimen processing differs for bacteria, fungi, viruses, and parasites and is discussed separately for each group of organisms.

Sample Processing for Bacterial and Fungal Culture

Processing CSF for routine bacterial culture includes concentration (if 1 mL or more of specimen is received), preparation of a smear by cyto-centrifugation for staining with Gram stain, and culture. Concentrate the fluid by centrifugation at a minimum of 1500 g for 15 minutes. The supernatant is decanted into a sterile tube, leaving about 0.5 mL of sediment and fluid, which is thoroughly mixed on a vortex mixer or by forcefully aspirating up and down into a sterile pipette.

Diagnosis of chronic bacterial meningitis requires specific requests because the CSF is handled differently for each entity. To diagnose brucellosis, the CSF is processed as described earlier for routine bacterial culture, but the media are incubated for 2–3 weeks. For leptospirosis, *Leptospira interrogans* may be cultured from the CSF during the first few weeks of illness. Special media (listed earlier under blood) are inoculated with a few drops of CSF and incubated as outlined in Chapter 57. The diagnosis of neurosyphilis is based on the following findings in the CSF: pleocytosis, elevated protein concentration, and a positive Venereal Disease Research

Figure 63-1 India ink preparation of cerebrospinal fluid shows encapsulated yeast forms of *Cryptococcus neoformans*. (x400)

Laboratory (VDRL) test (CSF VDRL), which currently is the only useful method for detecting antibodies to *Treponema pallidum* in the CSF (see Chapter 59). The CSF VDRL test is indicated only if the person has a positive serum test for syphilis (Albright, 1991a). The specimen should be refrigerated until it is tested. Involvement of the central nervous system by *B. burgdorferi* (Lyme disease) also is diagnosed serologically, by detection of specific IgM and IgG antibodies in CSF and serum.

Processing CSF for detection of mycobacteria is indicated only for samples with pleocytosis, or decreased glucose, or elevated protein values (Albright, 1991b). For optimal recovery, culture of at least 5 mL is recommended. The fluid is centrifuged at 3000–3600 g for 30 minutes, the supernatant is decanted, and the sediment is thoroughly mixed on a vortex mixer and used to prepare smears for staining and to inoculate appropriate media (see Chapter 60). Nucleic acid amplification, using a modification of a commercial assay or an assay developed in-house and validated, may be useful for direct detection of *Mycobacterium tuberculosis* complex in CSF (Cloud, 2004).

Processing CSF for detection of fungi is similar to that described for detecting bacteria. Organisms are concentrated by filtration or by centrifugation. A cyto-centrifuge preparation or a smear of the sediment stained with the Gram stain is examined, and appropriate media (e.g., brain–heart infusion or SABHI agar without antibiotics) are inoculated for culture.

Additional Diagnostic Tests

In addition to smears stained with the Gram stain and bacterial culture, the supernatant of a centrifuged specimen or the original fluid may be used to perform latex agglutination tests for detection of antigens of *Streptococcus agalactiae*, *S. pneumoniae*, some serotypes of *Neisseria meningitidis*, *Escherichia coli* (the K1 capsular antigen cross-reacts with that of *N. meningitidis* type B), and *H. influenzae* type b. These latex tests are most useful in diagnosing partially treated meningitis (Bhisitkul, 1994; Maxson, 1994) and in confirming a positive Gram-stained smear. The routine use of latex tests should be discouraged because, compared with smears stained with Gram stain, their sensitivity is not significantly greater and they are much more expensive (Kiska, 1995; Perkins, 1995). Although the value of latex tests for diagnosis of bacterial meningitis is questionable, an immunochromatographic test that detects the C polysaccharide cell wall antigen common to all serotypes of *S. pneumoniae*, has been shown to be very useful for rapid diagnosis of pneumococcal meningitis when testing CSF (Werno, 2008).

Two types of rapid tests are available for diagnosis of meningitis caused by *C. neoformans*: those specific for the capsular antigen (latex agglutination and enzyme-linked immunosorbent assay [ELISA]) and the nonspecific India ink preparation, which allow visualization of encapsulated yeast cells (Fig. 63-1). The sensitivity of the India ink stain, performed by mixing one drop of CSF sediment with one drop of India ink (available at art supply stores), is low, except in HIV-infected persons. Therefore, the cryptococcal latex agglutination test or the ELISA, both of which are highly specific and have sensitivities of more than 90%, is recommended for diagnosis. Supernatant of a centrifuged specimen, or unspun CSF can be used for these latter two tests. False-positive latex agglutination results occur, due to the presence of *Trichosporon asahii* or to the introduction of trace amounts of condensation from agar into the test fluid. To avoid the latter

problem, the latex test should be performed before culture or, better, on a separate sample (Heelan, 1991).

Sample Processing for Diagnosis of Viral and Parasite Infections

Currently, nucleic acid amplification tests are used most often for diagnosis of viral infections of the central nervous system. Other diagnostic methods are conventional cell culture (primarily for detection of enteroviruses, although PCR is preferred) and serologic tests for viruses that cause encephalitis (western equine, eastern equine, Venezuelan equine, St Louis, Japanese, and La Crosse and West Nile).

CSF is occasionally sent to the laboratory for diagnosis of African trypanosomiasis (*Trypanosoma gambiense* and *Trypanosoma rhodesiense*) or infection with free-living amoebae (*Naegleria fowleri* and species of *Acanthamoeba*). Once the specimen is received in the laboratory, it should be processed immediately. Wet preparations are prepared directly from the specimen and from the sediment, by first shaking the tube gently (a step necessary because the parasites often stick to the wall of the tube) and then centrifuging the specimen at 250 *g* for 10 minutes. Preparations are examined under the microscope with the condenser in a low position to allow visualization of trophozoites or, preferably, by phase contrast microscopy.

Cultures of free-living amoebae from CSF are done on nonnutritive agar plates covered with a suspension of *E. coli* or *Enterobacter aerogenes*. The fluid is centrifuged at 250 *g* for 10 minutes, the supernatant is removed with a sterile pipette, and the sediment is mixed with 0.5 mL of saline solution and poured at the center of the plate. The culture is incubated at 37° C and examined for amoebas daily for 10 days using a microscope, under a 10× objective (Martinez, 1991).

OTHER BODY FLUIDS

Fluid is collected from the pericardial, thoracic, or peritoneal cavity, or from joint spaces, by aspirating with a needle and syringe. A volume of 1–5 mL is adequate for isolating most bacteria, but 10–15 mL is optimal for recovery of mycobacteria and fungi, which are generally present in low numbers. Moreover, to diagnose peritonitis associated with chronic ambulatory peritoneal dialysis, collection of at least 50 mL of fluid may improve recovery of the responsible pathogen (Dawson, 1985). To transport the fluid, it is aspirated into a sterile container and delivered promptly to the laboratory. Alternatively, peritoneal fluid may be directly inoculated into blood culture bottles at the patient's bedside; however submission of fluid in blood culture bottles eliminates the possibility of direct Gram staining and delays the identification and susceptibility testing of any pathogens isolated.

Enteroviruses, primarily Coxsackie viruses A and B, are among the most common causes of infectious pericarditis. These viruses may be detected in pericardial fluid by conventional cell culture but, because they are not recovered in all cases, collection of throat washings and stool (which are more likely to yield the virus), in addition to pericardial fluid, is strongly recommended for virus isolation from persons with suspected enteroviral pericarditis. Other viruses (HSV, varicella zoster virus [VZV], CMV, EBV, HBV, mumps virus, and influenza virus) are infrequent agents of pericarditis and usually are not detected in pericardial fluid.

Sample Processing for Bacterial Culture

Processing fluid from body cavities for detection of bacteria involves preparing a smear for Gram stain and inoculating appropriate media for culture. As mentioned previously, the sample may be inoculated into blood culture bottles at the bedside, although this is not optimal, or it may be processed in the laboratory. In the laboratory, the fluid is centrifuged at 1500–2500 *g* for 20–30 minutes. The supernatant is removed, leaving about 0.5 mL fluid in addition to the sediment, which is mixed thoroughly and then used to prepare smears and inoculate media. Alternatively, a small volume of noncloudy, nonviscous fluid (about 0.1 mL) may be removed before centrifugation and used to prepare a cytocentrifuged smear.

Fluid specimens submitted for detection of mycobacteria are processed as described earlier for CSF. Fluids for fungal culture should be concentrated by centrifugation as described for bacteria. The supernatant is removed, leaving 1.5–2.0 mL, in which the sediment is thoroughly mixed. A smear of the sediment is prepared for staining with Gram or Calcofluor white. Ideally, 0.5–1.0 mL of sediment is inoculated to primary fungal planting media (as for CSF), but lesser volumes are acceptable.

Parasitological Examination

Body fluids are rarely collected for detection of parasites; however, *Entamoeba histolytica* may be found in the pericardial, pleural, or peritoneal cavity as a result of rupture of an abscess of the liver (into the peritoneal, pleural, or pericardial cavity) or of the lungs (into the pleural or pericardial cavity) or to perforation of amebic ulcers (into the peritoneal cavity). Hydatid cysts are infrequently diagnosed by examination of body cavity fluid, also due to rupture of a cyst into a viscus contiguous to the cavity in question. The fluid collected is usually clear and contains hydatid sand (see Chapter 62) but rarely is turbid because of superimposed bacterial infection. Uncommonly, in individuals with a filarial infection, examination of wet preparations of a body cavity fluid may demonstrate the microfilariae; in patients with *Strongyloides* hyperinfection, larvae may be detected in body cavity fluids.

TISSUES

Tissue specimens obtained surgically are procured at great expense and at considerable risk to the patient; therefore it behooves the surgeon to obtain an amount of material that is adequate for both histopathologic and microbiological examination. Swabs are rarely adequate for this purpose. The histopathology of the lesion serves not only to differentiate between infection and malignancy but also to distinguish between a suppurative and a granulomatous process. In some cases, special stains are helpful in establishing the etiology of the process. In chronic lesions the differential diagnosis includes disease due to actinomycetes, brucellas, mycobacteria, and fungi, any one of which may be present only in small numbers, again emphasizing the need for obtaining adequate samples for examination and culture.

SPECIMEN COLLECTION AND PROCESSING

Tissue obtained surgically for culture should be placed into a sterile, wide-mouthed, screw-capped container. As a general rule, tissue should be bisected aseptically by the surgeon in the operating room and material representative of the pathologic process should be submitted for both histopathologic and microbiological examination. Good communication between anatomic pathologist and microbiologist is important, especially in cases of fever of unknown origin for which an exploratory laparotomy is being performed and multiple biopsy specimens are taken.

Tissue received in the laboratory is finely minced with sterile scissors or scalpels, added to a small volume of broth, and then rendered homogeneous either in a tissue grinder, mortar and pestle, or stomacher to provide a 20% suspension. This suspension is used to inoculate all of the necessary culture media and is then stored under refrigeration for at least 2 weeks before being discarded.

EYE

CONJUNCTIVAL SPECIMENS

Conjunctival scrapings or swab specimens are collected to determine the etiologic agent of conjunctivitis. Bacteria are the most common etiologic agents of infectious conjunctivitis, and those most frequently implicated are *S. pneumoniae* and *Staphylococcus aureus* in adults; and *H. influenzae*, *S. pneumoniae*, and *S. aureus* in children. Trachoma, caused by *C. trachomatis*, is a leading cause of blindness worldwide. *C. trachomatis* also may cause inclusion conjunctivitis in newborns and, less commonly, in adults. Viruses are responsible for about 15–20% of cases of acute infectious conjunctivitis, and in the United States, most epidemics of viral conjunctivitis are caused by adenoviruses or herpes simplex virus. Rarely, parasites are causes of conjunctivitis.

Specimen Collection and Processing

Conjunctival cells are obtained from the superior and inferior tarsal conjunctiva by using a swab moistened with broth or a sterile platinum spatula. Ideally, smears are prepared and, if a bacterial or fungal infection is suspected, culture media are inoculated directly by the individual collecting the sample. If direct preparation of smears and inoculation of media is not possible, swab specimens may be collected. Smears should be air-dried and promptly transported, with the inoculated media, to the laboratory. If viral culture is requested, a second sample (swab or scrapings) is collected, placed in viral transport medium, and delivered promptly to the laboratory, or refrigerated for a short time and then transported on wet ice. A rapid diagnosis may be provided by direct or indirect immunofluorescent

staining of smears of conjunctival cells with virus-specific antibodies, but cell culture is the most sensitive method for detecting potential viral pathogens and always should be done.

To detect *C. trachomatis*, a smear prepared directly from conjunctival scrapings may be stained with the Giemsa stain and examined for epithelial cells with basophilic intracytoplasmic inclusions diagnostic of *C. trachomatis*, or preferably with monoclonal antibodies, which are more sensitive and specific than Giemsa. For optimal results with the direct fluorescent antibody test, the collection kit provided by the manufacturer should be used (see Chapter 56). The swab is rolled across the surface of the glass slide provided, the material is fixed, and the slide is transported promptly to the laboratory and held at room temperature or refrigerated for a short time. Slides are stained according to the manufacturer's directions and examined with a fluorescent microscope for elementary bodies (see Chapter 56). Specimens containing less than 10 columnar or metaplastic squamous cells are considered inadequate and results should be reported as inconclusive, with an explanation, and another specimen should be requested. Culture is the reference method for detection of *C. trachomatis* and should be performed when a diagnosis of chlamydial conjunctivitis is strongly suspected and the direct fluorescent antibody test is negative.

CORNEAL SPECIMENS

Corneal scrapings and biopsy specimens are useful in determining the etiologic agent of keratitis, an infection that can potentially produce loss of vision and requires immediate attention. Bacteria account for 65–90% of cases of keratitis, and in the United States, *S. aureus*, *S. pneumoniae*, *Pseudomonas aeruginosa*, and species of *Moraxella* are most frequently implicated.

Specimen Collection and Transport

Corneal scrapings are collected with a sterile platinum spatula and are used for preparation of smears by directly transferring them to glass slides for staining, and for inoculation to appropriate media for culture. If viral culture is requested, scrapings should be placed directly into viral transport media and delivered promptly to the laboratory or refrigerated for a short time and transported on wet ice. Frequently, the conjunctiva and the eyelids of the involved and the uninvolved eye are cultured concomitantly to determine the normal flora, useful in assessing the results of the corneal cultures. When the culture of scrapings of a suspicious corneal ulcer is negative, superficial keratectomy or corneal biopsy specimen may be obtained by the ophthalmologist, an approach especially useful for detection of fungi and *Acanthamoeba*.

RESPIRATORY TRACT

NASOPHARYNGEAL SPECIMENS

Nasopharyngeal aspirates, washings, and swab specimens are collected predominantly for diagnosis of viral respiratory infections but also pneumonia due to *C. trachomatis* or *Chlamydia pneumoniae*, pertussis, and rarely diphtheria. Specimens from the nose also are used to identify carriers of methicillin-resistant *S. aureus* (MRSA).

Specimen Collection, Transport, and Processing

Nasopharyngeal aspirates and washings are superior to swabs for recovery of viruses, but swabs frequently are submitted because they are more convenient. Washings or swab specimens are collected for detection of *Bordetella pertussis*; a swab is the preferred specimen for *C. trachomatis*, *C. pneumoniae*, and *Corynebacterium diphtheriae*. An aspirate is collected with a plastic tube (e.g., one used to feed premature infants) attached to a 1-mL syringe or a suction catheter with a mucus trap. A wash is obtained with a rubber suction bulb by instilling and withdrawing 3–7 mL of sterile phosphate-buffered saline. To collect nasopharyngeal cells with a swab, all mucus from the nasal cavity is removed, then a small flexible nasopharyngeal swab is inserted along the nasal septum to the posterior pharynx and rotated against the mucosa several times.

To detect viruses, nasopharyngeal specimens are placed into an appropriate transport medium, with or without antibiotics, and transported promptly to the laboratory or stored briefly in the refrigerator and packed in ice for transport as soon as possible. Viral detection methods are discussed in more detail in Chapter 55.

For detection of *C. trachomatis*, a nasopharyngeal swab specimen is collected with a polyester-tipped swab, which may be used for culture or for preparation of a smear for direct fluorescent antibody staining.

Detection methods are discussed in Chapter 56. For culture of *C. trachomatis* or *C. pneumoniae*, the swab should be placed in an appropriate transport medium and transported to the laboratory as soon as possible or refrigerated for a short time.

To detect *B. pertussis* by culture, inoculation of washings or swab specimens (preferably collected with a calcium alginate swab) at the bedside is optimal. If this is not possible, the sample is placed into sterile casamino broth, transported promptly to the laboratory, and processed within 1–2 hours for culture. If the sample must be sent to a reference laboratory for culture, the swab should be inoculated into and left in a solid transport media such as Regan–Lowe or Jones–Kendrick, incubated at 37° C for 48 hours, and then shipped at ambient temperature. The direct fluorescent antibody staining method, which provides a rapid diagnosis but is associated with false-positive and false-negative results (Friedman, 1988), can be performed on a smear prepared from a nasopharyngeal swab or washing. Currently, the recommended medium for culture is Regan–Lowe agar (composed of Oxoid charcoal agar and 10% horse blood and containing cephalixin), rather than the traditional Bordet–Gengou agar (potato infusion agar with 20% sheep blood). However, the most sensitive method for detecting *B. pertussis* is PCR, for which the optimal sample is a nasopharyngeal swab specimen collected with a Dacron swab (alginate fibers and aluminum in the shaft are inhibitory). If the sample must be transported to a reference laboratory for PCR, the swab should be shipped dry or in saline.

Carriers of MRSA may be detected within a few hours by commercial nucleic acid amplification assays or after 24 to 48 hours using MRSA-specific chromogenic agar media (Tacconelli, 2009; Bischof, 2009; Bocher, 2008). Nasal secretions are collected from the anterior nares with a polyester-tipped swab, which is placed in a tube transport system and promptly delivered to the laboratory. If a nucleic acid amplification assay is used, the specimen must be collected with the swab recommended by the manufacturer.

THROAT SPECIMENS

Throat swab specimens are most commonly collected to diagnose group A streptococcal pharyngitis; however, Lancefield groups C and G streptococci have also been implicated in pharyngitis. Throat swabs received in the clinical laboratory for routine bacterial culture should be evaluated for these streptococci only. Throat washings or swab specimens are useful for detection of viruses shed in oral secretions without causing pharyngitis (HSV, CMV, or enteroviruses). Throat swab specimens may also be helpful in determining the etiologic agent of epiglottitis, a rapidly progressing cellulitis with the potential to cause obstruction of the airway (almost always due to *H. influenzae* type b, but occasionally *S. aureus* or *S. pneumoniae*) and in diagnosing gonorrhea, *Mycoplasma pneumoniae* pneumonia, diphtheria, and Vincent's angina.

Specimen Collection and Transport

Throat swab specimens are collected by depressing the tongue with a tongue blade, introducing the swab between the tonsillar pillars and behind the uvula without touching the lateral walls of the buccal cavity, and swabbing back and forth across the posterior pharynx. Swab specimens collected for detection of viruses should be placed in a viral transport medium and those for detection of bacteria, in a tube transport system containing modified Stuart's medium. Throat washings for diagnosis of viral infections are obtained by gargling with 5 mL of viral transport medium containing antibiotics. Throat washings and swab specimens should be delivered promptly to the laboratory, or refrigerated for a short time if a delay in transport is unavoidable.

Specimen Processing

For diagnosis of group A streptococcal pharyngitis, culture is most sensitive; however, this requires overnight incubation. Use of a selective medium increases the recovery of *S. pyogenes* by inhibiting overgrowth of normal flora; but because the amount of growth of *S. pyogenes* on selective media at 24 hours often is insufficient for testing, plates may need to be reincubated an additional day before confirmatory testing can be performed. For rapid diagnosis, a commercial direct probe is the most sensitive and can be used as a replacement for culture (Gerber, 2004). Other rapid, direct tests for group A streptococcus (several are commercially available) are less sensitive (as low as 70%); therefore, if one of these is used two throat swab specimens should be collected. If the direct test is positive, the second swab may be discarded; but in children if the direct test is negative, confirmatory culture must be performed, using the second

swab (Bisno, 2002). In adults, because the incidence of streptococcal infection and the risk of rheumatic fever are low, diagnosis of group A streptococcal pharyngitis on the basis of a rapid, direct test, without confirming a negative result with culture, is an acceptable alternative (Bisno, 2002).

To determine the etiologic agent of epiglottitis, a swab specimen should be collected by a physician in a setting where intubation of the patient may be performed immediately if necessary. To detect *N. gonorrhoeae* in the throat, the swab specimen should be inoculated at the bedside or transported to the laboratory within 2 hours and inoculated as soon as possible on to a selective medium, such as modified Thayer–Martin agar. If a delay in processing is unavoidable, the swab should be held at room temperature. For diagnosis of diphtheria, both nasopharyngeal and throat swab specimens are collected and transported to the laboratory immediately. If laboratory personnel are not experienced in the recovery and identification of *C. diphtheriae*, the specimens should be sent in a semisolid transport media (e.g., Amies) to a reference laboratory. A differential inhibitory medium containing potassium tellurite, such as Tinsdale medium, is optimal for cultivating *C. diphtheriae*. This medium, however, is expensive, has a short shelf-life, and is difficult to obtain from commercial vendors; therefore it is seldom used in clinical laboratories. Colistin–naladixic acid blood agar (CNA) is an acceptable alternative for the cultivation of *C. diphtheriae*, but because CNA is not a differential medium, all diphtheroid colony types must be evaluated to exclude *C. diphtheriae* when this agent is suspected. In addition, a sheep blood agar plate should be inoculated and examined for group A streptococci.

Vincent's angina is an acute necrotizing ulcerative tonsillitis that may be caused by *Fusobacterium necrophorum* and other anaerobes. An illness with this clinical presentation may presumptively be called Vincent's angina if gram-negative fusiform bacilli and spirochetes are seen in smears prepared from a swab specimen of the ulcerated lesion and stained with Gram stain. Cultures of the involved area are not usually helpful because many species of anaerobes are present in the oral cavity. However, blood cultures should be collected because the illness is commonly accompanied by sepsis.

SPUTUM AND TRACHEAL ASPIRATES

Microbiological studies of sputum (expectorated and induced) and tracheal aspirate specimens are done primarily to determine the etiologic agents of pneumonia. Guidelines for diagnosis of community-acquired pneumonia have been published jointly by the Infectious Diseases Society of America and the American Thoracic Society (Mandell, 2007). Tracheal aspirates represent lower respiratory secretions collected in a Lukens trap from patients with tracheostomies. Patients with tracheostomies rapidly become colonized with gram-negative bacteria and other potential nosocomial pathogens, and because bacteria colonizing the respiratory tract cannot be differentiated from bacteria causing invasive disease by culture of tracheal aspirates, interpretation of routine culture results is difficult. Culture for *Legionella*, mycobacteria, and fungi must be requested separately from routine culture as each of these require special media for cultivation.

Specimen Collection and Transport

Optimally, expectorated sputum is collected early in the morning before eating. The individual rinses his or her mouth with water and then expectorates a specimen, preferably 5–10 mL, resulting from a deep cough. For persons with nonproductive coughs, a specimen may be induced by allowing the individual to breathe aerosolized droplets of a solution of 15% sodium chloride and 10% glycerin for about 10 minutes or until a cough reflex is initiated. Sputum and tracheal aspirate specimens should be delivered promptly to the laboratory or refrigerated for a short time if a delay is unavoidable.

Specimen Processing

Both specimen types should be screened before they are plated for routine bacterial culture to determine whether they are representative of lower respiratory secretions or of saliva. A smear prepared from a portion of the specimen consisting of purulent material is stained with the Gram stain. In general, specimens with more than 10 epithelial cells per low-power field by screen (Fig. 63-2) are considered to have significant contamination with saliva and should be rejected. Specimens with fewer than 25 epithelial cells and more than 25 neutrophils per low-power field are probably acceptable (Murray, 1975). The number of neutrophils is not usually considered when determining specimen quality, because the individual from whom the sputum was collected may be neutropenic. Screening induced sputum specimens and expectorated sputum samples submitted for detection of *M. pneumoniae*, species of *Legionella*, and mycobacteria to assess their quality

Figure 63-2 Gram stain of a sputum specimen demonstrating greater than 10 squamous epithelial cells per low-power field, which is unacceptable for culture. (×10)

Figure 63-3 Gram stain of a sputum specimen showing encapsulated, lancet-shaped, gram-positive diplococci, consistent with *Streptococcus pneumoniae*. (×100)

is not generally required (Ingram, 1994; Havlik, 1995). However, data from one study suggest that screening sputum specimens for the presence of neutrophils is an effective method to evaluate the acceptability of sputum for mycobacterial smear and culture (McCarter, 1996).

The Gram-stained smears prepared from specimens that are acceptable for culture are examined under oil immersion to determine the relative amounts of organisms. The quantity of organisms (rare, few, moderate, or many) is estimated for each kind of bacterium (e.g., gram-positive cocci in pairs (Fig. 63-3), chains or clusters; gram-positive bacilli; gram-negative diplococci, and gram-negative rods), noting whether or not they are intracellular. Tracheal aspirates for which no organisms are observed in the Gram-stained smear should probably be rejected (Gilligan, 1999). Portions of acceptable specimens containing purulent material are inoculated as outlined in Chapter 57. For specimens from persons with cystic fibrosis, also inoculating a medium selective for *Burkholderia cepacia* is recommended.

When legionnaires' disease is suspected, *Legionella* culture and a rapid, direct test (fluorescent antibody on a respiratory specimen or *Legionella* antigen on a urine specimen) are recommended. Direct fluorescent antibody staining, which can provide results in several hours rather than the 3–7 days required for culture, should be used to supplement but not replace culture. PCR also can be performed but is considerably more expensive than culture, direct fluorescent antibody (DFA), or urine antigen testing. Culture is the most sensitive of these methods and should always be performed. Several drops of the specimen should be inoculated to each selective and nonselective buffered charcoal yeast extract agar plate. Use of the selective agar inhibits the growth of most other respiratory flora;

however, some strains of *Legionella* are susceptible to the medium's inhibitory agents. Thus a nonselective plate should always be included.

For optimal detection of mycobacteria in sputum, collection of three samples on three separate days is recommended. Sputum and other respiratory secretions must be decontaminated to prevent the normal respiratory flora from overgrowing the slower-growing mycobacteria. This process and detection methods are discussed in Chapter 60. All specimens submitted for mycobacterial stain, culture, and molecular testing should be processed in a biological safety cabinet, preferably in an isolated room with negative air pressure (level 3 laboratory).

All specimens submitted for fungal culture should also be handled as described for mycobacteria. The quality of the specimens should be determined by screening with smears stained with Gram stain (as described earlier for bacteria). Acceptable expectorated sputum, induced sputum, and tracheal aspirate specimens should be inoculated to culture media for recovery of fungi. In general, to culture fungi media with and without blood enrichment, and media containing antimicrobial agents should be used. However, when making media selection, the laboratory director also should consider cost and the types of fungus usually encountered in the patient population served by the laboratory.

BRONCHOSCOPY SPECIMENS

Bronchoalveolar lavage fluid and protected brush specimens are useful for diagnosis of bacterial pneumonia in ventilated patients who have not received antimicrobial therapy, and for detection of opportunistic pathogens in immunocompromised patients with pneumonia (Baselski, 1994; Carroll, 2002). Data indicate that culture of bronchoalveolar lavage specimens is also useful for diagnosis of acute bacterial pneumonia (Baselski, 1994). All bronchoscopy specimens should be plated quantitatively to determine significance of potential pathogens recovered. Only protected brush specimens are suitable for anaerobic culture (Baselski, 1994). For culture of species of *Legionella*, sputum specimens are preferable because bronchoalveolar lavage samples are diluted with saline and may contain small amounts of the anesthetic used locally, which inhibits the organism.

Specimen Collection and Transport

The protected brush sample is collected with a small brush that holds 0.001–0.01 mL of secretions, placed in a catheter, within a double cannula. The outer cannula has a displaceable polyethylene glycol plug at the tip. To obtain a specimen, the cannula is inserted to the desired area via bronchoscopy, the inner cannula is pushed out, dislodging the protective plug (water-soluble), and the brush is extended even farther, beyond the inner cannula. Once the sample is taken, the brush is pulled back into the inner cannula, and both brush and inner cannula are pulled into the outer cannula to prevent contamination of the brush when the catheter is removed. The brush then is placed in 1 mL of sterile saline or broth. The specimen should be transported immediately to the laboratory and processed as soon as possible. If a delay is unavoidable, the specimen should be stored in the refrigerator.

To collect bronchoalveolar fluid, the tip of the bronchoscope is carefully wedged into an airway lumen. A volume of saline (usually >140 mL) in three to four aliquots is injected through the lumen, sampling an estimated 1 million alveoli. The total volume returned varies based on the volume instilled, but is typically 10–100 mL. The transport time to the laboratory should be minimal (<30 min) and, once it is in the laboratory, the specimen should be processed as soon as possible. If a delay cannot be avoided, the fluid should be stored in the refrigerator.

Specimen Processing

To process the protected brush specimen, the fluid in which the brush is suspended is agitated on a vortex mixer and the resulting suspension is used for a cytospin preparation and for culture inoculum. Using a calibrated 0.01 mL inoculating loop, the suspension is plated onto appropriate media and carefully streaked for isolation. Colony counts of more than 1000 CFU/mL of potential pathogens (corresponding to 10^6 organisms/mL of the original specimen) appear to correlate with infection (Baselski, 1994). The bronchoalveolar sample is inoculated onto agar media by using a 0.001-mL calibrated inoculating loop (as used for urine cultures, described in the following section). The presence of more than 10,000 CFU/mL of fluid correlates with disease. Staining cytocentrifuge preparations of the fluid with Gram stain is recommended; visualizing one or more bacteria without squamous epithelial cells per oil immersion field strongly suggests acute bacterial pneumonia (Kahn, 1987; Baselski, 1994).

Figure 63-4 Cytologic preparation of bronchoalveolar lavage fluid shows an enlarged cell with intranuclear and intracytoplasmic inclusions, consistent with cytomegalovirus. (Papanicolaou stain, $\times 250$) (Courtesy Vicki J. Schnadig, MD, Department of Pathology, University of Texas Medical Branch, Galveston, Tex.)

Processing bronchoalveolar lavage specimens for detection of viruses includes direct microscopic examination and conventional cell culture. Examination of cytocentrifuge preparations stained with the Papanicolaou stain allows detection of cytopathic changes, especially useful for diagnosis of CMV pneumonia (Fig. 63-4) (Woods, 1990). Cytospin preparations also may be stained with an acid-fast stain; with specific antibodies, such as those for detection of *Legionella* species or *P. jirovecii*; or with nonspecific stains (e.g., silver stain, Calcofluor white, or Giemsa) for detection of *P. jirovecii* or other fungi. For detection of mycobacteria, the specimen should be decontaminated and handled as described in Chapter 60. To recover fungi, the sediment of a centrifuged specimen should be inoculated on to primary fungal media.

URINARY TRACT

The urinary tract above the urethra is sterile in healthy humans, but the urethra is normally colonized with many different bacteria, so urine specimens collected by a noninvasive method (e.g., clean-catch, midstream specimen) become contaminated during their passage. Commensal bacteria are differentiated from potential pathogens by quantitative cultures of urine, a procedure initially promoted by Kass (1956). Originally, growth of $\geq 10^5$ CFU of bacteria per milliliter of urine was considered highly indicative of infection, but this criterion has been modified for different situations. For example, in young, sexually active women with the acute urethral syndrome (dysuria, frequency, and urgency), as few as 10^2 CFU/mL is considered significant in the presence of concomitant pyuria (Stamm, 1982). True urinary infections associated with fewer than 10^5 CFU/mL may occur in infants and children, in males, and in persons who are catheterized, were recently treated with antimicrobial agents, drink large amounts of fluids (which dilutes urine), have symptoms and concomitant pyuria, have urinary obstruction, or have pyelonephritis acquired from hematogenous spread (especially infections due to yeast and *S. aureus*). Consequently, proper interpretation of urine culture results requires communication between clinicians and laboratory personnel.

SPECIMEN COLLECTION AND TRANSPORT

Acceptable methods of urine collection include midstream clean catch (preferably a first voided morning specimen), catheterization, and suprapubic aspiration. In general, 24-hour urine specimens should be rejected, except when detection of *Schistosoma haematobium* is requested specifically. Most commonly, the midstream flow of a clean-catch urine is collected. For women, the periurethral area and perineum is first cleansed with soapy sterile gauze pads in a front-to-back motion, rinsed with a moistened sterile gauze pad, and dried with a dry sterile gauze pad. For males, cleansing the genital area may not improve the detection of bacteriuria significantly and may not be necessary (Lipsky, 1984). During voiding, women should hold the labia apart and men who are not circumcised should hold back the foreskin. The first few milliliters of urine are passed into the toilet bowl or a bedpan, to flush out bacteria normally colonizing the urethra, and the midstream portion is collected in a sterile container with a wide mouth and tightly fitting lid.

Figure 63-5 Technique for inoculating urine onto agar plates. (Redrawn from Woods GL, Gutierrez Y, editors. *Diagnostic pathology of infectious diseases*. Philadelphia: Lea & Febiger; 1993, p. 602.)

Catheterization is associated with the risk of inducing a nosocomial infection and should therefore be restricted to persons who are unable to produce a midstream sample; for example, individuals with an altered sensorium or those unable to void for neurologic or urologic reasons. Using strict aseptic technique, the catheter is inserted into the urethra, the first few milliliters of urine passed are discarded to clear organisms that may have entered the tip of the catheter during placement, and the mid-portion of the sample is obtained for culture. Urine may be collected from an indwelling catheter by aspirating with a 28-gauge needle and syringe through the rubber connector between the catheter and the collecting tubing, taking care to first disinfect the puncture site. Urine should not be collected from catheter bags, and Foley catheter tips should not be accepted for culture because they almost always are contaminated with urethral organisms.

Suprapubic aspiration is used primarily for neonates. The procedure requires a full bladder; the overlying skin is disinfected, the bladder is punctured above the symphysis pubis with a 22-gauge needle on a syringe, and about 10 mL of urine is aspirated.

All urine specimens should be transported promptly to the laboratory and should be processed within 2 hours after collection. If a delay in transport or processing cannot be avoided, specimens may be refrigerated up to 24 hours. Collection kits containing preservatives to maintain the bacterial population stable for 24 hours at room temperature are commercially available but offer no advantage over refrigeration.

SPECIMEN PROCESSING

Quantitative bacterial culture of a urine specimen is done by inoculating appropriate media (see Chapter 57) with a measured amount of urine, most commonly with a plastic or wire calibrated loop designed to deliver a known volume. A 0.001-mL loop is used to inoculate all urine specimens except those collected from women with suspected acute urethral syndrome and suprapubic aspirates. Both the latter are inoculated with a 0.01-mL loop. The appropriate loop is inserted vertically into the well-mixed urine sample, and the loopful of urine removed is spread over the surface of the agar plate as illustrated in Figure 63-5. Without reflaming, the loop is again inserted vertically into the urine, and the removed sample is inoculated to a second plate.

Some bacteria are not detected by routine culture of urine and, when these pathogens are suspected, specific tests must be requested. For example, urine is an acceptable specimen for detection of *N. gonorrhoeae* and *C. trachomatis* by nucleic acid amplification. The manufacturer's directions for urine collection and processing must be followed. *Leptospira*

interrogans may be detected in urine after the first week of illness and for several months thereafter. To detect *L. interrogans* in urine, the specimen should be processed as soon as possible after collection, because acidity may harm the organisms. One or two drops of undiluted urine, and urine diluted 1:10 in broth, are inoculated to 5 mL of Fletcher's medium or Ellinghausen–McCullough–Johnson–Harris medium containing 5-fluorouracil. Culture of urine for mycobacteria is discussed in Chapter 60. Yeasts may be recovered from urine on the media plated for routine bacterial culture but, if fungal culture is specifically requested, the sediment of a centrifuged urine specimen should be plated on to media such as inhibitory mold or SABHI agar containing antibacterial agents.

Urine specimens collected for culture of viruses should be submitted in liquid media containing antibiotics (e.g., penicillin, gentamicin, and amphotericin B), or antibiotics should be added to the sample when it is received in the laboratory, to minimize bacterial contamination of cell cultures. Cell lines are selected for inoculation based on the viruses most commonly isolated—CMV, adenovirus, and HSV. Detection of BK virus in urine may be requested; however, PCR, rather than culture, is recommended. Because BK virus PCR is offered primarily by reference laboratories, it is best to contact that laboratory for collection and shipping requirements.

More than half of urine specimens submitted to the clinical laboratory for culture yield no growth or have bacterial counts below levels considered clinically significant. Therefore screening tests that can quickly identify urine samples yielding “negative” culture results have been evaluated as a means to provide rapid results, eliminate negative specimens, and allow more time for positive specimens, thus improving efficiency and cost. In general, urine screen and culture results correlate well when 10^5 CFU/mL or greater is the reference, but they compare less favorably in the presence of lower colony counts. Commercial automated screening methods have been developed but are either no longer available or not actively marketed. Screening urine specimens by staining with Gram stain is economical, but because examination of smears is tedious and time-consuming, this approach rarely is adopted in the clinical laboratory. The commercial dipstick test that combines nitrate reductase (an enzyme present in most of the gram-negative bacilli that cause urinary tract infections) and leukocyte esterase (an enzyme produced by neutrophils) is rapid, inexpensive, and simple to perform, and is most useful as a tool to exclude urinary tract infection if both markers are negative, especially in symptomatic patients (Deville, 2004; St. John, 2006).

GENITAL TRACT

Specimens from genital sites are submitted for detection of microorganisms responsible for several clinical syndromes, each of which are associated with certain pathogens. The syndromes each have a distinctive clinical presentation and require specific collection, transport, and testing procedures. For many tests the manufacturer's collection and transport devices must be used for optimal detection of the responsible pathogen.

VAGINAL SECRETIONS

Vaginal secretions are useful in determining the etiologic agent of vulvovaginitis and bacterial vaginosis (so named because the condition is non-invasive). In postpubescent females, the most common pathogens are *Gardnerella vaginalis* (in association with anaerobes such as *Mobiluncus* spp.), species of *Candida*, and *Trichomonas vaginalis*. A wet-mount preparation is the most valuable diagnostic test and may be performed by the attending physician; cultures are not necessary for diagnosis. A swab of the discharge is placed in a tube containing about 1 mL of normal saline and transported to the laboratory. In the laboratory, the swab is removed from the saline, the tip is firmly pressed against a glass slide to express liquid and cellular material. The slide is coverslipped and examined under low- and high-power magnifications, looking for “clue cells” (epithelial cells covered with small coccobacillary bacteria) (Fig. 63-6), consistent with the diagnosis of nonspecific vaginosis; pseudohyphae, suggestive of vaginal candidiasis; and motile trichomonads. Detection of all three pathogens also can be accomplished with a commercial vaginal pathogens PCR test (Briselden, 1994). Swabs and transport tubes supplied by the test manufacturer must be used.

Other useful diagnostic tests are vaginal pH and the “whiff test,” both of which can be done by the clinician examining the patient. The vaginal pH is usually about 4.5 in women with vulvovaginal candidiasis but is above 4.5 in those with bacterial vaginosis or trichomoniasis. A positive whiff test is determined by the generation of a pungent, fishy odor after addition of

Figure 63-6 “Clue cells” in a smear of vaginal discharge. (Papanicolaou stain, ×400) (Courtesy Vicki J. Schnadig, MD, Department of Pathology, University of Texas Medical Branch, Galveston, Tex.)

10% potassium hydroxide to a drop of vaginal discharge placed on a slide or on the speculum. This is associated predominantly with bacterial vaginosis but occasionally occurs with trichomoniasis.

ENDOCERVICAL AND URETHRAL SPECIMENS

Endocervical specimens are collected to determine the etiologic agents of cervicitis and to identify asymptomatic persons infected with an organism that causes sexually transmitted disease. Endocervical specimens are obtained after the cervix is visualized with the aid of a speculum moistened only with warm water, because lubricants may contain antibacterial agents. If a Papanicolaou smear is indicated, that sample should be collected first.

Specimens for microbiological studies are generally collected with a swab. As discussed earlier, using a polyester-tipped swab with a plastic shaft is recommended. If a nonculture test kit is used for organism detection, the specimen must be collected with the swab supplied or specified by the manufacturer. Before collecting specimens for detection of *N. gonorrhoeae* and *C. trachomatis*, all secretions and discharge must be removed from the cervical os. The swab or brush then is inserted 1–2 cm into the endocervical canal (past the squamocolumnar junction), rotated firmly against the wall for 10–30 seconds, withdrawn without touching the surface of the vagina, and placed in the appropriate transport medium or tube system used to prepare a slide for direct fluorescent antibody staining (for *C. trachomatis*) or used to immediately inoculate an agar medium for recovery of *N. gonorrhoeae*.

Specimen handling varies based on the organism sought. To isolate *N. gonorrhoeae*, direct inoculation of a selective agar medium, such as modified Thayer–Martin, within a container to which a CO₂-generating tablet is added, is optimal. Alternatively, the swab specimen can be placed in a tube transport system and delivered to the laboratory within 2 hours. If a delay in transport cannot be avoided, the swab should be left at room temperature, never refrigerated. If a DNA probe or nucleic acid amplification is used for detection of *N. gonorrhoeae*, the collection kit provided by the manufacturer must be used and the storage and transport instructions followed.

For detection of *C. trachomatis*, culture or nonculture methods may be used (see Chapter 56). For chlamydial culture, the specimen should be transported in an appropriate transport medium containing antibiotics to inhibit overgrowth of bacteria and fungi (e.g., M4 medium). To maintain the viability of *Chlamydia* organisms, the specimen should be transported to the laboratory immediately or stored in the refrigerator if immediate transport is not feasible. In the laboratory, the specimen should be processed as soon as possible. If a delay in processing is unavoidable, specimens should be stored in the refrigerator if they can be processed within 48 hours. To detect chlamydial elementary bodies by DFA staining, the collection kit provided by the manufacturer must be used and the directions followed. The swab specimen is rolled over the microscope slide, allowed to dry, and the fixative provided is applied. For enzyme immunoassay, DNA probes, and nucleic acid amplification, the collection kit/transport system provided by the manufacturer must be used, unless the manufacturer specifically states that an alternative transport system is acceptable. Manufacturers’ guidelines concerning transport conditions, storage requirements, and time to processing must also be followed.

Figure 63-7 Multinucleate giant cell with intranuclear inclusions consistent with herpes simplex virus in a smear of endocervical cells. (Papanicolaou stain, ×400) (Courtesy Vicki J. Schnadig, MD, Department of Pathology, University of Texas Medical Branch, Galveston, Tex.)

For optimal detection of HSV, nucleic acid amplification or cell culture is recommended. For nucleic acid amplification, specimen collection and transport guidelines provided by the manufacturer or reference laboratory to which the sample is being sent should be followed. For culture, the swab specimen is placed in viral transport medium such as M4 and transported as soon as possible to the laboratory. If immediate delivery is not feasible, the specimen should be stored in the refrigerator. For patients who have visible lesions on the cervix, viral cytopathic changes may be seen in smears prepared from scrapings of the lesion base. Smears are fixed immediately and stained with Wright’s or Giemsa stain (Tzanck preparation), which will not distinguish HSV and VZV, or with a monoclonal antibody.

Genital tract infection with human papilloma virus (HPV) is thought to be the most common sexually transmitted disease in the United States, and infection with a high-risk type is the major risk factor for development of cervical carcinoma. Because it is not possible to culture the virus in vitro, other diagnostic methods must be used. Squamous cell changes can be visualized on exfoliated cell samples (Papanicolaou smear), but molecular techniques (e.g., nucleic acid hybridization with signal amplification and PCR) are more sensitive. Kit manufacturers’ collection and transport instructions must be followed.

To detect *C. trachomatis* and *N. gonorrhoeae* in males, a urethral swab specimen or first-voided urine sample, depending on the detection method used, should be obtained. Optimally, urethral swab specimens are collected at least 2 hours after the patient has voided. Samples for *N. gonorrhoeae* are obtained first. The conditions concerning types of swab and specimen transport are the same as those described for endocervical swab specimens, although the smaller urogenital swabs are used. The swab is inserted into the urethra for 2–4 cm, rotated in one direction for 5 seconds, withdrawn, and placed in the appropriate transport medium or used to prepare smears for direct fluorescent antibody staining to detect *C. trachomatis* or for Gram staining to diagnose gonorrhea (detection of intracellular gram-negative diplococci in a smear of urethral discharge from symptomatic men provides a presumptive diagnosis).

VESICLES

Vesicular genital lesions are sampled to confirm HSV infection. The vesicle fluid is aspirated with a small-gauge needle on a tuberculin syringe. If only a small vesicle is present, it is unroofed and the base is firmly scraped with a Dacron swab or tongue depressor to ensure collection of cells. Vesicle fluid or swab specimens should be placed in a viral transport medium and processed for conventional cell culture or tested by nucleic acid amplification (Strick, 2006). HSV may also be detected directly in clinical specimens by direct staining of smears, but this is less sensitive than nucleic acid amplification or culture, so a negative result does not exclude the diagnosis. To make a smear, cells collected with a tongue depressor or a Dacron swab are spread on a glass slide, and the material is fixed in acetone. The smear may be stained with the Papanicolaou, Wright’s, or Giemsa stain for detection of typical cytopathic changes typical of HSV (VZV has an identical appearance) (Fig. 63-7), or with specific monoclonal antibodies.

ULCERS

Material from genital ulcers is collected to identify the responsible pathogen; HSV, *Haemophilus ducreyi*, *T. pallidum*, *C. trachomatis* (serogroups L1, L2, L3), and *Klebsiella* (formerly *Calymmatobacterium*) *granulomatis* should be considered in the differential diagnosis. Collection, transport, and processing of material from ulcerative lesions for detection of HSV are identical to the protocol discussed for vesicles. In general, the sensitivity of the direct tests previously described and recovery of the virus are lower in ulcerative lesions.

If infection with *H. ducreyi* is suspected, material from the base of the ulcer is collected on two cotton or Dacron swabs. One swab is used to inoculate a chocolate agar plate at the bedside. If bedside inoculation is not possible, the swab should be transported in modified Stuart's medium to the laboratory and held at room temperature until processed. The second swab is used to prepare a smear for staining with Gram stain. Observing many small pleomorphic gram-negative coccobacilli arranged in groups of chains resembling a "school of fish" suggests *H. ducreyi*. Culture, however, is more sensitive and is necessary for confirmation.

T. pallidum spirochetes may be detected in genital or other lesions but syphilis is usually diagnosed serologically. Gloves should be worn when examining lesions of suspected syphilis and when handling specimens obtained from those lesions. To collect the specimens, the surface of the lesion (if multiple lesions are present, the youngest should be selected) is cleaned with saline and blotted dry, and crusts are removed if present. The lesion is superficially abraded until slight bleeding occurs, and gentle pressure is applied to its base. The clear serum exudate from the subsurface is collected by touching the fluid with a glass slide or by using a capillary pipette and transferring the fluid to a glass slide. A coverslip is placed on the fluid and the specimen is examined immediately by dark-field microscopy. Alternatively, lesion material is aspirated with a 26-gauge needle inserted at the base, after which a drop of saline is drawn into the needle. The material then is expressed onto a glass slide, covered with a cover glass, and examined immediately by dark-field microscopy. The spirochetes of *T. pallidum* are 10–13 µm long by about 0.15 µm wide, have a regular tight coil, and are pointed at the ends.

Serogroups L1, L2, and L3 of *C. trachomatis* may be detected by cell culture in a biopsy of the ulcerated lesion or in cellular material collected by first removing any exudate from the lesion and then firmly rotating a swab (on a plastic stick) against its base. Specimen transport and processing are the same as discussed for endocervical swab specimens. For optimal detection of *K. granulomatis*, subsurface tissue from an area of active granulation is biopsied and immediately transported to the laboratory in a sterile, dry container or in one containing a small amount of sterile saline without preservatives. Smears are prepared from a crushed piece of the tissue and stained with Giemsa or Dieterle's stain. The diagnosis is based on finding characteristic, encapsulated *K. granulomatis* organisms within macrophages.

FECES

Feces and, in some cases, rectal swab specimens are useful for determining the etiologic agent of infectious diarrhea or food poisoning, confirming the diagnosis of botulism, and diagnosing infections caused by adenoviruses, enteroviruses, some sexually transmitted pathogens, intestinal protozoa and helminths, and, in some instances, helminths of the respiratory and biliary tracts. Collection, transport, and processing of these specimens are different for viruses, bacteria, and parasites and are discussed separately for each group.

VIRUSES

Specimen Collection and Transport

Stool is preferred for detection of enteroviruses and the viruses responsible for gastroenteritis. Specimens should be collected in a clean container with a tight lid. If feces cannot be obtained, a swab is inserted beyond the anal sphincter, rotated, withdrawn, and placed in viral transport medium. Deliver specimens promptly to the laboratory; if not, refrigerate for a short time and transport on wet ice. If the specimen must be mailed to a reference laboratory, store at –70° C and ship on dry ice.

Specimen Processing

Cell culture is recommended for detection of enteroviruses. To detect rotaviruses and enteric adenoviruses, an ELISA is used most commonly.

Latex agglutination kits also are available but appear to be less sensitive. Specimens are processed according to the manufacturer's directions. Direct examination of stool specimens by electron microscopy is the reference method for detection of rotavirus and is useful for detection of caliciviruses, astroviruses, and noroviruses. Noroviruses also can be detected by PCR.

BACTERIAL PATHOGENS

Collection and Transport

Stool also is preferred for detection of bacteria responsible for infectious diarrhea but a rectal swab specimen is an acceptable alternative. Stool cultures for patients who have been hospitalized for more than 3 days are inappropriate. Stool specimens should be collected in a clean container with a tight lid, and the specimen should not be contaminated with urine, barium, or toilet paper. Rectal swab specimens, obtained as described earlier for viruses, are placed in a tube transport system containing modified Stuart's medium. Both specimen types should be transported promptly (within 2 hours) to the laboratory and processed as soon as possible, because the drop in pH that occurs as the stool cools may inhibit the growth of some pathogens, especially *Shigella*. If a delay in processing is unavoidable, or if the specimen must be mailed to a reference laboratory, transport of an aliquot of the specimen in transport media such as Cary Blair is recommended. For diagnosis of *C. difficile* disease, 20–50 mL of liquid stool should be submitted in a sterile container. The stool specimen is stable for 2 days, refrigerated, or frozen for 1 week.

Specimen Processing

Processing stool or rectal swab specimens for detection of bacteria is based on the organism or group of organisms expected to be present. Specimens received for "routine" bacterial culture should be processed to allow recovery of *Shigella*, *Salmonella*, and *Campylobacter jejuni/coli* by plating to appropriate differential, inhibitory and noninhibitory media (see Chapter 57). The microbiology laboratory director also might consider routinely examining stool for shiga-like toxin producing *E. coli* (STEC) and *Aeromonas* species, depending on the prevalence of disease caused by these bacteria. The prevalence of gastroenteritis caused by *Yersinia enterocolitica*, *Vibrio cholerae*, or other *Vibrio* species, or *Plesiomonas shigelloides* is low in most parts of the United States; therefore, specific requests for their detection are most cost effective.

To detect STEC, the stool specimen is inoculated onto sorbitol–MacConkey agar (containing 1% D-sorbitol instead of lactose), a medium that differentiates isolates of STEC, which do not ferment sorbitol, from almost all other *E. coli*, which are sorbitol-positive. A more sensitive method than culture for detection of STEC is detection of toxin in the stool or stool filtrate by enzyme immunoassay or PCR (Gavin, 2004; Pulz, 2003). When isolation of *Y. enterocolitica* is requested, CIN agar is inoculated and incubated at room temperature. The organism also can be recovered by inoculating media typically used for routine bacterial culture (see Chapter 57). A MacConkey plate may be incubated at room temperature for 48 hours. Colonies of *Y. enterocolitica* are purple and pinhead in size. Species of *Vibrio* frequently grow on the media used for routine stool culture but, for their optimal recovery, thiosulfate citrate bile salts sucrose agar is inoculated. *Plesiomonas shigelloides* also grows on media used for routine culture, but because up to 30% of *P. shigelloides* isolates ferment lactose, their colonies do not appear sufficiently distinct to be recognized on these media, and screening all colonies for *Plesiomonas* is not cost-effective. For this reason, culture of stool or rectal swab specimens for *P. shigelloides* should be requested specifically. Use of the selective-differential medium inositol brilliant green bile salts agar has been suggested but is not essential.

Rectal swab specimens submitted for detection of *C. trachomatis* are placed in transport medium and delivered promptly to the laboratory or are refrigerated for a short time. Rectal swab specimens collected to diagnose gonorrhea are treated as discussed earlier for endocervical specimens.

Stool specimens or gastric contents collected from persons with short-incubation food poisoning should be evaluated for *S. aureus* and *Bacillus cereus*, and specimens from patients with long-incubation food poisoning should be evaluated for *C. perfringens*. This testing is normally conducted by experts at public health laboratories, who should be contacted regarding appropriate specimen collection and transport. The clinical diagnoses of food-borne botulism and infant botulism may be confirmed by detecting botulinum toxin, *Clostridium botulinum*, or both in feces. Most clinical laboratories are not properly equipped to process specimens from persons with suspected botulism. In the United States, when a case of botulism is

identified, investigators at the Centers for Disease Control and Prevention should be notified to ensure appropriate specimen collection and transport, diagnosis, treatment, and investigation of the potential outbreak.

Diseases associated with *C. difficile*, such as pseudomembranous colitis and antibiotic-associated diarrhea, are caused by the toxins produced by the organism and are diagnosed by detecting toxin A and/or B or the toxin B gene in feces. The most sensitive method for detecting toxin is culture followed by testing colonies of *C. difficile* for toxin production. The reference method for detection of the cytotoxin is cell culture assay. To extract toxin, the stool specimen is clarified by centrifugation at 2000 g for 20 minutes or 10,000 g for 10 minutes and filtered through a 0.45 µm membrane filter. Serial dilutions are prepared and inoculated to cell monolayers, which are incubated for 24–48 hours. Alternatively, toxin A or both toxins A and B may be detected in stool samples by ELISA testing, which provides results within a few hours. The sensitivity and specificity of different commercial ELISAs, however, varies (Eastwood, 2009). Tests for detection of the common antigen glutamate dehydrogenase (GDH) are also commercially available. These tests, like bacterial culture, do not distinguish isolates that produce toxin from those that do not. Even so, the common antigen, which has a turnaround time of 15–45 minutes, has been shown to be a useful screening test in certain institutions. Specimens yielding negative results require no further testing, whereas GDH-positive specimens should be tested for toxins. Most recently, commercial PCR tests for detection of the toxin B gene have been shown to be considerably more sensitive than ELISAs (Eastwood, 2009; Kvach, 2010).

For epidemiologic studies, *C. difficile* may be isolated from stool or from rectal swab specimens placed in an anaerobic transport system. Because many bacteria are present in stool, procedures that select for *C. difficile* must be used. The most effective medium for this purpose is cycloserine cefoxitin fructose egg yolk agar (CCFA), with or without horse blood. The organism grows more quickly and luxuriantly on formulations containing horse blood. The medium is incubated anaerobically for 48 hours and the plates are examined for colonies that have a peripheral fringe and a “horse stable” odor. Alternatively, *C. difficile* may be isolated by using an alcohol spore selection procedure, where 1 mL of the original specimen is mixed with 1 mL of absolute ethanol. The mixture is allowed to stand for 1 hour at room temperature, followed by subculture to CCFA and incubation anaerobically.

With regard to mycobacterial culture, stool specimens usually are submitted for isolation of *Mycobacterium avium* complex (primarily from patients with AIDS), but *M. tuberculosis* complex and other species of *Mycobacterium* also may be recovered. Processing the specimen (1–2 g of formed stool or 5 mL of liquid stool) involves decontamination and concentration, preparation of smears, and inoculation of media as discussed in Chapter 60.

PARASITES

The backbone of diagnostic parasitology in the clinical laboratory is examination of stool samples for parasitic protozoa and helminth eggs or larvae. Laboratories performing such tests should have adequate facilities for handling stool samples and a good microscope with a calibrated micrometer to measure the organisms found. Staining of fecal smears is also required for identification of intestinal protozoa.

Specimen Collection and Transport

The specimen (usually collected by the patient) can be collected in a clean, dry, wide-mouthed container. A portion of the sample is then aliquoted into two vials containing preservatives; one with modified polyvinyl alcohol (PVA) and the other with 10% formalin. Fecal specimens should not be collected from the toilet bowl and should not be contaminated with urine, water, mineral or castor oil, antidiarrheal compounds, or radiologic contrast medium. Once collected and preserved the sample should be delivered to the laboratory at the patient's convenience. The use of fresh stool is optimal for examination for *E. histolytica* trophozoites; however, it is usually very difficult to transport a fresh specimen to the laboratory and into the hands of the microbiologist within the 30–60 minutes after collection required to visualize motile trophozoites. Although it is rarely possible to perform wet mounts on fresh stools for motile trophozoites, they can still be identified on stained preparations, and the use of preserved specimens for examination minimizes the exposure of laboratory personnel to live organisms.

Several kits, some single vial and some consisting of two vials (one with formalin for helminth eggs and protozoan cysts, and the other with PVA for preparation of smears for staining), are commercially available for

collection and transport of fecal samples. The question of how many fecal specimens are required for identification of all individuals with intestinal protozoa or helminths is still without a definitive answer. It has been advised that a minimum of three specimens collected every other day be examined (Garcia, 2003; CLSI, 2005). For cost containment, the clinician should request examination of only one specimen, because about 90% of all infections are diagnosed on the first sample (Montessori, 1987). If a parasite is not detected in the first sample, a second or third should be requested. If two or more specimens collected on different days are received in the laboratory at the same time, it has been suggested they be pooled and evaluated as one (Peters, 1988). This practice, however, is controversial. Stool examinations for parasites in patients who have been hospitalized for more than 3 days are inappropriate (Siegel, 1990).

Specimen Processing

The examination of stool samples for parasites includes preparation of saline solution and of iodine (Lugol's)-stained wet mounts of freshly collected samples (i.e., those that can be examined within a few hours of collection). This is followed by concentration of cysts and helminth eggs, and finally by preparation of smears for staining with the trichrome stain. The wet preparations, if performed, should be made and examined before doing the concentration and trichrome staining. Even if a parasite is seen in the wet mount, examination of a concentrated specimen is recommended because specimens submitted for ova and parasite examination not uncommonly contain multiple parasites. In particular, helminth eggs are often only visible in the concentrate.

The standard fecal smear, which has about 2 mg of feces, is made from a fresh fecal sample as follows: one drop of saline solution is placed on a clear glass slide; with an applicator stick, a small amount of feces is picked up and with circular movements is mixed thoroughly with the saline (until enough sample is dissolved), and the mixture is covered with a 22-mm square cover glass. A good wet smear prepared as described, if placed on a paper with small print, should allow the print to be read through the smear. The smear stained with iodine is prepared in the same manner. Both the saline solution and the iodine solution wet preparations can be made on the same glass slide, at the same time mixing the feces with the saline solution first and then with the iodine solution. The saline solution smear will show trophozoites and cysts of protozoa, plus all the helminth eggs and larvae. The smear stained with iodine does not show trophozoites, because they are destroyed by the iodine unless the sample was previously fixed. The main advantage of the iodine stain is that it allows better visualization of some morphologic characteristics of cysts. The saline solution shows movement of trophozoites, which is useful for their identification. To prepare wet mounts from formalin-fixed material, the contents are mixed well and one drop is placed directly on to the glass slide and on to a drop of iodine solution.

Examination of the saline solution smear is carried out with medium power (10× objective) at first. Beginning at the left upper corner of the cover slide, the slide is moved horizontally from the right to the left. The operation is repeated until the entire 22-mm square cover glass is examined. All helminth eggs or larvae and all protozoan cysts should be noted. Examination with the high-power objective is done next for detection and identification of protozoa, looking randomly for about 5–10 minutes per preparation.

The concentration technique, which can be done both on fresh and fixed specimens, is particularly useful because it allows detection of organisms present in low numbers. The concentration methods used for routine evaluation are described in detail in Chapter 62. Also discussed in that chapter are special stains required for detection of *Cryptosporidium*, microsporidia, and *Cyclospora*.

SKIN AND SUBCUTANEOUS LESIONS

VESICLES, BULLAE, AND PUSTULES

Specimen Collection and Transport

Fluid is the optimal specimen and may be collected from a vesicle or bulla by aspirating with a needle and syringe, removing the needle, capping the syringe and transporting the syringe to the laboratory. If viral culture is desired inoculate a portion of the fluid into an appropriate transport medium. Vesicles and bullae may also be sampled by unroofing the lesion and vigorously rubbing the base with a swab, and then submitting the swab for testing. Pustules are similarly sampled with a swab after removing any crusted material. A minimum of two swab specimens should be collected,

one for culture, the other for preparation of smears for staining. However, if detection of more than one group of organisms (e.g., viruses and bacteria, or bacteria and fungi) is requested, collecting at least three swab specimens is optimal. For suspected viral infection, the individual collecting the specimen should prepare a smear at the bedside by rolling the entire surface of the swab over a glass slide and allowing the material to air dry.

All swabs for bacterial or fungal testing may be placed in tube transport systems containing modified Stuart's medium; if anaerobic culture is ordered, one swab should be placed in an anaerobic transport device. Transport smears, fluid, and swab specimens promptly to the laboratory.

Specimen Processing

Processing specimens from vesicles or pustules for detection of viruses involves cell culture; and for VZV, and possibly HSV, examination of stained smears is helpful. Specimens for culture are refrigerated for a short time until they are processed. Swab specimens received in viral transport medium are vigorously agitated on a vortex mixer, and then the swab is removed and discarded. Processing specimens for detection of bacteria and/or fungi involves preparation of a smear for staining with Gram stain (for bacteria) or Calcofluor white (for fungi) and inoculation of appropriate media for culture, as discussed in Chapters 57 and 61.

CUTANEOUS ULCERS

Aspirates and swab specimens are collected from cutaneous ulcers for microbiological studies. Lesions may be primary (e.g., those caused by viruses, *Bacillus anthracis*, *C. diphtheriae*, *Francisella tularensis*, *P. aeruginosa*, mycobacteria, or fungi), or decubitus ulcers may become secondarily colonized or infected with aerobic and anaerobic bacteria.

Collection, transport, and processing of swab specimens obtained from cutaneous ulcers for detection of viruses are identical to what were described earlier for vesicles and pustules. Handling of specimens obtained from cutaneous ulcers differs for bacteria and fungi and is discussed separately for each of the organisms that cause primary lesions and for the bacteria associated with chronic ulcers.

B. anthracis causes anthrax, a rare disease in the United States, limited to persons working with raw imported wool and other animal products contaminated with spores of *B. anthracis* and persons exposed to spores through an act of bioterrorism. Cutaneous anthrax begins as a painless papule but becomes vesicular, then hemorrhagic, necrotic, and covered with an eschar. For optimal diagnosis, sending specimens to a public health laboratory where nucleic acid amplification can be performed is recommended. Instructions for specimen collection and transport provided by the public health laboratory should be followed. If specimens are processed in the clinical laboratory, they must be handled in a biological safety cabinet. The swab for culture is inoculated onto sheep blood agar, which is incubated in ambient air.

C. diphtheriae is the cause of cutaneous diphtheria, an ulcerative lesion covered with a layer of necrotic debris resembling a membrane. For optimal diagnosis, a smear for staining with methylene blue is prepared from material collected from the edge of the membrane, and two swab specimens from the membrane are collected. One swab is used for routine bacterial culture and the other for inoculation of media selective for *C. diphtheriae* (e.g. cysteine tellurite agar) if available.

Ecthyma gangrenosum is an ulcerative cutaneous lesion that almost always occurs during bacteremia with *P. aeruginosa* but rarely develops

during bacteremia with other gram-negative bacilli. Ideally, two swab specimens are collected from the ulcer base; one is used to prepare a smear for staining with Gram stain and the other to inoculate media for culture.

The diagnosis of the ulceroglandular form of tularemia requires the collection of a swab specimen from material at the base of the ulcer. The swab is processed in a biological safety cabinet for routine bacterial culture, and the plates are held for a full 7 days, as *F. tularensis* is a slowly growing bacterium, producing pinpoint colonies in 3–5 days on chocolate agar, but does not grow on sheep blood agar. Suspicious isolates should be referred immediately to the nearest public health laboratory for identification.

Mycobacteria most commonly isolated from cutaneous ulcers include *Mycobacterium fortuitum*, *Mycobacterium abscessus*, *Mycobacterium chelonae*, *Mycobacterium marinum*, and *Mycobacterium haemophilum*. *Mycobacterium ulcerans* is a common cause of skin lesions in some parts of the world but is rather difficult to culture. Exudate aspirated with a needle and syringe or a tissue sample is optimal for recovery of mycobacteria. To transport the aspirate, the material is expelled into a sterile tube, which is tightly capped and delivered promptly to the laboratory. Tissue samples are placed on sterile, moist gauze in a sterile container, which is tightly capped. Swab samples are not acceptable for processing for mycobacteria, as mycobacteria become entrapped in the fibers of the swab and are difficult to dislodge. Specimens may be refrigerated for a short time until they are processed (see Chapter 60).

Many aerobic, facultative, and anaerobic bacteria colonize chronic skin ulcers. To identify the organisms responsible, cultures of deep tissues or a deep aspirate of purulent material collected with a needle and syringe provide the most useful bacteriologic information. To transport aspirated pus, remove and discard the needle, cap the syringe, and deliver it promptly to the laboratory. If transport will be delayed, inject a portion of the aspirate into an anaerobic gel transport tube. Tissue samples are transported in a sterile cup with moist sterile gauze to keep tissue from drying out. Processing the specimen involves preparing a smear for staining with Gram stain and inoculating appropriate media for aerobic and anaerobic culture.

An aspirate of the exudate from the active margin of an ulcer (transported as described earlier for bacteria) or a tissue sample is optimal for detection of fungi. A swab specimen of the exudate is suboptimal and should be discouraged. Processing the specimen for detection of fungi involves preparing a smear for direct microscopic examination (potassium hydroxide or calcofluor white preparation) and inoculation of appropriate media for culture, such as brain-heart infusion, inhibitory mold, or SABHI agar containing antibiotics and cycloheximide.

WOUND INFECTIONS AND ABSCESES

Ideally, purulent material is aspirated with a needle and syringe and transported as described earlier for ulcerative lesions. If an aspirate cannot be obtained, swab specimens of exudate collected from the deep portion of the lesion are acceptable. For routine bacterial culture, two swab specimens are optimal: one to prepare a smear for staining with Gram stain and one for culture. To recover anaerobes, an additional swab specimen must be collected and placed in an anaerobic transport system. All specimens should be delivered promptly to the laboratory and processed as soon as possible. If a delay in processing is unavoidable, specimens may be stored in the refrigerator, except those for recovery of anaerobes, which should be maintained at room temperature.

KEY POINTS

- The revolution in molecular biology has had a profound impact on the field of clinical pathology (diagnostic medicine).
- Techniques, including polymerase chain reaction and other amplification and hybridization methods, are capable of detecting DNA in very small quantities in tissue and body fluids, enabling detection of various disease states, including cancer.
- The human genome project has created robust high-throughput and highly sensitive genetic methods (such as microarrays) not only for detecting abnormal genes in patient specimens but also for establishing patterns of gene expression that are characteristic of specific diseases.
- Proteomic methods in detecting protein expression on serum samples from patients allow for diagnosis of different types of cancers.
- Gene array and proteomic methodologies require sophisticated mathematical methods of pattern recognition that allow for detection of disease.

THE MOLECULAR BIOLOGY REVOLUTION AND ITS IMPACT ON THE PRACTICE OF PATHOLOGY

Molecular pathology refers to the analysis of nucleic acids and proteins to diagnose disease, predict the occurrence of disease, predict the prognosis of diagnosed disease and guide therapy. Recent advances in molecular biology have revolutionized the practice of medicine, especially diagnostic medicine. These revolutionary changes result from our abilities to clone disease-causing genes and the proteins that they encode and to detect the presence of these genes and proteins in the serum and other body fluids and tissues of patients, even though they may be present in minute quantities. This detection has been made possible by a veritable explosion of new, highly sensitive techniques involving amplification methods such as polymerase chain reaction (PCR), branched-DNA (BDNA), fluorescent in situ hybridization (FISH) and mass spectroscopy, the latter highly effective for the identification of proteins that are implicated in causing disease (Pincus, 2003). Many of these techniques have been developed to the stage where they are employed in so-called high-throughput processes that enable single patient samples to be analyzed for multiple genes or proteins. Some of these processes have already become completely automated.

A major consequence of the revolution in molecular biology has the mapping of the human genome in the Human Genome Project (Venter, 2001) and the genomes of a number of other species. These projects have identified numerous novel genes of unknown function whose functions can now be determined and whose expressions can be monitored in different disease states. In addition, the techniques employed in these projects have been proving exceptionally useful in studying patterns of gene expression in different disease states (see, for example, Golub, 1999).

DISCUSSION OF DIAGNOSTIC MOLECULAR PATHOLOGY

These methods are described in Parts 8 and 9 of this book. In Part 8, the principles that underlie the main diagnostic approaches used in clinical molecular biology are discussed. Chapter 65 describes the basic principles in gene hybridization, including use of Southern and Northern blots, and gene cloning, and Chapter 66 discusses amplification methodology, including PCR and BDNA, which allows gene identification and quantification of gene expression. Chapter 67 discusses how the expression of multiple genes—in fact, of whole genomes—can now be assayed on microarrays.

One of the motivations for detecting genetic abnormalities in specific diseases is the finding that, in many such disease states, there are well-defined, reproducible chromosomal abnormalities. In fact, increasing numbers of genes that have been strongly implicated in causing disease can be identified on chromosomes using FISH technology, which enables detection of gene rearrangements and gene deletions in a number of diseases, especially in cancers. Chapter 68 discusses the cytogenetics of human diseases and shows how FISH technology has enabled major advances in diagnosis of disease. All of these diagnostic approaches constitute diagnostic or clinical molecular biology or molecular diagnostics. Chapter 69 discusses how a molecular diagnostics laboratory is established. In Chapter 70, how molecular biology techniques are used to diagnose genetic diseases is demonstrated.

One of the consequences of the genetic revolution has been the ability to identify single gene mutations in patients' DNA that may either result in disease or may simply be polymorphisms. The latter is advantageous in establishing the parentage of children and in the investigation of crime. Consequently, there has been a dramatic increase in the use of the molecular diagnostics laboratory for forensic purposes. Chapter 71 describes how single nucleotide polymorphisms are used to establish parentage and the identities of the victims and perpetrators of crime.

Mapping of the human genome reveals that these polymorphisms occur in the human genome approximately 1 per 1000 base pairs. Some of these

polymorphisms are in genes, principally those that encode cytochrome P450, some of which are discussed in Chapters 21 and 23, whose functions are important in response of individual patients to therapy (Evans, 1999; Rodriguez-Antona, 2010).

Genes that encode drug-metabolizing enzymes, both activating and inactivating, and genes that encode ligands and receptors may show polymorphisms that either decrease or increase the therapeutic effectiveness or toxicity of drugs already in wide use, accounting for some idiosyncratic responses previously not understood or predictable. Thus there has been a major advance in testing patients for genetic expression of these isoforms allowing prediction of which drugs would be the most effective ones. This has revolutionized medical practice and has given rise to so-called personalized medicine wherein patients are tested genetically for the most appropriate drug therapy and to the field of pharmacogenomics in which this testing is performed. The techniques and screening practices for the design of effective drug therapy are described in a new chapter, Chapter 72, entitled "Pharmacogenomics and Personalized Medicine."

As more polymorphisms are identified and correlated with individual patient's response to treatment, the pathologist will be called upon increasingly to profile common polymorphisms in patients who are beginning therapy for common diseases such as coronary artery disease, congestive heart failure, diabetes, thrombosis, hypertension, cancer, and infections. The laboratory's definition of the individual patient's genotype/phenotype will determine the specific drugs and doses suitable for that patient. This evolution has placed the pathologist in a more definitive position to determine appropriate therapy than traditional prediction of disease behavior based on morphology of lesions or culture characteristics of infectious organisms.

In fact, with respect to infectious organisms, the pathologist is further being called upon for genotyping of infectious agents such as human immunodeficiency virus. Different strains show markedly different drug susceptibilities. Thus determination of the genotypes of infectious agents has major therapeutic implications (Tozzi, 2010).

APPLICATION OF MOLECULAR PATHOLOGY TO DETECTION OF CANCER

Part 9 of this textbook is devoted to new developments in laboratory testing for cancer. A momentous consequence of the revolution in molecular biology has been the identification of genes, called oncogenes, and their encoded proteins, called oncoproteins, that cause specific forms of cancer. Mutations in these genes, produced by mutational events associated with, for instance, carcinogens and oncogenic viruses, often result in abnormal activation or overexpression of their encoded proteins.

Many of these oncogenic proteins are critical components of so-called signal transduction pathways, in which ligands, such as growth factors, bind to cell membrane receptors, setting in motion a chain of protein activation cascades that are ultimately transmitted to the nucleus, resulting in increased transcription and ultimately high levels of expression of promitotic proteins such as the cyclins. When one or more of the proteins on mitogenic signal transduction pathways become mutated, the cells in which they are expressed become transformed into cancer cells. Once transformed, cancer cells express a number of proteins, in addition to the mutated or overexpressed oncoproteins, that are not expressed by normal cells even in growth phase.

These findings have been translated into new clinical diagnostic methods for the detection of these abnormal proteins in the early detection of cancer in patients. Therefore, Part 9 of this book is devoted to the way in which these proteins are used in early tumor detection and to following the efficacy of the treatment of cancer. One of the major findings in this area has been that screening for cancer is most effective when multiple oncoproteins are assayed. A pathbreaking step in this area of multiple protein assays has been the development of new mass-spectroscopic techniques that enable detection of patterns of protein expression in serum that are unique to specific cancers, in a field known as proteomics that is showing great promise in screening for a number of different major human cancers.

A major impact of the human genome project has been the ability to study multiple gene expression, mainly using microarrays, in normal individuals and in specific disease states. Cancer is a major area in which the differential expression of specific genes characterizes particular tumors. Combination of gene expression with proteomics now allows for diagnosis of and screening for a number of different types of tumors, uniting molecular genetic and proteomic approaches.

Many oncoproteins and oncogenes can be used very effectively as tumor markers when detected in serum, urine, and other body fluids. Chapter 73 discusses how proteins that are expressed predominantly in specific tissues can be used in the diagnosis and, mainly, the following of the efficacy of anticancer therapy. These so-called tumor markers include prostate-specific antigen for prostate cancer, carcinoembryonic antigen for colon cancer and other gastrointestinal tumors, and α -fetoprotein for hepatocellular carcinoma. Use of these proteins for early detection is included in Chapter 74 along with discussions of how the proteins in mitogenic signal transduction pathways such as epidermal growth factor receptor, neu/HER2, ras-p21, raf, myc, and p53 proteins can be employed very effectively as tumor markers.

In the previous edition of this book, the chapter on the molecular biology of hematopoietic cancers was included in the Molecular Pathology section (VIII). In view of major advances in the molecular biology of human cancers, we now include this chapter (74) in Part 9, on the molecular pathology of cancers. There has been a veritable explosion of information on the genetics and molecular biology of a wide variety of solid tissue (epithelial cell) tumors and sarcomas, over the past several years that complement the information concerning the serodiagnostic markers for a number of these tumors. Therefore, we have included in this edition a new chapter, Chapter 76, that discusses the molecular genetics of these tumors, and we have summarized the major genetic findings for these tumors which we hope the reader will find a convenient reference. One of the most revolutionary advances that has been made in recent years has been the sequencing of the entire human genome. This momentous achievement now enables us to study expression of genes and groups of genes in different cancers so as to develop patterns of gene expression that characterize specific cancers. Patients with these patterns can then be screened for these cancers on a regular basis, allowing early tumor detection and effective therapeutic intervention (in most cases, surgical excision). Chapter 77 discusses the methodologies used in mapping the genome because these approaches are involved in screening for different diseases. As the functions of more genes become known, it will become increasingly feasible to screen the genomes of patients for gene abnormalities, especially those causing or predisposing patients to develop cancer. To an increasing degree, clinical laboratories will be called upon to perform this type of analysis.

IMPLICATIONS OF MOLECULAR DIAGNOSTICS ON THE PRACTICE OF PATHOLOGY AND MEDICINE REDEFINING DISEASE

The availability of the sequence of the human genome and the identification of all the human genes immediately change our understanding of health, disease susceptibility and precursors, and disease (Pandey, 2000). An ability to identify the gene expression pattern that makes a disease entity unique further allows the pathologist to delineate uniquely clinically different diseases that may be difficult or impossible to distinguish on the basis of morphology or other laboratory data alone (Heller, 1997; Golub, 1999; Talaulikar and Dahlstrom, 2009). A poignant example of this phenomenon is the diagnosis of leukemias and lymphomas. Morphologically and even immunophenotypically it may prove difficult to distinguish among different types of each disease; however, as discussed in Chapter 75, specific gene rearrangements and patterns of gene expression now enable distinction of different types. In addition, the relationships among diseases are also more sharply defined, and sometimes radically changed, by comparisons among the diseases' gene expression profiles (Anbazhagan, 1999; Bacher, 2009).

In the opposite direction, sequencing of disease genes and testing for mutations are demonstrating that diseases have broad spectrums of presentation that range from mild symptoms that are unrecognized as part of the disease, and may even include complexes not previously recognized in isolation as forms of the disease, to full manifestation of the disease. A compelling example of this marked expansion of the syndromes comprising a disease is cystic fibrosis (Friedman, 1999), discussed in Chapter 70. In addition to the severe and milder pulmonary and pancreatic dysfunctions long accepted as cystic fibrosis, isolated examples of congenital bilateral absence of the vas deferens, chronic pancreatitis, and sinopulmonary complaints have been associated with mutations of the cystic fibrosis gene. These mutations are not always associated with the severe classical form of the disease (Ferrari and Cremonesi, 1996). Recognition of symptom

complexes extending the definition of diseases on the basis of gene mutations will both focus appropriate patient management in the milder or atypical forms of the disease and define pathobiology, not only of whole genes but also of affected specific exons and introns.

USE OF MOLECULAR BIOLOGY IN THE TREATMENT OF DISEASE

As discussed, genetic screening for the presence of isoforms of cytochrome P450 and other proteins involved in drug metabolism and the genotyping of infectious organisms has enabled the design of the effective treatment of patients on an individualized basis. Likewise, proteomic approaches to cancer detection have also resulted in the development of new therapies.

For example, many breast cancers express the neu/HER2 growth factor receptor, whose presence can be detected in serum by immunoassay. As described in Chapter 73, a cytotoxic antibody, Herceptin, to this receptor, which does not cross-react with the diagnostic antibodies, has been found to destroy breast cancer cells and is now used to treat neu/HER2-positive breast cancers effectively.

DATA ANALYSIS

To capitalize fully on the power of molecular pathology, wholly new approaches to data analysis and relating data to disease management are being developed. Pathologic investigation of disease and of basic biology has traditionally analyzed and related only one or a few markers such as antigens, enzymes, structural proteins, and the like. Molecular techniques are now producing data on many thousands of genes, including their expression and their sequences. Digesting all these data, organizing them into profiles of diseases or patients, and relating different profiles demand new approaches to bioinformatics toward appropriate application of biomarkers in disease diagnosis and prognosis (Klee, 2008). As discussed in Chapter 77, this involves the use of mathematical algorithms that allow pattern recognition, such as neural network theory (Khan, 2001). Thus the pathologist must work closely with mathematicians and must learn more sophisticated analytic approaches to diagnosis (Bitner, 1999).

QUALITY ASSURANCE

As with all laboratory methods, excellent quality assurance programs are required to ensure that molecular pathologic results are accurate and useful. As discussed in Chapter 69, two essential components of quality assurance programs are standardization of methods and interlaboratory

comparison of test results. Standardized methods for performance of the most common clinical molecular pathologic tests are published by the Clinical and Laboratory Standards Institute (formerly National Committee for Clinical Laboratory Standards). Use of these guidelines ensures that the data generated in molecular pathology laboratories are produced by methods that are the standard of excellent practice. Interlaboratory comparison of test performance is provided by the College of American Pathologists (CAP; www.cap.org). The CAP interlaboratory comparison surveys include molecular microbiology, genetics, hematology, parentage and identity, and general forensic applications.

Applying established standards of quality assurance and using molecular pathologic techniques with a thorough understanding of their respective strengths and weaknesses as presented in the following chapters, the pathologist will continue to capitalize on the opportunities these techniques offer for improved patient care and the understanding of basic pathobiology.

CAVEATS

As will be seen throughout this section and the next, molecular diagnostic techniques provide new insights into disease that were never before possible. However, these techniques must not be used alone but in coordination with traditional laboratory tests. For example, in the diagnostic workup of leukemias, the traditional morphologic and immunochemical testing must always be performed. Gene analysis becomes critical when there is a question as to the type of leukemia or the characterization of the types of gene rearrangement that have occurred. In cases of tissue pathology, the morphologic skills involved in histopathology and cytopathology must be employed to ensure that appropriate cells and tissues are analyzed molecularly. Otherwise, analysis of other than targeted cells/tissues, despite high-quality technical methods interpreted with skill and experience, can lead to erroneous, sometimes dangerously misleading, results.

On the other hand, rapid progress in the development of highly sensitive molecular biological and proteomic techniques are allowing some standalone capabilities for molecular diagnostics. For example, use of FISH to detect bladder cancer in urine is now recognized as an excellent means of diagnosing this condition. Other, similar developments in molecular biological approaches are showing promise in screening for specific diseases.

In summary, molecular pathology is penetrating and permeating the entire clinical laboratory just as immunopathology did over two decades ago. Section boundaries or barriers will continue to break down and dissolve in this transformation of laboratory medicine through the impact of the new biology of medicine, "cell and molecular biology."

SELECTED REFERENCES, 1270**KEY POINTS**

- Familiarity with the basics of nucleic acid biochemistry and biology is required to understand molecular diagnostic testing.
- The chemical stability of double-stranded DNA stands in contrast to the lability of RNA.
- Base pairing of nucleic acids is dictated by energetically favorable rules and forms the basis for DNA replication, RNA transcription as well as hybridization assays.
- The chemical similarity of nucleic acid molecules, regardless of their source, means that methods of extraction, storage and handling are similar.
- Enzymes that synthesize and modify nucleic acids (e.g., polymerases, transcriptases, nucleases, ligases) may be harnessed as tools for molecular biology and molecular diagnostics.
- Nucleic acid analyses include electrophoresis, hybridization assays, amplification techniques, sequencing, and polymorphism detection. Complete assays or diagnostic tests often combine several of these techniques, such as amplification, electrophoresis and hybridization.
- Molecular diagnostics is now part of the mainstream of laboratory diagnostics.

Nucleic acids are the critical molecules of life. Deoxyribonucleic acid (DNA) resides in the nucleus of eukaryotic cells and maintains all the information necessary for maintenance of the organism and for transfer of the information to successive generations. Ribonucleic acid (RNA) carries information from DNA to the cytoplasm of a cell and directs synthesis of the proteins necessary for the function of the organism. The normal state of health depends on the stability of DNA and on accurate DNA duplication and translation into protein. Modern cell biology seeks to determine the basic mechanisms of cell structure and function, and studies are increasingly focused at the level of the gene, the protein-coding units of

DNA. As a consequence, diagnostic methods are also being directed toward nucleic acid evaluation. The goal of this chapter is to provide the conceptual framework for diagnostic applications of nucleic acid analyses.

NUCLEIC ACID BIOCHEMISTRY AND BIOLOGY

Nucleic acid biochemistry is central to modern cell biology and dictates many aspects of diagnostic applications. Many of the enzymes associated with *in vivo* nucleic acid synthesis, degradation, and repair have become basic laboratory tools for manipulation and analysis of DNA and RNA. Cellular mechanisms that operate to direct and control DNA replication, transcription, and translation address the basic biology of the cell in health and disease. Diagnosis, therapy, and research are all increasingly directed at a molecular level of cellular function. This first section provides an overview of those aspects of nucleic acid biochemistry and biology that are required to understand the current diagnostic applications of molecular biology. Further details are available from textbooks of cell biology (e.g., Alberts, 2007).

MOLECULAR COMPOSITION AND STRUCTURE

DNA is a long, double-stranded polymeric molecule (dsDNA) that exists predominantly in the form of a right-handed double helix. Each single-stranded DNA molecule (ssDNA) is composed of a small number of building blocks. The backbone of the ssDNA polymer is the sugar deoxyribose connected by phosphate groups (Fig. 65-1, 4). Phosphodiester bonds between the 3' carbon of one sugar ring and the 5' carbon of the next give the backbone its invariant structure and its 5' to 3' directionality. Linked to the 1' carbon of each sugar is one of four possible bases: thymine (T) and cytosine (C) (pyrimidines); adenine (A) and guanine (G) (purines). The bases can occur in any sequence order, and thus form the variable

Figure 65-1 Repeating backbone of DNA and complementary base pairs. *A*, A single-stranded DNA chain. Repeating nucleotide units are linked by phosphodiester bonds that join the 5' carbon of one sugar to the 3' carbon of the next. *B*, Purine and pyrimidine bases and the formation of complementary base pairs. Shaded bars indicate the formation of hydrogen bonds. (Adapted from Piper MA, Unger ER. *Nucleic acid probes: a primer for pathologists*. Chicago: ASCP Press; 1989, with permission.) *In RNA, the sugar is ribose, which has a 2' hydroxyl added to deoxyribose. †In RNA, thymine is replaced by uracil, which differs from thymine only in the lack of the methyl group.

portion of ssDNA. The building blocks of the single-stranded polymer are the four deoxyribonucleotide triphosphates (dTTP, dCTP, dATP, dGTP), each consisting of a sugar molecule, a triphosphate group, and one base. During DNA synthesis, nucleotides are first stripped of two phosphate groups and then enzymatically linked together by phosphodiester bonds to form a chain.

DNA is an extraordinarily stable molecule, losing its normal conformational structure only at extremes of heat, pH, or in the presence of destabilizing agents. The double-stranded helix is the most energetically favorable state for DNA, and an examination of the components of DNA explains this fact. Both sugar and phosphate groups are hydrophilic, forming stable hydrogen bonds with surrounding water molecules in solution. Bases, however, are hydrophobic and are not soluble in water at neutral pH. A stable molecule of DNA must ensure that the bases do not contact water. This is possible when two antiparallel ssDNA polymers (one running in the 3' to 5' direction, the other 5' to 3') twist around the same axis. This arrangement allows planar hydrogen bonds to form between adenine and thymine, and between guanine and cytosine (see Fig. 65-1, *B*). As long as the two chains have base sequences in complementary order, the strands of the helix have a ladder-like structure with rungs (base pairs [bp]) of consistent size. The flexibility of the carbon-oxygen linkages in the phosphodiester bond allows the ladder to twist, forming a regular helix such that the planar base pairs are stacked on top of each other, leaving no room for water molecules in between. The polymeric series of base pair hydrogen bonds holds the ssDNA chains tightly together, and the helical conformation protects the base pairs from water, exposing only the hydrophilic backbones.

Helical dsDNA is stable over a pH range of approximately 4–9. Solutions with pH outside these limits have the capacity to disrupt the base pair bonds and cause the DNA helix to denature or unwind into two separate, random coils. Extreme heat and hydrogen bond disrupters, such as formamide, also have the same effect. This helix-to-coil transition can be followed spectrophotometrically at A_{260} (Fig. 65-2). The bases absorb ultraviolet (UV) light maximally at this wavelength, but at a lower molar absorptivity in dsDNA; absorptivity increases 20%–30% when dsDNA is converted to ssDNA. Because temperature is often used to effect this transition, the process has been referred to as *melting*, and the temperature at which 50% of dsDNA is converted to ssDNA is called the *melting point* or T_m of the DNA. The T_m of DNA molecules depends on the relative G-C versus A-T base pair content, because the three hydrogen bonds of G-C base pairs require more energy to disrupt than the two hydrogen bonds of A-T base pairs. Lowering the temperature can reverse the melting

Figure 65-2 Melting/annealing curve of double-stranded helical nucleic acid. (Adapted from Piper MA, Unger ER. *Nucleic acid probes: a primer for pathologists*. Chicago: ASCP Press; 1989, with permission.)

process, and the two complementary strands reform the original helix if the base pairs reform in the correct linear conformation.

The length of a fully extended eukaryotic DNA molecule would be about 3 m per genome, much longer than the cell itself. Undegraded purified DNA forms a stringy viscous solution, reflecting the extreme length of genomic DNA (Fig. 65-3). In vivo, however, DNA is organized into highly compacted, regular units called chromosomes. A chromosome is composed of its DNA strand wound around DNA-associated proteins (chromatin) in a highly structured fashion. The chromosome structure

Figure 65-3 Photograph of purified DNA demonstrating stringy viscous nature of minimally sheared genomic DNA.

TABLE 65-1

Comparison of Key Features of DNA and RNA

Feature	DNA	RNA
Sugar	Deoxyribose	Ribose
Base pairs	Thymine–adenine Cytosine–guanine	Uracil–adenine Cytosine–guanine
Structure	Double-stranded Alpha helix	Single-stranded Random (see text)
Stability	Stable Degraded by DNase	Subject to base hydrolysis Degraded by RNase
Function	Maintains genetic information in nucleus	Carries genetic information to cytoplasm

involves several hierarchical levels of chromatin packing, from a “beads-on-a-string” nucleosome (146 nucleotide pairs wound around a histone core) to highly condensed loops each containing about 100,000 bp of DNA. Each human cell nucleus contains two sets of 23 chromosomes of characteristic length and unique base pair sequence. Together these chromosomes constitute the *human genome*. As a result of the Human Genome Project, the complete sequence of the 3 billion chemical base pairs that make up the human genome was finished in 2001 (The Human Genome Project is discussed in Chapter 77).

RNA differs from DNA in chemical composition, structure, and function (Table 65-1). In RNA the sugar is ribose, containing a hydroxyl group at the 2' position, and thymine is replaced by the methylated uracil (U). RNA exists predominately as a single-stranded molecule and in much shorter lengths than DNA. The structure of RNA is more irregular, owing to the single-stranded nature of the molecule, but may contain some helical sections and hairpin loops. RNA molecules of the same base sequence, however, will form the same three-dimensional structure as a result of adopting the most energetically favorable conformation. RNA is much less stable than DNA, due not only to the single-stranded more random structure but also to its susceptibility to alkaline hydrolysis via the 2' hydroxyl group of the ribose moiety. RNA-specific enzymes that are ubiquitous also rapidly degrade RNA.

TABLE 65-2

Nucleic Acid Enzymes and Associated Functions

Enzyme	In Vivo Function
Polymerases DNA polymerases RNA polymerases	Polymerases join DNA or RNA nucleotides together to form a single-stranded daughter molecule using a stretch of single-stranded parent molecule as a template. These enzymes perform syntheses according to base pair rules and proceed in the 5' to 3' direction.
Reverse transcriptase	Mostly of viral origin, reverse transcriptase catalyzes the synthesis of DNA from either an RNA or DNA template.
DNA ligases	Joins DNA fragments formed by discontinuous synthesis in DNA replication or by DNA repair pathways.
Nucleases DNases, RNases Endonucleases Exonucleases	Nucleases “digest” nucleic acid molecules by breaking phosphodiester bonds. Endonucleases digest nucleic acids from the middle of the molecule whereas exonucleases begin at a free end and may require a 3' or 5' end. Nucleases may have single-stranded, double-stranded, DNA, or RNA specificity. Some polymerases also have nuclease activity.
Restriction endonucleases	Bacterial endonucleases that recognize specific short DNA base pair sequences and cleave the DNA molecule only at the recognition site.

NUCLEIC ACID-ASSOCIATED ENZYMES

DNA must be duplicated prior to cell division so that daughter cells retain an exact copy of the genetic information contained in parent chromosomes. RNA must be synthesized by all functioning cells to direct the synthesis of necessary proteins. DNA must be degraded during repair of damaged segments, and RNA is continually degraded and resynthesized. Enzymes that operate directly on nucleic acids affect these and other functions. Table 65-2 lists major categories of nucleic acid-specific enzymes and their in vivo functions. In vitro, purified enzymes have become laboratory *tools* for the molecular biologist, allowing genetic engineering and facilitating many nucleic acid assays.

Nucleic acid-specific enzymes include polymerases, which catalyze the formation of phosphodiester bonds during synthesis; and nucleases, which hydrolyze these bonds. RNA-specific nucleases (RNases) are present virtually everywhere. Because of this, it requires much greater care in laboratory practice to work with RNA in vitro than with DNA. Restriction endonucleases are a special category of nucleases found only in bacteria, where they function to destroy foreign DNA. The recognition sites for restriction enzymes are located anywhere within the DNA molecules, are sequence-specific, and can vary approximately 4–12 bp in length. At the recognition sequence or nearby, restriction endonucleases make specific asymmetric or blunt end cuts in DNA molecules (Fig. 65-4). More than 3000 restriction endonucleases have been discovered and categorized according to the structure of their corresponding sequence recognition sites (Pingoud, 2001). The in vivo function and in vitro utility of many of these enzymes are discussed in the following sections.

REPLICATION OF DNA

The DNA duplication process, known as *semiconservative replication*, uses each strand of the parent molecule to direct the synthesis of a daughter strand (Virshup, 1990). Because the base sequence of the parent strand dictates the sequence of the daughter strand, replication is faithful and the replication products consist of two dsDNA molecules, composed of one parent strand and one daughter strand each, with exactly the same base pair sequence. Although this is conceptually simple, the process is complicated and involves a number of accessory proteins and enzymes. First, for synthesis to begin, a small single-stranded region must be produced. This is not energetically favorable, and must be accomplished using proteins that unwind and separate the strands of the helix. Next, a short RNA primer is synthesized complementary to the single-stranded sequence. DNA polymerase III proceeds with DNA synthesis and later the RNA primer is excised and replaced with DNA by DNA polymerase I. Chromosomal DNA contains many initiation sites for replication, and this

Figure 65-4 Examples of DNA restriction enzymes and their specificities. Enzymes are named for the bacteria from which they are isolated. (*N is any base, and N' is its pairing counterpart.)

process occurs simultaneously across the chromosome. Interestingly, DNA polymerase III is a directional enzyme, and can synthesize DNA only in the 5' to 3' direction because it requires a free 3'OH end. This means that only one daughter strand, called the *leading strand*, can be synthesized continuously. The opposite strand, called the *lagging strand*, is primed by RNA primase that does not require a free 3'OH end. It is synthesized discontinuously in short fragments (Okazaki fragments) as the replication fork is opened up. These fragments are then joined together by DNA ligase. DNA polymerase III is also unique in that it has *proofreading* and exonuclease activity. If an incorrect nucleotide is added to the growing chain, it is detected and excised by the nuclease portion of the enzyme, and the correct nucleotide is then added. This helps explain the extraordinary fidelity of the DNA replication process. Postsynthesis repair mechanisms also contribute to the accuracy of replication (see later under *Mechanisms of DNA Repair*).

TRANSCRIPTION OF DNA TO RNA

Sections of DNA that specify amino acid sequences of proteins are called genes; one gene contains the amino acid sequence code for one protein as well as DNA sequences necessary for the regulation of the production of that protein. Within the 6 billion nucleotides of the human genome, there are about 20,000–25,000 protein-coding genes. Although these coding sequences are of paramount importance to the cell and to the function of the organism as a whole, they actually make up less than 5% of the nucleotides. The vast majority of the human genome is composed of noncoding DNA regions, sometimes referred to as “*junk DNA*.” It appears that much of it may well have some purpose such as secondary regulatory roles in gene expression (see later section on *Gene Regulation Mediated by Small RNA*).

Protein synthesis begins with the activation of the appropriate gene. A copy of the gene is made from DNA in the form of RNA. Because the RNA copy carries the code from the DNA in the cell nucleus to the cytoplasm where amino acid synthesis takes place, this type of RNA is called *messenger RNA* (mRNA). Messenger RNA is synthesized from only one strand of the DNA gene; the complementary DNA strand is not used. This is accomplished by a process called *transcription*. Synthesis of mRNA proceeds in much the same fashion as DNA replication, with the ssDNA sequence dictating the mRNA sequence using the same rules of base pair complementarity (uracil base pairs with adenine). When the end of the gene is reached, mRNA synthesis is terminated. Some genes are always expressed, while others are only active in certain physiologic situations. The rate of transcription also varies in different cells (see section on *Transcriptional Control* later).

POSTTRANSCRIPTIONAL MODIFICATION

Before export to the cytoplasm, the mRNA molecule is modified in several ways (Rosenthal, 1994). Messenger RNA contains both amino acid coding sequences (exons) and noncoding sequences (introns); introns are excised from the mRNA molecule before protein synthesis. A molecular complex

called a spliceosome (Sharp, 1988), which is composed of both low molecular weight RNA and protein, recognizes mRNA sequences that identify the boundaries of an intron, joins the flanking exons, and releases the intron. Splicing must be exact, as the addition or subtraction of a single nucleotide at the splice junction would change the 3-nucleotide reading frame in the nucleotide sequences that follow.

Further modifications to the mRNA molecule include the addition of 7-methyl guanosine residues to the 5' end in a unique 5'-5' phosphodiester bond. This is called a *cap* and aids in the binding of the ribosome to the mRNA molecule for initiation of protein synthesis. A poly-A *tail*, which may be necessary for stability and transport to the cytoplasm, is added to the 3' end. The polyadenylation locus is specified in part by the sequence AAUAAA usually found in the 3' untranslated region of the RNA transcript. At this point, the mRNA molecule is ready to direct the synthesis of its corresponding protein.

TRANSLATION OF RNA TO PROTEIN

Protein synthesis requires translation from the language of nucleotides to that of amino acids. Twenty-one different amino acids are used in protein synthesis; each amino acid is specified by one or more mRNA nucleotide triplets called *codons*. For example, AAG is the codon for lysine and UCG is the triplet for serine. Thus an amino acid coding sequence is read in groups of three nucleotides running in the 5' to 3' direction; this is the *reading frame* of a protein coding sequence. Three specific codons, (UAG, UGA, or UAA), do not code for amino acids but instead signal the end of a gene (*stop codons*). Because an amino acid can be encoded by more than one codon, the code is referred to as a *degenerate code*.

Translation from the mRNA nucleotide code to protein is mediated by ribosomes in the cytoplasm of the cell. A ribosome binds to the 5' end of the mRNA and provides a stable chemical environment for all the molecules involved in protein synthesis. Amino acids are linked in the correct sequence by the action of small, adaptor RNA molecules called *transfer RNAs* (tRNAs). Each tRNA molecule contains a region that is complementary to a particular mRNA codon: the *anticodon*. Linked to one end of the tRNA is the amino acid that corresponds to the complementary mRNA codon of the tRNA. A tRNA with the correct complementary anticodon binds to the first codon in the mRNA sequence, which is always AUG. When another specific tRNA binds to the next codon, ribosomal enzymes catalyze the formation of a peptide bond between the two amino acids linked to the tRNAs, removing the linkage between the first amino acid and its tRNA molecule. The first tRNA is ejected from the ribosome and a new tRNA binds to the next codon. As this process continues, the ribosome moves along the mRNA molecule, completing the synthesis of the amino acid chain. When a stop codon is reached, the ribosome detaches from the mRNA. In reality, several ribosomes can move along the same mRNA molecule, each translating the mRNA code into a new protein molecule.

TRANSCRIPTIONAL CONTROL

To allow for cellular differentiation and response to environmental stimuli, there must be mechanisms controlling the repertoire of gene transcription and protein translation. Some of these mechanisms operate at the level of DNA and control the transcription of mRNA (Rosenthal, 1994). For example, promoters are DNA sequences that are important for the initiation of mRNA transcription. Promoters are found upstream (toward the 5' end) at a relatively invariant distance from the beginning of the protein coding sequence. There are several different kinds of promoter consensus sequences (nucleotide sequences that are found in many examples). The most common promoters are rich in adenine and thymine and have been called *TATA boxes*. Because A-T base pair bonds are weaker than G-C base pair bonds, DNA unwinds more easily at repeat A-T sequences. Other recognized promoter sequences are the *GC box* and the *CAA motif*. After transcriptional activation, a local ssDNA region is produced and stabilized by the assembly of a complex of RNA polymerase and general transcription factors (Fig. 65-5). Messenger RNA is synthesized from the local region of ssDNA and the mRNA is quickly ejected as the DNA returns to its more energetically favorable double-stranded helical state.

Enhancers are DNA sequences that can augment mRNA transcription and may be found in different locations relative to the gene that they affect. Gene-specific transcription factors are proteins that bind to enhancers and promoters and selectively stimulate or inhibit mRNA transcription (Papavassiliou, 1995). In eukaryotes, enhancers commonly contain multiple binding sites for several transcription factors, so it is the net effect of

Figure 65-5 Assembly of the polymerase II transcription initiation complex. (1) The basal TFIID complex assembles as the TATA-box binding protein (TBP) and associated factors (TAFs) at the TATA box of the promoter region. (2) Additional transcription factors TFIIA and TFIIB are recruited to enable the polymerase II enzyme and TFIIF to bind. (3) The complex is stabilized with TFIIE, TFIIH and TFIIJ. Typically, binding of additional factors to upstream enhancer sites like CCAAT or GGGCGG are required for effective RNA transcription.

factors binding to these DNA elements that determines the activation and rate of expression. The availability of transcription factors, in turn, is controlled by cellular events such as phosphorylation, or by other proteins such as hormones and growth factors. A network of intracellular and extracellular chemical communications can thus select and control the synthesis of necessary proteins.

Because mRNA is far less stable than DNA, the half-life of mRNA is very short. New mRNA molecules are continually transcribed from DNA. As the cell responds to changes in transcriptional signals, the genes that are transcribed into mRNA can be quickly changed, resulting in the immediate synthesis of new proteins. Thus the cell has the ability to rapidly adjust its protein output in response to its environment.

Gene Regulation Mediated by Small RNA

Recently a novel mechanism of gene regulation by another class of RNAs—small RNAs—was discovered. Small RNAs are short, noncoding ribonucleotides that function as posttranscriptional regulators of gene expression. First discovered in the 1990s, they were found in cells of many eukaryotic organisms including mammals (Fire, 1998). The small RNAs are divided into several different subgroups, most notably small interfering RNA (siRNA) and micro RNA (miRNA).

The DNA sequences for siRNAs and miRNAs are often located in noncoding regions between genes. They generally have their own promoters and transcription is mediated by polymerase II. The immediate product is an miRNA precursor that forms a double-stranded hairpin structure (Fig. 65-6). An enzyme called Dicer processes it to short RNA duplex molecules and further into single-stranded RNAs 22 to 26 nucleotides in length. The small RNA strand attaches to an RNA-induced silencing complex (RISC), which mediates binding to complementary sequences of mRNAs. siRNAs pair perfectly with the target mRNA and trigger a series of molecular mechanisms that lead to its degradation. This process is also called RNA interference (RNAi). miRNAs bind imperfectly to their target mRNA, causing conformational changes, bulging, and subsequent blockage of protein translation at the ribosome. Small RNAs are abundant in eukaryotic cells (several hundred) and it is thought that each one can target multiple mRNAs either as siRNA or miRNA. They are often tissue specific and have been implicated in the regulation of all major cellular processes such as proliferation, differentiation, metabolism, and cell death. siRNAs have also been recognized as a new RNA-based immune system against viruses that is based on silencing through the RNAi mechanism. Furthermore, changes in miRNA expression patterns can be found in many malignancies, and specific miRNAs were found abundantly in certain tumors (Iorio, 2009).

Figure 65-6 Diagram of the RNAi pathway: (1) Sense-antisense transcripts build a dsRNA with hairpin structure (2). This molecule is recognized by the Dicer complex (3) and processed into smaller fragments of 21–24 nucleotides (4). The RNA-induced silencing complex (RISC) protein complex assembles with these molecules and unwinds them into single strand oligos (5). Active RISC binds to target mRNAs with either perfect complementary sequence (6a), which initiates cleavage and degradation, or imperfect sequence match (6b), resulting in bulging, interference with translation, and subsequent silencing.

Epigenetics and Gene Regulation

Epigenetics refers to changes in gene expression that are not dependent on DNA sequence. In most instances, this involves a change in the chromatin structure that facilitates or blocks gene transcription. This is a dynamic process involving enzymes that chemically modify DNA or histone proteins. A methyl group added to the fifth carbon of cytosine results in 5-methyl cytosine. This generally occurs on cytosines located next to guanines (CpG) that are often repeated in islands or patches located in the promoter region. DNA methylation tends to result in condensed chromatin and reduce transcription. DNA methyltransferases are the enzymes responsible for DNA methylation. Chromatin proteins may be acetylated, deacetylated, or methylated. There is evidence that small RNA chemistry may directly interact with a variety of epigenetic mechanisms (Moazed, 2009). Epigenetic changes are recognized to be important in tissue-specific gene transcription, and alterations may be factors in cancers, aging, and stress response.

MECHANISMS OF DNA REPAIR

Errors in DNA replication and damage to DNA during the normal cellular lifetime must be minimized to preserve the health of the entire organism. Several mechanisms operate to maintain the normal DNA sequence. First are the error-avoidance mechanisms that operate during DNA replication. The DNA polymerase that synthesizes new DNA polymers selects each successive nucleotide monomer based on its complementarity to the next nucleotide in the template strand. Fidelity at this level is high and most errors in synthesis are avoided at this stage. Nevertheless, an occasional base may be incorrectly added to the growing strand. To adjust for this, the proofreading activity of the polymerase can recognize the error, remove the incorrect base, and proceed again with synthesis. Together, the error avoidance mechanisms reduce base pair mismatches to approximately 1 in 10 million (Radman, 1988). This represents a 100,000-fold increase in efficiency compared with the error rate of 1 in 100 bases for in vitro solid phase oligonucleotide synthesis.

Despite the remarkable error avoidance in DNA replication, occasional mistakes do occur. In addition, DNA can be damaged by normal biochemical reactions and by nonphysiologic agents such as UV light and environmental carcinogens. Several repair mechanisms mend damaged DNA (Yu, 1999) (Table 65-3).

Direct repair mechanisms repair lesions in a single-step reaction. For example, O⁶-methylguanine DNA methyltransferase repairs alkylation lesions by transferring the alkyl group from the lesion to the active site of

TABLE 65-3

DNA Repair Pathways

Direct repair	Repairs certain types of DNA damage in a single-step reaction.
Mismatch repair	Checks for errors made when DNA is replicated. Any mispaired bases in the daughter strand are removed and replaced with the correct match.
Base excision repair	Repairs small, nonhelix-deforming adducts such as those produced by methylation, oxidation, reduction, or base fragmentation by ionizing radiation.
Nucleotide excision repair	Removes bulky DNA adducts such as thymine dimers and certain photoproducts as well as chemical adducts and cross-links.
Double-strand break repair	Repairs double-strand breaks that result from physiologic processes or from ionizing radiation and oxidative insults.

the enzyme. Other direct repair mechanisms characterized in *Escherichia coli* may also exist in human cells (Yu, 1999).

Mismatch repair (MMR) functions immediately after DNA replication to replace mismatched bases with the correct ones (Modrich, 1994). Several MMR proteins recognize the error in the newly synthesized daughter strand and excise a region that includes the mismatch. DNA polymerase III and ligase restore the correct sequence and integrity of the daughter strand. The importance of this mechanism in stabilizing the genome is evidenced by recent studies associating hereditary nonpolyposis colorectal cancer with defects in MMR proteins.

Base excision repair targets small, nonhelix-deforming adducts such as those produced by methylation, oxidation, reduction, or base fragmentation by ionizing radiation. Base excision leaves 3–4 nucleotide sequence gaps that are then filled with the correct nucleotides; nicks are sealed with ligase. Larger, bulky adducts or dimers that distort the DNA helix may be caused by UV radiation, carcinogens, and therapeutic drugs, among other agents. Such damage is removed by the nucleotide excision repair (NER) pathway, which uses an enzyme system composed of many proteins to excise a single-stranded oligonucleotide containing the lesion (Sancar, 1994). The gap is then filled in by DNA polymerase and ligated. There are two NER pathways: one, in which lesions that block transcription are rapidly removed (transcription-coupled repair; Hanawalt, 1994); and a second a global pathway that repairs bulk DNA, including the nontranscribed strand of active genes. Some of the possible consequences of the loss of NER activity are exemplified by the disease xeroderma pigmentosum (XP), which is caused by mutations in *NER*. XP results in extreme sensitivity to sunlight, with skin cancers occurring at an early age (Weeda, 1998).

Double-strand breaks occurring rarely or produced by ionizing radiation and oxidative damage, present significant repair problems. If unresolved, replication and transcription of involved sequences will be blocked. To maintain local and overall genomic integrity, double-stranded breaks are repaired by nonhomologous or allelic recombinational repair mechanisms.

It is now clear that DNA repair plays a central role in the life of the cell. Recent evidence also indicates that several proteins that are primary repair proteins also function in transcription and in regulation of the cell cycle. Thus the processes involving DNA appear to be highly integrated and are increasingly studied as a whole and in relation to human disease.

DNA MUTATIONS

Despite extensive repair mechanisms, alterations in DNA base sequence (mutations) occur. Yet for an individual organism, some mutations are clearly harmful and can be associated with cancer and with inherited genetic disease. Studies of these diseases have led to the characterization of the various types of mutations that occur in the human genome (Weatherall, 1987). These can be conceptually grouped into a few major categories (Table 65-4). A point mutation is found in the β -globin gene in sickle cell anemia (Kan, 1992). A thymine base replaces an adenine base, causing a critical change in the structure of hemoglobin. As described in Chapter 70, muscular dystrophy is caused by deletions in the gene for the muscle protein dystrophin. In the Becker form of the disease, the deletions do not disrupt the reading frame, but in most cases of the more severe

TABLE 65-4

Types of DNA Mutations and Examples of Associated Diseases

Mutation	Description	Disease
Point	Single base pair substitution	Sickle cell anemia
Deletion/insertion	Subtraction/addition of amino acid codons in multiples of three. Reading frame is retained.	Becker muscular dystrophy
Deletion/insertion with frameshift	Subtraction/addition of amino acid codons in non-multiples of three. Results in a shift of the reading frame and a completely different amino acid coding sequence from the mutation on.	Duchenne muscular dystrophy
Amplification/trinucleotide repeat	Increase in the number of repeat sequences in microsatellite DNA. Results in disruption of gene expression.	Fragile X syndrome
Translocation	Interchromosomal exchange of large chromosome segments. Results in a new protein with different function.	Chronic myelogenous leukemia

Duchenne form, the reading frame is changed by the deletions, effectively abolishing the function of the protein (Liechti-Gallati, 1989).

Human DNA contains many short sequences of nucleotides (microsatellite DNA) that are sometimes grouped in tandem arrays and are repeated many times throughout the human genome. The number of tandem repeats at particular locations is a heritable trait. Some trinucleotide repeats have been found to increase in number in association with disease (Sutherland, 1994). In fragile X syndrome (Chapter 70), expression of the disease is associated with amplification of the intragenic trinucleotide repeat sequence beyond a critical number of copies. The expansion of the trinucleotide repeats beyond this critical number disrupts expression of the gene.

Translocations may not always be detectable by chromosomal karyotype analysis. At the gene level, a translocation may create a fusion gene, the combination of two different genes abnormally joined at the translocation site. This can create not only an altered gene transcript, but may also bring the product of one gene under the transcriptional control of the other. For example, as discussed at length in Chapter 75, the Philadelphia chromosome, found in most cases of chronic myelogenous leukemia, results from a reciprocal translocation between the *c-abl* gene on chromosome 9 and a region termed the *breakpoint cluster region* (*bcr*) on chromosome 22. The fusion gene produced by this chromosomal rearrangement, consisting of most of the *c-abl* gene and a truncated *bcr*, codes for a *c-abl* protein that is larger than the normal product, has increased enzymatic activity, and is thought to interfere with signal transduction pathways normally involved in the control of cell death and proliferation.

It is both the type of mutation as well as its location in relation to the gene that determines the ultimate effect on the protein product. Mutations may have no effect on protein expression or functional activity; many human proteins exist in detectable variants that have no disease association. Mutations occurring in intron regions presumably have no effect at all. Even small mutations, however, in regions that code for key functional domains (exons) may drastically alter or eliminate function. “Nonsense mutations,” mutations that change an amino acid codon to a stop codon, or vice versa, result in abnormally short or long protein products, respectively. *Missense mutations*, those that change the code from one amino acid to another, may or may not alter protein function, depending on the change and the function of the amino acid. Similarly, mutations within sequences that denote intron-exon splice sites could eliminate exons or introduce introns into the transcribed mRNA. Mutations may also occur in regulatory sequences, such as promoters or enhancers, producing dramatic effects on the levels of transcription.

NUCLEIC ACID ANALYSES

The unique biochemical properties of nucleic acids have been exploited to yield information about the biology or biochemistry of a system. While some of the assays, such as electrophoresis, are applicable to other biochemical building blocks such as proteins and lipids, the majority are particular to nucleic acids. The following sections briefly describe the

Figure 65-7 Photograph of loading sample and dye through buffer into wells of agarose gel in submarine gel electrophoresis apparatus.

principles of the basic categories of analyses used to characterize DNA and RNA: electrophoretic separations, hybridization assays, amplification techniques, sequencing, and polymorphism-based analyses. In practice, the categories are often combined to produce novel variations of the same theme; for example, a complete assay may involve amplification, electrophoresis, and hybridization.

ELECTROPHORETIC SEPARATION

The repeating sugar-phosphate backbone of nucleic acids results in a net negative charge evenly distributed over these linear molecules. Therefore, movement of DNA or RNA in response to an electric field will be proportional to the molecular weight or length of the molecule. This property is used to characterize the size of nucleic acid fragments by electrophoretic separation. The format is analogous to that used for the separation of proteins according to size. Multiple samples are applied in separate wells at one end of a solid but porous separation medium. When a voltage is applied, the samples move toward the positive electrode in a linear fashion, each sample well forming one lane of migration. The solid electrophoretic medium and array of sample wells is known as a *gel*. Size standards, referred to as *DNA* or *RNA ladders*, are mixtures of nucleic acids of known fragment length that are analyzed in one or more lanes of the gel. Comparison of the distance of migration of an unknown sample with the ladder, either by “eye” or by computer-assisted measurement, allows size determination.

The composition and concentration of the separation medium determines the size of the fragments, which may be separated into distinct bands. Other variables that contribute to resolution are the thickness of the gel, the length of the electrophoresis path, the time of electrophoresis, and the applied voltage. In practice, these factors are adjusted empirically and controlled as carefully as possible to ensure reproducibility from day to day. Agarose is the separation medium most often used, usually in conjunction with a horizontal electrophoresis bed in which the gel is submerged in buffer. Samples are made heavy with sucrose or Ficoll and loaded into slots in the gel through the buffer (Fig. 65-7). Higher resolving power, allowing differentiation of a single base pair in length, is achieved with acrylamide, usually used in a vertical format although increasingly capillary formats are being adopted which decrease both the time of the separation and the amount of sample required. The simplest approach to visualizing the bands separated by electrophoresis is by staining with intercalating dyes (e.g., ethidium bromide), which insert between stacked bases, and viewing with UV transillumination. Direct visualization requires that the band achieve a significant concentration. Increased sensitivity may be achieved in some applications that label the nucleic acid fragments with a radioactive or fluorescent tag.

The molecules in genomic DNA are reduced to fragments that may be resolved by electrophoresis through digestion with restriction enzymes. Restriction enzymes with a relatively simple recognition sequence produce fragments less than 50 kilobase pairs (kb) in length. Extremely large DNA fragments, measured in megabase pairs, are produced from digestion with enzymes with a complex recognition sequence and must be separated in special electrophoretic systems utilizing a pulsed electrical field. Most

Figure 65-8 Illustration of stringency. As the stringency of the hybridization solution is increased, fewer mismatches are tolerated in a hybrid duplex. At very high stringency, even a single base pair mismatch disrupts the duplex.

applications of DNA electrophoresis utilize nondenaturing conditions (i.e., the fragments resolved into bands are double-stranded). By contrast, most RNA separations utilize denaturing conditions (either formamide or glyoxal) to eliminate secondary structure of the single-stranded molecules. RNA molecules, as transcripts of DNA, are “presized” and relatively small, so that no digestion is required before electrophoresis.

NUCLEIC ACID HYBRIDIZATION

Hybridization is a fundamental concept in nucleic acid biochemistry; it is defined as the interaction between two single-stranded nucleic acid molecules to form a duplex (double-stranded) molecule based on the complementary base pairing of their respective sequences. Hybridization is a direct consequence of the stable double-stranded structure of DNA under physiologic conditions. As discussed earlier, the helix is formed of two antiparallel strands of DNA held together by the combined strength of many specific hydrogen bonds between complementary base pairs as well as by hydrophobic shielding of bases from an aqueous environment. Central to the hybridization reaction is the fact that the binding between separate, complementary molecules (strands) is both reversible and base sequence-specific.

When neither DNA strand is labeled, the process of reforming the stable double-stranded structure is referred to as *annealing*. If one strand is labeled (i.e., has a marker that is capable of being detected in some fashion), the labeled strand is referred to as a *probe* and the process is called *hybridization* because a hybrid molecule is formed between a labeled and unlabeled strand. RNA molecules can also participate in the hybridization process. Base pairing may occur between complementary strands of DNA, between DNA and RNA, and between complementary strands of RNA, resulting in DNA-DNA, DNA-RNA, and RNA-RNA duplex structures. Duplex molecules with exact complementarity in base sequence form the most stable structures, but structures with varying degrees of base pair mismatch may form depending on the conditions. The relative instability of these mismatched duplexes are reflected in the lowered temperature of their disassociation (lower T_m , see Fig. 65-2).

Environmental conditions can be manipulated to control the degree of base pair mismatching that will be tolerated in a duplex structure (i.e., the *stringency* of the sequence match) (Fig. 65-8). Low stringency refers to conditions such as high salt, low temperature, and no formamide, which favor shielding of hydrophobic bases from the aqueous environment even without perfect alignment; the match need not be perfect. High stringency conditions—high temperature (close to T_m), low salt, and high formamide—will only allow the most perfectly matched duplex structures to remain in a stable helix conformation.

HYBRIDIZATION ASSAYS: BASIC COMPONENTS

When the hybridization reaction is used to analyze the nucleic acid content of an unknown sample, the process is known as a *hybridization assay*.

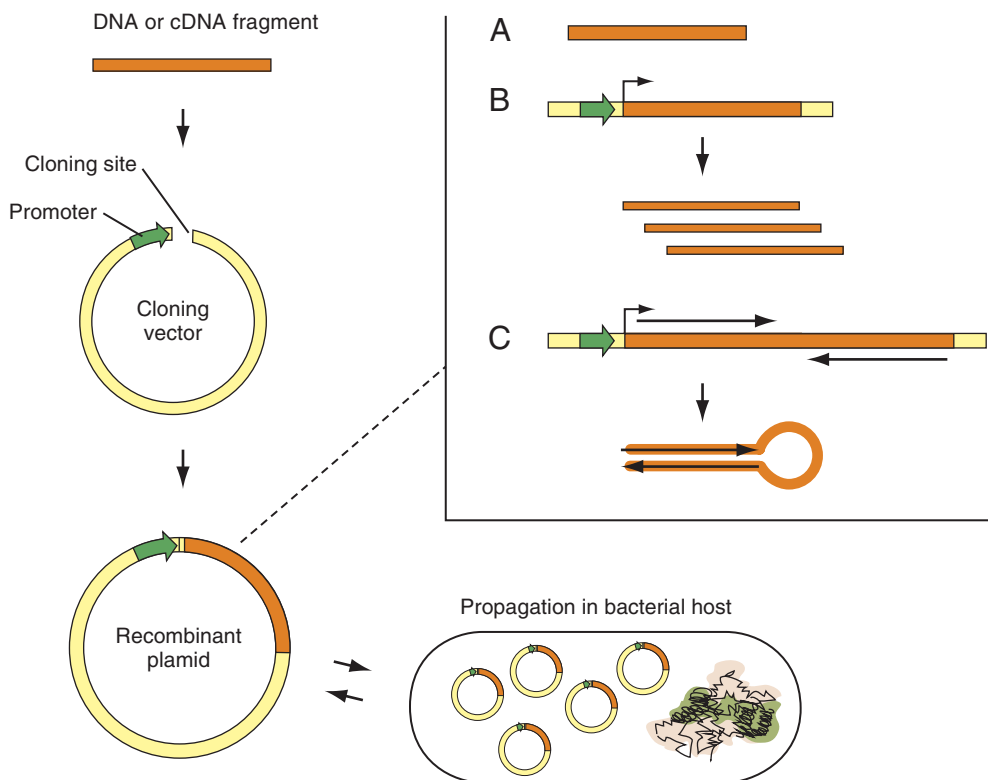

Figure 65-9 Production of cloned DNA or RNA. A DNA fragment or RNA that was converted into cDNA can be inserted into a cloning vector. The recombinant plasmid is transformed into a bacterial host where it is rapidly propagated to millions of copies. The multiplied DNA fragment can either be isolated by excision through restriction enzymes that recognize sequences at the borders of the insert (A) or can be used to initiate RNA in vitro transcription with a promoter sequence in the plasmid (B). Such systems are also used to produce double-stranded RNA by cloning two complementary sequences in sense and antisense direction, typically with a spacer that forms a stabilizing loop in the dsRNA fragment (C).

Hybridization assays include a wide variety of formats (see next section) such as Southern blots, Northern blots, fluorescent in situ hybridization (FISH) and microarrays (“DNA chips”). The property of complementary base pairing allows fragments of known composition (the probe) to interrogate an unknown for the presence of matching (complementary) sequences. All hybridization assays, therefore, require several basic elements: a probe, a sample, controlled conditions permissive to complementary base pairing, and a method for detection of specific probe-sample hybrids. Each of these elements will be briefly discussed below, as well as the variations in formats that have been developed to allow hybridization assays to be performed and interpreted.

Probe

The probe determines the specificity of the hybridization reaction; thus the probe is central to a hybridization assay in the same way that the primary antibody is central to an immunoassay. A probe is a well-characterized fragment of nucleic acid, either DNA or RNA. In most assay formats it is the probe that carries the reporter group for detection of hybridized molecules into the reaction, although variations occur. Reporter groups may be radioactive or nonradioactive (i.e., affinity label).

Many probes are produced through recombinant nucleic acid technology, as illustrated in Figure 65-9. Plasmids—short, circular, double-stranded segments of DNA—are harnessed as vectors to propagate desired sequences in bacteria. The segment of interest is introduced into the plasmid using restriction enzyme digestion and ligation resulting in a new “recombined” molecule that retains the ability to be propagated in bacteria and includes the DNA sequence of interest. Bacteria containing the recombinant plasmid can be grown in culture, and the small circular plasmids can be easily separated from the bacterial genome on the basis of size. Many identical copies are obtained; thus the DNA is often referred to as *cloned*. Purified plasmid may be used as probe in assays where vector sequences do not interfere with the specificity of the reaction. In many applications the inserted DNA sequence is separated from the vector sequence by digesting the isolated plasmid with the same restriction enzyme originally used in construction of the recombinant molecule. The probe resulting from either of these approaches is a double-stranded DNA molecule. Double-stranded probes must be denatured prior to use, and probe reannealing limits the extent of hybridization of probe with target.

Plasmid vector that does not contain cloned DNA is a commonly used negative control for this type of probe.

Plasmid vectors have been constructed to include RNA promoter regions adjacent to the inserted DNA sequence. These recombinant plasmids are used to produce RNA transcripts of the DNA insert. The result is a single-stranded RNA probe that will not undergo self-hybridization. Controlling the orientation of the DNA insert with respect to the RNA promoter allows production of transcripts in the *sense* (same as mRNA) or *antisense* (complementary to mRNA) direction. In many applications the sense transcripts form ideal negative control probes for hybridization reactions with antisense probes. Non-specifically bound RNA probe (i.e., RNA not in a stable duplex structure) can be removed with the use of RNase specific for single-stranded RNA. The lability of RNA requires that the probes be handled with extreme care to prevent degradation (sterile technique, treated water, and glassware).

Recombinant probes, whether DNA or RNA, are genetically complex; that is, they may include many kilobases of genetic information. By contrast, probes produced by synthetic methods are relatively short segments of DNA. Oligonucleotide probes produced by automated chemical reactions are usually 15–45 bases in length synthesized to produce a specified base sequence. Probes with very high specificity of hybridization can be designed on the basis of sequence information available in data banks. They can be generated in a sense or antisense direction at a relatively low cost. These short probes are single-stranded, diffuse into target and hybridize rapidly because of their small size, and are extremely sensitive to even single base pair mismatches. The final sensitivity achieved with oligonucleotide probes is lower than that achieved with recombinant probes because of their limited genetic complexity. Multiple oligonucleotide probes directed to different areas of the same target have in some instances been used to increase the sensitivity by increasing the representation of the target sequence in the probe mixture. This approach is analogous to the use of a blend of monoclonal antibodies that react to different epitopes of the same complex antigen.

Probes longer than those obtained by direct chemical synthesis may be generated with the polymerase chain reaction or other amplification technology. These probes may be single-stranded or double-stranded depending on the conditions employed and may be as long as the product of the amplification reaction; in most cases 100 bp to 1 kb in length.

Sample

Whereas probe selection and preparation are central to determining the sensitivity and specificity of the hybridization assay, the contribution of sample preparation to a successful assay cannot be overlooked. In clinical applications, samples of interest may be quite diverse. For example, a microbiology laboratory could anticipate testing specimens of blood, urine, stool, and sputum. Integrity of RNA targets may be difficult to maintain under such conditions and even DNA may be degraded with improper handling. The goal of sample preparation is to maintain nucleic acid integrity and make the target genetic information available for interaction with the probe. For some applications, the requirement of target integrity will dictate immediate snap freezing or addition of lysis buffers containing potent RNase and DNase inhibitors. In other applications, more routine methods of sample collection will allow adequate target preservation.

The physical and chemical similarities of nucleic acids, regardless of source, allows for uniform methods of extraction and purification. For many assays it is preferable to extensively purify DNA or RNA to remove inhibitors of enzymes to be added to the assay (e.g., a restriction enzyme or polymerase) and to maximize accessibility of target to probe. Complete purification schemes, however, are time-consuming and require a relatively large amount of starting sample. In many applications, relatively abbreviated sample purifications can be used. Purifications commonly use cell lysis (mechanical, chemical, or both), protease treatment, and organic or inorganic extractions. Automated methods are now available to standardize and streamline sample extraction.

Controlled Conditions Permissive for Complementary Base Pairing

The sensitivity and specificity of the hybridization reaction are greatly influenced by the physical-chemical environment during the reaction and subsequent detection/collecting of hybrid molecules. In practice, the hybridization cocktail is the medium used to control the environment of the hybridization reaction. Empirically designed, the *hybridization cocktail* is a mixture of reagents selected to favor interaction of nucleic acids through sequence-specific hydrogen bonds rather than via charge. The components vary widely, but include buffers, salts, denaturants such as formamide, high molecular weight polymers, carrier DNA or RNA, and various components added to reduce background (such as detergents, bovine serum albumin, Ficoll). Such a complex mixture is conveniently referred to as a *cocktail*. The ionic strength of both the hybridization cocktail and the subsequent washes is most often modulated by the concentration of a saline sodium citrate buffer (SSC), composed of 0.15 mol/L sodium chloride, 0.015 mol/L trisodium citrate, pH 7.0. The shorthand notation for these conditions refers to the strength of SSC; that is, $2 \times \text{SSC}$, $0.1 \times \text{SSC}$. The final stringency of the hybridization reaction is controlled by the formamide and salt concentration of the hybridization cocktail, the temperature of the hybridization reaction, and the temperature and salt concentration of the washing steps.

Detection of Hybrids

A wide variety of techniques have been applied to collection and analysis of specific hybrids, discussed briefly later under Hybridization Assay Formats. Once specific hybrids have been collected, methods of detection are obviously linked to methods of labeling. Radioactive labels such as phosphorus-32 (^{32}P), iodine-125 (^{125}I), sulfur-35 (^{35}S), carbon-14 (^{14}C), and tritium (^3H) are detected through autoradiography or scintillation counting, and the specific activity of the label directly influenced the sensitivity of the detection. Because radioactive probes have a relatively short half-life, making one of the key reagents in the hybridization assay unstable, are hazardous to laboratory personnel, and generate expensive waste disposal problems, they have been nearly entirely replaced by nonradioactive methods. Nonisotopically labeled probes are stable reagents, greatly facilitating the commercial production and standardization that are crucial for assay reproducibility.

Nonisotopic labeling and detection methods for nucleic acids have many similarities to immunochemical assays developed for nonisotopic protein detection. In some applications, nucleic acids are directly linked to a signal-generating compound, usually a fluorochrome but occasionally an enzyme. This situation is analogous to immunoassays in which the primary antibody is labeled. More commonly, nucleic acids are indirectly detected in a multistep assay similar in concept to an indirect antibody reaction. Biotin, a commonly used affinity label for immunoassays, was the first affinity label introduced into nucleic acids (Langer, 1981). Biotin itself

Figure 65-10 Examples of affinity-labeled probe detection systems. (From Unger ER, Piper MA. *Nucleic acid biochemistry and diagnostic applications*. In: Burtis CA, Ashwood ER, editors. *Tietz textbook of clinical chemistry*, 2nd ed. Philadelphia: WB Saunders; 1994, with permission.)

generates no signal, but is detected by high-affinity interaction with an avidin or streptavidin molecule that is, in turn, complexed or conjugated to a signal-generating enzyme, fluorochrome, or metallic particles detected by light scattering (Yguerabide, 2001). Many other functional groups have been developed as nonisotopic labels such as bromodeoxyuridine, digoxigenin, and sulfone. Detection in these cases is achieved with high-affinity antibodies directed against the functional group. These antibodies are usually directly linked to a signal-generating enzyme or fluorochrome, functioning like a labeled secondary antibody in an immunohistochemistry reaction. Biotin may also be detected with an anti-biotin antibody rather than an avidin or streptavidin molecule.

Because affinity labels are detected with large bulky proteins such as avidin or antibody, availability of the label to the detection reagent is a crucial factor in determination of sensitivity. Increasing the number of affinity tags will not necessarily increase the number of detecting molecules that will be bound to the nucleic acid. In addition, because affinity labels are themselves bulky, overincorporation into the nucleic acid molecule can lead to steric hindrance of the hybridization reaction. For these reasons, the specific activity of the affinity label does not directly control the sensitivity of the detection.

One advantage of the indirect detection of affinity labels is that a variety of detection methods can be used for the same label (Fig. 65-10). For example, biotin may be detected with avidin linked to an enzyme with subsequent color or chemiluminescent detection, or avidin with fluorescent tag. For all nonradioactive methods, the detection portion of the assay is crucial in obtaining optimal sensitivity. Detection reagents with poor background and suboptimal signal generation can mar an effective hybridization reaction. The choice of the enzyme labels (peroxidase vs. alkaline phosphatase), enzyme substrate (colorimetric vs. chemiluminescent), and even source of reagents are critical for optimal results.

HYBRIDIZATION ASSAY FORMATS

A wide variety of hybridization assay formats have been developed, each designed to solve the methodologic problems of the hybridization assay: conditions permitting specific complementary base pairing, a method to detect hybrids, and interpretation of the result. Each method has particular strengths and weaknesses and the clinical setting and particular diagnostic question dictate selection of format. There is no one perfect assay. Several of the basic formats are briefly described herein, along with their particular strengths and weaknesses.

Each hybridization assay requires both positive and negative controls for validation. A positive sample control is one known to contain sequences complementary to the probe. This is used to establish that sample preparation is adequate to release target for the hybridization assay, and to ensure that probe will hybridize with the specific target under the assay conditions. The sample control may also be used to monitor the sensitivity of the assay, if the positive control is chosen near the lower limits of detection. A negative sample control (i.e., one known not to contain sequences complementary to the probe) is used to monitor specificity of the probe target interactions. Controls for the probe include vector sequences or unrelated probes labeled, hybridized, and detected under identical assay conditions. These latter controls allow monitoring of the background signal generated

by localization of probe through non-hybridized interactions such as charge or trapping. In clinical practice, additional controls may be employed to monitor each step of the hybridization assay.

Liquid or Solution Phase Hybridization

In liquid hybridization assays, both the sample and probe interact in solution, which maximizes the kinetics of the reaction. The sample nucleic acids are generally purified from contaminating proteins and lipids, which could interfere with the collection of hybrids at the end of the assay, and some sample degradation is tolerated by the assay. The sample is denatured and randomly sheared before addition of single-stranded probe lacking the ability to self-hybridize.

Hybridization may be detected by the specific binding of hybrids to a solid matrix such as hydroxyapatite, which binds only duplex structures. Once hybrids are bound, unhybridized probe may be efficiently removed by washing. Detection of the label on the bound probe permits quantitation of the hybridization reaction. In a variation of this approach, one commercial assay (Digene Hybrid-Capture, Qiagen USA, Valencia, Calif.) uses an antibody specific for RNA-DNA hybrids to specifically bind duplex structures formed of the DNA target and RNA probe. An alternative analysis involves digestion of the hybridization reaction mixture with S1 nuclease, an enzyme that acts only on single-stranded nucleic acid. Duplex structures resistant to digestion may then be precipitated by treatment with trichloroacetic acid. In the hybridization protection assay, label on the probe is protected from chemical degradation only when the probe is involved in a duplex structure.

Many other variations of the solution-phase hybridization assay are in use. Optimal kinetics, toleration for abbreviated purification steps, and some sample degradation make the assay adaptable for clinical application. Quantitation of the reaction product may be achieved, depending on the detection system. The solution phase format does not permit identification of the size of the hybridizing product. Low positive reactions are difficult to interpret, because low levels of specific target and high levels of weakly cross-reacting target will yield similar results. Solution phase hybridization is adaptable to the 96-well format with an enzyme-linked immunosorbent assay-type readout, and increasing automation of the assay can be anticipated.

Solid-Support Hybridization

Variations of the solid-support hybridization assays include dot or blot hybridization, Southern and northern hybridization, microarray hybridizations ("DNA chips") and in situ hybridization. In these assays, the hybridization occurs in a biphasic environment, a solid phase (usually sample) and a liquid phase (usually probe). The kinetics of hybridization to a nucleic acid bound to a solid support is greatly slowed, and the extent of the hybridization reaction is limited. These disadvantages are often outweighed by the convenience of having a solid medium to carry through multiple steps of the assay.

Dot/Blot Hybridization

In this assay format, multiple samples are immobilized in a geometric array on a nitrocellulose or nylon membrane. The name of the assay comes from the shape of each sample on the membrane. When samples are applied by hand, the shape is more random (blot). With the use of commercially available manifolds, samples are usually applied with the use of suction, the sample shape is very regular—round (dot) or elongated (slot). The solid matrix allows multiple samples to be processed through all steps of the assay simultaneously. The fact that all samples and controls are exposed to exactly the same reagents and conditions increases the standardization of the assay.

The extent of sample preparation varies from complete purification of nucleic acids before application to the filter, to direct application of unpurified sample. Some degree of sample degradation is tolerated by the assay. Purified nucleic acids have the advantage of being most available for interaction with probe and having the least problems with background. Individual sample purification, however, is time-consuming and labor intensive. Applications using direct application of unpurified sample take the entire array through an abbreviated purification procedure, which usually involves lysis and denaturation, protein digestion, and washing with detergent. The advantages of this approach are that it is applicable to small amounts of starting material and minimizes sample preparation time. However, the final sensitivity of the reaction is lower, and background from nonspecific probe interactions can make the assay unreliable.

Interpretation of the results of a dot/blot hybridization assay is relatively straightforward. If hybridization has occurred, a signal is

generated in the specified spot. Depending on the label used for signal generation, results may be quantitated; however, usually a simple yes/no interpretation is given (i.e., the sample has more or less signal than adjacent samples and known positive and negative controls). Weak signals, which may result from a very small amount of specific target or from a large amount of weakly cross-reacting target, may cause problems in interpretation. No information is available about the size of the hybridizing fragments.

One interesting variation of the dot/blot assay is known as the reverse dot/line blot assay. In this format, applied in situations where one sample must be tested with many different probes and sample may be limited, the label is carried into the assay by the sample. The unlabeled probes, or targets, are fixed to the solid support in a linear or matrix array. Areas of specific hybrid formation are identified and interpreted as in the standard dot blot assay. This assay format is a convenient means of identifying the product of an amplification assay (vide infra and Chapter 66), such as in human leucocyte antigen analysis (Bugawan, 1994) or human papilloma-virus typing (Gravitt, 1998).

Southern and Northern Hybridizations

Both Southern and northern hybridizations combine electrophoretic separation of test nucleic acid with transfer to a solid support and subsequent hybridization. These assays, therefore, not only give information about the presence of hybridization, but also permit determination of the molecular weight of the hybridizing species.

The original procedure was termed Southern blot hybridization or Southern blotting, after its inventor, E. M. Southern (Southern, 1975). In this assay, the sample is DNA. Northern blotting was named by analogy for the technique using RNA samples. (Extending the analogy even further, the western blot is a similar procedure in which proteins are subjected to electrophoresis and transfer; a southwestern blot has been described for a technique separating and blotting DNA followed by incubation with protein solutions to permit evaluation of specific DNA-binding proteins.)

Sample preparation is time-consuming and labor intensive for both of these techniques. Degradation of sample nucleic acids is not tolerated by the assays, and a relatively large amount of starting material is required. For Southern hybridizations, the DNA must be purified with minimal shearing. This is because sizing of the DNA fragments is achieved through digestion with one or more restriction enzymes. Shearing and degradation introduce random breaks in the sample, reducing the quantity available to be specifically cut at appropriate recognition sequences. Impurities in the sample may interfere with the activity and sequence specificity of the restriction enzyme. Partially or improperly digested samples can produce spurious band sizes or result in such a reduced concentration of the specific band that it is no longer detected during hybridization. For northern hybridizations, the starting material is RNA, and extreme care must be taken to avoid degradation during sample collection and preparation because of the ubiquitous nature of RNases. RNA is composed of fragment sizes determined by transcription and processing of message and ribosomal RNA. It is not digested before electrophoresis, but is separated under denaturing conditions to remove secondary structure.

The size-separated fragments in the agarose gel are then transferred to a nylon or nitrocellulose filter. As originally designed, the transfer occurred passively through capillary action. Most current applications use vacuum or pressure to speed the transfer. After transfer, baking or UV cross-linking immobilizes the nucleic acids and the entire membrane is hybridized with labeled probe.

Hybridization is followed by autoradiographic, colorimetric, or chemiluminescent detection of bands containing sequences complementary to the probe. Interpretation involves both detection of a hybridizing species and determination of the molecular weight of the molecule. These technically demanding assays require several days to perform but may be required in clinical applications in which the information cannot be obtained in any other format. The presence of bands at molecular weights different from normal or germline (developmentally unaltered) samples can indicate a change in the genetic material.

Microarray Hybridization ("DNA Chip Technology")

Microarray hybridizations can be thought of as a variation of the dot-blot format in which the dotted material is arranged in a regular gridlike pattern with each feature reduced to a very small size so that hundreds to thousands of features can be placed on one solid surface, currently most often

Figure 65-11 Example polymorphism analysis by gel electrophoresis [Allelic typing of the serotonin transporter gene (5-HTTLPR)]. A polymorphism consisting of a 44-bp insertion/deletion polymorphism in the 5' regulatory region is suggested to be associated with major depressive disorder. The presence of the two different alleles can be screened using PCR primers upstream and downstream of the site producing fragments of distinct length. The amplicons are then separated by gel electrophoresis and stained with ethidium bromide. An individual is either homozygous for the long version (L allele = upper band), heterozygous with both alleles (two bands), or homozygous for the short version (S allele = lower band). a glass microscope slide. By convention in these applications, the sample is labeled and the arrayed features are referred to as *probes*. Microarrays allow genome-wide transcription profiling or sequence determination in a single experiment. The technique and applications are described in greater detail in Chapter 67.

In Situ Hybridization

In situ hybridization is simply detection of specific genetic information within a morphologic context. This specialized type of solid-support assay involves taking morphologically intact tissue, cells, or chromosomes affixed to a glass microscope slide through the hybridization process. Autoradiographic, colorimetric, and fluorescent methods of detection have been applied. Evaluation of the final product is very analogous to evaluation of immunohistochemistry and requires experience in histopathology. The strength of the method lies in linking microscopic morphologic evaluation with detection of hybridization.

The method also has applications in cytogenetic analysis of metaphase chromosome spreads or of interphase nuclei (see Chapter 68). In this context, the detection is usually fluorescent, and the technique is referred to as FISH. Detecting numerical aberrations or translocations of chromosomes can be achieved rapidly using probes for specific targets. FISH avoids some of the difficulties of conventional cytogenetics and may have greater sensitivity for some targets. Although FISH cannot completely replace karyotyping, it can complement and reduce the need for the frequency of cytogenetic analysis. Newer variations of FISH (Luke, 1998) are exploiting the possibilities of automation (fast-FISH) and expanding the information that can be obtained in a single assay. FICTION (fluorescence immunophenotyping and interphase cytogenetics as a tool for investigation of neoplasms) combines immunophenotyping with FISH; fiber FISH makes it possible to simultaneously detect and map chromosomal break points. In situ hybridization can be very labor intensive and tedious. Recent improvements resulting in automated processing of slides through the assay hold much promise for more widespread adoption of this technique.

AMPLIFICATION METHODS

It is virtually impossible to read any medical journal without encountering at least one application of polymerase chain reaction (PCR) technology. The PCR has forever changed the scope of research questions that can be addressed by virtually eliminating the problem of limited sample size. The importance and elegance of the concept has been recognized through awarding of the Nobel Prize in Chemistry to its inventor, Kary Mullis, less than 10 years after publication of the first practical application of PCR (Saiki, 1985). There are now other methodologies that result in multiplication of target, probe, or signal. These may be grouped together as amplification technologies and are described in Chapter 66.

POLYMORPHISM DETECTION ASSAYS

Although greater than 99% of the human genome is identical in all individuals, there are still millions of regions of DNA that vary between individuals. While most polymorphisms have no recognized functional consequence, changes in promoter or enhancer regions may result in altered transcription regulation, cause variation in the mRNA splice

products if present in intron-exon junctions, or produce altered amino acid sequences if an exon is affected. The serotonin transporter gene, for instance, exists in two alternative allelic variants characterized by a 44-bp insertion/deletion polymorphism in the promoter region. This polymorphism has been associated with major depressive disorders and the two allelic versions can be distinguished by PCR amplification of the relevant DNA region resulting in two different sized products (Fig. 65-11). Most of the variations occur in the form of an individual base change known as single nucleotide polymorphisms (SNPs). An example would be the alteration of a DNA fragment ACGT to ACTT by replacement of the third base from a guanine to a thymine. Two unrelated individuals will have approximately 3 million SNPs that differ between them.

The sequence-specific recognition features of restriction enzymes have been used since the 1970s for the detection of such sequence variations. In such assays, called restriction fragment length polymorphism (RFLP, “rif-lip”), DNA is digested with a restriction enzyme and the fragments analyzed by gel electrophoresis followed by band visualization or Southern blot analysis with a site-specific probe. Changes in the sequence of the DNA may result in alteration of the recognition sequence of the enzyme. An SNP alteration may introduce additional restriction enzyme sites, remove restriction sites, or insert or delete sequences between restriction sites. These changes will be reflected in a change in the band size visualized in a gel or hybridizing to the site-specific probe. Although the approach has been applied with considerable success in family studies, RFLP is a relatively crude method. Sequence polymorphism can only be detected if the distance between two restriction sites is directly affected and the majority of SNPs would not be detected.

Because of the tremendous potential of polymorphism assays to predict inheritance of altered alleles, and changes that predict drug interactions (see Chapter 72), considerable effort has been made in recent years to improve the speed, precision, and cost effectiveness of these methods. The completion of the Human Genome Project in 2001 provided a reference against which all other sequencing data can be compared. Researchers are also systematically screening the genome to discover new SNPs. High throughput SNP analysis methods have been developed which simultaneously scan thousands of SNPs in thousands of samples. Comprehensive mapping of an individual's SNP pattern is also termed *genotyping*. Genotyping is somewhat easier, in that one form of the known gene sequence (allele) can be compared with an alternative form at a specific predetermined site. Currently there are a wide variety of approaches for allelic discrimination that typically use a combination of molecular techniques. For more information, see Chen & Sullivan (2002).

DNA SEQUENCING

Methods for directly determining the base sequence of DNA first became available in the 1970s. Originally prohibitively time-consuming and expensive for diagnostic applications, automation and miniaturization have resulted in instrumentation capable of rapidly and inexpensively sequencing segments of DNA. Sequencing the first human genome was completed by the Human Genome Project in 2001 using the Sanger method (Fig. 65-12) that is based on enzymatic incorporation of chain terminating di-deoxynucleotides. The rapidly evolving field of “next-generation” sequencing has produced a variety of different platforms and sequencing chemistries that allow extremely high-throughput sequencing based on

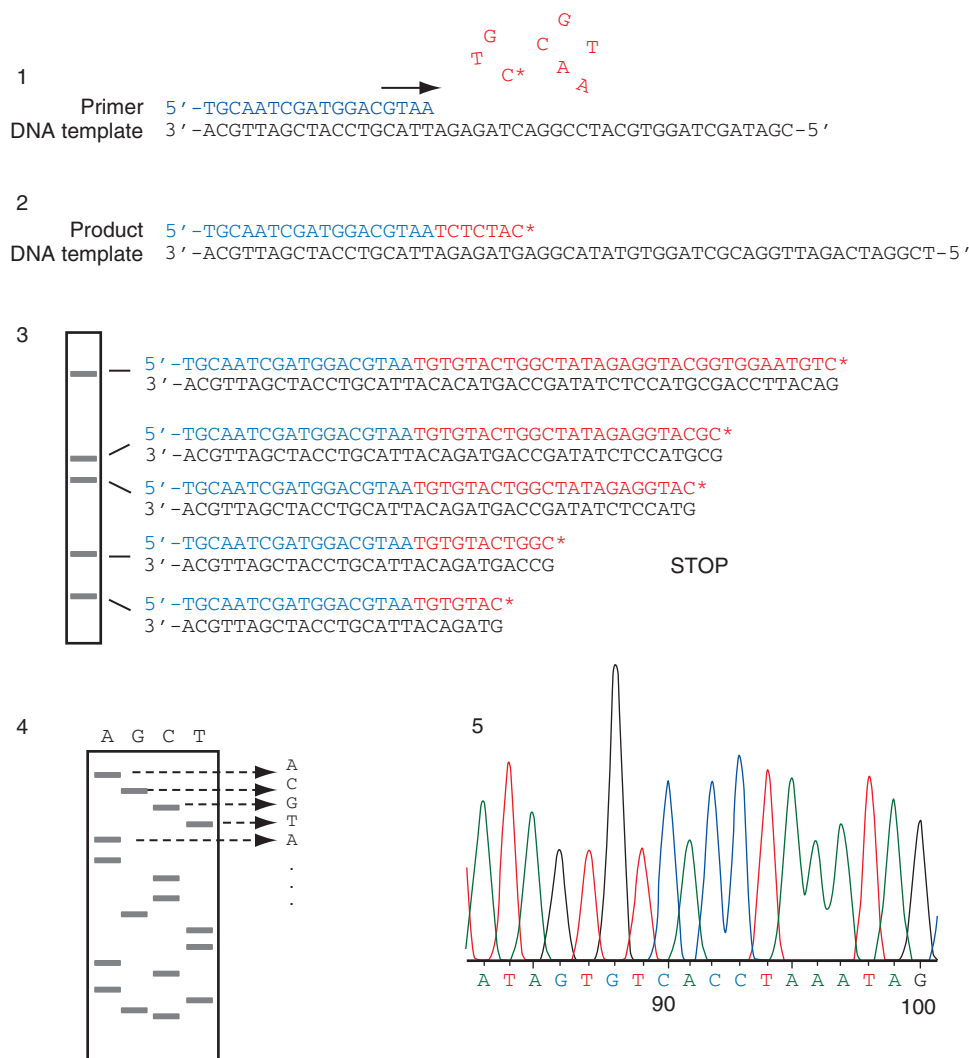

Figure 65-12 Principle of the Sanger DNA sequencing method.

1. A short primer (in blue) is annealed to a known sequence in the DNA template. In the presence of the four "usual" deoxynucleotides (dATP, dCTP, dGTP, dTTP) and an additional di-deoxynucleotide at a low concentration, here ddCTP (marked with an asterisk), DNA polymerase initiates synthesis.
2. When ddCTP is incorporated further polymerization cannot occur because it lacks the 3'-OH group required to accommodate another nucleotide (see Fig. 65-1) and the chain is terminated.
3. Random incorporation of ddCTP generates a series of DNA strands of different sizes, all ending at "C." These products start with the same primer sequence and are sized by electrophoresis to determine the position of each "C."
4. Dividing the reaction into four tubes, each with a different dideoxynucleotide, and electrophoresing all four reactions in parallel allows the complete sequence to be read from the order of the bands in each the ladders of each lane.
5. Most current applications use fluorescently tagged ddNTPs, each with a different color dye. With this approach the reaction is in a single tube and products are separated in a single lane. A laser is used to record the wavelength and order of the bands.

massively parallel sequencing in flow cells (Voelkerding, 2009; see Chapter 77). Currently too expensive for routine clinical applications, these techniques have the power to make the "\$1000 genome," that is, provide an individual's complete genetic sequence for \$1000, a reality. These deep sequencing methods can be applied to evaluate the transcriptome and are beginning to rival microarray technology in systems biology applications. Currently the diagnostic utility of the complete genome is not clear, but direct sequencing is used to determine viral types (e.g., human papillomavirus) and identify mutations (e.g., BRCA1 and BRCA2). Early explorations of how to use an individual's genome for clinical management are underway (Ashley, 2010).

RELATIONSHIP TO LABORATORY EVALUATION OF DISEASE

Subsequent chapters describe the current applications of molecular diagnostics. It is clear that this new technology has impacted all areas of laboratory diagnosis. Molecular methods also have the potential to redefine laboratory evaluation of disease to include issues beyond disease diagnosis.

MOLECULAR DIAGNOSIS

The advantages of a molecular approach to diagnosis is described in detail for each aspect of current application. Increased automation and commercially designed methods have reduced costs and the level of technical expertise required to perform the tests. Increasingly, molecular technology is being integrated into the mainstream of laboratory testing.

Detecting mutations and associating them with disease is at the heart of the current explosion of information in medical science and of many applications in molecular diagnostics. One of the most important consequences of the revolution in molecular genetics has been the ability to locate a gene responsible for a disease without knowing the protein product. Termed *positional cloning*, this process uses RFLP linkage analysis of families that carry and express the disease to locate polymorphic markers closer and closer to the disease gene until it is ultimately located. Closely linked polymorphic markers that tend to segregate with disease may be used in clinically useful diagnostic tests even before the gene is completely characterized and the protein product finally identified. In this scenario, molecular diagnostic tests are developed and used first, to be replaced by simpler, more cost-effective methods directed at the level of the gene product when the consequence of mutation is fully understood.

BEYOND DIAGNOSIS

Molecular analyses have the potential to greatly expand the role of the laboratory in areas beyond disease diagnosis. Molecular analysis of the somatic mutations in cancer has the potential to provide prognostic information, guide selection of optimal therapy, and monitor response to therapy. The implications of using molecular markers to detect neoplastic cells in the absence of clinical or morphologic evidence of disease, known as *minimal residual disease*, are now being explored in a variety of

malignancy types (see Chapter 73). This approach of using molecular markers for disease detection can also be anticipated to impact secondary methods of cancer prevention (screening) and assessment of adequacy of surgical resection (evaluation of margins). Gene therapy for inherited genetic disease as well as cancer is being introduced based on a detailed understanding of the underlying disease. Monitoring these patients for presence and activity of the introduced therapeutic gene will add another aspect to the laboratory evaluation of disease as the application to personalized medicine continues to develop (see also Chapter 72).

KEY POINTS

- Nucleic amplification technology has created new opportunities for the clinical laboratory to affect patient care.
- Although the polymerase chain reaction (PCR) is the most mature and widely used nucleic acid amplification method, other methods have diagnostic applications.
- Clinical applications of the technology cut across the traditional disciplines in laboratory medicine.
- An understanding of the basic principles and relative strengths and limitations of the nucleic amplification methods is important for all involved in the practice of clinical pathology.
- The development of the PCR by Mullis and colleagues (Saiki, 1988) was a milestone in biotechnology that heralded the beginning of molecular diagnostics. Although PCR is the most widely used nucleic acid amplification method, other approaches have been developed, and several have unique properties and advantages. These methods are based on target, probe, or signal amplification. Examples of each category are discussed in the sections that follow. These techniques have analytical sensitivity unparalleled in laboratory medicine, creating new opportunities for the clinical laboratory to impact patient care.

TARGET AMPLIFICATION METHODS

PCR, transcription-based amplification, and strand displacement amplification are all examples of target amplification methods. These methods share certain fundamental characteristics. They are enzyme-mediated processes in which a single enzyme or multiple enzymes synthesize copies of target nucleic acid. The amplification products in all the techniques are defined by two oligonucleotide primers that bind to complementary sequences on opposite strands of double-stranded targets. All result in the production of millions to billions of copies of the targeted sequence in a matter of hours and, in each case, the amplification products can serve as templates for subsequent rounds of amplification. Consequently, all the techniques are sensitive to contamination with product molecules from

previous amplifications, which can lead to false-positive reactions. However, special laboratory design, practices, and workflow have been developed to reduce the possibility of false-positive reactions to acceptable levels.

POLYMERASE CHAIN REACTION

PCR is a simple in vitro chemical reaction that permits the synthesis of essentially limitless quantities of a targeted nucleic acid sequence. This is accomplished through the action of a deoxyribonucleic acid (DNA) polymerase that, under the right conditions, can copy a strand of DNA. At its simplest, a PCR consists of target DNA, a molar excess of two oligonucleotide primers, a heat-stable DNA polymerase, an equimolar mixture of deoxyribonucleotide triphosphates (dATP, dCTP, dGTP, and dTTP), $MgCl_2$, KCl, and a Tris-HCl buffer. The two primers flank the sequence to be amplified, are typically 18–30 bases long, and are complementary to opposite strands of the target.

To initiate a PCR, the reaction mixture is heated to separate the two strands of target DNA (denaturation) and then cooled to permit the primers to anneal to the target DNA in a sequence-specific manner (annealing) (Fig. 66-1). The DNA polymerase then initiates extension of each primer at its 3' end (extension). The primer extension products are dissociated from the target DNA by heating. Each extension product, as well as the original target, can serve as a template for subsequent rounds of primer annealing and extension.

A PCR cycle consists of three steps: denaturation, annealing, and extension. At the end of each cycle, the PCR products are theoretically doubled. Thus, after n PCR cycles, the target sequence can be amplified 2^n -fold. The whole procedure is carried out in a programmable thermal cycler that precisely controls the temperature at which the steps occur, the length of time that the reaction is held at the different temperatures, and the number of cycles. Ideally, after 20 cycles of PCR, a million-fold amplification is achieved and, after 30 cycles, a billion-fold. In practice, the amplification may not be completely efficient, because of failure to optimize the reaction conditions or the presence of inhibitors of the DNA polymerase. In such cases, the total amplification is best described by the expression $(1 + e)^n$, where e is the amplification efficiency ($0 < e \leq 1$) and n is the total number of cycles.

Reverse-Transcriptase Polymerase Chain Reaction

PCR, as it was originally described, was a technique for DNA amplification. Reverse-transcriptase PCR (RT-PCR) was developed to amplify ribonucleic acid (RNA) targets. In this process complementary DNA (cDNA) is first produced from RNA targets by reverse transcription, and then the cDNA is amplified by PCR. As originally described, RT-PCR employed two enzymes, a heat-labile RT such as avian myeloblastosis virus reverse transcriptase (AMV-RT) and a thermostable DNA polymerase. Because of the temperature requirements of the heat-labile enzyme, cDNA synthesis had to occur at lower temperatures. This presented problems both in terms of the nonspecific primer annealing and inefficient primer extension due to formation of RNA secondary structures. These problems have been largely overcome by the development of a thermostable DNA polymerase derived from *Thermus thermophilus*, which, under the proper conditions, can function efficiently as both an RT and a DNA polymerase (Myers, 1991). RT-PCRs using this enzyme are more specific and efficient than previous protocols using conventional, heat-labile RT enzymes. Commercially available kits (AMPLICOR, Roche Diagnostics, Indianapolis, Ind.) employing this single-enzyme RT-PCR are available for detection of hepatitis C virus (HCV) RNA and for quantification of human

immunodeficiency virus (HIV)-1 and HCV RNA in clinical specimens. RNA targets may present problems due to secondary or tertiary structure that may require special conditions or alternative target sites for efficient cDNA synthesis.

While the single enzyme RT-PCR has improved specificity and efficiency for problematic targets, there remain many applications that use a two-enzyme system. Modified heat-labile RT enzymes and optimized mixtures of reverse transcriptases with improved specificity and efficiency are now commercially available. Performing a separate RT reaction with random sequence primers allows PCR analysis of multiple targets from a single RT reaction. The RT reaction may be performed with oligo-dT primers providing cDNA of the messenger RNAs only. This scheme also allows PCR to be performed for multiple targets from a single RT reaction.

Nested Polymerase Chain Reaction

Nested PCR was developed to increase both the sensitivity and specificity of PCR (Haqqi, 1988). It employs two pairs of amplification primers and two rounds of PCR. Typically, one primer pair is used in the first round of PCR of 15–30 cycles. The products of the first round of amplification are then subjected to a second round of amplification using the second set of primers, which anneal to a sequence internal to the sequence amplified

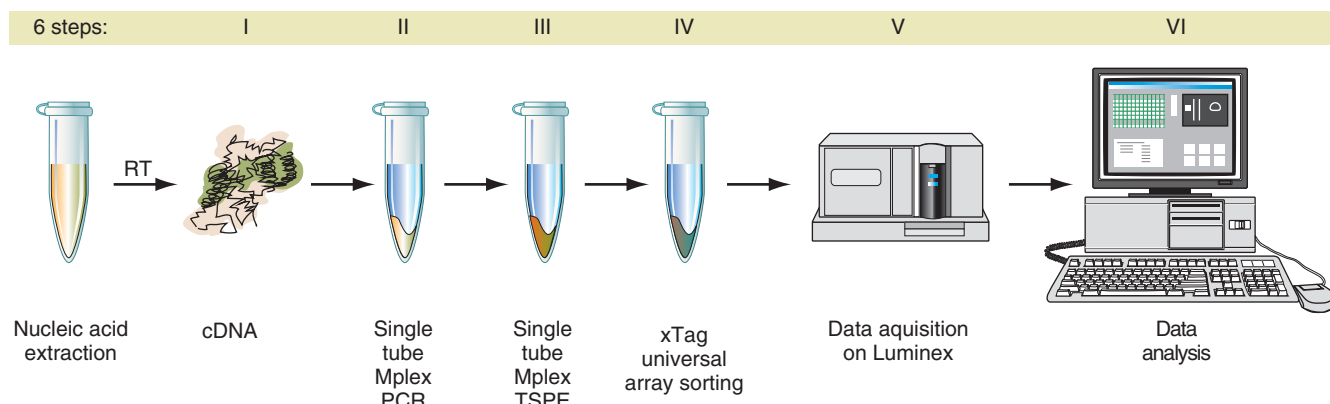

Figure 66-2 Major steps in multiplex, reverse transcriptase-PCR analysis using the xMAP system (Luminex). (Courtesy Luminex.) Mplex, Multiplex; PCR, polymerase chain reaction; RT, reverse transcription; TSPE, target-specific primer extension.

by the first primer set. The increased sensitivity arises from the high total cycle number and the increased specificity arises from the annealing of the second primer set to sequences found only in the first-round products, thus verifying the identity of the first-round product. The major disadvantage of nested PCR is the high rate of contamination that can occur during the transfer of first-round products to the second tube for the second round of amplification. This can be avoided either by physically separating the first- and second-round amplification mixtures with a layer of wax or oil, or by designing single-tube amplification protocols. In practice, the enhanced sensitivity afforded by nested PCR protocols is rarely required in diagnostic applications, and the identity of an amplification product is usually confirmed by hybridization with a nucleic acid probe.

Multiplex Polymerase Chain Reaction

In multiplex PCR, two or more primer sets designed for amplification of different targets are included in the same reaction mixture (Chamberlain, 1988). With this technique, more than one target sequence in a clinical specimen can be coamplified in a single tube. The primers used in multiplexed reactions must be selected carefully to have similar annealing temperatures and must be noncomplementary to each other to avoid primer-dimers and inefficient reactions. Multiplex PCRs are more complicated to develop and are often less sensitive than single-primer-set PCR reactions, but they allow multiple targets to be detected from a single specimen in one reaction.

A promising new platform for multiplex PCR analysis is the xMAP system (Luminex Corp., Austin, Tex.). The xMAP system incorporates a proprietary process to internally dye polystyrene microspheres with two spectrally distinct fluorochromes. By using precise ratios of these fluorochromes, an array is created consisting of 100 different microsphere sets with specific spectral addresses. Each microsphere set can possess a different reactant on its surface. For nucleic acid analysis, oligonucleotide probes would be covalently bound to the microsphere surface by carbodiimide coupling. Because each microsphere set can be distinguished by its spectral address, the sets can be combined, allowing up to 100 different analytes to be measured simultaneously in a single reaction vessel. A third fluorochrome coupled to a reporter molecule quantifies the biomolecular interaction that occurs at the microsphere surface.

Microspheres are interrogated individually in a rapidly flowing liquid stream as they pass by two separate lasers in the Luminex xMAP flow cytometer. High-speed digital signal processing classifies each microsphere based on its spectral address and quantifies the reaction on its surface. Thousands of microspheres are investigated per second, resulting in an analysis system capable of analyzing and reporting up to 100 different reactions in a single reaction vessel in a few seconds.

Multiplex assays run on the Luminex platform typically consist of three major steps: nucleic acid amplification by PCR, target specific extension, and liquid bead array decoding (Merante, 2007). The steps in a Luminex xMAP assay are shown in Figure 66-2. After PCR amplification, the amplicons are mixed with a second set of tagged primers specific for each target. If the target is present, the tagged primer will be extended through a process called *target specific extension*. During this extension a label is incorporated into the extension product. The color-coded beads are added to identify the tagged and labeled extension products. Attached to each differently colored bead is oligonucleotide complementary to the tag sequence for each target. Samples are then placed in the Luminex xMAP flow

cytometer where the beads are read by two color lasers. One laser identifies the color of the bead and the other laser detects the presence or absence of a labeled extension product on that bead.

Another promising technology for high-order multiplex PCR is the Film Array developed by Idaho Technology, Salt Lake City, Utah. It is a completely automated, integrated, and self-contained lab-in-a-pouch system. The film portion of the pouch has stations for cell lysis, nucleic acid purification, reverse transcription to detect RNA targets, first stage PCR multiplex PCR, and an array of up to 120 second-stage nested PCRs. After extracting and purifying nucleic acids from the unprocessed sample, the Film Array performs a nested multiplex PCR that is executed in two stages. During the first stage PCR, the Film Array performs a single, large-volume, massively multiplexed reaction. The products from first stage PCR are then diluted and combined with a fresh, primer-free master mix. Aliquots of this second master mix solution are then distributed to each well of the array. Each well of the array is prespotted with a single set of primers. In the second stage, small-volume PCR is performed in singleplex fashion in each well of the array. Even though this assay uses nested PCR, the entire test is performed within a sealed pouch, thus eliminating concerns of carryover contamination. Using amplification and melting curve data, the Film Array software automatically generates a result for each target. A Film Array for detection of 20 different respiratory pathogens is in development.

End-Point Quantitative Polymerase Chain Reaction

A linear relationship should exist between the quantity of input template and the amount of amplification product. However, because the final amount of PCR product depends on exponential amplification of the initial quantity of template, minor differences in amplification efficiency may lead to very large and unpredictable differences in the final product yield (Clementi, 1993). The tube-to-tube differences may depend on sample preparation and nucleic acid purification procedures, presence of inhibitors, and thermal cycler performance. For these reasons, simple quantification of product accumulated at the end of the reaction and the use of external standard curves do not provide reliable quantification of the amount of template initially present in the sample.

A variety of PCR-based strategies have been developed to accurately quantify DNA and RNA targets in clinical specimens but the competitive PCR (cPCR) approach has proved reliable and robust for clinical applications (Gilliland, 1990; Piatak, 1993). The basic concept behind cPCR is the coamplification in the same reaction tube of two different templates of equal or similar lengths and with the same primer binding sequences. Because both templates are amplified with the same primer pair, identical thermodynamics and amplification efficiency are ensured. The amount of one of the templates must be known and, after amplification, products from both templates must be distinguishable. Different types of competitor have been used in cPCR but, in general, competitors that are similar in size and base composition to the target work most effectively. RNA competitors should be used in quantitative RT-PCRs to address the problem of variable RT efficiency.

The yield of PCR product is described by the equation, $Y = I(1 + e)^n$, where Y is the quantity of PCR product, I is the quantity of template at the beginning of the reaction, e is the efficiency of the reaction, and n is

the number of cycles. In cPCR, this equation is written for both templates, as follows: competitor, $Y_c = I_c(1 + e)^n$; and target, $Y_t = I_t(1 + e)^n$. Because e and n are the same for both the competitor and target, the relative product ratio Y_c/Y_t directly depends on their initial concentration ratio I_c/I_t and the function $Y_c/Y_t = I_c/I_t$ is linear.

A single concentration of competitor is sufficient, in theory, to quantify an unknown amount of target without the use of a standard curve. However, because analysis of two template species present in a sample at widely different amounts may be difficult and imprecise in practice, cPCR using several concentrations of competitor within the expected concentration range of the target were generally performed. However, this approach provided no more accurate results than the use of a single concentration of competitor in a study of different approaches to standardization of cPCR (Haberhausen, 1998). The commercially available end-point quantitative PCR assays for HIV-1 and HCV (Amplicor Monitor Tests, Roche Diagnostics, Indianapolis) use a single concentration of a competitor to determine the initial concentration of the target.

End-point PCR is rapidly being replaced in the clinical laboratory by homogenous kinetic (real-time) methods for product detection (Barbeau, 2004) (see next section). These methods provide for more precise measurements of initial template concentrations because the analysis is performed early in the log phase of product accumulation and, as a result, are less prone to error resulting from differences in sample-to-sample amplification efficiency.

Real-Time (Homogeneous, Kinetic) Polymerase Chain Reaction

Real-time PCR describes methods by which the target amplification and detection steps occur simultaneously in the same tube (homogeneous). These methods require special thermal cyclers with precision optics that can monitor the fluorescence emission from the sample wells. The computer software supporting the thermocycler monitors the data throughout the PCR at every cycle (kinetic) and generates an amplification plot for each reaction. A typical amplification plot is shown in Figure 66-3. The amplification plot shows the normalized fluorescence signal from the reporter (Rn) at each cycle number. In the initial cycles there is little change in the amount of fluorescence. This defines the baseline of the plot. An increase above the baseline indicates detection of accumulated PCR product. A fixed fluorescence threshold can be set above the baseline to call positive samples. The PCR cycle at which the sample fluorescence passes the threshold is defined as the *cycle threshold* (CT). There is an inverse linear relationship between the log of the initial target concentration and the CT. Alternatively, the cycle number corresponding to the maximal rate change in fluorescence, the second derivative maximum, has a similar relationship to initial target concentration.

In the simplest format, PCR product is detected as it is produced using fluorescent dyes that preferentially bind to double-stranded DNA (dsDNA). SYBR Green I is one such dye that has been used in this application (Morrison, 1998). In the unbound state, the fluorescence is relatively low but when bound to dsDNA the fluorescence is greatly enhanced. The DNA-binding dye will bind to any dsDNA and therefore will bind both specific and nonspecific PCR products equally well. The specificity of the detection can be improved through melting curve analysis. As the

Figure 66-3 Real-time PCR amplification plot. (Courtesy Applied Biosystems.) PCR, Polymerase chain reaction.

temperature is raised slowly, the two strands of the amplicon melt apart and the amount of fluorescence decreases. The data are transformed and analyzed by plotting the first derivative of fluorescence on the y-axis and temperature on the x-axis. The specific amplified product will have a characteristic melting peak at its predicted melting temperature (T_m), whereas the primer dimers and other nonspecific products should have a different T_m or give broader peaks (Ririe, 1997).

The specificity of real-time PCR can also be increased by including hybridization probes in the reactions mixture. These probes are labeled with fluorescent dyes or with combinations of fluorescent and a quencher dye. In the 5' nuclease (TaqMan) PCR assay, the 5'-3' exonuclease activity of Taq DNA polymerase is used to cleave a nonextendable hybridization probe during the primer extension phase of PCR (Holland, 1991). This approach uses dual-labeled fluorogenic hybridization probes. One fluorescent dye serves as reporter and its emission spectrum is quenched by the second fluorescent dye. The nuclease degradation of the hybridization probe releases the reporter dye, resulting in an increase in its peak fluorescent emission (Fig. 66-4). The increase in fluorescent emission indicates that specific PCR product has been made and the intensity of fluorescence is related to the amount of product (Heid, 1996). Specificity is increased because signal is generated only when the primer and probe are bound to the same template strand.

Fluorescence resonance energy transfer (FRET) probes can also be used to detect PCR product as it is generated (Lay, 1997). This method requires two specially designed sequence-specific oligonucleotide probes. These hybridization probes hybridize next to each other on the product molecule. As shown in Figure 66-5, the 3' end of one probe is labeled with a donor dye and the 5' end of the other probe is labeled with an acceptor dye. The donor dye is excited by an external light source and, instead of emitting light, transfers its energy to the acceptor dye by a process called FRET. The excited acceptor dye emits light at a longer wavelength than the unbound donor dye and the intensity of the acceptor dye light emission is proportional to the amount of PCR product.

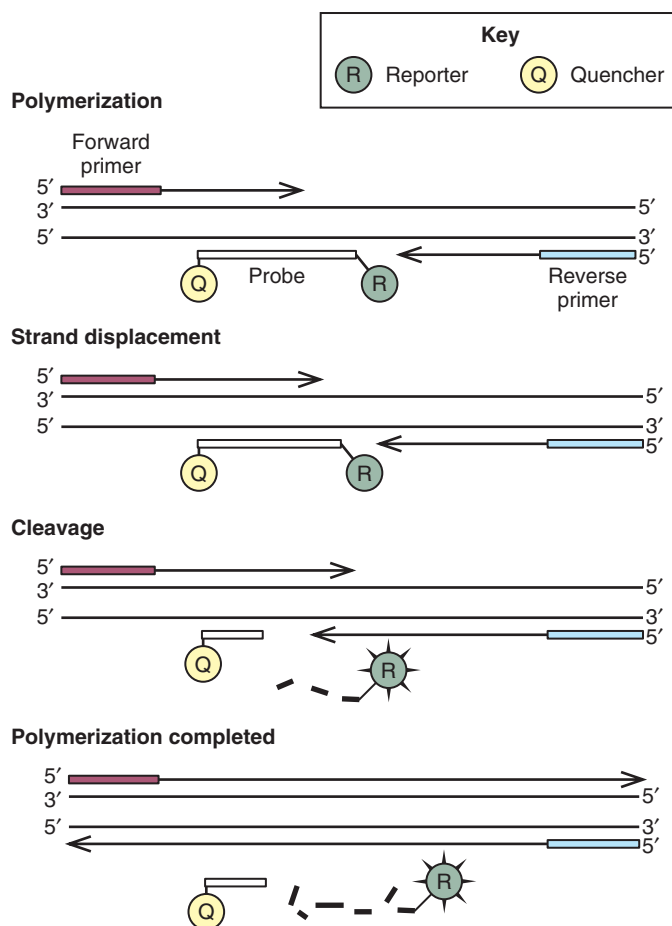

Figure 66-4 Mechanism of signal generation in 5' nuclease PCR assays. (Courtesy Applied Biosystems.) PCR, Polymerase chain reaction.

Real-time detection and quantification of PCR product can also be accomplished using molecular beacons (Tyagi, 1998). Molecular beacons are hairpin-shaped oligonucleotide probes with an internally quenched fluorophore whose fluorescence is restored when they bind to a target nucleic acid (Fig. 66-6). They are designed in such a way that the loop portion of the probe molecule is complementary to the target sequence. The stem is formed by the annealing of complementary arm sequences on the ends of the probe. A fluorescent dye is attached to one end of one arm and a quenching molecule is attached to the end of the other arm. The stem keeps the fluorophore and quencher in close proximity such that no light emission occurs. When the probe encounters a target molecule, it forms a hybrid that is longer and more stable than the stem, and undergoes a conformational change that forces the stem apart and causes the fluorophore and quencher to move away from each other, restoring the fluorescence.

Figure 66-5 Fluorescence resonance energy transfer probes. (Redrawn from Wolk D, Mitchell S, Patel R. *Principles of molecular microbiology testing methods*. Infect Dis Clin N Am 2008;15(4):1157–1204.)

It is not absolutely necessary to have a stem loop structure to use nonhydrolyzable probes in real-time PCR applications. Dark quencher probes contain a fluorophore on the 5' end, and a nonfluorescent quencher molecule on the 3' end (Afonina, 2002). The fluorescence is quenched when the probe is in a random coil configuration and emitted when the probe anneals to the target sequence. Similar to molecular beacons or FRET probes, the DNA polymerase does not degrade these probes during target amplification. Because the dark quencher is not fluorescent, it does not contribute to background signal. This has the advantage of improved signal-to-noise ratio for the detection system, which may improve sensitivity. These probes also incorporate a hybridization-stabilizing compound, known as a *minor groove binder*. It is a small, crescent-shaped molecule that is covalently linked to 3' end of the probe that spans about 3–4 nt and snugly fits into the minor groove of DNA where it forms hydrogen bonds with the template. The minor groove binder allows the use of shorter probes and enables improved T_m leveling, which improves the specificity of the detection reaction (Kutyavin, 2000).

Scorpion probes combine a PCR primer with a molecular beacon (Thelwell, 2000). Intramolecular hybridization of the loop structure to a downstream portion of the amplification product separates the reporter and quencher dyes. The hybridization kinetics of scorpion probes is generally faster than those of molecular beacons because the primer and probe are located on the same molecule.

Another approach to detection, characterization, and quantification of real-time PCR amplicons involves the use of a nonstandard DNA base pair constructed from isoG and isoC (Sherrill, 2004). These synthetic bases pair with each other, but not with the natural bases guanine and cytosine and can be covalently coupled to a wide variety of reporter groups. In the MultiCode-RTx assays (EraGen Biosciences, Madison, Wis.) the target is amplified using a forward primer with a single isoC nucleotide with fluorescent label at 5' end and an unlabeled standard base reverse primer. Amplification is performed in the presence of isoG coupled to a fluorescence quencher molecule and site-specific incorporation by the DNA polymerase place the quencher in close proximity to the fluorophore resulting in a decrease of fluorescence with every PCR cycle. The number of cycles in which the fluorescence change can be detected is dependent on the initial number of target molecules in the reaction. The decrease in fluorescence is easily monitored by a number of different standard real-time PCR instruments. Postreaction amplicon melting curve analysis can be performed to confirm the identity of the amplicon and to detect sequence variants.

Real-time PCR methods decrease the time required to perform nucleic acid assays because there are no post-PCR processing steps. Also, because amplification and detection occur in the same closed tube, these methods eliminate the postamplification manipulations that can lead to laboratory contamination with amplicon. In addition, real-time PCR methods lend themselves well to quantitative applications because analysis is performed

Figure 66-6 Molecular beacon probes. (Redrawn from Wolk D, Mitchell S, Patel R. *Principles of molecular microbiology testing methods*. Infect Dis Clin N Am 2008;15(4):1157–1204.)

early in the log phase of product accumulation and as a result are less prone to error that may result from differences in amplification efficiency between samples.

Relative concentrations of DNA present during the exponential phase of the reaction are determined by plotting fluorescence against cycle number on a logarithmic scale (so an exponentially increasing quantity will give a straight line). A threshold for detection of fluorescence above background is determined and the CT determined. The quantity of DNA theoretically doubles every cycle during the exponential phase and relative amounts of DNA can be calculated (e.g., a sample whose C_t is three cycles earlier than another's has $2^3 = 8$ times more template). Because all sets of primers do not work equally well, one has to calculate the reaction efficiency first. Thus, by using this as the base and the cycle difference (C_d) as the exponent, the precise difference in starting template can be calculated (in previous example, if efficiency was 1.96, then the sample would have 7.53 times more template).

Amounts of RNA or DNA are then determined by comparing the results to a standard curve produced by real-time PCR of serial dilutions (e.g., undiluted, 1:4, 1:16, 1:64) of a known amount of RNA or DNA. As mentioned earlier, to accurately quantify gene expression, the measured amount of RNA from the gene of interest is divided by the amount of RNA from a housekeeping gene measured in the same sample to normalize for possible variation in the amount and quality of RNA between different samples. This normalization permits accurate comparison of expression of the gene of interest between different samples, as long as the expression of the reference (housekeeping) gene used in the normalization is very similar across all the samples. Choosing a reference gene that fulfills this criterion is therefore of high importance, and often challenging, because only very few genes show equal levels of expression across a range of different conditions or tissues.

Real-time PCR can be used to quantify nucleic acids by two strategies—relative quantification and absolute quantification (VanGuilder, 2008). Relative quantification measures the fold-difference ($2\times$, $3\times$, etc.) in the target amount. For gene expression analysis, relative concentrations may be determined by the $2^{-\Delta\Delta CT}$ method in which for each sample the difference in CT values for the gene of interest and the endogenous gene control is calculated (ΔCT). Next, subtraction of the control-condition ΔCT from the treated-condition ΔCT yields the $\Delta\Delta CT$. The negative value of this subtraction, $-\Delta\Delta CT$, is used as the exponent of 2 in the equation and represents the difference in corrected number of cycles to threshold. This value is often referred to as the *relative quantity value*.

Absolute quantification gives the exact number of target molecules present by comparing with known standards. The quality of standard is important for accurate quantification.

Rapid-Cycle Polymerase Chain Reaction

While real-time PCR methods have had a significant impact on assay time, a great deal of emphasis continues to be placed on reducing the assay time for the various PCR formats. Rapid-cycle PCR is not chemically different from any of the standard PCR formats (Wittwer, 1991). The polymerases used in PCR are capable of incorporating 35–100 nucleotides per second. Most of the time consumed in performing PCR is temperature equilibration for the solution so that efficient annealing and extension occur, as well as significant amount of time changing the temperature. By reducing the thermal profile of the solution using thin-walled tubes or capillaries that force the reaction solution into thin columns or sheets of fluid, it is possible to improve thermal transfer rates as well as equilibration rates such that thermocycling time can be significantly reduced. In highly optimized systems, it is possible to approach the ideal processivity rate of the polymerase such that a 40-cycle PCR may be performed in 30 minutes or less using standard or real-time PCR chemistries.

Digital Polymerase Chain Reaction

PCR exponentially amplifies nucleic acids and the number of amplification cycles and the amount of amplicon allows the computation of the starting quantity of targeted nucleic acid. However, many factors complicate this calculation, often creating uncertainties and inaccuracies particularly when the starting concentration is low. Digital PCR attempts to overcome these difficulties by transforming the exponential data from conventional PCR to digital signals that simply indicate whether or not amplification occurred (Vogelstein, 1999).

Digital PCR is accomplished by capturing or isolating each individual nucleic acid molecule present in a sample within many chambers, zones, or regions that are able to localize and concentrate the amplification product to detectable levels. After PCR amplification, a count of the areas

containing PCR product is a direct measure of the absolute quantity of nucleic acid in the sample. The capture or isolation of individual nucleic acid molecules may be done in capillaries, microemulsions, arrays of miniaturized chambers, or on surfaces that bind nucleic acids. Digital PCR has many applications including detection and quantification of low levels of pathogen sequences, rare genetic sequences, gene expression in single cells, and clonal amplification of nucleic acids for sequencing mixed nucleic acid samples. Clonal amplification enabled by digital PCR is a key element of many of the “next-generation” sequencing methods.

TRANSCRIPTION-BASED AMPLIFICATION

Transcription-based amplification includes transcription-mediated amplification (TMA) and nucleic acid sequence-based amplification (NASBA). Both TMA and NASBA are isothermal nucleic acid amplification techniques that, although slightly different in practice, are identical in concept, and are described together (Kwoh, 1989; Compton, 1991). TMA and NASBA are the intellectual properties of Gen-Probe, San Diego, and bioMérieux, Durham, N.C., respectively. These techniques essentially recapitulate retroviral replication in vitro, converting RNA into DNA and then using the DNA as a template for transcription of multiple copies of RNA.

The process begins with an RNA target, which in most cases exists as a single-stranded entity, removing the need for thermal denaturation of the template before amplification (Fig. 66-7). A sequence-specific DNA primer binds to the RNA target. Reverse transcriptase then extends the primer, creating a DNA–RNA heteroduplex. The 5' end of the sequence-specific primer contains the promoter for a T7 bacteriophage polymerase. The presence of this T7 promoter in the 5' end of the primer results in the synthesis of a DNA strand complementary to the initial RNA target containing the T7 promoter at its 5' end. In the case of TMA, the reverse-transcriptase enzyme itself degrades the initial RNA template as it synthesizes its complementary DNA. In NASBA, a separate enzyme, RNase H, degrades the initial RNA template. RNase H selectively cleaves RNA, which is heteroduplexed to DNA, but not RNA alone. In either case, the resultant single-stranded, complementary DNA with the T7 promoter sequence binds to a second primer at its 3' end. The DNA polymerase extends from this second primer, resulting in the synthesis of a dsDNA molecule containing an intact T7 promoter. This DNA molecule can now serve as a template for T7 polymerase, a bacteriophage enzyme that specifically recognizes the T7 promoter and synthesizes multiple copies of RNA. Each of these newly synthesized RNA molecules is antisense to the initial target, allowing it to hybridize to the second primer. The reverse-transcriptase, second primer, RNase H, and DNA polymerase then use this antisense RNA molecule as a template to synthesize new dsDNA templates, which in turn make more RNA template. A 10^9 -fold amplification of target RNA can be achieved with these methods in 2 hours or less.

TMA and NASBA have several distinct advantages over other RNA amplification techniques. Perhaps the most significant of these advantages is that no initial denaturation is required for the amplification to occur. Hence, dsDNA sequences are not denatured, and thus are incapable of binding to primers in the reaction. DNA contamination can be particularly problematic when techniques such as PCR are used to assay for the RNA transcripts of retroviral or intronless eukaryotic genes. NASBA and TMA eliminate the problem of DNA contamination giving a falsely elevated determination of RNA. A second advantage is that this technology uses isothermal processes that obviate the need for sophisticated thermocyclers because the whole process occurs at a single temperature. Combining this technology with molecular beacons or other sequence-specific probes that can be added directly to the amplification mixture creates a closed-tube system, which aids in preventing amplicon cross-contamination in the laboratory.

NASBA and TMA have been used successfully in a wide variety of applications. They have been used to detect a number of pathogens, including viruses such as HIV, HCV, varicella zoster virus, cytomegalovirus (CMV), rhinovirus, enterovirus, measles, human papillomavirus, and bacteria such as *Mycobacterium tuberculosis*, *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Mycoplasma pneumoniae*, and *Campylobacter jejuni*. In addition, quantitative tests for HIV and HCV have been developed using this technology. Furthermore, human genetic applications such as human leukocyte antigen typing and factor V Leiden mutation detection have been described.

In summary, TMA and NASBA are isothermal RNA amplification techniques with a widespread applicability and several unique advantages over other amplification methods, especially for the elimination of DNA

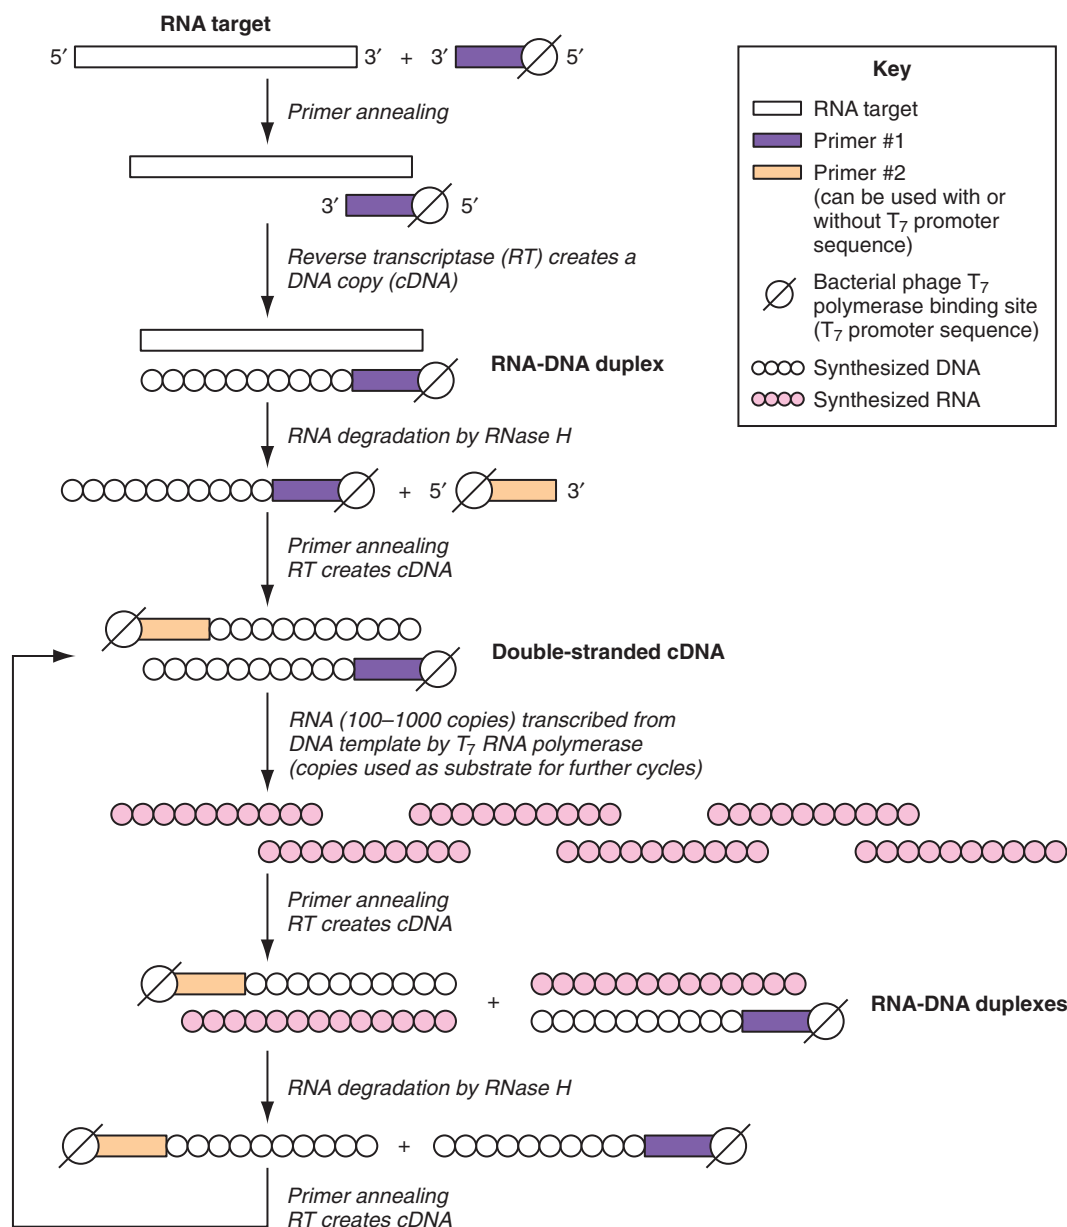

Figure 66-7 Transcription-based amplification. (Redrawn from Wolk D, Mitchell S, Patel R. *Principles of molecular microbiology testing methods*. Infect Dis Clin N Am 2008;15(4):1157–1204.)

contamination issues, particularly those related to retroviral and intronless genes. Combining these techniques with fluorescent probes allows one-step, closed-tube, real-time amplification without the need for thermal cycling.

STRAND-DISPLACEMENT AMPLIFICATION

Strand-displacement amplification (SDA) is an isothermal template amplification technique that can be used to detect trace amounts of DNA or RNA of a particular sequence. SDA as it was first described was a conceptually straightforward amplification process with some technical limitations (Walker, 1992a, 1992b). Since its initial description, however, it has evolved into a highly versatile tool that is technically simple to perform but conceptually complex. In its current iteration, SDA occurs in two discrete phases: target generation and exponential target amplification (Little, 1999). Only the target amplification phase is shown in Figure 66-8. In the target generation phase, a dsDNA target is denatured and hybridized to two different primer pairs, designated as *bumper* and *amplification* primers. The amplification primers include the single-stranded restriction endonuclease enzyme sequence for BsoB1 located at the 5' end of the target binding sequence. The bumper primers are shorter and anneal to the target DNA just upstream of the region to be amplified. In the presence of BsoB1, an exonuclease-free DNA polymerase, and a dNTP mixture

consisting of dUTP, dATP, dGTP, and thiolated dCTP (Cs), simultaneous extension products of both the bumper and amplification primers are generated. This process displaces the amplification primer products, which are available for hybridization with the opposite-strand products with the opposite-strand bumper and amplification primers.

The simultaneous extension of opposite-strand primers produces strands complementary to the products formed by extension of the first amplification primer with Cs incorporated into the BsoB1 cleavage site. This product enters the exponential target amplification phase of the reaction. The BsoB1 enzyme recognizes the double-stranded site, but because one strand contains Cs, it is nicked rather than cleaved by the enzyme. The DNA polymerase then binds to the nick and begins synthesis of a new strand while simultaneously displacing the downstream strand. This step recreates the double-stranded species with the hemimodified restriction endonuclease recognition sequence, and the iterative nicking and displacement process repeats. The displaced strands are capable of binding to opposite-strand primers, which produces exponential amplification of the target sequences.

These single-stranded products also bind to detector probes for real-time detection. The detector probes are single-stranded DNA (ssDNA) molecules with fluorescein and rhodamine labels. The region between the labels includes a stem-loop structure. The loop contains the recognition site for the BsoB1 enzyme. The target specific sequences are located 3' to

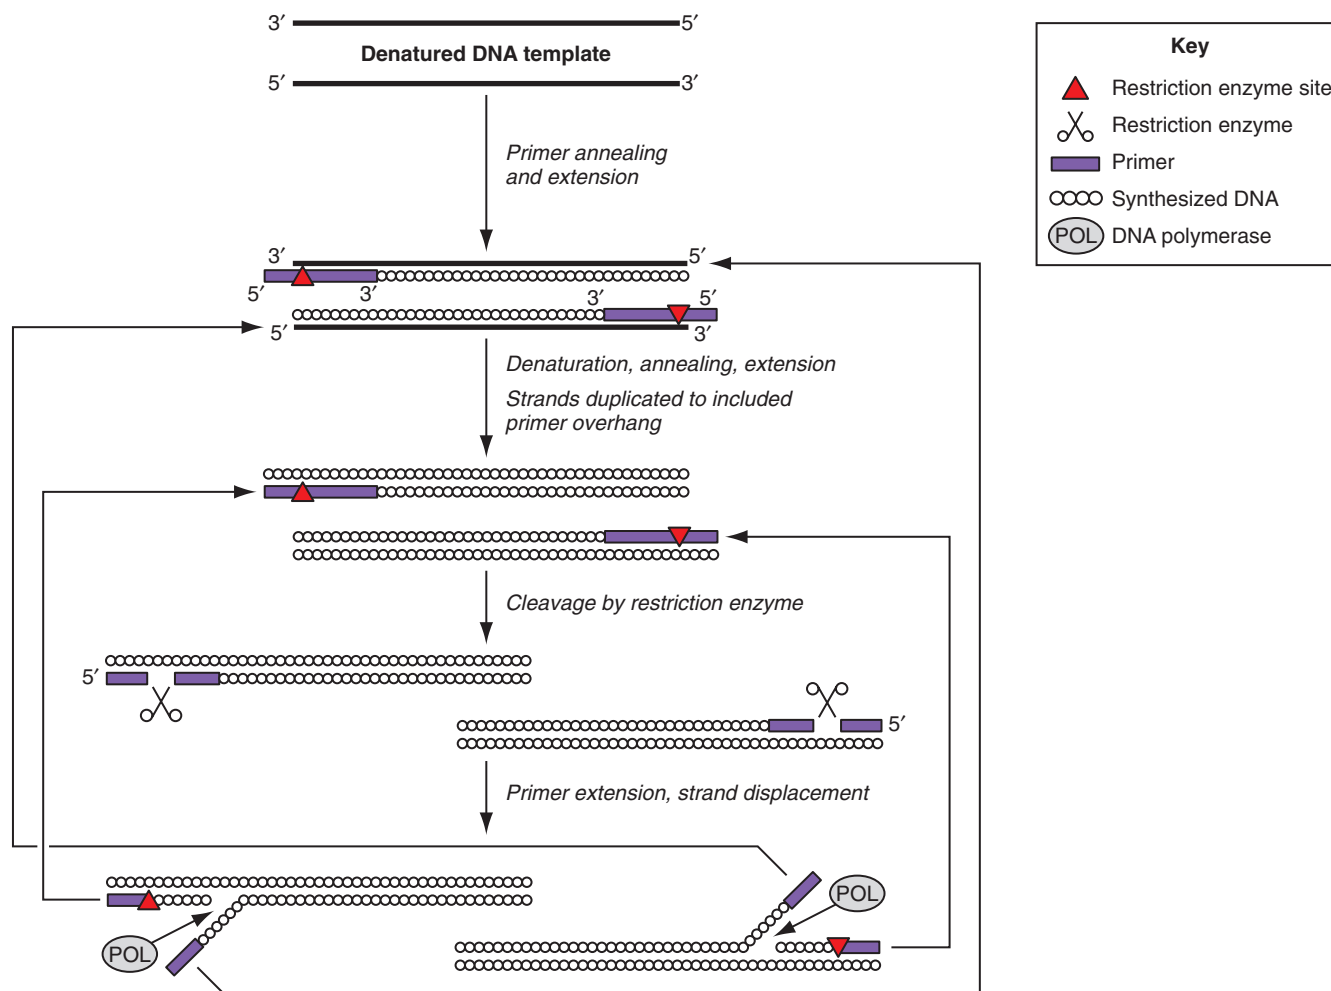

Figure 66-8 Strand displacement amplification. (Redrawn from Wolk D, Mitchell S, Patel R. *Principles of molecular microbiology testing methods*. Infect Dis Clin N Am 2008;15(4):1157–1204.)

the rhodamine label. In the absence of the target the stem-loop structure is maintained with the fluorescein and rhodamine labels in close proximity. The net effect is that very little emission for the fluorescein is detected after excitation. After SDA, the probe is converted to a double-stranded species, which is cleaved by BsoB1. The cleavage causes physical separation of the fluorescein and rhodamine labels, which results in an increase in emission from the fluorescein label.

The diagnostic applications of SDA include the direct detection of *M. tuberculosis*, *C. trachomatis*, and *N. gonorrhoeae* in clinical specimens. SDA has a reported sensitivity high enough to detect as few as 10–50 copies of a target molecule (Walker, 1992a). By using a primer set designed to amplify a repetitive sequence with 10 copies in the *M. tuberculosis* genome, the assay is sensitive enough to detect 1–5 genome copies of the bacterium. Recently, SDA has been adapted to quantify RNA by adding a reverse-transcriptase step (RT-SDA). In this case, a primer hybridizes to the target RNA and a reverse-transcriptase synthesizes a cDNA. This cDNA can then serve as a template for primer incorporation and strand displacement. The products of this strand displacement then feed into the amplification scheme described. RT-SDA has been used for the determination of HIV viral load (Nycz, 1998).

The main advantage of SDA is that it is an isothermal process that, unlike PCR, can be performed at a single temperature after initial target denaturation. This eliminates the need for expensive thermocyclers. Furthermore, samples can be subjected to SDA in a single tube, with amplification times varying from 30 minutes to 2 hours. The main disadvantage of SDA lies in the fact that, unlike PCR, the relatively low temperature at which SDA is carried out (52.5°C) can result in nonspecific primer hybridization to sequences found in complex mixtures such as genomic DNA. Hence, when the target is in low abundance compared to background DNA, nonspecific amplification products can swamp the system, decreasing the sensitivity of the technique. However, the use of organic solvents to increase stringency at low temperatures and the recent introduction of

more thermostable polymerases capable of strand displacement have alleviated much of this problem.

LOOP-MEDIATED AMPLIFICATION

Loop-mediated amplification (LAMP) is an isothermal method that relies on autocycling strand displacement DNA synthesis by *Bst* DNA polymerase and a set of four to six primers (Notomi, 2000). Two inner and two outer primers define the target sequence and an additional set of loop primers are added to increase the sensitivity of the reaction. The final products of the LAMP reaction are DNA molecules with a cauliflower-like structure of multiple loops consisting of repeats of the target sequence. The products can be analyzed in real-time by monitoring of the turbidity in the reaction tube resulting from production of magnesium pyrophosphate precipitate during the DNA amplification. Amplification products can also be visualized in agarose gels after electrophoresis and staining with ethidium bromide or SYBR Green.

Because LAMP is an isothermal process and positive reactions can be detected by simple turbidity measurements or visualized directly with the naked eye it requires no expensive equipment. These attributes make it an attractive technology for resource-poor settings and field use. However, primer design for LAMP is more complex than for PCR with specialized training and software required for their design. Meridian Bioscience, Inc. (Cincinnati, Ohio) has licensed LAMP technology from Eiken Chemical Company, Ltd., Japan, for the development of infectious disease diagnostics in the United States.

HELICASE-DEPENDENT AMPLIFICATION

Helicase-dependent amplification (HDA) is an isothermal process developed by BioHelix, Beverly, Mass., that uses helicase to separate dsDNA and generate single-stranded templates for primer hybridization

Figure 66-9 Invasive cleavage and detection of an oligonucleotide probe using a FEN-1 DNA polymerase. (Redrawn from Wolk D, Mitchell S, Patel R. *Principles of molecular microbiology testing methods*. Infect Dis Clin N Am 2008;15(4):1157–1204.) FEN-1, Flap endonuclease-1; FRET, fluorescence resonance energy transfer.

and subsequent extension by a DNA polymerase (Vincent, 2004). As the helicase unwinds dsDNA enzymatically, the initial heat denaturation and subsequent thermocycling steps required by PCR can all be omitted. In HDA, strands of dsDNA are separated by the DNA helicase and the ssDNA coated ssDNA-binding proteins. Two sequence-specific primers hybridize to each border of the target sequence and a DNA polymerase extend the primers annealed to the target sequence to produce dsDNA. The two newly synthesized products are used as substrates by the helicase in the next round of amplification. Thus a simultaneous chain reaction proceeds, resulting in exponential amplification of the selected target sequence.

HDA is compatible with multiple detection technologies, including qualitative and quantitative fluorescent technologies and with instruments designed for real-time PCR (Tong, 2008). Furthermore, HDA has shown potential for the development of simple, portable DNA diagnostic devices to be used in the field or at the point-of-care.

PROBE AMPLIFICATION METHODS

Probe amplification methods differ from target amplification in that the amplification products contain a sequence only present in the initial probes. Cleavase/invader technology is an example of probe amplification method that is used currently as an important diagnostic application, the detection of high-risk genotypes of human papilloma viruses (HPV) in cervical samples (Ginocchio, 2008).

CLEAVASE/INVADER TECHNOLOGY

Cleavase/invader technology is a probe amplification method that relies on the specific recognition and cleavage of particular DNA structures by members of the flap endonuclease-1 family of DNA polymerases (Lyamichev, 1999). These polymerases cleave the 5' single-stranded flap of a branched base-paired duplex and are termed *cleavases*. This enzymatic activity probably plays an essential role in the elimination of complex nucleic acid structures that arise during DNA replication and repair in

vivo. Because these structures may occur anywhere in the replicating genome, the enzyme recognizes the molecular structure of the substrate without regard to the sequence of the nucleic acids making up the DNA complex (Lieber, 1996). This enzymatic activity has proved to be a very useful tool for DNA analysis and is the basis of this technology.

In cleavase/invader assays two primers are designed that hybridize to the target sequence in an overlapping fashion (Fig. 66-9). Under the proper annealing conditions, signal and invader probes bind to the target sequence such that the invader hybridizes upstream of the signal probe with a region of overlap between the 3' end of invader and the 5' end of signal probe. Under the proper conditions, the overlap of binding sites for the primers results in a displacement equilibrium between the primers. Cleavase only cleaves 5' flaps; thus the 5' end of the signal probe is released. The target sequence acts as a scaffold upon which the proper DNA structure can form. Because the DNA structure that serves as the cleavase substrate only occurs in the presence of the target sequence, the generation of cleavage products indicates the presence of the target. The cleaved product is detected by binding to and serving as an invader probe for a FRET probe. The 5' end of the FRET probe is cut by cleavase, releasing the reporter molecule in the same way that it releases the 5' end of the signal probe.

Use of a thermostable cleavase enzyme allows the reactions to be run at high enough temperatures for a primer exchange equilibrium to exist. This allows multiple cleavase products to form from a single target molecule. Hence, the invader assay can be run under isothermal conditions, removing the need for thermal cycling. This technology has been used for detection, quantification, and characterization of a variety of microbial and human nucleic acid targets (Rosetti, 1997; Ryan, 1999; Wong, 2008).

The cleavase/invader technology has several inherent advantages over other amplification strategies. Because of the fact that the overlap in the invader probe need only be one base pair, this technology can easily be adapted to detect point mutations of interest by designing the overlap region to encompass the mutation to be detected. In addition, unlike target amplification techniques in which the target sequence itself is amplified,

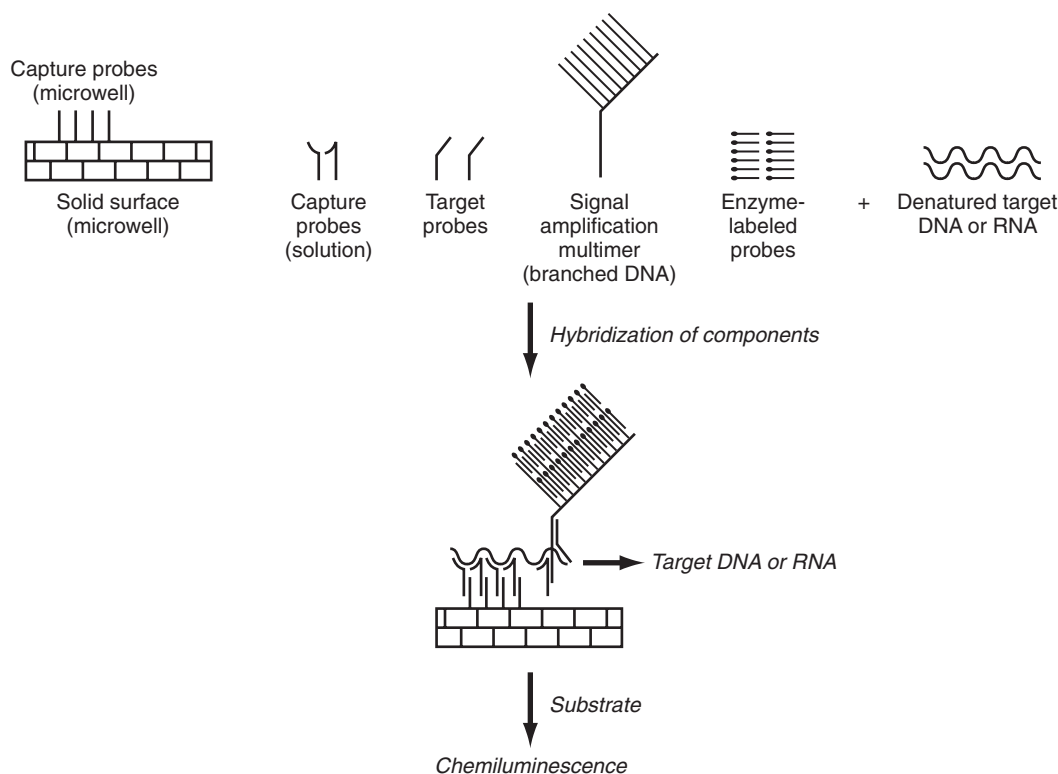

Figure 66-10 Branched DNA amplification. (Redrawn from Wolk D, Mitchell S, Patel R. *Principles of molecular microbiology testing methods*. Infect Dis Clin N Am 2008;15(4):1157–1204.)

the invader assay does not increase the amount of the target sequence. Thus the invader assay is less prone to problems of false-positive results due to amplicon cross-contamination.

In addition to the invader assay, cleavase can also be used to generate fragment-length polymorphisms (in a fashion analogous to restriction fragment-length polymorphism). By melting genomic DNA and cooling rapidly, highly reproducible hairpin loop secondary structures will form in the DNA that can serve as substrates for cleavase. Digestion of the DNA results in a distinct pattern that has been successfully employed to screen for interferon- α -resistant hepatitis C (Sreevatsan, 1998), and to detect specific mutations in human genes (Rosetti, 1997). Because hairpin loops occur with a greater diversity than most restriction enzyme recognition sites, this offers a versatile fragmentation pattern analysis.

Thus structure-specific endonucleases can be used to detect nucleic acid targets of a particular sequence, employed in assay for point mutations, and applied to generate diverse fragmentation patterns capable of distinguishing complex genotypes. These enzymes are powerful tools for nucleic acid analysis.

SIGNAL AMPLIFICATION METHODS

In signal amplification methods, the concentration of probe or target does not increase. The increased analytical sensitivity comes from increasing the concentration of label molecules attached to the target nucleic acid. Multiple enzymes, multiple probes, multiple layers of probes, and reduction of background noise have been used to enhance target detection (Kricka, 1999). Target amplification systems generally have greater analytical sensitivity than signal amplification methods, but technological developments, particularly in branched DNA (bDNA) assays, have lowered the limits of detection to levels that may rival target amplification assays in some applications (Kern, 1996).

Signal amplification assays have several advantages over target amplification assays. In signal amplification systems, the number of target molecules is not altered and, as a result, the signal is directly proportional to the amount of target sequence present in the clinical specimen. This reduces concerns about false-positives due to cross contamination and simplifies the development of quantitative assays. Because signal amplification systems are not dependent on enzymatic processes to amplify target sequences, they are not affected by the presence of enzyme inhibitors in

clinical specimens. Consequently, less cumbersome nucleic acid extraction methods may be used. Typically, signal amplification systems employ either larger probes or more probes than target amplification systems and, consequently, are less susceptible to errors resulting from target sequence heterogeneity. Finally, RNA can be measured directly, without the synthesis of a cDNA intermediate. Branched DNA and hybrid capture are examples of signal amplification systems that have developed into diagnostic tests.

BRANCHED DNA

The bDNA is a solid-phase, sandwich hybridization assay incorporating multiple sets of synthetic oligonucleotide probes (Nolte, 1998). The key to this technology is the amplifier molecule, a DNA molecule with 15 identical branches, each of which can bind three labeled probes.

Multiple target-specific probes are used to capture the target nucleic acid on to the surface of a microtiter well (Fig. 66-10). A second set of target-specific probes also binds to the target. Preamplifier molecules bind to the second set of target probes and up to eight bDNA amplifiers. Three alkaline-phosphatase-labeled probes hybridize to each branch of the amplifier. Detection of the bound labeled probes is achieved by incubating the complex with an enzyme-triggerable substrate, dioxetane, and then measuring the light emission in a luminometer. The resulting signal is directly proportional to the quantity of target in the sample. The quantity of target in the sample is determined from an external standard curve.

Nonspecific hybridization of any of the amplification probes and non-target nucleic acids leads to amplification of the background signal. To reduce the hybridization potential to all nontarget, the nonnatural bases isocytidine (isoC) and isoguanosine (isoG) were incorporated into the amplification probes of the third-generation bDNA assays (Collins, 1995). IsoC and isoG bases pair with each other but not with any of the four naturally occurring bases (Piccirilli, 1990). The use of isoC and isoG probes in bDNA assays increases target-specific amplification without a concomitant increase in background, thereby greatly enhancing the detection limits. The detection limit of the third-generation bDNA assay for HIV-1 RNA is 50 copies/mL (Kern, 1996). bDNA assays for the quantification of HBV DNA, HCV RNA, and HIV-1 RNA are commercially available (Bayer Diagnostics). An instrument platform

for bDNA assays automates the incubation, washing, reading, and data processing.

HYBRID CAPTURE ASSAYS

The hybrid capture system is a solution hybridization antibody capture assay that uses chemiluminescent detection. The target DNA in the specimen is denatured and hybridized with a specific RNA probe (Fig. 66-11). The DNA–RNA hybrids are captured by antibodies specific for DNA–RNA hybrids that are coated on to the surface of a tube. Alkaline-phosphatase-conjugated antihybrid antibodies bind to the immobilized hybrids. The bound enzyme–antibody conjugate is detected with a chemiluminescent substrate and the light emitted is measured in a luminometer. Signal amplification results from the large number of antibody binding sites and the efficiency of the enzyme–substrate reaction. The intensity of the emitted light is proportional to the amount of target DNA in the specimen. Hybrid capture assays for detection of HPV (Cope, 1997) and CMV (Mazzulli, 1999) in clinical specimens are commercially available (Digene, Gaithersburg, Md.).

WHOLE GENOME AMPLIFICATION

Many new techniques, such as array based comparative genomic hybridization, require large amounts of DNA and requests for molecular analysis of very minute samples are increasing. To facilitate these types of analyses, whole genome amplification may be employed to generate sufficient template. Whole genome amplification may be accomplished by a few methods. Multiple Displacement Amplification uses random hexamer primers and phi29 polymerase in an isothermal reaction (Dean, 2002). As the newly synthesized strands encounter primer positions downstream, they displace the product allowing further priming of that displaced strand in the opposite direction. The enzyme used must have high processivity, meaning that it synthesizes a long strand prior to disengaging the template. Other methods have been developed to convert fragmented DNA into “libraries” using a combination of nick translation and ligation of adapters with subsequent PCR amplification by universal primers (Rubicon Genomics, Ann Arbor, Mich.). Continued refinement of these techniques will allow more comprehensive molecular analysis of limited or precious clinical samples.

SUMMARY

This chapter provides a basis for understanding the principles underlying the various nucleic acid amplification methods and their relative strengths and limitations. The technology has already had a tremendous impact on the diagnosis of infectious diseases and genetic disorders and promises to revolutionize the diagnosis and management of patients with cancer. The real power of the technology lies in its ability to cut across traditional disciplines in laboratory medicine. Consequently, a thorough understanding of the basic principles of nucleic acid amplification technology is important for all involved in the practice of laboratory medicine.

KEY POINTS

- Array technology provides a unique and powerful approach to screen a sample for dozens to thousands of genes.
- Current array fabrications allow for diverse platforms with better detection and reduced cost for high-density applications.
- Positive signals are generated when a tagged nucleic acid moiety hybridizes with its complementary probe localized on a solid support (i.e., “chip”).
- Care must be taken when performing and interpreting microarray experiments, because numerous factors must be considered in analysis.
- Numerous applications of array technology have been proposed in the past few years, ranging from molecular staging of tumors to the identification and characterization of microbial agents.
- Improvement of quality and yield of nucleic acid extraction from fixed and frozen tissues combined with continued miniaturization and cost reduction of platforms are making array technology more commonplace and user friendly.

In only a few short years, hybridization array technology, which enables the performance of thousands of simultaneous hybridization reactions on a solid substrate within a single analytical procedure, has gone from theoretical construct to practical reality. Such massively parallel determinations offer previously unimaginable opportunities for diagnostic application, ranging from gene sequencing and detection of genetic polymorphisms to measurement of gene expression profiles in cancer cells. Microarray-based systems offer a platform for quantifying the expression of thousands of genes at the same time. Therefore an unprecedented advantage of this technology is that it affords analysis of whole cassettes of genes, or patterns of gene expression, rather than analysis of one, two, or three genes at a time. The general schema for microarray processing includes the generation of nucleic acid (i.e., deoxyribonucleic acid [DNA]) complementary to genes of interest, that is laid out in microscopic quantities on solid surfaces at defined positions (the “probe”) nucleic acid (genomic DNA or complementary DNA [cDNA]) from samples is added over the surface—cDNA binds and the presence of bound DNA is detected by fluorescence following laser excitation (for general review, see Friend, 2002).

It is clear that hybridization array technology has revolutionized the way we approach the study of disease. The one gene—one protein—one function approach is no longer the mainstay of scientific design. Array technology introduced a complicated mirror image of this approach, in other words, multiple functions, multiple proteins, multiple genes. The power of this technology lies in the “screening” capability that it provides. Under defined experimental conditions, one now has the ability to

determine changes in the patterns of genes, identifying multiple genes acting in concert. These patterns can then be “mined” through various computer algorithms, grouped into functional categories (e.g., respiratory genes, inflammatory genes), and used to derive signatures diagnostic of disease or to generate novel hypotheses about pathogenesis and cell function. The relationship of these genes to one another (increased versus decreased expression) are determined and generally expressed as fold-change. Microarray findings of differential gene expression require confirmation by other techniques such as quantitative reverse-transcriptase polymerase chain reaction (RT-PCR) or additional independent microarray studies.

Once candidate genes or groups of genes are identified, classic approaches to gene function (i.e., gene knockout or gene knockdown) can then be employed to elucidate or validate gene function. More importantly, hybridization array technology, with subsequent data mining, allows genes not previously known to be associated with the disease to be considered, generating new paradigms for future study. Similar platforms can be used to sequence large genes and to scan the genome for single nucleotide polymorphisms and methylation sites. This chapter reviews the theoretical basis for the various matrix hybridization platforms and provides a perspective on their clinical application, both currently and in the future.

ARRAY TECHNOLOGIES

A hybridization array is the molecular equivalent of a spreadsheet, where each cell or address reveals a specific piece of data, usually inferred from the binding of a ligand to its specific target. The first array-based methods were exploited in immunoassays (Ekins, 1987, 1999) and arrays also have been proposed for parallel studies of diverse targets such as proteins, lipids, carbohydrates, and small molecules (Fodor, 1991; Pirrung, 1992; Southern, 1996a; Guschin, 1997; Schena, 1998). Similar to antigen–antibody interactions on immunoarrays, the fundamental principle of nucleic acid arrays is detection of specific hybridization between complementary strands. The principles of nucleic acid hybridization and an overview of various platforms are covered in Chapter 65. The effectiveness of solid-support hybridization formats was pioneered with the use of nitrocellulose membranes (Gillespie, 1965) for dot blots (Kafatos, 1979), line probes, and Southern blots (Southern, 1975). Changing the labeled entity from the probe to the sample was first referred to as *reverse line-blot* (or *dot blot*) hybridization, and led to the beginning of interrogating one sample for multiple potential targets. Moving from dozens to thousands of targets has come about rapidly over the last few years, driven in part by the unique convergence of microfabrication, robotics, and bioinformatics technologies and the demand for high-throughput genetic analysis resulting from the Human Genome Project.

The field is bursting with potential, and many investigators foresee diagnostic and prognostic applications in tumor classification, chemotherapeutic responsiveness, pathogen detection, monitoring antibiotic

resistance, and characterizing inflammatory responses. Array technology may make the dream of personalized molecular medicine, where the genes of an individual patient may be assessed for risk factors and disease susceptibility and to predict response to therapy, a reality. Studies using gene expression profiling to predict diseases include identifying which trauma and burn patients will develop sepsis and multisystem organ failure (www.gluegrant.org); genes involved in the pathogenesis of chronic obstructive pulmonary disease (Wang, 2008); and which patients would likely have recurrence of cancer (Potti, 2006), among others. However, challenges of reproducibility and laboratory quality control remain to be addressed before this enormous potential is realized.

MACROARRAYS

The term *macroarray* has been applied to formats in which areas of probe localization, often called *features*, are large enough to be visualized without magnification. These have been manufactured on nylon or nitrocellulose membranes or as plastic strips with linear arrays of bound target. Because of the size of the features, the density of macroarrays is much lower than microarrays, ranging from a few dozen to hundreds or even thousands of probes. They are usually deposited on to the membrane by printing or dot blotting, then dried and stored for future use.

Nylon, plastic and glass (silicon wafer) are standard supports to make macroarrays. Nylon suffers several drawbacks when compared to silicon, which is a preferred matrix for hybridization arrays. Besides its porous nature, nylon displays high autofluorescence, limiting the sensitivity of fluorescence-based detection because of high background values. The latter also precludes the possibility to develop ratiometric (or two-color) assays. This approach uses two targets, each labeled with a different fluor. Most commonly, one is a constant reference control used in direct comparison to the unknown sample, with results expressed as a ratio of the two emitted fluorescent signals (Duggan, 1999).

Macroarrays are currently used for targeted applications. For example, some commercial arrays target all the known cytokine genes or those within specific signal transduction pathways that are activated during infectious and inflammatory processes. Other arrays, targeting the genes altered during oncogenesis, have been used in cancer research (e.g., Atlas Human Arrays, Clontech, Palo Alto, Calif., or GeneFilters, Research Genetics, Huntsville, Ala.). Other commercial applications, usually in kit format, are used to detect and type specific PCR products, such as in the cystic fibrosis mutation screen, or human leukocyte antigen typing or human papillomavirus typing. Furthermore, nylon-based arrays have been used to detect bacterial colony based gene expression (Barsalobres-Cavallari, 2006) and thyroid cancer detection (Durand, 2008). The advantages of macroarrays include the ability to use standard hybridization equipment, simplified reading or scanning, and affordability.

Some groups have been successful in producing high-density nylon arrays on a custom basis for gene discovery purposes (Gress, 1992; Takahashi, 1995; Granjeaud, 1996; Pietu, 1996; Clark, 1999; Durand, 2008). Even in high-density configurations, the size of the nylon arrays requires a relatively large volume of hybridization fluid, a practical limitation with respect to generating probe from small amounts of diagnostic material. Because microarrays, rather than macroarrays, represent the high-density, high-throughput platform of choice, the bulk of this chapter focuses on applications of microarrays.

MICROARRAYS

Assay miniaturization saves time while cutting costs in biomedical diagnostic applications and research. Working with smaller volumes reduces reagent consumption, increases sample concentration, and improves reaction kinetics. These improvements allow the investigator to determine hundreds or thousands of results in the time formerly required for a single experiment. Microarrays are now available from several commercial suppliers, along with reading and fabrication equipment for custom manufacture of dedicated arrays for specific research or diagnostic applications.

MICROARRAY SUBSTRATES

A major distinction between microarrays and macroarrays consists of the choice of a nonporous solid support. By preventing diffusion of the target nucleic acids, nonporous surfaces (plastic, glass, or silicon substrates) allow faster hybridization kinetics and easier washing steps. In order to allow spatial discrimination of numerous reactions performed simultaneously, the molecular probes are bound to a solid surface in defined arrays.

Deposition of probes on a solid substrate is also more amenable to automation and enables higher array densities with optimal image definition. These features apply to any type of microarray, from synthetic oligonucleotides to cloned cDNAs or PCR products (Southern, 1999). Most microarrays are now developed on glass. As opposed to plastic derivatives, glass transparency and lack of autofluorescence allows low-background, fluorescence-based detection. However, as materials science becomes more involved in array technologies, alternative substrates, including coated glass and plastic substrates, may become available.

MICROARRAY FABRICATION

3'-End functionalization (i.e., chemical modification) of nucleic acids—oligonucleotides, PCR products, cDNAs, or peptide nucleic acid oligomers—is required for covalent immobilization on either glass or polypropylene surfaces (Matson, 1995; Beier, 1999). For example, treatment of glass slides with silane allows amino-covered glass to bind amino-linked probes, using bifunctional molecules such as a dialdehyde or a diisothiocyanate (Case-Green, 1994; Guo, 1994). Alternatively, glass coating with a polycation (e.g., polylysine) allows direct charge-coupled binding of polyanionic DNA probes (Maskos, 1993a), an ultraviolet photocrosslinking step adds covalent bonds to the ionic interaction. Covalent binding is essential to permit stringent washes and therefore accurate discrimination of hybridized species. Several protocols have been published to address surface activation (Maskos, 1992; Beattie, 1995; Matson, 1995; Beier, 1999). An interesting alternative consists of deposition of small patches of activated polyacrylamide to which presynthesized oligonucleotides are attached by microinjection (Khrapko, 1991; Yershov, 1996; Guschin, 1997).

Packing density of probes attached to solid surfaces will influence greatly the performance of hybridization matrices. Poor coupling efficiency, which is often encountered on glass matrices, can result in low probe density and low signal:noise ratios. On the other hand, overly dense packing of oligonucleotides on to a solid surface causes spatial hindrance. This problem may be even more formidable with longer biomolecules such as cDNAs. Hybridization yields can be increased by up to two orders of magnitude by introducing spacers between the surface and the oligonucleotides (Southern, 1999). The longer the spacer, the better the hybridization but, interestingly, there is an optimal spacer length beyond which hybridization yield declines (Shchepinov, 1997; Duggan, 1999). For example, a 40-carbon atom spacer provides a reported 150-fold hybridization enhancement (Shchepinov, 1997). The density of oligonucleotides is approximately 0.1 pmol/mm² on a glass surface, two orders of magnitude less than on aminated polypropylene. Thus a potential advantage of glass over plastic matrices at present is an optimal oligonucleotide density associated with lower spatial hindrance (Southern, 1999). Improved surface chemistries may one day allow production of arrays on plastic sheets or films, which may dramatically reduce production costs. To this end, film-based chip arrays have recently been described (Erali, 2009).

The terminal composition (5' end) of the oligonucleotides influences their duplex yield as measured by relative intensity. As expected, G:C rich 5' extremities lead to a better yield than their homologues (same composition but different sequences) (Maskos, 1993b). Approaches to modify the 5' end of oligonucleotides (e.g., covalent addition of a degenerated linker) can therefore be considered to minimize this contribution. Alternatively, knowledge that mismatches at the ends are less destabilizing and therefore more difficult to discriminate by hybridization (Southern, 1999) has led to clever improvements for detection of hybridization events. As polymerases and ligases are most sensitive to terminal (as opposed to internal) mismatches, enzymatic methods have been developed with improved detection stringency (solid-phase minisequencing [Pastinen, 1997, 1998; Syvanen, 1999], genetic-bit analysis [Nikiforov, 1994], or ligation-assays [Landegren, 1988; Nickerson, 1990]).

Commercially available arrays have been previously reviewed by Marshall (1998). Fabrication of microarrays falls into two broad categories: those made by direct probe delivery on to the solid surface and those made by in situ synthesis. A third method, developed by Nanogen (San Diego), consists of prefabricated oligonucleotides captured on to electroactive spots on silicon wafers (Edman, 1997; Sosnowski, 1997; Cheng, 1998; Heller, 1998; Jang, 2009). Modification of the electric field through independent, spatially addressable electrodes can speed up hybridization and, when the polarity is reversed, provide stringent washing (Edman, 1997). Recently, an approach using single-stranded large circular-sense molecules were utilized as probes for DNA microarrays and showed stronger binding signals than those of PCR-amplified cDNA probes (Doh, 2010).

Figure 67-1 Photolithographic synthesis. Ultraviolet light is transmitted through a photolithographic mask, allowing localized photodeprotection of specific chemical building blocks. (Courtesy Affymetrix.)

Delivery Technologies

Deposition of presynthesized biomolecules was initiated by Pat Brown and colleagues (Schena, 1995; Shalon, 1996). Biochemical substances (e.g., proteins, peptides, oligonucleotides, cDNAs) are prepared, purified, and stored in microtiter plates. Small quantities of molecules are mechanically delivered on precisely defined locations on a solid surface, using different precision robotic systems. This method is very flexible in terms of biochemical composition, microarray topology (e.g., size and density of the spots, replicate spots for each molecule), and ease of prototyping, allowing for design alteration for different applications. Mechanical methods allow the synthesis of moderate- to high-density microarrays (up to about 16,000 probes/cm² [Graves, 1999]). It is the method of choice when large numbers of microarrays are needed with the same composition, as well as for long sequences using PCR products. Several companies are now manufacturing and selling premanufactured arrays (e.g., MicroMax, NEN Life Science, Boston) or arrayers based on deposition (Cheung, 1999) as an alternative to building an arrayer (Brown, 2000).

Delivery procedures consist of different microprinting systems. Most arrayers use fountain pen-like microdispensing tips (e.g., Cartesian Technologies, Irvine, Calif.), but some original systems such as the pin-and-ring technique have been developed (Genetic Microsystems, Woburn, Mass.). In general, because of surface tension, static, and other effects, the reproducibility of printed arrays is lower than in situ synthesis and must be corrected by separate experiments (repeats), replicate spots (on the same slide), multicolor fluorescence detection, and/or other specific detection algorithms (Chen, 1997; Jang, 2009). Because of its flexibility and availability, printed array technology will probably have the largest impact on research and clinical laboratories over the next few years.

In Situ Synthesis

In situ synthesis allows higher yields, lower chip-to-chip variation, and higher probe densities. These methods also permit the manufacture of true “random access” arrays, meaning that each oligonucleotide in any position can have any chosen sequence (Southern, 1999). Combinatorial strategies refer to methods developed to make microarrays containing all sequences of a given length (also referred to as *generic arrays*). Combinatorial arrays have been promoted mostly to study large-scale hybridization behavior (Southern, 1994) or for solid-state nucleic acid sequencing (Macevitz, 1991; Strezoska, 1991; Drmanac, 1993a, 1993b, 1999, 1998; Lipshutz, 1993).

Manufacturing techniques include photolithographic masks to control chemical activation by photodeprotection steps (Fodor, 1991), ink-jet deposition (Stimpson, 1998), as well as physical barriers to sequential flooding of precursors (Maskos, 1993c). Affymetrix has coupled photochemical deprotection to solid-phase DNA synthesis by adapting techniques from the semiconductor industry (Pease, 1994; Lockhart, 1996; Lipshutz, 1999). Synthetic linkers modified with photochemically removable protecting groups are attached to silicon wafers. By shining ultraviolet light through a photolithographic mask, localized photodeprotection occurs and permits specific chemical building blocks (hydroxyl-protected deoxynucleosides) to react with the deprotected groups (Fodor, 1991) (Fig. 67-1). Cycles alternating photodeprotection and incubation with different chemical building blocks allow light-directed synthesis of polydeoxynucleotides (Fig. 67-2). The synthesized oligonucleotides have a maximum practical length because of the limited efficiency of the photodeprotection (80%–95% at each cycle) (Forman, 1999). Therefore, the proportion of

Figure 67-2 Diagram of GeneChip array manufacture using a unique combination of photolithography and combinatorial chemistry. (Courtesy Affymetrix.)

20-mers displaying the predefined sequence is between 1% and 36% ($0.8E20$ – $0.95E20$) (Fodor, 1991).

Mechanical masks or barriers permit confinement of surface areas before flooding with defined precursors. Physical masks of different shapes (circular, diamond) allow in situ synthesis of a given precursor in known locations. Sequential displacement of masks followed by the flooding of another precursor allows synthesis of large combinatorial deoxynucleotide arrays (Southern, 1992, 1996b; Maskos, 1993c). To date, Affymetrix is able to synthesize up to 400,000 different polydeoxynucleotides in a 1.6 cm² area (Fodor, 1991). Critical to this step is the precise alignment of the mask with the wafer before each synthesis step. To ensure that this critical step is accurately completed, chrome marks on the wafer and on the mask are perfectly aligned. Although the process is highly efficient, some activated molecules fail to attach the new nucleotide. To prevent these outliers from becoming probes with missing nucleotides, a capping step is used to truncate them. In addition, the side chains of the nucleotides are protected to prevent the formation of branched oligonucleotides (www.affymetrix.com). Despite high cost, this is the method of choice for large-scale differential gene expression studies because of sensitivity, reproducibility, and redundancy of information.

Ink-jet technologies owe their development to the printer industry and are in continuous development by several companies such as Incyte Pharmaceuticals (Palo Alto, Calif.), Protogene (Palo Alto, Calif.), and Rosetta Inpharmatics (Kirkland, Wash.) (Blanchard, 1996). This technology is also commercially available (Ink-Jet, Packard Instruments, Meriden, Conn.; Piezoelectric pump, GeSiM, Grosserkmannsdorf, Germany). This technology gave rise to the ability to place an oligonucleotide or other entity (i.e., small molecule or tag) in two-dimensional space. Such an approach offers versatility in the biomolecules being delivered and eliminates the need for physical contact with the surface of the array; this last property may be of relevance for the development of arrays coated with thin layers of metals and using different detection methods (Heyse, 1998; Schmid, 1998). Light scattering from microparticles tagging target sequences can be detected as an evanescent wave immediately above the surface of the glass. This method allows real-time affinity measurement with a very low background (Stimpson, 1996).

OLIGONUCLEOTIDE MICROARRAYS

Thermodynamics, kinetics of hybridization, and quantitative aspects of oligonucleotide hybridization have been extensively studied (reviewed by Wetmur, 1991; Hoheisel, 1996; Pozhitkov, 2007). Oligonucleotide arrays have a lower sensitivity than cDNA arrays for detection of rare messages or hybridization targets, and poor predictability of hybridization characteristics because hybridization potential, and therefore the expected signal intensity, do not correlate well with the G:C content or the melting temperature (Lockhart, 1996; Graves, 1999). On the other hand, oligonucleotide arrays are easier to construct using deposition of synthesized product

or in situ synthesis described above. In addition, hybridization conditions can be more homogenous than on a cDNA array, provided that the array is designed with oligonucleotides of equivalent sizes.

Oligonucleotide arrays have applications in gene expression profiling as well as in DNA sequencing. For sequencing applications, they can be divided into two fields: generic arrays (representing a random oligonucleotide matrix) or dedicated arrays (for molecular variants of a predetermined target). Generic arrays have been proposed as an inexpensive alternative to sequencing. Using all possible combinations of an *n*-mer allows “walking” at every position along a nucleotide sequence. This type of array is the only one capable of detecting sequences that are lacking in large electronic libraries. In contrast, dedicated arrays are used for repetitive sequencing (resequencing) of the same target for detection of nucleotide polymorphisms or functional mutations. This implies knowledge of the targets and their most frequent variants, in order to incorporate predetermined sets of oligonucleotides on the diagnostic array. This approach has been used for detection of genetic polymorphisms associated with human immunodeficiency virus (HIV) drug resistance as well as other polymorphisms. Oligonucleotide arrays can also be used to define single nucleotide polymorphisms (Guo, 1994), even by comparing two samples with multicolor fluorescence (Chee, 1996). Further examples and applications of polymorphism to disease treatment and management are described later and in Chapter 72.

The search for oligomers of higher affinity has opened the way for chemical modifications of the oligonucleotide probe and template in order to improve the kinetics and thermodynamics of binding. Peptide nucleic acid probes (PNAs) allow hybridization to be performed at a higher stringency, because of the high-stability of PNA–DNA duplexes (Corey, 1997) and are able to recognize exclusively single strands of DNA and ribonucleic acid (RNA) in antiparallel fashion (Moggio, 2007). Methylated RNA probes (Corey, 1998) display relatively similar affinities. However, PNAs display more rapid hybridization conditions than their nucleic acid counterparts, primarily because of their neutral backbone structure (Freeman, 1999). Overall, it can be said that, although the reduction of the hybridization time from hours to minutes would be a clear asset, the problem of unpredictability of the melting points of these high-affinity oligomers must be overcome before implementation on microarrays (Weiler, 1997). In addition to probes, targets can be chemically modified to locally enhance signals. Pyrimidine-rich target regions can generate higher hybridization signal by incorporating 5-methyluridine during in vitro transcription (Woski, 1998).

cDNA MICROARRAYS

Microarrays of cDNA sequences allow hybridization-based monitoring of the expression of the cognate genes. Therefore this strategy implies access to clones or the possibility of generating PCR products. To date, the best strategies use two-color fluorescence detection to discriminate between a sample and its control and check for differential level of expression. This method has been pioneered and validated by Pat Brown and colleagues at Stanford University (Schena, 1995, 1996; Shalon, 1996). Advantages of this approach are calculating a ratio on every probe, to control for the quality of the probe, the specific hybridization properties of each target/probe pair, and the labeling efficacy. Synteni (a subsidiary of Incyte, Palo Alto, Calif.) has developed its Gene Expression Micro-arrays for this purpose (Schena, 1998). NEN Life Science is selling glass slides prespotted with 2400 known human genes (MicroMax) and continuous miniaturization is allowing for greater gene representation in a smaller area.

Although they appear to be inherently less reproducible, cDNA microarrays currently offer the greatest versatility in terms of probe deposition and accessibility of the technology. Several companies now offer equipment for array manufacture and reading of hybridized matrices. It is likely that cDNA arrays and high-density oligonucleotide arrays will play complementary roles in research laboratories over the next few years; high-density arrays will be used primarily for the discovery of diagnostically relevant loci and dedicated arrays will be used increasingly for the medium- to low-density analysis of diagnostically relevant loci discovered by high-density array analysis.

SEQUENCING ARRAYS

Nucleic acid sequence data are fundamental to modern molecular biology. Conventional methods (Maxam, 1977; Sanger, 1977) are time-consuming, labor intensive, and costly. Alternative sequencing methods using solid-phase hybridization were proposed on a theoretical basis (Bains, 1988;

Khrapko, 1989) within 15 years of the discovery of these methods (Southern, 1975). The theoretical articles were followed shortly by data confirming the principles of array-based sequencing for short artificial templates (Southern, 1992; Pease, 1994; Parinov, 1996). A well-written review of microarray sequencing methods was published in 1999 (Hacia, 1999). The reader might note, however, that much of the work published and cited in this area is provided by researchers with some financial interest in one or more of the proprietary devices evaluated in these publications. Rather than endorsing a particular device or method, this chapter acquaints the reader with basic principles involved in the assay.

Any nucleic acid sequence can in theory be broken down into subsets of length *n*. All the possible oligonucleotides of length *n* (*n*-mers) can then be placed at fixed locations on a solid surface. Nucleic acid to be sequenced (the template) is amplified if necessary, labeled with a direct (fluorescent, luminescent, radioactive) or indirect (affinity) label, and allowed to hybridize to the bound collection of *n*-mers. Detection of label allows the sequencer to verify a match with an *n*-mer at a particular locus on the solid surface. The intensity of signal at that locus should be directly proportional to the number of domains in the template corresponding to the *n*-mer at that locus. Methods for all these steps are outlined in preceding sections of this chapter.

For sequencing applications, the *n*-mers that match the template are then assembled into a definite order by analysis of *n*-mers with overlapping sequence, similar in principle to the arrangement of contigs by large-scale sequencing programs. Consider a nonanucleotide template that, under stringent conditions, is bound only to the loci containing the following four tetramers on an array with all 256 possible tetramers:

Tetramer	Intensity
5' ACTG	2
5' CTGA	2
5' TGAC	1
5' GACT	1

It is trivial to reason from the areas of overlap that the nonanucleotide template was 5' ACTGACTGA. Computational analysis of this kind is straightforward. Because the computation, the scanning of the array to detect label, the labeling itself, and to some extent even the extraction and amplification of the DNA can be automated, it is lovely to envision a “black box” that accomplishes all this in an afternoon. Consider, however, a nonanucleotide that binds to loci containing the following tetramers:

Tetramer	Intensity
5' TCTA	1
5' CTAC	1
5' TACT	1
5' ACTT	1
5' CTTC	1
5' TTCT	1

This could represent 5' TCTACTTCT or 5' TTCTACTTC; there is no computational way to resolve it. Where *n* is less than half the length of the template, repeats of the same length as *n*/2 can render the data ambiguous. Computation becomes increasingly difficult as template length becomes an increasingly higher multiple of *n*; hence it is desirable to have as long an *n* as possible for sequencing unknown domains. The practical length of *n* remains limited by technology, however, because 4^{*n*} (the number of loci required for universal representation) exceeds 1 million for *n* = 10. This approaches the current limits of the number of distinct oligonucleotides that can be differentiated on a photolithographic chip (Lipshutz, 1999).

HYBRIDIZATION, DETECTION, AND IMAGE ANALYSIS

A critical component of microarray assays is the quality and labeling of the probe. Because sample carries the label, sample-to-sample variation in probe preparation and labeling can be anticipated. When microarrays are used for gene expression profiling, this step is even more critical because of the difficulties in obtaining high-quality messenger RNA (mRNA). Insufficient, degraded, or poor-quality RNA can deliver erroneous results that lead, after data mining, to improper conclusions (Russo, 2003). Although there are many protocols available for high yield of RNA, a final yield of at least a few micrograms of mRNA per experiment has been desirable in most applications, although protocols have used smaller amounts of RNA with subsequent amplification using cDNA

Figure 67-4 Standard eukaryotic gene expression assay. Labeled complementary DNA or RNA targets derived from the messenger RNA (mRNA) of an experimental sample are hybridized to nucleic acid probes attached to the solid support. By monitoring the amount of label associated with each DNA location, it is possible to infer the abundance of each mRNA species represented. (Courtesy Affymetrix.)

intermediates that incorporate an RNA promoter and allow amplification with an RNA polymerase. Initial approaches (Auffray, 1980) converted mRNA to a fluorescent cDNA probe with direct incorporation of fluorescent nucleotides. Currently most approaches use total RNA and there are numerous variations of incorporation of label into cDNA or RNA probes, including indirect affinity labels such as biotin with detection using antibody/avidin/streptavidin tagged with fluors or light-scattering gold particles (Figs. 67-3 and 67-4). Each step of probe preparation from extraction through labeling must be carefully controlled to ensure reproducible results.

The usual consideration of time, temperature, stringency, and probe concentration determine the conditions of the microarray hybridization. Arrays often include negative control probes to allow optimal stringency to be determined. Because of the extremely high complexity of the probe used in gene expression profiling, hybridization times are generally extended to allow low-abundance messages to hybridize. Washes are designed to remove nonspecifically bound probe and reduce background.

Shining a laser light at GeneChip array causes tagged DNA fragments that hybridized to glow

Figure 67-5 Cartoon depicting scanning of tagged and untagged probes on an Affymetrix GeneChip microarray. (Courtesy Affymetrix.)

All steps need to be optimized and standardized. After a successful hybridization, labeled nucleic acid is bound to complementary sequences that are tethered to the array (Fig. 67-5). Some form of image analysis is used to capture signal. In most approaches, the entire slide is scanned (fluorescence, autoradiographic or light scattering) and an algorithm is used to link features with intensities and gene lists. Software associated with the scanner can generate a “mask” to align image with grid used to construct the array. Data acquisition generates large data sets (one image uses typically 10–50 megabytes) that have to be stored under standard formats (e.g., BMP, GIF, JPG). Image processing software will become increasingly automated to ensure proper grid adjustment, detect artifacts, and identify features to extract meaningful information.

Microarray technology has grown over the past decade to incorporate miniaturization of fabrication platforms, enhancement of high throughput automation (see also Chapter 77), and cost reduction. Many platforms exist to support individual user needs whether they be interrogation of an entire genome, exonic mRNA expression, or limited to a subset of genes involved in specific pathways of interest. Affymetrix (www.affymetrix.com) pioneered mass application of array technology to the scientific community and continues as a leader in the field. Illumina (www.illumina.com) has facilitated RNA analysis of specific genes or regions of interest, with the development of its cDNA-mediated Annealing, Selection, extension, and Ligation (DASL) assay (Fan, 2004). This assay reportedly allows for RNA profiling of up to 1536 targets using partially degraded RNA as found in formalin-fixed, paraffin-embedded (FFPE) samples. Array technology has also been adapted to interrogate single nucleotide polymorphisms, copy number variations, and structural variants, which differ among individuals and populations (Coulombe-Huntington, 2009; Stankiewicz and Lupski, 2010). Such variations influence how individuals differ in their risk of disease and their response to therapeutic treatments (see Chapter 72). Other improvements across the industry include the ability to detect low abundance transcripts, reduced requirements for the quantity of sample to a few hundred nanograms or less of total RNA (versus micrograms), automation for low per-sample pricing, and improved consistency in methodology and quality control (Yauk, 2005). As a result of the variations in array technologies and differences in sample preparation and signal processing, the Minimal Information About a Microarray Experiment (MIAME) guidelines have been implemented to ensure that all relevant experimental information is presented in a consistent and complete manner that will ensure published data and publically available microarray data sets can be interpreted accurately (Yauk, 2004).

BIOINFORMATICS

The most challenging aspect of microarrays starts here, when large data sets have been assembled and purged of artifacts, background noise, and await analysis (Draghici, 2003; Parmigiana, 2003; Gopalappa, 2009; Zhang, 2009). The approach depends on the nature of the question and design of

the experiment. An initial exploration of the data set is used to evaluate the quality, usually including an assessment of background and mean intensity of the features on the array. To facilitate statistical comparisons between arrays, intensities are commonly log transformed and arrays are “normalized” to each other.

A popular approach to normalizing gene expression is predicated on the assumption that the conditions being compared (e.g., normal versus tumor or infected versus noninfected) would affect the gene expression of relatively few genes, leaving most unaffected. In the absence of systematic bias, the median intensity of all features on the array should be unchanged. Thus a common normalization method is to divide each intensity measurement on the array by the median intensity of the array (Kano, 2003). These assumptions are reasonable when the array contains a large number of genes that represent a wide range of biological function.

One caveat of the total intensity normalization methods arises from its implicit assumption that systematic variation is constant across the entire range of expression intensities of the array. However, as data from technical replicate arrays show, systematic variation is often intensity dependent, or nonlinear. In other words, systematic variation observed at low expression intensities differs from systematic variation observed at medium and high intensities (Simon, 2005). Thus linear adjustments, such as dividing each measurement on an array with the median intensity of the array, would not be appropriate for some genes. For perhaps 80% of the arrays, systematic variation is close enough to linear so that total intensity normalization methods are sufficient. However, for the remaining 20% of the arrays, nonlinear normalization methods are required (Genomics and Bioinformatics Group, 2005).

Quantile normalization is a nonlinear normalization method that is often performed on microarrays. In addition to assuming that most genes are unchanged in their expression across experimental conditions, quantile normalization also makes the strong assumption that the distribution of gene expression intensities must also be invariant across the arrays (Irizarry, 2003). Thus, not only should the median intensity be the same for each array, but the intensity at every quantile of the array should also be the same. Given this assumption, quantile normalization sorts all intensity values on the array by increasing intensity values and adjusts the intensities so that the smallest intensity value on each array is identical, the second smallest values are identical, and so forth. The gene with the smallest intensity value on one array may be different from the gene with the smallest intensity value on another array.

Intensity-dependent systematic variation has also been shown for two-color technology arrays. Intensity-dependent dye bias was first identified by Terry Speed's laboratory, where it was observed that low-abundance genes appear to be upregulated in the Cy5 channel and moderately expressed genes appear to be upregulated in the Cy3 channel (Yang, 2002). This systematic artifact can be effectively corrected by performing a locally weighted linear regression (lowess) (Fig. 67-6). The validity of using housekeeping genes for normalization has been called into question in the past few years. In this method, it is assumed that the expression levels of housekeeping genes are constant across experimental conditions. Thus intensity measurements of an array can be normalized to the mean intensities of these genes. However, the expression levels of some housekeeping genes have been shown to vary considerably across some experimental conditions (Thellin, 1999).

Once data have been normalized, quality control is performed at both the sample level and gene level. Sample-level quality control assesses sample data globally to identify outliers or, in cases where replicate reproducibility is generally observed, one or a few samples that may represent outliers. Potential outliers may be identified as those that do not cluster with replicate samples or those that do not correlate highly with replicate samples. Hierarchical clustering, principal component analysis, class prediction algorithms, and similarity metrics are often used to perform sample-level quality control (Grewal, 2003).

Gene-level quality control filters out genes for which the large proportion of measurements fall within the noise range, to create a restricted set of genes for further analysis. Genes that are removed correspond to those that are not expressed in the tissues of concern or whose expression levels are so low that the technology is not sufficiently sensitive to detect differences in expression. Removal of such genes generally reduces noise, the likelihood of false-positive reactions in subsequent differential expression filters, and the severity of multiple testing corrections required in downstream statistical analyses.

Once normalization and quality control of imported data have been completed, one can perform analyses to isolate the genes of interest. One basic objective in a microarray experiment is to identify genes that may be

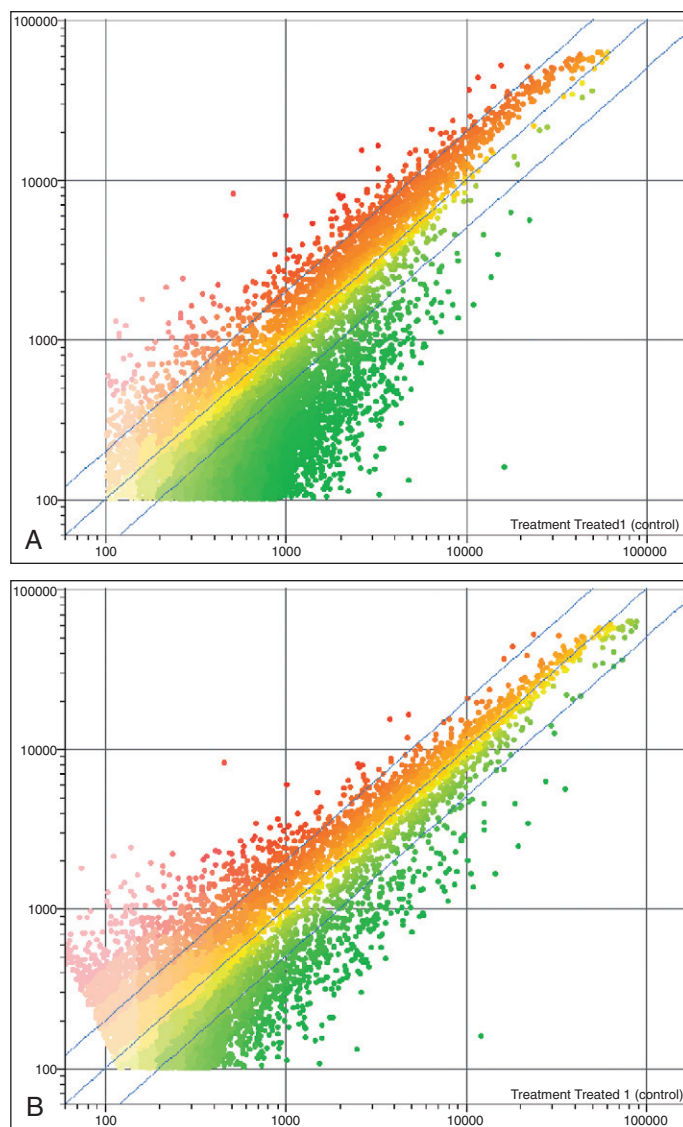

Figure 67-6 Lowess intensity-dependent normalization is used for two-color data. It is a type of within-slide normalization scheme that adjusts for intensity-dependent variation due to dye properties. Dye bias is caused by inconsistencies in the relative fluorescence intensity between Cy5 and Cy3. These inconsistencies often result in nonlinear relationship between the two dyes and a curve occurs in a scatter plot. **A**, Data before normalization. **B**, By applying lowess normalization, a locally weighted regression is fitted to the data to adjust the control value for each measurement. As a result, the plot of signal versus control value will be linear. (Courtesy Agilent Technologies.)

differentially expressed among the different experimental conditions. Researchers rely on many different variants of common statistical tests to identify differentially expressed genes. One caveat to using statistical tests to identify differentially expressed genes is that the number of false-positive reactions from the statistical analysis is proportional to the number of tests that are performed. Because hundreds or thousands of genes are often tested at once, the number of false-positive reactions from the analysis can potentially dominate the list of candidate genes that are thought to be differentially expressed. Thus it is important to limit the number of false-positive reactions in a statistical analysis by performing multiple testing correction. Two categories of multiple testing correction are those that determine the family-wise error rate (FWER) and those that determine the false discovery rate (FDR). FWER tests control the overall chance that at most one gene is incorrectly identified as being differentially expressed after the statistical analysis and after performing the multiple testing correction (Grewal, 2003). Examples of FWER tests are the Bonferroni, Holms–Bonferroni step-down, and Westfall and Young Permutation. FDR tests confine the probability of false-positive reactions to be proportional to the number of genes that pass the statistical test instead of the total number of genes tested by the statistical analysis. An example of a FDR test is the Benjamini and Hochberg false discovery rate (Benjamini,

Figure 67-7 Hierarchical clustering dendrogram of duodenal genes from different celiac disease (orange bar) and control (blue) biopsy samples. Clustering of 109 genes across 22 samples clusters the seven control samples (blue bar) separately from the 15 celiac disease patients (orange bar). Each column represents a celiac disease or a control sample and each row represents an individual gene. For each gene, a green signal represents underexpression, black signals denote similarly expressed genes, a red signal represents overexpressed genes, and gray signals denote missing data. (Adapted with permission of the BMJ Publishing Group from Diosdado B, Wapenaar MC, Franke L, et al. A microarray screen for novel candidate genes in coeliac disease pathogenesis. *Gut* 2004;53:944.)

1995). There are several excellent statistical packages available online (e.g., BRB Tools, SAM, Focus, D Chip, R Bioconductor Library, PAM).

Clustering analysis (Fig. 67-7) is suitable for grouping genes that behave similarly across multiple conditions of an experiment. Clustering has many applications in expression data analysis. It allows one to infer the previously unknown function of a gene from the functions of the genes that it clusters with. This is based on the assumption that genes that share similar functions share similar expression behavior across experimental conditions. Clustering may also be useful in finding genes that may be co-regulated. This is based on the assumption that genes that are co-regulated share similar expression profiles. Thus it may be useful to analyze the promoter regions of genes that cluster together to find common regulatory elements (Grewal, 2003; Gollub and Sherlock, 2006).

The generated genes of interest can then be integrated with known biology. The ability to cross-reference gene lists from differential expression analysis and/or clustering analysis against gene ontology or other gene function lists to ascertain significance of overlap is available in some programs (e.g., Agilent/GeneSpring). Other popular programs include Bioconductor—an open source and open development software project for the analysis and comprehension of genomic data, based on the R programming language (Zhang, 2009); the oligonucleotide centric DChip (www.Dchip.org); TIGRsuite (www.tigr.org), and BeadStudio (array platform- and manufacturer-specific; www.illumina.com). (For review, see Gollub and Sherlock, 2006; Platts, 2006). In addition, genes can be referenced to known biological pathways, and/or public databases (GenBank, LocusLink, UniGene, serial analysis of gene expression [SAGE]).

Thus, because of the intensive need for pattern recognition, multi-dimensional data interpretation, and cross-platform comparison, microarray technology will enjoy a close relationship with bioinformatics, and coevolution of both hardware and software appears to be inevitable (see Chapter 77).

INTELLECTUAL PROPERTY ISSUES

Microarray technology is a rapidly moving field with fierce competition. It is therefore important to emphasize that numerous patents have been filed, some of which are directly relevant to clinical diagnosis. Therefore intellectual property remains an important concern in this ever evolving field (Rouse and Hardiman, 2003). For instance, Affymetrix (www.affymetrix.com, Santa Clara, Calif.) possesses broad patent rights on high-density oligonucleotide arrays (Chee, 1998; Holmes, 1998), regardless of the means by which they are made. Assuming that a laboratory decides to develop in-house moderate-density arrays for tumor testing and to charge for such a service, this array might infringe Affymetrix's patents if it exceeds 400 features/cm², regardless of the synthesis method (Fodor, 1998). Array technologies using micromatrices of polyacrylamide gel pads (three-dimensional gel elements) represent a new approach that might not infringe Affymetrix claims (Khrapko, 1991; Yershov, 1996; Guschin, 1997). Furthermore, the intellectual property related to the methodology and application of DNA array technology to identify medicinal versus toxic components in natural remedies, species-specific fingerprinting, and identification of unknown DNA has generated additional patent applications (Shaw, 2009). It is hoped that, as occurred with nucleic acid amplification technologies, competition between manufacturers will bring down costs of high- and medium-density arrays and allow for the democratization of this powerful technology.

CLINICAL APPLICATIONS OF ARRAY TECHNOLOGY

Numerous applications of microarray technology have been proposed in the past few years, ranging from molecular staging of tumors to the identification and characterization of microbial agents. This has led many to speculate that array technology represents the next wave of technologic advances to have a practical impact on the diagnosis of human disease, second only to PCR as a core technology in the clinical molecular diagnostics laboratory. This section focuses on current and future applications of array technology.

ARRAY TECHNOLOGY IN THE CLINICAL LABORATORY

Although not currently widespread, clinical laboratory utilization of array technology appears to be on the horizon. Roth and colleagues (Roth, 2004) have employed array analysis to detect common respiratory pathogens and compared this with conventional culture from middle ear fluid samples. The sensitivities of the array assay compared to culture for *Haemophilus influenzae*, *Moraxella catarrhalis*, *Streptococcus pyogenes*, and *Streptococcus pneumoniae* were 96% (93% for culture), 73% (93% for culture), 93% (80% for culture), and 100% (78% for culture), respectively. Furthermore, tissue microarrays have been used as a tool for internal quality control to improve the interpretation of immunohistochemical staining (Packeisen, 2002; Gulmann, 2004). The U.S. Food and Drug Administration has granted 501(k) clearance to Roche Molecular Systems to market its AmpliChip CP450 Genotyping test to determine cytochrome P450 2D6 and 2C19 genotypes using the Affymetrix instrumentation system (Malone, 2005). As cytochrome genes code for liver enzymes important in drug metabolism, clinician will use the results to optimize drug dosing and minimize side effects on the basis of individual genotype. This is the first time a microarray chip has been given marketing clearance as a diagnostic device for use in the clinical laboratory, heralding the potentially new era of personalized medicine. Small-scale, automated, microfluidic array instruments that have the technical discrimination and dynamic range required to detect RNA species at a frequency of 1:100,000 with a short turnaround time and low coefficient of variation (0.09–0.11) have also been described (Baum, 2003). However, methodologic consistency, quality control, and disease-specific application will have to be addressed prior to implementation as a routine test to the clinical laboratory.

ARRAY TECHNOLOGY IN CLINICAL DISEASE

Microarray technology has provided the ability to screen genes that are differentially regulated in experimental and clinical disease and allow further correlation of select genes with their function. For example, Ji and colleagues (Ji, 2003) used microarray technology to screen for genes that are upregulated in the early stage of acute pancreatitis using two different experimental models of the disease. Many genes were upregulated in both experimental systems, suggesting their importance in the human condition. However, one gene in particular, EGR1, further analyzed through classical approaches (gene knockout), was shown to be a key regulator that may be important in the development of early acute pancreatitis. Others (Iacobuzio-Donahue, 2003) have performed a comprehensive evaluation and comparison of gene expression profiles of 39 samples of pancreatic cancer and identified between six and 40 genes that were highly expressed when examined by multiple methods (oligonucleotide arrays, cDNA arrays, or SAGE). These may eventually be translated into clinically useful targets for therapy or diagnosis.

Microarray analysis of cells and tissues as a means to identify key therapeutic candidates continues to evolve. Malignancies or their tissue components that have been analyzed in the quest for identifying key targets, diagnostic or prognostic indicators (Ma, 2009), or novel pathways include melanoma (Nambiar, 2004), leukemias (Moos, 2002; Jaakson, 2003), lymphomas (Hedvat, 2002; Kobayashi, 2003; Azambuja, 2009), myelodysplastic syndromes (Pellagatti, 2004), and carcinomas of prostate (Pettus, 2004), bladder (Dyrskjot, 2003), kidney (Moch, 1999), colon/rectum (Frederiksen, 2003), breast (Jeffrey, 2002; Wilson, 2004), ovary (Rosen, 2004; Yang, 2009), and endometrium (Saidi, 2004; DeRycke, 2009).

Other clinical applications that utilize the gene screening capability of microarray technology include the study of the effect of ionizing radiation (Amundson, 1999), detection of hepatitis D virus (Sun, 2004), identification of central nervous system pathogens (Hanson, 2004), karyotyping of cell-free DNA in amniotic fluid (Larrabee, 2004), viral diagnosis (Striebel, 2003), providing molecular markers for allergic (Jahn-Schmid, 2003), urologic (Cheung, 2009), cardiac (Bostjancic, 2009), and inflammatory disorders (Bennett, 2003), Alzheimer's disease (Pasinetti, 2001), multiple sclerosis (Whitney, 1999), dystonia (Walter, 2010), diabetes (Sreekumar, 2002; Mootha, 2003), transplant rejection (Flechner, 2004), and pulmonary hypertension (Geraci, 2001). The ability to predict adverse drug reactions (Guzey, 2002), response to therapy (Sotiriou, 2002), drug sensitivity (Stein, 2004), and toxicity profiles (Waring, 2001), among others (Cox, 2001; Day, 2009; Stankiewicz, 2010), have also been reported.

LIMITATIONS

Despite the excitement and increase in the potential clinical application of microarray technology, care must be taken in its interpretation. Clinical application will require procedures for quality control and quality assurance. The challenge to ensuring reproducibility of the high-density data presented in microarrays is unprecedented in the clinical laboratory. Each

of the large number of steps from sample extraction, labeling, hybridization, image analysis, and data analysis, contributes to difficulties in data reproducibility, and can differ between commercially available systems (Kothapalli, 2002; Yauk, 2004; Pozhitkov, 2007). Furthermore, factors such as varying the method used for nucleic acid isolation (Feezor, 2004) or detection, tissue type (solid, glandular, or blood derived), type of specimen (FFPE versus frozen tissue) (Penland, 2007), and time to processing can affect results of gene expression profiling.

Approaches to further validate and confirm array-based results include verification of each clone sequence before printing the microarray; performing experiments in duplicate or triplicate where possible; and verification of candidate genes by classic methods (e.g., PCR, northern blotting, RNase protection assay). Some investigators (Rajeevan, 2001) have shown that the majority of array results were qualitatively accurate in cross-validation experiments using real-time RT-PCR. However, for genes showing less than a fourfold difference on the arrays, consistent cross-validation with real-time RT-PCR was not achieved. It is also very important to determine whether the difference in mRNA expression translates to a difference in the expression levels of the corresponding protein products. Currently, how frequently a difference in mRNA level translates to a difference in protein expression level is not clear.

Caution must also be exercised in interpreting differentially regulated genes during tumor progression (staging microarray). Any nucleic acid source derived from biopsy tissue is made up of many different cell populations and may represent homogeneous tissue only after the tumor mass has reached a large enough size (i.e., late stage). While certain methods are available to isolate specific cells of interest in smaller tumors (e.g., laser capture microdissection), they are technically demanding, time-consuming, and not universally available.

Like all sequencing strategies, microarrays have limited sensitivity for minority alleles, although newer platforms and analysis approaches claim to improve detection in this regard (Coulombe-Huntington, 2009; Stankiewicz, 2010). An example of sequence-based identification of drug resistance in HIV will be particularly instructive. Microarray sequencing of clinical isolates can correctly predict some instances of drug resistance on the basis of specific mutations (Race, 1998) and is evolving toward standard practice (Perez-Olmeda, 1999). Even making the optimistic assumption that sequencing can detect a resistance allele when represented in 1% of the viral population or more, however, there is reason to doubt the predictive value of a test that is negative for resistance. Few virologists would argue that 0.5% prevalence of drug resistance is unimportant in a virus that generates more than a billion copies a day. Therefore, it should be understood that the power of this technology currently lies in its ability to screen for the regulation of genes in defined parameters (Russo, 2003).

Further advances in diagnosis, classification, and prognosis await discovery by microarray-based methods in the near future. As emphasized earlier, it is not merely improvements in apparatus that make this possible, but more sophisticated analytic strategies, detection sensitivity, throughput, automation, miniaturization, ease of use, and cost that evolve to keep up with the more complex data generated by these devices (Bassett, 1999; Zhang, 2009).

KEY POINTS

- Identification of chromosomal abnormalities often correlates to disease and phenotypic abnormalities that will aid in clinical diagnosis and treatment.
- Standard morphology and a specific banding pattern have been established for all human chromosomes. A variety of different staining technologies are used to uniquely identify chromosomes and determine if anomalies exist.
- The two basic categories of cytogenetic abnormality are numerical and structural.
- Many syndromes have been specifically linked to particular chromosomal anomalies; for example, trisomy 21 in Down syndrome, 45,X in Turner syndrome, and deletion of 22q11.2 in velocardiofacial syndrome.
- Cytogenetic abnormalities may be either de novo or inherited. Detection may occur at any stage of a person's life from prenatal to adulthood.
- Identification of a cytogenetically abnormal clone in a cancer can provide information on diagnosis, prognosis, treatment, and disease progression.
- Fluorescence in situ hybridization (FISH), a unique diagnostic tool combining technologies from both cytogenetics and molecular genetics, can provide important information on the status of genes.
- Microdeletion syndromes may require a combination of karyotype analysis, FISH, and clinical evaluation for diagnosis.
- Cytogenetic analysis can be used in nearly every medical specialty and is an important element in clinical laboratory medicine.

Genetics is broadly defined as the scientific study of heredity but, in clinical laboratory medicine, interest is focused on two subspecialties of this field: (1) human genetics, the study of heredity in man; and (2) medical genetics, the study of human genetic variation of medical significance. Medical genetics can be further subdivided into five groups, two primarily clinical fields (clinical genetics and genetic counseling) and three laboratory sciences (cytogenetics, molecular genetics, and biochemical genetics).

Groundbreaking discoveries in the field of medicine can be attributed to genetics. Research, including the information obtained from the Human Genome Project (as described in Chapter 77) continues to identify new genes and mutations directly related to disease. Knowing the underlying cause of a disease provides new opportunities for diagnosis, and, opens up the possibility for gene therapy and the likelihood of curing some genetic diseases in the future. Currently, there is a growing demand for ways to use this information to benefit individual patients. This has led to new laboratory techniques in molecular genetics and cytogenetics that are providing improved methods of diagnosis and treatment. The major emphasis of this chapter is cytogenetics; discussion of molecular diagnostics is found in Chapter 70.

DEFINITIONS

As in all areas of medicine, genetics relies on the proper use of specific terms for communication. The following definitions provide a basic vocabulary for this field.

Gene: a sequence of nucleotides that represents a functional unit of inheritance; a region of DNA that codes for a product, either RNA or protein.

Chromosome: a highly ordered structure composed of DNA and proteins that carries the genetic information. In humans, there are 46 chromosomes ordered in pairs.

Autosome: all chromosomes other than the X and Y chromosomes, which are designated the *sex chromosomes*.

Homologous chromosomes or homologs: sister chromosomes, the members of a pair of chromosomes in which one is inherited from the mother and the other from the father.

Locus: the position of a gene on a chromosome.

Allele: an alternative form of a gene occupying the same locus. An allele may be the result of a mutation. There is a maximum of two alleles per diploid chromosome complement (one allele per chromosome), but multiple alleles may exist within a population.

Mutation: a permanent heritable change in the sequence of genomic DNA. This may manifest at both the molecular and cytogenetic levels. Not all mutations are negative events. Many are benign (e.g., blue eye color) and some have positive effects (e.g., sickle cell trait in countries with a significant risk of malaria). Individuals with a *constitutional mutation* (i.e., a mutation present in every cell of the body) may pass that mutation on

to their progeny by germline transmission. In some cases, notably cancer, an *acquired mutation* may arise in a single somatic cell, which then divides mitotically, giving rise to a new clone of cells. The mutation will be limited to this clone and will not be transmitted to progeny of the individual. In rare instances of *gonadal mosaicism*, a de novo acquired mutation may arise in the gonads, resulting in a mixed population of normal and mutant gametes. Progeny receiving the new mutation may display a phenotype not present in either parent.

Karyotype: the chromosome constitution of an individual.

Karyogram: a figure showing the paired chromosomes from a cell arrayed in a standard sequence.

Diploid: the presence of two copies of each unique chromosome per cell. In humans, the chromosomes occur in pairs and the diploid ($2N$) number is 46.

Haploid: one copy of each unique chromosome. In humans, the gametes are haploid ($N = 23$).

Homozygous: both alleles at a locus are the same. (In the ABO system, an AA complement represents homozygosity.)

Heterozygous: the two alleles at a locus are different. (In the ABO system, an AO complement represents heterozygosity.)

Hemizygous: the presence of only one chromosome or chromosome segment rather than the usual two; applies to males with a single X chromosome.

Genotype: the genetic constitution of an individual or organism (i.e., what alleles are present). (In the ABO system, AA, AO, BB, BO, AB, and OO are genotypes.)

Phenotype: the appearance of an individual that results from the interaction of environment and genotype. (In the ABO system, A, B, and O blood types represent the phenotypic expression of the alleles for a given individual.)

Dominant allele: an allele that is expressed when present in only a single dose (i.e., it “dominates” over the other allele present). (In the ABO system, A is dominant over O such that an AO genotype results in an A blood type phenotype. Similarly, the presence of pigment (T) is dominant to the absence of pigment (t) (i.e., albinism), such that Tt results in pigmentation.)

Recessive allele: in a diploid organism, an allele that is only expressed when homozygous. (In the ABO system, the O blood group is only seen with a OO genotype; O is recessive to A and B. Similarly, t is recessive to T, and an albino phenotype only occurs with a tt genotype.)

Codominant alleles: in a diploid organism, alleles that show no dominance or recessivity to each other but, when present together, are both fully expressed. (In the ABO system, A and B are codominant such that an AB genotype expresses both A and B antigens.)

Independent assortment: random assortment of chromosomes (paternal and maternal) in the gametes; 50:50 chance of inheriting a given chromosome from one parent.

Linkage: the presence of two or more genes on the same chromosome that tend to be inherited together.

Crossing over: the physical exchange of genetic material between homologous chromosomes.

Recombination: the generation of new allelic combinations on chromosomes, usually by crossing over.

Mitosis: somatic cell division in which the DNA replicates and is evenly distributed to two equal daughter cells.

Meiosis: cell division in the gonads that produces the gametes. A single DNA replication is followed by two cell divisions which reduces the total DNA content of a cell from $2N$ to N . Recombination occurs to increase genetic diversity within a population.

Nondisjunction: failure of chromosomes or chromatids to separate to opposite poles in cell division. Usually results in one too many or one too few chromosomes in a cell.

CYTOGENETICS

Cytogenetics is defined as the science that combines the methods and findings of cytology and genetics to allow the investigation of heredity at the cellular level. This involves careful evaluation of the chromosomes, structures composed of double-stranded DNA that is complexed with histone and nonhistone proteins. Chromosomes were first observed in tumor cells by Walther Fleming in 1882, only 16 years after Mendel established genetics as a new field of science, making cytogenetics one of the oldest fields of genetics. Just after the turn of the century, the importance of the sex chromosomes was established, and in 1959, cytogenetic studies were first used in clinical laboratory studies. The ability to detect changes in

Figure 68-1 Karyogram of male human chromosome complement; 46 total chromosomes are ordered in pairs. Note the nonhomologous pair of sex chromosomes with one X and one Y chromosome (lower right).

chromosome structure and directly correlate them to disease and phenotypic anomalies in individuals proved a major advancement in clinical diagnosis. Over the years, the number and types of studies have grown and many of the tests performed have become the gold standard for diagnosis. In today's world, with a growing number of disease genes being cloned, there is an increasing emphasis on developing molecular direct mutation analyses (see Chapter 70). These studies work well when a diagnosis is known or suspected but, in the absence of a known disorder, cytogenetics still retains its position as the only clinical laboratory test to be able to survey the cellular genetic constitution of an individual with a single assay. Consequently, clinical applications for cytogenetic analysis can be found in all age groups and range from prenatal diagnosis to cancer evaluation.

CHROMOSOMES

In order to recognize abnormalities, it is first important to understand what makes up a “normal” chromosome set. The human chromosome complement includes 46 chromosomes ordered in 23 pairs (Fig. 68-1). One member of each pair is inherited from an individual's mother and the other comes from the father. Twenty-two pairs are known as *autosomes* and appear as homologs of each other (i.e., they are indistinguishable from each other). The 23rd pair includes the sex chromosomes, which are homologous in a female, who has two X chromosomes, and are nonhomologous (structurally different) in a male, with one X and one Y chromosome (see Fig. 68-1). Genes are encoded in the DNA and are arrayed along the length of the chromosomes. During the cell cycle, the absolute length of the chromosomes vary but the most condensed form is reached in metaphase, at which time chromosomes can most easily be observed. Consequently, metaphase chromosomes are the basis for most cytogenetic studies. Complete evaluation of a set of chromosome is known as *karyotype analysis* and an ordered image of the chromosomes from a cell is called a *karyogram*.

Chromosome Structure

A single metaphase chromosome is composed of two DNA double helices. Each double helix is termed a *chromatid* and the two chromatids are held together by an as yet unreplicated region of DNA known as the *centromere*, or primary constriction. In addition to its function in cell division, the centromere acts as a landmark and divides the chromosome into two distinct regions known as *arms* (Fig. 68-2, A). The shorter of the two arms is designated the *p arm* and the longer arm is known as the *q arm*. When the centromere is approximately equidistant from both ends, the chromosome is said to be metacentric but if it is closer to one end than the other, the chromosome is submetacentric (see Fig. 68-2, B). Five pairs of

Figure 68-2 Chromosome structure. **A**, Schematic of metaphase chromosome anatomy showing major landmarks. Each chromosome is composed of two chromatids held together by the centromere. The telomere is the end structure of the chromosome. A typical metacentric form is contrasted with an acrocentric having a modified short arm structure composed of stalks and satellites. In all cases, the shorter, or p, arm is oriented up and the longer, or q, arm is oriented down. **B**, The relative position of the centromere can vary, resulting in metacentric (centromere near the middle), submetacentric (centromere closer to one end), and acrocentric (modified short arm) chromosomes.

acrocentric chromosomes have modified short arms with stalks containing only multiple copies of rRNA genes that are capped by a modified telomere termed a *satellite* (see Fig. 68-2, **A**).

The end of a chromosome is the *telomere*. These regions are known to be composed of tandemly repeated DNA with the sequence (TTAGGG)_n that functions to stabilize the chromosomes. The mechanics of DNA replication are such that not all of the telomere DNA can be replicated at each division so there is a shortening of the telomeres over time. It has been postulated that total loss of the telomeres leads to an increase in chromosomal aberrations that may, in part, be responsible for the human aging process (Harley, 1990; Wright, 1992; de Lange, 1998).

Cell Culture

To obtain metaphase cells for a chromosome analysis, cells from a patient must be cultured *in vitro*. The average human cell divides once every 24 hours, so only about 1% of the cell population is dividing at any given time. However, some cells, such as lymphocytes in a normal healthy individual, do not divide at all. Special culture techniques have therefore been developed to stimulate the cells to divide and increase the yield of metaphase cells.

Specimens

Virtually any viable, nucleated cell sample can be used for cytogenetic analysis. However, certain types of cells are easier to obtain and culture, and are therefore favored for chromosomal preparations. For routine cytogenetic studies of adults and children, heparinized peripheral blood is the preferred specimen. Obtaining a sample via standard phlebotomy is usually easy to arrange and relatively painless for the patient. In hematologic disorders, the best results are obtained from bone marrow samples, because this is the origin of the disease. Fibroblast cultures from skin biopsies or skin punches provide an adequate source of metaphase cells. Tissues such as liver, kidney, lung, and muscle are not routinely used because of the invasive nature of acquiring such specimens; however, these tissues frequently provide an excellent resource if obtained soon after death during autopsy or from a fetal loss. Products-of-conception samples may contain a mix of maternal and fetal tissue and so require extra care in establishing a culture (De Martinville, 1984).

The most common specimen for prenatal analysis is amniotic fluid collected by amniocentesis. Under ultrasound guidance, the physician passes a needle through the mother's abdomen and uterus into the amniotic sac. This is typically done between 16 and 18 weeks of gestation, at

which time 20–30 mL of amniotic fluid (fetal urine) can be withdrawn without endangering the fetus. Cells present in the sample are derived from the fetus and provide a source of material for cytogenetic, molecular genetic, and biochemical assays. The fluid itself contains α -fetoprotein (AFP) as well as other proteins and enzymes and forms the substrate for other prenatal assays. The risk of fetal loss due to amniocentesis is approximately 0.5%.

Another prenatal procedure is chorionic villus sampling, which provides tissue from the developing placenta (chorionic villi) (Blakemore, 1988; Rhoads, 1989). The transabdominal or transvaginal procedure is performed at 10–14 weeks' gestation and has a risk of fetal loss of approximately 1%. Because no amniotic fluid is collected, no AFP or related testing can be done, although standard cytogenetic, biochemical, and molecular analyses are possible.

Cordocentesis, or percutaneous umbilical blood sampling, results in a fetal blood specimen that can be used for rapid karyotyping or molecular studies. This procedure is done at later gestational ages (≥ 20 weeks) and carries a higher risk of fetal loss (2%–5%).

All clinical samples for cytogenetic analysis must be collected in a sterile manner. The presence of bacteria or fungi severely compromises the study because prokaryotic cells usually outcompete and overgrow any human cells that are present. To maximize the number of viable cells, specimens should be transported to the laboratory as soon as possible after collection. Blood, bone marrow, amniotic fluid, and chorionic villi should be maintained at room temperature, whereas solid tissue is transported on wet ice. The difference in temperature of transport is due to the native conditions of the sample. Blood, bone marrow, and amniotic fluid cells exist as individual cells in a fluid substrate, and the integrity of the sample will not be compromised as long as its temperature is maintained close to body temperature. However, tissue collection requires cells to be excised from the body, leaving broken and dying cells at the periphery of the sample. The resultant release of lysosomal enzymes facilitates degradation of the dead cells, but the enzymes will also attack and destroy adjacent living cells. If the temperature is dropped to near 4° C, enzyme activity will be inhibited and the viability of the sample is maintained.

Cell Culture Technique

Depending on the cell type, either a suspension (floating) or monolayer (fixed to a surface) culture technique may be employed. Blood and bone marrow cells are grown in suspension, so cells from the sample can be aliquoted directly into an appropriate culture medium. Bone marrow is typically cultured for 24–48 hours, whereas lymphocytes require 3–4 days in culture for maximum yield. Furthermore, because lymphocytes do not normally divide in culture, they must be induced using a mitogen, usually phytohemagglutinin. The resultant metaphase cells can then be collected by use of a mitotic inhibitor such as colcemid. Amniotic fluid cells, chorionic villi, and solid tissue are all grown as a monolayer *in situ*. Tissue and chorionic villi are first disaggregated using a mild collagenase treatment, and the individual cells are then seeded on to glass coverslips and covered with culture medium. In an amniotic fluid sample, the cells must be separated from the fluid by centrifugation before being plated in dishes and allowed to form *in situ* colonies. Typical culture times are 5–7 days for chorionic villi and amniocytes and up to 2 weeks for solid tissue culture.

Once maximum growth has been achieved, all cell types are harvested using similar techniques. The cells are swelled hypotonically (to the point that the cell membrane is stretched but not broken) and are then fixed. Gentle blowing on the coverslip containing fixed cells from *in situ* cultures results in the rupture of the cell membrane and a spreading of the metaphase chromosomes. For suspension cultures, the fixed cells must be dropped on to a clean microscope slide, which mechanically breaks the membranes and leaves the chromosomes separated slightly from each other but in a discrete region occupied by a single cell (Fig. 68-3). After air drying, the slides are suitable for staining. In some cases, artificial aging of the cells at 65° C for 30–60 minutes improves the quality of the staining. Although most laboratories still perform these steps manually, an automated robotic harvester has been developed that can process large numbers of cultures quite efficiently.

Staining

Chromosomes are routinely stained using Giemsa or Wright's stain, positively charged dyes that bind to the negatively charged DNA molecule. Mild trypsinization of the chromosomes before staining apparently weakens the DNA–protein interactions, yielding a defined pattern of alternating light and dark regions after the stain is applied. This is called the *banding pattern* (G-banding for Giemsa banding) (Yunis, 1973; Burkholder,

Figure 68-3 Metaphase chromosome spread. Chromosomes from a single cell as seen on a microscope slide.

1977; Holmquist, 1982). Each pair of chromosomes has a unique band pattern that is schematically represented as an ideogram (ISCN, 2009) (Fig. 68-4), and this is used to identify each chromosome and the chromosomal subregions.

Although standard G-banding is adequate for most situations, additional information about chromosome structure can be obtained with other special staining technologies. The most common special stains include Q-banding, C-banding, and R-banding. Q-banding, or quinacrine fluorescence staining, was originally used in routine chromosome analysis (Comings, 1975). However, because the fluorescence is transient, it has been replaced by G-banding, which allows a permanently stained preparation (Sumner, 1973). The current major application of Q-banding is for rapid identification of the Y chromosome. The distal end of the long arm of the Y chromosome is composed of heterochromatin and is the most brightly fluorescent region in a human metaphase (Fig. 68-5, A). In cases of ambiguous genitalia, a quick Q-banded preparation can usually answer the question of the presence or absence of a Y chromosome in the patient. C-banding, constitutive or centromere banding, is used to evaluate constitutive heterochromatin or to determine whether a chromosome has two centromeres (dicentric). Normally, a centromere appears as a single dark spot on an overall pale-staining chromosome (Holmquist, 1979). In the case of a dicentric chromosome, the presence of two dark regions clearly identifies the two centromeres (see Fig. 68-5, B). R-banding, or reverse banding, results in chromosomes with the same banding pattern as that seen in G-banding, but the light and dark bands are reversed, hence the name. Because the telomeres of the chromosomes tend to be small, light-staining bands, a deletion may not be easily detected using standard G-banding. In R-banding, however, the telomeres should appear as dark bands and their absence as the result of a deletion is more obvious.

Karyotype Analysis

To perform a cytogenetic (karyotype) analysis, it is essential to be able to rapidly and accurately identify each chromosome and determine when chromosome abnormalities are present. The first step is to count the number of chromosomes present in the cell being evaluated. The number

Figure 68-4 Examples of ideograms for chromosomes 1, 7, 14, and Y showing the expected pattern of alternating light and dark bands.

Figure 68-5 **A**, Q-banded metaphase showing bright fluorescence of the Y chromosome (arrow). **B**, C-banded chromosomes showing the dark staining centromeres. A dicentric chromosome was detected with two dark bands (arrows).

of active centromeres defines the total number of chromosomes and will total 46 in a normal human diploid cell. Too many or too few chromosomes indicate a potential numerical abnormality. In vitro culture can result in culture artifacts, so no single cell is used to define an individual's chromosome complement. A typical clinical study requires analysis of 15–20 cells. Single cells with abnormalities are considered artifacts. Three or more cells with the same chromosome loss or two or more cells with the same additional chromosome define a true abnormality. In cases of mosaicism or for other special situations, 10–30 additional cells may be evaluated.

Individual chromosomes are identified based on the overall size of each chromosome, the position of its centromere, and the banding pattern. Any variation in chromosome structure should be detected at this time. In most circumstances, routine G-banding of metaphase chromosomes is sufficient for clinical diagnostic purposes. However, some disorders are associated with very small deletions of chromosomal material that may not be resolved at this level, so high-resolution analysis is used. Special culture conditions are employed, and the cells are harvested at a slightly earlier stage of cell division, prometaphase. At this point in the cell cycle, the chromosomes are less condensed and physically longer, making the presence of small abnormalities easier to detect.

The analysis is performed by a technologist viewing the cells at the microscope and, once the study is complete, a determination is made as to whether the chromosome complement is normal or abnormal. For

documentation, representative metaphase cells are captured and karyograms (illustrations of the chromosomes of a given cell, see Fig. 68-1) are prepared. Traditionally, the capture has been performed by photography using a 35-mm camera mounted on the microscope. The film is then developed and photographic prints are made. The chromosomes can be cut out and attached to a sheet of paper. The homologous pairs are arrayed from large to small with special placement for the pair of sex chromosomes. By convention, the shorter arm, the p arm, is oriented up, and the longer q arm is oriented down.

Computer-Assisted Imaging

Currently, most cytogenetics laboratories have moved to computer-assisted imaging. Although photographic prints give a high-resolution image, the technique requires significant time and effort. It is now possible to mount a charge-coupled device video camera on the microscope in place of the 35-mm camera. Using specially designed software, an image of a metaphase cell is captured using a standard frame grabber, digitized, and displayed on the computer monitor. At this point, the software allows the image to be modified by lightening, darkening, or changing the contrast, and a variety of manipulations of the chromosomes are possible, including straightening and importing chromosomes from other fields. A karyogram can then be generated using a pattern-recognition subroutine that will automatically identify the chromosomes and place them in their proper places on a karyogram form. Depending on the software and the quality of the image, the accuracy of this process can vary from 10% to 85%. After the computer has taken its “best guess,” a trained cytogenetic technologist must make the appropriate corrections. Once the chromosomes are properly positioned, additional cosmetic enhancements are possible to eliminate ragged edges or bits of background. The final version of the karyogram is then printed out directly by a high-resolution printer. Although the overall quality is not as high as a photographic rendering, there is a tremendous saving of time using the computerized system. A routine karyogram from capture to printing should take a trained technologist on average 15–20 minutes. Another major advantage of the computer-assisted system is in fluorescence microscopy.

Fluorescence In Situ Hybridization

The classic cytogenetic staining discussed earlier is the result of dyes that bind to the DNA or protein of a chromosome and allow visualization by light microscopy. In situ hybridization, a combination of molecular and cytogenetic technologies, opened another door that has allowed further investigation of chromosome anomalies. Here, instead of a dye, a molecular probe (i.e., a fragment of DNA) binds to the chromosome. In early studies, the probe was labeled with a radioactive compound (usually tritium) such that after 5–10 days of exposure to radiograph film, a pattern of silver grains could be detected identifying the chromosomal location of that probe. This technique facilitated gene mapping by identifying gene loci (Trask, 1991).

Autoradiography was useful, but only one probe at a time could be used; it required a significant length of time for exposure, and there was a degree of scatter of the silver grains that necessitated statistical analysis of the data obtained. In the mid-1980s, a variation of the technique was developed that has proven to be extremely useful in clinical applications. The new technology, fluorescence in situ hybridization (FISH), is quicker, more specific, and allows the use of multiple probes in a single hybridization procedure. Furthermore, instead of radioactively labeled probes, a fluorescent dye is used that is visualized using fluorescence microscopy (Ledbetter, 1989).

In clinical applications of FISH, the most common goal is to determine whether a gene, a specific mutation, or a particular chromosomal rearrangement is present, so the molecular probes used must be well characterized and specific to the locus in question. There are three basic types of probe. *Chromosome painting* probes are actually a cocktail of many unique DNA fragments from along the entire length of a chromosome, such that, following hybridization, the entire chromosome fluoresces (Fig. 68-6, A). *Repeat sequence* probes are isolated from telomere or centromere regions. Centromere probes are usually used in chromosome enumeration (i.e., to detect the gain or loss of specific chromosomes) (Lichter, 1990). A true telomere probe recognizes the six base repeat present at the ends of all chromosomes and will confirm the presence or absence of the telomeric regions. In practice, however, both true centromere and telomere probes are not particularly useful because so many signals are generated. Chromosome-specific pericentromeric and subtelomeric probes are now in use (see Figs. 68-6, C and D). A *unique sequence* probe is usually isolated from cloned DNA of a disease-causing gene or a fragment of DNA of

Figure 68-6 Fluorescence in situ hybridization. **A**, Whole chromosome paint probe highlighting the two X chromosomes in a female cell. **B**, Chromosomes showing hybridization with subtelomere probes. The p arm subtelomere is indicated by the green signals, and the q arm subtelomere is indicated by the red signals. Paired red and green signals are seen in the interphase nucleus to the left. **C** and **D**, Repeat sequence centromere probe for chromosome 21. **C**, Trisomy 21 seen at left in an interphase nucleus and at right in a metaphase (arrows). **D**, Normal complement of two copies of chromosome 21 (arrows) seen in interphase (left and right) and in a metaphase (center).

known location associated with a particular gene. This type of probe is used to identify the presence or absence of the gene, gene region, or chromosomal rearrangement of interest (Cherif, 1989; Lindsay, 1993). *Subtelomere* probes are a subset of this category. Research revealed that there are unique sequences just proximal to the telomere of each chromosome arm that can be used for specific identification of each arm. The subtelomere probes that have been generated have become very valuable in characterizing cryptic rearrangements by determining whether all subtelomeres are present and located on the correct chromosome arms, and, if not, if a rearrangement has occurred (see Fig. 68-6, *B*). Furthermore, it has been shown that 3%–5% of patients with unexplained mental retardation have a cytogenetically undetectable terminal deletion of a chromosome (Flint, 1995, 2003; Rosenberg, 2001). Subtelomere FISH now allows identification of such deletions and localization to the specific chromosome affected (National Institutes of Health and Institute of Molecular Medicine Collaboration, 1996; Irons, 2003).

Technique

FISH can be performed on either metaphase or interphase cells. For metaphase FISH, cells are cultured and harvested as for a routine karyotype analysis, but no culture is required for interphase FISH. Fixed cells are collected and slides are made as described for karyotyping. The DNA on the slides is then denatured, and a fluorescently labeled single-stranded molecular probe is allowed to hybridize to the chromosomal DNA using an annealing temperature that favors hybridization of homologous regions of DNA (Fig. 68-7, *A*). After an appropriate period of hybridization, excess probe is washed away and the nonhybridized DNA is counterstained with another fluorochrome to allow visualization of the entire chromosome complement. A fluorescent microscope with light from a 100 W mercury

bulb in combination with appropriate sets of exciter filters allows evaluation of the cells. Due to the optical limitations of the glass filters, a maximum of three colors can be visualized on a typical fluorescent microscope. For documentation, a 35-mm camera attached to the microscope can be used, although superior results are obtained using a computer-assisted system to acquire the fluorescent images. Software packages also allow enhancement of weak signals and sharpening of the image.

One of the most critical elements in FISH is the selection of a specific probe or probes that will help to answer a clinical question. For example, one of the most useful clinical applications of FISH is the detection of microdeletions too small to be seen using classical cytogenetics (see Figs. 68-7, *B* to *D*). The gene must be known and the probe used must be homologous to the critical region of the gene that is usually deleted. Hybridization with the probe should result in a fluorescent signal only at the target locus. If a signal is present, DNA complementary to the probe is present, so there is no deletion (see Fig. 68-7, *B*). However, the absence of signal indicates that a deletion exists (i.e., there is no DNA sequence present on the chromosome that is complementary to the probe, so no hybridization can occur) (see Fig. 68-7, *D*). A control probe to a different region of the chromosome being tested is usually used as a hybridization control (see Fig. 68-7, *C*). Therefore, when evaluating a disease related probe, an unaffected individual should have two signals per cell for each autosomal gene, one signal for each chromosome of the pair (Fig. 68-8, *A*). An affected individual with a deletion should have a single signal per cell, showing one normal and one deleted chromosome (see Fig. 68-8, *B*). For both affected and unaffected, the control probe should show two signals per cell in all cells that are scored. In a metaphase cell, the chromosomes may be short and condensed, with each chromatid individually visible, resulting in a discrete FISH signal on each chromatid. In these

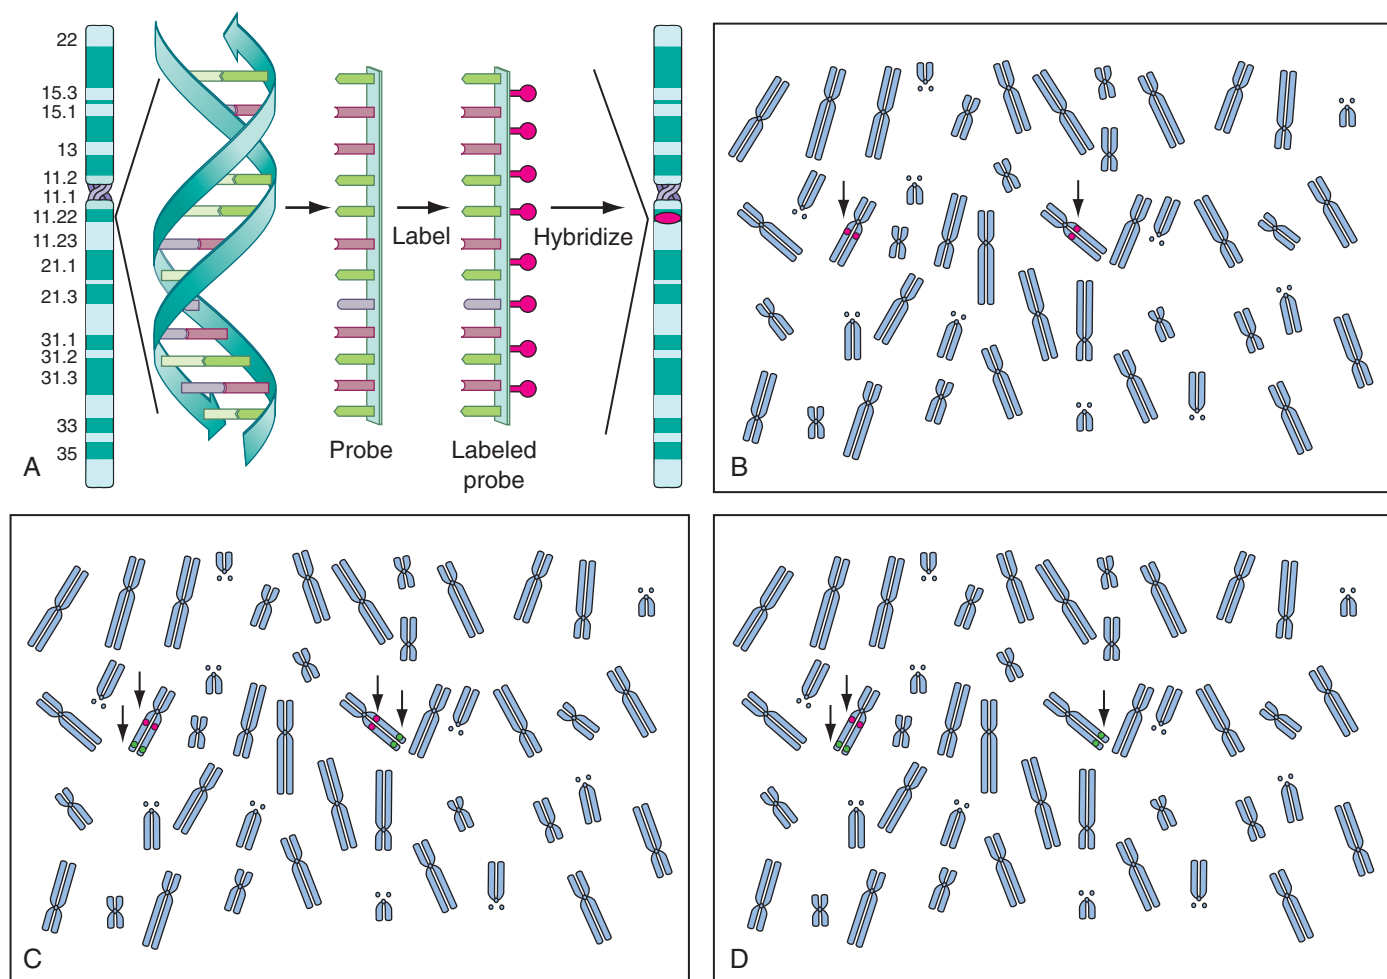

Figure 68-7 **A**, Schematic of fluorescence in situ hybridization (FISH) technology. DNA derived from a known gene is rendered single stranded, labeled with a fluorescent tag, then hybridized back to the chromosomes of a metaphase cell. **B** to **D**, Depiction of a metaphase cell with 46 chromosomes that has been processed using FISH technology. The labeled probes hybridized to targets are indicated with arrows. **B**, Dual signals indicating hybridization to both alleles of target gene. **C**, Target gene indicated by red signal and a control probe indicated in green. Complete hybridization to all alleles. **D**, Hybridization of both controls (green) but presence of only a single target gene indicating deletion of one allele.

Figure 68-8 Fluorescence in situ hybridization detection of a microdeletion of chromosome 22 associated with velocardiofacial syndrome. **A**, An individual with no deletion showing the presence of one red (gene locus) and one green (control locus) signal for each chromosome 22. **B**, Patient with a deletion seen as a chromosome with only a single green (control) signal. The homologous chromosome 22 is "normal" with one red and one green signal.

cells, there may appear to be two signals per chromosome for a total of four signals but, in actual scoring, only complete chromosomes are considered so a signal on one or both chromatids would be counted as just one positive signal.

One of the problems with this detection system is that the lack of signal is the positive indication of a deletion. Technical failure of hybridization

may also result in absence of signal. To eliminate this as a source of error, a minimum of 20 cells must be evaluated, and all cells must agree in signal count. If mosaicism is suspected, additional cells may be surveyed. In addition, unique sequence probes are currently used in combination with a control probe (see Fig. 68-7, C). The secondary probe is localized to the same arm of the chromosome as the deletion locus. It may be labeled with

Figure 68-9 Multicolor fluorescence in situ hybridization. **A**, Diagram of the staining pattern for five probes (chromosomes 13, 18, 21, X, and Y) in an interphase cell. Table at the left shows relative proportions of the red and yellow fluorochromes used for each probe. **B**, The same cell depicted in **A**, now showing the computer-derived artificial color assignments (key shown in box to left). This cell can now be interpreted as having two copies each for chromosomes 13, 21, and X, three copies of chromosome 18, and one Y chromosome.

the same fluorochrome as the deletion locus probe but it has been found that the interpretation of the hybridization results is easier if the control site probe is labeled with a fluorochrome of a different color. In all cells evaluated, two clear control signals must be seen, and then the corresponding signals for the disease locus can be recorded. This provides a hybridization control as well as a marker for the chromosome of interest (see Fig. 68-7, *D*). If a dual color system is used, results may be obtained in interphase as well as metaphase cells.

Chromosome painting probes are most useful in identifying complex rearrangements or marker chromosomes. If an individual has an abnormal chromosome with extra material of unknown origin, it may be possible to use chromosome painting to identify the source of the extra DNA. This may help in either diagnosis or prognosis of the individual. For example, in the case of a patient with only one identifiable X chromosome and a small, unidentified marker chromosome, it will be important to determine if the origin of the marker is an X or a Y chromosome. This can be accomplished using chromosome paints for the X and Y chromosomes labeled with different fluorochromes.

FISH probes are most informative when evaluated in metaphase cells where it is possible to identify the specific chromosome to which the probe hybridizes. However, in some cell preparations, very few metaphase cells may be present, and, in these cases, information may be obtained with unique sequence or repeat sequence probes in interphase nuclei. Here, the technical problems are increased as a result of random loss of signal, extra signals, and overlapping signals in cells, so additional cells (a total of 50–200) must be counted to obtain a statistically significant result.

Multicolor Fluorescence In Situ Hybridization

Another advantage of FISH is the ability to hybridize multiple probes to a single slide to obtain a better understanding of chromosome rearrangements (Schrock, 1996; Speicher, 1996). For most FISH probes, the maximum number of colors is three (one target sequence, one control sequence, and one counterstain), and this can be handled by a typical fluorescent microscope. However, if more than three colors are needed, a computer-assisted imaging system is required. This is because a fluorescent image is the result of the light from the mercury bulb passing through an exciter filter, hitting the fluorochrome on the slide, and transmitting an image of the appropriate color to the eyepiece for viewing. Each fluorochrome requires its own filter so, for each additional color desired, the light must pass through additional thicknesses of glass. The optical properties of glass and light limit the total number of viewable colors to three. However, with a computer-assisted system, detection of multiple colors becomes possible. The computer does not actually “see” more colors but it can detect subtle differences in shades better than the human eye. In a relatively simple example, two fluorochromes are used and mixed in varying proportions to give a range of colors. In the example in Figure 68-9, *A*, a red fluorochrome is mixed with a yellow fluorochrome generating intermediate colors from red to yellow. Eight signals are seen, but as viewed through the microscope, it is impossible to be absolutely sure which signal corresponds to a particular chromosome. Although difficult to distinguish by the human eye, the computer can register each color as a different shade of gray and then the software assigns a unique color to that shade for display on the computer monitor. Figure 68-9, *B*, shows the final multicolor version using many different colors now easily distinguishable but very different from the original presentation (see Fig. 68-9, *A*). Using

the key to the left, the following chromosomes are detected: two each for chromosomes 13, 21, and X; three chromosomes 18, and one Y chromosome. This cell is therefore trisomic for chromosome 18 with an XXY sex chromosome complement. Combinations of fluorochromes have been developed that allow detection of each of the 24 different chromosomes followed by a unique color assignment by the computer (Reid, 1992a, 1992b; Divane, 1994).

Microarray Technology

Adding FISH to the options for cytogenetic testing has greatly increased the detection rate of chromosomal abnormalities. However, there are still individuals who test normal yet present with findings suggestive of a chromosome anomaly. To obtain even more detailed information on the chromosomes of these problematic patients, use of microarray analysis was investigated and has proven to be quite valuable in genetic diagnosis. Since 2006, it has gained acceptance as a clinical tool, adding yet another dimension to cytogenetic analysis.

The function of a cytogenetic microarray is to screen the genome for copy number variation (CNV). (See Chapter 67 for a discussion of the technology behind microarray analysis.) There are three different levels of microarray: (1) bacterial artificial chromosome (BAC) arrays, (2) oligonucleotide arrays, and (3) single nucleotide polymorphism (SNP) arrays. In the order given, the size of the probes decrease while the total number of probes per genome increases. Thus, BAC arrays provide a general overview to the human genome and are usually targeted to regions of known association with genetic disease (markers spaced on average about 1 MB apart). Oligonucleotide arrays generally also target known disease genes, but add in background sequences so these arrays have an overall coverage of the genome with probes spaced 50 to 100 KB. SNP arrays provide significantly more detailed coverage with probes on average every 100 to 1000 base pairs. The choice of which platform to use depends on the question being asked. Early analyses used BAC arrays exclusively because the information desired was usually associated with specific diseases. It is now well documented that a patient’s anomalies may be due to a genetic lesion that has not been previously described and, therefore, is not characteristic of a known genetic disease. This has led to a desire for a fuller examination of the genome by the use of either oligonucleotide or SNP arrays.

When performed correctly, a microarray assay will detect deletions, duplications, aneuploidies, and unbalanced translocations with a gain or loss of sequences. Some of the more advanced assays can also identify methylation patterns and so are useful in evaluating cases of uniparental disomy. Using microarray analysis has allowed the identification of genomic lesions too small or too cryptic to be detected by other types of assays, and this has led to a diagnosis for many patients for whom the cause of their anomalies had previously been unknown (Pickering, 2008; Saam, 2008).

However, as with all technologies, microarray is not a perfect solution for all situations. One drawback is that these microarrays will not detect balanced chromosome rearrangements, including translocations and inversions. In addition, the assay will identify all existing CNVs, from large to small, including polymorphic variants. As of 2011, the human genome has not been completely analyzed, so the existence and significance of all CNVs have not been cataloged. It is not unusual for an assay to report the presence of CNVs for which the clinical significance is unknown. In these cases, it is difficult for the clinician to know whether or not they have found

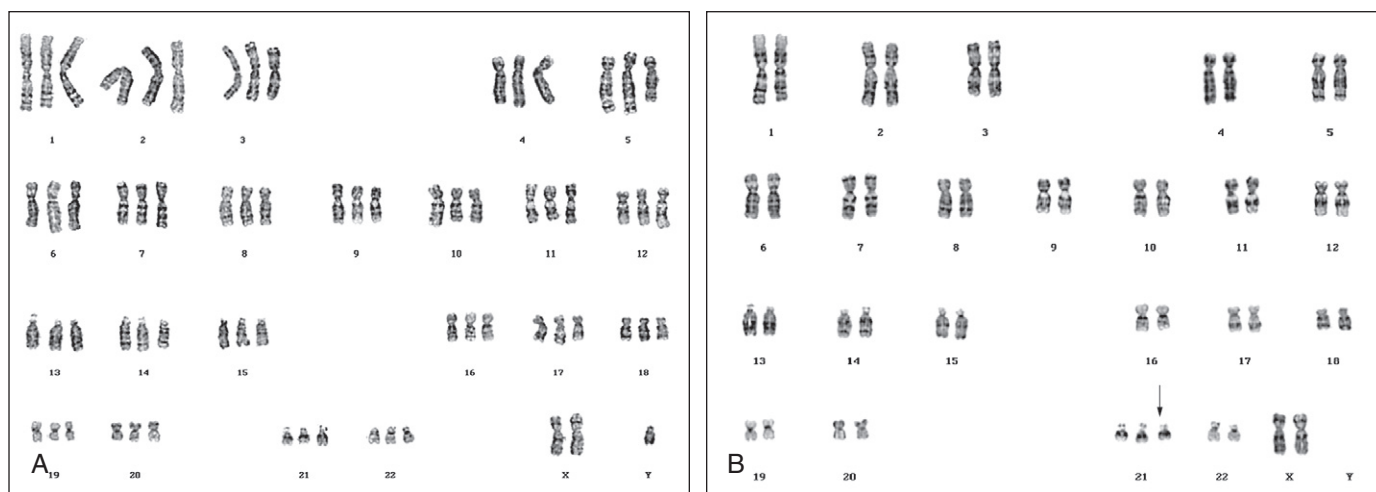

Figure 68-10 Numerical chromosome abnormalities. **A**, Triploid (3N) chromosome complement with three copies of each chromosome (69,XXY). **B**, Trisomy 21 (47,XX,+21) with one extra chromosome 21 (arrow).

the cause of the patient's problems. A similar problem occurred when FISH was first implemented in clinical testing, but over the years, data have been compiled and the understanding of the possible outcomes is now well understood. Having learned from this experience, clinical laboratories performing microarray analyses are encouraged to report all of their findings to one of two international databases that are collecting the new information. These searchable databases will aid in better interpretation of CNVs.

CHROMOSOME ABNORMALITIES

Clinical cytogenetic testing is an integral part of clinical medicine. Finding a particular chromosome anomaly may explain a physical problem or phenotypic abnormality in the patient and be directly associated with a disease diagnosis. It is therefore critical to determine whether an affected individual has a chromosome complement that differs from the standard pattern of 23 pairs of chromosomes with known morphology. There are two basic categories of cytogenetically detectable variation: (1) numerical and (2) structural change.

Numerical Abnormalities

In humans and other mammals, the chromosomes occur in pairs, so, of the 46 human chromosomes, there are only 23 uniquely different chromosomes. A set of 23 comprises the haploid (N) number of chromosomes, which is the number of chromosomes in a gamete. At fertilization, two haploid complements join to form a zygote with 46 chromosomes, the diploid ($2N$) complement. Errors in division can give rise to chromosome complements that have more or less than 46 chromosomes. Exact multiples of the haploid set of chromosomes is called *euploidy*. Gain or loss of one or a few chromosomes is known as *aneuploidy*.

Euploidy

Diploidy, the normal state of human cells, is a form of euploidy. Abnormal euploidies include triploidy ($3N = 69$ chromosomes) and tetraploidy ($4N = 92$ chromosomes), but these are not compatible with life and are detected primarily in spontaneous abortus tissues. Triploidy (Fig. 68-10, A) may be due to the failure in gametogenesis of one of the meiotic divisions, giving rise to a $2N$ gamete that, when combined with a haploid gamete from the other parent, produces a triploid zygote. Alternatively, a $3N$ complement may be derived from dispermy, the fertilization of a haploid egg by two sperm, and this generally results in a partial hydatidiform mole. Tetraploidy, on the other hand, is usually a postmeiotic event and presents as a duplication of a diploid complement (XXXX or XYYY), most probably due to failure of an early mitotic cleavage division in the zygote.

Aneuploidy

More common are nondisjunctional errors resulting in aneuploidy. Here, a single pair of chromosomes fails to disjoin properly in division, giving rise to one extra chromosome or one missing chromosome per cell. Occasionally, more than one pair of chromosomes may be involved, but these cases are extremely rare. Nondisjunction errors may occur in either meiosis or mitosis. Early mitotic nondisjunction in a zygote may result in an

individual with the aberrant chromosome complement in all cells of the body, but a latter division error usually produces a *mosaic*, an individual with two cell lines that differ only by a single chromosome.

In normal meiosis, one DNA replication is followed by two cell divisions resulting in four haploid (N) gametes (one copy of each chromosome) (Fig. 68-11, A). The first meiotic division is the reduction division, in which the total number of chromosomes per cell is reduced by half. The second meiotic division is a simple mitotic type of division with a separation of the centromeres and distribution of the chromosomes to daughter cells. Meiotic errors may result in gametes with either an extra or missing chromosome (Angell, 1994). A nondisjunction error in the first meiotic division (see Fig. 68-11, B) leads to two gametes that are disomic for one chromosome and two gametes that are missing that chromosome (nullosomic). When fertilized, the former will give a trisomic conception for the nondisjoined chromosome (example: trisomy 21 in Fig. 68-10, B), and the latter will result in a monosomy. Similarly, Figure 68-11, C, shows an error in the second meiotic division resulting in two normal haploid gametes, one disomic gamete, and one nullosomic gamete.

Trisomy or monosomy may occur for any chromosome, but most of these are incompatible with life and will terminate spontaneously. Trisomy 16, for example, is the most commonly detected trisomy in spontaneous abortus tissue but is not reported in liveborn individuals. Liveborn autosomal trisomies include chromosomes 13, 18, and 21. Infrequently, patients with a mosaic chromosome complement for trisomies 8, 9, or 22 are identified. Sex chromosome trisomies are viable and well documented (see later). The only viable monosomy is of the X chromosome (45,X). Examples of clinically significant aneuploidies are discussed later in this chapter.

Because trisomies and monosomies are largely incompatible with life, it had been assumed that these would result in fetal wastage. However, molecular analyses have shown that a small fraction of these aneuploid conceptions are "rescued" and go on to produce liveborn children. In the case of a monosomy, the rescue is accomplished by duplication of the single existing chromosome, resulting in a chromosome complement with *uniparental isodisomy* for that chromosome (two copies of the same chromosome inherited from one parent) (Fig. 68-12, right) (Ledbetter, 1995). This is exemplified by several reported cases in the literature in which a child affected with cystic fibrosis was shown to be homozygous for the $\Delta F508$ mutation, although molecular tests on both parents revealed that only one was a carrier of $\Delta F508$ (Spence, 1988; Voss, 1989). The interpretation is that the conception was a nonviable monosomy 7 rescued by duplication of the existing chromosome 7 that happened to be carrying the mutation for cystic fibrosis. A similar situation is possible in the case of a trisomy. Again, most trisomies are nonviable but, if one of the three chromosomes is lost, a disomy for that chromosome pair is reinstated (see Fig. 68-12, left). In a set of three chromosomes, loss of a single chromosome results in a complement with one maternal and one paternal chromosome (*biparental heterodisomy*) two out of three times. One third of the time, the two remaining chromosomes are from a single parent (i.e., uniparental disomy). In this situation, it makes a difference in which meiotic division the error occurred. A first-division nondisjunction results in heterodisomy, which is two homologous but heterozygous chromosomes (one grandmaternal and one grandpaternal); however, a second division error results in duplicate

Figure 68-11 Meiosis and meiotic nondisjunction errors resulting in aneuploid gametes. **A**, Normal meiosis generating four gametes with a haploid chromosome set. **B**, Nondisjunction in meiosis I leading to an extra copy of chromosome A (heterodisomy) in two gametes (left) but the lack of any A chromosome (nullosomy) in the remaining two gametes (right). **C**, Nondisjunction in meiosis II results in two gametes with a normal chromosome complement (right), one gamete missing an A chromosome (left center), and one gamete with an extra duplicated chromosome (two copies of A1), resulting in isodisomy for chromosome A1 (left).

Figure 68-12 Generation of uniparental disomy from nondisjunction errors. On the left, heterodisomy resulting from reduction of a trisomy to a disomy is illustrated. On the right, isodisomy as the result of monosomy rescue (duplication of a single existing chromosome) is seen.

copies of a single chromosome, isodisomy (see Figs. 68-11, B and C, and 68-13). In the past, it was thought that having two chromosomes per pair was sufficient, but data strongly indicate that, in some cases, it is essential for the pairs to comprise one maternal and one paternal chromosome. This issue, including the problems of uniparental versus biparental disomy and isodisomy versus heterodisomy, is of major importance in understanding issues of *imprinting*, a topic discussed in detail in Chapter 70 (Nicholls, 1998; Hall, 1990; Cassidy, 1992; Petersen, 1992).

Structural Chromosome Abnormalities

Chromosomes are not static structures but undergo recombination in both meiosis and mitosis. This is a natural process that is critical in generating variation in the species, so a highly developed regulatory system is in place to prevent error from occurring. Nevertheless, errors do occur, sometimes resulting in chromosome rearrangements that change the structure of one or more chromosomes. Such abnormalities are quite varied and are often patient-specific. Rearrangements may be (1) *balanced*, if all the

Figure 68-13 Isodisomy versus heterodisomy. The expected conformation of a cell is biparental heterodisomy (*right*), that is, one chromosome from each parent. Division errors can result in an aberrant distribution of parental chromosomes such that two copies of one chromosome from one parent (uniparental isodisomy) (*left*) or two different chromosomes from the same parent (uniparental heterodisomy) (*center*) occur.

chromosomal material is present and functional but simply arranged in a different conformation; or (2) *unbalanced*, if there is loss and/or duplication of some chromosomal material. Balanced rearrangements are usually clinically benign and tend to be stably transmitted but may increase the risk of errors in meiosis resulting in chromosomal imbalances in fetuses or liveborn children. Unbalanced chromosome complements are generally associated with an abnormal clinical phenotype that often includes developmental delay and mental retardation.

A *deletion* is the loss of a part of a chromosome and leads to partial monosomy of the chromosome involved (Fig. 68-14, *B*). Deletions vary in size from quite large to very small and may be *terminal*, which is loss of a portion of the chromosome including the telomere, or *interstitial*, which is loss of an internal piece of chromosome. Chromosome breakage, unequal crossing over, or nondisjunction errors involving chromosome rearrangements may result in a deletion. In general, larger deletions result in more severe clinical abnormalities because of the greater number of gene loci that are missing.

A *duplication* is the presence of an additional copy of a chromosome segment that leads to partial trisomy for that chromosome (see Fig. 68-14, *C*). This anomaly may also be *terminal* or *interstitial*. True duplications appear to be quite rare and are usually sporadic. Duplications are generated by the same mechanisms as deletions and may be the reciprocal outcome of those processes. As is true of deletions, the larger the duplicated piece of chromosome, the greater the genomic imbalance, and the more severe the clinical abnormalities tend to be.

An *inversion* is a reversal of a chromosomal segment with respect to the normal gene arrangement and requires a minimum of two breaks in one chromosome (see Fig. 68-14, *D*). Inversions are classified as either (1) *paracentric*, where the two breaks occur on the same side of the centromere (i.e., in the same arm), or (2) *pericentric*, where the breaks occur on opposite sides of the centromere and the inversion involves both arms (Fig. 68-15, *A*). The majority of inversions are balanced but, if the chromosome breaks within a gene and disrupts normal production of a required gene product, clinical abnormalities may be detected. There is an increased risk of meiotic error, and inversion carriers frequently exhibit infertility or early spontaneous fetal loss due to unbalanced chromosome products.

For an inversion carrier, meiosis begins as normal, with the pairing of the homologous chromosomes. The process is a little more complex for an inverted chromosome, which must form a structure known as an *inversion loop* (see Fig. 68-15, *B*) in order for the homologous loci to pair (i.e., A to a, B to b, C to c, etc.). If no recombination occurs while the loop is present and the chromosomes separate normally, the gametes will not be negatively impacted. However, crossing over within the inversion loop can lead to unbalanced meiotic products. For a paracentric inversion, the results of recombination are usually nonviable acentric and dicentric chromosomes, so there is an apparent suppression of recombination (i.e., the only viable gametes produced are from nonrecombined chromosomes) (see Fig. 68-15, *B*). For pericentric inversions, it is possible that gametes with a chromosome duplication and/or deletion may be derived. In general, larger pericentric inversions result in smaller duplications/deficiencies and increase the likelihood that a child will be liveborn with a chromosome

imbalance and probably phenotypic abnormalities. Once an inversion carrier has been identified, prenatal diagnosis can be used to assess the chromosomes for each conception.

Translocations are rearrangements involving two or more nonhomologous chromosomes. Each chromosome breaks once and the pieces exchange places, establishing two (or more) derivative chromosomes (see Fig. 68-14, *E*). As with inversions, the majority of translocations are balanced, and only when an important structural gene is disrupted does the translocation have clinical ramifications.

The primary danger of a balanced translocation is that carriers are at increased risk for chromosomally abnormal liveborn children. In the first meiotic division, translocated chromosomes assume a cross-shaped structure in order for all alleles to pair properly (Fig. 68-16). At anaphase, the alternate chromosomes must segregate together to generate balanced gametes. Up to one third of the time, the chromosomes will not segregate in this manner and the resulting gametes will be unbalanced. The most common errors are termed adjacent-1 and adjacent-2 segregation. Although both of these patterns result in duplication/deficiency of chromosomal material in the gametes, adjacent-2 is more deleterious, in that it is characterized by the unnatural occurrence of homologous centromeres in a single cell. Viability of a fetus receiving an unbalanced gamete is dependent on the chromosomes and genes involved in the translocation and the size of the duplication and/or deletion. Chromosomes may also follow a 3:1 segregation pattern (see Fig. 68-16, *right*), in which three chromosomes separate to one cell with the remaining chromosome in the second cell. This results in gross imbalances of chromosomal material and is usually lethal in utero. Once a translocation carrier has been identified, prenatal diagnosis is possible.

Robertsonian translocations are a variation of the classic translocation. They occur only between two acrocentric chromosomes and appear to be a fusion of the long arms at the centromere, with the resulting loss of both short arms (see Fig. 68-14, *E*). Loss of the acrocentric short arms is not deleterious, because multiple copies of the rRNA genes present there are located on all acrocentric chromosomes. An individual who is a Robertsonian translocation carrier has a chromosome count of 45 because two chromosomes have functionally become one and share one centromere. These individuals are at increased risk for meiotic nondisjunction errors resulting in children who are trisomic for one of the rearranged chromosomes. The most common example of this is an individual with a Robertsonian translocation involving chromosomes 13 and 14 who has liveborn children with trisomy 13 (Fig. 68-17). The affected child will have 46 chromosomes, including two free copies of chromosomes 13 and the Robertsonian translocation. Another common rearrangement is a Robertsonian 14;21 translocation (see Fig. 68-14, *E*), which could give rise to trisomy 21 progeny.

Although the most common Robertsonian translocations occur between nonhomologous acrocentric chromosomes, it is possible to have such a rearrangement between homologous chromosomes. For example, an individual with a Robertsonian 21;21 translocation would have a total of 45 chromosomes including the translocation in which the two 21s are joined at the centromere. This type of rearrangement is virtually always *de novo*, because carriers of the abnormality are unlikely to have normal progeny. Possible gametes include (1) a cell with the Robertsonian translocation (two copies of chromosome 21), which, if fertilized, will give rise to a Down syndrome child, or (2) a cell with no copies of chromosome 21, which, if fertilized, will result in a monosomy 21, which is not compatible with life.

An *isochromosome* is a chromosome that is the result of misdivision of the centromere during cell division, resulting in two copies of one chromosome arm but missing the other arm (see Fig. 68-14, *F*). This mechanism can result in two derivative chromosomes—one with an inverted duplication of the short arm and one with an inverted duplication of the long arm. If both derivative chromosomes are retained in the cell, it would be trisomic for that chromosome, a condition that is usually lethal. In a living individual, therefore, it is most common that one of the two derivative chromosomes is lost, resulting in a carrier who is trisomic for only one duplicated arm and monosomic for the other arm. The best known example is the isochromosome of the long arm of the X. A patient with Turner syndrome (see later under *Sex Chromosome Aneuploidies*) may have one intact X chromosome and one isochromosome Xq (trisomy for the long arm but a monosomy for the short arm of the X). Because two functional copies of the X short arm are required for normal female development, this chromosome arrangement results in abnormal development. Acrocentric chromosomes may also form isochromosomes (inverted duplication of the long arm), but the resulting homozygosity of all loci present could lead to expression of recessive disorders that would otherwise not have been evident.

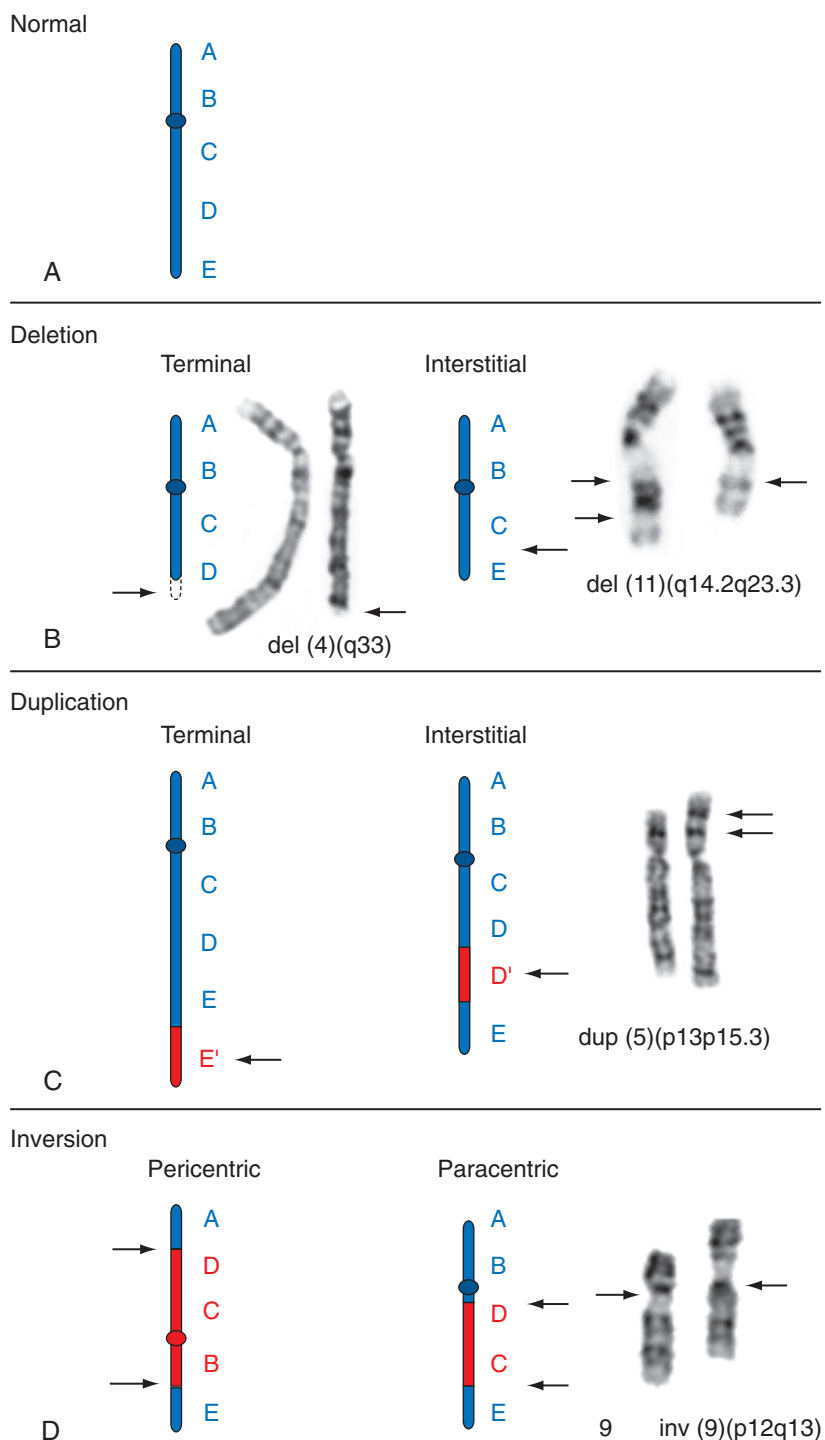

Figure 68-14 Schematic representations of different structural chromosome anomalies described in the text associated with examples of each anomaly. **A**, The normal configuration of a generalized chromosome, where A to E represent different gene loci and the centromere is represented by a dot located between the B and C loci. **B**, Deletion: Chromosome deletion showing terminal (loss of E locus) and interstitial (loss of D locus) configurations. Examples: Terminal deletion of the long arm of chromosome 4, and an interstitial deletion of the long arm of chromosome 11. **C**, Duplication: Chromosome duplication showing terminal (gain of E') and interstitial (gain of D') configurations. Example: Terminal duplication of the short arm of chromosome 5 (double arrows indicate duplicated band). **D**, Inversion: Chromosome inversion showing pericentric and paracentric forms. Example: Pericentric inversion of chromosome 9 (arrows indicate centromeres).

A *ring chromosome* occurs when both telomeres of a chromosome are lost and the remaining portion of the chromosome circularizes to reestablish chromosome stability (see Fig. 68-14, G). Unfortunately, these constructs are usually unstable because replication can result in interlinked circles that lead to chromosome breakage and loss when the homologs attempt to separate at anaphase. Under certain circumstances, however, rings can be stably transmitted in cell lines. This usually occurs when the ring contains genetic material that is essential for normal cell function.

A *marker chromosome* is a chromosome with a centromere that is stably transmitted to daughter cells but cannot be clearly identified because either it is too small or the banding pattern is too ambiguous. Multicolor FISH is a useful tool to determine the origin of markers. By “painting” the entire metaphase and generating an image with a unique color for each chromosome pair, it should be possible to identify the origin of the marker chromosome, because its color should match the color for one of the other known chromosomes of the set.

Conclusions

Chromosome abnormalities, either numerical or structural, that result in an unbalanced chromosome complement are usually associated with some type of abnormal clinical finding, and the size of the imbalance tends to be proportional to the severity of the problem. Most individuals with a constitutional chromosome abnormality have only a single chromosome defect. However, there are rare instances in which one person may have two or more chromosomal errors. Acquired chromosome abnormalities (seen in cancer cells) may be more complex and may have multiple numerical and structural changes in a single cell line.

Nomenclature

With such a broad range of chromosome variation, it was necessary to develop a system of classification that would allow each individual's chromosome complement to be succinctly described and understood worldwide. The first cytogenetic nomenclature provided a framework, and the

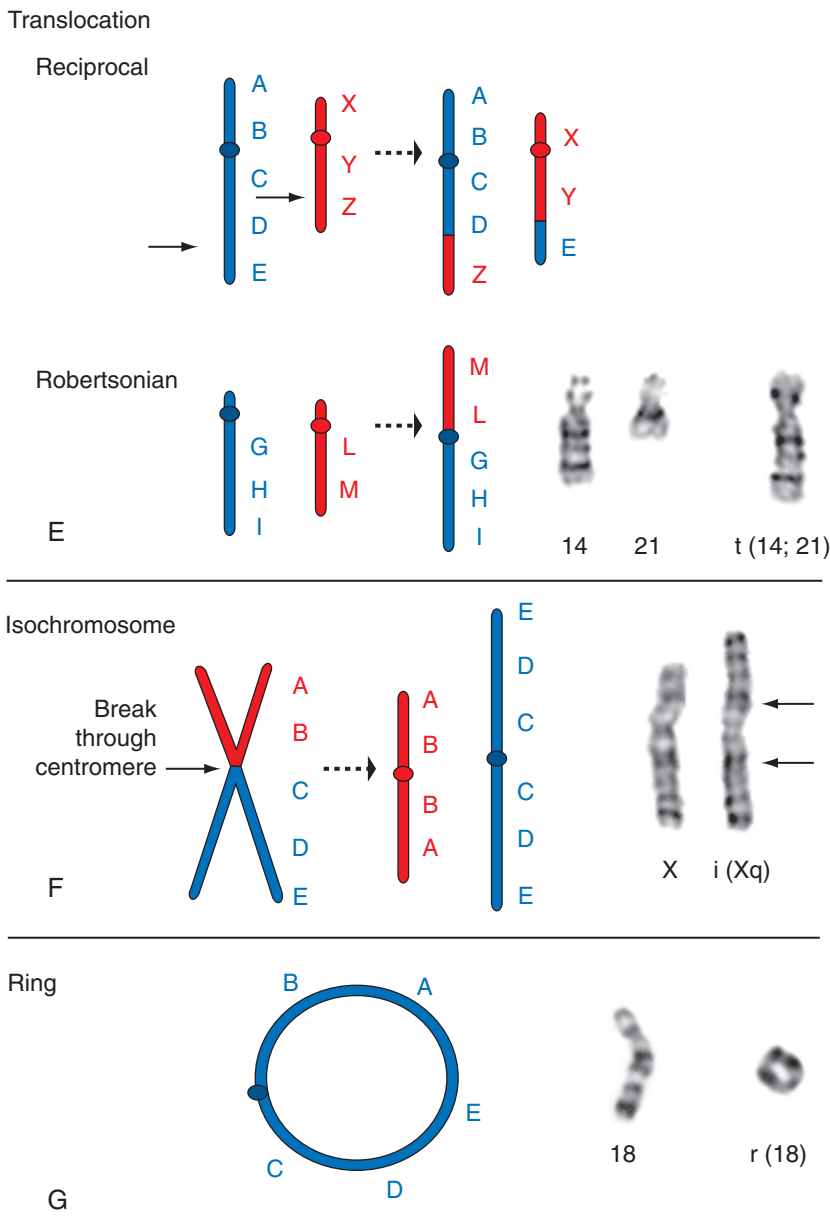

Figure 68-14, cont'd E, Translocation: Reciprocal translocation, where the E and Z loci exchange places. Below is a Robertsonian translocation shown by the fusion of two acrocentric chromosomes at the centromere. Example: Chromosomes 14 and 21 followed by the 14;21 Robertsonian translocation. **F**, Isochromosome: Results from a misdivision of the centromere, generating inverted duplications of the long and short arms of the original chromosome. Example: Isochromosome of the long arm of the X chromosome. **G**, Ring chromosome. Example: Chromosome 18 and ring 18.

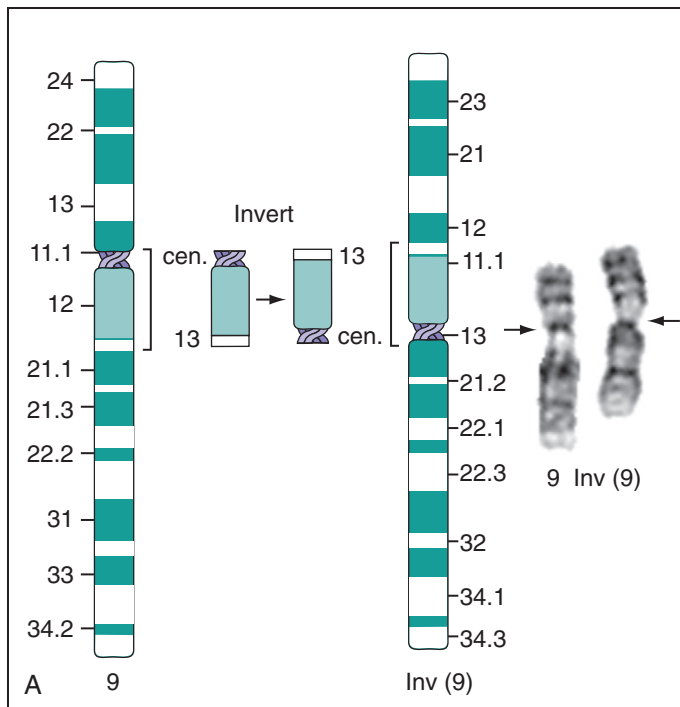

Figure 68-15 Chromosome inversion. **A**, Diagram of a pericentric inversion of chromosome 9 using ideograms to illustrate the mechanism of inversion. Banded chromosomes demonstrating this inversion are shown to the right. **B**, Inversion loop showing the pairing of homologs in meiosis for one normal chromosome (dark green) and one with a paracentric inversion (light green). If recombination occurs at the point indicated by the X in the loop, recombinant chromosomes would be generated as shown at the bottom. In the case of a paracentric inversion, the recombinant chromosomes produced would be either dicentric or acentric.

Figure 68-16 Chromosome translocation. Generation of gametes from a hypothetical translocation in meiosis is diagrammed. The chromosomes pair in a cross-shaped configuration in meiosis I. Alternate segregation will result in balanced gametes. Adjacent 1, adjacent 2, or 3:1 segregation will produce unbalanced gametes, which may give rise to an abnormal liveborn child. (Only one of several possible 3:1 segregations is shown.)

Figure 68-17 Pedigree and banded chromosomes showing inheritance of a Robertsonian translocation of chromosomes 13 and 14. The mother carries the 13;14 translocation in a balanced form, but a meiotic error results in the transmission of both the Robertsonian translocation chromosome and the chromosome 13 from the mother to the child. The child has trisomy 13 and the Robertsonian translocation. Note: The second copy of chromosome 14 is not missing, but is present as part of the Robertsonian rearrangement. *M*, maternal chromosomes; *P*, paternal chromosomes.

apparently normal female would be coded as 46,XX and a male would be 46,XY. If two or more cell lines are present, they are listed sequentially, separated by a slant line, with a normal diploid clone, if present, always listed last (45,X/46,XX). Other clones are ordered by size, with the largest clone placed first. The number of cells in each clone is indicated by a number enclosed in brackets (45,X[15]/47,XXX[3]/46,XX[12]). For numerical anomalies, the total number of chromosomes would be increased or decreased to indicate the overall change, and the specific chromosome gained or lost would be noted at the end. For example, trisomy 13 in a female would be written as 47,XX,+13, and monosomy 8 in a male would be written 45,XY,-8. However, for a sex chromosome variation that is known to be constitutional, it is not necessary to use a + or - sign, because the change in chromosome complement can be noted directly. Monosomy X becomes 45,X and gain of a sex chromosome would be 47,XXX, or 47,XYY. On the other hand, if the sex chromosome change is acquired, as in some cancer cell lines, a + or - indicating this would be required (e.g., 45,X,-Y for a male whose Y chromosome has been lost as a result of his disease).

Structural changes in the chromosomes usually do not affect the total number of chromosomes present but should be noted at the end of the nomenclature to clarify the status of the rearranged chromosomes. In order to streamline the nomenclature, a series of abbreviations for the common structural anomalies has been generated that shortens the overall nomenclature (Table 68-1). A structural abnormality is indicated by the abbreviation of the abnormality followed by the chromosome involved and breakpoints on the chromosome. For rearrangements in which two chromosomes are involved, a first set of parentheses gives the chromosomes (lowest numbered or sex chromosome first) followed by the breakpoints of the rearrangement in the same relative order; that is, t(4;9)(q21.2;p22) is a translocation between chromosomes 4 and 9 with breakpoints 4q21.2 and 9p22.

Examples include the following:

Deletion:	46,XX,del(4)(p15)	Terminal deletion of the short arm of 4 at band 15
Duplication:	46,XX,dup(11)(q13q23)	Interstitial duplication of the long arm of 11 involving the region from q13 to q23
Translocation:	46,XY,t(4;9)(q21.2;p22)	Translocation between 4q and 9p
Inversion:	46,XY,inv(9)(p11q21.1)	Pericentric inversion in 9 between bands p11 and q21.1

“language” has been evolving ever since. Currently, the International System of Cytogenetic Nomenclature is recognized as the standard.

The nomenclature describing a chromosome complement can be broken down into three basic parts: (1) the total number of chromosomes, (2) the sex chromosome complement, and (3) any chromosome abnormalities. These units are listed in order, separated by commas. So, an

CLINICAL

CLINICAL APPLICATIONS

Cytogenetic abnormalities may be found in apparently normal individuals as well as in patients with phenotypic anomalies or with a diagnosed genetic disorder. Diagnosis may occur at any stage of life. When the same set of features is seen in several unrelated individuals, it may be possible to establish a syndrome. The characteristics associated with a syndrome are assumed to have a common basis, which can often be shown to be a specific chromosome abnormality. However, although a syndrome is defined by a certain set of characters, there is variability in affected individuals and not all will show an identical phenotype.

Prenatal Cytogenetics

Studies have shown that 1 in 13 conceptuses has a chromosomal abnormality, but, of these, only 6 in 1000 are live born, indicating that most errors are recognized and biologically eliminated. For example, of all 45,X conceptions, 95% will spontaneously terminate. Similar frequencies of termination are recorded for the liveborn trisomies (90% of trisomy 13 conceptions, 80% of trisomy 18 conceptions, and 65% of trisomy 21 conceptions terminate). On average, 15% of all recognized pregnancies end in a spontaneous fetal loss, with 80% of these occurring in the first trimester. Of all spontaneous abortions, 60% are chromosomally abnormal (Table 68-2), and of these, 52% are autosomal trisomies. The most common trisomy seen in abortus material is trisomy 16, but the most frequent class of chromosome error in spontaneous losses is 45,X.

One of the most important statistics is the direct correlation between advanced maternal age and births with chromosomal abnormalities. Although the exact reason for the phenomenon is unclear, population studies have shown that women older than age 35 years have an increased risk for a chromosomally abnormal conception (Hassold, 1985) with the most common abnormality being Down syndrome (trisomy 21) (see Figs. 68-10, B, and 68-18). This becomes important in a society in which women are delaying childbearing until later in life, so prenatal diagnosis has become a major area of clinical cytogenetic study. In addition to screening

for an age-related risk, other common reasons for referral include a family history of or previous child with a chromosome abnormality, abnormal levels of AFP in a screening test, and an abnormality detected on ultrasound.

The most common chromosome abnormalities detected in prenatal testing are the liveborn trisomies and the sex chromosome aneuploidies. Because these are usually the result of a meiotic nondisjunction error, there is a very low risk of recurrence. Occasionally, a child with a balanced or unbalanced structural chromosome abnormality will be identified. In these circumstances, karyotype analysis on both biological parents is used to differentiate between an inherited rearrangement and a *de novo* anomaly in the child. For example, a child with an inherited balanced translocation has a less than 1% risk that the chromosome rearrangement will pose any problem. However, if the apparently balanced translocation seen in the fetus is not detected in either biological parent, it must have arisen *de novo* in the child, and there is a 5%–10% risk of related impairment for the infant. Unfortunately, finding an *unbalanced* translocation in a fetus, regardless of the carrier status of the parents, is a serious situation and almost always results in some type of genetic defect for the child. Follow-up to determine whether one of the parents is a balanced translocation carrier will provide information about recurrence risk for future pregnancies.

Postnatal

Approximately 0.6% of newborns have a chromosome abnormality. If an infant presents with signs or symptoms of a defined syndrome, karyotype analysis may confirm a diagnosis. If the newborn has clinical anomalies unrelated to a specific disorder, karyotype analysis may

TABLE 68-1

Common Abbreviations for Chromosome Abnormalities

Abbreviation	Meaning

Chromosome Abnormalities in Spontaneous Fetal Losses and in Liveborn Infants

Abnormality	Chromosome	Spontaneous fetal losses (%)	Incidence in live births
45,X		18.0	1/4000
Triploidy		17.0	1/60000
Tetraploid		6.0	0
Trisomy	16	16.4	0
	22	5.7	0
	21	4.7	1/830
	15	4.2	0
	14	3.7	0
	18	3.0	1/7500
	13	2.0	1/5000
	Other	12.3	1/10000
Unbalanced rearrangement		3.0	1/2000
Balanced rearrangement		4.0	3/1000

Data from Hook, 1977; Jacobs, 1992; Nussbaum, 2009; Turnpenny, 2005.

Figure 68-18 Increased risk of a Down syndrome conception with increased maternal age. The number of live births is lower at older ages due to the intervention of prenatal diagnosis followed by termination of abnormal pregnancies.

provide information on a chromosome abnormality related to the clinical findings. Ambiguous genitalia may be related to an abnormal sex chromosome complement, but, if the chromosomes are shown to be normal, the physician knows that another cause for the patient's abnormality must be sought. If the child dies shortly after birth, cytogenetic analysis may provide information critical in understanding the demise, and these data should be correlated with autopsy results to substantiate a diagnosis.

Childhood and Adult

A common misconception about genetic disorders is that, because they are inherited, the diagnosis will be obvious at birth. In fact, the full clinical presentation of many disorders takes time to develop and may not be fully expressed until later in life. Consequently, some of the most difficult diagnostic problems occur in children and adults. In addition to considering the full range of cytogenetic possibilities, molecular and biochemical options must also be taken into account.

CANCER GENETICS

Another area of medicine in which cytogenetics is increasingly important is oncology. Although most solid tumors are difficult to culture and analyze cytogenetically, excellent clinical data exist for leukemias and lymphomas, including specific chromosome rearrangements that are directly associated with tumorigenesis (Table 68-3) (see Chapter 75) (Block, 1999). Karyotype findings were originally used primarily as confirmation of a clinical diagnosis, but the role of genetics in patient management changed dramatically in 2001 when the World Health Organization (WHO) published a revised classification for leukemias and lymphomas (Swerdlow, 2008). The new methodology is based on data collected by clinical study groups that had shown a direct correlation between the presence of various chromosomal abnormalities and patients' response to therapy. Thus, in the revised classification system, the importance of the genetic findings, either cytogenetic or molecular, became a key element for final diagnosis in most hematologic disorders. Cytogenetics had suddenly been pushed to the forefront of testing for oncology patients.

In addition to diagnosis, karyotype analysis can provide other valuable information regarding a cancer patient's disease. Once a chromosome abnormality has been detected, the progress of the disease can be monitored. If treatment is successful, most chromosome abnormalities are no longer evident in the bone marrow and, as long as the karyotype appears to be "normal," the patient is said to be in cytogenetic remission. However, if the treatment does not eliminate the aberrant cell line completely, remission may be merely an interlude in which the disease-causing cells are suppressed to such low levels that they are not detectable by routine karyotype analysis. Then at relapse, the same chromosome anomalies will reappear and may be accompanied by additional abnormalities and/or more complex cell lines, findings consistent with disease progression. An increase in complexity over time is known as *karyotype evolution*. In general, poor prognosis and severity of disease is directly correlated to the number and type of chromosome abnormalities seen.

FISH has become a valuable tool in clinical oncology studies with many probes commercially available (Cremer, 1988; Anastasi, 1991). Studies can be done on either interphase or metaphase cells, with the choice resting on the type of data desired. Using interphase cells is often preferred because it provides a much larger sample that can be quickly assayed, giving results with a higher level of statistical significance (Werner, 1997).

For translocations, combination FISH probes have been developed that hybridize to the opposite sides of the translocation breakpoints. There are two common strategies employed to detect a translocation. Splitting of the signals may occur if the translocation separates two probes, generating two different-colored signals in place of the original single-color signal. Alternatively, fusion may occur if the translocation results in relocation of the probes, bringing two different probes into proximity and generating a two-color fusion that creates a new color. For example, FISH fusion technology has been used to identify the 9;22 translocation in leukemia. This rearrangement is characterized by a translocation between the *ABL* proto-oncogene on chromosome 9 (9q34.1) and the *BCR* gene on chromosome 22 (22q11.2) (Fig. 68-19, A), which produces a disease-associated chimeric gene on the derivative chromosome 22, also known as the *Philadelphia chromosome* (Ph') (see also Chapter 75). The translocation is seen in chronic myelogenous leukemia (CML), acute myeloid leukemia (AML), and acute lymphoblastic leukemia (ALL) (see Table 68-3), and, cytogenetically, it appears to be the same in all diseases. However, at the molecular level, the translocation can be separated into two classes: (1) the major breakpoint

(*M-BCR*) rearrangement that results in a chimeric protein of 210 kD (most common in CML) and (2) the minor breakpoint (*m-BCR*) rearrangement that results in a chimeric protein of 190 kD (seen in some adults and about 50% of childhood ALL). A FISH assay has been engineered to detect both rearrangements (Abbott Molecular). A pair of probes is used: (1) red—localized to the *ABL* locus on chromosome 9, and (2) green—located at the *BCR* locus (chromosome 22) encompassing the m-BCR breakpoint but proximal to the M-BCR breakpoint. When no translocation is present, two green signals (detecting each *ABL* allele) and two red signals (detecting each *BCR* allele) should be present in each cell (see Fig. 68-19, B and C). When the M-BCR rearrangement occurs, the translocation breaks chromosome 22 distal to the probe recognition site such that the entire green signal remains on chromosome 22. On chromosome 9, the translocation splits the red *ABL* signal such that a small red signal is left on the derivative chromosome 9 and the remainder of the red signal moves to chromosome 22. This brings one green and one red signal adjacent to one another on the derivative chromosome 22 (Ph'), and, with the resolution of the light microscope, the two signals merge, giving a single yellow fusion signal. Therefore, a cell with a M-BCR translocation will have four signals: one green (chromosome 22), one large red (chromosome 9), one small red (the rearranged chromosome 9), and one yellow fusion signal detecting the Ph' chromosome (see Fig. 68-19, B and D). The m-BCR rearrangement is slightly different. Chromosome 22 is broken within the green probe recognition site, such that one portion of the green signal will stay on chromosome 22 but the distal section will move to the derivative chromosome 9. The red probe site on chromosome 9 is split as described earlier, with one portion remaining on chromosome 9 and the distal section moving to chromosome 22. This reciprocal translocation thus results in two yellow fusion signals (derivative 9 is red fused to green, and derivative 22 is green fused to red). The net result of the m-BCR FISH assay is four probe signals: one green (chromosome 22), one red (chromosome 9), and two yellow fusion signals detecting the 9;22 translocation (see Figs. 68-19, B and E). Being able to determine which of the two rearrangements is present in a patient sample simplifies the diagnosis and leads to the most appropriate treatment methodology for the individual. Other FISH detection assays using other disease gene specific probes can be designed to evaluate for a wide array of different cancer related chromosome rearrangements.

In addition, chromosomal aneuploidies in cancer cells can be easily detected. For example: (1) use of a chromosome 12-specific centromere probe to screen an interphase cell population for trisomy 12 cells indicative of CLL, (2) use of a chromosome 7 probe to detect monosomy 7 in myelodysplastic syndrome and AML, and (3) use of a chromosome 8 probe to identify trisomy 8 in both chronic and acute disorders. The use of different-colored X and Y probes in evaluating the success of a bone marrow transplant when the donor and recipient are of opposite sexes has also been highly successful. Following transplantation, a male who has received female donor cells should have an XX complement. Failure of the engraftment may be signaled by the presence of a high frequency of XY cells. The FISH can be repeated at regular intervals to monitor the progress and provide an early warning if the patient's leukemic cell population begins to proliferate.

Initially, clinicians were concerned about apparently discrepant results from karyotype analysis and FISH on the same patient sample. For example, by karyotype, a patient with CML may show all cells with a t(9;22), but only 30% of cells will be positive for the translocation by interphase FISH. These data are actually consistent. Karyotype can only be performed on dividing cells and, because cancer cells tend to divide frequently, a karyotype analysis would typically show 100% leukemic cells. FISH, on the other hand, detects all nucleated cells, but not all cells in a bone marrow sample are necessarily from the same clone. An affected individual usually also has a normal cell population. Interphase FISH can quantify the relative numbers of normal and disease cells, thus providing a more accurate estimate of disease involvement within the total population. This can be used advantageously to monitor a patient's response to treatment. Testing sequential samples over time can show a reduction in the disease cell population, and relapse will be reflected by a rise in the leukemic cell population. Thus, it is important to perform both karyotype analysis and FISH on a diagnosis specimen. The karyotype will define the chromosomal abnormalities present, and the FISH will establish the baseline frequency of the leukemic clone(s). These data can then be used as a reference point for all future testing for the patient.

Multicolor FISH has also been used to evaluate leukemic cell lines. The data being collected suggest that cancer cells actually undergo a significantly greater degree of chromosome rearrangement than was

TABLE 68-3

Common Cytogenetic Rearrangements in Leukemia and Lymphoma

previously appreciated. It is hoped that some of the new rearrangements being detected will give clues to new cancer-related genes (Veldman, 1997).

CYTOGENETIC DISORDERS

Chromosomal Aneuploidy Syndromes

Autosomal Aneuploidies

The most common cause of mental retardation is trisomy 21, or Down syndrome. This disorder has a birth incidence of 1 in 700 and is

characterized by hypotonia, flat facies, slanted palpebral fissures, small ears, protruding tongue, transverse palmar crease, heart defects, and hypogonadism. Approximately 92.5% of all Down syndrome individuals have 47 chromosomes including three copies of chromosome 21 resulting from a nondisjunction error in parental meiosis. Just under 3% of patients tend to express a milder phenotype and have been shown to be mosaics with two cell lines (47,XX,+21/46,XX or 47,XY,+21/46,XY), and about 5% of Down syndrome patients have only 46 chromosomes, because the extra 21 is part of a Robertsonian or other translocation. A child with a translocation is often indicative of the presence of a translocation carrier parent, so, in these cases, karyotype analysis of both parents is appropriate to

Figure 68-19 Fluorescence in situ hybridization (FISH) detection of the 9;22 translocation in CML. **A**, Banded chromosomes showing the 9;22 translocation. The derivative chromosome 22 is known as the *Ph'*, or *Philadelphia chromosome*. **B**, Diagram showing FISH detection for a normal cell with no translocation (*left*) and for both the major (M-BCR) and minor (m-BCR) breakpoint rearrangements. Upper right shows the signal pattern for the M-BCR translocation: chr. 9—red signal, der(9)—partial red signal with chromosome 22 material below (yellow) (*dashed arrow*), chr. 22—green signal, and the der(22), the *Ph'* chromosome with a green-red BCR-ABL fusion signal and chromosome 9 material below. The lower right shows the m-BCR signal pattern: chr. 9—red signal, der(9)—red-green fusion signal and chromosome 22 material below, chr. 22—green signal, and the der(22)—green-red fusion signal with chromosome 9 material below. **C** and **D**, Actual FISH images. **C**, No translocation is present as seen by two copies each of the chromosome 9 (red) and chromosome 22 (green) probes in both interphase (*left*) and metaphase (*right*) cells. **D**, Cells with a M-BCR translocation as detected by the single yellow fusion signal (*arrow*) plus one green, one large red, and one small red signal (metaphase on the *left* and interphase on the *right*). **E**, Cells with an m-BCR translocation as detected by two yellow fusion signals (*arrows*) plus one green and one red signal (metaphase on the *right* and interphase on the *left*). CML, Chronic myeloid leukemia.

determine whether the couple is at increased risk for having additional Down syndrome children in future pregnancies. Although it is most common for a Down syndrome patient to have three complete copies of chromosome 21, molecular studies of individuals with chromosome 21 rearrangements have clearly shown that it is only necessary to have three copies of the region of chromosome 21 encompassing bands 21q22.12–21q22.3, the Down syndrome critical region (Fig. 68-20) (Korenberg, 1990; Delabar, 1993).

The other two liveborn trisomies are trisomy 13 and trisomy 18. *Trisomy 13*, or Patau syndrome, with a birth incidence of 1 in 4000 to 1 in 10,000, is characterized by a small head, cleft lip and/or cleft palate, cyclopia, transverse palmar crease, polydactyly of the hands and/or feet, prominent heel, ventricular septal defect, and punched-out scalp.

Trisomy 18, or Edwards syndrome (Fig. 68-21, *A*), is seen in approximately 1 in 8000 newborns with features including a low birth weight, small mouth and jaw, ventricular septal defect, hypoplasia of the muscles, a prominent occiput, low-set malformed ears, rocker bottom feet, and crossed fingers.

Despite its often severe clinical consequences, Down syndrome is usually manageable, and patients live into the second or third decade of life. Trisomy 13 and trisomy 18 are considerably less compatible with life, and patients usually die within the first month of life. If an individual survives the first year, the outlook is bleak, because patients do not learn to talk, walk, or care for themselves. Because of this, counseling for prenatally diagnosed cases of trisomy 13 and 18 includes the option of termination of pregnancy.

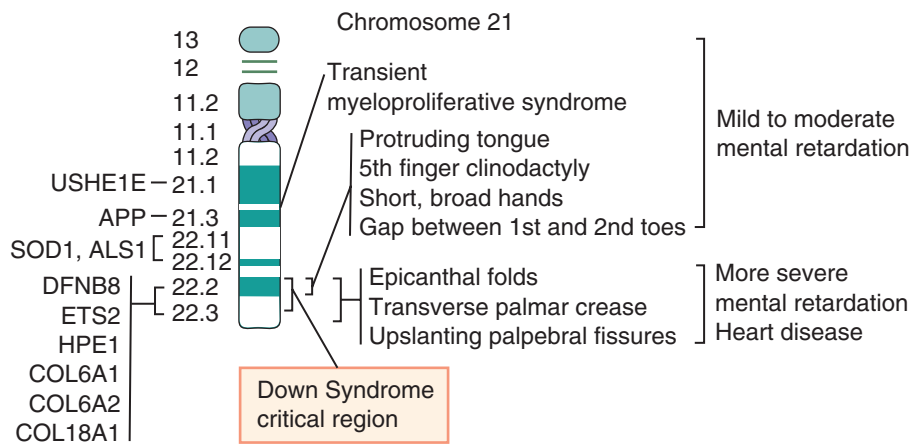

Figure 68-20 Map of chromosome 21 showing the Down syndrome critical region and relative positions of loci associated with various clinical features to the right. On the left, other mapped loci are shown. Sex Chromosome Aneuploidies

Sex chromosome aneuploidies are relatively common (overall frequency of 1 in 500 births), and are phenotypically milder than autosomal aneuploidies because of the effect of X inactivation and the limited number of genes present on the Y chromosome. Four disorders, including three trisomies and one monosomy, account for the majority of cases. All are the result of nondisjunction errors in meiosis and, except for XYY, which is exclusively paternal, the other disorders may result from either maternal or paternal error.

The aberrant karyotypes of individuals with three X chromosomes (47,XXX females) or with one X and two Y chromosomes (47,XYY males) often go undetected throughout life. The birth incidence is relatively high, 1 in 1000, but other than being somewhat taller than average, there are no striking features that would indicate a chromosomal abnormality. Some individuals have generalized learning difficulties and so may be identified by school screening programs. XXX females and XYY males are also detected in infertility clinics, although the cytogenetic abnormality is not related to the reason for referral, because comprehensive evaluations have shown that these individuals are fully fertile and generally have chromosomally normal children. XYY males do have an increased risk of behavioral problems, and early studies suggested that they also had criminal tendencies because there was a higher than expected incidence of XYY in inmates of penal institutions (Jacobs, 1968; Price, 1970). However, subsequent work has shown that (1) the conclusions of the original study were biased because of a sampling error, (2) criminality is most probably due to a combination of multiple causes, and (3) XYY males are no more prone to a criminal behavior than any other male (Witkin, 1976; Pitcher, 1982; Theilgaard, 1984).

Klinefelter syndrome (47,XXY) males tend to be tall and thin with relatively long legs, although early in life these findings seldom set them apart from their peers. Some individuals are identified in school because of their learning difficulties but the most common reason for referral is postpubertal hypogonadism, female-like breast development, and infertility due to small testicles, hyalinized testicular tubules, and azoospermia. A milder form of Klinefelter syndrome with the potential for fertility due to normal testicular development is seen in individuals with a mosaic chromosome complement including a 46,XY cell line (47,XXY/46,XY). The relative proportion of XY and XXY cells during sex determination in the early zygote and in the testes is the key for fertility. An excess of XXY cells will push the individual toward a true Klinefelter presentation, whereas higher numbers of XY cells should moderate the phenotype and increase the likelihood of fertility.

The most commonly recognized sex chromosome aneuploidy presenting with a female phenotype is 45,X: *Turner syndrome* (Fig. 68-21, B). In sex determination, normal female development is dependent on the presence of two active X chromosomes. The critical region for female differentiation has been narrowed to a region of the short arm of the X just proximal to the centromere. If that region is missing or inactive, an individual with Turner syndrome will result. About half of all Turner syndrome patients have the classic 45,X chromosome complement, which represents the only viable liveborn monosomy. The single X chromosome is usually maternal in origin, indicating that a paternal meiotic nondisjunction is the most common source of error. In addition to 45,X, more complex karyotypes are also possible (Table 68-4) (Palmer, 1976). The greatest concern is for individuals who possess a complete or partial Y chromosome in at least one cell line, who are at increased risk for gonadoblastoma.

TABLE 68-4

Distribution of Different Chromosome Complements That Give Rise to Turner Syndrome

Occurrence (%)	Chromosome anomaly
50	45,X
20	46,X,i(Xq)
15	X chromosome deletions or rings, or the presence of a Y chromosome
10	Mosaics: 45,X/46,XX; 45,X/46,XY

Figure 68-22 Diagram of relative locations of TDF, SRY, and the pseudoautosomal regions of the X and Y chromosomes. TDF, Testes determining factor; SRY, sex-determining region of the Y chromosome.

The phenotype for Turner syndrome is highly variable. Affected individuals are typically short (<150 cm) with gonadal dysgenesis and learning difficulties. Other common features include webbed neck resulting from cystic hygroma in utero, low posterior hairline, heart and renal anomalies, cubitus valgus (increased carrying angle of the elbow), and shield chest. At birth, patients may present with edema of the hands and feet. Turner syndrome patients are usually of normal intelligence, although this can vary and some individuals have significant mental handicaps. Furthermore, although infertility used to be accepted as the standard in Turner syndrome, it is now known that some patients, usually those with mosaic karyotypes, can reproduce successfully. Furthermore, using donor egg technologies, a Turner syndrome patient can complete a full pregnancy and deliver a normal child. Therefore, because of this great diversity of presentation, prenatal counseling for a couple with an identified Turner syndrome fetus is extremely difficult. In general, however, most liveborn Turner syndrome patients can live productive lives, and mildly affected individuals may not know that they are affected with the disorder until puberty.

Other Sex Chromosome Abnormalities

Sex determination in humans is the result of a complex biochemical pathway involving the interaction of proteins produced by genes present on the autosomes and the X and Y chromosomes. The default sex in humans is female, so in the absence of any male-determining stimuli, a female individual will develop. The primary trigger for male development is a gene located on the short arm of the Y chromosome designated *TDF*, the testes determining factor, which is located in the sex-determining region of the Y chromosome (*SRY*) (Fig. 68-22).

The protein produced by *TDF* initiates the male developmental pathway. A number of disorders associated with mutations in different genes within this pathway have been identified and can result in ambiguous

genitalia or genotype/phenotype mismatch (phenotypic male with an XX sex chromosome complement or a phenotypic female with an XY complement).

An XX male can usually be attributed to one of two causes. The more common of the two is virilization of a female fetus as a result of the autosomal recessive disorder congenital adrenal hyperplasia (CAH). The defect in CAH is the lack of the enzyme 21-hydroxylase. Without this enzyme, the normal biosynthetic pathway is blocked and androgens accumulate in the body. Excessive levels of male hormones in the female circulation may result in a male-appearing infant despite a female chromosome complement. Furthermore, because androgens are capable of crossing the placenta, a normal female fetus may develop ambiguous genitalia due to exposure from excess hormones from a CAH-affected mother.

A phenotypic male with an XX sex chromosome complement may also result from a cryptic translocation between the X and Y chromosomes. The distal ends of the short arms of the X and Y chromosomes are homologous and comprise what is termed the *pseudoautosomal regions* (see Fig. 68-22). This is the primary site of X and Y chromosome pairing during meiosis, and recombination may occur between X and Y alleles. Rarely, a recombination event outside the boundaries of the pseudoautosomal region takes place, resulting in the transfer of unique Y loci, including *SRY*, to the tip of the X chromosome. The amount of chromosome material involved in such an exchange is extremely small and cannot be cytogenetically detected. In a male with such a balanced translocation, there would be no clinical abnormalities, because the genes are all present, although in alternate locations. However, if this male transmits his rearranged X chromosome to an offspring who has received an X from the mother, the resultant child will have an apparent XX chromosome complement but a male or Klinefelter male phenotype due to the presence of the TDF protein that triggers the male developmental pathway.

The reciprocal of the aforementioned translocation may result in a Turner female with an apparent XY complement. The male developmental pathway will not be initiated in an individual with a Y chromosome that has no *TDF/SRY*, and sex determination will default to female. However, the lack of two intact copies of the proximal X short arm will prevent normal female development, and a Turner syndrome individual should result. This situation is quite rare. The more common finding for an XY female is androgen insensitivity, also known as *testicular feminization*. In these individuals, the Y chromosome is intact, and *TDF* is present and functional. The problem is a mutation of the androgen receptor gene located on the long arm of the X chromosome (Xq21.3) that results in no androgen receptor protein being produced. The TDF protein will initiate male development, but the pathway will be blocked at the point where the androgen receptor protein is required to form a complex between testosterone and dihydrotestosterone. Without this critical step, further male differentiation is not possible, and the phenotype will default back to female. However, these individuals are infertile because of the lack of any functional internal genitalia, and commonly present with a blind vagina and testes in the abdomen or inguinal canal.

Structural Chromosome Abnormalities

A reasonable number of syndromes directly related to a structural chromosome abnormality have been described. Most of these are quite rare. The following is a discussion of some of the more common syndromes (see also Jones, 2006).

Wolf-Hirschhorn syndrome, also known as *4p- syndrome*, is due to a terminal deletion of the short arm of chromosome 4, del(4)(p16). Clinical findings include microcephaly, micrognathia, hypotonia, epicanthal folds, and developmental delay. The characteristic facial appearance has been likened to a Greek warrior's helmet because of the arched eyebrows and long nose. Individuals with this disorder require special education and are at increased risk of seizures.

Cri-du-chat, or 5p- syndrome, del(5)(p15), is characterized by a distinctive high-pitched, catlike cry in infancy. Other features include low birth weight and subsequent slow growth, hypotonia, microcephaly, hypertelorism, epicanthal folds, cardiac anomalies, and mental retardation. Affected children have delayed development and may reach the cognitive and social level of a 5- or 6-year-old.

Microdeletion Syndromes and Contiguous Gene Syndromes

By definition, a microdeletion is a very small deletion, usually only a fraction of a single chromosome band. Microdeletions can be confused with

TABLE 68-5

Microdeletion and Contiguous Gene Syndromes

Disorder	Location	Genes	Clinical findings
Angelman syndrome	15q11.2	<i>UBE3A</i>	Severe MR, developmental delay, large mouth, prognathia, ataxia, seizures DiGeorge syndrome
DiGeorge syndrome	22q11.2, 10p	<i>DGS1, DGS2</i>	Characteristic facies, cleft palate, heart defect, hypoplasia of the thymus and parathyroids, severe hypocalcemia, seizures
Ichthyosis	Xp22.32	<i>STS</i>	Scaly skin, short stature, hypogonadism, MR
Kallmann syndrome	Xp22.3	<i>KAL1</i>	Hypogonadism, inability to smell
Langer-Giedion syndrome	8q24.11–q24.13	<i>TRPSI</i> <i>TRPSII</i> <i>EXT</i>	Craniofacial dysmorphism, skeletal abnormalities, mild to severe mental deficiency
Lissencephaly	17p13.3	<i>LIS1</i>	Smooth brain, profound retardation, seizures
Miller-Dieker syndrome	17p13.3	<i>LIS1</i> and other(s)	Lissencephaly, microcephaly, high forehead, small nose, micrognathia, low-set ears
Prader-Willi syndrome	15q11.2	<i>SNRPN</i>	Hypotonia at birth, almond-shaped eyes, moderate to severe MR, absent sense of satiation leading to overeating, small hands and feet, hypogonadism
Retinoblastoma	13q14.1–q14.2	<i>Rb1</i>	Tumors of the retinoblast cells of the eye
Rubinstein-Taybi syndrome	16p13.3	<i>CBP</i>	Beaked nose, prominent columella, hypoplastic maxilla, downslanted palpebral fissures, broad thumbs and first toes, MR, speech delay
Smith-Magenis syndrome	17p11.2		Brachycephaly, midface hypoplasia, broad nasal bridge, prominent jaw, short broad hands, hyperactivity, delayed speech, self-destructive behavior, MR
Velocardiofacial syndrome	22q11.2	<i>TBX1</i> and others	Palatal defects, hypoplastic alae nasi with long nose, learning disability, congenital heart disease
WAGR	11p13.3	<i>WT1, PAX6</i>	Wilms tumor, aniridia, genitourinary defects, and mental retardation
Williams syndrome	7q11.2	<i>ELN</i>	Low IQ, hypersensitivity to sound, blue eyes with stellate pattern in the iris, prominent lips, hoarse voice, supravalvular aortic stenosis or other cardiac defect, hypercalcemia, premature aging of the skin

MR, Mental retardation.

molecular deletions, so it is important to recognize that, although microdeletions are small, they are significantly larger (>500 kb) than the typical molecular deletion (1 base pair [bp] to several hundred bp), which can only be resolved by molecular technology (see Chapter 70). The actual size of a microdeletion can vary from patient to patient, and some may be large enough to identify by karyotype analysis, although most will require FISH for detection. Although originally thought to be deletions within single genes, it has now been shown that certain syndromes are actually due to deletions that encompass portions of several adjacent, unrelated genes. The clinical presentation may therefore be a combination of features due to the absence of several different gene products. The size of the deletion and number of genes affected may vary, such that the phenotype expressed may differ significantly between individuals. Collectively, these are called *contiguous gene syndromes*. Included in this group are many of the microdeletion syndromes (Table 68-5) as well as the larger, classic deletion syndromes such as Wolf-Hirschhorn and cri-du-chat.

Miller-Dieker syndrome clearly illustrates the overlap between microdeletion and contiguous gene syndromes. The disorder has been associated with a microdeletion of the distal short arm of chromosome 17 (17p13.3), and the cardinal clinical features are lissencephaly (smooth brain) and craniofacial anomalies. Isolated lissencephaly has also been recognized as an independent entity, so Miller-Dieker syndrome is a more complex presentation that couples the brain defect with characteristic facial features. Molecular analysis has shown there are at least two genes involved in Miller-Dieker syndrome, so it is a true contiguous gene syndrome resulting from a microdeletion. A smaller deletion of the *LIS1* gene only would result in isolated lissencephaly (Ledbetter, 1992).

Prader-Willi syndrome and *Angelman syndrome* are the best-known microdeletion syndromes. Both share the same interstitial deletion of the proximal long arm of chromosome 15, del(15)(q11.2q11.2), but the clinical presentations are significantly different. Prader-Willi patients are small and hypotonic at birth but change within the first year of life and begin to gain weight rapidly. If not placed on a controlled diet, they can become quite obese through overeating. Other characteristics include small hands and feet, hypogonadism, and a bad temper. Although they are developmentally delayed, most do well in special education classes. Because of their temper and difficulty in controlling their diet, Prader-Willi patients may be placed in special group homes that provide the proper environment. Angelman syndrome patients, on the other hand, are severely

mentally retarded. Although they are friendly, they usually cannot carry on a normal conversation, and discourse is often punctuated by bursts of inappropriate laughter. The disorder is also characterized by hyperactivity, short stature, microcephaly, seizures, and ataxia.

By routine or high-resolution cytogenetic analysis, the 15q deletion can be detected in about 60% of Prader-Willi individuals but only 10%–20% of Angelman syndrome patients. Use of FISH has provided a much better diagnostic tool and, for both syndromes, deletions can now be established in 80%–85% of cases. Although it was accepted that not all deletions would be visible at the cytogenetic level, it was considered odd that FISH was unable to detect a deletion in 100% of cases. This, in addition to the fact that Prader-Willi syndrome and Angelman syndrome appear to share the same deletion but have such entirely different phenotypes, suggested that there might be another cause for the disorders. It is now known that Prader-Willi syndrome and Angelman syndrome are examples of genetic imprinting, and that the mutational processes resulting in the diseases are much more complex than a simple deletion of DNA (Nicholls, 1989; Robinson, 1991) (see Chapter 70 for a discussion of imprinting and molecular detection of imprinted genes).

Williams syndrome has been associated with a deletion of the elastin gene (*ELN*) on the proximal long arm of chromosome 7 (7q11.23). The disorder is characterized by cardiac abnormalities, hypertension, hoarse voice, premature aging of the skin, and behavioral anomalies. Since elastin is known to be an important protein lending elasticity to tissues such as the heart, blood vessels, skin, and vocal cords, its absence explains many of the physical anomalies associated with this syndrome. The behavioral problems, however, could not be attributed to the lack of elastin, and further investigations have shown that Williams syndrome is actually a contiguous gene syndrome and that the variability of the phenotype is related to the number of adjacent genes deleted in combination with *ELN*.

A very well characterized contiguous gene syndrome is located on the short arm of chromosome 11 (11p13) and is known as *WAGR* (Wilms tumor, aniridia, genitourinary defects, and mental retardation). Except for the genitourinary defects, which appear to be due to a variant mutation in the Wilms tumor locus, each of the other three anomalies has been associated with a particular gene and these are arranged in tandem on the short arm of chromosome 11 (Fig. 68-23). The phenotype of an affected individual will vary depending on the size of the deletion. Statistically, about one in three children diagnosed with aniridia will also develop Wilms

Figure 68-23 Diagram of the contiguous gene syndrome WAGR showing relative positions of the different genes on the short arm of chromosome 11. WAGR Wilms tumor, aniridia, genitourinary defects, and mental retardation.

Figure 68-24 Diagram of the possible outcomes of mispairing and recombination at the velocardiofacial syndrome locus on chromosome 22 (22q11.2). Two chromosomes that have mispaired by association of repeat sequences are seen in the middle of the figure. Recombination may or may not occur. If it does occur, one outcome is a deletion (seen on the left) resulting from the complete loss of both gene sequences from both original chromosomes (indicated as genes A–C). The reciprocal event would be a tandem repeat of both gene sequences, one derived from each of the original chromosomes (seen on the right).

tumor. Conversely, only one in 50 Wilms patients has aniridia. With larger deletions, mental retardation and genitourinary defects may also be seen.

Velocardiofacial syndrome is possibly the most common microdeletion syndrome in humans but it is often not recognized because it has a broad spectrum of clinical features and a presentation that can be mild. The disorder is usually diagnosed in the newborn period because of feeding difficulties, cardiac defects, and characteristic facial dysmorphologies. Learning disabilities, short stature, and conductive hearing loss are noted as the individual ages. Interestingly, 10%–15% of patients will have a much more mildly affected parent with the same deletion. The 3 Mb deletion on the proximal long arm of chromosome 22 (22q11.2q11.2) is thought to be due to recombination between direct repeats that flank the common deletion region. The similarity in the repeats can result in slippage and mispairing between the chromosomes (Fig. 68-24). If recombination

Figure 68-25 Fragile X. Ideogram of the fragile X (left) and a representative pair of G-banded chromosomes showing the fragile X on the right.

occurs between the misaligned chromosomes, two recombinant products are possible: (1) a chromosome missing the 3 Mb region associated with velocardiofacial syndrome or (2) a chromosome with a duplication of the 3 Mb region. Individuals with the duplication have been identified. Their phenotype is significantly different than that of the velocardiofacial syndrome deletion individuals (McDermid, 2002).

A similar mechanism resulting in the classic Williams syndrome deletion has also been reported (Bayes, 2003). Recombination following mispairing of the chromosomes is a new recognized mutation strategy that could explain deletion formation in a variety of other diseases.

OTHER CYTOGENETIC PHENOMENA

Fragile X Syndrome

Fragile X syndrome is the second leading cause of mental retardation and is the primary cause of inherited mental retardation. The disorder was first described by Herbert Lubs in 1969, when he noted the correlation between retardation and a “marker” X in affected family members (Lubs, 1969). The marker X has subsequently become known as the *fragile X*, a break or gap in the structure of the X chromosome that can be detected cytogenetically (Fig. 68-25) by culturing cells in the appropriate induction medium. However, not all affected individuals express the fragile X cytogenetically, so the clinical test is flawed. Nevertheless, it was the only assay available for many years and provided much-needed confirmation of diagnosis in many individuals. In 1991, the gene associated with fragile X syndrome was cloned and the mutation was identified as an amplification of a trinucleotide repeat sequence, something that had never before been seen or associated as a disease-causing mechanism. This mutation is detectable at the molecular level, and a highly proficient clinical test has been developed to allow direct mutation detection for fragile X syndrome (Rousseau, 1991; Verkerk, 1991) (see Chapter 70), so the cytogenetic test is no longer used.

Breakage Syndromes

Chromosomal breakage syndromes (Table 68-6) are a set of autosomal recessive disorders that were originally grouped together because of the common finding of chromosome instability or fragility (Arlett, 1978). Consequently, cytogenetic testing was possible as an aid in diagnosis. Molecular studies have shown an additional commonality among the disorders in that the primary mutation in each is a defect in a DNA repair gene. This helped explain the other features of the syndromes, because inability to repair the DNA can lead to (1) breakage or increased recombination that can be characterized by chromosome instability and (2) widespread mutation and defect in DNA sequences that can lead to cancer.

SUMMARY

Cytogenetics is a relatively old, labor-intensive laboratory science, and it is still performed in much the same way it always has been, although the advent of the computer-assisted karyotyping system, the robotic harvester,

TABLE 68-6

Chromosome Breakage Syndromes

Disorder	Clinical features	Gene locus	Cytogenetic manifestation	Type of cancer	Dna repair defect	Miscellaneous
Fanconi anemia	Pancytopenia, prenatal or postnatal growth retardation, hypoplastic or missing thumbs, possible arm deformation, brownish pigmentation of skin	1. Group A: 16q24.3 2. Group C: 9q22.3 3. Group D: -3p22-p26 4. Group E—6p21-p22 5. Groups B, F, H unmapped	Increased chromosome breakage detected by treatment with mitomycin C and diepoxybutane	Increased risk of AML, and progressive bone marrow failure		Current therapy: Bone marrow transplantation
Bloom syndrome	Growth retardation, butterfly rash on face, possible malignancy	15q26.1	Increased sister chromatid exchange in response to UV light or BrdU incorporation		Abnormal DNA ligase I activity	High frequency in Ashkenazi Jewish population: 1/110 carrier frequency
Ataxia telangiectasia	Ataxia with degeneration of central nervous system, telangiectasia on face, deficiency in cellular immunity, degenerative, growth retardation	11q22.3	Increased spontaneous breakage, increased rings, triradials, and translocations, particularly with 7 and 14, induced with bleomycin or ionizing radiation	Various leukemias and solid tumors		
Xeroderma pigmentosum	Sensitivity to sun, neurological abnormalities, ataxia and spasticity	Incidence: 1 in 250,000 1. A: 9q22.3 2. C: 653p25 3. D: 19q13.2-q13.3 4. E: 11p11-p12 5. F: 16p13.1-13.2, 16p13.13-p13.3 6. G: 13q33	Increase in SCE and chromosome rearrangement in response to UV light	Increased incidence of skin cancer	1. Lack of excision of thymine dimers 2. Postreplication repair defect	
Cockayne syndrome	Dwarfism, premature aging, microcephaly, neurologic deficit, pigmentary degeneration, deafness, sensitivity to sunlight, MR	Chr. 5	UV sensitivity	Increased incidence of skin cancer	Possible DNA ligase deficiency or defect of transcription coupled repair	

AML, Acute myeloid leukemia; MR, mental retardation; UV, ultraviolet.

and microarray analysis have added an element of advanced technology to the laboratory. Although it was once predicted that molecular diagnostics would eliminate the need for cytogenetics, that has not occurred, and cytogenetics is still the only clinical assay that can provide a quick overview of the entire human genome. Karyotype analysis continues to be important in assessing numerical and structural chromosome anomalies and is the gold standard for diagnosis of many disorders. Determination of the cytogenetic lesion is currently required for diagnosis of many

cancers. To meet new challenges, cytogenetics has added new testing and new technologies. Use of FISH, and more recently microarray technology, have bridged the gap between cytogenetics and molecular diagnostics such that the two areas provide complementary information in many cases. However, despite the technologic advances, nothing has yet been able to replace karyotype analysis as a tool for genomic screening, so cytogenetics continues to hold an important place in clinical laboratory medicine.

SELECTED REFERENCES, 1329

During the past decade, a vast amount of knowledge has been gained regarding genes, gene products, and their role in human disease. This knowledge has allowed us to better understand many disease processes and start defining diseases and disease processes in terms of their molecular pathogenesis. Molecular diagnostics testing is a relatively recent specialty of laboratory medicine and is still in a state of flux at many levels, such as the choice of test, technology, automation and reimbursement. The scope of molecular testing has expanded rapidly since its introduction in the late 1980s. This has led to the development of new clinical molecular assays for use in diagnosis, prognosis, selection of therapeutic modalities, and monitoring of disease. The technologies that constitute molecular diagnostics—such as first-generation amplification, deoxyribonucleic acid (DNA) probes, fluorescent in situ hybridization (FISH), second-generation biochips and microfluidics, next-generation signal detection, biosensors, and molecular labels—are influencing the discovery of therapeutic molecules, the screening and diagnosis of patients, and the optimization of drug therapy. In the past few years, this rapidly evolving field has seen several fascinating developments. There are many applications of this technology to different areas of the clinical laboratory. Whereas testing for inherited genetic diseases, cancer diagnosis, viral load, and infectious diseases continues to predominate, the impact of pharmacogenomics on molecular diagnostics is unknown. The operation of a clinical molecular pathology laboratory requires integration of expertise in medical, scientific, and clinical molecular pathology; resources, including facilities, equipment, and personnel; and skills in organization, administration, management, and communication.

SPECIAL CONSIDERATIONS FOR MOLECULAR DIAGNOSTICS LABORATORIES

Whereas all molecular diagnostics tests share the use of nucleic acid technology, the different clinical applications may require different management considerations.

INFECTIOUS DISEASE

As molecular techniques have become more accepted, more and more microorganisms are detected or characterized by molecular methods, which in many cases have become the standard of practice, especially for microorganisms that are difficult to culture or when subsequent culture is needed to identify drug resistance. As volume of testing has grown, there has arisen a need for automation of different steps of testing as well as the need for standardized kits. We have seen a surge of different automation platforms. Automated platforms perform nucleic acid extraction from different types of specimens, automated liquid handling systems set up reactions, and real-time technology monitors and quantifies nucleic acids as they are being amplified. In addition, quantitative molecular methods have become standard of practice in monitoring response to therapy, especially in patients with human immunodeficiency virus (HIV), hepatitis B virus (HBV), and hepatitis C virus (HCV) infections. The need for confidentiality for patients undergoing HIV testing has prompted specific federal and state regulation to ensure the protection of patients and their families. In addition, each state might have a list of different organisms that, if detected, must be reported to the state health department.

CANCER

Molecular methods are currently used for hematopoietic neoplasms as well as for solid tumors. The nucleic acid changes, either DNA or ribonucleic acid (RNA), are present only in the affected populations of cells and are not part of the genetic makeup of the individual. Current technologies, such as real-time polymerase chain reaction (PCR) and microarray analysis, have provided greater diagnostic sensitivity and specificity for diagnostic testing, prognosis treatment selection, monitoring response to therapy, and detection of minimal residual disease. In addition, the exquisite sensitivity of these molecular methods has allowed the testing of very small amounts of nucleic acid from a wide range of sample types. Formalin-fixed paraffin-embedded tissue can provide good quality and quantity of DNA and RNA from processed tissues; however, very specific protocols either for DNA or RNA extraction must be followed. In contrast to

inherited genetic testing that needs to be done once per lifetime, molecular oncology tests often are performed repeatedly (eg, for initial diagnosis and during and after treatment for monitoring response to therapy). Molecular methods which identify rearrangements or mutations that cause specific tumor types may also be used to assess minimal residual disease. Molecular test results should be interpreted in the context of other laboratory testing, such as histopathology, flow cytometry, and clinical findings. The detection of a specific mutation in the tumor cells may also be used to determine appropriate course of therapy. This is the case for metastatic colon cancer. A number of studies have shown that antiepidermal growth factor receptor (*EGFR*) monoclonal antibodies are effective treatments for metastatic colorectal cancer, but only in patients with wild-type oncogene *KRAS*. The anti-*EGFR* monoclonal antibodies panitumumab and cetuximab are approved in the United States for treatment of metastatic colorectal cancer refractory to chemotherapy but are not recommended for use in patients with mutations in *KRAS* codons 12 or 13. Similarly, panitumumab is approved for the treatment of metastatic colorectal cancer only in patients with wild-type *KRAS* in Europe and Canada. It is clear that *KRAS* mutational analysis has become an important aspect of disease management in patients with metastatic colorectal cancer.

Laboratory issues specific for hematopoietic neoplasms and solid tumor testing include the need for fresh or frozen tissue for RNA-based testing, the use of microdissection to reduce nonmalignant cell population in the specimens, and the need to work with small tissue specimens such as needle biopsies.

INHERITED DISORDERS

All diseases have a genetic contribution, whether it is a specific genetic disease or an increased likelihood for developing a medical condition. Genetic disorders are primarily the result of a germline mutation or a mutation present in every cell of an individual. For this reason, genetic testing has far-reaching implications, because it could affect family members that might have inherited the same mutation. Molecular genetic testing is currently used for diagnosis, carrier status evaluation, and prenatal and presymptomatic DNA testing. Diagnostic testing is usually performed on affected individuals for establishing or confirming a clinical diagnosis.

Carrier testing is performed in an asymptomatic healthy individual to identify whether the individual is a carrier for an autosomal or X-linked recessive condition and whether the individual is at risk for having an affected child. This application can be used for individuals with a family history of a genetic disorder or for population screening, such as in screening for cystic fibrosis (CF). Carrier testing can be done first by testing an affected family member to identify the specific mutation present in the family. Once a specific mutation is identified, family members can be tested for that particular mutation, thus improving the accuracy of the risk assessment for the individuals in that family with a negative test result. In contrast, population screening focuses on the most common or prevalent mutation, most of the time with different rate of detection for different ethnic populations. Prenatal testing is performed to identify a fetus with a genetic disease or condition. Prenatal testing analyzes fetal cells obtained by amniocentesis or by chorionic villus sampling. This type of testing is usually initiated because family history or maternal factors suggest it. In addition, some laboratories offer preimplantation genetic testing in the setting of in vitro fertilization for couples with a family history of a specific genetic disease. Presymptomatic testing is used primarily for the identification of adult onset of a genetic condition that will occur later in life, such as Huntington disease. Presymptomatic testing is the most problematic and challenging type of testing in terms of its psychological effect on the individual and hence requires extensive protocols for pregenetic and post-genetic testing counseling.

Several other issues are of critical relevance. Genetic testing requires special attention to informed consent, appropriateness, and urgency. There are no federal regulations regarding the process of informed consent, but a number of states have specific laws that govern the process of informed consent. Each laboratory director should evaluate state laws to determine what the regulations stipulate. Many laboratories require documentation of informed consent before performing the genetic test. Informed consent can be documented by several means such as requesting the actual signed informed consent or a copy of it, or by confirmation by the physician or health care provider on the requisition that the informed consent was obtained and is documented in the patient's chart. Until required documentation of informed consent is obtained, the laboratory can stabilize the patient specimen, extract and store the nucleic acid. The

laboratory can start the testing once the required documentation is received. In addition to documentation of informed consent, the laboratory should review clinical indications for testing and determine whether the test is appropriate for a specific patient. Despite the tremendous advances in the understanding of the human genome, the full benefit of genetic testing for a particular patient is not always clear. Testing may be warranted, even if the results are inconclusive or preventive strategies or treatments are not available. Genetic information raises critical ethical, legal, and social issues for both the individual being tested as well as for family members. Special attention should be given to genetic testing in minors. For example, should carrier testing of minors be deferred until the minor is an adult? Similarly, a request for testing of an asymptomatic individual for a dominant disease should include arrangements for adequate genetic counseling. In addition, the laboratory should understand and communicate to health care providers the sensitivity and limitations of the test performed so that patients can be counseled appropriately as to the expectations of the testing and the significance of the testing results.

Genetic testing results often require interpretation using complex risk assessment calculations. Health care professionals must correctly interpret laboratory test results in the context of the particular patient and be able to convey the test results and interpretation to the patients and family members. Communication of genetic test results to patients and families can be complex and time-consuming. Clinicians trained in medical genetics as well as genetic counselors are well equipped to communicate the complex and involved information. Benefits of this approach have been well documented in the literature. Misinterpretation of negative genetic test results by inadequately trained physicians may result in inappropriately suggesting that patients discontinue recommended aggressive surveillance for the genetic condition. For these reasons, most genetic testing should be ordered through health care providers trained in genetics to ensure that the benefits and risks of testing have been explained to the patient during the informed consent process.

REGULATION AND REGULATORY AGENCIES

CLINICAL LABORATORY IMPROVEMENT ACTS 1988, 2003

Laboratories performing clinical testing must comply with numerous regulations. Laboratories performing testing on human specimens for the purposes of diagnosis, prevention, or treatment of diseases are subject to federal regulation imposed by Clinical Laboratory Improvement Act of 1988 (CLIA '88). CLIA '88 set standards designed to improve quality in laboratory practices and expanded federal oversight to almost every clinical laboratory in the United States. Laboratories performing research are not subject to CLIA '88 unless the research laboratory reports specific results to the individuals tested, their families, and/or the treating physician, even when there is a disclaimer in the final report that states that the test results should be used for research purposes only and/or there is no charge for the test. CLIA '88 describes specific standards in all areas of the testing process, personnel training, proficiency testing (PT), quality control (QC), and quality assurance (QA). The federal regulation establishes a registry, sanctions, and enforcement procedures to ensure that the standards defined in the federal regulation are maintained. The regulations for implementing CLIA '88 were developed by the Department of Health and Human Services through the Public Health Service. At that time, the Centers for Disease Control and Prevention (CDC) was assigned to categorize analytes and supervise implementation of standards. The U.S. Food and Drug Administration (FDA) was assigned to review and guarantee the safety and effectiveness of tests and the Center for Medicare and Medicaid Services (CMS), formerly known as Health Care Finance Administration, was to collect fees, issue permits, survey laboratories, and initiate sanctions when necessary. Under CLIA '88, tests are categorized as *waived*, *provider-performed microscopy*, *moderate complexity*, and *high complexity*. Tests are placed into moderate and high complexity testing categories on the basis of a numerical scoring system. The scoring system takes into account the following factors: knowledge required for performing the test, training and expertise, availability of calibrators, QC, PT, operational characteristics, degree of interpretation, and judgment, among others. In 2003, new extensively revised CLIA regulations were published and nicknamed *CLIA '03*. The changes include major reorganization and consolidation of the regulations by passing requirements on the flow of a patient sample

through the laboratory and updating the requirements to accommodate new technologies.

All laboratories performing clinical testing must seek CLIA certification. Molecular diagnostics laboratories are considered high complexity laboratories and as such must comply with CLIA requirements for high complexity laboratory testing. Some of these requirements include qualifications of personnel performing and overseeing the testing process procedure manual specifications, method verifications of performance specifications, PT, QA, patient test management, and inspection. CLIA, however, does not provide specific guidelines for molecular testing and therefore each molecular diagnostics laboratory is responsible for the development of a test management program according to CLIA. Recently the CDC published a *Morbidity and Mortality Weekly Report*: “Best practices for molecular genetic testing for heritable diseases and conditions,” which provides detailed recommendations regarding good laboratory practices for ensuring the quality of molecular genetic testing for heritable conditions. The recommended practices address the total testing process including preanalytical, analytical, and postanalytical, laboratory responsibilities regarding authorized persons, confidentiality of patient information, personnel competency, considerations before introducing a new test, and the quality management system approach to molecular genetic testing. The report can be found at www.cdc.gov.

Molecular diagnostic tests are considered high complexity testing and as such laboratories performing this testing must seek certification from CMS. CLIA regulations allow CMS to approve nonprofit professional organizations that have laboratory testing and inspection standards equivalent to or more stringent than CLIA to inspect clinical laboratories in place of a CLIA inspection. The two major organizations providing CLIA inspections are The Joint Commission, which accredits more than 80% of U.S. health care organizations, and the Laboratory Accreditation Program of the College of American Pathologists (LAP-CAP). Most laboratories performing molecular diagnostic testing are CLIA '88 accredited through the LAP-CAP program. When a test site meets the accreditation agency's requirements, as assessed by inspection, the laboratory, meets CLIA requirements and receives a CLIA certificate of accreditation. CAP introduced a molecular pathology checklist in 1993 and it has been updated yearly since then. All laboratories must follow the Laboratory General checklist and the specific laboratory checklist. In addition, the molecular pathology checklist is a great resource when developing a molecular diagnostic laboratory, particularly for the development of QC, QA programs, specimen requisition, and reporting.

GENETIC INFORMATION NONDISCRIMINATION ACT

The Genetic Information Nondiscrimination Act of 2008, also referred to as GINA, is a federal law that prohibits discrimination in health coverage and employment based on genetic information. The law has two titles: title I, relates to health insurance coverage, and title II, relates to employment. GINA took effect in November 2009 and prohibits group and individual health insurers from using a person's genetic information in determining eligibility or premiums; it also prohibits an insurer from requesting or requiring that a person undergo a genetic test. In addition, GINA prohibits employers from using a person's genetic information to make employment decisions such as hiring, firing, job assignments, or any other terms of employment, and it prohibits employers from requesting, requiring, or purchasing genetic information about persons or their family members. GINA does not prevent health care providers from recommending genetic tests to their patients, it does not mandate coverage for any particular test or treatment, it does not prohibit medical underwriting based on current health status, it does not cover life, disability, or long-term-care insurance, and it does not apply to members of the military.

One key term used in GINA is *genetic information*, which includes information about a person's genetic tests (including genetic tests done as part of a research study), genetic tests of a person's family (up to and including fourth-degree relatives), any manifestation of a disease or disorder in a family member, and participation of a person or family member in research that includes genetic testing, counseling, or education. GINA defines *genetic tests* as tests that assess genotypes, mutations, or chromosomal changes. Examples of protected tests are tests for *BRCA1/BRCA2* (breast cancer) or *HNPCC* (colon cancer) mutations, classifications of genetic properties of an existing tumor to help determine therapy, tests for Huntington's disease mutations, and carrier screening for disorders such as CF, sickle cell anemia, spinal muscular atrophy, and the fragile

X syndrome. On the other hand, routine tests such as complete blood counts, cholesterol tests, and liver function tests are not protected under GINA.

Although GINA protects patient information from misuse by insurers, employers, and other administrative agencies, it is important to recognize the stigma test results can have on the patient. Unlike other general laboratory analytes that are accepted in the lay public as routine testing (e.g., cholesterol) for disease stratification or management, carrying a gene often carries an ominous forecast because of the erroneous interpretation that carrying the gene equals manifesting the disease. Genetic counseling is essential for patients to understand what it means to be a “carrier.” The issues relating to disease penetrance, allelic variability, polymorphisms, and confounding factors associated with a given gene must be related to the physician-patient-counselor unit toward appropriate interpretation. Otherwise the psychological well-being of the patient can be drastically affected. Examples of such stigmata include being labeled a genetic carrier for Tay-Sachs, CF, and *BRCA1/BRCA2*, which could affect the patient's decisions pertaining to marriage, family planning, surgical options, and social acceptance.

FOOD AND DRUG ADMINISTRATION

Analyte-Specific Reagents

The term *analyte-specific reagent* (ASR) was devised by the FDA for reagents used in clinical testing that confer specificity for detection of the target analyte. The FDA defines ASRs as “antibodies, monoclonal and polyclonal, specific receptors, proteins, ligands, nucleic acid sequences, and similar reagents which through specific binding or chemical reaction with substances in a specimen are intended for use in a diagnostic application for identification and quantification of an individual chemical substance or ligand in biological specimens.” Primers and probes developed specifically to detect a certain DNA or RNA target used in any laboratory developed assay are considered ASRs. Under this definition, ASRs are not diagnostic tests, nor are they combinations of reagents, controls, disposable labware, or instrumentation provided for the performance of diagnostic tests. Rather, an ASR is a single (albeit key) component, such as a probe or primer pair, in any diagnostic test manufactured anywhere in the world, including in clinical laboratories, in vitro diagnostic (IVD) device manufacturing facilities, and forensic or research laboratories. However, ASRs are only subject to regulation as medical devices when they are purchased by clinical laboratories for use in a laboratory developed test (LDT) or certain IVD tests. As of November 1998, clinical laboratories using laboratory developed assays that contain ASRs must comply with the FDA's final rule on ASRs published in the *Federal Register*. As part of this final rule laboratories are required to include a very specific disclaimer in the reports, stating, “This test was developed and its performance characteristics determined by (laboratory name). It has not been cleared by the U.S. Food and Drug Administration.” But at the same time, the FDA has allowed laboratories to add in the report that ASRs do not require FDA approval, that the test using the particular ASR can be used for clinical purposes, and that the laboratory is certified under CLIA '88 to perform high complexity testing.

In addition to the definition of ASRs, the FDA proposed a set of controls and restrictions to be applied to their use to ensure their quality and consistency and to clarify that laboratories that develop their own assays are responsible for the performance of the test. Interestingly, these controls apply not only to the laboratory developing their own assays that use ASRs, but also to the manufacturers of these reagents. Laboratories are required to meet CLIA '88 high complexity certification requirements and to determine the performance characteristics of the laboratory developed assay following CLIA '88 regulations. Manufacturers of ASRs are required to register with the FDA, to follow good manufacturing practices, and to restrict the sale of this type of reagent to laboratories certified under CLIA for high complexity testing. Manufacturers are also responsible for reporting to the FDA any adverse events as a result of failure in the manufacturing process.

To control the use of ASRs, the FDA imposed a comprehensive set of restrictions. For example, ASRs may only be sold to (1) diagnostic device manufacturers; (2) clinical laboratories that are CLIA certified to perform high complexity testing under 42 CFR Part 493, or clinical laboratories regulated under the Veteran's Health Administration Directive 1106; or (3) organizations that use the reagents to make tests for forensic, academic, research, and other nonclinical (nonmedical) uses. In addition, ASRs may be sold only for use in LDTs that are ordered on a prescription basis.

In Vitro Multivariate Index Assay or IVDMA Draft Guidance

IVD multivariate index assays (IVDMAs) are considered a subset of LDTs that combine multiple variables (e.g., gender, age, weight, clinical lab results) using an interpretation function (e.g., algorithm) to generate a patient-specific result (e.g., score, risk level, classification) for the purpose of diagnosing, treating, or mitigating a disease. In addition, it provides a result whose derivation is nontransparent and cannot be independently derived or verified by the end user. These types of tests are developed based on observed correlations between multivariate data and clinical outcome, such that the clinical validity of the claims is not transparent to patients, laboratorians, and clinicians who order these tests. Additionally, IVDMAs frequently have a high risk intended use. The FDA is concerned that patients are relying upon IVDMAs with high risk intended uses to make critical health care decisions when the FDA has not ensured that the IVDMA has been clinically validated and the health care practitioners are unable to clinically validate the test themselves. The second point of the definition will likely attract the most attention if and when this becomes final. Although individual genetic and proteomic markers have diagnostic and prognostic relevance, the aggregate results obtained for multiple markers should in theory increase the diagnostic, prognostic, or theranostic power over that obtained from the results of one or just a few markers. IVDMAs offer the treating physician a synthesis of multiple results in a simplified form. In this age of mushrooming information, those making treatment decisions eagerly seek simplification and distillation of important facts that are needed to best treat patients. The first draft of the FDA's IVDMA guidance was issued on September 7, 2006, but after much criticism and comments, the FDA issued a revised draft on July 26, 2007. One of the main criticisms of the first draft was the definition of an IVDMA. Determining whether a result is "nontransparent" or "cannot be independently derived or verified" will be challenged by industry. The FDA provided examples of what it perceived to be an IVDMA, but there will almost certainly be controversy over whether a particular test falls inside or outside the FDA's IVDMA definition. The new guidelines include a more detailed definition of what the agency considers an IVDMA and exclude terms *test system* and *algorithm* that were criticized for being too ambiguous in the first version. Additionally, the guidelines clarify the agency's risk-based approach, provide a transition period to test developers during which the agency will exercise enforcement discretion over certain requirements, and include provisions for orphan-disease testing. With this draft guidance document, the FDA seeks to identify IVDMAs as a discrete category of device and to clarify that, even when offered as LDTs, IVDMAs must meet premarket and postmarket device requirements under the Federal Food, Drug, and Cosmetic Act and FDA regulations, including premarket review requirements in the case of most Class II and III devices. Devices that the agency would not consider IVDMAs include tests that interpret multiple variables but that health care providers could otherwise interpret themselves. Examples of products that the FDA identified as being outside the scope of the draft guidance were devices that determine genotype and chromosomal copy number, conduct common clinical calculations, store clinical information, and calculate common, public demographic risk. The current version of the guidelines highlights the FDA's risk-based approach and the increased risks associated with IVDMAs compared with other laboratory-developed tests.

LABORATORY DESIGN AND REQUIREMENTS

The power of molecular diagnostics is derived from the exquisite sensitivity and specificity when using nucleic acid as the analyte. The high sensitivity is derived from in vitro amplification of specific nucleic acid target sequences present in a patient's specimen. In vitro amplification creates millions or billions of copies of the target sequence and thus enables detection of as little as a single target molecule in the patient specimen. At the same time, however, this high sensitivity poses major challenges for the use of this technology in the clinical laboratory. Thus one of the major advantages of this technology is also one of its major limitations. Opening and closing the microcentrifuge tubes containing amplified product can aerosolize microdroplets that can carry 10 to 100 copies of the amplified target sequence. These microdroplets can subsequently be deposited on bench tops, instruments, furniture, floor, dust, hair, exposed skin, virtually any surface. Another important source of contamination is the target nucleic acid itself. Sample handling procedures must always protect against

cross-contamination of patient specimens. Another source of contamination by nucleic acid that is sometimes overlooked occurs from processing patient samples in an environment in which the target nucleic acid has been amplified biologically either by cloning or by culturing of the cell or microorganism. Thus it is necessary to carefully design the molecular diagnostics laboratory to ensure sufficient and adequate space for personnel and equipment but also to minimize the potential problem of specimen contamination with natural nucleic acid or template and/or nucleic acid from in vitro amplification (amplicon).

LABORATORY DESIGN

Laboratory space should be designed to minimize the risk of contamination and maximize workflow. Barrier containment through the use of physically separate work areas for reagent preparation, specimen accessioning, nucleic acid extraction, and analysis of the amplified material is highly desirable. An ideal laboratory is composed of three completely independent rooms or areas. Two of these rooms are considered clean rooms in that all tasks and duties before in vitro amplification are performed in these laboratories. These rooms are called *preamplification rooms*. The third room is considered a dirty room because it is dedicated for in vitro amplification and analysis of the amplified material. This room is called a *postamplification room*. The air handling systems for each of these rooms should be completely independent. If this is not possible, it is highly recommended that the preamplification laboratories be located closest to the source of air in reference to both laboratories. The preamplification laboratories should be under positive air pressure, which impedes the entrance of any airborne contaminant into the preamplification laboratory when the door is opened. In addition, the postamplification laboratory should be under negative air pressure to impede anything from coming out of this laboratory and contaminating the surrounding environment. Construction of an anteroom into each laboratory is an inexpensive way of creating differential pressure for the laboratory. A positive pressurized anteroom for a preamplification laboratory can be created by use of a fan in the ceiling of the anteroom that draws air from inside the laboratory and blows it into the anteroom. This positively pressurized anteroom serves much the same purpose as having the entire laboratory under positive pressure. Similarly, an anteroom for the postamplification room can be easily made into a negatively pressurized room by having the fan draw air out of the anteroom and blow it into the laboratory. This anteroom should contain a seal around the door separating the anteroom from the laboratory to avoid air within the laboratory going back into the anteroom. It is important to emphasize that the door leading into the anteroom from the outside and the door to the inside of the laboratories should never be opened at the same time. An additional safety feature is to add sticky mats at the entrance of each anteroom or laboratory. The size of the anteroom is determined by what activities will be carried out in it. In addition, if disposable dedicated laboratory coats, hats, and booties are used, space is needed for storing these items.

Different activities are carried out in each of the three rooms/areas. In vitro amplification is never carried out in the two preamplification laboratories. One of these rooms is dedicated to reagent preparation and the other for specimen accessioning, specimen preparation, and reaction setup. If there is limited space, the two preamplification rooms can be combined into one laboratory. The use of dead air boxes for reagent preparation and reaction setup is highly recommended, and is more critical when both laboratories are combined. Dead air boxes provide a tightly controlled environment where reagent and reaction preparation can be carried out. It is important to situate this area in a section of the laboratory with low traffic. No genomic or plasmid DNA, RNA, or patient specimens should be introduced into the dead air box where reagent preparation takes place. This dead air box should be furnished with an ultraviolet (UV) light connected to a timer. The surface areas of the dead air boxes should be treated with UV light, then wiped with freshly made 10% sodium hypochlorite solution and finally with 75% ethanol solution before and after working in this area. These areas should contain dedicated equipment and instrumentation (e.g., pipetters, vortex, tips, tubes) that are not shared with any other area. Dedicated laboratory wear and gloves should be put on before starting work in this environment.

The second clean room or area within the preamplification laboratory is where specimen accessioning, specimen processing, and addition of nucleic acid to the appropriate reaction tube is carried out. This area should be furnished with at least one environmental biosafety cabinet for specimen processing and nucleic acid extraction in addition to dedicated laboratory equipment that is solely used for this purpose. Another

completely separate environmental biosafety cabinet should be available if any tissue culture is carried out in this laboratory, and separate laboratory equipment should be dedicated for this function. Also, if organic nucleic acid extractions are used in the laboratory, a chemical safety cabinet for handling of the phenol and chloroform steps during the extraction procedure should be available. If both DNA and RNA extraction are carried out in the same preamplification laboratory, one should perform these procedures in separate areas of the laboratory and have dedicated instruments, pipettes, and filtered tips for each procedure. When space is a major issue and it is not possible to dedicate two completely separate areas, extraction of DNA and RNA should be performed at different times or on different days after thoroughly cleaning the areas before working. As previously described, all areas should be wiped with a solution of daily-prepared 10% sodium hypochlorite and with a solution of 75% ethanol.

The postamplification laboratory is where *in vitro* amplification and analysis of nucleic acid is carried out. Instruments used in this laboratory should not be shared with the preamplification areas. If thermocyclers are used for *in vitro* amplification of nucleic acid, they should be placed in this laboratory. If thermocyclers are placed in the preamplification laboratory under no circumstances can reaction tubes be opened after amplification in this room. In addition, thermocyclers should be plugged into dedicated power lines with their own circuit breaker to avoid any fluctuation in electricity that could affect their performance. Normally this laboratory requires more space than the preamplification laboratory because instrumentation for analysis of amplified product tends to be more extensive than that required for reagent preparation and nucleic acid extraction. Gel electrophoresis, for example, frequently uses significant open bench space. A darkroom with a dedicated automatic film processor and a freezer is highly recommended. It is however preferable to place the darkroom outside the postamplification laboratory so as to have access without having to go into the postamplification laboratory.

Real-time technology has recently been introduced in the clinical laboratory with major success. One of the great benefits of these instruments is that as they perform *in vitro* amplification, they can simultaneously detect the amplified product. This allows detection and quantitation of specific nucleic acid sequences without further manipulation or opening of test tubes, and dramatically reduces the risk of amplicon contamination. For assays developed and performed using these types of instruments, the risks of amplicon contamination will be significantly reduced. However, at this juncture, molecular diagnostics laboratories must continue to rely on standard "open" platforms for many tests, particularly those developed in house using analyte-specific reagents. For these assays, the risk of amplicon contamination still remains a significant issue that must be addressed through laboratory design and practices to minimize the risk for amplicon contamination.

PRACTICES TO AID IN CONTAMINATION CONTROL

The introduction of simple practices in the daily routine can aid in the control of amplicon and target contamination. Unidirectional workflow must be strictly followed whereby personnel perform tasks in the clean rooms first and only after completing their tasks in that room do they move on to the postamplification room. No personnel that have worked in the postamplification laboratory should return to the preamplification area before showering and changing clothes. Use of disposable laboratory coats, booties, and hats is recommended. If cloth lab coats are used, there should be dedicated lab coats for each laboratory and they should be kept inside each laboratory and not worn in the office space. Use of different colored lab coats for each area is one way to remind personnel of the strict workflow. Control of workflow of housekeeping personnel is likewise important. The safest approach it is to have laboratory staff perform some of the housekeeping duties by bagging the trash from each laboratory and placing it outside the laboratory for pick up by housekeeping staff. If this is done, housekeeping personnel must be instructed to remove trash first from the preamplification room, then the office space, and finally the postamplification room.

Protection of countertops with absorbent, plastic-backed paper is not recommended because paper can collect dust and with it amplified material if not changed often. If used, this type of paper should be discarded immediately after each use. The use of bleach appears to be the most generally accepted method for decontaminating surfaces. Decontamination of countertops, laboratory equipment, and furniture should be performed by wiping with a freshly made solution of 10% bleach and then with a 75%

ethanol solution or even water to dilute the bleach that could corrode the surfaces. All pipette tips should contain a hydrophobic filter to prevent contamination of the tip of the pipetter with template or amplified material. Evaluation of the effectiveness of the hydrophobic barrier can be assessed by setting the pipette beyond its upper limit and drawing fluid from a colored solution into the disposable pipette tip that contains the hydrophobic barrier. If the tip of the pipette becomes stained by the fluid, then the barrier is inadequate. In this manner, routine QC measures such as mean volume and associated coefficient of variation to determine accuracy of pipette draws are frequently instituted to detect faulty pipettors, which can affect results. After use, disposable pipette tips should be placed into ziplock bags, making sure that the bags are completely sealed before discarding them. Gloves should be changed periodically or as soon as any contamination is suspected.

Another approach to preventing amplicon contamination is to chemically treat the unwanted amplicon so that it will not support amplification, even if accidentally added to another sample. The most widely used means of destroying amplicons is through the use of UV irradiation. UV treatment of DNA induces cross-linking of the two strands of DNA by forming thymidine dimers. This cross-linked DNA can no longer serve as an effective template. One disadvantage of UV treatment is that it is most effective in sequences of more than 700 nucleotides in length. In most clinical assays, the length of the amplicon is less than 700 base pairs. A chemical means of inactivating or sterilizing amplicon is through the use of deoxyuridine triphosphate instead of deoxythymidine triphosphate during the amplification procedure. In this procedure, deoxyuridine monophosphate is incorporated into the amplicon instead of thymidine monophosphate. After amplification, this uracil-containing amplicon can be destroyed by treating the sample with uracil-N-glycosylase (UNG). The uracil-containing amplicon is the substrate for UNG, while the thymine-containing template is not. The UNG removes uracil residues from the amplicon, still leaving an intact phosphodiester backbone on the amplicon. During the first denaturation step of the amplification procedure, the phosphodiester bonds break at the sites where the uracil residues are located. The fragmented amplicon is no longer able to act as a template. Use of deoxyuracil triphosphate and UNG are effective in controlling contamination if the uracil-containing amplicon does not exceed 10^6 to 10^7 copies per reaction. Isoporsalens have also been used with some success. After amplification, exposure to long-wave UV light produces adducts between the isoporsalens and the cytosines present in the amplified material, rendering them ineffective templates for amplification.

Transfer of paper such as written procedures or notes regarding specific samples between laboratories and office is also a concern. This should be reduced as much as possible, especially for paperwork used in the postamplification laboratory. It is highly recommended that a computer network be put in place in the laboratory with a number of computer terminals throughout the different laboratories and office areas in order to reduce or eliminate the movement of paper throughout the laboratory and back into the office area. It is important that the network server be backed up daily.

EQUIPMENT

Laboratory equipment necessary for successfully conducting current typical molecular diagnostics tests can include instrumentation not generally found in the typical clinical laboratory. Even where there is overlap in the type of equipment that is used, it is important that the molecular diagnostics laboratory contain its own equipment for purposes of contamination control. Some of the specialized equipment, depending on the scope of the testing menu, includes automatic DNA sequencers, real-time thermocyclers, capillary electrophoresis instruments, and high-performance liquid chromatography. These specialized instruments are expensive, which can make implementation of tests that require them difficult. More recently, a new tactic for acquisition of instrumentation through reagent rental agreements has become possible through some of the manufacturers of *in vitro* diagnostic tests and analyte specific reagents. This funding mechanism has been in use for many years in other areas of the clinical laboratory but is new for molecular diagnostics.

PERSONNEL

Laboratories performing molecular diagnostics testing are classified as high complexity testing laboratories under CLIA '88, which imposes specific personnel standards for education and training. These tests are more complex than standard laboratory tests, and many are developed in-house.

As new technology is introduced, these assays are constantly being modified to improve specificity, sensitivity, turnaround time (TAT), and workflow.

LABORATORY DIRECTOR

According to CLIA '88, directors of high complexity testing laboratories must be either a doctor of medicine (MD) or doctor of osteopathy (DO) with training in clinical or anatomical pathology; an MD or DO with 2 years of experience directing or supervising a high complexity testing laboratory; or hold an earned doctorate degree in one of the biological sciences and be certified and continue to be certified by a board approved by the Department of Health and Human Services.

The responsibilities of the laboratory director are test selection, implementation, and resolution of technical difficulties. The laboratory director is also responsible for developing laboratory programs for analytical and clinical validation of new molecular tests and development of management guidelines and practices that ensure reliable performance of clinical testing. In addition, the laboratory director must also be responsible for the development, implementation, and review of the laboratory quality assurance and control programs.

TECHNICAL SUPERVISOR

According to CLIA '88 a technical supervisor must be either an MD or DO with 1 year of experience in a high complexity testing laboratory; have a master's degree with 2 years of experience; or have a bachelor's degree with 4 years of experience.

MEDICAL TECHNOLOGISTS AND MOLECULAR BIOLOGY TECHNICIANS

Medical technologists and molecular biology technicians are responsible for tasks and duties necessary for the daily operation of the laboratory testing agenda. These individuals are responsible for specimen accessioning and processing, performing daily testing, maintaining appropriate testing and QC records, adhering to written procedures and QC policies, identifying problems, and documenting equipment maintenance. Record keeping for laboratory procedures is complicated because assays that are developed in-house are constantly being modified to improve the testing process. In addition, some laboratory instruments are used solely for molecular diagnostic testing and there is little clinical laboratory experience with them. It is important for the technical staff, particularly the senior technical staff, to have a high sense of professional commitment and to display constant interest and effort in improving their education and training. It is also important for the staff to acquire as many advanced laboratory skills as possible and to be cross-trained in most or all of the different tests used in the laboratory. It is crucial for the technical personnel to fully understand the scientific basics of the methodology and the clinical applications and implications of the different molecular tests.

Involvement of residents, fellows, and graduate students can contribute significantly to the success of a molecular diagnostics laboratory. The value of these individuals comes from their high level of professional commitment and their insight into the clinical utility of individual tests. If such individuals are provided time to work in the molecular diagnostics laboratory, they are frequently able to rapidly develop and validate a new molecular assay. In return these individuals gain expertise in an area of laboratory medicine that is rapidly growing and this may provide them with an advantage when seeking future employment. As part of their training in molecular diagnostics, it is important for residents, fellows, and graduate students to gain experience in each of the different areas of testing, including infectious disease, genetic disease, and cancer. Training should include basic principles in molecular biology, hands-on experience in optimizing, validating, and performing molecular diagnostic testing, test result interpretation, and preparation of reports for review. Laboratory directors should also familiarize trainees with the different issues involved in laboratory management.

CERTIFICATION OF PERSONNEL IN MOLECULAR DIAGNOSTICS

Certification of doctoral level personnel working in molecular diagnostic laboratories can follow several different routes depending on the type of doctoral degree as well as other training experience. The American Board of Pathology (ABP) and the American Board of Medical Genetics (ABMG)

offer a joint subspecialty certification in Molecular Genetic Pathology. The ABP and the ABMG are members of the American Board of Medical Specialties, which is the parent organization for boards that provide certification in pathology, pediatrics, internal medicine, surgery, and other medical specialties. Certification consists of required training in an accredited program followed by a subspecialty examination. Candidates for this certification in MGP must hold an MD or DO degree, have primary certification in either pathology or genetics by their respective boards, have a valid unrestricted license to practice medicine or osteopathy in the United States, and have completed a year of training in an Accreditation Council of Graduate Medical Education (ACGME) accredited program. There are at least 31 MGP programs that have received full accreditation by the ACGME. Additional programs will likely seek accreditation in the future. Standards for training in molecular genetic pathology have been published by the different organizations involved in certification. Central to this effort is the use of competency-based education, which involves specific learning objectives around the curriculum. Fellows need to demonstrate performance at the level of a new practitioner in six general competencies: patient care, medical knowledge, practice based learning and improvement, interpersonal and communication skills, professionalism, and system based practice as provided by the Association for Molecular Pathology and other professional bodies. The candidate must present a logbook of 150 clinical molecular cases. The examination is offered every other year.

Another avenue open to individuals with either an MD or PhD is provided by the ABMG and is intended for individuals who provide services in medical genetics. The ABMG offers certification in clinical genetics, medical genetics, clinical cytogenetics, clinical biochemical genetics, and clinical molecular genetics. Only the requirements for certification in clinical molecular genetics are discussed here. In addition to possessing the appropriate doctoral degree, the candidate for clinical molecular genetics must complete 2 years of training in a fully accredited program. The candidate must present a logbook of 150 clinical molecular cases and method competency list signed by the laboratory director with half of the time of the training spent at the bench. The examination is offered every 3 years.

In addition, the American Board of Clinical Chemistry (ABCC) has offered certification in molecular diagnostics since June 2000. The ABCC is an independent, not for profit corporation that certifies doctoral level professionals in clinical and toxicologic chemistry. The ABCC certification in molecular diagnostics requires the applicant to possess an MD or a doctoral degree or equivalent in biochemistry, molecular biology, or other natural sciences. The applicant must demonstrate 5 years of full-time diverse professional experience in clinical molecular diagnostics or at least 2 years of full-time diverse experience in clinical molecular diagnostics, and must document primary certification in one the following boards: ABCC, American Board of Medical Microbiology, American Board of Pathology, American Board of Medical Laboratory Immunology, American Board of Bioanalysis, or the American Board of Histocompatibility and Immunogenetics. Applicants must meet education and experience requirements in addition to holding three letters of recommendation to attest to the familiarity with the applicant's professional expertise and length of experience in the field. The examination is offered once a year. The American Board of Bioanalysis also offers a certification for High Complexity Laboratory Director in Molecular Diagnostics (www.abb.org).

Subspecialty certification in molecular diagnostics is also offered to nondoctoral-level individuals including medical technologists and molecular biology technicians through the American Society of Clinical Pathology (ASCP) Board of Certification. The ASCP Board of Certification was the result of the unification of the National Credentialing Agency and the ASCP Board of Registry. The ASCP Board of Certification is an administratively independent certification agency that prepares relevant standards and develops procedures that ensure the competence of nonphysician medical laboratory personnel. Medical technologists and molecular biology technicians become certified as technologists in molecular biology. There are four routes for eligibility:

1. ASCP certified as a technologist (MT, MLS, CG, CT, HTL, BB, C, H, I, or M) or specialist (SBB, SC, SCT, SH, SI, SM, or SV) and a baccalaureate degree from a regionally accredited college or university.
2. Baccalaureate degree from a regionally accredited college/university, including courses in biological science, chemistry, and mathematics and successful completion of a National Accrediting Agency for Clinical Laboratory Sciences–approved baccalaureate diagnostics molecular science program within the last 5 years.

3. Baccalaureate degree in biological or chemical sciences from a regionally accredited college/university and 12 months of acceptable clinical laboratory experience in molecular diagnostics in a CLIA-regulated accredited clinical laboratory in the past 5 years.
4. Graduate level degree (master's or doctorate) in chemistry, biology, immunology, microbiology, allied health, clinical laboratory sciences, or an appropriate related field from a regionally accredited college/university and 6 months of acceptable clinical laboratory experience in molecular diagnostics in a CLIA-regulated accredited clinical laboratory within the last 5 years.

FINANCIAL MANAGEMENT

REIMBURSEMENT FOR MOLECULAR DIAGNOSTICS TESTS

Reimbursement for laboratory tests is a complex process that can be broken down into three phases—coverage, coding, and payment. Coverage decisions are usually determined by each of the different health care plans. In the United States, health insurance coverage is provided by public programs such as Medicare and Medicaid or by private health plans purchased individually or through one's employer. In general, the scope of coverage provided by a health plan is outlined in broad benefits categories; decisions about specific services are made on a case-by-case basis during claims processing. Health plans may develop formal coverage policies that describe whether a particular service is covered and the conditions under which it will be covered. Medical directors, the federal and state governments, medical policy advisory committees, employers, and unions are among some of the entities involved in making coverage decisions. Medical necessity is the primary criterion used by health plans when making coverage decisions, although the definition of medical necessity is subject to different interpretation. Another criterion is that the service must have approval from the appropriate government regulatory body. Thirdly, scientific evidence must permit conclusions concerning the effect of the technology on health outcomes.

Billing for molecular diagnostics test follows the same procedure as any other laboratory tests. Generally, Current Procedural Terminology (CPT) codes (to document the procedure) and International Classification of Disease diagnostic codes (to document the medical condition which makes the procedure necessary) are required by the the billing process to convey what services or procedures were performed and why. Beyond this, the reimbursement process is usually institution-specific and relies on computerized and manual billing procedures. It is important to determine in advance the requirements regarding documentation and computer access needed in order to generate a bill. There are two kinds of CPT codes for molecular diagnostics testing: pathogen-specific CPT codes for molecular testing for infectious disease organisms, and procedure-specific CPT codes for noninfectious disease molecular testing. Pathogen-specific CPT codes for molecular infectious disease tests, such as HIV-1 detection, HCV viral load, and HSV detection are global codes that include the entire test procedure including interpretation and report in a single code (e.g., nucleic acid extraction, amplification quantitation, detection, interpretation and report). There are more than 80 analyte-specific codes used for molecular microbiologic tests, and it is anticipated that more analyte specific codes will be introduced in practice. These codes are represented by the code range 87470-87801 in the CPT code set. There are usually three different codes for each analyte: one for direct probe technique, another for in vitro amplification technique, and another for quantitation regardless of the technology used. For those organisms without specific CPT codes, three generic CPT codes are included, designated *Not otherwise specified*. For all other molecular tests without an analyte-specific CPT code, a combination (or stacking) of procedural CPT codes can be used. These codes are represented by the code range 83890-83914. For example, nucleic acid extraction, amplification, and capillary electrophoresis all have separate CPT codes. A single test using all these procedures is billed using a combination of all appropriate CPT codes, used multiple times as needed. Most molecular codes describe a generic molecular procedure rather than a specific method. For example, a nucleic acid extraction can be performed for DNA or RNA, using very different methods, each using different instrument, reagents and personnel, but both are billed using the same CPT code for nucleic acid extraction. In addition to the procedure-specific codes, there is a specific code for interpretation and report (83912) that may be reported at the technical level or the professional level but not both. For molecular pathology testing that requires a professional interpretation, the professional component is coded using the 83912 with a modifier "26". When

TABLE 69-1

CPT Code Billing for Molecular Tests

Test	CPT code	Number of times CPT code billed	Type of procedure or test
Factor V Leiden	83890	1	Nucleic acid isolation
by Real Time	83898	1	Amplification
Technology	83892	2	Probe, each
	83912	1	Interpretation and report
t(9;22) by Real	83890	1	Nucleic acid isolation
Time RT-PCR	83902	2	Reverse transcription
	83898	2	Amplification
	83894	2	Probe, each
	83912	1	Interpretation and report
HIV-1 Viral Load	87536	1	HIV quantitative
CMV Viral Load	87497	1	CMV quantitative
HCV Viral Load	87522	1	HCV quantitative

CMV, Cytomegalovirus; CPT, Current Procedural Terminology; HCV, hepatitis C virus; HIV, human immunodeficiency virus; RT-PCR, reverse-transcriptase polymerase chain reaction.

83912 is reported without the 26 modifier, it is paid from the clinical laboratory fee schedule. When 83912 is reported with the 26 modifier, it is paid from the physician fee schedule. Listed in Table 69-1 are examples of billing using analyte specific CPT codes and procedure specific CPT codes. Because of the limited nature and description of the procedure CPT codes, there is lack of consistency in reporting. Furthermore, there is a lack of representation of newer technologies such as bead array, real-time PCR, and microarray that are widely used by a large number of clinical laboratories. Due to limitations in the current CPT code set, laboratories might be forced to "under code." A complete list of the CPT codes can be found in the "CPT Current Procedural Terminology" published by the American Medical Association.

A set of two-character alphanumeric modifiers has been devised to add granularity and more precise descriptions of service for the procedure-specific CPT codes. The purpose of these alphanumeric modifiers is to help third-party payers identify more specifically the services for which they are paying. The first (numeric) character identifies the disease category (e.g., neoplasia [solid tumors], neoplasia [lymphoid/hematopoietic], nonneoplastic hematology/coagulation, histocompatibility/blood typing, neurologic nonneoplastic, muscular nonneoplastic, metabolic, other; metabolic transport, metabolic-pharmacogenetics, and dysmorphology). The second (alpha) character denotes the gene type (e.g., BRCA1 or Rb).

Reimbursement levels for individual tests are set by third-party payers and may bear little relationship to the actual cost of performing the test. Some third-party payers may reimburse at high levels but others may follow laboratory fee schedules based on the Medicare Clinical Laboratory Fee Schedule or Physician Fee Schedule for the specific CPT codes. FDA approval is not required for billing for these tests and a disclaimer for those non-FDA-cleared tests to reflect this issue should be added to the final report (see later). Some third-party payers will deny reimbursement for tests bearing such disclaimers because they believe that the cost of performing such testing should be borne by research grants even though the performance characteristics and clinical utility of the test have been validated by the clinical laboratory.

PATENT ISSUES

Patents can cover a specific method of testing for an analyte, any method of testing for an analyte, or a mutation-gene-disease association in general. The vast majority of the in vitro amplification procedures are patented processes, and a license agreement for the use of these procedures must be obtained or the laboratory using the procedure is liable for patent infringement. Traditionally, licensure is obtained for a particular procedure by purchasing an FDA-approved set of reagents sold by a manufacturer who holds the patent to the amplification process. The number of FDA-approved/cleared tests is limited and does not cover all molecular tests currently performed in molecular diagnostics laboratories. Thus a laboratory using a particular patented process must first negotiate a license agreement with the patent holder. Importantly, depending on the complexity of the institution seeking the agreement and the complexity of the

agreement, it may take from 3 months to a full year to obtain license to perform and bill the procedure for clinical purposes.

Similar consideration must be given to the use of sequence information required to design an assay. Sequences of newly discovered genes (e.g., human genes, virus genomes) are frequently patented by their discoverers, and use of the sequence information without a license agreement runs the same risk of liability for patent infringement. Examples of such patents include apolipoprotein E genotyping for Alzheimer disease, Canavan disease, and Charcot-Marie-Tooth disease type 1A. The terms and conditions offered by the patent holder vary greatly. In some instances, the laboratory cannot offer a test for a patented gene sequence because the patent has been exclusively licensed to a single laboratory. Because of diversity of sources for sequence information, it is not always clear whether the sequence has been patented or even who owns the patent. Before undertaking development of any test based on published sequences wherein a major commitment of resources is planned, check with the investigators who first described the sequence, and search patent and patent applications to determine whether the new test might infringe on any existing or pending patents. Internet resources provided by the U.S. Patent and Trademark Office (<http://www.uspto.gov>) allow laboratories to perform searches on granted or pending patents in the United States.

LABORATORY INFORMATION SYSTEM

Clinical laboratories have been among the first hospital departments to actively exploit computers and software for reporting results and for managing internal work processes and quality. Most pathology laboratories now require a computerized laboratory information system (LIS) to handle the large volume of data that is both received and reported. These systems support all aspects of the contemporary clinical and specialty laboratory, helping technologists manage the quality and integrity of test samples (preanalytical), all aspects of the testing and results review process (analytical phase), and the reporting of finalized results, interpretations, and diagnosis (postanalytical phase). LISs have evolved beyond departmental workload functions and today often include advanced features, such as laboratory-specific medical records, direct clinician access via secure web connections, full-blown billing modules, and sophisticated interface engines for routing orders and results to external systems. The recent explosion of molecular diagnostics methods has expanded molecular and gene-based diagnostic testing into routine laboratory testing, forcing vendors and users to either adapt existing LIS functions to new modes of testing or to develop completely new subsystems.

To date, a number of commercial LIS vendors offer genetic testing modules, and several niche suppliers have emerged. The data management aspect of genomic/proteomic laboratory testing is one of the most active areas of pathology informatics research. This will have significant impact on future laboratory information systems and electronic medical record designs and will be used as genetic data become a core part of the patient's medical record. The LIS must be flexible enough to handle the demands posed by the new laboratory tests and technologies. In particular, the quantity of specimens and type of testing involved in genetic testing pose a significant challenge for an LIS. Molecular diagnostics and genetic testing requirements include increased data storage requirements, ability to manage reporting of genetic changes such as rearrangements and other abnormalities associated with malignant disease and hereditary genetic abnormalities, and ability to access patient records that contain personal gene databank and family tree information. Decision support, specimen tracking, and automation of QC and QA documentation features also must accommodate the demands of genetic testing. Extension of data management to genetic findings requires an LIS to standardize information and support genomics-based inference. Current vocabularies can be insufficient to describe the findings generated by some new molecular tests. Vocabularies such as the Clinical Bioinformatics Ontology developed by Cerner Corporation have been designed for clinical molecular diagnostics and cytogenetics. In order for LISs to handle the nature and volume of genomic tests, current discrepancies between how genetic mutations are described in the literature and how they are described in the Internet databases must be resolved. Laboratory processes in molecular diagnostics are currently highly complex and have proven difficult to standardize and automate. Contributors to this complexity include the wide variety of tissue sample types that can be tested, the numerous steps involved in material preparation, frequent implementation of novel technical platforms leading to variable and unpredictable assay performance, and complex posttesting analysis methods. Another component of the complexity, especially in molecular oncology, is that a variety of tumor samples

are required for different order sets, including multistep and reflex testing. One of the unique workflow requirements of the molecular diagnostics laboratory is the need to document significant amounts of nonclinical information generated during the processing of a sample (e.g., during DNA or RNA isolation or PCR analysis). An additional requirement is the ability to offer significant flexibility in reordering or canceling tests and procedures in response to poor quality specimens or other procedural failures.

TEST MANAGEMENT

MENU/SELECTION

As with any other clinical laboratory, the primary goal of the molecular diagnostics laboratory is to provide reliable and timely test results deemed necessary by the medical community for patient care. Appropriate selection of tests to include on the laboratory's test menu is critical for the success of the molecular diagnostics laboratory. Several key considerations are important in test selection. Clinical needs, as well as advances in basic and translational research, often prompt the development of new molecular tests. Prior discussions with the intended users to determine their level of interest and understanding are extremely helpful during the test selection.

Any new test should provide a less expensive or more effective avenue for diagnosis and/or management of the patient. It is important to base test selection not only on cost but also on how the new test could impact overall patient care and management. Even though adding an expensive new test for a particular clinical condition may seem at first to increase the cost of patient management, in the long run the new test may result in more cost effective and efficient patient management. For example, HIV-1 viral load testing monitors disease progression and effectiveness of drug therapy in infected individuals. Many patients infected with HIV-1 are currently treated with a combination of different drugs, which includes protease inhibitors and nonnucleoside and nucleoside reverse transcriptase inhibitors. These drugs are expensive and the virus may become resistant to them. Thus, even though addition of HIV-1 viral load testing adds cost to managing HIV-1 infected patients, the test provides a means for rapidly and accurately determining the effectiveness of the expensive drug treatment regimens. In this regard, molecular diagnostics is poised to greatly impact the emergence of pharmacogenomics and personalized medicine toward individual therapy (see Chapter 72).

A molecular test may be more cost effective than an existing laboratory test and may be introduced to replace that existing test. Even if the direct cost of the molecular test is more than the direct cost of the test being replaced, increased sensitivity, increased specificity, or reduced TAT may result in significant overall savings in patient management. For example, in a case of presumptive *Mycobacterium tuberculosis* infection during the period of time when this diagnosis cannot be ruled out, the patients are placed on treatment with potentially liver toxic drugs or placed in isolation. The standard laboratory test of directly observing an acid-fast stain of the patient's sputum for the presence of *M. tuberculosis* is fast, but lacks sensitivity. Culture is extremely sensitive, but could take up to 6 weeks for a result. A molecular test that allows for a more rapid diagnosis with a high degree of sensitivity and specificity would allow discontinuation of drug therapy or isolation for those patients without the disease.

Identifying molecular tests that would be potentially useful at the medical center is a responsibility of the medical and technical directors. Clinicians and pathologists can be a valuable source for identifying the testing needs for the medical center, but it is important for the laboratory director to establish where there is a need for improvement. Clinicians who learn of a new test that seems interesting may request that the molecular laboratory make the test available, regardless of whether that test has been analytically or clinically validated. Each laboratory should have a formal, systematic process to develop a strategic menu. The menu of molecular pathology laboratories may vary significantly and is determined by three principal factors: clinical requirements and usefulness, laboratory competency, and test costs. When considering which tests to add to a laboratory menu, matching of the technical capabilities of the laboratory with real-world clinical needs in terms of test volume, TAT, and associated costs should be realistic. Introduction of any new test should include a clinical trial period that allows for evaluation of the clinical utility of the test and may provide a useful marketing opportunity. If carefully designed, this approach allows the laboratory to directly work with the end user of the test and provides an avenue for end users to understand the clinical utility of the test and its limitations. It is important to clearly define metrics that

can be evaluated at the end of the clinical trial to justify implementation of the test.

METHODS

Once a particular analyte has been identified for testing by molecular means, it is important to consider the various approaches that may be available. The technologies available for molecular diagnostics testing are considerably more complex than in other areas of the clinical laboratory. Adding to the challenge is the rapid rate of technological change.

In conventional sections of the clinical laboratory, the platforms available for performing a test are usually inclusive from primary sample handling to result. In contrast, the molecular diagnostic laboratory is usually required to piece together several disparate methods to achieve the same result. In fact, few manufacturers of molecular assays have considered the equally important issues of sample procurement and nucleic acid extraction, that is often necessary for each representative sample type. The successful integration plan would address the combination of procedures needed for the advancement of samples through these front-end requirements. One exercise that will aid in the development of a strategic test menu is the categorization of proposed tests into groups defined by the basic genetics of the diseases for which the tests are designed. In general, only a few types of testing methodologies exist for detection of nucleic acid sequences, detection of a particular mutation or single nucleotide polymorphism, or quantitative analysis of a specific sequence. The goal is to implement the strategic test menu onto one or two technical platforms. Consider several ancillary questions to determine whether it is possible to use fewer technologies:

- Do the selected platforms accommodate the full spectrum of sample types used for the tests on the laboratory's menu?
- Is it more important to address the volume of tests or the complexity of the analytic results?
- Are the platforms flexible enough to handle test offerings that may be added to the laboratory's test menu?
- Does the laboratory really need quantitative or real-time technologies?

Having fewer platforms will facilitate using information technology to extract more value from those systems. For example, some analytes may be analyzed using Southern blot hybridization, in vitro nucleic acid amplification, cytogenetics, or FISH. Before selecting a particular method, it is important to consider the clinical condition and the advantages and disadvantages of each methodology for managing a particular clinical condition.

CLINICAL TEST FORMATS

There are two basic types of assay formats. One type is developed and sold commercially by IVD manufacturers, and the other is developed in house by each laboratory (i.e., LDTs). In the first category, complete kits are developed to provide quality-controlled reagents to perform an entire molecular test for a determined clinical condition. For example, kits to monitor patients with HIV-1 infection through quantification of plasma HIV-1 RNA. These kits usually include all the reagents necessary for nucleic acid isolation, amplification, and detection or quantitation. These complete assay kits include information about sensitivity, specificity, and test limitations for the particular clinical condition. They may be labeled by the manufacturer as *FDA-approved*, *FDA-cleared*, *for research use only*, or *for investigational use only*.

There is also a significant demand for assays for which there are no commercially available kits. Thus clinical laboratories must frequently develop their own assays to accommodate the local demands. LDTs are fully established and validated by the laboratory that performs them. They are also referred to as "home-brew" tests. Usually these assays use a combination of reagents that are purchased separately from a variety of manufacturers. Each laboratory determines the performance characteristics of the assay for a specific clinical condition and a particular patient population. There are a number of commercially available kits that are developed by a manufacturer to provide quality-controlled reagents to perform a particular step in molecular testing. For example, there are a variety of commercially available kits for nucleic acid extraction, amplification including controls, and detection systems. The laboratory may develop a particular molecular test by combining two or more kits from the same or even different manufacturers. The analytical and clinical validation of the entire testing process is the responsibility of each laboratory.

AUTOMATED PLATFORMS FOR MOLECULAR TESTING

In recent years, the development and introduction of automated platforms for molecular diagnostics testing has become more common. Automated devices that consume less time, handle small volumes, and in theory allow for better precision have replaced many manual molecular diagnostic procedures. Many of these platforms have been developed by different manufacturers to provide automation for a single step or several steps of the testing process. The evolution of molecular diagnostics automation has occurred in stages. In this chapter, devices are grouped according to function.

Single function automated instruments have been in use for some time in the molecular diagnostics laboratory. The typical example of a single-function automated instrument is a thermocycler, because it provides automated amplification of nucleic acid by performing all steps necessary for the amplification of nucleic acids. Nucleic acid extractors are another early example of single-function devices that convert a six-step procedure into a single-step process. These early nucleic acid extractors were based on phenol/chloroform extraction and mimicked the corresponding manually performed method by using nearly the same reagents and protocols. These and other single-step automated instruments, including robots for reagent preparation and aliquoting, and automatic DNA sequencers, have been widely incorporated into molecular diagnostics laboratories. The use of magnetic beads has dramatically changed how laboratories process and isolate nucleic samples from patient specimens. Molecular diagnostics laboratories are rapidly embracing these automatic nucleic acid extractors because this specific step in the testing process is one of the most labor-intensive of the entire testing process. These devices provide higher throughput capabilities, greater precision, and reduced personnel demands.

Recently, automated instruments that perform more than a single function have been developed and introduced into molecular diagnostics laboratories. The Roche Molecular Systems COBAS Ampliprep/COBAS TaqMan analyzer is an example of one such automated platform. This instrument contains an automatic extractor module, reaction setup, and real-time PCR that allows the processing of patient specimens—nucleic acid extraction, amplification, and quantitation—in a single instrument. Real time PCR technology simultaneously acquires the amplification signal, permitting qualitative and quantitative analysis of the PCR reaction as it occurs, thereby eliminating the need for postamplification processing for detection and quantitation of target sequence. This feature allows a dramatic reduction of the TAT for molecular diagnostics tests from days to hours. The throughput of these devices is greatly enhanced and molecular diagnostics laboratories now use them routinely for much of their diagnostic testing.

The greater availability of these automated devices poses many opportunities for clinical laboratories. One core issue in this decision is cost. Whereas the cost of manually performing molecular testing is substantial, the cost of acquiring automated instruments to perform these steps/tests can also be significant. Laboratories must wisely evaluate the cost/benefit of these automated devices in relation to the anticipated revenue. A number of manufacturers have started offering reagent rental programs for many of these automated platforms. Laboratories must carefully compare the cost of performing the test manually to the cost of automation.

QUALITY ASSURANCE AND QUALITY CONTROL OF THE TESTING PROCESS

QUALITY ASSURANCE

Every molecular diagnostics laboratory should develop a comprehensive written QA program. The objective of the QA program is to systematically monitor and evaluate the quality and appropriateness of the test results. The QA program includes aspects of clinical testing that do not directly bear on the analytical accuracy of the test result and thus are generally not part of the QC program for clinical testing. Some of these parameters are regular review of TATs, normal and abnormal results, specimen rejection criteria, the log of rejected specimens, and other indicators of test quality. The QA program should address every aspect of the testing process—preanalytical, analytical, and postanalytical. The program must include written policies and documentation for education and training of personnel, continuing medical education, PT, internal and external inspections, including documentation of corrective actions for

deficiencies cited, QC programs for the clinical testing, equipment performance, and safety. Establishment of molecular diagnostics tests, particularly amplification assays, requires many considerations at every stage, including reagent preparation, specimen collection, specimen aliquoting and performance of the actual assay. A number of considerations apply to all molecular assays and are important to guarantee reliable results. The amount of QA and QC performed for any molecular assay depends on the type of test.

As part of the preanalytical phase, special attention should be given to specimen collection, transport, and storage, because specimen handling often affects the results. Test results that could influence treatment decisions should reflect the patient status and not specimen mishandling.

Key components of any QA program are PT and alternative assessment (AA). PT and AA performance reflects the accuracy of the laboratory's testing process and can also serve as an educational activity for the laboratory staff. The laboratory's testing performance on unknown challenge specimens is compared to an external standard. The external standard is generally the mean of values obtained by other laboratories using the same test method, but it may be assigned by a reference method or some other procedure. Laboratories engage in PT two or three times a year. PT programs are available from a number of vendors, including CAP. There are special requirements for CLIA-regulated analytes, in that CMS must approve the PT program. However, none of the analytes usually tested for in a molecular diagnostics laboratory is CLIA regulated. The laboratory must have a quality assurance plan that establishes the accuracy and reliability of the testing at least twice per year. AA is a twice-yearly assessment of the laboratory's testing performance when PT is not available. Examples of AA are split-sample testing between two or more laboratories that share test results with all participants, repeat testing on previously analyzed specimens whose earlier results were blinded to the laboratory technical staff, and testing by a different method. Ongoing monitoring of PT allows the laboratory to assess and monitor the quality of its test results and identify testing problems that may not surface with other quality control activities. Such information enables the laboratory to take preventive action and avoid future unacceptable results or inaccuracies in patient testing. Likewise, the investigation of unacceptable results can identify clerical errors, methodologic problems, equipment problems, technical problems, problems with the PT material, and problems with test interpretation. The PT provider provides individual laboratories with unknown "challenge" specimens for testing. Quantitative tests are usually expected to perform within 2 standard deviations of the mean or within a specified percentage deviation from the mean to be considered acceptable. Acceptable performance criteria may vary by analyte. In general, qualitative tests should agree with the response provided by 80% of peer laboratories or 80% of reference laboratories. Performance on a mailing is considered "satisfactory" when at least 80% of a laboratory's responses to challenges in a single mailing are acceptable. However, for many molecular tests there are only two shipments per year and three challenges per shipment, so the criteria may be different. When a PT survey is developed for a new analyte or new testing method/technology, the entire survey may be considered educational and not graded for 1 or more years, ensuring field validation. At a minimum, CLIA requires laboratories to review and evaluate the results obtained on PT. For any unsatisfactory testing event, CLIA also requires laboratories to document and retain their remedial actions for 2 years. The documentation is reviewed during the onsite laboratory inspection. Failure to perform AA, document results, review results, or take corrective action for an unacceptable performance leads to a deficiency citation upon laboratory inspection.

Well-characterized reference materials are fundamental to laboratory QA programs, including both external assessment by PT and internal QA activities such as QC and test development/validation. PT program vendors usually solicit large hospital centers or commercial vendors to obtain blood and tissue specimens from affected patients to support the PT programs. These materials must be validated before use. For some genetic tests, including many disorders in the CAP PT surveys, sufficient and appropriate material is not publicly available. For example, until recently, genomic DNA materials for allele repeat lengths representing important phenotypic classes and diagnostic cutoffs for fragile X were not publicly available. The absence of such materials for routine QC, PT, and test development may have accounted for the differences in laboratory performance in some recent CAP PT fragile X surveys. The CDC, in partnership with the genetics community, has established the Genetic Testing Reference Materials (GeT-RM) Coordination Program. Its goal is to improve the supply of publicly available and well-characterized genomic DNA that can be used as reference materials for PT, QC, test

development/validation, and research studies. The GeT-RM program has recently characterized 57 cell lines to be used as reference materials for disorders such as fragile X syndrome, Huntington disease, and disorders on the Ashkenazi Jewish panel (e.g., Bloom syndrome, Canavan disease, Fanconi anemia, familial dysautonomia, Gaucher disease, mucopolidiosis IV, Niemann Pick disease, and Tay-Sachs disease). These materials are or will soon be publicly available from Coriell Cell Repositories, which houses several National Institutes of Health (NIH)-funded collections of essential research reagents. A characterization study of 14 DNA materials with important mutations causing CF is currently underway in six collaborating clinical laboratories. Additionally, the GeT-RM program is characterizing a panel of DNA specimens with identifiable gene mutations for confirmatory testing in disorders included in state newborn screening panels. This includes disorders such as congenital adrenal hyperplasia, medium-chain acyl-CoA dehydrogenase deficiency, maple syrup urine disease, CF, and galactosemia. Additional materials are in development for gene mutations found in Gaucher disease, Tay-Sachs disease, and Canavan disorders. Development of materials will soon be initiated for other disorders, including inherited breast cancer (caused by *BRCA1* or *BRCA2* mutations), alpha-1 antitrypsin deficiency, and type 2 multiple endocrine neoplasia. To date, the GeT-RM program has focused its efforts on DNA-based testing for inherited genetic disorders. Other areas of genetics, including molecular oncology, molecular infectious disease testing, and biochemical genetic testing, however, are also facing a paucity of reference and PT materials. To address these needs, the GeT-RM program, together with the genetics community, professional organizations, and other governmental agencies outside of CDC, is trying to assess what reference materials are currently available for laboratory QA programs and is beginning to formulate plans for collecting and characterizing materials where shortages exist.

As with any laboratory test, a well thought out and well written laboratory procedure is a key factor for the reproducibility of the assay. It is one of the most important aids during hands-on training of new personnel or for procedures that are not performed very often. The clinical laboratory technical procedure manual should be written according to specific guidelines of the Clinical and Laboratory Standards Institute. Performance of nucleic acid-based methods usually requires specific setup and/or workflow.

ASSAY DESIGN AND DEVELOPMENT

A well thought out process for assay design and development is critical to ensure the success of a new test development and implementation. Once specific analytes, assay techniques, and specimen types have been identified, the assay design and development can begin. Table 69-2 describes the different steps of the testing process that need to be taken into consideration when designing an LDT. The first task is to optimize each step of the analytical process, which includes nucleic acid extraction, target amplification, detection, quantification, and result interpretation. Several review and research articles provide detailed descriptions of the key parameters that may influence the performance of different *in vitro* nucleic acid methodologies, including standard PCR, both uniplex or multiplex. After optimization of the assay, it is necessary to evaluate and document preanalytical variables that might have an impact on the performance characteristics of the assay. Common preanalytical variables are specimen type, transport, storage and handling, as well as interfering substances such as lipids, hemoglobin, and bilirubin.

Establishment of molecular diagnostic tests, particularly amplification assays, requires development of controls for each step of the testing process, including reagent preparation, specimen collection, specimen aliquoting, and performing the actual assay. A careful selection of control reagents is vital for the correct interpretation of test results. Several types of controls are used throughout the execution of an assay to ensure appropriate performance. For qualitative tests, negative and positive controls are required by CLIA '88 regulations and must be processed in every clinical test run. Failure to obtain the correct result for any of the controls invalidates the entire test and requires re-testing of all samples. Whenever possible, positive and negative control reagents should closely resemble a patient specimen. Furthermore, a positive control should represent a clinically relevant level of the nucleic acid target sequence in a background of negative nucleic acid target sequence. The negative control should contain "background" nucleic acid sequences expected to be present in the patient's sample. In addition to the negative and positive controls, a blank control should be included with every assay, which contains all the components of

TABLE 69-2

Conducting the Clinical Testing Process

Activity type	Considerations
Reagent preparation	<ol style="list-style-type: none"> 1. Perform in cleanest environment. 2. Store working stock solutions in single-use aliquots. 3. Quality control each new set of reagents before use in clinical testing; use low copy number sample for sensitivity evaluation. 4. Preparation of master mixes reduces variability and errors.
Specimen collection	<ol style="list-style-type: none"> 1. Establish acceptable tolerance limits for each specimen type to be tested (e.g., storage temperature, transport time, anticoagulant). 2. Distribute protocols for proper specimen handling to all potential users. 3. Capture clinical and analytical information on requisition.
Specimen processing	<ol style="list-style-type: none"> 1. Specimen must be received and stored in preamplification (clean) laboratory. 2. Develop guidelines to ensure against specimen mixup and to preserve integrity of target sequence.
Analysis of specimen	
a. Extraction procedure	<ol style="list-style-type: none"> 1. Evaluate extraction procedures for presence of inhibitors and factors that decrease yield of target. 2. Internal control added to the sample at the time of extraction to determine false-negative reactions due to inhibitors or determine this rate by some other means. If an internal control is not to be evaluated with each patient sample, then the rate of false-negative reactions should be stated on the report in a disclaimer in case of negative results.
b. Assay setup, amplification, and detection	<ol style="list-style-type: none"> 1. Optimize concentration of primers, magnesium chloride ($MgCl_2$), deoxynucleotide triphosphates (dNTPs); volume; cycling conditions and detection system. 2. Develop guidelines to minimize possibility of contamination by template nucleic acid or amplicon (see sections on quality control). 3. Control specimens must be processed in the same manner as patient specimens. 4. Develop guidelines to set up assay to avoid cross-contamination of specimens and controls.
Interpretation and report	<ol style="list-style-type: none"> 1. Develop guidelines for interpretation and report. 2. Interpretation should be performed by at least two individuals independently. 3. Develop guidelines for report distribution.

the reaction mixture except nucleic acid. In addition to these controls, in some instances it is imperative to include an internal control to check for the presence of inhibitors in the individual patient samples. If this latter control is not used, then when a negative result is obtained, it is not clear whether the absence of amplicon is due to the absence of the target sequence in the patient specimen or to the presence of substances that inhibited the amplification reaction. To avoid this situation, amplification of an internal positive control sequence is recommended. The internal positive control can be an endogenous nucleic acid sequence that is unrelated to the target sequence of the clinical assay but is constitutively present in the sample. Alternatively, it may represent a sequence that is spiked into the clinical sample at some step in the testing process. The former endogenous internal positive control generally requires a separate set of primers and may require a separate reaction. The spiked control is generally a sequence that shares the same primer sequence that is used for the clinical target and is usually amplified in the same reaction tube as the clinical sample. As is the case with the external clinical positive control, the internal control should be used at a concentration that is relevant to the clinical testing process. The internal positive controls are also valuable to assess the presence of amplifiable nucleic acid and the absence of inhibitors, as well as to assess that the amplification and detection reactions are performed according to the specifications.

The use of a series of positive controls at different concentrations of target sequence can be helpful in monitoring the assay for changes in sensitivity over time. In addition, inclusion of a positive control where the concentration of target sequence is below the detection threshold of the assay can be useful for detecting low levels of amplicon.

A common approach to developing internal controls is to create synthetic materials, such as in vitro synthesized plasmids, that can be spiked into the specimen before testing. The most common internal controls are synthetic segments of nucleic acid that use the same primer sequence as the target sequence. A sequence internal to the primer's binding site that is unique to the internal control allows separate detection and quantitation from the target. In addition, this internal control can be used for internal calibration. An internal calibrator contains a determined amount of this modified target that can be added directly to a clinical specimen and undergoes the same manipulation as the target of the patient specimen. One caveat for internal controls is that they must have the same

or a very similar efficiency of amplification. Moreover, when the internal control fails to be detected, it is not possible to determine whether an inhibitor is present or there is an amplification problem. It is important to use a low amount of the internal control to avoid competition with the target of the patient specimen. When detecting and/or quantifying RNA from tissue or cells, amplification of a housekeeping gene (e.g., GAPDH, β -actin) can be used as an internal control. Most housekeeping genes are highly abundant and might not be the most appropriate internal control. The use of RNA from a gene with the same approximate abundance as the target sequence should be used.

NEW TEST VERIFICATION/VALIDATION

As with any other area of the clinical laboratory, the introduction of a new test requires proper validation. There are major differences between the implementation of an FDA-approved test and one that is not. CLIA '88 provides specific guidance for validation of these assays. Laboratories implementing FDA-approved tests must verify and document the performance characteristics of the test for the indications for use in populations similar to those in which the manufacturer has established performance. Implementation of in-house developed assays requires a more involved process, with extensive documentation on test performance and QC programs that ensure reproducible performance of the test. Table 69-3 provides a list of guidelines and standards for molecular diagnostics testing that can be used as references during assay development and verification. Table 69-4 describes the different aspects of documentation that would be useful to capture during the validation process.

Verification of a new test is a complex process that can be divided into two phases: analytical and clinical verification. Analytical verification provides information about the analytical performance of the test. Clinical verification provides information about the clinical utility of the test with regard to the intended use. Determination of the intended use provides information about the appropriate settings, including disease states and populations for which the test can be useful. In this text, the phrase *intended use* refers to the DNA or RNA target that a molecular assay detects or quantifies, whereas *indications for use* refers to the clinical syndrome/condition for which the assay can be used for diagnosis, management, or monitoring of disease.

TABLE 69-4

Documentation Checklist for Assay Validation

Test name	Name of the test including technology used—Be sure that the name identifies the particular organism and/or disease/condition to be tested.
Intended use	What the test measures and for what purpose—Identify the particular microorganism and parameters tested, and indicate the use of the test (e.g., diagnosis, prognosis, monitoring response to treatment, guiding therapy).
Indications for use	Provide clinical conditions—Use reference standard definitions as found in Online Mendelian Inheritance in Man (OMIM), www.ncbi.nlm.nih.gov/omim
Method category	Identify methodology used for the test.
Testing procedure	Information with regard to specimen types, specimen handling and transport procedures, nucleic acid isolation and storage, description of the test procedure, data reports, expected results, and technical interpretation of results—All these parameters should be included in policies and procedures for the particular test.
Test results	Examples of results
Analytical verification	Analytical sensitivity, specificity, precision, dynamic range, cross reactivity, interfering substances
Quality control and quality assurance	Delineate QC and QA program—Identify informal proficiency program if no Department of Health and Human Services-approved program exists.
Assay limitations	Clearly explain and/or discuss potential limitations of the assay.
Clinical data	Primary objective of the study, clinical condition evaluated, patient population, demographics, and sample size estimate
Clinical verification	Clinical sensitivity, specificity, and positive and negative predictive value
Reporting of tests results	Clinical interpretation
Clinical utility	Potential clinical benefit to patient

TABLE 69-5

Commercial Sources of Control and Reference Materials

Company	Available material
Seracare (www.seracare.com)	Quantitative and qualitative controls, external run controls, qualification, verification and performance panels for HCV, HIV, HBV, external run controls for CMV, HSV, EBV, HPV, <i>Chlamydia trachomatis</i> , <i>Mycobacterium tuberculosis</i> , CFTR, warfarin sensitivity, MTHFR.
Advanced Biotechnology (www.abionline.com)	Control DNA, virus and cell lines (HIV, HTLV, EBV, CMV, HSV, VZV, HCV, SIV, rubella). Native and recombinant products purified viruses, antigens, proteins and antibodies
Stratagene (www.stratagene.com)	Universal human reference RNA for micro array technology
AcroMetrix (www.acrometrix.com)	External run controls, secondary reference controls, verification panels for HIV, HCV and HBV, HIV genotyping
National Institute for Biomedical Standards and Controls (www.nibsc.ac.uk)	Evaluation/statistics service, working reagents for HIV-1 RNA, HCV, HBV, HAV, Parvovirus B19
American Type Culture Collection (www.atcc.org)	Bacteria, bacteriophages, cell lines, hybridomas, filamentous fungi and yeast, tissue cultures, viruses
Coriell Repository (http://ccr.coriell.org)	Provide essential reagents to the scientific community by establishing, verifying, maintaining, and distributing cell cultures and DNA derived from cell cultures with mutations in different clinically relevant genes
Paragon Dx (www.paragondx.com)	DNA control material for cytochrome P450 2C9 (CYP2C9), cytochrome P450 4F2 (CYP4F2), and vitamin K epoxide reductase complex, subunit 1 (VKORC1), cytochrome P450 2C19 (CYP2C19), cytochrome P450 2D6 (CYP2D6), MTHFR, UGT1A1, NAT2 genes
Maine Molecular (www.mmqci.com)	Control product to monitor the analytical performance of extraction, amplification, and detection of test systems used in qualitative measurement of factor II (prothrombin) and factor V genes for the mutations factor II G20210A and factor V Leiden (G1691A), CFTR gene, cytochrome P450 2C9 (CYP2C9), cytochrome P450 4F2 (CYP4F2), and vitamin K epoxide reductase complex, subunit 1 (VKORC1)

CFTR, Cystic fibrosis transmembrane conductance regulator; CMV, cytomegalovirus; DNA, deoxyribonucleic acid; EBV, Epstein-Barr virus; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HTLV, human T-lymphotropic virus; MTHFR, methylenetetrahydrofolate reductase; RNA, ribonucleic acid; VZV, varicella zoster virus; SIV, simian immunodeficiency virus.

ANALYTICAL VERIFICATION

Before a new or improved test is introduced, careful evaluation of the performance characteristics of the assay under laboratory conditions needs to be done. The analytical verification process provides information regarding the performance of the assay but also can provide practical information needed for daily operation of the test. Historically, analytical validation programs has been challenging because of the lack of standards and reference materials for many nucleic acid targets. This shortfall has impacted the laboratory's ability to determine assay sensitivity and accuracy. Table 69-5 lists suppliers of commercially available reference materials that can be used during analytical verification and as a source of QC material.

As part of the analytical verification, laboratories must determine the assay's analytical sensitivity, analytical specificity, accuracy, and precision.

For quantitative assays, information regarding the linear dynamic range or reportable range determines when a measurement or change in the quantity of the analyte is clinically relevant or due to inherent test error. A number of national and international organizations are taking steps to develop standard reference materials. The National Institute of Standards and Technology developed one of the first nucleic acid standard reference materials for human identity testing. More recently, the World Health Organization (WHO) introduced a standard reference material for HIV, HCV, and HBV that has been used for verification of nucleic acid tests for screening of blood and blood products. Reference panels calibrated to WHO standard reference material are commercially available (SeraCare Life Sciences).

When standardized reference materials are not available, laboratories must rely on alternatives to validate tests. Laboratories can develop their own reference materials for analytical validation and monitoring daily

performance of the assay. These reference materials may be available in-house or from an outside source such as a collaborating laboratory, government agency (CDC, FDA, NIH), or commercial supplier (SeraCare Life Sciences, AcroMetrix). Examples include intact virus particles, bacteria that naturally contain the target in their genome, cell lines that contain a specific genetic change, plasmids, and intracellular RNA or DNA. When it is difficult to obtain a natural analytical reference material, laboratories develop synthetic reference materials. These synthetic reference materials may be in the form of single- or double-stranded DNA or RNA that is manufactured in vitro and that can be accurately quantified by several physical and/or biochemical methods. Examples include synthesized DNA in the form of oligonucleotides, single-stranded DNA produced by cloning recombinant phage, double stranded DNA produced by cloning into vectors such as plasmids, or a DNA fragment produced by chemical or physical method from a larger DNA molecule followed by purification. Synthetic RNA reference materials can be generated by in vitro transcription of DNA templates.

Test validation requires verifying the new test results with those of another independently established method. Alternatively, the laboratory can split samples for a comparison study with another laboratory that performs a similar molecular test.

The evaluation of the precision of an assay is necessary to be able to determine what constitutes a biological change in the analyte versus expected analytical variability of the laboratory measurement. Evaluation of the precision should take into account the entire testing process—nucleic acid extraction, amplification, detection, and quantitation. Precision studies should be carried out using test material or reference material that is similar to or closely resembling the intended patient specimen. Such material may be obtained by serial dilution of a target-positive specimen to below the limits of detection. If a characterized patient specimen is not available, then reference material may be created by mixing a cell line or purified virus microorganism into a pool of the patient specimens known to be negative for the specific analyte. These materials could be used for daily monitoring of the assay's performance as well. Daily QC for qualitative assays should include at least a single positive reference control with a concentration close to the limit of detection. Daily QC for quantitative methods should include at least two concentrations which span the linear dynamic range of the assay and, when possible, include the values used for clinical decision making.

Determination of the accuracy of molecular methods has been challenging because molecular methods have proven to be more sensitive than a large number of well-established methods, even criterion standard (gold standard) methods. Generally, when evaluating a new test, the results obtained should be compared with the results obtained from an established test that is considered a criterion standard method. In the absence of a criterion standard, a laboratory could purchase reference material to be used for the analytical verification.

Determination of the linearity of a quantitative assay may be performed by testing at least four different levels of the analyte. Again, test material could be prepared by spiking the analyte into negative patient sample or by performing serial dilution of a patient specimen known to contain a very high level of the analyte. The analytical sensitivity represents the ability of a test to obtain a positive result in concordance with positive results obtained by a reference method. For quantitative molecular methods, the lowest amount that the method can detect might be different from the lower limit of quantification for a particular nucleic acid or microorganism. The lower limit of quantification is the lowest amount of a nucleic acid sequence that can be detected with acceptable precision. Analytical sensitivity could be determined by performing serial dilutions of an appropriate number of samples containing different concentration of the analyte. Analytical specificity is the ability of an analytical method to detect and/or quantify what the analyte is intended to measure. One aspect of specificity that can easily be measured is the lack of cross-reactivity with closely related nucleic acid sequences or organisms. In addition, for infectious disease testing, it is important to determine lack of cross-reactivity with nucleic acid from organisms present in the normal flora or that would normally be present in a patient specimen.

It is also important to determine interfering substances that might affect the ability of a test to detect and/or quantitate the analyte of interest. The source of the interfering substance could be endogenous or exogenous. Exogenous interfering substances include drugs, parenteral nutrition, or anticoagulants. Some anticoagulants (e.g., heparin) may interfere with the amplification process. Endogenous interfering substances (e.g., lipids, bilirubin) could be result of pathologic conditions. There are several approaches for detecting interfering substances. One can add target nucleic

acid (e.g., purified nucleic acid, cells, or microorganisms) to specimens that contain various interfering substances. One can also add the specific nucleic acid target to specimens from patients with various conditions (e.g., jaundice) or who are receiving specific drug treatment.

Appropriate specimen handling, including specimen collection and transport conditions, is critical to the testing process to ensure specimen integrity. Inappropriate specimen handling could result in nucleic acid degradation, which can lead to falsely negative detection or inaccurate quantitation of nucleic acid. This is critical for assays that detect and/or measure eukaryote RNA and viral RNA. The best specimen type and quantity should be determined because molecular tests are applied to a variety of specimen types. Appropriate selection of specimen type will depend on multiple factors, including the clinical condition being studied and the type of nucleic acid required for the test. The format of the molecular assay being developed could greatly affect the amount of specimen required. Tests that require samples to be run in duplicate will require more specimen than those run in singleton. Specimen transport and storage should be evaluated for every assay and type of nucleic acid. Specimen transport and storage conditions could vary significantly between specimen type, analyte (RNA vs. DNA), cells, and microorganism and must be determined by each laboratory. There are special requirements for specimen transport and storage for RNA, because it is highly susceptible to degradation by ubiquitous enzymes. Transport and storage conditions can vary greatly from storage at room temperature to having to centrifuge samples, remove plasma or serum, and storage at -80°C until tested.

CLINICAL VERIFICATION

Laboratory methods provide information for managing patients and addressing relevant clinical questions. The usefulness of a method depends on both the analytical performance and the clinical characteristics of the test (clinical sensitivity, specificity, and predictive value). The clinical significance of a test should be defined in terms of the disease or syndrome that is the subject of the test. These include disease prevalence, possible outcome, and cost to the patient and others for incorrect information (false-positive or false-negative results). Validation of clinical utility of an assay is a complex process that possesses many challenges. *Clinical utility* is referred to here as the indications for use. For example, the assay is intended to quantify a nucleic acid (analyte), but is indicated for certain clinical conditions or scenarios.

The first step of the analytical verification is to formulate a clinical question and to identify the target population to which the test will be applied. There are three parts in the definition of a clinical question: (1) characterize the subject population, (2) define the clinical management decision, and (3) identify the role of the test in clinical decision making. When the clinical use of each test is being considered, it is assumed that the test's analytical performance characteristics are well understood. Known analytical limitations (e.g., reportable range for quantifying, precision for nonclinical samples) should be taken into consideration when determining the clinical use for each particular assay. Clinical verification requires evaluation of the clinical sensitivity of the test by evaluating an appropriate number of samples from patients known to have the disease or condition. The population and type of sample should be fully described because the results for a test in a given population using a specified sample type may not be suitable for another population, or even for another sample type within the same population. It is important to define the purpose (i.e., what is the test measuring) and indications (i.e., what are the clinical circumstances in which the test will be useful) before starting the clinical verification. For example, indication for use of an assay could be diagnosis, screening in a population, confirming results from another assay, resolution of disease, or prognosis. Clinical specificity can be determined by analyzing samples from patients diagnosed with a different disease that is in the differential diagnosis and that might be confused with the indicated disease. In addition, specimens from healthy donors can be appropriate for determining the clinical specificity of the test. The other parameters that need to be determined are the positive and negative predictive values, as well as a predictive value of the test over the course of disease or therapy. Furthermore, in order to determine the clinical utility of a new LDT, variables that could affect results and their interpretation should also be considered. For example, for infectious disease, some of these variables could be microbial host interactions, microbial dynamics, variants and mutations, or replicative fitness of the microbial agent.

Data generated during the clinical verification of each assay should be gathered and kept organized to satisfy the requirements of the different

regulatory bodies. Within the documentation, the laboratory should have available a list of indications for which the assay has been verified (see Table 69-4).

QUALITY CONTROL OF THE TESTING PROCESS

It is extremely important to implement a QC program for LDTs for validating the strength, purity, and performance of every critical reagent of the testing process. Every critical reagent should be tested before being approved for clinical testing. Tolerance limits should be established for every critical reagent. When possible, the tolerance limits should be established using a quantitative measurement to avoid subjective evaluation of the quality of the critical reagent.

QUALITY CONTROL OF EQUIPMENT

All equipment used in the molecular diagnostic laboratory must have written maintenance procedures and calibration checks. As with any other clinical laboratory equipment, tolerance limits for acceptable performance and calibration checks for all laboratory equipment used during the testing process should be clearly defined and monitored in a regular fashion to assure continued production of accurate and reliable test results. When performance or calibration checks fall outside the tolerance limit defined for any particular instrument, the latter should be immediately taken out of service for repair. After repair the equipment should be calibrated before being placed back in use. As part of the QA program developed by each laboratory, documentation of all maintenance, performance checks, calibration, or repair for each piece of equipment should be maintained and kept according to the laboratory policy of document retention.

Thermocyclers are a crucial item to any molecular diagnostic laboratory. Any change in the performance of thermocyclers has direct impact in the sensitivity and precision of the assay performed in that piece of equipment. Maintenance, calibration and QC performance of all instruments should follow manufacturer's recommendations. Briefly, as part of

the performance monitoring for thermocyclers, determination and documentation of the cycling time, verification of the setpoint error, and any error messages should be recorded. Cycling times between different runs should not differ more than a couple of minutes. Fluctuations in the cycling times are a warning sign that the thermocycler needs to be adjusted and restored to its original condition. In addition, it is recommended that the chiller, heater, and block temperature uniformity tests be performed according to the manufacturer's recommendations. The block temperature uniformity check can be accomplished by using a thermocouple with a temperature probe.

Another important equipment item that is used daily in a molecular diagnostics laboratory is the pipetter. Pipettors are used for almost every step of the testing procedure. Special emphasis should be placed on the maintenance of the pipettors because they could be a major source of error. All other pieces of equipment should be maintained according to the manufacturer's recommendation. When possible, calibration of the equipment should be performed by using certified standards or reference materials.

CONCLUSIONS

It is clear that the molecular diagnostics laboratory provides valuable contributions to patient care. Ongoing issues of test specificity, sensitivity, quality, interpretation, limitations, instrument performance, consumables, intellectual property, patient confidentiality, and reimbursement will continue to mature in the development of this discipline. One concern is the emergence of direct to consumer marketing of over-the-counter test kits and fee-for-service enterprises that provide reports to customers that predict the "risk" of carrying or getting a disease or diseases based on DNA typing (e.g., cheek swab). These reports can confuse the patient and his or her physician as well as institute undue alarm and stigma. Such testing should include careful interpretation and genetic counseling. Future developments in this field will undoubtedly continue to provide opportunities for improving diagnostic and prognostic information as we realize the promises of personalized medicine and more effective patient management.

KEY POINTS

- Molecular testing for inherited disorders may be the most rapidly growing area of molecular pathology, owing to the plethora of disease genes discovered through the Human Genome Project.
- The mutations for single-gene disorders, whether dominant or recessive, can be detected by a variety of molecular diagnostic techniques, either specific to the mutation in question, if it is known, or by comprehensive gene sequencing or mutation scanning approaches if the mutation is not known.
- Certain disorders, such as cystic fibrosis, have sufficiently high mutation carrier frequencies that they have become targets for large-scale population screening programs.
- Late-onset dominant disorders, such as Huntington disease and familial cancers, are appropriate targets of presymptomatic testing, providing sufficient attention is paid to the associated ethical concerns.
- Ethical issues raised by each of these applications involve genetic privacy, informed consent, pregnancy termination, potential stigmatization, and theoretical risk of insurance discrimination.

Probably the fastest growing, and perhaps most controversial, area of molecular pathology, diagnostic molecular genetics holds promise of becoming the most powerful diagnostic and screening tool of the 21st century. With the rapidly accelerating pace of identification of new disease genes after completion of the Human Genome Project and the recognition that virtually all diseases, including neoplastic and even infectious ones, have some genetic component, the clinical utility of this subspecialty can

only continue to expand. Moreover, its unique capability to diagnose disease both prenatally and presymptomatically should confer on it a primary role in preventive medicine, a focus of increasing urgency in the present era of medical care cost containment. Even beyond that, diagnostic molecular genetics leads naturally into therapeutic molecular genetics, because essentially the same normal gene sequences used to detect molecular genetic defects by deoxyribonucleic acid (DNA) hybridization could theoretically be used to correct such defects by gene replacement therapy. Whereas the pace of advances in the latter activity has remained frustratingly slow, it is safe to say that it will become an important therapeutic modality during this century. When that happens, it will become even further intertwined with the activities of the molecular diagnostics laboratory, which will have the responsibility of confirming proper insertion and monitoring appropriate expression of the replacement gene.

Yet such progress does not come unencumbered by appreciable obstacles. Aside from the considerable technical sophistication and complexity of these procedures, they are inextricably bound up with a number of thorny ethical dilemmas. Dissecting a patient's most fundamental constitutional makeup, and the inborn errors therein, raises problematic questions about genetic discrimination, stigmatization, ethnic differences, privacy, informed consent, and confidentiality. Because at the molecular genetic level everything becomes a preexisting condition, the very definition of insurability may need to be revised, and instances of insurance and employment discrimination as a result of genetic testing, although rare (Hall, 2000), have been reported (Billings, 1992). It is reassuring that in the United States, where privately insured health care is most vulnerable to such abuses, we now have federal legislation, the Genetic Information Nondiscrimination Act, prohibiting discrimination in health insurance and employment based on genetic test results, although certain limitations still remain (Baruch, 2008). Furthermore, discovery of any such heritable mutations in an individual has profound implications far beyond the

immediate patient who requested the DNA test (the proband), extending to all the other members of that person's family, none of whom may have consented to exploring or revealing this type of information. Indeed, with the almost unlimited power of DNA testing afforded by amplification techniques such as the polymerase chain reaction (PCR) and high-throughput genomic analysis technologies (see Chapters 66 and 77), it becomes quite easy to perform genetic analysis without the patient's consent or even knowledge, because the testing can be done on minute portions of tissue or fluid samples obtained for other unrelated purposes. Prenatal diagnosis—and, by extension, preconception genetic carrier screening of couples—becomes caught up in the passionate ethical and religious debates over abortion. And gene therapy, despite general consensus that it should be directed only at somatic rather than germline cellular targets (and even this notion is beginning to change), raises the specter of eugenics among those who do not have to remember back all that far to times when such notions were not only accepted but actively espoused.

Much of diagnostic molecular genetics involves the assessment of risk for occurrence or recurrence of a disorder in an individual or family. For reasons described more fully later in this chapter, the test results obtained are often expressed not in terms of a numerical concentration or as a yes/no answer, but rather as a probability, which sometimes is derived by multifactorial Bayesian analysis (Ojino, 2004). The accurate and meaningful conveyance of such complex uncertainties to patients and even referring physicians can be quite difficult and time-consuming. For this reason, and owing to the serious ethical implications of these tests as described previously, this area of laboratory medicine, perhaps more than most others, requires very close communication between the laboratory and the referring clinician or genetic counselor. In fact, some of these tests, particularly the emotionally charged predictive ones, should only be ordered through a medical geneticist or genetic counselor, because these are the specialists who are best qualified to assess the appropriateness of the test and explain the results to the patient. Some large academic and commercial reference laboratories specializing in this type of testing even employ their own genetic counselors on staff as a further safeguard to ensure appropriate use and communication with primary care physicians who may not be well-versed in these matters.

CHOICE OF TECHNIQUES

With so many genetic disease genes, loci, and mutational mechanisms known, diagnostic molecular genetics must take advantage of the entire spectrum of modern molecular biological techniques available. These include, among others (see Chapters 65–68):

- PCR
- Southern blotting
- Allele-specific probe hybridization
- DNA sequencing
- Real-time PCR
- Nucleic acid microarrays
- Invader assay
- Amplification refractory mutation system (ARMS)
- Oligonucleotide ligation assay (OLA)
- Multiplex ligation-dependent probe amplification (MLPA)
- Mutation scanning methods, such as denaturing gradient gel electrophoresis (DGGE)
- Single-strand conformation polymorphism (SSCP)
- Mass spectrometry

The choice of which technique to use in a particular case will depend, to a large extent, on two factors: (1) the present knowledge of the gene(s) associated with the disease in question and (2) its degree of molecular heterogeneity. The first criterion roughly divides all genetic diseases into two categories: those for which the causative gene has been isolated and those for which it has not. Those in the first category can often be approached by direct gene/mutation analysis; those in the latter can only be approached by linkage analysis using polymorphic DNA markers nearby on the same chromosome, as long as the disease has been mapped to that rather crude level. The second concept, heterogeneity, refers to the number of different genes, or the variety of mutations within a single gene, that can cause the same disease. The greater the heterogeneity, the more difficult, labor-intensive, and expensive the DNA test becomes (and the more complex the results reporting and genetic counseling). In other disorders, one or more mutations may be of sufficiently high frequency in particular racial/ethnic populations that screening for those few, while ignoring the many rarer mutations reported, can provide a test of sufficient yield to justify the targeted approach.

Figure 70-1 Schematic example of detection of a point mutation by differential cleavage with a restriction enzyme. In this case, the sickle cell mutation, substitution of T for A in codon 6 of the β-globin gene destroys an MstII cleavage site so that digestion of a polymerase chain reaction product from the region will produce two DNA fragments in normals but only one fragment in HbS homozygotes. Mutation of the first nucleotide in this codon, found in hemoglobin C disease, does not destroy the MstII site (because the enzyme can accommodate any nucleotide in this position) and thus cannot be detected by this method.

To make such tests practical and of reasonable cost, a number of *multiplexing strategies* for simultaneous mutation detection have been devised. All of these involve some compromise as to overall test sensitivity. Indeed, the field of molecular genetic testing tolerates, by necessity, a number of screening tests with clinical sensitivities noticeably below those that would be considered acceptable in other areas of the clinical laboratory. The decision of just how low the acceptable sensitivity cutoff should be often comes down to public health considerations. Most geneticists have reasoned that, at least for screening tests, the potential public health benefits of offering a test of admittedly suboptimal sensitivity outweigh the arguments for withholding it, as long as sufficient education and counseling are provided to patients so that they understand the residual risk inherent in a negative test result. It is important to keep in mind that this discussion is about clinical sensitivity, not analytical sensitivity. It is assumed that the test is capable of detecting a given mutation whenever it is present; it is just that many rarer mutations will not be targeted by the assay, so that some proportion of carriers will be “missed”—a sort of “clinical false-negative” (Palomaki 2004).

Direct mutation tests have been simplified immeasurably by the advent of PCR. Through the judicious choice of primers, this technique allows the laboratory to hone in on the precise mutation of interest, or a “hot spot” within a gene containing several possible mutation sites, using minute amounts of starting material. Once the region containing the suspected mutation is amplified, it can be analyzed by gel or capillary electrophoresis, sequencing, or DNA probe hybridization. For a deletion that would be expected to alter the length of the amplicon, accurate molecular sizing of the PCR products by electrophoresis will be sufficient. Alternatively, if the deletion or point mutation disrupts (or creates) a restriction endonuclease cleavage site, it can be detected by electrophoretic analysis of PCR products digested with that enzyme (Fig. 70-1). Another option is to hybridize the PCR products with allele-specific oligonucleotide (ASO) probes, short DNA fragments that are precisely complementary to either the normal or mutant target sequence. As discussed in Chapter 67, if the hybridization, usually in a dot- or line-blot format, is performed under sufficiently stringent conditions, target DNA containing the mutation will hybridize only with the mutant probe, and

vice versa for wild type target DNA. Several mutation hot spots in a gene can be amplified together by multiplex PCR. As a variation on this approach, any number of allelic probes can be spread out on a solid support for subsequent hybridization with the specimen DNA (or amplicons) in the form of a microarray or in suspension on microbeads. Lastly, a number of commercial reagents and instruments are available that detect point mutations by differential probe/quencher hybridization or by capillary electrophoresis and other sophisticated techniques, as described in Chapters 67 and 77.

To screen a disease gene for unknown mutations that may lie anywhere within it, several *mutation scanning* techniques that cast a wider net are available. SSCP, DGGE, denaturing high-performance liquid chromatography, and other variations of the same principle can theoretically detect point mutations anywhere within a gene by virtue of the altered topology that the substituted nucleotides induce in single-stranded or mismatched double-stranded DNA. These approaches obviate the need for separate and specific ASO probes for every possible mutation, although they can only be performed on limited PCR-amplified stretches of the gene (usually single exons or parts of exons) at one time and they are not 100% sensitive. The protein truncation test detects mutations, causing premature termination of the gene's polypeptide product; it requires an involved *in vitro* transcription/translation approach and will only pick up "stop" mutations (and some frameshifts and splicing variants) while overlooking common single-nucleotide substitutions (missense mutations). The only technique that should be 100% sensitive in detecting all possible point mutations, at least in theory, is complete DNA sequencing of the gene, although even it will miss mutations that lie outside the usual coding region targets (e.g., in introns, promoters, or enhancer regions).

Disorders caused by gene expansion by a trinucleotide repeat mutation can be diagnosed by Southern blot or PCR, in either case by observing a larger-than-normal target DNA fragment. Disorders caused by large deletions may be diagnosed by Southern blot by observing loss or decrease in size of a target fragment, by PCR, through loss of a product normally amplified from that site or appearance of a new "junction" fragment, or by MLPA.

For those disorders with too many unknown mutations, or an unknown gene, predictive diagnosis by *linkage analysis* is possible in certain families. Because the analysis requires comparative testing of other affected and unaffected siblings and parents, not every family will be accessible or informative using this approach. Also required is knowledge of closely linked, preferably flanking or even intragenic polymorphic DNA markers that can be observed to co-segregate consistently with either the normal or disease phenotype within the family. Traditionally, the markers used have been restriction fragment length polymorphisms (RFLPs) detected by Southern blot. More recently, microsatellite polymorphisms—tandem oligonucleotide sequences of variable repeat length—that are detectable by PCR and gel or capillary electrophoresis have become favored because of their abundance throughout the genome, the multiallelic nature of their polymorphisms, and the relative ease of the testing method. Very large genes, such as those for neurofibromatosis and Duchenne muscular dystrophy (DMD), will usually have intragenic microsatellites that can be accessed, minimizing the chances of recombination between the mutation and the marker.

Linkage techniques are less favored than the direct mutation detection approach because of the need to test multiple family members and because meiotic recombination between the gene and the marker can disrupt the apparent phase of linkage between parent and offspring, leading to false-positive or false-negative interpretation of results. For each centimorgan of map distance between the two loci, 1% recombination can be expected (1 cM = 1 million base pairs [bp]). For example, in Figure 70-2 the fetus is predicted to be affected, having inherited the same upper RFLP fragment as the previously affected son. But if the polymorphic restriction endonuclease site being tested is 5cM away from the disease gene, one can only conclude that the fetus is at 95% risk of being affected. However, because the completion of the human genome sequence, which is saturated with polymorphic markers (both short tandem repeats and single-nucleotide polymorphisms), there is no longer any need to rely on linked marker that is so far away from the disease gene.

Although this chapter is primarily concerned with molecular testing for single-gene mendelian disorders, it would be remiss not to acknowledge the newer techniques now available for *whole-genome analysis*. This can be done using either high-density oligonucleotide microarray platforms or so-called highly parallel or "next-generation" DNA sequencing. At present, only the former is in routine use in clinical genetics, in the form of array comparative genomic hybridization. This technique employs a high

Figure 70-2 Example of restriction fragment length polymorphism analysis for prenatal diagnosis of an autosomal dominant disorder. In this Southern blot, the upper band from the father is the one that co-segregates with the disease phenotype, as seen in the affected son. Because the fetus (?) has also inherited this band, it is predicted to be affected. The precise risk depends on the map distance between the disease gene and the restriction fragment length polymorphism (RFLP) marker.

number (500,000 to more than 1,000,000) DNA probes on the array, chosen so that their complementary genomic sequences span the entire genome at regular intervals. Total genomic DNA from the patient competes for hybridization to the array against a "normal" total genomic control sample, each labeled with a different fluorescent dye. If the patient's DNA contains a deletion on a certain chromosome, this will be indicated by an excess of the control DNA hybridizing to the probes on the array that span the deletion site (Fig. 70-3). Conversely, if the patient's DNA contains a duplication of a chromosomal region, an excess of patient DNA will compete for hybridization to the encompassed probes on the array. The resolution for detecting these *copy number variants* (CNVs) is much finer than can be achieved by classic karyotype analysis under the light microscope, and is continually improving as ever greater numbers of probes, at ever diminishing base-pair intervals, are added to the arrays. And it is far more cost-effective and comprehensive than the previous analogous alternative of running many different fluorescence *in situ* hybridization (FISH) probes in series. As such, it has rapidly become a predominant technique for detecting deletions/duplications in patients with congenital problems that do not readily suggest a particular known genetic syndrome, including those with nonspecific physical malformations/dysmorphisms, developmental delay, and/or autism (Manning 2010; Miller 2010). However, it does have some limitations. First, because all it does is examine differences in hybridization intensity across the total genomic DNA, balanced translocations with no gain or loss of genetic material will not be detected. Second, all human genomes contain a great many CNVs that are nonpathologic. Some of these are well-known polymorphisms and thus can be discounted as etiologic if observed in a patient; but many others are not yet known or studied extensively, producing the challenging "CNV of uncertain clinical significance." Aside from using intuition based on the particular genes encompassed by the deletion, testing of the parents may also be helpful. If a normal parent carries the same deletion, it is less likely to be pathologic (though there are exceptions). The ultimate gold standard for identifying all possible mutations would of course be whole-genome sequencing. It took 13 years to completely sequence the consensus human genome under the Human Genome Project using conventional Sanger sequencing platforms (see Chapter 77). Now we have a new generation of automated DNA sequencers based on radically different chemistries, involving single-molecule pyrosequencing of millions of short fragments, which are then assembled into the full genome by the analysis software. These instruments are capable of sequencing a billion or more bases per day, at last putting the whole human genome in reach for routine analysis. However, at this point the appropriate clinical applications of the technology remain to be discerned. For one thing, the tremendous amount of data obtained would represent extreme overkill for the single-gene and

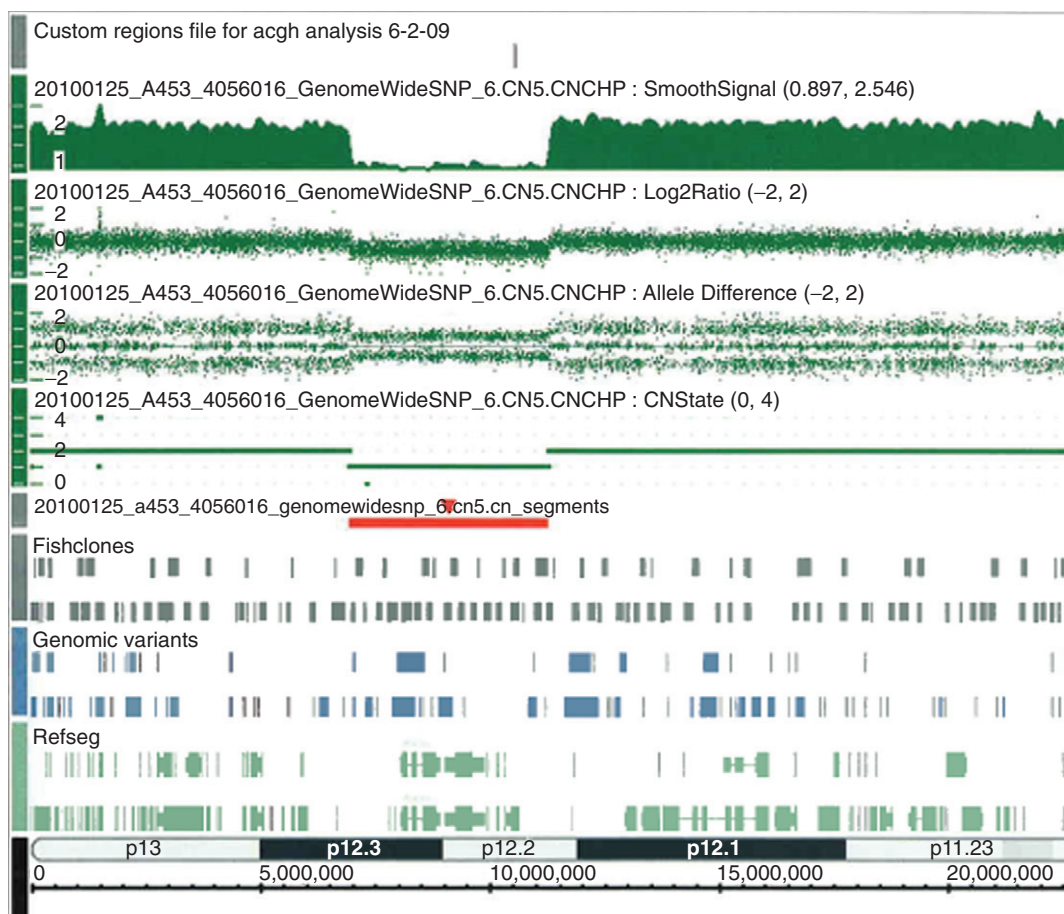

Figure 70-3 Example of a typical deletion result by array comparative hybridization. The gap in hybridization signal demarcated by the red line indicates a 4.329 Mb hemizygous deletion on chromosome 20p12.2-12.3 (6975661–11304543 bp). This deletion encompasses multiple genes, including *JAG1*, the gene implicated in Alagille syndrome, which was the clinical diagnosis in the tested patient. (Courtesy Dr. Xinmin Li.)

small multiplex applications we have today. Secondly, the data would reveal potentially concerning mutations in many other genes besides the ones immediately implicated in the patient's condition. And perhaps most importantly, for every real pathologic mutation detected, many thousands of missense variants of uncertain clinical significance would be revealed, potentially worrying the patient unnecessarily and demanding an endless amount of investigation on the part of the laboratory to sort them out (ten Bosch, 2008).

CHOICE OF APPLICATIONS

To some extent, the choice of technique will also depend on the application or clinical indication. In medical genetics, these applications fall into five major areas: carrier screening, newborn screening, diagnostic testing, pre-symptomatic DNA testing, and prenatal testing.

Carrier screening is the term applied to detection of recessive mutations in healthy individuals for purposes of genetic counseling and family planning. This application is further subdivided into screening of those individuals with a family history of the disorder and population-based screening of large numbers of individuals who have negative family history but who may be at risk for the disorder because of its prevalence within their ethnic group or in the population at large. In either case, the ultimate purpose is to identify couples at risk (i.e., both the man and the woman are heterozygous for mutations within the gene) who would then have a 25% chance of having an affected child with each pregnancy. But the testing strategies chosen for the two groups will differ. A person whose sibling has the disorder is at much higher risk of being a carrier than someone in the general population. That person may therefore warrant more aggressive testing (e.g., screening for a greater number of mutations or possibly linkage analysis or even complete gene sequencing) than would be cost-effective for a member of the general population. On the other hand, access to the affected sibling's DNA may allow prior identification of the

familial mutation, which would render subsequent testing of other family members much easier. Population-based screening, in contrast, typically strives to keep the testing procedure as rapid and inexpensive as possible, focusing on perhaps a few of the more prevalent mutations, sacrificing clinical test sensitivity for cost-effectiveness and expediency. And, with negative family history there are no affected family members to make either single-site mutation testing or linkage analysis an option.

Like population-based carrier screening, **newborn screening** aims to identify relatively prevalent (as genetic diseases go) inherited defects in otherwise asymptomatic individuals. Indeed, the most important disease targets, such as phenylketonuria, galactosemia, sickle cell disease, and cystic fibrosis, are likewise autosomal recessive disorders. In this case, however, the goal is to ascertain affected babies early in life so that treatment (dietary or pharmaceutical) can be initiated before irreversible damage occurs. Currently, molecular genetic methods in this setting are employed mainly as a backup for confirmation of positive results ascertained by less expensive and more comprehensive biochemical or enzymatic methods, but this situation could reverse itself as molecular methods become increasingly cost-effective, high-throughput, and comprehensive.

Diagnostic genetic testing is, by definition, performed on a symptomatic individual. Because the DNA tests for genetic disease are absolutely disease-specific and the diseases themselves quite rare, these procedures do not cast a wide enough net to be used for extensive differential diagnosis; the symptoms must be sufficiently suggestive of the disorder in question to justify ordering the test. Also, one must weigh the DNA test against more traditional methods with regard to cost, convenience, and utility. For example, hemoglobin (Hb) electrophoresis may be more convenient and comprehensive for sorting out a suspected hemoglobinopathy than the specific DNA test for the sickle cell disease mutation alone. On the other hand, molecular testing may be more advantageous for early or atypical clinical presentations. For example, molecular testing for cystic

fibrosis (CF) mutations can be performed in the newborn period when traditional sweat chloride analysis is either inconvenient or unreliable. In such cases it is also important to determine that the test represents the appropriate demographic. If not, a “negative” test may not be truly accurate. DNA tests also have the advantage of working well postmortem, when classic biochemical analytes can no longer be assessed.

Presymptomatic DNA testing is applied primarily to late-onset dominant disorders, in which the offspring of an affected parent are aware that they are at 50% risk of having inherited the disease gene and desire to know their status before its clinical onset to make informed reproductive, employment, and lifestyle decisions or initiate surveillance or preventive interventions. The prototypic disorders in this group are Huntington disease and the heritable cancer syndromes, although such diseases as neurofibromatosis, Marfan syndrome, adult polycystic kidney disease, and tuberous sclerosis are also relevant. This sort of testing has been the most problematic, from a psychosocial and ethical standpoint, of any in diagnostic molecular genetics, with the risk of severe adverse consequences of results reporting, including suicide. Because of this, established testing protocols include stipulations for informed consent, concurrent clinical assessment, extensive pretest and posttest genetic counseling, and psychosocial support (Huntington’s Disease Society of America, 1989; American College of Medical Genetics, 1999).

Finally, there is the clinical application most distinctive to medical genetics: *prenatal testing*, or the detection of genetic disease in the fetus. With a few exceptions (e.g., hydrops fetalis in homozygous β -thalassemia, thanatophoric dwarfism, and type I osteogenesis imperfecta), most mendelian disorders, especially inborn errors of metabolism, are not expressed either visibly (by ultrasound) or biochemically in the fetus, so predictive diagnosis can only be made at the DNA level. Even for those disorders that might be detected biochemically, DNA often proves to be a far more accessible substrate, from an obstetric point of view, than the affected protein products or metabolic substrates. Whereas molecular analysis can be performed on minute amounts of amniotic fluid or chorionic villus samples collected by routine methods, even if obtained for other purposes, unless the protein product is expressed in fibroblasts (and thus amniocytes), biochemical analysis will require invasive biopsy of deep fetal tissues. For example, assay of phenylalanine hydroxylase activity to diagnose phenylketonuria would require fetal liver biopsy, and quantification of dystrophin to diagnose DMD would require fetal muscle biopsy.

The primary objective in prenatal diagnosis is the identification of an affected fetus in a timely manner so that a practical option of pregnancy termination can be offered to the couple. Even though some may argue an advantage for obtaining diagnosis prenatally so that therapy can be instituted promptly at birth, or for psychological reassurance of a couple if the fetus is found to be unaffected, it may be difficult to justify the risk (albeit low) of miscarriage from amniocentesis and chorionic villus sampling performed for these other purposes. For an affected fetus, unless one intends to initiate therapy in utero, provisional treatment at birth while awaiting confirmatory neonatal testing is perfectly acceptable.

Although prenatal genetic counseling is always nondirective, with moral and/or religious objections to abortion respected, both the clinical counselor and the DNA testing laboratory have a legitimate right and, indeed, responsibility to question the appropriateness of a prenatal test request, with its attendant risk and expense, from a couple for whom termination is not an option (the same would apply to requests coming too late in pregnancy for termination to be performed). It is because of these problems that invasive prenatal testing is not offered as a general population screening tool in women with no family history of the disorder in question. The power of PCR to enable single-cell genetic analysis has opened the way for preimplantation diagnosis, usually approached by performing in vitro fertilization and microdissection of a single blastomere from the early embryo. This strategy, initially applied to selected cases at risk for CF (Handyside, 1992) and other disorders, could potentially be offered to any at-risk couple for whom abortion is not an option, although it is not without its own ethical (and economic) objections. Recently it has begun to be used to diagnose adult-onset diseases such as familial breast/ovarian cancer (*BRCA1* and *BRCA2* genes), which, because they are late-onset, incompletely penetrant, and potentially treatable, would otherwise raise uncomfortable objections to traditional amniocentesis and pregnancy termination (Sagi, 2009).

Despite all these medical and moral dilemmas, when performed in appropriate circumstances, prenatal molecular genetic testing can offer at-risk couples, many of whom have already suffered the trauma of at least one affected child, one of the most valuable services in all of clinical medicine.

SPECIAL CONCEPTS UNIQUE TO MOLECULAR GENETIC DISORDERS

Whereas the DNA analysis techniques discussed in this chapter for diagnosis of genetic disease are generally the same as those used for molecular diagnosis of cancer or infectious diseases, their application in the former has revealed a number of unusual phenomena that one must keep in mind when dealing with particular hereditary disorders. Some of these phenomena were known since Mendel’s time but can now be understood mechanistically at the DNA level; others have emerged much more recently as unexpected byproducts of the molecular dissection of specific disease genes.

MOLECULAR HETEROGENEITY

Few genetic disorders are associated with a single mutation consistently identified in all affected cases (e.g., the missense mutation in codon 6 of the β -globin gene causing sickle cell disease). The vast majority of genetic disorders can be caused by more than one—sometimes hundreds—of different mutations within the disease gene (e.g., the *CFTR* gene of cystic fibrosis), and sometimes even by more than one gene (e.g., the *TSC1* and *TSC2* genes of tuberous sclerosis or the *BRCA1* and *BRCA2* genes of familial breast/ovarian cancer). Obviously, identifying the causative mutations in such disorders is technically much more difficult or sometimes impossible. A corollary of such molecular heterogeneity is that not all of the mutations will produce equally severe disease: some may cause only mild forms or even related syndromes with little resemblance to the classic phenotype (e.g., isolated absence of the vas deferens caused by certain mutations in the *CFTR* gene, or either multiple endocrine neoplasia or Hirschsprung disease caused by different mutations in the *RET* gene). All of this variability adds greatly to the complexity of genetic counseling and genetic testing.

VARIABLE PENETRANCE AND EXPRESSIVITY

Penetrance refers to the proportion of individuals who, having inherited a mutant disease gene, will actually display the disease phenotype. Usually applied to dominant disorders, it can produce the striking appearance of generation-skipping in disease pedigrees. This can complicate both molecular diagnostics and genetic counseling, because it may not be clear whether the proband inherited the disease from a parent or instead represents a new mutation in the family. It is a feature of such relatively common genetic disorders as Marfan syndrome and neurofibromatosis.

Variable expressivity refers to the appearance of different signs and symptoms of a disorder in individuals inheriting the same mutation(s). Like penetrance, it is probably a reflection of differential gene effects within dissimilar genetic backgrounds (in other words, the modulation of phenotypic expression by other nonallelic genes). It, too, makes ascertainment and counseling difficult, and raises ethical issues in considering abortion for diseases of variable and unpredictable severity.

UNIPARENTAL DISOMY

This unusual cause of a recessive single-gene disorder was first discovered in a CF patient, only one of whose parents was a carrier (Spence, 1988). By DNA haplotyping using polymorphic markers, it was shown that the patient had inherited two copies of the carrier parent’s chromosome 7 containing the mutant *CFTR* gene and no chromosome 7 from the other parent. The phenomenon has since been observed in other cases of CF and diseases involving other chromosomes as well. For some diseases, such as Prader-Willi and Angelman syndromes (see later discussion), the incidence of uniparental disomy approaches that of classic mutation mechanisms in the molecular pathogenesis, justifying routine testing for this phenomenon.

IMPRINTING

Imprinting refers to the differential expression of a gene in an offspring, depending on whether it was inherited from the mother or the father, or sometimes on other epigenetic influences. Some genes are only expressed or, conversely, turned off, when they pass through the oocyte lineage, and others only when they pass through the spermatocyte line. If an individual inherits the normal allele through the nonexpressing parental line, it cannot counteract a recessive mutation inherited from the other parent.

In at least some cases, the molecular mechanism appears to be differential methylation of chromosome regions and regulatory elements. This is the basis for both the deletional and uniparental disomy cases of Prader-Willi and Angelman syndromes (Gurrieri, 2009) (see later discussion).

ANTICIPATION

Anticipation refers to a progressive increase in severity and/or decrease in age of onset of a genetic disorder in subsequent generations of a family. It is typically associated with the trinucleotide repeat disorders, such as myotonic dystrophy and Huntington disease, in which the increasing severity can be correlated with further expansion of the repeat region. In the former disease, especially severe cases with childhood or infantile onset have been born to affected mothers, while in the latter disease the phenomenon occurs solely with paternal transmission, invoking an influence by imprinting as well (Koshy, 1997). It is for these reasons that accurate molecular sizing of trinucleotide repeat lengths is so important for diagnosis and genetic counseling in these disorders.

EPIGENETIC INFLUENCES AND NONMENDELIAN INHERITANCE

Epigenetic changes are heritable but potentially reversible changes in gene expression that do not represent a change in the sequence of the cell's genomic DNA. The most striking examples of epigenetic inheritance are genomic imprinting (discussed previously) and mammalian X-chromosome inactivation, both involving transcriptional silencing of genes by methylation of cytosines at CpG dinucleotides. The methylation status of DNA is maintained following DNA replication by methylases, which act on hemimethylated double-stranded DNA to methylate the newly synthesized DNA strand as well. The process is perpetuated indefinitely in succeeding cell divisions. Recent evidence suggests that *de novo* methylation of CpG doublets may take place in the promoters of some tumor suppressor genes, silencing these genes and in essence constituting one or both of the "hits" in a tumor suppressor gene that leads to tumor development (Jacinto, 2007).

Another category of epigenetic inheritance that is less clearly understood involves the property of some proteins to influence the conformation of newly synthesized or assembled proteins in a self-perpetuating manner. The most notable examples in mammals are the prion diseases, responsible for scrapie and bovine spongiform encephalopathy in animals and kuru and Creutzfeldt-Jakob disease in humans. The disease-producing prion protein, which may result from a coding sequence mutation in familial cases, is folded into an abnormal conformation and exerts an effect on newly synthesized prions in such a way that it perpetuates and proliferates the conformational abnormality that produces disease (Cobb, 2009).

ALLELE FREQUENCIES AND MASS POPULATION SCREENING

Reference has already been made to the application of carrier screening for recessive mutations on a population-wide basis. To justify, from a public health standpoint, the effort and expenditure required to perform a DNA test on thousands or millions of people, the incidence of the disease must be sufficiently high, either in the whole population or in the particular racial or ethnic groups being targeted for screening. For any autosomal recessive disease of appreciable incidence, the law of Hardy-Weinberg equilibrium predicts that the carrier frequency will be a good deal higher than the prevalence of affected individuals. In addition, the candidate disease target must be sufficiently severe and/or amenable to some medical intervention upon identification. Several disorders appear to fit these criteria. Mutations associated with hereditary hemochromatosis and activated protein C resistance (factor V Leiden) are found in 5%–10% of the Caucasian population, while the carrier frequency of the sickle cell mutation approaches 10% in the African American population. Unfortunately, controversies over disease penetrance in the first two and complex socioeconomic issues in the third have limited the application of these genes to screening (Grody, 2003a; Imperatore, 2003). Screening for thalassemia in Mediterranean and Asian populations, and for a panel of recessive disorders such as Tay-Sachs disease and Gaucher disease in the Ashkenazi-Jewish population, is similarly justified by allele frequencies in the target group. CF mutations, while of lower frequency, potentially place such a large majority of North American couples at risk that they have been

chosen as the first target for general molecular genetic population screening in the United States (see later discussion). Other disease targets proposed for large-scale screening include spinal muscular atrophy, fragile X syndrome, and hereditary deafness. This migration of molecular genetic testing out of the realm of rare or esoteric diseases and into the setting of common traits will have a profound effect on preventive medicine and public health, and will drive new developments in DNA test automation in the coming years.

PREDICTIVE GENETIC TESTING

Unique among molecular pathology tests, and indeed among clinical laboratory tests in general, molecular genetic tests possess the ability to predict future disease in individuals with no signs or symptoms of the disorder at the time of testing. This predictive ability exceeds that imparted to such tests as human immunodeficiency virus antibody screening in individuals with no symptoms of acquired immunodeficiency syndrome, or cholesterol levels as a risk factor for future atherosclerosis. For those tests, one could argue that the serologic, microbiologic, or biochemical signs of the disorder are already present, even if the patient does not yet feel any symptoms. Molecular genetic testing, in contrast, enables prediction of future disease even in the absence of *any* biochemical or physiologic abnormalities: Huntington disease can be predicted decades before there is any brain degeneration, or breast cancer years or decades before even a single breast epithelial cell has turned malignant. The potential psychosocial impact of revealing such information in a healthy individual cannot be overemphasized. For that reason, predictive or presymptomatic genetic testing must be accompanied by pretest and posttest genetic counseling and psychiatric support. Furthermore, such tests should be restricted to those who truly have an actionable need for them, in the sense that a positive DNA test will prompt some sort of early surveillance or preventive interventions or, at the very least, some indicated lifestyle or life-planning changes. Because it is difficult to imagine such conditions existing in the case of a child tested for an adult-onset disease, there is a strong convention in the field that healthy children younger than 18 years of age should not be offered predictive genetic tests for adult-onset disorders, so as to avoid potential stigmatization, discrimination, or adverse psychosocial effects of genetic information that is of no medical use to the child (Holtzman, 1997).

SPECIFIC DISEASE EXAMPLES

CYSTIC FIBROSIS

Because of its high carrier frequency in North America and northern Europe, its serious clinical nature, its straightforward mendelian (autosomal recessive) inheritance pattern, and its well-studied yet complex gene, CF has emerged as the paradigmatic disorder for large-scale molecular genetic screening. Within its scope can be found the full panoply of applicable molecular genetic techniques and the full spectrum of scientific and ethical dilemmas arising from the clinical variability of the disease, the extreme molecular heterogeneity of the causative mutations, and the anticipated advent of novel treatments, including exon-skipping and gene replacement therapy. With a carrier frequency as high as 1 in 29 in Caucasians of northern European ancestry (and progressively less in southern Europeans, Hispanics, African Americans, and Asians), there was ample motivation to screen the general population in order to identify couples at 1 in 4 risk of having an affected child with each pregnancy. But because carriers are asymptomatic and have normal sweat chloride levels, this screening could only be done after isolation of the gene in 1989 (Kerem, 1989; Riordan, 1989). Even though the gene had been mapped to chromosome 7 some years earlier, allowing for prenatal diagnosis by linkage analysis in informative families, screening and testing in others, especially those with no family history of the disorder, could only be considered once the gene was cloned and the mutations identified.

Even with that laudable accomplishment, however, the history of DNA testing for CF has been fraught with problems and controversies. The gene is more than 250,000bp long and encodes a large ion channel protein called the cystic fibrosis transmembrane conductance regulator (CFTR) (Collins, 1992). Most notably, the spectrum of mutations observed is remarkably heterogeneous. Whereas a three-nucleotide deletion of phenylalanine codon 508 (designated $\Delta\Delta F508$) accounts for about 70% of the mutations in non-Hispanic Caucasians (and significantly less in other ethnic/racial groups), more than 1500 additional mutations have so far been reported. Most of these are so rare that it is neither feasible nor cost-effective to include them in testing panels; only about seven (in addition to $\Delta F508$)

*Mutations subsequently removed from the panel (Watson, 2004).

account for more than 1% each of CF mutations in most Caucasian populations (Tsui, 1992) (Table 70-1). The sensitivity of carrier screening with mutation panels of between six and 25 alleles ranges from a high of 97% in Ashkenazi Jews (Abeliovich, 1992) to 75%–90% in non-Ashkenazi North American Caucasians, about 60% in Hispanic Americans, 50% in African Americans, and less than 10% in Asians (Ober, 1992; Grebe, 1994; Macek, 1997). Such variable and suboptimal sensitivity in an ethnically heterogeneous population like that of the United States, and the difficulties involved in counseling patients as to the residual carrier risk of negative test results, made population-based carrier screening for CF mutations a controversial subject (Grody, 1999). After much debate and several pilot screening studies, a consensus conference recommended that screening be offered to all pregnant couples and those planning pregnancy (NIH Consensus Statement Online, 1997). A steering committee representing the American College of Medical Genetics (ACMG), the American College of Obstetricians and Gynecologists (ACOG), and the National Human Genome Research Institute decided on a core screening panel of the 25 most prevalent mutations in the general mixed population (Grody, 2001a). The same group produced accompanying educational materials providing guidance to obstetricians on how the screening test should be offered, patient education brochures, and tables for determining the residual risk in those whose test results are negative.

With the launch of these guidelines in 2001, *CFTR* mutation analysis instantly became the highest volume molecular genetic test and one of the highest in all of molecular diagnostics. Given such a market, reagent and instrumentation vendors soon came forward with a variety of assays and platforms, which have now largely replaced the in-house methods previously employed by individual laboratories. The commercial methods, which incorporate at least the core panel of 25 mutations (revised downward to 23 in 2004 by Watson et al, 2004), and sometimes more, include ASO probes on paper strips, ARMS, OLA, Invader assay, microbead arrays, and microarray chips (Richards, 2004). In addition, complete gene sequencing is offered by a few laboratories (Strom, 2003), although it is too expensive for general carrier screening and is used primarily to assist in diagnosis of atypical CF cases or to identify parental mutations in affected offspring to enable prenatal diagnosis in future pregnancies.

Even years after launch, the CF carrier screening program continues to prove challenging for both the referring obstetricians and the genetic testing laboratories. Questions remain about uptake, proper communication of results, the utility of offering extended mutation panels (especially for those couples who test positive–negative in the initial screen), and even which mutations should be included in the core panel. The panel has already been modified once, after early data from national screening indicated that one of the mutations (1078delT) was more rare than previously thought, and another one (I148T) was not a mutation at all but a benign polymorphism; both of these have since been dropped (Watson, 2004). And at the other extreme, driven largely by marketing considerations, laboratories have been compelled to offer ever-larger mutation screening panels, and concern has been raised regarding the clinical significance of some of the added mutations (Grody, 2007). One large series has shown that the core mutation panel is indeed adequate for identifying the vast majority of carriers, with no additional mutations recurring in sufficient numbers to justify their incorporation into an expanded panel (Strom, 2011).

Another problem with genetic counseling for CF is the variable clinical severity of the disorder and the inconsistency of genotype–phenotype correlations. Beyond the finding that ΔΔF508 homozygotes tend to have pancreatic insufficiency, there is little about disease severity or complications that can be predicted reliably from knowing an affected individual's two mutations (Moskowitz, 2008). Even homozygotes for ΔΔF508, considered the prototypical severe mutation, can show a wide range in their

degree of pulmonary compromise (Burke, 1992). Conversely, there are mutations that cause pulmonary disease yet maintain normal sweat chloride levels (Highsmith, 1994), and there are mutations and polymorphisms (e.g., R117H coupled with certain lengths of an intronic polythymidine tract) that do not cause CF at all but rather male infertility due to congenital absence of the vas deferens (Anguiano, 1992; Gervais, 1993). Taken together with the ever-increasing median lifespan of CF patients and the eventual advent of effective gene replacement therapies, these factors render genetic counseling and reproductive decision-making for the disorder difficult.

Cystic fibrosis is one of the targets of universal newborn screening in most states, along with a large panel of metabolic disorders (CDC, 2008). Protocols vary by state, but in most cases begin with a biochemical screen for immunoreactive trypsinogen, followed by (in positive specimens) molecular testing for anywhere from one to more than 30 mutations. It is important to remember that the mutation panels chosen for newborn screening are up to the individual states and are not tied in any way to the ACMG/ACOG panel developed for population carrier screening. Likewise, mutations tested in the course of diagnostic workup of a symptomatic patient are also flexible (in the sense that they have never been defined by professional guidelines) and may range from just a few ethnic-specific mutations to complete gene sequencing.

DUCHENNE MUSCULAR DYSTROPHY

This X-linked progressive myopathy was the first disorder whose causative gene was isolated by the process of positional cloning (Rowland, 1988). Before that discovery, the only tests that could be offered to at-risk families were detection of some female carriers by the finding of elevated serum creatine phosphokinase levels, followed by prenatal sex determination with the option to terminate a male fetus (even though 50% of these pregnancies would be normal). Genetic counseling was rendered even more problematic because about one third of cases of DMD arise from new mutations.

Even after its discovery, translation to clinical application was not easy because the gene, dubbed *dystrophin*, proved to be the largest yet discovered, spanning 2.4 million bp and composed of 79 exons (Ahn, 1993). Use of full-length or partial cDNA probes to detect the variety of deletions accounting for two thirds of cases was labor-intensive and time-consuming (Darras, 1988; Prior, 1991). It was only with the advent of multiplex PCR, described in Chapter 66, that a system was developed for rapid and inexpensive identification of more than 98% of dystrophin deletions and their localization to specific exons of the gene (Beggs, 1990; Multicenter Study Group, 1992). In this system a deletion is identified by absence of one or more of the multiple expected amplicons on ethidium bromide-stained electrophoresis gels or capillary electrophoresis instruments (because a target gene deletion will abolish the hybridization site[s] of one or more primers, causing PCR failure) (Fig. 70-4). Such fine-structure mapping combined with sequencing has also revealed important insights into the molecular pathogenesis of DMD and the milder allelic variant, Becker muscular dystrophy (BMD). Both are most often caused by large dystrophin deletions, but those in BMD typically preserve the correct reading frame in the resulting processed transcript, while deletions in DMD more often produce frameshift mutations and a more truncated protein product (Monaco, 1988).

The remaining one third of patients with DMD and 15% of patients with BMD in whom no deletion is detected usually have point mutations or microdeletions/insertions. Because the gene is so large, it is not an easy matter to identify these lesions directly, although gene scanning by conformational analysis (SSCP, DGGE) followed by sequencing has been used effectively (Prior 1995; Torella 2010). Until recently, if that method failed,

Figure 70-4 Multiplex polymerase chain reaction (PCR) analysis for dystrophin gene deletions in Duchenne muscular dystrophy. DNA samples from five patients were amplified simultaneously with five primer pairs (left half of gel) and nine primer pairs (right half of gel) and the products were analyzed by polyacrylamide gel electrophoresis. Absence of an expected PCR product band is indicative of a deletion. Patient 2 lacks the top band in the five-plex and the second-from-top band in the nine-plex; these correspond to deletions in exons 50 and 48, respectively, in the dystrophin gene. (Band 4 in the nine-plex is light but present in all of the samples.) (Courtesy Dr Kathryn E. Kronquist.)

one had to revert to linkage analysis. Now, however, full-gene sequencing, even of this large locus, has become feasible using both capillary or next-generation sequencing (Hamed, 2006). Alternatively, studies at the protein level can be performed by observing decreased or absent dystrophin in DMD, and dystrophin of abnormal molecular weight in BMD, by western blot or immunohistochemistry of muscle biopsy tissue (Hoffman, 1988). This procedure has serious limitations for prenatal diagnosis, for which a fetal muscle biopsy would be required, but it can be used for proband diagnosis. Thus the molecular diagnosis of DMD has come full circle: from identification of the gene without knowing the protein product (reverse genetics) to identification and diagnostic use of the protein product from knowing the gene. This sort of evolution can be expected in the laboratory diagnosis of many genetic diseases, because functional studies of a gene product are by definition more comprehensive than attempting to track down countless individual mutations at the DNA level.

SICKLE CELL ANEMIA AND OTHER HEMOGLOBINOPATHIES

Given the long history of study of the protein product, diagnosis of molecular defects in the genes encoding the globin polypeptides did not come about through techniques of reverse genetics; rather, these genes were cloned by classic methods, using antiglobin antibodies for polysome precipitation to isolate the relevant messenger ribonucleic acids (mRNAs). As such, Hb mutations, and the one causing sickle cell anemia in particular, were among the very first to be diagnosed at the DNA level. The sickle cell point mutation in codon 6 of the β -globin gene lies within (and thus destroys) a restriction endonuclease cleavage site (for *MstII*, *MnII* or *DdeI*), providing a rapid method of detection using either Southern blot or restriction enzyme digestion of β -globin PCR products (Hatcher, 1992) (see Fig. 70-1). Alternatively, the HbS and HbA sequences can be distinguished by dot blot using allele-specific oligonucleotide probes complementary to either the normal or mutant sequence (Conner, 1983). More recently, higher-throughput techniques have come to predominate, such as real-time PCR and melting curve analysis (Traeger-Synodinos, 2008). These DNA-based techniques can be used for diagnosis, carrier screening, or prenatal diagnosis on amniocytes, in the latter case obviating the need for invasive fetal blood sampling and classic Hb electrophoresis. In addition, as more states initiate newborn screening programs for sickle cell disease, even if done by biochemical methods, the DNA test becomes important for backup confirmation of positives and ambiguous screening results, as in compound heterozygous states involving HbS and a thalassemia mutation. Several studies have shown that these DNA tests can be done on the same filter-paper blood spots collected for the initial newborn screening (McCabe, 2004). A different mutation in codon 6, causing HbC disease, does not abolish the *MstII* restriction endonuclease recognition sequence (because it occurs at a flexible nucleotide position for the enzyme) and so must be distinguished by ASO probes (Maggio, 1993).

Figure 70-5 Detection of the factor V Leiden mutation by real-time polymerase chain reaction (PCR) and melting curve analysis. Mismatch of the amplified mutant allele lowers the melting temperature when hybridized with a wild type DNA probe. The black line indicates the melting curve profile for an R506Q heterozygote, whereas the red curve represents a homozygous mutant sample.

The thalassemias involve both qualitative and quantitative alterations in one or more globin chains with hundreds of sequence variants known, and their diagnosis at the molecular level is correspondingly more complex than that of sickle cell anemia. α -Thalassemia is the more straightforward, because it is usually caused by deletion of either or both of the two contiguous α genes on one or the other or both chromosomes 16. This can be detected by Southern blot or quantitative PCR, allowing differentiation of the silent carrier state (one α gene missing) from the very severe hydrops fetalis (all four genes missing) and the two intermediate states (Oron-Karni, 1998). Molecular diagnosis of β -thalassemia is more complicated because of the wide variety of promoter, termination, deletion, splice site, and frameshift mutations that have been documented. However, within each at-risk population (Mediterranean, Asian, African), a limited subset of mutations (usually 10 or less) accounts for the majority of cases and carriers. Therefore testing with a panel of mutation-specific probes/primers, along the lines of CF screening, is reasonable (Naja, 2004; Patrinos, 2005). In addition, the β -globin gene is not that large, so sequencing or gene scanning can also be employed.

HEREDITARY THROMBOPHILIAS

CF is not the only disorder with sufficiently high mutation frequency to consider population screening using molecular methods. Several other disease genes have revealed carrier frequencies several times higher than that for cystic fibrosis. Included in this group are genes involved in the anticoagulant system, which, as discussed in Part V keeps the clotting cascade in check. The most notable such allele is the factor V Leiden mutation, a single nucleotide change causing an amino acid substitution (R506Q) in the clotting factor V protein, rendering it resistant to cleavage by activated protein C (Bertina, 1994). The allele is carried in 5%–7% of the Caucasian population and is responsible for more than 90% of clinical activated protein C (APC) resistance, resulting in a tendency toward idiopathic venous thromboembolism (Ridker, 1997a). It produces a relative risk of thrombosis of about sevenfold in the heterozygous state and about eightyfold in the homozygous state. It is also associated with pregnancy complications such as recurrent miscarriage. Testing for the mutation is straightforward because, like the sickle cell mutation, it destroys a restriction endonuclease cleavage site, and automated methods for higher throughput have been developed, such as real-time PCR (Louis, 2004) (Fig. 70-5) and the Invader assay, which relies on signal amplification by fluorescent resonance energy transfer and a cleavage enzyme (Ryan, 1999), as described in Chapter 66.

As for cystic fibrosis, however, there are controversies over which patients should be offered screening. Despite the dramatically increased relative risk, the absolute risk conferred by this mutation is rather low, with a lifetime penetrance for thrombotic symptoms of about 10%. Most carriers therefore would not be candidates for anticoagulant therapy, with its risks of hemorrhage and stroke, and so it is uncertain whether such screening would alter patient management in a meaningful way. Some have proposed screening individuals with environmental risk factors known to act synergistically with the factor V Leiden risk, such as women on oral contraceptives. Yet here too it could be argued that obligating such women with positive test results to turn to less effective methods of birth control might cause more harm than good, increasing the pregnancy rate with its

own attendant complications, some of which are thrombotic in nature (Kupferminc, 1999). At present, most requests received by molecular genetics laboratories for factor V Leiden testing are on patients who have already experienced an otherwise unexplained thromboembolic event, and two professional consensus statements, by the ACMG and the College of American Pathologists (CAP), have designated this as the primary unequivocal indication for testing (Grody 2001b; Press, 2002).

Along with factor V Leiden, there are other inherited mutations of high allele frequency that confer thrombotic risk (also discussed in Part 5). The prothrombin 20210A variant, a single nucleotide change in the 3' untranslated region of the prothrombin gene, results in increased circulating prothrombin levels and a phenotype similar to that of factor V Leiden; it is present in 1%–2% of the general population (Poort, 1996). The 677C→T variant of methylenetetrahydrofolate reductase, an enzyme involved in the folate cycle of homocysteine metabolism, is carried by 30%–40% of the general population and is associated with elevated plasma homocysteine levels and theoretical risk of vascular (including coronary artery) thrombosis. Indications for this test are even more nebulous, because not everyone with the variant has hyperhomocysteinemia, and not all hyperhomocysteinemia is caused by this variant. Thus biochemical measurement of plasma homocysteine levels may be a more effective screening method. Also, folate fortification of foods may make the genetic factor less relevant by broadly reducing homocysteine levels in the population. And recent studies have even called into question whether there is any relationship at all between homocysteine levels and thrombotic risk

(Ducros, 2009). Even so, the mutations for each of these factors can act synergistically with one another, so that patients carrying two or even three of these defects, including also the rarer deficiencies of protein S and C, are at greater increased risk (Koeleman, 1994; Ridker, 1997b). DNA tests for several of these thrombophilia mutations can be multiplexed in a single assay (Louis, 2004).

TRINUCLEOTIDE REPEAT EXPANSION DISORDERS

An important class of disease-causing mutations was revealed in 1991 with the discovery that X-linked spinal and bulbar muscular atrophy (Kennedy's disease, SBMA) and fragile X syndrome (FRAXA) are associated with amplification of unstable trinucleotide repeat sequences in the androgen receptor (*AR*) and *FMRI* (fragile X mental retardation) genes, respectively. Since that time, similar disease-producing mutations have been associated with several additional neurologic and muscle disorders (Table 70-2), and in the process have provided a molecular classification of the spinocerebellar ataxias. The affected gene in each of these disorders normally contains a repeated sequence of 3bp, for example, (CGG)_n in the *FMRI* gene, where *n* is variable but normally limited in its range. In the disease state, however, the size of the triplet repeat is expanded outside the normal range, sometimes only slightly and in other instances markedly. The mechanisms by which these expanded repeat sequences produce disease are

TABLE 70-2

Disorders Characterized by Unstable Expansions of DNA Trinucleotide Repeats

Disorder	Chromosome Location	Normal Alleles, Intermediate Alleles	Expanded Alleles	Anticipation	Transmission Sex Bias	Position of Repeat	Gene Product
Fragile Site/Mental Retardation Associated with CGG or GCC Expansion (X-Linked)							
Fragile X syndrome (CGG), FRAXA	Xq27	6–54 55–200	>200	Yes	Maternal, full mutation	5'-UTR	FMR-1
Fragile X syndrome (GCC), FRAXE	Xq28	6–25	>200			5'-UTR	FMR-2
Diseases Associated with CAG Repeat Expansion (Autosomal Dominant Except for X-Linked Kennedy's Disease)							
Spinobulbar muscular atrophy (Kennedy's disease)	Xq11–12	11–33	36–62			Coding	Androgen receptor
Huntington disease	4p16	6–35 36–39	40–121	Marked in juvenile cases	Paternal, early onset	Coding	Huntingtin
Dentatorubral-pallidoluysian atrophy	12p13	3–35	49–85	Yes	Paternal	Coding	Atrophin
Spinocerebellar ataxia 1	6p23	6–44	40–81	Marked in juvenile cases	Paternal, early onset	Coding	Ataxin 1
Spinocerebellar ataxia 2	12q24	16–31	36–64	Yes	Paternal	Coding	Ataxin 2
Spinocerebellar ataxia 3 (Machado-Joseph disease)	14q24–q31	12–41	55–84	Yes	Paternal	Coding	Ataxin 3
Spinocerebellar ataxia 6	19p13	6–17	21–30	Yes	Paternal	Coding	CACNA1A
Spinocerebellar ataxia 7	3p21–p12	4–35 28–3	37→200	Yes	Paternal	Coding	Ataxin-7
Spinocerebellar ataxia 12	5q31–q33	7–28	66–78	Yes	Paternal	5'-UTR	PPP2R2B
Spinocerebellar ataxia 17	6p27	25–42	45–63	Yes	Paternal	Coding	TBP
Diseases Associated with CTG Expansion (Autosomal Dominant)							
Myotonic dystrophy	19q13	5–35	50→200	Yes	Maternal congenital form	3'-UTR	Myotonin protein kinase
Spinocerebellar ataxia 8	13q21	16–92	110–130	Yes	Maternal	Noncoding	
Disease Associated with GAA Expansion (Autosomal Recessive)							
Friedreich ataxia	9q13	6–36	200→900	No		Intron	Fratxin

various, and include gene silencing and toxic gain-of-function by mutant proteins.

Fragile XA and Fragile XE Syndromes

FRAXA is the most common single-gene defect causing moderate to severe mental retardation in males. Affected males with this X-linked disorder typically also exhibit dysmorphic features including large ears, a long face, prominent jaw, and macroorchidism. Approximately 1 in 2500 females are heterozygous carriers of the FRAXA mutation, and one third of these may show evidence of mental impairment or learning disability in the absence of the classic dysmorphism seen in affected males.

As explained in Chapter 68, the cytogenetic hallmark of FRAXA is a fragile site on the X chromosome at Xq27.3, resulting from a failure of normal chromatin condensation during mitosis. Although the inheritance pattern of the disease is clearly X-linked, it does not correspond in a straightforward manner to either a recessive or dominant pattern of gene expression. Before the molecular mechanism was elucidated, the most puzzling feature had been the presence of phenotypically normal men (transmitting males) who are obligate carriers of the genetic abnormality. These men are sons of proven FRAXA carriers, they pass the carrier state to all of their daughters, and their daughters in turn transmit the fully expressed disease to a high proportion of their sons.

The discovery in 1991 of the genetic abnormality that causes FRAXA immediately explained its unusual pattern of inheritance (Fu, 1991). The 5' untranslated region of the *FMR1* gene at chromosome Xq27.3 carries a (CGG)_n triplet repeat of variable size. In normal individuals, *n* ranges up to about 54, but in individuals with clinically apparent FRAXA, *n* is greater than 200 (referred to as a *full mutation*). Both men and women who carry an X chromosome where *n* is between 55 and about 200–230 (referred to as a *premutation*) do not show signs of classic fragile X syndrome, but are at risk of passing an allele of even larger size to their children. This is because of the instability of the premutation alleles and their tendency to increase in size during the meiotic cell divisions that produce the male and female gametes. Alleles of normal size are not unstable and generally pass unchanged, although there is now recognized a so-called gray area of repeats between 46 and 54 that has a low risk of slight expansion into the premutation range (Kronquist, 2008). Thus it appears that there is a pool of small premutation (and gray area) alleles in the population, possibly of ancient origin, that is at risk of undergoing further expansion with each passage through another generation. As the premutation allele increases in size, the likelihood that it will expand further in the next generation increases, ranging from very low likelihood for repeats in the 60s to almost 100% for repeats above 100 (Nolin, 2003). Curiously, expansion to a full mutation occurs only in female meioses, never in males, which corresponds to the observation that the daughters of normal transmitting males are always phenotypically normal. Fig. 70-6, B, illustrates a family with FRAXA: a premutation allele is transmitted from the first to the second generation, and then expands to a full mutation in the third generation.

The mechanism by which the expanded triplet repeat in the 5' noncoding region of the *FMR1* gene produces the FRAXA phenotype is under active investigation. As the size of the repeat expands, there is progressive methylation of the regulatory region of the *FMR1* gene and decreased expression of FMR-1 protein. This RNA-binding protein is widely expressed in the developing brain and in other tissues. Its loss of expression in FRAXA presumably disturbs normal brain development and leads to mental retardation. Rare patients with typical fragile X syndrome do not have triplet repeat expansion or gene hypermethylation but do have inactivating point mutations leading to loss of FMR1 protein expression. Conversely, rare phenotypically normal or high-functioning males with full *FMR1* gene repeat expansions and cytogenetically visible fragile sites, but with no gene hypermethylation and normal FMR1 protein expression, have been described (Hagerman, 1994; Smeets, 1995). These findings all support the hypothesis that it is lack of FMR1 protein expression, usually caused by hypermethylation-related downregulation of gene transcription, that is responsible for the disease phenotype.

Because the premutation is not methylated and the phenomenon of “normal” transmitting males was widely observed, it was long assumed that these alleles had no direct phenotypic effect. It was therefore quite surprising when more recent studies documented cases of premature ovarian failure and an unusual tremor-ataxia-dementia syndrome in female and male premutation carriers, respectively. The penetrance appears to be about 20% for the former (Sherman, 2000) and as high as 75% for the latter (Jacquemont, 2004), although it is difficult to accurately define such numbers in the absence of molecular screening of normal populations. The molecular mechanism may be related to premutation *FMR1* mRNAs being

translated less efficiently and/or interfering with translation of the normal allele or other interacting genes. These revelations have made genetic counseling for fragile X syndrome even more complicated. They also raise additional concerns regarding the ethical merits of population screening for fragile X premutations or routine testing of pregnant women, which appears to be increasing. Babies born to women who have undergone testing may be identified with a potentially devastating adult-onset disease for which no known preventive intervention is possible, something that is not done for predictive genetic testing of other late-onset disorders in children for the reasons discussed in the section on Predictive Genetic Testing above.

Rare families with X-linked mental retardation and a cytogenetically demonstrable fragile site at chromosome Xq27–28, but no hypermethylation or expansion of the (CGG)_n repeat in *FMR1*, led to the discovery of a second, more distal fragile site at Xq28 associated with hypermethylation and expansion of a (GCC)_n repeat (FRAXE). Most affected males show only mild mental impairment without the dysmorphic features of FRAXA; this plus the extreme rarity of the condition have called into question the indications for testing and screening (Brown, 1996), and in practice the test is seldom ordered.

Neurodegenerative Disorders: Huntington Disease, X-linked Spinal and Bulbar Muscular Atrophy, Spinocerebellar Ataxias, and Dentatorubral-Pallidoluysian Atrophy

Huntington disease, X-linked spinal and bulbar muscular atrophy (SBMA), the spinocerebellar ataxias, and dentatorubral-pallidoluysian atrophy (DRPLA) are autosomal dominant or X-linked (SBMA) diseases characterized by selective neuronal degeneration in the central nervous system. In each of these disorders there is expansion of a (CAG)_n trinucleotide repeat in the coding region of the respective gene that produces abnormal elongation of a polyglutamine tract. The resultant abnormal protein produces intranuclear neuronal inclusions. It is postulated that the expanded polyglutamine sequences in each of these proteins leads to alterations in their folding and binding characteristics and a gain in function that is toxic to neurons in a selective manner, causing apoptosis (Everett, 2004). Intranuclear neuronal inclusions, produced by these abnormal proteins, have been demonstrated in several of these disorders.

In common with the other triplet repeat disorders, the expanded repeats in the neurodegenerative disorders are unstable and tend to increase in size in subsequent generations. There is a positive, but not absolute, correlation between increasing repeat size, early disease onset, and clinical severity. In contrast to fragile X and myotonic dystrophy, where the most dramatic increases in repeat size occur in maternal meioses, paternal transmission produces the largest expansions in the exonic repeat neurodegenerative disorders. Consequently, juvenile-onset cases of Huntington disease, DRPLA, and the spinocerebellar ataxias are typically transmitted by an affected father.

Molecular diagnosis of these disorders is used for either diagnostic or, because they are late-onset, predictive purposes. Because they have no treatment, the emotions involved in the testing and fear of a positive result are considerable.

Myotonic Dystrophy

Myotonic dystrophy is an autosomal dominant, multisystem disorder with a wide range of clinical expression. In late childhood or early adulthood, the most typical patients develop progressive myotonia and weakness and atrophy of the muscles of the distal extremities and face. Cataracts, cardiac conduction defects, and testicular atrophy are also common. However, the disease may be so mild as to consist solely of cataracts developing in old age or so severe as to present at birth with marked muscle degeneration and mental retardation proceeding to early death. Sometimes the full spectrum of the disease can be observed in the same family, occurring in a pattern that clearly reflects the phenomenon of anticipation. As noted, anticipation is present in virtually all of the trinucleotide repeat disorders, but it is most striking in myotonic dystrophy, in which the clinical phenotype can progress from cataracts to severe congenital disease in three generations.

Myotonic dystrophy is caused by expansion of a (CTG)_n repeat in the 3' untranslated region of the myotonin protein kinase gene on chromosome 19q13.3 (Fu, 1992; Mahadevan, 1992). In normal individuals, this repeat ranges in size from 5 to 35 and is genetically stable. CTG repeats greater than 50 are genetically unstable and prone to expansion as they are passed to subsequent generations. In the range of 50–100, these repeats

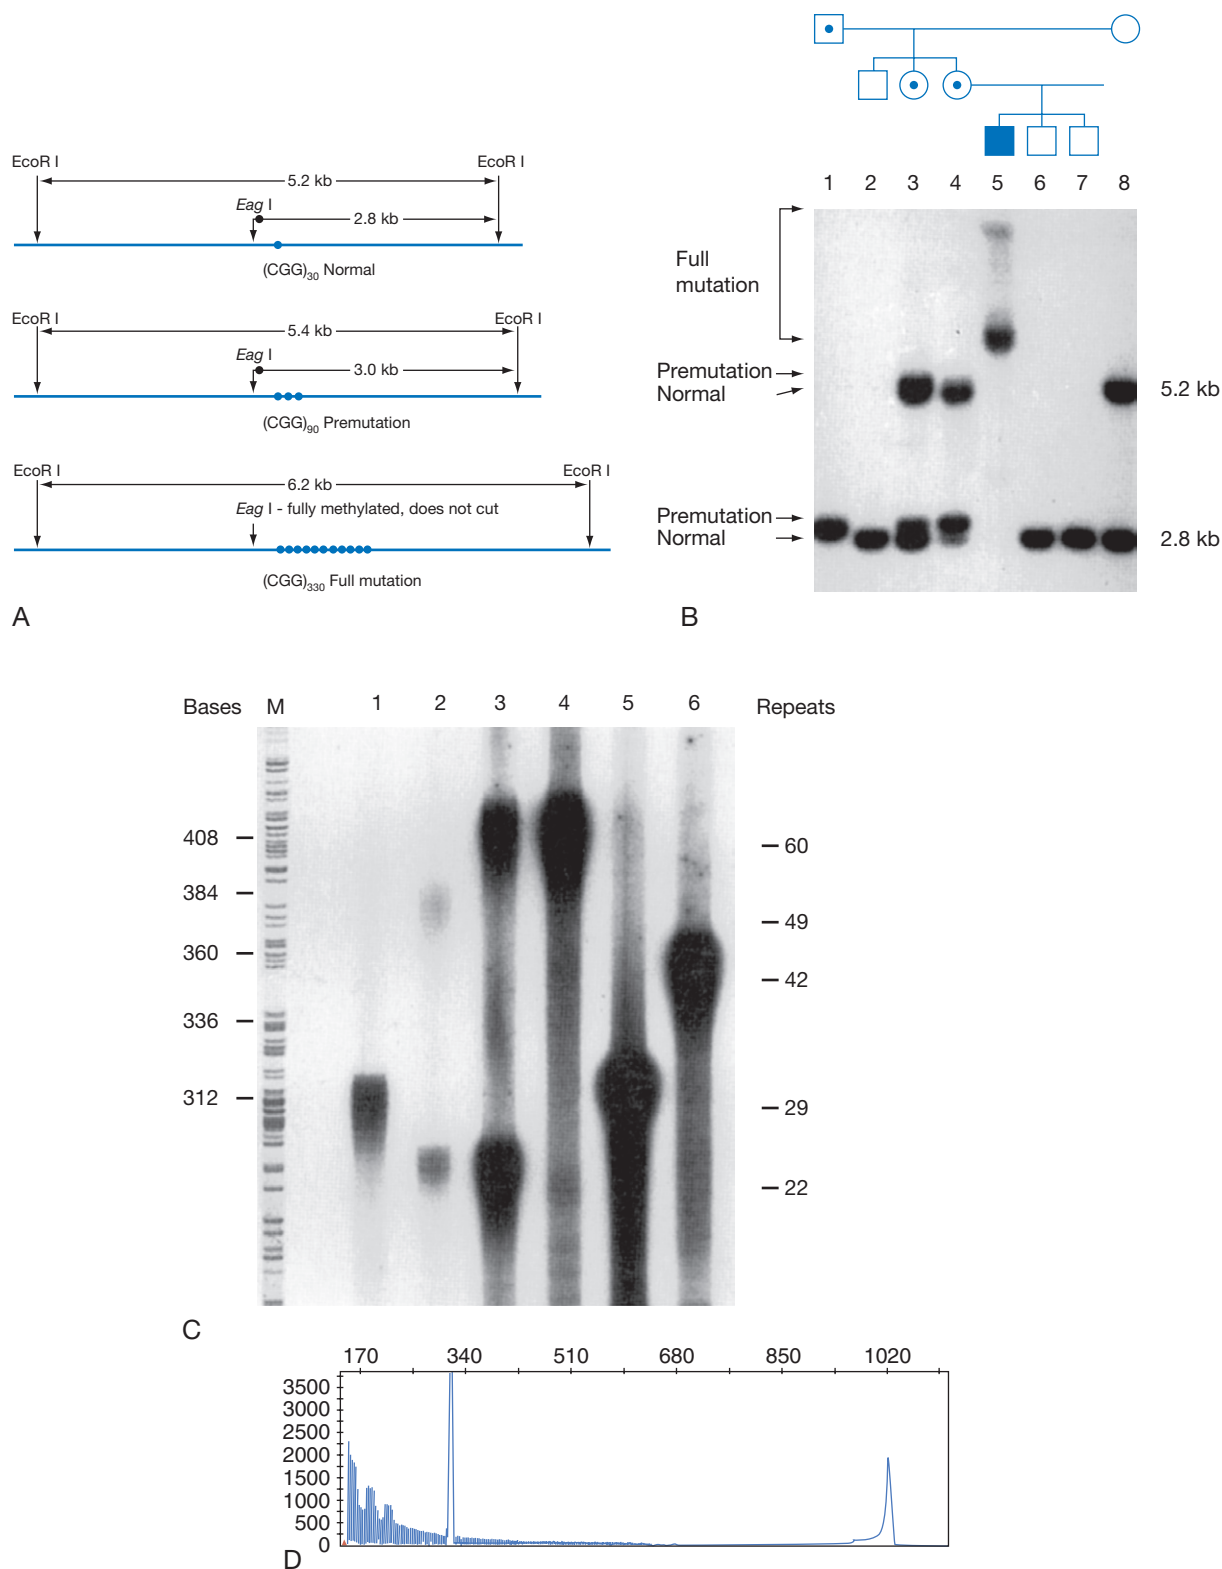

Figure 70-6 Detection of the (CGG)_n repeat expansion in fragile X syndrome. **A**, Diagram of normal, premutation, and full-mutation alleles at the FRAXA locus. When expansion of the repeat to a full mutation occurs, the *EagI* restriction enzyme site becomes methylated and does not cut with the enzyme. **B**, Family of a patient (darkened square) with fragile X syndrome. A Southern blot of *EcoRI*/*EagI*-digested DNA from each individual in the pedigree was examined with a labeled DNA probe that hybridizes 3' to the repeat. The three individuals on the right of the figure are normal (open squares and circles). Note that the two males each have a single 2.8-kb band, while the female has both a 2.8- and a 5.2-kb band. This is the expected result. The 5.2-kb band in the female is from the normal inactive (therefore methylated) X chromosome in each of her cells. Because the DNA on this chromosome is methylated, it is not cut by *EagI*. The 2.8-kb band, however, is from the normal unmethylated active X chromosome (*EagI* will cut the DNA in this case) in the female and in the males. The affected male has a greatly enlarged band. This is a consequence of marked expansion of the trinucleotide repeat as well as methylation of the *EagI* restriction enzyme site. The three individuals marked by bold dots are carriers of premutation alleles. In the females, the distinction between normal and expanded alleles is seen most clearly in DNA from their active (unmethylated) X chromosomes. Here, there are distinct bands of 2.8 and 3 kb. Higher in the gel the resolution is not as good, and the 5.2- and 5.4-kb alleles are barely separated. Note that in this peripheral blood sample from the mother of the affected patient, X chromosome inactivation is skewed with respect to the repeat expansion: a greater proportion of normal X chromosomes in this cell population have randomly been inactivated compared to the X chromosomes carrying the premutation allele. **C**, Sizing of trinucleotide repeats by gel electrophoresis following amplification of the locus by the polymerase chain reaction (PCR). Lanes 1 through 6 represent six different individuals; lane M contains a size marker. The PCR products were labeled by incorporation of ³²P-dCTP during the amplification reaction and the dried gel was exposed to X-ray film. Heterozygous females show two alleles; males and homozygous females show single alleles. The multiple bands produced with each allele are due to "slippage" of the DNA polymerase during the PCR reaction; the most intense band is taken as representative of the actual size of the allele. **D**, Successful PCR amplification of both the normal (left peak, 30 CGG repeats) and full-mutation (right peak) alleles in a female heterozygote, using reagents from Asuragen, Austin, Texas). (**C**, Courtesy Dr Anne Maddalena; **D**, courtesy Dr. Joshua Deignan.)

are often asymptomatic or produce minimal symptoms. When more than 100 repeats are present, the typical myotonic dystrophy phenotype is likely. Although there is a general correlation between repeat length and clinical severity, the size of the repeat is not a reliable prognostic indicator in the individual case. The extreme expansions to 1000–2000 repeats seen in congenital myotonic dystrophy occur only with female transmission of the unstable repeat; thus congenital myotonic dystrophy is always inherited from an affected mother.

The mechanism by which the expanded trinucleotide repeat in the myotonin protein kinase gene produces the myotonic dystrophy phenotype is not known. Because the repeat is not located in the coding region of the gene, it is possible that protein expression is altered or that RNA processing interactions are perturbed.

Friedreich Ataxia

Friedreich ataxia is the most common of the hereditary ataxias, with an incidence of 2 per 100,000. Unlike the other trinucleotide repeat disorders, Friedreich ataxia is inherited as an autosomal recessive disease and shows no evidence of anticipation. The expanded (GAA)_n repeat is located in the first intron of the *FRDA* gene and reduces the expression of frataxin, a mitochondrial targeted protein, probably through some interference with transcription or RNA processing. Frataxin is involved in mitochondrial respiration, iron balance, and response to oxidative stress. Some 97% of mutant *FRDA* alleles are due to (GAA)_n expansions; the remaining alleles are due to other inactivating mutations, including point mutations (Lodi, 1999).

Laboratory Testing for Trinucleotide Repeat Disorders

Depending on the length of the repeat segment, expansions of trinucleotide repeats are readily demonstrated by either Southern blot or PCR. PCR, followed by sizing of the products on an electrophoretic gel or capillary, is generally preferred for most of these disorders because of its speed, simplicity, and ability to resolve alleles differing in size by just one repeat unit. This is of particular importance when it is necessary to differentiate stable alleles at the upper size limit from small premutation or disease-causing alleles. For example, it is critically important to distinguish a 40-repeat from a 39-repeat in Huntington disease because of the dramatically different clinical implications and the psychosocial impact of a positive result. PCR is also the method of choice for accurate sizing of *FRAXA* premutation alleles, which is necessary for graded risk counseling of female carriers. However, where triplet expansions are very large, as in fully expressed *FRAXA* or myotonic dystrophy, it may not be possible to amplify the greatly expanded DNA segment by PCR; in this case, Southern blotting has traditionally been required. Southern blotting is also helpful in determining the methylation status of *FRAXA* full mutations, through the use of methylation-sensitive restriction endonucleases, and in assuring that a large Huntington disease or *FRAXA* allele has not been missed in a patient who appears homozygous normal by PCR. Similarly, it more reliably identifies mosaic males whose cells show a mixture of premutation and full mutation alleles. Recently, however, methods for analyzing large premutations and even the full mutation of *FMR1* by PCR alone have begun to enter practice, supported by the availability of commercial reagents (Hantash, 2010). Figure 70-5 illustrates the use of both Southern blotting and PCR to detect full *FRAXA* mutations and *FRAXA* premutation alleles.

PRADER-WILLI AND ANGELMAN SYNDROMES

Prader-Willi and Angelman syndromes, whose genes lie at approximately the same locus on chromosome 15, are almost always discussed together, even though they are caused by two different genes and have almost nothing in common phenotypically. Prader-Willi syndrome is characterized by obesity, mental retardation, hypoplastic genitalia, and dysmorphic features, while Angelman syndrome exhibits ataxia, puppet-like facies, mental retardation, paroxysmal laughter, and seizures. What they do share, remarkably, is a powerful imprinting mechanism determining disease expression. Both disorders are almost always sporadic. Prader-Willi syndrome, whose gene is not yet known, is most often caused by a deletion at 15q12 in the paternally inherited chromosome only; this is pathologic because only the paternal *PWS* gene is expressed. The opposite is true for

Figure 70-7 Polymerase chain reaction-based electrophoretic analysis of methylation patterns in Prader-Willi and Angelman syndromes using the sodium bisulfite method of Kosaki (1997). In Prader-Willi syndrome, only the methylated maternal allele (upper band) is present, due to either deletion of the paternal allele or uniparental disomy for the maternal allele. In Angelman syndrome, only the unmethylated paternal allele (lower band) is present, due to either deletion of the maternal allele or uniparental disomy for the paternal allele. Similar analysis can also be done by Southern blot using methylation-sensitive restriction enzymes.

Angelman syndrome, which is most often caused by deletion of a known gene (*UBE3A*) exclusively on the maternally inherited chromosome, which is the only allele normally expressed (Knoll, 1989; Matsuura, 1997). Alternatively, Prader-Willi syndrome can be caused by uniparental disomy for the maternal chromosome 15, which carries only the nonexpressing copy of the gene; likewise, Angelman syndrome can be caused by uniparental disomy for the paternal chromosome 15. These phenomena can be detected by FISH, discussed in Chapter 68, chromosome haplotyping with microsatellite markers, or Southern blotting with methylation-sensitive restriction enzymes that can distinguish the methylated maternal critical region from the unmethylated paternal critical region. A differential PCR scheme that amplifies either the methylated or unmethylated allele of the nearby *SNRPN* gene within the critical region, based on resistance of methylated cytosines to chemical modification by sodium bisulfite (Kosaki, 1997), is also available (Fig. 70-7). Neither the Southern blot nor the PCR method will distinguish between the deletional or uniparental disomy mechanisms, nor will they detect cases (more frequent in Angelman syndrome) due to point mutations within the causative gene. These methods also will not distinguish rare cases of Angelman syndrome or Prader-Willi syndrome due to primary imprinting defects (resulting from aberrant methylation caused by a mutation in the chromosome 15 imprinting center) (Burger, 1997), which would have a much higher recurrence risk.

FAMILIAL CANCERS

All cancers are genetic disorders at the cellular level, caused by mutations in genes that control cell proliferation and differentiation. These genes may be divided broadly into two groups, those that promote proliferation (proto-oncogenes or, simply, oncogenes), and those that restrain cell growth (tumor suppressor genes). Both sets of genes are discussed in Chapter 76. Most often, mutations in these genes occur in somatic cells, usually requiring alterations over many cell cycles in several oncogenes or tumor suppressor genes before a cancer develops. However, in some individuals the initial mutation in this progression may be a germline lesion, inherited from a parent and present in every cell of that individual's body.

TABLE 70-3

Hereditary Cancer Syndromes

Disorder (OMIM Entry)	Associated Tumors	Population Incidence	Gene	Chromosome Location
Tumor Suppressor Genes (Autosomal Dominant Mode of Inheritance)				
Basal cell nevus (Gorlin) syndrome (109400)	Basal cell carcinoma, medulloblastoma	1/40,000	PTCH	9q22
Cowden syndrome (158350)	Breast, thyroid carcinoma	1/200,000	PTEN	10q23
Familial adenomatous polyposis (175100)	Colorectal, duodenal carcinoma	1/10,000	APC	5q21
Hereditary breast-ovarian cancer syndrome (113705, 600185)	Breast, ovarian, pancreatic, prostate carcinoma	1/300–1/500	BRCA1 BRCA2	17q21 13q12
Hereditary diffuse gastric carcinoma (137215)	Gastric carcinoma	Rare	CDH1	16q22
Hereditary leiomyomatosis and renal cell carcinoma (150800, 605839)	Cutaneous and uterine leiomyomas, papillary renal cell carcinoma	Rare	FH	1q42
Hereditary melanoma (600160, 606719)	Melanoma, pancreatic carcinoma	Unknown	CDKN2A (p16)	9p21
Hereditary paraganglioma (602690, 185470, 602413)	Paraganglioma, pheochromocytoma	Rare	SDHD SDHB SDHC	11q23 1p35–36 1q21
Juvenile polyposis syndrome (174900)	Gastrointestinal cancer	1/10,000	SMAD4 BMPR1A	18q21 10q22
Tumor Suppressor Genes (Autosomal Dominant Mode of Inheritance)				
Li-Fraumeni syndrome (151623)	Sarcomas, breast carcinoma, leukemia, brain tumors	Rare	p53	17p13
Multiple endocrine neoplasia, type 1 (MEN1) (131100)	Pancreatic islet cell, pituitary, parathyroid tumors	1/100,000	MEN1	11q13
Neurofibromatosis type 1 (162200)	Neurofibroma/sarcoma, pheochromocytoma	1/3000	NF1	17q11
Neurofibromatosis, type 2 (101000)	Acoustic neuroma, meningioma	1/40,000	NF2	22q12
Peutz-Jeghers syndrome (175200)	Gastrointestinal tumors	1/200,000	STK11	19p13
Retinoblastoma, hereditary (180200)	Retinoblastoma, osteosarcoma	1/20,000	RB1	13q14
Von Hippel-Lindau disease (193300)	Hemangioblastoma, renal cell carcinoma, pheochromocytoma	1/40,000	VHL	3p25
Oncogenes (Autosomal Dominant Mode of Inheritance)				
Hereditary melanoma (123829)	Melanoma	Rare	CDK4	12q13
Multiple endocrine neoplasia type 2A and type 2B (171400, 162300)	Medullary thyroid carcinoma, pheochromocytoma, parathyroid hyperplasia/adenoma; multiple mucosal neuromas (type 2B)	1/30,000	RET	10q12
Hereditary papillary renal carcinoma (605074)	Papillary renal carcinoma	Rare	MET	7q31
DNA Repair Genes (Autosomal Dominant Mode of Inheritance)				
Hereditary nonpolyposis colorectal cancer (114500)	Colorectal, endometrial, ovarian carcinoma	1/400–1/700	MSH2 MLH1 MSH6 PMS2	2p16 3p21 2p16 7p22
DNA Repair Genes (Autosomal Recessive Mode of Inheritance)				
Ataxia telangiectasia (208900)	Lymphomas, others	1/40,000–1/100,000	ATM	11q22
Bloom syndrome (210900)	Various	Rare	BLM	15p26
Fanconi anemia (607139, 300515, 227645, 605724, 227646, 600901, 603467, 602956)	Acute myelogenous leukemia, others	1/100,000	FANCA-G	Various
MYH-associated polyposis (608456)	Colorectal carcinoma, duodenal polyposis	1/10,000	MYH	1p34
Xeroderma pigmentosum (278700, 133510, 278720, 278730, 278740, 133520, 133530, 603968)	Cutaneous basal carcinoma and squamous carcinoma	Rare	XPA-G, POLH	Various

OMIM, Online Mendelian Inheritance in Man.

Heritable cancer-causing mutations have been found most often in tumor suppressor genes, including several groups of genes that encode proteins with DNA repair functions, but have also been found in a few oncogenes (Table 70-3). The inherited mutation should be viewed as the initiating event in tumor development, not in itself sufficient to cause

cancer but merely the first step in a series of mutations that ultimately lead to uncontrolled cell growth, analogous to the first somatic mutation that initiates tumor development in a sporadic cancer. It is likely that most of the heritable mutations that contribute to cancer development have not been identified, because they are by themselves not highly penetrant and

require the interaction of other genetic and environmental factors to initiate tumor development—a complex situation that is difficult to unravel. However, a number of highly penetrant genes have been identified that are major initiators of tumor development in what are recognizable heritable cancer syndromes (see Table 70-3).

Compared with their sporadic counterparts, hereditary cancers often develop at an earlier age, are more often multifocal, and appear bilaterally in paired organs. Noting these distinguishing features in sporadic retinoblastoma and familial retinoblastoma, Knudson postulated that at least two mutational events are necessary to produce a tumor (Knudson, 1971). In the case of a sporadic tumor, two independent mutational events in the same cell are necessary to initiate tumor development, whereas in the case of a hereditary tumor, the first mutation is already present at birth in every cell of the body, making it more likely that a second mutational event will occur at an earlier age and often in more than one cell. Knudson's two-hit hypothesis is an important concept that has guided many studies of the genetic basis of cancer. Elucidation of the heritable mutations in the hereditary cancer syndromes has been enormously informative, not only in understanding these rare disorders but also in understanding the fundamental changes responsible for common malignancies.

In the following discussion, some fundamental concepts of hereditary cancer syndromes are explained in the context of a disorder caused by a tumor suppressor gene, retinoblastoma, and a disorder caused by an oncogene, multiple endocrine neoplasia type 2. This is followed by descriptions of hereditary breast-ovarian cancer (HBOC) and hereditary colorectal cancer, the most common hereditary cancer syndromes, for which more than a million individuals in the United States are at risk. Table 70-3 lists these disorders and a number of other hereditary cancer syndromes. The section ends with a discussion of current approaches to genetic testing for these disorders.

Tumor Suppressor Genes: Retinoblastoma as a Paradigm

Although familial cancer syndromes due to mutations in tumor suppressor genes follow a dominant pattern of inheritance, at the cellular level the changes often appear recessive, because tumorigenesis is initiated (in most cases) only when both copies of the tumor suppressor gene are inactivated. Loss of the normal gene inherited from the unaffected parent may occur as the result of a second novel pathogenic mutation, by large-scale deletion (appearing in certain molecular assays as loss-of-heterozygosity), by replacement with a duplicated copy of the mutant gene inherited from the affected parent by genetic mechanisms such as chromosomal nondisjunction or mitotic recombination, or by gene silencing due to hypermethylation. These events occur in retinoblastoma, a tumor of the retina caused by functional loss of both copies of the *RB1* gene, which encodes the RB protein that is involved in cell cycle and transcriptional regulation. In sporadic cases, both of these mutational events occur somatically and a solitary, sporadic tumor develops. But in the hereditary cases, the first *RB1* mutation is present in the germline of the affected child, having been inherited from a similarly affected parent or occurring as a new mutation during gametogenesis. When this is the case, the likelihood that the remaining normal *RB1* gene will undergo mutation in at least one retinal precursor cell is greater than 90%. As Knudson observed, in most patients with familial disease, the tumors are bilateral and multifocal (Knudson, 1971), implying that several cells have sustained additional *RB1* mutations. It is not known if *RB1* mutations alone are sufficient for tumorigenesis, but they certainly appear to be the initiating or key event.

Familial retinoblastoma has served as a model in guiding important cancer research. This has led to the discovery of a large number of tumor suppressor genes that are key determinants of the pathogenesis of several hereditary cancer syndromes, including HBOC and hereditary colorectal cancer. These tumor suppressor genes are also critical to the development of many common sporadic cancers.

Oncogenes: Multiple Endocrine Neoplasia Type 2 as a Paradigm

There are just a few familial cancer syndromes that are known to be caused by a heritable mutation in an oncogene (see Table 70-3). Of these, multiple endocrine neoplasia type 2A (MEN2A) and its variants, familial medullary thyroid carcinoma (FMTC) and multiple endocrine neoplasia type 2B (MEN2B), are best known. Single, activating mutations in just one allele of the proto-oncogene *RET* are sufficient to initiate tumorigenesis in these disorders (Eng, 1999).

All three of these syndromes are characterized by hyperplasia of thyroid C cells and medullary thyroid carcinoma. In families afflicted with MEN2A, pheochromocytomas and/or parathyroid adenomas or parathyroid hyperplasia are also present. MEN2B is further characterized by the presence of multiple mucosal neuromas of the lips, mouth, and gastrointestinal tract, a marfanoid habitus, a particularly aggressive clinical course, and a high proportion of affected individuals due to new *RET* mutations.

RET is a signaling molecule with extracellular receptor and intracellular tyrosine kinase domains. With few exceptions, the known FMTC and MEN2A mutations are single base substitutions in one of five codons in the extracellular domain, in each case producing substitution of a cysteine by another amino acid. More than 95% of the MEN2B mutations are identical, consisting of a single base substitution producing a missense mutation in the tyrosine kinase domain.

Hereditary Breast-Ovarian Cancer

HBOC affects more individuals than any other hereditary cancer syndrome (Narod, 2004). It is caused by germline mutations in *BRCA1* and *BRCA2*, autosomal tumor suppressor genes with roles in DNA repair, transcription regulation, and cell cycle control. The combined carrier prevalence of abnormal variants of these two genes in the general U.S. population is estimated to be 1/500–1/300. Three founder mutations in Ashkenazi Jews are responsible for increasing the prevalence tenfold (1/40) in this population. HBOC accounts for 5%–10% of female breast cancer cases and 12% of ovarian cancer cases. Whereas the lifetime risk to women of developing breast or ovarian cancer in the general population is 11% and 1%, respectively, the risk to mutation carriers is 56%–87% for breast cancer (the risk of a second, contralateral cancer approaches 60%) and 23%–45% for ovarian cancer. Other cancers, especially breast cancer in men, pancreatic cancer, colon cancer, and prostate cancer are more prevalent as well. Characteristically, tumors occur at an earlier age than their sporadic counterparts, with average age of diagnosis of breast cancer in the 40s compared to the average age of diagnosis of sporadic breast cancer in the mid-60s. Development of breast cancer at an early age is one of the strongest predictors of the presence of HBOC.

BRCA1 and *BRCA2* are both large genes, encoding proteins of 1863 amino acids and 3418 amino acids, respectively. Disease-causing mutations, mostly frameshift or nonsense mutations which cause protein truncation, are distributed widely across both genes. Many hundreds of unique deleterious mutations have been identified. Although the presence of founder mutations permits a targeted approach to mutation identification in Ashkenazi Jews (with just two common mutations in *BRCA1* and one in *BRCA2*), whole-gene sequencing or gene scanning techniques are required for mutation detection in the heterogeneous general U.S. population at large. This approach has a high yield of detecting mutations (as long as they exist in the coding regions of the genes) but, analogous to the caveat about array-CGH testing discussed earlier, also reveals new missense variants of undetermined clinical significance, which then have to be dealt with (Richards, 2008). Also, some HBOC patients have large deletions in one of the genes rather than a point mutation, and detection of these requires an alternate approach such as Southern blot or MLPA.

Genetic testing for *BRCA1* and *BRCA2* mutations in high-risk patients and family members is now a high-profile service in clinical genetics and oncology practice. Effective cancer prevention strategies for mutation carriers (increased surveillance, chemoprevention, prophylactic surgery) have markedly reduced the incidence of ovarian cancer and primary and secondary breast cancers (Narod, 2004). Individuals at high risk can be identified by their personal history of ovarian or early-onset breast cancer in women or breast cancer in men, and/or by a family history of these cancers in either the paternal or maternal lineages (National Comprehensive Cancer Network, 2005). Because HBOC is an autosomal dominant disorder, first-degree relatives of mutation carriers have a 50% risk of carrying the same mutation. Once the familial mutation is known, testing of at-risk relatives no longer requires whole-gene sequencing but rather can be targeted to the particular nucleotide, saving significant time and expense.

The Hereditary Colorectal Cancer Syndromes

Hereditary nonpolyposis colorectal cancer (HNPCC, or Lynch syndrome), as its name implies, is a hereditary colorectal cancer syndrome that is not associated with an abundance of adenomatous polyps. In contrast, familial adenomatous polyposis (FAP) and MYH-associated polyposis (MAP) are hereditary disorders in which variable and sometimes large numbers of adenomatous polyps may be present. This useful, if imperfect, clinical distinction is an important guide to the evaluation of individuals who are at risk for these disorders.

Hereditary Nonpolyposis Colorectal Cancer

HNPCC is the second most common hereditary cancer syndrome, affecting almost as many individuals as are affected by HBOC. However, because it is almost equally penetrant in both sexes, its public health impact is equivalent to that of HBOC. Notably, and often unrecognized, endometrial cancer is a prominent part of the syndrome, with more affected women developing endometrial cancer than colorectal cancer. HNPCC accounts for 3%–5% of all colorectal cancers and 2%–3% of all endometrial cancers. The disease is caused by germline mutations in one of five DNA mismatch repair genes, *MSH2*, *MLH1*, *MSH6*, *PMS2*, and *PMS1*, each contributing roughly 50%, 40%, 10%, <1%, and <1%, respectively, to the overall incidence of the disorder. The combined carrier prevalence of abnormal variants of *MSH2* and *MSH1*, which account for approximately 90% of HNPCC, is estimated to be between 1/700 and 1/400. Colorectal cancer in HNPCC is characterized by early age of onset (average 44 years, compared to 72 years for sporadic colorectal cancer), occurs predominantly on the right side of the colon, and may occur as multiple primary tumors simultaneously or over a period of time (synchronous or metachronous). The lifetime risk to male and female mutation carriers of developing colorectal cancer is approximately 80% (compared with a 2% lifetime general population risk), while the lifetime risk of endometrial cancer is 40%–60% (compared with a 1.5% lifetime general population risk). The lifetime risks of gastric cancer (13%) and of ovarian cancer (12%) are also increased (compared with 1% for the general population).

A number of guidelines for identifying individuals at risk for HNPCC have been described that use a combination of personal and family history of cancer: for example, the Amsterdam Criteria and Bethesda Guidelines, which have gone through several revisions (Lipton, 2004). In practice, one need not hold dogmatically to these schemes, because a detailed personal and family history will usually suggest which patients are at risk. Early-onset colorectal cancer and/or endometrial cancer are the strongest predictors of the disorder, particularly when they are seen together in an individual or family, are accompanied by other tumors associated with the disease, and occur in more than one generation of the family.

Another predictor of HNPCC in an affected patient is the presence of microsatellite instability (MSI) in the DNA of that individual's colorectal cancer. The term describes an alteration in the length of short tandem repeat DNA sequences (microsatellites) in the tumor due to mismatch repair errors during DNA replication. Microsatellite instability is highly sensitive but not entirely specific in identifying a colorectal tumor as due to HNPCC, because about 15% of sporadic colon cancers will also demonstrate MSI. The DNA mismatch repair genes are moderately large genes, with *MSH2* encoding a protein of 935 amino acids and *MLH1* encoding a protein of 757 amino acids. Although there are a few mutations that have a high relative prevalence in some populations due to founder effects, the vast majority are distributed widely across both genes. Most mutations are frameshift or nonsense mutations that cause loss of gene expression due to RNA instability, protein instability or protein truncation. In addition, large deletions of single or multiple exons account for approximately one third of the mutations present in *MSH2* and for a smaller fraction of the mutations in *MLH1*.

Genetic testing for *MSH2* and *MLH1* mutations in high-risk patients and family members has moved into clinical practice in a manner similar to that which has occurred for *BRCA1* and *BRCA2* testing for HBOC. For those individuals who are identified as carrying deleterious mutations, complete colonoscopy, beginning at an early age and at regular intervals, is very effective at identifying premalignant adenomatous polyps (the term HNPCC should not be taken to imply that there are no polyps involved in the syndrome), while endometrial biopsy and transvaginal ultrasound may identify early endometrial cancer. If colorectal cancer does develop, subtotal colectomy may be considered as an alternative to segmental resection because of the high rate of synchronous and metachronous tumors in patients with HNPCC. Prophylactic hysterectomy–bilateral salpingo-oophorectomy may be considered in women who have completed their families. As in all autosomal dominant disorders, first-degree family members of mutation carriers have a 50% risk of also carrying that same mutation, and their testing becomes relatively straightforward.

Familial Adenomatous Polyposis and Attenuated Familial Adenomatous Polyposis

Familial adenomatous polyposis is a hereditary colorectal cancer syndrome that can present with a striking phenotype in the colon—multifocal

colorectal cancer in a background of thousands of adenomatous polyps. It is now recognized that the FAP phenotype is diverse and the number of colonic polyps can vary markedly. Accordingly, *classic* FAP is now diagnosed when an individual develops at least 100 adenomatous polyps over his/her lifetime, whereas *attenuated* FAP (AFAP) is the term applied to a patient whose lifetime polyp burden is in the range of 20–100 polyps. The distinction is entirely clinical, because both disorders are caused by germline mutations in the *APC* (adenomatous polyposis coli) gene, a tumor suppressor gene with several important cellular functions and a likely initiator of sporadic colorectal cancer development as well. Germline *APC* mutations are carried by 1/10,000–1/5000 individuals; most of these mutations have been inherited from a similarly affected parent, but 20%–30% are de novo mutations. Accordingly, FAP or AFAP cannot be ruled out because of an absence of a positive family history, which is particularly important to keep in mind when assessing a patient with a low polyp burden.

Early-onset colorectal cancer (average age 39 years for FAP, approximately 50 years for AFAP) requires early diagnosis and close clinical monitoring for individuals determined to be at risk by family history and/or genetic testing. Screening sigmoidoscopies should be started at age 10 and prophylactic colectomy performed when polyps have developed. For individuals at risk for the less florid AFAP, screening may begin later in the teens, but colonoscopy is advised because polyps preferentially develop in the right side of the colon. Colectomy is performed when the polyp burden is no longer manageable by polypectomy. Upper gastrointestinal surveillance is also indicated because gastric and small bowel polyps also develop. This is particularly important in the duodenum, especially in the periampullary region, where the lifetime risk of progression to cancer is 5%–12% for FAP.

Patients with FAP and AFAP are also at higher risk for a number of other cancers (gastric, pancreatic, biliary tract, thyroid) and frequently have other clinical findings: desmoid tumors, osteomas, dental abnormalities, epidermoid cysts, and congenital hypertrophy of the retinal pigmented epithelium (CHRPE). Of these, desmoid tumors, affecting approximately 10% of patients with FAP, are the most important. These clonal proliferations of myofibroblasts form in the abdominal wall or the abdominal cavity where they are locally invasive, compress abdominal organs, and may cause serious morbidity and mortality.

APC is a large gene, encoding a protein of 2843 amino acids. Most disease-causing mutations are frameshift or nonsense mutations producing protein truncation. These mutations are distributed widely along the gene, requiring full-gene sequencing unless the familial mutation is already known. Some genotype–phenotype correlations are possible: mutations that produce extraintestinal features tend to map to particular regions of the gene, while those that are associated with AFAP cluster in the 5′- and 3′-most regions of the gene.

MYH-Associated Polyposis

MYH-associated polyposis is a recently recognized autosomal recessive hereditary cancer syndrome caused by mutations in the human homolog of the bacterial *mutY* gene, *MYH* (Wang, 2004). The clinical phenotype is very similar to that of AFAP or the less florid variants of FAP: that is, a polyp burden in the tens to hundreds, not thousands. As with FAP/AFAP, patients are at risk for duodenal polyposis and some have been reported to have some of the extraintestinal manifestations, CHRPE and osteomas, as well. Because of the autosomal recessive nature of this disorder, MAP families typically show no evidence of vertical transmission of the disease, as would be true for the autosomal dominant FAP/AFAP, but might include affected siblings. It is estimated that the carrier frequency for mutant *MYH* alleles is approximately 2%, which implies a 1/10,000 frequency of biallelic (affected) individuals. This is very similar to the number of patients who have FAP/AFAP. The close similarity of the MAP and FAP/AFAP phenotypes, and the fact that as many as 30% of individuals with FAP have no evidence of vertical transmission in the family because they carry de novo *APC* mutations, can make diagnosis difficult, especially when the polyp burden is not large. In many cases it is necessary to perform mutation analysis for both *APC* and *MYH* to arrive at a diagnosis.

Laboratory Testing for Familial Cancer Mutations

DNA analysis for heritable, cancer-predisposing mutations has enormous potential for disease prevention and early treatment. If a very high proportion of the cancer-causing mutations in a particular gene or ethnic group are known, and these mutations are relatively few in number, direct

Figure 70-8 Detection of the Ashkenazi Jewish founder mutation 185delAG in the *BRCA1* gene by DNA sequencing. Because familial breast-ovarian cancer is a dominant disorder, the mutation is heterozygous, and because it results in the deletion of two nucleotides from one of the alleles, the sequence profile is “out of frame” from the mutation site onward (starting at nucleotide 79 in this particular readout). This causes overlapping of different nucleotides between the two alleles, which the automated sequencer has trouble identifying (hence the frequent notation “N” for the nucleotide calls).

analysis for these mutations may be simple and inexpensive. Fortunately, this may sometimes be the case with an oncogene, because activation of the gene can only be achieved in a limited number of ways. As mentioned earlier, the spectrum of mutations in *RET* that are responsible for MEN2 is quite small, with just a handful of well-defined mutations accounting for more than 95% of the total.

If, on the other hand, the gene is large, and cancer-causing mutations are numerous and widely dispersed (which is commonly the case with tumor suppressor genes, because they can be inactivated in many different ways), then mutation analysis must of necessity be less targeted and be capable of screening large stretches of DNA. In that case, direct DNA sequencing or gene scanning techniques such as DHPLC, SSCP, or heteroduplex analysis must be used. In addition, whole exon deletions or duplications, or even whole gene deletions that are not detectable by sequencing or gene scanning may constitute a significant percentage of the deleterious mutations in a particular gene. In this case, techniques that are capable of assessing gene dosage, such as Southern blotting, some variation of quantitative PCR, MLPA, or a hybridization platform that is capable of measuring sequence dosage in a comparative way, must be used. **Figure 70-8** illustrates the DNA sequence tracing of the Ashkenazi-Jewish founder mutation 185delAG in *BRCA1*.

HEMOCHROMATOSIS

Hereditary hemochromatosis, first recognized in its full clinical expression as the triad of cirrhosis, diabetes mellitus, and bronzing of the skin, was originally thought to be a rare disorder of iron overload affecting about 1 in 5000 or fewer Caucasians. However, when genetic studies linked the disease-causing gene to the HLA locus on chromosome 6, and biochemical tests of iron overload (principally transferrin saturation) were utilized, it was recognized that the underlying genetic predisposition to iron overload was extremely common. Indeed, hereditary hemochromatosis is now recognized as an autosomal recessive disorder with a carrier frequency as high as one in eight in people of northern European descent, making it the most common genetic disorder in the U.S. Caucasian population. The incidence of at-risk homozygotes is 1 in 250, but only a fraction of these accumulate sufficient excess iron to produce the tissue injury associated with the classic disorder.

Our understanding of hereditary hemochromatosis entered a new era with the identification of the *HFE* gene (initially called *HLA-H*) within the major histocompatibility locus on chromosome 6 (Feder, 1996). The *HFE* protein, although it is a major histocompatibility complex class I-like molecule, does not bind and present endogenous peptides and is not thought to have an immunologic function. Rather, as discussed in Chapter 49 evidence is accumulating that the *HFE* protein interacts with the transferrin receptor and modulates enteric absorption of dietary iron (Waheed, 1999). Mutations in *HFE* impair this regulatory function, leading to excess iron absorption and storage in tissues.

As noted in Chapter 49 a single missense mutation in *HFE*, C282Y, which results in a tyrosine substitution for cystine at amino acid 282 in the *HFE* protein, is present in the homozygous state in 80%–90% of Caucasians with hemochromatosis. An additional small percentage of patients with hemochromatosis are compound heterozygotes, carrying one chromosome with a C282Y mutation and another with an H63D mutation. H63D is a common variant, with a carrier frequency of approximately 20%, and its association with iron overload is very low (1%–2%) in the compound heterozygous state and probably even lower when homozygous

(Gochee, 2002). Over the years since its discovery, the penetrance of the C282Y homozygous state has also been questioned, and may be appreciably lower than the 80% earlier quoted, perhaps as low as 10% or even 1% (Beutler, 2002; Pietrangelo, 2004). For this reason, population screening for these mutations in individuals with no clinical or biochemical signs of hemochromatosis has not been recommended. Similar to what was discussed for factor V Leiden earlier, the DNA test is best reserved for differential diagnosis in patients already exhibiting the clinical disorder or elevated transferrin saturation detected on biochemical screening. The C282Y and H63D mutations are single-nucleotide substitutions and may be analyzed easily by a variety of PCR, real-time PCR, microarray, microplate, or sequencing methods.

SPINAL MUSCULAR ATROPHY

Spinal muscular atrophy is an autosomal recessive motor neuron disorder characterized by proximal muscle weakness and wasting. The most severe form, type I (also called Werdnig–Hoffmann disease), presents with hypotonia in infancy and early childhood death due to respiratory failure. Intermediate and atypical forms are also described. The disease is caused by mutations in the *SMN1* gene on chromosome 5q13. With a carrier frequency of 1 in 50, spinal muscular atrophy is one of the more common lethal recessive disorders, approaching the incidence of cystic fibrosis.

The majority (95%) of affected patients exhibit loss of the *SMN1* gene, either through complete gene deletion or through a gene conversion event involving sequences in the adjacent *SMN2* gene which differs by a single nucleotide in exon 7. The *SMN2* gene is believed to be nonessential because both alleles are absent in 5%–10% of normal individuals, yet is partially protective as demonstrated by the finding of higher *SMN2* copy number in patients with less severe forms of the disease (Mailman, 2002). The presence of this closely homologous pseudogene has necessitated the development of meticulously designed allele-specific PCR/restriction endonuclease assays to determine homozygous deletion of *SMN1* in the presence of *SMN2* (Prior, 2010). Identification of carriers, based on *SMN1* gene dosage analysis, is even more challenging and requires the use of quantitative or real-time PCR methods (Ojino, 2004b); this problem, along with questions about genotype–phenotype correlation, have led to some controversy over whether SMA should be a target of general population carrier screening along the lines of CF (Prior, 2008; ACOG, 2009). The small percentage of patients not showing loss or conversion of both *SMN1* genes usually carry a small intragenic mutation in one allele, of which a large number have been reported. These can be detected by sequencing or by multiplex allele-specific PCR assays (Mailman, 2002).

MITOCHONDRIAL DNA DISORDERS

In addition to the 6 billion bp of DNA that comprise the human nuclear diploid genome, vital genetic information is also encoded in DNA molecules carried by the mitochondria in the cytoplasm. These 16,500 bp, double-stranded circular DNA molecules are present in 2–10 copies in each of the up to several hundred mitochondria of the cell. Mitochondrial DNA codes for 13 of the proteins of the respiratory chain and adenosine triphosphate (ATP) synthase, 22 transfer RNAs required for their translation, and two ribosomal RNAs. Mitochondrial DNA is self-replicating and is transmitted strictly by maternal inheritance, because the mitochondria of a spermatozoon are not incorporated into the zygote upon fertilization of an ovum.

Disease-causing abnormalities of mitochondrial DNA may result from several different mechanisms (Ruiz-Pesini et al., 2007). Single large deletions (and, rarely, duplications) that apparently occur sporadically in oogenesis are typical of Kearns–Sayre syndrome, a myopathy characterized principally by progressive external ophthalmoplegia and pigmentary retinopathy. A wide range of disorders are characterized by multiple small deletions and show typical mendelian autosomal dominant or autosomal recessive patterns of inheritance, apparently because they are due to undefined defects in nuclear genes important for mitochondrial DNA replication. Most distinctive from a genetic point of view are the disorders that follow a pattern of strict maternal inheritance, never showing transmission from an affected male and passing from an affected female equally to her sons and daughters. These diseases are most often due to point mutations in one of the genes encoding a transfer RNA (e.g., myoclonic epilepsy and ragged red fibers [*MERRF*] and mitochondrial myopathy, encephalopathy, lactic acidosis, and strokelike episodes [*MELAS*] or a mitochondrial protein (e.g., Leber hereditary optic neuropathy [*LHON*]). In addition to

the inherited encephalomyopathies, there is growing evidence that tissue-specific accumulations of somatic mitochondrial mutations may contribute to the development of many common late-onset degenerative disorders, and perhaps to aging itself.

Laboratory confirmation of the large mitochondrial DNA deletions often present in Kearns-Sayre syndrome is easily accomplished by Southern blot analysis of mitochondrial DNA from affected tissues using labeled whole mitochondrial DNA as a probe. Point mutations in other disorders may be analyzed by a number of techniques. Often the clinical presentation will guide the choice of mutation panel testing in a stepwise fashion, because particular mutations are associated with each of the major syndromes (e.g., missense mutations G11778A, T14484C, and G3460A with LHON). If these tests are negative, one can proceed to a second-tier panel or to complete mtDNA sequencing. The situation is complicated by the finding that some mutations are found in more than one syndrome and by the phenomenon of heteroplasmy—the occurrence of different proportions of mutant and normal mitochondria in different tissues. For this latter reason, mitochondrial DNA testing may require biopsy of the involved tissue (e.g., muscle) because the mutation may not be represented highly enough in blood to be detectable. This is where the advent of next-generation sequencing may come to the fore, in that it would allow sequencing of the complete mtDNA genome in a short time while also detecting minor populations of mutant mitochondria, perhaps even outside the affected tissue (Vasta, 2009).

OTHER TARGETS OF MOLECULAR GENETIC TESTING AND SCREENING

The specific disease examples covered in this chapter are among those tested most widely by clinical molecular genetics laboratories, a market that is reflected by their inclusion in the CAP/ACMG proficiency testing programs. This in turn has been dictated largely by their mutation carrier frequency or disease prevalence in the general population, and by their clinical severity. As previously described, if the carrier frequency of a recessive mutation is sufficiently high in the target population, general screening may be justified. For these and other disorders, the application of the test to differential diagnosis, prenatal diagnosis, or presymptomatic diagnosis may also be of value. With more than 10,000 genetic diseases catalogued, there are obviously many others that could be considered; currently there are almost 1900 different molecular genetic disease tests available as listed in the useful online database GeneTests (<http://www.ncbi.nlm.nih.gov/sites/GeneTests/lab?db=GeneTests>) (GeneTests, 2010). Many of these are esoteric and offered by only one or a few laboratories. Tests for extremely rare, or *orphan*, genetic diseases may only be available in the research laboratory that cloned the gene. This has led to some problems because such laboratories, although performing a vital service to the small number of families at risk, are not Clinical Laboratory Improvement Act (CLIA)-certified and on legal grounds should not be releasing test results for medical management. A number of solutions have been proposed, such as modifying certain CLIA requirements for such settings, partnering of the research laboratory with a clinical laboratory in their own institution, or establishing a network of dedicated orphan disease laboratories (Grody, 2008).

Some disorders that are rare in the general population are sufficiently prevalent in a particular racial or ethnic group to justify limited population screening. For example, a number of laboratories offer an Ashkenazi-Jewish carrier screening panel to include any or all of the following autosomal recessive diseases, which have carrier frequencies ranging from 1/100 to 1/15: Tay-Sachs disease, Gaucher disease, Canavan disease, cystic fibrosis, familial dysautonomia, Niemann-Pick disease A, Fanconi anemia C, Bloom syndrome, and connexin-26-related hearing loss. Screening of just the first four of these diseases has a positive yield of 1 in 6 in this population (Eng, 1997).

Beyond the driver of service to a particular indigenous patient population, the choice of molecular genetic test menu from the large and ever-expanding universe of known disease genes will depend on both intellectual and economic factors (Amos, 2004). Development of a molecular genetic test may be spurred by a clinical colleague's interest in a particular disease and accrual of a stable of patients and at-risk relatives. A molecular test may be needed as backup to a biochemical test done at the same institution, as for hemoglobinopathies or α_1 -antitrypsin deficiency, or for statewide expanded newborn screening by tandem mass spectrometry (CDC, 2008). Of course, a strong motivator is the availability of robust commercially

distributed platforms for performing the test (instrumentation, analyte-specific reagents, and/or FDA-approved kits), and this in turn will be driven by the potential market the vendors perceive for the disease in question. Naturally, carrier screening tests will always be of higher throughput than diagnostic tests, which explains the proliferation of commercial reagents and instruments for CF mutation detection that followed the ACMG/ACOG screening recommendations. Meanwhile, an economic factor pushing in the opposite direction, toward less widespread testing, is the specter of exclusive gene patents. Depending on the restrictions and sublicensing royalty arrangements of the patent-holder, clinical laboratories may not have access to certain desired tests, even if done by in-house-developed methods. For example, mutations in the connexin-26 (*GJB2*) gene, which account for about half of all cases of congenital non-syndromic deafness and thus could be envisioned as a target of newborn screening (Schimmenti, 2008), are subject to an exclusive patent license. Recently, the constitutionality of patenting such “products of nature” has been challenged in the federal courts (Matloff, 2010). Finally, any new test being considered must first be shown to have clinical utility and analytic validity.

FUTURE DIRECTIONS

Molecular testing for genetic diseases has now come of age and in fact lies at a crucial juncture in the history of medicine. As is discussed in Chapter 77, with the sequencing phase of the Human Genome Project now completed, essentially any test for an inherited mutation is within our grasp. Moreover, continued advances in high-speed DNA sequencing and microarray technology may soon make routine comprehensive analysis of an individual patient's genome economically feasible. But just because something becomes analytically practical does not make it clinically valid, and the many potential problems of whole-genome analysis have already been raised in this chapter. Despite this, several high-profile commercial firms have begun to offer such services through direct-to-consumer marketing over the internet, with no genetic counselor or physician in the loop (Caulfield, 2010). Will whole-genome scanning become the equivalent of today's much-advertised whole-body CT scans, chasing shadows of uncertain clinical significance?

Closely tied to the increasing technologic invasiveness of genetic testing are the ethical concerns raised at the beginning of this chapter: genetic privacy, discrimination, stigmatization, confidentiality, informed consent. These have been discussed and written about extensively, including in the context of the new technology (Grody, 2003b). Because of these concerns, a widespread belief has arisen that molecular genetic test results are different in a fundamental way (mostly owing to their predictive power) from all other medical information, and must be subject to more stringent oversight. Others think that the results of these tests, while far-reaching, need be no more emotionally charged than many other clinical studies performed in laboratory medicine and pathology. Nevertheless, many states and countries are pursuing regulatory solutions to the perceived potential for abuse, and in the United States a variety of legislative initiatives aimed at safeguarding genetic information and privacy are pending or already passed.

While molecular analysis becomes more invasive, specimen collection techniques in genetic testing may become less invasive. Just as such approaches as buccal brushing can replace phlebotomy and biopsy for detection of a germline mutation, development of more sensitive and selective techniques for obtaining fetal samples may make the invasiveness of amniocentesis and chorionic villus sampling less necessary for prenatal diagnosis. These include isolation of fetal cells or DNA from maternal blood (Hahn, 2009) or vaginal contents. At the same time, the power of single-cell PCR for early-embryo biopsy and preimplantation genetic diagnosis can be used to obviate the invasiveness and emotional trauma of later prenatal diagnosis and pregnancy termination (Geraedts, 2009). Aside from questions about access due to its high cost, preimplantation genetic diagnosis raises the prospect of another ethical minefield previously the domain of science fiction: the ability to select offspring for nondisease traits. In fact, this is already occurring, as embryos have been HLA-typed through single-cell PCR and used for selective implantation based on the predicted suitability of the offspring to serve as bone marrow donors for existing siblings with hematopoietic disorders (Verlinsky, 2004). Can selection for other nondisease traits be far behind?

The applications presented in this chapter are all single-gene defects, because that is all our current knowledge and technology can handle. In

the future it is hoped that molecular genetic testing will also be applied to the most common chronic diseases of medicine, which are all polygenic: atherosclerosis, diabetes mellitus, hypertension, schizophrenia. It is toward this end that a tremendous effort is being expended to identify single-nucleotide polymorphisms and other variants within candidate genes that may in aggregate produce quantitative trait effects on homeostasis,

vascular tone, lipid metabolism, and so on. It is hoped that the discovery of these determinants will enable population risk screening programs followed by targeted therapies and preventive interventions. In this way, molecular genetic testing will be the central modality behind an ever-greater proportion of medical practice in the 21st century, and virtually every patient, whether healthy or ill, will feel its impact.

KEY POINTS

- Standardized marker systems with known allelic polymorphisms are used in testing panels. Alleles with short tandem repeats form the basis of commercially available kits.
- Forensic testing requires documentation of all steps taken during collection, extraction, and testing so results can withstand legal challenges.
- Deoxyribonucleic acid (DNA) can be obtained from any sample that contains cellular material. The stability of DNA allows it to withstand harsh environmental conditions and long postmortem intervals.
- Care must be taken to maintain the integrity of DNA evidence and to avoid contact or exposure of the evidence to any conditions that may contaminate the original stain/evidence.
- Mitochondrial DNA can be extracted from bone and teeth after hundreds of years because it is small and present at hundreds to thousands of copies per cell. Mitochondrial DNA is maternally inherited and can be useful for identifying remains.
- DNA is used in identification of remains and can be used to link a suspect to a crime, to exculpate falsely accused suspects, to recognize serial crimes, and to distinguish copycat crimes, or to aid in accident reconstruction (e.g., to determine who was driving a car by the identification of the bloodstains on the driver's side of the windshield).
- Pathology laboratories can use DNA testing to resolve specimen mixups such as when samples are inadvertently switched or pathologic material floats onto a histologic or cytologic slide.
- Standards and quality assurance guidelines for parentage and forensics laboratories have been developed by the American Association of Blood Banks and the Federal Bureau of Investigation's DNA Advisory Board, respectively.

In parentage testing, samples obtained from multiple individuals are compared for inherited similarities; most often in forensic DNA testing, crime scene samples are evaluated for an exact match with a suspect.

A frequently quoted early reference to disputed parentage appears in the Bible (1 Kings 3:16–27), in which Solomon makes a decision about the

maternity of a disputed child by threatening to use his sword to provide each claimant with a portion of the child. When paternity is in dispute, the arbiter of truth often is faced with the dilemma similar to that faced by Solomon: lack of witnesses to the event and the likelihood that the principals might not know or tell the truth. Similarly, short of eyewitnesses or confession, identifying a person at a crime scene is difficult to accomplish and most evidence merely suggests a suspect linkage. The availability of biological evidence, such as DNA, provides information that can lead to clear resolution of disputed facts.

HISTORICAL BACKGROUND

The discovery of the ABO blood group system by Landsteiner in 1900 (Landsteiner, 1901) and the recognition that these measurable characteristics followed the genetic rules described by Gregor Mendel (Mendel, 1866) provided objective laboratory evidence that could be used by courts to aid in deciding when a person had been falsely accused of paternity. In the United States, laws addressing the use of genetic markers for proving nonpaternity were enacted in 1935 (Schatkin, 1952). In the ensuing years, knowledge about useful genetic marker systems increased dramatically. By 1976, joint guidelines developed by an American Medical Association–American Bar Association committee recommended seven systems for routine blood group investigations in cases of disputed parentage: ABO, Rh, MNs, Kell, Duffy, Kidd, and HLA (Miale, 1976). Other genetic systems such as polymorphic serum proteins and red cell enzymes were also recognized as useful. Many of these same genetic markers have also been used to match crime scene evidence with suspects or victims.

In 1980, DNA restriction fragment length polymorphism (RFLP) was described by Botstein (Botstein, 1980). Sir Alec Jeffreys is credited with the first report in the scientific literature to suggest that DNA typing might be useful for forensic identification, and coined the term “DNA fingerprint” in his *Nature* article in 1985 (Jeffreys, 1985a, 1985b). Commercial laboratories began using DNA testing for parentage and criminalistics casework in 1986, and government crime laboratories began using DNA testing in 1989 (Weedn, 1993a). Today, several hundred laboratories worldwide use DNA testing for the criminal justice system. In 1990, when the first edition of *Standards for Parentage Testing Laboratories* (American Association of Blood Banks, 1990) was published, specific requirements for RFLP testing were included along with those for what are now referred to as *classic systems* (red blood cell surface antigens, human leukocyte

antigens, red cell enzymes, and serum protein genetic markers). DNA testing has replaced traditional serologic techniques. The forensic DNA testing community has endured many iterations of DNA methods and technologies, and has standardized its testing with a set of 13 core short tandem repeat (STR) loci as the current mainstay of testing in order to build its international offender databases. This core set of loci is supplemented by other DNA testing, gender analysis (Amelogenin), Y chromosome markers, and mitochondrial DNA (mtDNA) sequencing. Capillary electrophoresis is the main instrument platform with fluorescence detection.

These same technologies are used to identify victims of war or mass disasters (Budowle, 2005), whether the disaster is natural, man-made, or industrial, and in cases of wildlife forensics. DNA testing is also used for accident reconstruction, in medical cases of sample mixups, and in animal husbandry. DNA technology is here to stay; newer technologies will be adopted that offer higher powers of discrimination, lower costs, enhanced sensitivity, increased efficiency, and even information on the physical traits of the remains or biological material left at a crime scene. As these newer technologies evolve and are validated, so will the field of forensic sciences.

ADVANTAGES OF DNA

DNA permits the direct identification of the individual source because it is personal and manifests biological variation. DNA is useful as an identity marker because it is (1) present throughout all cells of the body (except mature red cells); (2) the same in all cells of the body (except haploid sex gametes); (3) the same throughout life from the time of conception (except that a progenitor stem cell transplantation can result in the presence of donor characteristics rather than the recipient's inherited DNA); (4) different in all individuals (except identical twins). The human genome is approximately 99.9% the same between individuals; it is the 0.1% difference of the human genome that forensic scientists interrogate to individually identify stains, remains recovered from accidents and mass disasters, and biological relatives.

DNA tests have a sensitivity that is far superior to traditional serologic markers. Polymerase chain reaction (PCR)-based testing can be accomplished on minute samples and even invisible trace DNA deposits. DNA is a robust molecule resistant to strong acids, alkalis, detergents, and environmental factors (Kobilinsky, 1992). The typing information from DNA is found within the sequence of nucleotides. Consequently, DNA is more successfully performed than serology tests on specimens that are older and that have been exposed to greater environmental insults.

The bulk of the casework for crime laboratories in the United States is from sexual assaults. Vaginal swabs contain bacteria and female epithelial cells as well as the male sperm. DNA from sperm can be separated from nonsperm DNA by a differential lysis procedure because of the protective capsule of spermatozoa (see later under DNA Extraction and Quantification). This allows for individualization of the source of the semen without the confounding data of the nonsemen evidence. DNA targets are also generally human- or primate-specific so the presence of bacterial DNA is of no consequence.

CHOOSING GENETIC MARKERS

The model genetic system for testing would be one in which the individual has a unique marker. In determining relationships, this marker can be found in both the child and the putative parent. At present, short of gene sequencing, none of the marker systems provide such specific findings. Thus multiple genetic systems that meet certain criteria are used for parentage and identity testing. Ideally, the system should have multiple alleles distributed in the population so that there is a high power of exclusion and the least common phenotype has a frequency that can be determined reliably. All markers in the system should be expressed (no null alleles) as codominant, mutation rates should be known and low, and phenotypes should be stable under usual storage conditions. Methods for detecting the markers should be reliable, reproducible, and feasible for a large number of laboratories. The genetics of the system must be known and follow established inheritance patterns (Mendelian laws). The system should be independent of other markers routinely tested. If the system is intended for calculating estimates of paternity or identity, the gene frequencies in various populations must be established (Budowle, 2001).

The DNA from every human (except identical twins) is unique, because of the presence of polymorphisms, which are differences in the DNA between individuals. However, the vast preponderance of the DNA

sequence is identical between individuals. On average, only 1 in 1300 nucleotide bases differs between individuals. Nonetheless, this amounts to an average of 3 million bases that differ between any two individuals and accounts for the tremendous genetic variation among individuals. Although the diversity in the coding regions of DNA (genes) is significant, the noncoding regions of DNA also give rise to a great deal of diversity.

Length-based polymorphisms are found in repetitive DNA. More than 90% of the human genome is composed of noncoding, or "junk," DNA, of which approximately 20%–30% is composed of repetitive regions. Many of the repetitive regions vary in the number of core repeats between different individuals; so-called variable number of tandem repeat (VNTR) loci. DNA fragments containing VNTRs vary in length and are thus useful for analysis. Dinucleotide repeats are most common, but larger core repeats are more useful for forensic purposes. RFLP, amplified DNA fragment length polymorphisms, and STRs are examples of fragment-length analytic techniques. Sequence polymorphisms exist within the DNA sequence of similarly sized DNA fragments. Sequence polymorphisms consist of differences in one or more bases in the DNA sequence at a particular location in the genome. Sequence variations can manifest as regions of alternative alleles or base substitutions, additions, or deletions. Most sequence polymorphisms are mere point mutations within repetitive and nonrepetitive regions and are known as single nucleotide polymorphisms (SNPs). SNPs, sequence-specific oligonucleotides, and mtDNA tests are examples of sequence-based tests. Identity testing has not yet adopted the power of the more than 2 million SNPs in the human genome but this is clearly on the forefront of the technology.

SAMPLES AND SPECIMEN COLLECTION

For parentage testing and entering information into DNA databases, buccal swabs, fresh whole blood, and/or bloodstains on filter paper are most frequently used. Results from testing are often used in legal proceedings. Thus all aspects of the procedures used should be well-documented, because they may be subject to challenge by one of the parties. It is important to ensure documentation of the identification of the tested individuals, the collection, and the labeling of samples. Although many parentage disputes are civil actions, some jurisdictions require documents showing the chain of custody of samples similar to those used in criminal matters. American Association of Blood Banks (AABB)-accredited laboratories are required to obtain a history of any recent transfusion (in the preceding 3 months) or a hematopoietic stem cell transplant. A photographic identification and appropriate informed consent must also accompany each sample. The consent for a minor should be from an individual with legal rights to the custody of the child.

Proper specimen collection at a crime scene is very important. The evidence must be recognized before it can be properly collected. This is often accomplished with the help of chemicals and/or alternate light sources to make bloodstains visible. Blood spatter pattern analysis is also employed to help the investigator interpret and intelligently collect specimens from large pools of blood and bloodstains. Adequate chain of custody documentation, packaging and sealing, and preservation of the specimen are as important as the initial collection.

Items with biological fluids (e.g., blood on a piece of clothing) should be collected and packaged separately. When a biological fluid has been deposited on a surface or an item that cannot be collected, the fluid should be sampled with clean sterile swabs moistened with sterile distilled water. For bite marks on bodies, a technique has been described (Sweet, 1997) that involves rubbing with a wet swab followed by a dry swab. Control swabs are collected from an unstained area adjacent to the fluid stain. The stain and control swabs should be air-dried and packaged separately.

Ethylenediamine tetraacetic acid (EDTA) and citrate phosphate dextrose (CPD) remain the anticoagulants of choice for DNA testing. Heparin-anticoagulated blood is not recommended for DNA testing. Even though mature red blood cells are devoid of DNA (both nuclear and mitochondrial), ample DNA is present from circulating white blood cells for testing. Despite inhibition of the PCR reaction by heme, blood is a good source of DNA for PCR testing because the inhibitory activity of heme can easily be diluted and removed.

However, in postmortem settings, sources of DNA other than blood are preferred if there is significant putrefaction. Virtually any tissue may be successfully used for DNA typing purposes. Some tissues that may be intuitively thought to be better sources of DNA, because they are more densely cellular and would contain higher concentrations of DNA, are in fact, less optimal because of higher rates of postmortem degradation (Kobilinsky, 1992). Among soft tissues, liver DNA appears to degrade

quickly from autolytic enzymes, whereas brain tissue is a relatively good source in the intermediate postmortem period. Bone and teeth are stable sources of postmortem tissue DNA. Informative DNA is routinely obtained from skeletal remains that are decades old. Generally, the greater the body decomposition and the longer the postmortem period, the greater the degradation of the DNA from cadaveric tissues.

Great care should be taken to prevent contamination of the specimen by other sources of DNA. Specimens should be collected using gloves and pristine instruments. When possible, nonexposed tissue should be collected by an incisional biopsy technique. The specimens should be kept cold or preferably frozen (although repeated freezing and thawing is destructive of large DNA fragments). Desiccation, even simple air-drying, may be an adequate method of storage of some DNA specimens (e.g., bloodstains and bone). Tissues in formalin are not optimal but can often be used for PCR-based DNA testing. No tissues or biological fluids should be discarded as inadequate without first attempting DNA testing.

DNA in most specimens will undergo progressive random fragmentation or degradation, reducing the high molecular weight DNA to low molecular weight DNA (Kobilinsky, 1992). High molecular weight DNA is not generally isolated from tissue after a few days. On the other hand, high molecular weight DNA from desiccated or frozen materials may be retained for years. Residual smaller DNA fragments may persist despite considerable degradation. Because of its high copy number (hundreds to tens of thousands of copies per cell), mtDNA often survives when no nuclear DNA is recovered. Consequently, mtDNA testing is routinely used to identify old skeletal remains (Ivanov, 1996).

Rapid DNA degradation or damage may be produced under certain conditions (Parsons, 1997). Chemical hydrolysis of DNA is normally quite slow. Tests have shown that mixing DNA with detergents, oil, gasoline, and other adulterants does not alter the DNA result. However, metal ions may catalyze oxidative hydrolysis. Ultraviolet radiation is known to cause thymidine dimerization. Depurination has been described for "ancient DNA."

DNA EXTRACTION AND QUANTIFICATION

The first and most critical step for evidence is the extraction of DNA from blood, biological stains, or other biological sources. DNA from a bloodstain, a vaginal swabbing, or other source must be isolated from other cell components and environmental contaminants. The classic organic chloroform/phenol extraction with ethanol precipitation, although cumbersome, is an efficient and reliable method that separates proteins and other cellular materials from the DNA molecules. A chelating resin, Chelex 100 (Bio-Rad Laboratories, Hercules, Calif.), when boiled in the presence of biological samples, will break open cells and release the DNA (Walsh, 1991). The Chelex 100 binds to polyvalent metal ions, thus inactivating nucleases and polymerases. Even though the extract is relatively crude, the resultant single-stranded DNA yield is high and the purity is sufficient for most PCR-based testing, especially reference materials, and is fast and less expensive than other extraction methods. Solid-phase column extraction methods (e.g., Qiagen columns) and magnetic resin particles are increasingly used for DNA extraction, particularly in high-volume operations where automation may be required (Plopper, 2006). Compared with Chelex extraction, the column extraction methods yield DNA that is more highly purified but at a higher cost. Contaminants such as those found in cigarette butts and certain dyes may be removed. Silicon beads are another excellent method to purify DNA when inhibitors need to be removed. Many laboratories eliminate the extraction step altogether by performing PCR directly from a punch of a bloodstained item. This technique is most commonly used on bloodstains on FTA paper (specially treated filter paper) (Rogers, 1997) and untreated cotton paper from archived databank samples and blood reference standards.

As mentioned earlier, vaginal swabs require special conditions for extraction using a differential lysis procedure because of the need to separate the male DNA in sperm from the female DNA in epithelial cells (Crouse, 1993). The female fraction is easily produced by standard extraction procedures from the fragile epithelial cells present. The male fraction is then recovered by breaking the disulfide bridges of the protective capsule of spermatozoa with a dithiothreitol solution. Sensitive PCR-based systems often exhibit female source DNA in the male fraction, producing mixed DNA profiles.

Once the samples are extracted, quantification is performed. The forensic standards require quantification of forensic evidence, when

possible. When performing quantification and knowing the amount of DNA in a sample, amplification is usually more successful. Too little or too much DNA in a PCR-based assay results in nonoptimal amplification, which can produce poor results. Early quantification methods include absorbance at 260 nm using a spectrophotometer; agarose gel electrophoresis and visualization with an intercalating dye such as ethidium bromide; and DNA bound on a nylon membrane and hybridized with a human-specific probe (Walsh, 1992). Today, real-time quantitative PCR techniques provide for a more sensitive and objective assay (Green, 2005).

TEST METHODS AND MARKER SYSTEMS

SHORT TANDEM REPEATS

Loci consisting of repeat units of three to seven nucleotides occur throughout the genome (Weber, 1989). Alleles at these STR loci are defined by the number of repeat units in the PCR-amplified product. The basic PCR techniques employed are discussed in Chapter 66. Extracted sample DNA is added to a PCR reaction mix containing *Thermus aquaticus* (Taq) polymerase, a specific forward and reverse primer for each locus tested, deoxynucleoside triphosphates, magnesium, a buffer solution, and bovine serum albumin. The PCR reaction mixture is amplified in a thermal cycler using carefully defined parameters to maximize detection of the alleles. Several primers with different fluorescent labels are used in a multiplex reaction to detect alleles at several loci in a single amplification. The PCR products, which vary in length, are separated by capillary electrophoresis. Detection is performed using a laser to excite the labeled fluorophore that has been incorporated in the primer. The loci in the multiplex reaction differ by size and color (Fig. 71-1). Sizing is accomplished by introducing a size standard with each sample injected in the capillary and using sophisticated software algorithms; phenotyping of each peak is achieved by comparing the peaks in the sample to an allelic ladder accounting for most alleles for each locus and using sophisticated software algorithms for allele calls that adjust for minor variations in electrophoresis for each injection (Fig. 71-2).

The most commonly used markers in forensic and parentage laboratories in the United States are the 13 STR loci (CSF1PO, D3S1358, D5S818, D7S820, D8S1179, D13S317, D16S539, D18S51, D21S11, FGA, TH01, TPOX, VWA) that have been standardized for use in obtaining genetic profiles of individuals who have been convicted of various criminal offenses. These were identified by a consortium of scientists sponsored by the Federal Bureau of Investigation (FBI) for use in the Combined DNA Index System (CODIS). The STR marker systems have discrete alleles and are not as polymorphic as the RFLP marker systems. An STR locus may have three or four common alleles (frequencies of 0.15–0.25) and several rare alleles (frequencies of <0.01). Thus in order to obtain a high cumulative probability of exclusion (CPE) and combined paternity index (PI), it is usually necessary to test at least six or more STR loci. In a series of 50 paternity cases tested in parallel by both RFLP and nine STR loci, Alford and colleagues reported (Alford, 1994) that both methods excluded the same 13 alleged fathers (based on two or more loci). The likelihood of paternity for the 37 nonexcluded men based on the STR systems was more than 99% in 36 cases. When all 13 CODIS STR loci are obtained, the average random match probability is rarer than one in one trillion among unrelated individuals (Chakraborty, 1999).

X AND Y CHROMOSOME MARKERS

Sex determination is now commonly performed using the Amelogenin locus (see Fig. 71-1). The primer for this locus amplifies an X-specific band (Xp22.1–22.3) and a Y-specific band. This locus is coamplified and coanalyzed with many multiplexed STR systems. Sex determination marks a departure from all other routine identity markers, in that it provides specific phenotypic information about the source individual. It may also be important in the investigation of potential suspects as well as in the categorization of specimens as originating from a victim or suspect.

Although polymorphic Y chromosome markers (Fig. 71-3) are not used for sex determination, they are extremely useful in the typing of sexual assault evidence that displays a mixture of both the female epithelial cell DNA and male sperm DNA because these results are only obtained from males. They also are used to characterize the paternal lineage in human remains identifications. The characterization of the Thomas Jefferson family lineage was accomplished using Y chromosome markers (Foster,

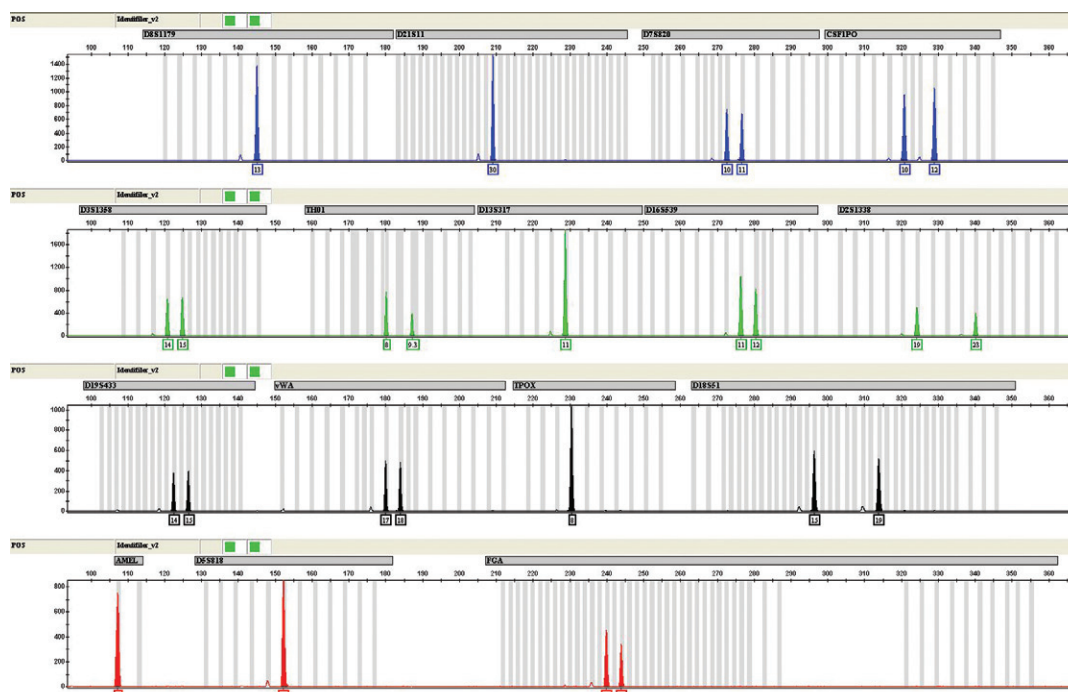

Figure 71-1 The results of the kit-included positive control 9947A amplified with the AmpFLSTR Identifier PCR Amplification Kit (Applied Biosystems, Foster City, Calif.) (Collins, 2004) and electrophoresed on the ABI PRISM 3130xl Genetic Analyzer (Applied Biosystems) and typed with GeneMapper ID Software v. 3.1.2 (Applied Biosystems). The results for the 15 autosomal STR loci and Amelogenin, a sexing marker, are visualized. This image displays the phenotype of the positive control amplified in this megamultiplex. The locus name is shown in the gray bar above the peaks, the allele call(s) for each locus is just below the highlighted peak.

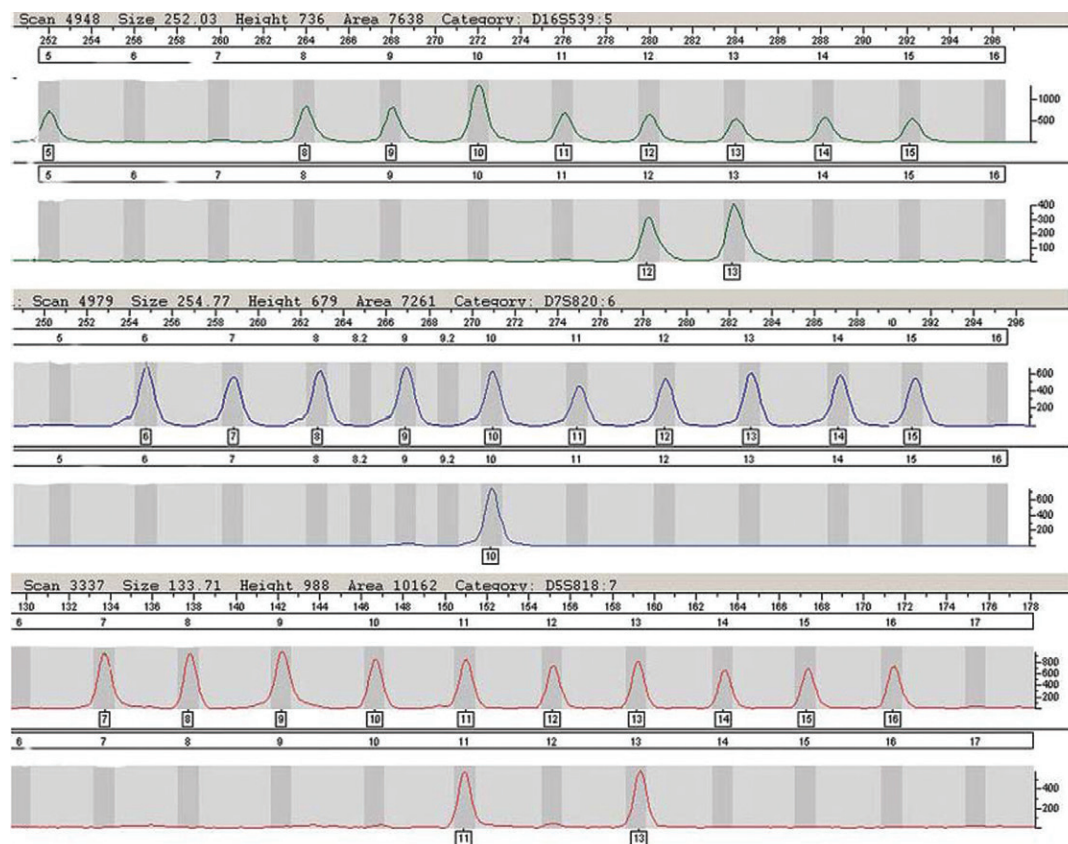

Figure 71-2 The results of a sample electrophoresed on the ABI PRISM 3100 Genetic Analyzer (Applied Biosystems) and amplified with the AmpFLSTR Identifier PCR Amplification Kit. The ladders and accompanying results for three loci, D16S539 (alleles 12, 13), D7S820 (allele 10), and D5S818 (alleles 11, 13), are visualized in these images. The images demonstrate excellent resolution in the electrophoresis.

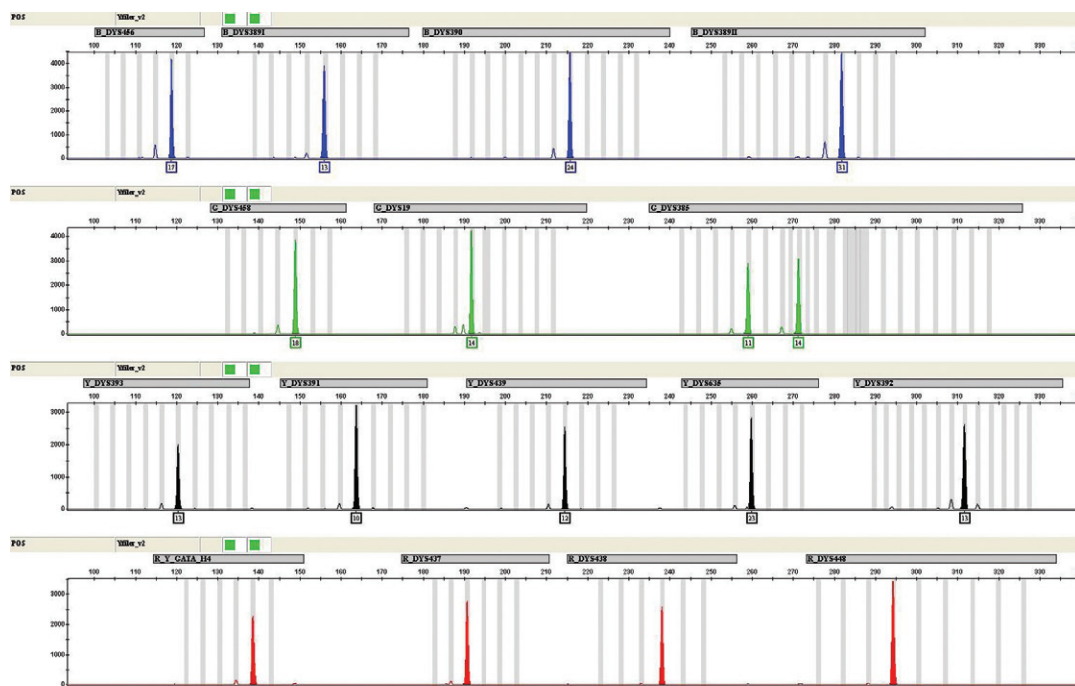

Figure 71-3 The results of the kit-included positive control 9948 amplified with the AmpFLSTR Yfiler PCR Amplification Kit (Applied Biosystems, Foster City, Calif.) (Mulero, 2006), electrophoresed on the ABI PRISM 3130xl Genetic Analyzer, and typed with GeneMapper ID Software v. 3.1.2. The results for the 17 Y-STR loci are visualized. This image displays the phenotype of the positive control amplified in this mega-multiplex. The locus name is shown in the gray bar above the peaks; the allele call for each locus is just below the highlighted peak.

1998), an example of a historic and genealogic study. Data from extensive Y-STR typings have shown that certain haplotypes are indicative of ethnic origin and can be used for human migration and evolutionary studies. A haplotype is generated from Y-STRs versus a phenotype in autosomal STRs; haplotypes do not afford the same level of discrimination as STR profiles.

MITOCHONDRIAL DNA SEQUENCING

Mitochondrial DNA (mtDNA) sequencing is applicable when extremely small quantities of sample DNA are present or when the DNA is extremely degraded, such as in shed hairs (which have virtually no detectable nuclear DNA) and skeletal remains (Butler, 1998; Holland, 1999). Hundreds to thousands of copies of mtDNA are present within a single cell with only one copy of nuclear DNA. Accordingly, a mtDNA profile can often be obtained when a nuclear DNA profile cannot. Even a single distant relative in the maternal line may be used as a reference, so mtDNA is also useful when reference samples are limited, because nuclear DNA testing generally requires multiple close relatives.

Mitochondrial DNA is composed of a circular piece of DNA 16,569 base pairs (bp) in length. Because no significant regions of repetitive DNA exist in mtDNA, only sequence differences are reported. The region of mtDNA that is analyzed for human identification is the noncoding displacement loop (D-loop), also known as the *control region*. This locus spans approximately 1100 bp and contains two hypervariable regions. At present, direct sequencing is the method used to obtain mtDNA results.

Mitochondria are maternally inherited, so mtDNA has no paternal contribution. Unlike nuclear DNA, which is present in pairs of chromosomes, generally only a single mtDNA sequence is present in the cell (homoplasmic) and consequently no genetic recombination occurs. An exact mtDNA sequence match can be traced through the maternal lineage of a family for many generations. However, the discriminatory power of mtDNA sequencing is limited—on the order of one in a few thousand. Furthermore, this testing is very expensive and time-consuming.

OTHER SYSTEMS

Mini-STRs is a term referring to autosomal STRs in the multiplex kits where the primers have been moved closer to the tandem repeat to achieve a smaller amplicon product size. Hence, those samples that are severely degraded or include PCR inhibitors may produce a mini-STR result when

the standard kits fail (Mulero, 2008). However, fewer markers are included in the mini-STR kits compared with standard kits (Fig. 71-4).

Methods to detect single nucleotide polymorphisms, also known as SNPs, are used to determine a single base change in a sequence at a specific location. Because of the limited variability at these loci, as many as 70 SNPs need to be tested to get the same level of information about relatedness, powers of discrimination, and mixture resolution as provided by a multiplex of several STR loci. These markers have been used in the identification of highly degraded samples such as those that were recovered at the World Trade Center site. There are millions of SNPs in individuals. SNPs could be very powerful for identity testing. SNPs may provide information when traditional STRs may not because they can be designed to amplify smaller amplicons. In addition, specific SNPs may be used to provide information regarding the physical traits of an individual, and they can be designed to predict ethnic origin.

ANALYSIS AND USE OF TEST DATA

DNA IN THE CRIME LABORATORY

DNA testing has become routine in crime laboratories (National Research Council, 1996), and DNA evidence is routinely admitted into court. In the United States, a large percentage of the criminal DNA tests involves sexual assault and a significant proportion involves homicide. Approximately one third of DNA tests exonerate wrongfully accused suspects (Fig. 71-5), one fourth are inconclusive, and somewhat less than half result in a match of the suspect to a crime. Only a fraction of the cases in which DNA evidence is tested are actually litigated, because most cases result in a plea bargain. In the criminalistics context, DNA can be used to link a suspect to a crime, to exculpate falsely accused suspects, to recognize serial crimes, and to distinguish copycat crimes, or to aid in accident reconstruction (e.g., to determine who was driving a car by the identification of the bloodstains on the driver's side of the windshield). In addition to the use of DNA for associative evidence at scenes of crimes, DNA is used in the identification of human remains.

DNA IN THE PATHOLOGY LABORATORY

DNA identity tests can be used to resolve specimen mixups (Weedn, 1993b), such as when samples are inadvertently switched or pathologic material floats onto a histologic or cytologic slide. A small fragment of

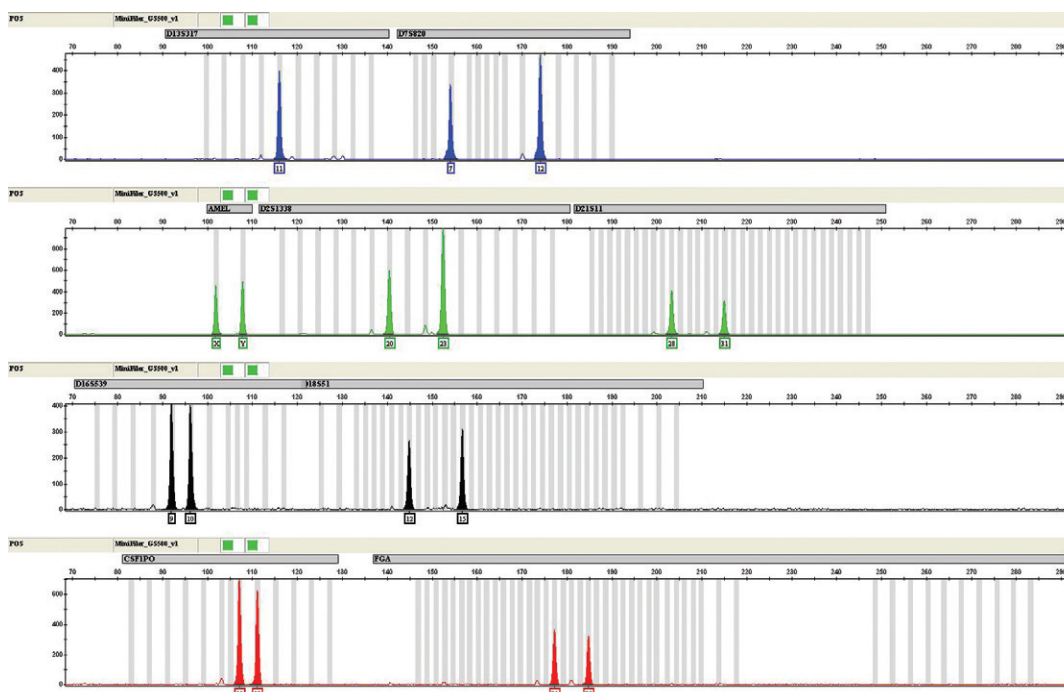

Figure 71-4 The results of the kit-included positive control 007 amplified with the AmpFLSTR MinFile PCR Amplification Kit (Applied Biosystems) (Mulero, 2008), electrophoresed on the ABI PRISM 3130x/ Genetic Analyzer, and typed with GeneMapper ID Software v. 3.1.2. The results for the 8 STR loci are visualized. This image displays the phenotype of the positive control amplified in this multiplex. The locus name is shown in the gray bar above the peaks, the allele call for each locus is just below the highlighted peak. The loci in this kit are smaller (the size of the peaks can be measured on the x-axis) than the corresponding loci in the AmpFLSTR Identifier PCR Amplification Kit (see Fig 71-1).

Figure 71-5 Exclusion of suspect when compared to crime scene evidence. The profile for the evidence at D8S1179, D21S11, and CSF1PO is clearly different from the suspect's profile. The evidence could not have been contributed by the suspect.

cancerous tissue (“floater”) on a glass microscope slide can be determined to be from someone other than the patient (Table 71-1). DNA testing may be used to confirm or refute mislabeling of biopsy specimens. In addition, urine drug tests that have been challenged on the basis of alleged sample switching may be resolved by DNA testing (Weedn, 1996).

STR markers are also used to evaluate engraftment of marrow after transplantation (Scharf, 1995). When the donor is related to the recipient,

testing of multiple markers may be required to find an informative locus because related people share many alleles.

EXCLUSION OF PARENTAGE

The primary goal of genetic marker testing in cases of disputed parentage is to identify the biological parent of a given child. Although this cannot

TABLE 71-1

Identification of Possible 'Floater'

STR locus	Floater	Tissue block	Patient sample	Frequency of patient's phenotype
CSF1PO	10,12	10,12	10,12	0.191
D3S1358	15,16	16,17	16,17	0.099
D5S818	11	11,12	11,12	0.024
D7S820	9,11	11	11	0.0529
D8S1179	13	12,14	12,14	0.0976
D13S317	11	11	11	0.0798
D16S539	9,11	11,12	11,12	0.1764
D18S51	14,15	14,15	14,15	0.0477
D21S11	30	28,31.2	28,31.2	0.0341

Shaded results indicate the DNA results from the floater are different than the DNA from the patient and the tissue block. The chance that the tissue block has the same genetic markers as the patient compared to a random Caucasian individual is greater than 1.86×10^{10} .

	B (bb, b?)	C (cc, c?)	AB (ab)	b or ?
				(maternal)
	B (bb, b?)	Not available	A (aa, a?)	b or ?

Examples of direct, two-haplotype, and indirect exclusions of the tested man. The capital letters represent the phenotype and the small letters in parentheses represent the possible genotype. The question mark (?) represents a possible null, or silent, allele.

*Mutation must be considered.

be done with absolute certainty, genetic marker tests can provide objective evidence of nonparentage. By using multiple genetic systems, it is possible to exclude most (>99%), but not all, nonparents.

In systems that follow the rules of Mendelian genetics, exclusions are identified by finding exceptions to the expected inheritance pattern. Interpretation of test results when paternity is in question usually depends on assuming that the sample defined as maternal is from the child's biological mother. The child's and mother's phenotypes should be compared to determine whether results are consistent with expected inheritance patterns. An allele present in the child but not in the mother is referred to as the *obligatory paternal gene* (OG). If both alleles in the child and mother are identical, then there are alternative (two) possibilities for the paternal gene.

If the tested man does not have the possibility of passing the OG and the marker for the gene is absent in the presumed mother, the exclusion observed is termed *direct exclusion* (Table 71-2). This type of exclusion in one of the classic systems was usually enough to conclude that the tested man is not the biological father of the child in question. In DNA systems, because the rate of mutation is orders of magnitude greater than observed in classic systems, an exclusion at a single locus is not considered enough evidence to establish nonpaternity ([American Association of Blood Banks](#),

Figure 71-6 Cumulative probability of exclusion (each added test; PE = 0.4). The percentage of the population excluded by each additional test becomes smaller and smaller. The overall exclusion probability of the six tests is 95.3%. If a seventh test with PE = 0.5 was performed, only an additional 2.4% of the population would be excluded ($[(1-0.953) \times 0.5 = 0.0235]$).

2009). A direct exclusion also occurs when the child or the tested male is heterozygous (two alleles present) and the two markers are absent in the other person. This type of direct exclusion sometimes is referred to as a *two-haplotype exclusion*. When only the child and one alleged parent are available for testing, if the tested individual or child has two haplotypes, neither of which is in the other, it is possible to establish nonparentage.

Absence of an expected genetic marker in the child when the parent in question appears to be homozygous (one allele present) for the gene is called an *indirect exclusion*. This is sometimes also known as *reverse homozygosity*. One indirect exclusion is not sufficient evidence to conclude that the tested individual is not the parent. Interpretation of reverse homozygosity as an indirect exclusion presumes that the tested subjects both have two identical alleles at the locus. In PCR testing of STRs, this absence of an expected allele may occur if there is a binding site mutation (Harrison, 2004; Leibel, 2003) in one of the tested individuals, or it is possible that a rare null allele (or other undetected allele) or mutation is present in the child as well as the parent in question. The finding of indirect exclusions in at least two independent systems usually is sufficient evidence to reach a conclusion of nonpaternity.

PROBABILITY OF EXCLUSION

Before testing, it is possible to provide an estimate of the average chance that testing will prove nonparentage if the accused is not the parent. This is referred to as the *probability of exclusion*, PE, and is defined as the probability of excluding a random individual from the population given the alleles of the child and the mother; the genetic information of the tested man is not considered. For each genetic system, an average PE can be calculated based on the gene frequencies (p and q) for the alleles in the system. The general equation for a two-allele system was reported by Wiener (Wiener, 1930). When a system has multiple alleles, more complex formulas are required (Walker, 1978). A highly polymorphic system has a greater power of exclusion than a system with only a few alleles or one that has one or two common alleles and many rare alleles.

CUMULATIVE PROBABILITY OF EXCLUSION

The individual probability of exclusion (PE) is calculated for each of the genetic systems (for each locus) analyzed. The overall combined probability of exclusion (CPE), or the probability of excluding a falsely accused man in a given case, can be calculated by using the following formula:

$$CPE = [(1 - PE_1) \times (1 - PE_2) \times (1 - PE_3) \times \dots \times (1 - PE_N)]$$

where PE is the probability of exclusion for each system used. As shown in Figure 71-6, as more and more systems are used, fewer and fewer individuals are excluded by each additional test. With an appropriately selected

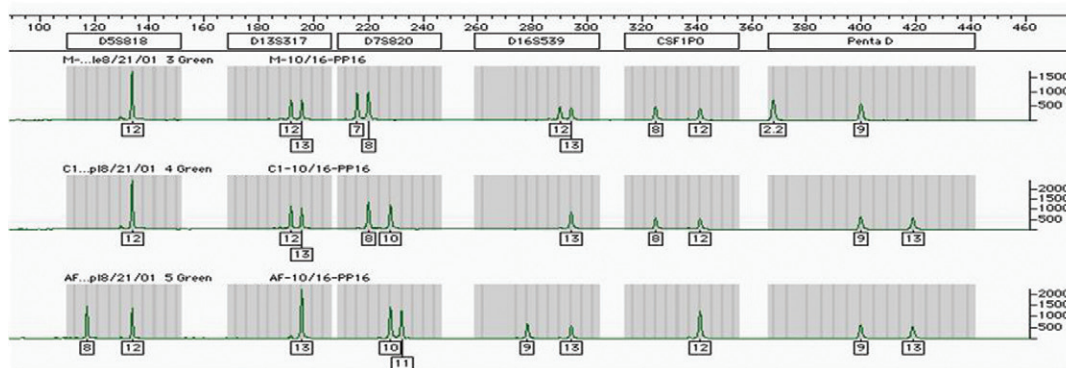

Figure 71-7 Example of family analysis using short tandem repeats testing. Note the alleles shared between the mother (top panel) and the child (middle panel). The alleles from the tested man (bottom panel) also matches the child. The tested man is not excluded as the biological father of this child.

TABLE 71-3

Calculation of the System* Likelihood Ratio (Paternity Index)

Mother	Child	Obligatory gene(s)	Tested man	X	Y	Formula for Y frequency	X/Y
A	A	a	A	1	0.25	p	4
A	A	a	AB	0.5	0.25	p	2
A	AB	b	B	1	0.4	q	2.5
A	AB	b	AB	0.5	0.4	q	1.25
AB	AB	a or b	A	1	0.65	p + q	1.54

battery of DNA marker systems, a CPE of 0.995 or greater is easily achieved.

INCLUSION OF PARENTAGE

If, after testing multiple independent systems, the parent in dispute is not excluded (Fig. 71-7), then an estimate of the possibility that the tested person could be the biological parent should be calculated. If the tested male is not excluded, it always can be argued that the amount of testing was inadequate, that evidence for exclusion will be found by testing another genetic system, or that the true parent is a close relative of the tested man. This line of reasoning could be correct only if the tested male has been falsely accused. In addition to the average probability of exclusion described previously, it also is possible to calculate the frequency with which a random male will not be excluded based on a mother-child pair exhibiting the observed phenotypes (Salmon, 1983). This value is related to the actual probability of exclusion for the tests performed.

In providing estimates of inclusion of paternity, appropriate gene frequency tables are used. In general, this means that a population of random persons of the same race has been phenotyped, that the size of the sample is large enough to provide gene frequencies with minimum errors of estimation for the alleles in the system, and that the tested male and biological father are from the same population. When multiple systems have been tested, the differences observed in gene frequencies in populations from various geographic locations become unimportant in calculations of the likelihood of paternity (Hummel, 1981). When the tested male is of mixed racial background or from a population for which there are inadequate frequency tables, it may be impossible to provide a precise estimate of paternity. However, when multiple systems with a high power of exclusion have been used and the PI value using a reference population is high, there is a minimal chance that frequencies from a more-defined population will

have a significant effect on the conclusion of parentage. In these situations, comparisons with frequencies for several defined racial groups may also be helpful.

PATERNITY INDEX CALCULATION

In cases in which a trio has been tested, a general approach referred to as the *comparison of sperm method* is usually applied (Walker, 1978). This calculation compares the chance (x) that a sperm from a male of the phenotype of the tested male could have fertilized the ovum of the presumed mother to the chance (y) that a sperm from an untested male in the random population could have produced the child. Likelihood ratios (x/y) are calculated for each independent genetic system by comparing the tested male to the frequencies for the obligatory gene or alternate paternal genetic contribution in the random population of the same race of the tested male. These values are then multiplied to derive the PI, which reflects the genetic odds in favor of paternity, given the phenotypes of the trio. Table 71-3 displays the formulas for calculating the indexes with various phenotype combinations. Table 71-4 is an example using these formulas to determine the possible father of a fetus in a possible rape case. In this example, Tested Man 2 is clearly excluded as the biological father of this fetus.

PI values in cases where no exclusion is observed can have a numeric value greater than zero to a number approaching infinity. The current AABB Standards (2009) require that, to determine parentage, the testing should result in a PI of at least 100. This means that the odds (likelihood ratio) for the tested man being the father are 99 to 1.

LIKELIHOOD OF PARENTAGE

Another useful estimate, the likelihood of parentage, combines the genetic testing with assumptions about prior events. Essen-Möller (1938)

TABLE 71-4

Determining Parentage from Fetal Tissue

STR locus	Fetal tissue*	Mother	Tested man 1 (TM 1)	Tested man 2 (TM 2)	Paternity index TM 1	Paternity index TM 2

TABLE 71-5

Formula for the Likelihood of Parentage (W)

Bayes' theorem is used to combine p with PI:

$$W = (p)(PI) / [(p)(PI) + (1 - p)]$$

where p = prior probability of nongenetic events, and PI (paternity index) = summary of testing results.

described this calculation based on Bayes' theorem (Table 71-5). The estimate uses the PI to summarize the genetic information and p (a value for the prior probability) to account for the assumptions that the tested man:

1. Was not sterile
2. Had access during the conceptive period
3. Is not a close (first-degree) relative of the father
4. And that other possible fathers are from a population with similar gene frequencies.

If a p of 0.5 is used, this assigns an equal prior chance to the tested man and one untested man. Using this value, the likelihood of paternity (W) is equal to $PI/(PI + 1)$. Other values for the prior probability can be used in this calculation, but they introduce a bias against the tested man if greater than 0.5, and against the mother if less than 0.5.

The mathematical values obtained from calculation of the PI or likelihood have special significance because in many jurisdictions the reported value may change the legal standing of the parties. For example, the Minnesota Statute Section 257.55 (Parentage Act, 2004) shifts the burden of disproving paternity to the man if the testing indicates a greater than 99% likelihood that he is the father.

ESTIMATING PARENTAGE WITH AN ABSENT PARENT

If one of the parents is unavailable for testing, it is still possible to provide an estimate of parentage. The most common situation is one in which a sample is available from the child and alleged father, but not the mother. In this situation the child must share at least one gene at each locus with the tested man. Formulas (Table 71-6) to estimate the paternity index and likelihood of paternity are similar to those used when a trio is tested (see Table 71-3) except that the estimates must include an adjustment for the frequency of the allele passed by the absent mother (Brenner, 1993). The calculation is more complicated if the missing mother and untested man are of different races (Traver, 1996). If the

TABLE 71-6

Calculation of the System* Likelihood Ratio (Parentage Index) When Only One Parent Is Tested

Child	Tested parent	Parental gene(s) in child	Obligatory gene(s) in other parent	Formula to calculate system ratio

A	BC		a	Exclusion
AB	B	b	a or b	1/2q
AB	AB	a or b	a or b	(p+q)/4pq
AC	AB	a	a or c	1/4p
BC	A		b or c	Exclusion
AD	BD	d	a or d	1/4s

*Hypothetical locus with four alleles A, B, C, and D (frequency of genes a = p, b = q, c = r, and d = s).

tested man or child has two alleles at a locus, neither of which is present in the other tested individual, then the tested man is excluded. If reverse homozygosity is present in the child and tested man, this also suggests nonpaternity.

RECONSTRUCTION OF FAMILIES

Many situations occur in which it is important to establish a relationship between individuals. This happens when individuals are trying to gain status as an immigrant or discover whether they share a parent, or when there is a question related to inheritance. DNA testing can be informative in identifying parents of fetal material found in a dumpster or products of conception in rape cases. Reconstruction is also very important when trying to identify bodies or body parts following a mass disaster. Because only a parent and child will share at least one allele at each locus, relatives may have systems in which they do not share any alleles. Formulas taking into account that alleles may be shared by descent are used to estimate the closeness of the relationship of two individuals (Wenk, 1986). Full siblings have a 0.25 chance of not sharing an allele in a system, whereas half sibs, aunts, or uncles have a 0.5 chance. In cases where the alleged father is deceased, his probable phenotype can be reconstructed if testing is performed with his biological parents (Mayr, 1983). The child and putative grandparents must share the obligatory paternal alleles in all systems. A PI can be calculated using a frequency for x that takes into account the chance that the deceased could pass the allele (Fig. 71-8). Reconstructions

System	Child	Mother	OG	?GF	?GM*	Possible phenotypes of ?AF	Formula to calculate system index
CSF1PO	10,12	9,12	10	10,13	10,11	10;10,11; 10,13; 11,13	$0.5/p$
D3S1358	14,15	14,17	15	15,16	16,17	15,16; 15,17; 16,17;16	$0.25/p$
D7S820	10,11	10,11	10 or 11	8,9	11	8,11; 9,11	$0.5/p+q$
D16S539	9,12	9,13	12	10,12	12	10,12;12	$0.75/p$
TPOX	8	8, 11	8	8	8	8	$1/p$
vWA31/A	18	18	18	18	18	18	$1/p$

Figure 71-8 Family testing to establish paternity. Interpretation assumes that the deceased ?AF is the child of the persons tested (?GF, ?GM) and p and q are the frequencies of the obligatory paternal allele(s). In this case the presumed parents of the deceased alleged father were tested to reconstruct his probable phenotype. In each of the systems tested, the obligatory paternal gene (OG) is present in one of the child's presumed grandparents. Note: For D7S820, either allele in the child could be maternal. The combined paternity index and likelihood of paternity are obtained by multiplying the values for the individual systems.

System	AF1	AF2	Child 1	Child 2	Child 3	Child 4
CSF1PO	10, 11	11, 12	10, 14	12, 14	9 , 12	11, 14

DYS391	10	11		11	11	

Figure 71-9 Family study—presumed mother (M) is deceased. All four children in this family study could have the same mother. The probable maternal allele in each system is shown in bold. Note: In some systems either marker could be maternal in one of the children (D3S1358 in child 1). Alleged father 1 (AF1) shares an allele with child 1 in all systems and is excluded as the possible father of children 2, 3, and 4 in several systems. AF2 is excluded as the father of child 1 in every system except D3S1358 and TPOX. AF2 is also excluded as the father of child 3 in two systems (D3S1358 and TH01). The finding of a possible match in nine of 11 systems, including two Y-STRs, suggests that the true father of child 3 might be a relative of AF2, or two mutations have occurred.

can also be conducted by using data from multiple presumed relatives as shown in Figure 71-9.

SOFTWARE SYSTEMS

New software systems have been introduced in both the forensic and parentage laboratories. These software systems include expert systems programs that display rule firings, or flags, when specific laboratory-defined thresholds have not been met. Currently, expert systems are used by laboratories for the review of single source reference standard samples. In addition, forensic laboratories are evaluating mixture deconvolution software tools to assist the forensic analyst in the review of mixed data as is often observed with sexual assault evidence. Identity testing laboratories worldwide have implemented sophisticated software programs to perform kinship analyses. Laboratory Information Systems, LIMS, are also used to assist a laboratory in managing its casework.

QUALITY ASSURANCE STANDARDS

Laboratories that perform forensic (parentage and criminalistic) DNA testing must follow appropriate standards, obtain accreditation, and participate in proficiency testing programs. The possibility of significant judicial scrutiny of every step of the procedures and practices used from collection of samples to reporting of results is to be expected. Challenges

to the validation of the methods, the source of the databases used in statistical reports, and the qualification of the personnel are not uncommon. There is general agreement as to proper laboratory procedures that should be used in DNA testing and, although the DNA typing methods are not specifically standardized, procedures are remarkably uniform.

The FBI's Technical Working Group on DNA Analysis Methods, now known as the Scientific Working Group on DNA Analysis Methods, promulgated early guidelines for DNA analytic procedures that became de facto standards (Technical Working Group, 1989, 1995). These standards were modified by the FBI's DNA Advisory Board and adopted by the FBI Director pursuant to the DNA Identification Act, a component of the Crime Bill passed in 1994. These standards apply to crime laboratories that submit DNA results to the FBI's National DNA Index System or that accept certain federal grants. The American Society of Crime Laboratory Directors has an accreditation program for crime laboratories. The American Board of Criminalists certifies criminalists and has a subspecialty category for DNA analysts. Analysts who work on casework samples must have college credit (or equivalent) in genetics, biochemistry, and molecular biology and 1 year of forensic biology experience. Each of these standards calls for proficiency testing by each analyst twice a year.

The AABB began developing standards and accrediting parentage testing laboratories in 1984. The 9th edition, renamed *Standards for Relationship Testing Laboratories*, was published in 2009 (American Association of Blood Banks, 2009). All aspects of parentage testing from laboratory organization to process control and improvement are covered. The Standards include requirements for documents and records, report content, and interpretation of results. Laboratories are required to participate in graded proficiency testing.

CONCLUSION

Scientific evidence that will aid in resolving cases of disputed parentage, questions of relatedness, and identity can be obtained from testing multiple DNA systems. Current technology provides test results that exclude more than 99.9% of falsely accused individuals in parentage and criminal cases. It is not possible to prove paternity or guilt by laboratory tests. The

mathematical estimates derived from genetic marker tests when no exclusion is found or there is a match between sample and suspect are a significant source of data that can be used to establish parentage or guilt.

KEY POINTS

- High throughput array technologies such as genomics and proteomics have provided unprecedented ability to personalize output of biomarkers implicated in select disease states.
- Pharmacogenomics, through utilization of novel technologies, can detect unique polymorphisms to serve as diagnostic and/or prognostic biomarkers, which relate to an individual or group response to particular therapies.
- Elucidation of unique or personal responses can tailor therapy to the individual, thereby maximizing drug choice, dose, and effect.
- Interpretation of pharmacogenomic responses can be discretionary in that many genotypic and phenotypic variables are often involved

OVERVIEW

Pharmacogenomics refers to the reciprocal effect of how drug responses relate to the human genome. As such, these responses can encompass genetic (transcription, translation, polymorphisms) and epigenetic (environmental) components with respect to a drug's efficacy and toxicity. The new era of personalized medicine, which integrates the uniqueness of an individual with respect to drug pharmacokinetics, pharmacodynamics, and clinical effects, and downplays the "one drug fits all" convention, holds promise as a means to provide greater safety and efficacy in drug design and development. This approach is a result of application of biotechnology, high throughput multiplex analysis (microarray, proteomics), and bioinformatics and highlights interindividual and interethnic variabilities, including genetic polymorphisms, to ensure that the proper drug class or derivative is administered at the optimally effective dose to the appropriate individual. This chapter highlights select areas of pharmacogenomics and the emerging concepts of personalized medicine in maturing disciplines and sensitizes the pathologist and laboratorian to its emerging and potential effects with respect to diagnosis and prognosis in human disease, as well as its limitations in interpretation and application in the clinical marketplace.

BASIC CONCEPTS

The concept of a relationship between a substance and its effect on genes, rudimentary pharmacogenetics, has been present since the early 1900s. Dr. Archibald Garrod described that genetic variations could cause adverse biological reactions when chemical substances were ingested (Garrod, 1902). Garrod's work on alcaptonuria constituted the first proof of Mendelian genetics in humans. As a result of these studies, he advanced the hypothesis that genetically determined differences in biochemical processes could affect outcome after drug administration (Mancinelli, 2000). The idea of pharmacogenomics, also referred to as *toxogenomics*, is considered to have matured from pharmacogenetics, a discipline comprising genetics, pharmacology, and biochemistry, as a fusion of pharmacogenetics and genomics. Whereas pharmacogenetics classically investigates the hereditary impacts upon the action of drugs, pharmacogenomics extends pharmacogenetics to include the multifactorial drug responses caused by many genetic alterations plus environmental factors (Kalow, 2008). The recognition of these complex interactions and the advance of genetics into genomics via high throughput analysis of gene interrogation algorithms have given rise to the application of this science as a means of personalizing drug effects to a group or individual. Each drug after it enters the body interacts with numerous proteins, such as carrier proteins, transporters, metabolizing enzymes, and multiple types of receptors. These protein interactions determine drug absorption, distribution, excretion, target site of action, and pharmacologic response. Moreover, drugs trigger downstream secondary events that may impact additional gene or protein expression responses; these can also vary among patients. As a result, multiple polymorphisms in many genes may affect drug response, requiring a genome-wide search for the responsible genes. The term "personalized medicine" has been coined toward the promise of making therapy more effective and safer by giving drugs that fit a person's genes. However, because gene function and expression are variable and contingent on the response of drugs on genes as much as they are to the response of genes on drugs, gene structure and protein-gene interaction, the interrogation of these responses to yield useful and functional biomarkers adapted as well. The topics that follow provide examples of the adaptations of pharmacogenomics and personalized medicine in select disease states and their current applications in the clinical laboratory toward patient care.

The events following a drug administration can be divided into two phases, a pharmacokinetic phase and a pharmacodynamic phase. The pharmacokinetic phase relates a dosage regimen to the drug concentration achieved with time; pharmacokinetics concerns the drug absorption, distribution, metabolism, and excretion (ADME). The pharmacodynamic phase relates the drug concentration to the magnitude of the desired or adverse effects produced with time; pharmacodynamics concerns drug target interaction, downstream signaling events, and pharmacologic response. Interindividual variability in both pharmacokinetics and pharmacodynamics contributes to the variability in drug response. Genetic variations in the genes involved in ADME (e.g., drug-metabolizing enzymes and transporters) can alter the pharmacokinetics of a drug, whereas those involved in drug target interactions (e.g., target receptors and enzymes) can modify the pharmacodynamics of a drug. The interactions between the pharmacokinetics, pharmacodynamics, and pharmacogenetics are depicted in Figure 72-1. Typically, the overall response to a drug is determined by the interplay of multiple genes that are involved in the pharmacokinetic and pharmacodynamic pathways of a drug. In general, important pharmacogenetic variation can be envisioned at the level of drug-metabolizing enzymes, drug transporters, and drug targets.

DRUG-METABOLIZING ENZYME PHARMACOGENOMICS

Drug-metabolizing enzymes are proteins that catalyze the biochemical modifications of xenobiotics (e.g., drugs) and endogenous chemicals (e.g., hormones, neurotransmitters). Drug metabolism can result in the activation (toxication) or deactivation (detoxication) of the chemical. Even though both occur, the majority of metabolites of most drugs are deactivation products. Broadly, drug-metabolizing enzymes are divided into two categories: phase I (functionalizing) enzymes that introduce or remove functional groups in a substrate through oxidation, reduction, or hydrolysis, and phase II (conjugating) enzymes that transfer moieties from a cofactor to a substrate. Essentially all of the major human metabolizing enzymes exhibit genetic polymorphisms at the genomic level, and many of these enzymes have clinically relevant genetic polymorphisms (Fig. 72-2). A gene is considered to be polymorphic when the frequency of a variant allele in a specific population is at least 1%.

PHASE I ENZYMES

Phase I metabolizing enzymes include those involved in oxidation (e.g., cytochrome P450 [CYP], alcohol dehydrogenase, aldehyde dehydrogenase,

dihydropyrimidine dehydrogenase, monoamine oxidase, and flavin-containing monooxygenase); reduction (e.g., nicotinamide adenine dinucleotide phosphate [NADPH]-cytochrome P450 reductase and reduced cytochrome P450); hydrolysis (e.g., epoxide hydrolase, esterases, and amidases).

The most important phase I enzymes that exhibit clinically relevant genetic polymorphisms are in the CYP superfamily, which represents the most important system responsible for catalyzing the oxidation of a large number of endogenous and exogenous compounds including drugs, toxins, and carcinogens. In this superfamily, 57 genes and 58 pseudogenes have been identified, which are divided into 18 families and 43 subfamilies (<http://ghr.nlm.nih.gov/geneFamily/cyp>). Among them, three subfamilies of CYPs—CYP1, CYP2, and CYP3—are the main ones contributing to the oxidative metabolism of more than 90% of clinically used drug.

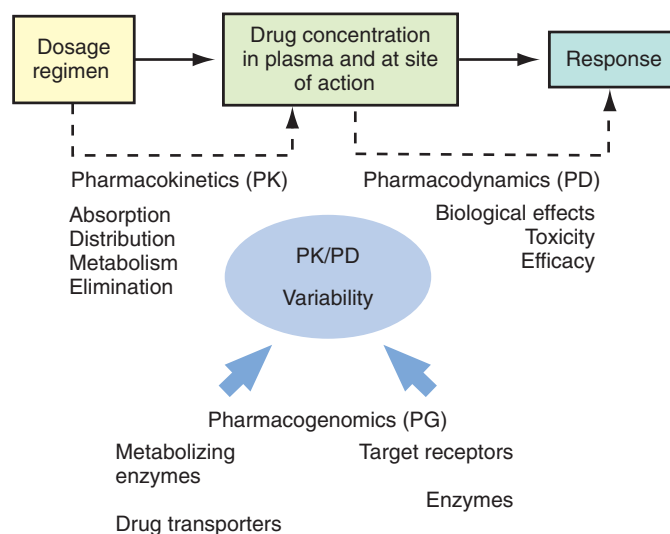

Figure 72-1 Schematic illustration of interactions between pharmacokinetics (PK), pharmacodynamics (PD), and pharmacogenomics. The PK relates a dosage regimen to drug concentration-time course in the body, and the PD relates the drug concentration to the magnitude of the desired or adverse effects produced. Genetic variations in the genes involved in drug disposition (e.g., drug-metabolizing enzyme and transporter genes) and drug action (e.g., target receptors and enzymes) contribute to the interindividual PK/PD variability.

Figure 72-2 Phase I and II drug-metabolizing enzymes that exhibit common genetic polymorphisms. The percentage of phase I and phase II metabolism of drugs that each enzyme contributes is estimated by the relative size of each section of the corresponding chart; those enzyme polymorphisms that have already been associated with changes in drug effects are separated from the corresponding pie charts. (Adapted from Evans WE, Relling MV. *Pharmacogenomics: translating functional genomics into rational therapeutics*. *Science* 1999;286[5439]:487–91.) ADH, Alcohol dehydrogenase; ALDH, aldehyde dehydrogenase; CYP, cytochrome P450; DPD, dihydropyrimidine dehydrogenase; NQO1, NADPH, quinone oxidoreductase or DT diaphorase; COMT, catechol O-methyltransferase; GST, glutathione S-transferase; HMT, histamine methyltransferase; NAT, N-acetyltransferase; STs, sulfotransferases; TPMT, thiopurine methyltransferase; UGTs, uridine 5'-triphosphate glucuronosyltransferases.

The human CYP genes are highly polymorphic. The polymorphisms within the CYP genes, which include gene deletions, missense mutations, deleterious mutations creating splicing defects or premature stop codon, and gene duplications, can result in abolished, reduced, normal, or enhanced enzyme activity. Based on the level of CYP enzyme activity, patients can be classified into four phenotypes: poor metabolizer (abolished activity), intermediate metabolizer (reduced activity), extensive metabolizer (normal activity), and ultrarapid metabolizer (enhanced activity). Poor metabolizers would have higher concentrations of a drug that is inactivated by that enzyme pathway and therefore would require a lower dose to avoid adverse reactions, whereas ultrarapid metabolizers would require a higher dose to achieve therapeutic effective drug concentrations. The opposite pattern of reactions would occur in response to a prodrug that undergoes metabolic activation. A prodrug may have little therapeutic effect in poor metabolizers but would produce a toxic level of active form in ultrarapid metabolizers. Indeed, a growing body of evidence suggests that genetic polymorphisms within the CYP genes have significant impact on drug disposition and/or response. The common functional polymorphisms in the major human CYP genes and their clinical relevance are summarized in Table 72-1. Comprehensive reviews on the pharmacogenetics/genomics of CYPs have been published (Ingelman-Sundberg, 2004; Andersson, 2005; van Schaik, 2005; Rodriguez-Antona, 2006; Zhou, 2009). Notably, the most pharmacologically and clinically relevant polymorphisms are found in *CYP2D6*, *CYP2C9*, and *CYP2C19*. Of the U.S. Food and Drug Administration (FDA)-approved drug labels referring to human genomic biomarkers, 62% pertain to polymorphisms in the CYP enzymes, with *CYP2D6* (35%), *CYP2C19* (17%), and *CYP2C9* (7%) being the most common (Frueh, 2008). For review, see Li and Bluth, 2011.

Unlike other CYPs, *CYP2D6* is not inducible; therefore the variations in enzyme expression and activity are largely attributable to the genetic polymorphisms. The *CYP2D6* gene is highly polymorphic with more than 63 functional variants identified to date (<http://www.cypalleles.ki.se>). These alleles result in abolished, decreased, normal, or ultrarapid *CYP2D6* enzyme activity. The most important null alleles are *CYP2D6*4* (splicing defect) and *CYP2D6*5* (gene deletion); the common alleles with severely reduced enzyme activity are represented by *CYP2D6*10*, **17*, and **41*; ultrarapid enzyme activity is derived from duplication or multiduplications of active *CYP2D6* genes (e.g., *CYP2D6*1xN* [*N*≥2]) (see Table 72-1). The distributions of *CYP2D6* alleles exhibit notable interethnic differences. The nonfunctional allele *CYP2D6*4* is prevalent in Caucasians (allelic frequency, ~25%), while the reduced function allele *CYP2D6*10* is common in Asians (allelic frequency, ~40%) and *CYP2D6*17* is common in Africans (allelic frequency, ~34%) (Bradford, 2002). As a result, poor metabolizers of *CYP2D6*, mainly derived from null allele *CYP2D6*4*, have a high frequency in Caucasians (5%–14%) compared with Africans (0%–5%) and Asians (0%–1%). In contrast, ultrarapid metabolizers of *CYP2D6*, derived from gene duplication or multiduplications, have a high frequency in Saudi Arabians (20%) and black Ethiopians (29%) compared with Caucasians (1%–10%) (Bradford, 2002). The interethnic difference in the *CYP2D6* genotypes may contribute to the interethnic variations in the disposition and response of substrate drugs. *CYP2D6* is involved in the metabolism of ~25% of all drugs in clinical use, although it accounts for ~2% of total hepatic CYP contents. *CYP2D6* genotype is of great importance for the pharmacokinetics and response of many drugs, including tricyclic antidepressants, antiarrhythmics, neuroleptics, analgesics, antiemetics, and anticancer drugs (for review, see Zhou, 2009).

The human *CYP2C9* and *CYP2C19* genes are highly homologous at the nucleotide level. The most common nonsynonymous *CYP2C9* polymorphisms, *CYP2C9*2* and *CYP2C9*3*, result in the enzyme with differing affinity or intrinsic clearance for different substrates. Whereas *CYP2C9*2* effects appear to be more substrate specific, *CYP2C9*3* variant exhibits reduced catalytic activity toward the majority of *CYP2C9* substrates. The clinical importance of *CYP2C9* polymorphisms is exemplified by the *CYP2C9* genotype-guided dosing of an oral anticoagulant warfarin. The patients carrying either *CYP2C9*2* or *CYP2C9*3* require significantly smaller daily dose of warfarin to maintain desired therapeutic effects while avoiding severe toxicity, compared with patients carrying the wild-type *CYP2C9* (Higashi, 2002). With regard to *CYP2C19*, a splice site mutation in exon 4 (*CYP2C19*2*) and a premature stop codon in exon 4 (*CYP2C19*3*) represent the two most predominant null alleles. It is estimated that by genotyping for *CYP2C19*2* and **3*, ~84%, ~100%, and >90% of poor *CYP2C19* metabolizers could be detected in Caucasians, Asians, and Africans, respectively. The poor metabolizer phenotype of *CYP2C19* occurs in

12%–23% of Asian population, in 1%–6% of Caucasians, and in 1%–7.5% of black Africans. Polymorphisms in *CYP2C19* are known to affect the pharmacokinetics and/or response of several classes of drugs, including proton pump inhibitors (e.g., omeprazole) and barbiturates (for review, see Zhou, 2009).

PHASE II ENZYMES

The most important phase II enzymes that exhibit functional and clinical relevant genetic polymorphisms are uridine diphosphate glucuronosyltransferase (UGT), sulfotransferase (SULT), glutathione S-transferases (GST), N-acetyltransferase (NAT), and thiopurine methyltransferase (TPMT) (see Fig. 72-2). Table 72-2 summarizes the most common functional polymorphisms in these phase II enzymes and highlights their clinical significance.

Uridine Diphosphate Glucuronosyltransferases

The human UGT superfamily is a group of conjugating enzymes that catalyze the transfer of the glucuronic acid group of uridine diphosphate-glucuronic acid to the functional group (e.g., hydroxyl, carboxyl, amino, sulfur) of a specific substrate (Guillemette, 2003). UGTs are membrane-bound enzymes localized in the endoplasmic reticulum of liver and many other extrahepatic tissues. Seventeen human UGT genes have been identified and are classified into two subfamilies (UGT1 and UGT2). Glucuronidation increases the polarity of the substrates and facilitates their excretion in bile or urine. Genetic polymorphisms have been identified for almost all the UGT family members. Genetic variations in the UGT genes could alter the function or expression of the protein, and potentially modify the glucuronidation capacity of the enzyme toward a given drug, carcinogen, or endogenous compounds. There is evidence that genetic variations in the UGT genes contribute to differential susceptibility to diseases (e.g., cancer) and influence the pharmacokinetics and clinical outcome of substrate drugs (for reviews, see Guillemette, 2003; Nagar, 2006). A representative example is that the *UGT1A1* low promoter activity alleles (i.e., *UGT1A1*28*) is associated with decreased glucuronidation of SN-38 (an active metabolite of irinotecan), thereby resulting in increased risk for irinotecan-induced toxicity. The pharmacogenetics of irinotecan is discussed in details later. The most common functional polymorphisms in the major UGT enzymes and their clinical relevance are highlighted in Table 72-2 (for comprehensive reviews, see Guillemette, 2003; Nagar, 2006).

Sulfotransferases

Cytosolic SULTs are phase II enzymes that catalyze the transfer of the sulfonyl group from the cofactor 3'-phosphoadenosine 5'-phosphosulfate to the nucleophilic sites of a variety of substrates including hormones and xenobiotics. Sulfo conjugation of xenobiotics leads to formation of polar, excretable products as well as reactive, potentially mutagenic and carcinogenic metabolites (Glatt, 2004). Eleven SULT proteins encoded by 10 genes have been identified in humans. They differ in substrate specificity and tissue distribution. Single nucleotide polymorphisms (SNPs) have been identified in most of the human SULT genes. Functional SNPs in SULTs that are associated with altered enzymatic activity have potential to influence therapeutic response and to modify cancer susceptibility (see reviews in Glatt, 2004; Nowell, 2006). One widely studied functional SNP is *SULT1A1*2* (Arg213His) that exhibits reduced enzymatic activity and thermal stability (see Table 72-2).

Glutathione S-Transferases

The superfamily of human GST catalyzes the conjugation of glutathione (GSH) to a wide range of endogenous metabolites and xenobiotics including alkylating and free radical-generating anticancer drugs (Lo, 2007). Human GSTs are categorized into three main families, cytosolic/nuclear, mitochondrial, and microsomal. The cytosolic GSTs are further divided into seven classes: alpha, mu, omega, pi, sigma, theta, and zeta. Besides their enzymatic function, GSTs also possess nonenzymatic functions, in which they act as regulators of cell signaling and posttranslational modification pathway in response to stress, growth factors, and deoxyribonucleic acid (DNA) damage, and in cell proliferation, cell death, and other processes that ultimately lead to tumor growth and drug resistance. These multiple functionalities establish the importance of GSTs as determinants of cancer susceptibility, therapeutic response, and prognosis (see reviews in McIlwain, 2006; Lo, 2007). Most human GSTs have SNPs and, less frequently, deletions. Increasing evidence has indicated linkage of GST

Most Common Naturally Occurring Functional Polymorphisms in the Major Human Cytochrome P450 Genes: Allele Frequency, Functional Effect, and Highlights of Clinical Relevance

Common allelic variants	Polymorphism/substitution	ALLELE FREQUENCY (%) ^a			Functional effect ^b	Highlights of clinical relevance ^c
		Ca	As	Af		
CYP1A1						Mainly expressed in extrahepatic tissues.
CYP1A1*2A	3698T>C(MspI)	6.6–19	33–54	22–28	↑Inducibility	CYP1A1, 1A2, and 1B1 play important role in the bioactivation of a variety of carcinogens.
CYP1A1*2B	I462V; 3698T>C(MspI)	–	–	–	↑Inducibility	↑Lung cancer risk generally associated with highly inducible or active CYP1A1 polymorphisms such as CYP1A1*2C.
CYP1A1*2C	I462V	2.2–8.9	28–31	0–2.7	↑Activity	
CYP1A1*3	3204T>C	0	0	7.6–14	Normal	CYP1A1 genotypes also associated with risk to breast, prostate, and ovarian cancers that are possibly related to estrogen activation.
CYP1A1*4	T461N	2.0–5.7	–	–	Normal	
CYP1A2						CYP1A2 accounts for ~13% of total hepatic CYP content.
CYP1A2*1C	-3860G>A				↓Inducibility	High inducible *1F genotype associated with ↑clearance of CYP1A2 substrates (e.g., caffeine) after smoking or omeprazole treatment.
CYP1A2*1F	-163C>A	33	68		↑Inducibility	*1K associated with ↓in vivo caffeine metabolism.
CYP1A2*1K	Haplotype (-63C>A, -739T>G, -729C>T)	0.5			↓Inducibility	CYP1A2 genotypes are associated with cancer risk.
CYP2A6					↓Activity	
CYP2A6*1X2	Gene duplication	1.7		0.4	↑Activity	CYP2A6 accounts for 1%–10% of total hepatic CYPs.
CYP2A6*2	L160H	1–3		<1	↓Activity	The frequency of CYP2A6 alleles has marked ethnic difference. CYP2A6*4 accounts for the majority of PMs in Asians.
CYP2A6*4	Gene deletion	0.5–1	7–22	15–20	Abolished activity	Because nicotine is converted to cotinine by CYP2A6, a high expression/activity of CYP2A6 is proposed to increase the susceptibility to nicotine addiction and the risk of tobacco-related cancers. Therefore CYP2A6 genetic variation could play a role in nicotine addiction and tobacco-related cancer risks.
CYP2B6						CYP2B6 is mainly expressed in the liver, accounting for 6% of total CYPs.
CYP2B6*4	K262R	5			↑Activity	The anticancer drugs cyclophosphamide (CPA) is bioactivated by CYP2B6. CYP2B6 polymorphisms would likely affect the PK and/or PD of CPA. For example, CYP2B6*6 carriers exhibited ↑CPA clearance and CPA 4-hydroxylation activity.
CYP2B6*5	R487C	11–14	1		↓Expression	
CYP2B6*6	Q172H; K262R	16–26	16		↑Activity	CYP2B6 polymorphisms may affect the PK and therapeutic outcome of anti-HIV agents such as efavirenz and nevirapine. For example, CYP2B6 Q172H variant is associated with ↑plasma concentrations of efavirenz and nevirapine.
CYP2B6*7	Q172H; K262R; R487C	13	0		↑Activity	CYP2C8 accounts for ~7% of total hepatic CYP contents.
CYP2C8						CYP2C8*3 is associated with ↓clearance of both R- and S-ibuprofen.
CYP2C8*2	I269F	0.4		18	↓Activity	
CYP2C8*3	R139K; K399R	13	0	2	↓Activity	
CYP2C8*4	I264M	7.5			↓Activity	
CYP2C9						CYP2C9 accounts for ~20% of total hepatic CYP contents.
CYP2C9*2	R144C	13–22	0	3	↓Activity	CYP2C9*2 and *3 have been shown to affect the oral clearance of at least 17 different CYP2C9 substrate drugs (e.g., S-warfarin, celecoxib, ibuprofen, and phenytoin).
CYP2C9*3	I359L	3–16	3	1.3	↓Activity	
CYP2C9*5	D360E	0	2	0	↓Activity	

TABLE 72-2

Most Common Naturally Occurring Functional Polymorphisms in Major Human Phase II Drug-Metabolizing Enzymes: Allele Frequency, Functional Effect, and Highlights of Clinical Relevance

Allelic variants	Polymorphism/ substitution	ALLELE FREQUENCY (%)			Functional effect	Highlights of clinical relevance
		Ca	As	Af		
UGT1A1 ^a						
UGT1A1*6	G71R	0	13–23	–	↓Activity	UGT1A1 low promoter activity alleles (e.g., UGT1A1*28) is significantly associated with ↓glucuronidation of SN-38 (the active metabolite of irinotecan), thereby resulting in ↑risk for irinotecan-induced toxicity.
UGT1A1*28	(TA)6>(TA)7 in promoter	2–9.40	13–16	36–43	↓Expression	
UGT1A1*33	(TA)6>(TA)5 in promoter	0–0.7	0	3–8	↑Expression	Genetic variations in UGT1A1 may modify susceptibility to steroid-related cancers including breast, ovarian, endometrial and prostate cancers.
UGT1A1*34	(TA)6>(TA)8 in promoter	0–0.7	0	0.9–7	↓Expression	
UGT1A6 ^a						UGT1A6 catalyses the glucuronidation of aspirin and acetaminophen.
UGT1A6*2	T181A, R184S	30	23		↓Activity	“Low activity” UGT1A6 variants, leading to increased salicylate levels in aspirin users, are associated with a lower risk of colon cancer.
UGT1A6*3	R184S	1–2	1.6		Unknown	
UGT1A6*4	T181A	2.4			Unknown	
UGT1A7 ^b						
UGT1A7*2	N129K, R131K	24–34	15	39	Similar activity	UGT1A7 is an important extrahepatic UGT that inactivates a variety of carcinogens.
UGT1A7*3	N129K, R131K, W208R	23–36	26	23	↓Activity	Low-activity UGT1A7 variants increases the risk of developing tobacco-related cancers, specifically orolaryngeal cancer.
UGT1A7*4	W208R	1–1.7	0	1	↓Activity	
UGT2B7 ^a						
UGT2B7*2	H268Y	49–54	27		Similar or decreased activity	UGT2B7 is of major significance for the glucuronidation of a number of clinically important drugs (e.g., morphinan derivatives, epiribicin, and zidovudine). Further studies are needed to elucidate the clinical impact of the UGT2B7 polymorphism.
UGT2B15 ^a						UGT2B15 is the most efficient UGT2B involved in the inactivation of steroid hormones, mainly androgens.
UGT2B15*2	D85Y	52–55	36–49	39	↑Activity	UGT2B15 polymorphisms have a potential role in a modified risk of prostate cancer.
SULT1A1 ^b						SULT1A1 is the most highly expressed hepatic SULT.
SULT1A1*2	R213H	25–36	4.5–17	27–29	↓Activity and ↓thermal stability	SULT1A1 plays an important role in the sulfation of the metabolites of tamoxifen, 4-hydroxy-tamoxifen and endoxifen. SULT1A1*2 is associated with decreased survival of breast cancer patients treated with tamoxifen.
SULT1A1*3	M223V	1.2	0.6	23	Similar activity	
GST ^c						
GSTA1*B	Promoter point mutation (T-631G, T-567G, C-69T, G-52A)	40		41	↓Expression	GSTA1 is involved in glutathione conjugation of the active metabolites of cyclophosphamide (CPA). GSTA1*B allele is associated with higher survival rate of breast cancer patients treated with CPA-containing chemotherapy.
GSTM1*0	Gene deletion	42–58		27–41	Abolished activity	The GSTM null genotype is associated with an increased risk of the lung, colon, and bladder cancer.
						AML patients carrying GSTM*0 appears to have a better response to Adriamycin and cyclophosphamide treatment.

GSTP1*B	I105V	6–40	54	↓Activity	The GSTP1*B allele is associated with lower clearance of etoposide and reduced risk of relapse in childhood ALL patients.
GSTT1*0	Gene deletion	2–42		Abolished activity	The GSTP1*B allele is associated with increased survival rate in patients with advance colorectal cancer or breast cancer.
NAT ^d					The GSTT1 deletion is associated with reduced risk of relapse in childhood ALL patients.
NAT1*4	Wild-type			Normal	The GSTT1 deletion is a poor prognostic factor for survival in adult ALL.
NAT1*14	R187Q			↓Activity	NAT1*14 and *17 are associated with slow acetylator phenotype.
NAT1*14	R187Stop	1.3–3.7		↓Activity	NAT2*5, *6, *7, *10, *14, and *19 lead to slow acetylator phenotype.
NAT1*17	R64W			↓Activity	NAT2 slow acetylator phenotype is associated with increased susceptibility to hydralazine- and isoniazid-induced toxicity.
NAT1*19	R33Stop			↓Activity	NAT2 slow acetylator phenotype is associated with increased risk of bladder cancer.
NAT1*22	D251V			↓Activity	
NAT2*4	Wild-type			Normal	
NAT2*5	I114T			↓Activity	
NAT2*6	R197Q			↓Activity	
NAT2*7	G286E			↓Activity	
NAT2*10	E167K			↓Activity	
NAT2*14	R64Q			↓Activity	
NAT2*17	Q145P			↓Activity	
NAT2*19	R64W			↓Activity	
TPMT ^e					TPMT is involved in the methylation reaction of mercaptopurine, an anticancer drug used in the treatment of childhood ALL.
TPMT*2	A80P	0–0.5	0	↓Activity	The TPMT genotype correlated well with in vivo enzyme activity and is clearly associated with a risk of mercaptopurine-induced toxicity. Patients with poor or intermediate TPMT activity may tolerate only one-tenth to half of the average mercaptopurine dose.
TPMT*3A	A154Y, Y240C	0–0.6	0–1	Abolished activity	
TPMT*3B	Y240C	–	0	9-fold ↓Activity	
TPMT*3C	A154Y	0.2–3.3	0–0.2	1.4-fold ↓Activity	

Af, African; ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; As, Asian; Ca, Caucasian; GST, glutathione S-transferase; NAT, N-acetyltransferase; SULT, sulfotransferase; TPMT, thiopurine methyltransferase; UGT, uridine diphosphate glucuronosyltransferase; ↑ indicates increased; ↓ indicates decreased.

^aData on UGT SNP allele frequencies, function effect, and clinical relevance are summarized from Guillemette, 2003; Nagar, 2006.

^bData on SULT1A1 SNP allele frequencies, function effect, and clinical relevance are summarized from Glatt, 2004; Nowell, 2006.

^cData on GST SNP allele frequencies, function effect, and clinical relevance are summarized from McIlwain, 2006; Lo, 2007.

^dData on NAT SNP allele frequencies, function effect, and clinical relevance are summarized from Hein, 2002; Agundez, 2008; Sim, 2008.

^eData on TPMT SNP allele frequencies, function effect, and clinical relevance are summarized from Hamdy, 2003; Zhou, 2006.

TABLE 72-3

Pharmacologically Most Important Efflux and Uptake Drug Transporters, Tissue Distribution, and Representative Substrate Drugs*

Gene	Protein	Tissue distribution	Polarity	Representative drug substrates
ABC Transporters				
ABCB1	MDR1 (P-gp)	Liver, intestine, kidney, blood-brain barrier, lymphocytes, placenta	AP	Anthracyclines, taxanes, vinca alkaloids, imatinib, etoposide, levofloxacin, erythromycin, cyclosporine, tacrolimus, digoxin, quinidine, verapamil, diltiazem, ritonavir, saquinavir, talinolol, phenytoin, cimetidine, simvastatin, morphine, hydrocortisone
ABCC1	MRP1 (GS-X)	Ubiquitous	BL	Anthracyclines, vinca alkaloids, irinotecan, SN-38, methotrexate, camptothecins, saquinavir, ritonavir, difloxacin, drug-glucuronate/-glutathione/-sulfate conjugates
ABCC2	MRP2 (cMOAT)	Liver, kidney, intestine	AP	Anthracyclines, vinca alkaloids, methotrexate, camptothecins, rifampin, pravastatin, and drug-glucuronate/-glutathione/-sulfate conjugates
ABCG2	BCRP	Liver, intestine, placenta, breast	AP	Anthracyclines, irinotecan, SN38, SN38G, imatinib, tamoxifen
SLC Transporters				
OATP Family				
SLC21A3	OATP1A2 (OATP-A)	Ubiquitous, with highest expression in brain and testis	BL	Rosuvastatin, methotrexate, ouabain, D-penicillamine
SLC21A6	OATP1B1 (OATP-C)	Liver	BL	Statin, pravastatin, fexofenadine, and repaglinide, rosuvastatin, ouabain, D-penicillamine, rifampin
SLC21A8	OATP1B3 (OATP8)	Liver	BL	Digoxin, rifampin, ouabain, methotrexate, D-penicillamine, rosuvastatin, cyclosporin
SLC21A9	OATP2B1 (OATP-B)	Ubiquitous	BL	Benzylpenicillin, rosuvastatin
OCT Family				
SLC22A1	OCT1	Liver	BL	Metformin, cisplatin, oxaliplatin, imatinib, procainamide, citalopram, cimetidine, quinidine, verapamil, acyclovir
SLC22A2	OCT2	Kidney	BL	Metformin, cisplatin, oxaliplatin, imatinib, procainamide, citalopram, cimetidine, quinidine, amantadine
SLC22A3	OCT3	Brain, liver, kidney, heart, muscle, placenta, and blood vessels	BL	Cimetidine, agmatine, adefovir, catecholamines
OAT Family				
SLC22A6	OAT1	Kidney, brain	BL	Methotrexate, salicylate, antiviral agents (e.g., acyclovir)
SLC22A7	OAT2	Liver, kidney,	BL	Methotrexate, salicylate, tetracyclines
SLC22A8	OAT3	Kidney, brain, muscle	BL	Methotrexate, antiviral agents (e.g., acyclovir), cimetidine, pravastatin, salicylate
SLC22A11	OAT4	Kidney, placenta	AP	Methotrexate, cimetidine, salicylate, tetracyclines

AP, Apical; BL, basolateral; BCRP, breast cancer resistance protein; GS-X, glutathione S-conjugate pump; MDR1, multidrug resistance 1; MOAT, multispecific organic anion transporter; MRP, multidrug resistance-related protein; OATP, organic anion transporting peptides; OCT, organic cation transporter; OAT, organic anion transporter; P-gp, P-glycoprotein.

*Comprehensive information on tissue distribution, substrates and other transporter-related information can be found at www.tp-search.jp, <http://www.bioparadigms.org/slc/menu.asp>, and <http://nutrigene.4t.com/humanabc.htm>.

polymorphisms with cancer incidence, treatment, and prognosis (Table 72-3) (for comprehensive reviews, see McIlwain, 2006; Lo, 2007).

N-Acetyltransferase

The human NATs catalyze the transfer of an acetyl group from acetylcoenzyme A to arylamines, arylhydroxylamines, and arylhydrazines (Blum, 1990). The two human NAT genes, *NAT1* and *NAT2*, carry functional polymorphisms that influence the enzyme activity. Based on the level of NAT activity, patients can be classified into two phenotypes: fast acetylator (wild-type NAT acetylation activity) and slow acetylator (reduced NAT enzyme activity). For example, polymorphisms or haplotypes in the *NAT1* (e.g., *NAT1**14, *15, *17, *19, and *22) and *NAT2* (e.g., *NAT2**5, *6, *7, *10, *14, and *17) lead to slow acetylation phenotype (for review, see Sim, 2008). A comprehensive list of the *NAT1/2* alleles is presented on the website <http://louisville.edu/medschool/pharmacology/NAT.html>. *NAT2* plays an important role in the activation and/or deactivation of a large and diverse number of aromatic amine and hydrazine drugs used in clinic, and therefore the *NAT2* genotype is particular relevant to the response to these drugs. One representative example is the association of the slow-acetylator *NAT2* phenotype with increased risk for an antituberculosis drug (isoniazid)-induced hepatitis (Huang, 2002). In addition, because *NAT1* and *NAT2* catalyze the bioactivation (via O-acetylation) of aromatic and heterocyclic

amine carcinogens, genetic variations in the *NAT1/2* genes may modify the cancer risk related to exposure to these carcinogens (Hein, 2002). For instance, the slow-acetylator *NAT2* phenotype is known to relate to a higher risk for bladder cancer (Cartwright, 1982; Garcia-Closas, 2005).

Thiopurine S-Methyltransferase

TPMT is best known for its key role in the metabolism of the thiopurine drugs (e.g., 6-mercaptopurine, azathiopurine, and 6-thioguanine) by catalyzing the S-methylation of thiopurine drugs via S-adenosyl-L-methionine as the S-methyl donor. These drugs are clinically used to treat cancers or as immunosuppressants. The *TPMT* gene exhibits significant genetic polymorphisms across all ethnic groups studied, with 18 *TPMT* alleles identified to date. The three main *TPMT* alleles, namely *TPMT**2 (reduced activity), *3A (abolished activity), and *3C (reduced activity), account for 80%–95% of the intermediate and poor metabolizers (for review, see Zhou, 2006). Patients who inherit defect *TPMT* alleles or *TPMT* deficiency (i.e., two nonfunctional alleles) are at significantly increased risk for thiopurine-induced toxicity (e.g., myelosuppression). Indeed, patients with absent *TPMT* activity (~0.3% prevalence) or low activity (~10% prevalence) may tolerate only 5%–50% of the average mercaptopurine dose. Clinical diagnostic tests are now available for the detection of the SNPs in the human *TPMT* gene that lead to decreased or abolished enzyme

activity. On the FDA-approved drug labels, *TPMT* variant pharmacogenetic test is recommended before treating patients with azathiopurine, mercaptopurine, and thioguanine.

DRUG-TRANSPORTER PHARMACOGENOMICS

In addition to drug-metabolizing enzymes, uptake and efflux transporters that facilitate the movement of drugs in or out of the cell are important determinants of drug disposition and response. Broadly, drug transporters are classified into two families, namely efflux transporters of the adenosine-5'-triphosphate (ATP)-binding cassette (ABC) family and uptake transporters of the solute carrier (SLC) family. In the ABC transporter family, 49 genes have been identified and classified into seven subfamilies from ABCA through ABCG based on the sequence homology (<http://nutrigene.4t.com/humanabc.htm>). The ABC transporters are responsible for transport of diverse substrates out of the cell using ATP as an energy source. Among these, ABCB1, ABCC1/2, and ABCG2 have been well characterized for their roles in drug disposition and response. In the SLC family, 360 genes have been identified and classified into 46 subfamilies (<http://www.bioparadigms.org/slc/menu.asp>). Of particular relevance to drug disposition are members of the organic anion transporting polypeptides (OATP), organic cation transporter (OCT), and organic anion transporter (OAT) subfamilies.

The pharmacologically most important efflux ABC transporters (including ABCB1, ABCC1/2, and ABCG2) and uptake SLC transporters (including OATP, OCT, and OAT families), their tissue distributions, and representative drug substrates are summarized in Table 72-3. These transporters play crucial roles in the intestinal absorption, biliary excretion, renal excretion, and tissue/cellular penetration of a wide variety of therapeutic drugs, and therefore they are important determinants of drug exposure in the system and at the site of action (Fig. 72-3). A growing body of evidence suggests that polymorphisms in the transporter genes, which may influence the expression, subcellular localization, substrate specificity, and/or intrinsic transport activity of the transporter proteins, influence the disposition and response of drug substrates. The following sections highlight the functional and clinical significance of the most commonly naturally occurring genetic polymorphisms within the pharmacologically most important ABC and SLC transporters with respect to drug disposition and response. A comprehensive list of genetic variants in the ABC and SLC transporters and related information are available in Pharmacogenetics Research network databases at <http://www.pharmGKB.org>.

ABCB1, ABCC1/2, AND ABCG2 EFFLUX TRANSPORTERS

ABCB1

The *ABCB1* gene, also named as the multidrug resistance 1 (*MDR1*) gene, encodes a polypeptide (P-glycoprotein) that has two halves, each containing six hydrophobic trans-membrane domains and an ATP-binding domain. ABCB1 is expressed in the intestinal epithelium, canalicular membrane of hepatocyte, brush border of the renal tubule, pancreatic ductile cell, trophoblast of placenta, capillary endothelial cells of brain and testes, and peripheral blood lymphocytes (see Table 72-3). ABCB1, located on the apical or luminal surface of the epithelial cells, functions as an efflux transporter in restricting intestinal absorption, facilitating hepatobiliary excretion and renal excretion, and protecting the brain and fetus from xenobiotics (see Fig. 72-3). In addition, ABCB1 overexpression in cancer cells is implicated in multidrug resistance to chemotherapeutic agents (Gottesman, 2002). ABCB1 transports a broad spectrum of structurally and functionally diverse drugs, including anticancer agents, antibiotics, immunosuppressants, cardiac drugs, calcium channel antagonists, and human immunodeficiency virus (HIV) protease inhibitors (see Table 72-3). There is a strong overlap in substrate specificity and tissue distribution for ABCB1 and CYP3A4/5 (Wacher, 1995).

More than 50 SNPs have been identified in the human *ABCB1* coding region. The most common SNPs are the synonymous 1236C>T and 3435C>T and the nonsynonymous 2677G>T (Ala899Ser). The allele frequencies of these three SNPs vary in different ethnic populations (Table 72-4). The 3435C>T SNP has strong linkage disequilibrium with other SNPs in the *ABCB1* gene, creating common haplotypes consisting of 3435C>T combined with 2677G>T and/or 1236C>T.

Figure 72-3 Schematic representation of drug uptake and efflux transporters as determinants of drug disposition. (Modified from Kerb R. Implications of genetic polymorphisms in drug transporters for pharmacotherapy. *Cancer Lett* 2006; 234[1]:4–33.)

Given the important role of ABCB1 in drug absorption and disposition, genetic polymorphisms in the *ABCB1* gene may influence the outcome of pharmacotherapy. The first investigation of the functional and clinical effect of ABCB1 polymorphism was reported in 2000 for a silent SNP 3435C>T, which was associated with decreased duodenal expression of ABCB1 and thereby increased plasma concentration of digoxin after oral administration in humans (Hoffmeyer, 2000). Recent evidence suggests that the 3435C>T SNP affects the timing of cotranslational folding and insertion of ABCB1 into the membrane, thereby altering substrate specificity (Kimchi-Sarfaty, 2007). In the past decade, a number of preclinical and clinical studies have been conducted investigating association of *ABCB1* genotype with its tissue expression and function, and with pharmacokinetics and pharmacodynamics of substrate drugs (see Table 72-4) (for review, see Ieiri, 2004). However, data reported on the functional and clinical impacts of *ABCB1* polymorphisms are often inconsistent (for reviews, see Ieiri, 2004; Marzolini, 2004a; Pauli-Magnus, 2004; Sakaeda, 2005; Kerb, 2006). The discrepancies may be partly explained by lack of standardized methodology and assays among different studies. In addition, SNPs may often result in very subtle functional outcomes. For example, a recent study suggests that the haplotype 1236C>T/2677G>T/3435C>T did not result in a change in substrate transport per se but affected the inhibition of transport by a small subset of modulators (Kimchi-Sarfaty, 2007). Conflicting results on the clinical impact of *ABCB1* polymorphisms may reflect the complex disposition pathway of the substrate drugs, for which other transporters or metabolizing enzymes are also involved. For example, the commonly used in vivo ABCB1 probe drugs such as digoxin,

TABLE 72-4

Most Common Functional Polymorphisms in Human ABCB1, ABCC1/2, and ABCG2: Allele Frequency and Functional Effects

Allele variants	Polymorphism/ substitution	ALLELE FREQUENCY (%) [*]			Functional effects
		Ca	As	Af	
ABCB1					
1236C>T	Silent	34–42	60–72	15–21	Affects cotranslational folding in nearby amino acids that are essential for ATP-binding and ATP hydrolysis (Fung, 2009)
2677G>T/A	A893S/T	38–47/1–10	32–62/3–22	15/ND	Affects ABCB1 expression or function, but data are inconsistent (Marzolini, 2004a)
3435C>T	Silent	48–59	37–66	10–27	Affects cotranslational folding in nearby amino acids, thereby altering substrate specificity (Kimchi-Sarfaty, 2007)
ABCB1*13	1236C>T/2677G>T/3435C>T haplotype	23–42	28–56	4.5–8.7	Affects the inhibition of ABCB1 by a small subset of modulators (Kimchi-Sarfaty, 2007)
ABCC1					
128G>C	C43S		1		Reduced plasma membrane localization, ↓vincristine resistance in transfected cells (Leslie, 2003)
1299G>T	R433S	1.4			Changes in transport and resistance (Conrad, 2002)
2012G>T	G671V	2.8			Associated with anthracycline-induced cardiotoxicity (Wojnowski, 2005)
ABCC2					
1271A>G	R412G				Dubin-Johnson syndrome; ↓ in methotrexate elimination (Hulot, 2005)
1249G>A	V417I	22–26	13–19	14	Changes in ABCC2 expression and localization (Vogelgesang, 2004; Merino, 2005; Meyer zu Schwabedissen, 2005)
3563T>A	V1188E	4–7	1		Associated with anthracycline-induced cardiotoxicity (Wojnowski, 2005)
4544G>A	C1515Y	4–9			Associated with anthracycline-induced cardiotoxicity (Wojnowski, 2005)
ABCG2					
34G>A	V12M	2–10	15–18	4–6	Changes in transport and resistance (Mizuarai, 2004; Tamura, 2007)
376C>T	Q126stop	0	0.9–1.7	0	Loss of transport activity (Tamura, 2006)
421C>A	Q141K	9–14	27–35	1–5	Affects the ATP-binding domain, thereby leading to reduced transport activity (Mizuarai, 2004; Tamura, 2007)

Af, African; As, Asian; ATP, adenosine-5'-triphosphate; Ca, Caucasian; ↑ indicates increased; ↓ indicates decreased.

^{*}Data of allele frequencies are obtained from Marzolini, 2004a; Gradhand, 2008.

fexofenadine, and talinolol are the dual substrates for both ABCB1 and OATP transporters; cyclosporine is not only transported by ABCB1 but also metabolized by CYP3A4. This means that a potential ABCB1 effect may be marked by the activity of OATP transporters or CYP3A4. Hence, a systemic analysis of polymorphisms in multiple genes known or suspected to contribute to drug disposition and response would provide better insights on the genetic impact on pharmacotherapy. In addition, the ABCB1 has multiple polymorphisms, some of which are in linkage disequilibrium, and therefore a haplotype approach would allow a more accurate prediction of clinical phenotypes.

ABCC1 and ABCC2

ABCC1/2, also called multidrug resistance-related proteins, plays an essential role in transport and excretion of organic anions including physiologic metabolites, carcinogens, and drugs. They are believed to confer multidrug resistance to chemotherapeutic agents (Hinoshita, 2000). ABCC1 and ABCC2 have overlapping substrate specificities, typically GSH, glucuronate, or sulfate conjugated and unconjugated drugs, including many anticancer agents such as vincristine and doxorubicin, HIV protease inhibitors such as ritonavir and saquinavir, and antibiotics such as difloxacin and grepafloxacin (see Table 72-3). Both ABCC1 and ABCC2 require cotransport of reduced GSH to transport some of their substrates (Rothnie, 2006). ABCC1 is located in basolateral membranes of polarized cells, whereas ABCC2 is located to the apical domain. While ABCC1 is ubiquitously expressed, ABCC2 is mainly expressed in hepatocytes, renal proximal tubule cells, intestine and brain (see Table 72-3).

The human *ABCC1* appears to be a conserved gene because many of the naturally occurring genetic variants in *ABCC1* are relative rare. Of the identified SNPs in the non-coding and coding region of *ABCC1*, 16 are known to result in amino acid changes, and some of them exhibit functional effects on either expression or function of the protein (see Table 72-4) (for review, see Gradhand, 2008). However, data on the role of *ABCC1* polymorphisms in terms of in vivo physiology and clinical drug resistance or toxicity are rather limited. Interestingly, one study has identified significant associations of *ABCC1* 2012G>T (Gly671Val) and a haplotype of *ABCC2* with anthracycline-induced cardiotoxicity among patients with non-Hodgkin lymphoma who have been treated with doxorubicin (Wojnowski, 2005).

Mutations in the *ABCC2* gene have been initially identified in Dubin-Johnson syndrome, a relatively rare recessive disorder characterized by conjugated hyperbilirubinemia resulting from loss of expression and function of *ABCC2* in the liver (see Chapter 21). However, the impact of this loss of hepatic *ABCC2*-mediated transport on the pharmacokinetics of substrate drugs in humans is yet to be determined. Among more commonly occurring *ABCC2* SNPs, the most widely studied is 1249G>A (Val417Ile). The effect of this SNP on *ABCC2* expression is different depending on the tissue examines. For example, 1249G>A SNP was associated with lower *ABCC2* messenger ribonucleic acid (mRNA) and protein levels in preterm placenta, but not in duodenum and liver (Meyer zu Schwabedissen, 2005; Meier, 2006). Of note, one study demonstrated a possible association of 1249G>A variant with tenofovir-induced renal proximal tubulopathy, suggesting this SNP may influence renal excretion

of some ABCC2 substrates (Izzedine, 2006). In addition, 1249G>A SNP was associated with changes in the ABCC2 localization in neuroepithelial tumors (Vogelgesang, 2004). A number of other nonsynonymous and synonymous SNPs have been studied for their potential functional influence on the ABCC2 expression and transport activity. *ABCC2* SNPs appear to have varying effect on different organs or substrates, or between in vitro and in vivo studies (for review, see Gradhand, 2008).

ABCG2

The ABCG2 (also known as BCRP, ABCP, or MXR) protein is an ATP-binding cassette (ABC) half-transporter that bears six trans-membrane domains and one ATP-binding domain. The protein actively extrudes a wide variety of chemically unrelated hydrophobic or partially hydrophobic compounds from the cells, including cytotoxic compounds (e.g., mitoxantrone, topotecan, SN-38, flavopiridol, and methotrexate), fluorescent dyes (e.g., Hoechst 33342) and toxic compounds found in normal food (e.g., pheophorbide A) (see Table 72-3). ABCG2 is expressed in the canalicular membrane of hepatocytes, in the epithelia of small intestine, colon, placenta, lung, kidney, adrenals, and sweat glands, as well as in the endothelia of the central nerve system vasculature. It is responsible for host detoxification and protection against potentially toxic xenobiotics (Jonker, 2000; Jonker, 2002; Krishnamurthy, 2006). ABCG2 transporter-mediated efflux has been increasingly recognized to not only confer drug resistance but also modulate drug absorption and disposition (Burger, 2004; Hirano, 2005; Kondo, 2005; Merino, 2005; Sparreboom, 2005).

More than 80 polymorphisms in the *ABCG2* gene have been identified in different ethnic populations (Iida, 2002; Imai, 2002; Zamber, 2003; Ishikawa, 2005). Several naturally occurring SNPs in *ABCG2* have been found to affect the function and/or expression of its encoded protein (Imai, 2002; Mitomo, 2003; Kobayashi, 2005; Lepper, 2005) and therefore may alter the pharmacokinetics and pharmacodynamics of substrate drugs. In particular, a functional SNP in exon 5 of the *ABCG2* gene, in which a C→A nucleotide transition at position 421 (*ABCG2* 421C>A), results in a nonsynonymous variant protein with a glutamine to lysine amino acid substitution in codon 141 (Q141K) (Imai, 2002). The *ABCG2* 421C>A variant has been associated with low ABCG2 expression levels and altered substrate specificity (Imai, 2002); it has been found to alter the pharmacokinetics of diflomotecan and topotecan (Sparreboom, 2004; Sparreboom, 2005). In addition, recent studies have demonstrated that the epidermal growth factor receptor (EGFR) tyrosine kinase inhibitors such as gefitinib and erlotinib are ABCG2 substrates, and the *ABCG2* 421C>A variant is associated with greater gefitinib accumulation at steady-state and related to higher incidence of gefitinib-induced grade 1 or 2 diarrhea in cancer patients compared with the wild-type ABCG2 (Cusatis, 2006; Li, 2007b).

OATP, OCT, AND OAT UPTAKE TRANSPORTERS

Organic Anion Transporting Polypeptides

OATPs are membrane influx transporters that facilitate cellular uptake of a wide range of endogenous compounds (e.g., bile salts, hormones, and steroid conjugates) and clinically important drugs (e.g., HMG-CoA-reductase inhibitors, cardiac glycosides, anticancer agents, and antibiotics) (see Table 72-3). Of the 11 human OATP transporters, OATP1A2, OATP1B1, OATP1B3, and OATP2B1 are best characterized for their roles in drug pharmacokinetics. OATP1A2 is expressed on the luminal membrane of small intestinal enterocytes and at the blood-brain barrier and may facilitate the intestinal absorption and brain penetration of its substrates. OATP1B1, OATP1B3, and OATP2B1 are mainly expressed on the sinusoidal membrane of hepatocytes and can facilitate the hepatic uptake of their substrate drugs for further metabolism or biliary excretion (Niemi, 2007).

A number of SNPs and other genetic variations have been identified in the *SLCO1B1* gene (encoding OATP1B1), and their allele frequencies vary markedly across different populations (Table 72-5) (for review, see Meyer zu Schwabedissen, 2009). Some *SLCO1B1* SNPs and haplotypes have been associated with impaired transport activity in vitro toward different substrates (Tirona, 2001; Kameyama, 2005; Nozawa, 2005). These functional impaired OATP1B1 variants may limit the uptake of the substrate drugs into the hepatocytes, thereby resulting in decreased biliary excretion or hepatic metabolism and thus increased systemic exposure. For example, a common variant allele, 521T>C, was associated with increased systemic exposure of several OATP1B1 substrate drugs, including repaglinide and statins (e.g., pravastatin) (Niemi, 2005; Niemi, 2006).

*OATP1B1**15 (a haplotype of 388A>G and 512T>C) is associated with increased plasma concentrations of pravastatin (Nishizato, 2003) and increased concentrations of SN-38 (Xiang, 2006; Han, 2008). *OATP1B1**17 (a haplotype of -11187G>A, 388A>G and 512T>C) is associated with increased effect of pravastatin on rate of cholesterol synthesis. A recent genome-wide association study has demonstrated that a noncoding rs4363657 SNP, which is in nearly complete linkage disequilibrium with the *SLCO1B1* 521T>C SNP, is the only strong marker associated with simvastatin-induced myopathy (Link, 2008). Collectively, these data suggest that knowledge of the patient's *SLCO1B1* genotype might be useful in tailoring of drug therapy.

Several nonsynonymous polymorphisms have been identified in the *SLCO1A2* gene (encoding OATP1A2), with some of these variants demonstrating decreased in vitro transport activity toward OATP1A2 substrates (see Table 72-5) (for review, see Franke, 2009). However, the impacts of these functional SNPs on the pharmacokinetics and clinical outcome of therapeutic drug use need further studies. For OATP1B1 and OATP2B1, there are few data on the clinical relevance of *SLCO1B3* and *SLCO2B1* polymorphisms, although some genetic variations within these two genes have been associated with altered *in vitro* transport activity of the protein (see Table 72-5) (Nozawa, 2002; Letschert, 2004).

Organic Cation Transporter

The OCTs belong to the solute carrier SLC22A family that mediate intracellular uptake of a broad range of structurally diverse small organic cations (molecular weight < 400). Three isoforms, OCT1, OCT2, and OCT3, with partially overlapping substrate spectrum, are identified in humans (see Table 72-3). OCT1 is primarily expressed in the sinusoidal membrane of hepatocytes, whereas OCT2 is predominantly expressed in the basolateral membrane of the kidney proximal tubules; OCT3 is expressed in many tissues including placenta, heart, liver, and skeletal muscle (see Table 72-3). The expression of OCTs was also detected in several cancer cell lines and tumor tissue samples (Hayer-Zillgen, 2002; Zhang, 2006).

A number of non-synonymous SNPs have been identified in the *SLC22A1* gene (encoding OCT1) and *SLC22A2* (encoding OCT2) from different ethnic groups, and some of them have demonstrated altered (mostly impaired) transport function in vitro (see Table 72-5) (Choi, 2008). By contrast, several synonymous SNPs have been identified in the *SLC22A3* (encoding OCT3); however, their functional consequence is yet to be determined. The functional polymorphisms in the *OCT* genes may influence the clinical pharmacokinetics and response of substrate drugs such as metformin. It is evident that functional polymorphisms in the *OCT1* and *OCT2* impact the clinical effect and pharmacokinetics of metformin, a drug used as a primary therapy for type 2 diabetes mellitus. Metformin is eliminated predominantly by renal excretion in humans (Pentikainen, 1979). Because of high expression of OCT2 in the kidney and the active renal secretion of metformin via OCT2, defect function in OCT2 transport would result in decreased renal clearance of this drug. Recent studies demonstrated a significant lower renal clearance and higher plasma concentration of metformin in carriers of homozygous for low activity OCT2 variant 270S compared with those homozygous for the active variant (270A) (Song, 2008; Wang, 2008). On the other hand, low-function OCT1 variants R61C, G401S, M420del, and G465R have been associated with significantly higher renal clearance of metformin (Tzvetkov, 2009). In addition to the effect on metformin pharmacokinetics, low-function OCT1 variants (R61C, G401S, M420del, and G465R) have been related to significantly decreased glucose-lowering response of metformin in healthy volunteers, probably by reducing the metformin uptake in hepatocytes, which is the major target site of action of metformin (Shu, 2007).

Organic Anion Transporter

The OATs belong to the SLC22 family of solute carriers that mediate cellular uptake of a broad range of structurally diverse small hydrophilic organic anions. OAT substrates include many clinically important anionic drugs, such as β -lactam antibiotics, diuretics, nonsteroidal antiinflammatory drugs, nucleoside/nucleotide antiviral drugs, and anticancer agents (see Table 72-3). There are at least six OAT members (OAT1-6). OAT1-3 localize to the basolateral membrane of the renal proximal tubule mediating the uptake of drug substrates from blood into the proximal tubule cells, whereas OAT4 localizes to the apical side of the renal proximal tubule functioning in the secretion of drug substrates into urine. Together, these transporters are responsible for the movement of drug substrates from the blood to the urine. Genetic variations in the genes encoding OATs may

^{*}Allele frequency data are obtained from Xu, 2005; Kerb, 2006; König, 2006; Choi, 2008.

[†]Functional effect data are summarized from Marzolini, 2004b; Zhou, 2007; Zair, 2008; Choi, 2008; Franke, 2009.

contribute to interindividual variability in the renal clearance of substrate drugs. To date, a number of polymorphisms have been reported in the coding region and 5' regulatory region of human *SLC22A6* (encoding OAT1), *SLC22A7* (encoding OAT2), *SLC22A8* (encoding OAT3), and *SLC22A11* gene (encoding OAT4) (see Table 72-5). Some of these polymorphisms resulted in altered in vitro transport activity of the protein (Xu, 2005; Bhatnagar, 2006). Notably, the coding region polymorphisms in these genes are infrequent (~1%), whereas the regulatory region polymorphisms of these genes, particularly *SLC22A8*, may be important in accounting for variation in the renal clearance of substrate drugs (Bhatnagar, 2006). The functional and clinical relevance of these coding and regulatory region polymorphisms need further studies.

DRUG TARGET PHARMACOGENOMICS

DNA REPAIR GENES

DNA repair is crucial to an organism's ability to maintain its genome integrity and function. Multiple DNA repair pathways exist to cope with a broad range of different DNA lesions or adducts induced by DNA damaging agents or radiation. The major DNA repair pathways include the following (Fig. 72-4): direct repair of alkyl adducts by methylguanine methyl transferase, repair of base damage and single-strand breaks by base excision repair, repair of bulky DNA adducts by nucleotide excision repair, repair of double-strand breaks by homologous recombination and nonhomologous end-joining repair, and repair of mismatches and insertion/deletion loops by DNA mismatch repair.

Chemotherapy and radiotherapy are designed to induce DNA damage that cause cell cycle arrest and cell death. The efficacy of DNA

damage-based cancer therapy can thus be modulated by DNA repair mechanisms that operate in cancer cells to recognize and rectify this damage. For example, the antitumor activity of chemotherapy or radiotherapy could be reduced by increasing activities of several DNA repair pathways in cancer cells. In addition, DNA repair activity may also affect normal tissue tolerance to DNA damaging agents or radiation. Inefficient DNA repair in normal cells would be expected to result in inefficient removal of damaged DNA and thus lead to accumulation of DNA damage within normal tissues and increased normal tissue toxicity.

To date, 130 human genes have been identified that are involved in DNA repair pathways (Wood, 2001), and genetic polymorphisms within several of DNA repair genes have been described recently. The key genes that are associated with human DNA repair are listed in Figure 72-4. Among these, apurinic endonuclease 1 (APEX1), X-ray repair cross-complementing group 1 (XRCC1), excision repair cross-complementing enzyme group 1 (ERCC1), excision repair cross-complementing rodent repair group 2 (ERCC2), breast cancer 1, early onset (BRCA1), and X-ray repair cross complementing protein 3 (XRCC3) are the most widely reported DNA repair genes for which genetic polymorphisms have been associated with the therapeutic response (efficacy or toxicity) to chemotherapy or radiotherapy (Table 72-6) (for review, see Gossage, 2007).

There is evidence that genetic variations within the DNA repair genes may modify the activities of DNA repair pathways within both cancer cells and normal cells, thereby influencing therapeutic resistance and normal tissue tolerance to chemotherapy and radiotherapy (Table 72-6). For example, variant alleles that reduced DNA repair proficiency may increase the toxicity of DNA-damaging drugs or radiation in cancer cells, thus resulting in better therapeutic effect; on the other hand, they would cause insufficient DNA repair in normal tissue cells, thereby reducing normal

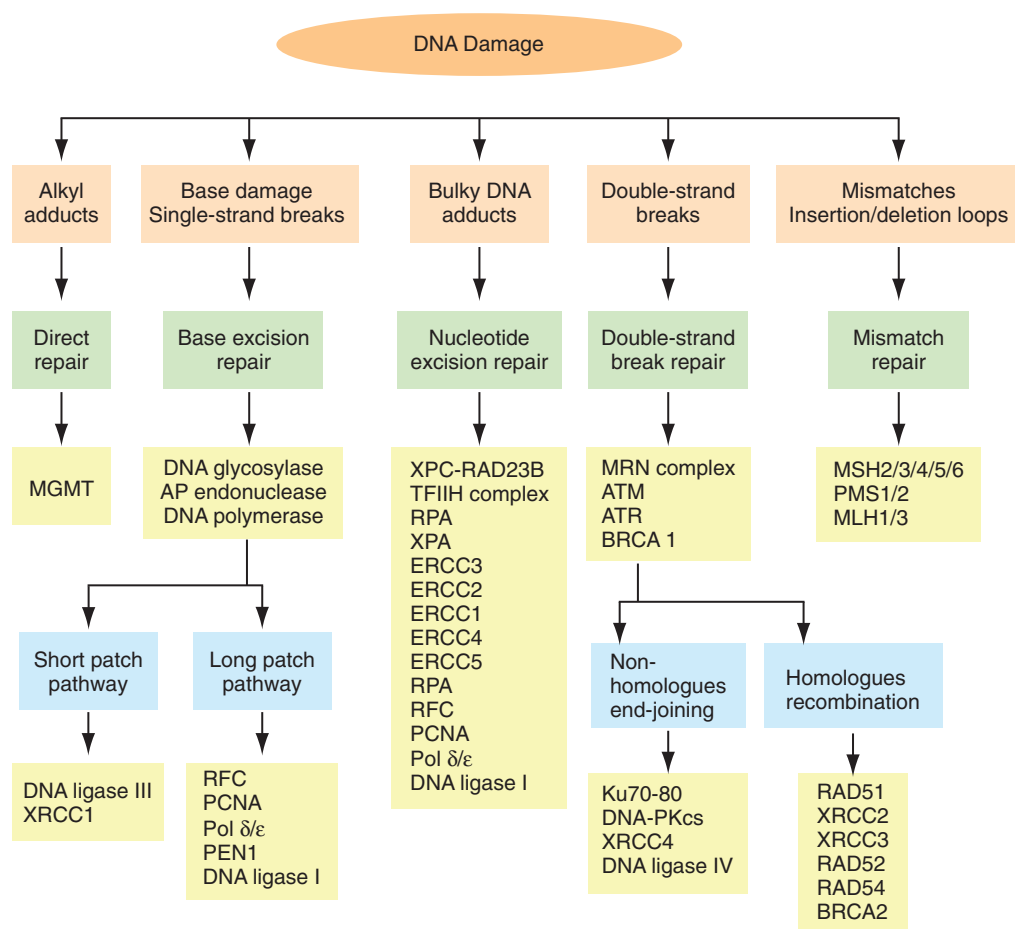

Figure 72-4 Key players in mammalian DNA repair pathway. (Modified from Gossage L, Madhusudan S. Cancer pharmacogenomics: role of DNA repair genetic polymorphisms in individualizing cancer therapy. *Mol Diagn Ther* 2007;11[6]:361–80.) TABLE 72-6

Most Widely Reported DNA Repair Gene Polymorphisms That Have Demonstrated Associations with the Response (Efficacy and Toxicity) to Chemotherapy or Radiotherapy

DNA repair pathway and genes	Gene functions	SNPs	Association with efficacy	Association with toxicity
Base Excision Repair (BER) Apurinic endonuclease 1 (APEX1)	APEX1 is a critical protein involved in BER that hydrolyses the phosphodiester backbone immediately 5' to an apurinic/apyrimidinic (AP) site following removal of the damage base by a DNA glycosylase.	Asp148Glu (most common SNP of APEX1)	↓Overall survival for 148Glu/Glu homozygotes in pancreatic cancer (Cx/RT/Both) (Li, 2007a)	↓Risk of acute skin reactions for 148Glu allele in normal weight breast cancer patients (adjuvant RT) (Chang-Claude, 2005)
X-ray repair cross-complementing group 1 (XRCC1)	XRCC1 interacts with DNA ligase III, polymerase β and poly (ADP-ribose) polymerase, and seals the remaining nick in DNA after DNA Pol β performs its one nucleotide gap filling reaction. XRCC1 is involved in the efficient repair of DNA single-strand breaks.	Arg194Trp Arg399Gln	↑Response rate for 194Trp variants in advanced NSCLC (platinum Cx) (Wang, 2004) ↑Survival for 194Trp/Trp homozygotes in pancreatic cancer (Cx/RT/Both) (Li, 2007a) ↑Response rate and ↑survival for 399Arg/Arg homozygotes in mCRC (FOLFOX), advanced NSCLC (platinum Cx), and oesophageal (platinum Cx, RT, and surgery) (Gurubhagavatula, 2004; Stoecklmaier, 2001; Wu, 2006) ↓Breast cancer-free survival and progression-free survival for Gln399 variant allele in metastatic breast cancer (high-dose Cx and stem-cell transplantation) (Bewick, 2006)	↑Risk of hematologic toxicity for 194Arg/Arg homozygotes in NSCLC (gemcitabine and docetaxel Cx) (Petty, 2007) ↑Risk of early/late adverse reaction for 194Trp allele in breast cancer (adjuvant RT) (Moullan, 2003) ↓Risk of late reactions for 194Trp allele in cervical or endometrial cancer (RT) (De Ruyck, 2005) ↓Risk of acute skin reactions for 399Glu allele in normal weight breast cancer patients (adjuvant RT) (Chang-Claude, 2005) ↑Risk of late skin toxicity for 399Arg/Arg homozygotes in breast cancer (adjuvant RT) (Andreassen, 2003)
Nucleotide Excision Repair (NER) Excision repair cross-complementing rodent repair group 2 (ERCC2)	ERCC2 is an ATP-dependent 5'-3' DNA helicase, and a component of the core-TFIIH basal transcription factor. It is involved in NER by opening DNA in the 5' to 3' direction around the damage.	Asp312Asn Lys751Gln	↓Survival for 312Asn variant allele in advanced NSCLC (platinum) (Gurubhagavatula, 2004) No association with response in advanced NSCLC (platinum) (Camps, 2003) 751Lys/Lys homozygotes more likely to relapse in stage 3&4 gastric cancer (surgery and chemoradiation) (Zarate, 2006) ↑Response rate and median survival for 751Lys/Lys homozygotes in mCRC (FOLFOX) (Park, 2001) ↑Disease-free and 1-year survival for 751Lys/Lys homozygotes in AML (Cx) (Allan, 2004) No association with response in advanced NSCLC (platinum Cx) (de las Penas, 2006)	ERCC2 genotype/haplotype associated with GI, GU, and liver toxicities in AML (daunorubicin and cytosine arabinoside Cx) (Kuptsova, 2007) ↓Risk of neutropenia for 751Gln/Gln homozygotes in NSCLC (gemcitabine and docetaxel Cx) (Petty, 2007)

Excision repair cross-complementing enzyme group 1 (ERCC1)	ERCC1 is a two-domained, noncatalytic protein that associates with ERCC4 (XPF) endonuclease to form an ERCC1-XPF heterodimer, whose role is to cleave DNA 5' to the lesion. ERCC1-XPF is the last factor to join the mammalian NER incision complex and is also known to be involved in recombinational DNA repair and in the repair of inter-strand crosslinks.	19007T>C	<p>↑Response rate or ↑survival for 19007C/C homozygotes for advanced NSCLC (platinum or cisplatin/docetaxel Cx) and mCRC (FOLFOX) (Park, 2003; Isla, 2004; Ryu, 2004)</p> <p>↑Prognosis for 19007T/T homozygotes for CRC (adjuvant FU based) (Moreno, 2006)</p> <p>↓Risk of platinum resistance in 19007T/C and T/T genotypes for ovarian cancer (Kang, 2006)</p> <p>↑Survival in 8092C/C homozygotes for NSCLC (platinum Cx) (Zhou, 2004)</p> <p>8092C>A</p>	<p>↑Risk of GI toxicity for 8092A allele in NSCLC (platinum Cx) (Suk, 2005)</p> <p>↓Risk of metabolic toxicity for 8092C/A heterozygotes and ↓risk of lung toxicity for 8092A/A homozygotes in AML (daunorubicin and cytosine arabinoside Cx) (Kuptsova, 2007)</p>
Double-Strand Break (DSB) Repair Breast cancer 1, early onset (BRCA1)	BRCA1 is a nuclear phosphoprotein that plays a role in maintaining genomic stability, and it also acts as a tumor suppressor. BRCA1 is associated with other tumor suppressors, DNA damage sensors, and signal transducers to form a large multi-subunit protein complex known as the BRCA1-associated genome surveillance complex (BASC). It plays a role in transcription, DNA repair of double-stranded breaks, and recombination.	BRCA1 mutations	<p>↑Clinical and pathological complete response for BRCA1 mutation in breast cancer (anthracycline-based Cx) (Chappuis, 2002)</p> <p>↑Response rate for BRCA heterozygotes in ovarian cancer (platinum-based Cx) (Cass, 2003)</p>	
X-ray repair cross complementing protein 3 (XRCC3)	XRCC3 participates in homologous recombination to maintain chromosome stability and repair DNA damage. It is involved in DSB repair, and functionally complements Chinese hamster irs1SF, a repair-deficient mutant that exhibits hypersensitivity to a number of different DNA-damaging agents.	Thr241Met	<p>↑Time to treatment failure for 241Met variant genotype in multiple myeloma (autologous bone marrow transplantation) (Vangsted, 2007)</p> <p>↑Survival for 241Met/Met homozygotes in advanced NSCLC (platinum Cx) (de las Penas, 2006)</p> <p>↓Survival for 241Met variant genotype in breast cancer (high-dose Cx and stem-cell transplantation) (Bewick, 2006)</p> <p>No association in advanced gastric cancer (platinum Cx) (Ruzzo, 2006)</p>	<p>↓Risk of 214Met variant in AML (daunorubicin and cytosine arabinoside Cx) (Kuptsova, 2007)</p> <p>↑Risk of late skin toxicity for 241Thr/Thr homozygotes in breast cancer (adjuvant RT) (Andreassen, 2003)</p>

Af, African; AML, acute myeloid leukemia; As, Asian; Ca, Caucasian; CRC, colorectal cancer; Cx, chemotherapy; FOLFOX, fluorouracil/oxaliplatin chemotherapy; FU, fluorouracil; GI, gastrointestinal; GU, genitourinary; mCRC, metastatic colorectal cancer; NSCLC, non-small cell lung cancer; RT, radiotherapy; SNPs, single nucleotide polymorphisms; ↑ indicates increased; ↓ indicates decreased.

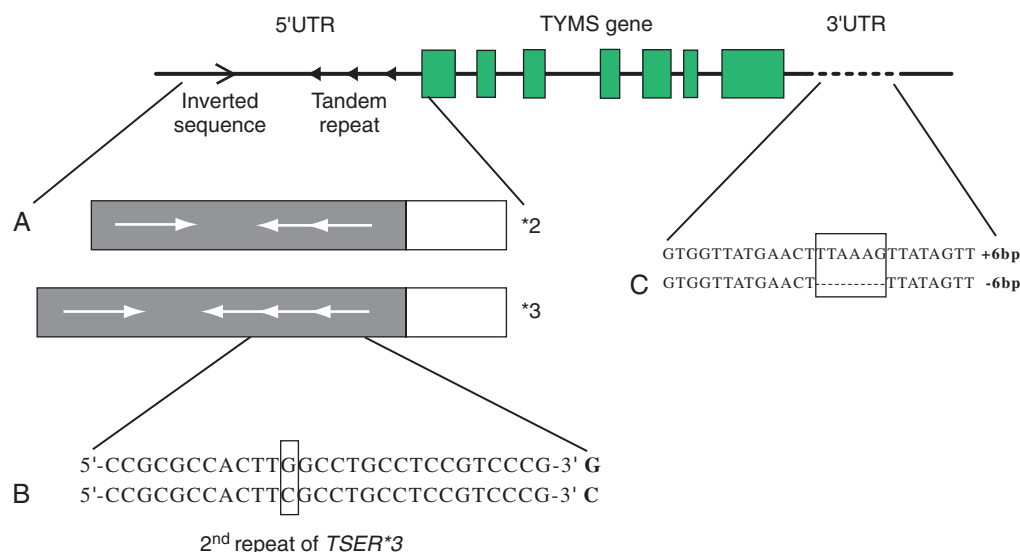

Figure 72-5 Three functional genetic polymorphisms in the 5' and 3' untranslated regions (5'UTR and 3'UTR) of the thymidylate synthase (TS) gene, including the following: **A**, a polymorphic tandem repeat of a 28-bp sequence that is present in either duplicate (2R) or in triplicate (3R) in the TS promoter enhancer region (TSER 2R>3R polymorphism); **B**, a G to C SNP within the second repeat when three repeats are present (TSER 3R G>C SNP); **C**, a 6-bp deletion in the 3'UTR of the TS gene (TS 1494del6bp). (Adapted from Marsh S. Thymidylate synthase pharmacogenetics. *Invest New Drugs* 2005;23[6]:533–7.)

tissue tolerance. It is worthy noting that data reported on the functional or clinical impacts of variant alleles of DNA repair genes are inconsistent in some instances (for review, see Gossage, 2007). For instance, whereas some studies suggested that variant alleles were associated with improved response, others found the opposite. The discrepancies may be explained in part by variations in study settings (e.g., different tumor types or stages, different treatment regimens, or different patient populations). In addition, most published studies have attempted to correlate a single SNP in two or three DNA repair genes to clinical outcome. The presence of other untested SNPs could confound the result interpretation. Moreover, many studies are largely limited by small sample size. To clarify the roles of DNA repair gene polymorphisms in cancer treatment, large prospective clinical trials are needed to systematically assess the combined impact of multiple polymorphisms involved in several relevant DNA repair pathways.

THYMIDYLATE SYNTHASE

Thymidylate synthase (TS) catalyzes the conversion of deoxyuridylate (dUMP) and 5,10-methylenetetrahydrofolate ($\text{CH}_2\text{H}_4\text{folate}$) to deoxythymidine monophosphate (dTMP) and 7,8-dihydrofolate. This reaction is the sole *de novo* biosynthesis of thymine in DNA, and therefore inhibition of TS blocks DNA synthesis, thereby causing cell death. Given its essential role in DNA synthesis, TS is an important target for chemotherapeutic drugs, such as 5-fluorouracil (5-FU) and capecitabine (orally bioavailable 5-FU prodrug). 5-FU exerts its cytotoxicity through inhibition of TS, blocking DNA synthesis and triggering apoptotic pathway and other cell death processes (Dananberg, 1977). 5-FU is the mainstay of therapeutic regimens for the treatment of colorectal cancer and other human malignancies. There is a wide variation in response and toxicity among patients receiving 5-FU-based chemotherapy. TS expression as a determinant of sensitivity to 5-FU has been demonstrated *in vitro* (Johnston, 1992). Importantly, substantial body of clinical data have suggested that response to 5-FU-based chemotherapy regimens is inversely associated with intratumoral TS mRNA and protein expression (Johnston, 1995; Leichman, 1997; Aschele, 1999; Salonga, 2000). A recent meta-analysis involving 887 patients with metastatic colorectal cancer and 2610 patients with localized colorectal cancer suggests that tumors expressing high levels of TS appear to have a poor overall survival compared with tumors expressing low levels (Popat, 2004).

There is evidence that TS expression is modulated by three functional significant germline polymorphisms in the 5' and 3' untranslated regions (5'UTR and 3'UTR) of the TS gene. These include a polymorphic tandem repeat of a 28 base pair (bp) sequence that is present in either duplicate (2R) or in triplicate (3R) in the TS promoter enhancer region (TSER 2R>3R polymorphism), a SNP (G>C) in the second repeat when three repeats are present (TSER 3R G>C SNP), and a 6 bp deletion in the

3'UTR of the TS gene (TS 1494del6bp) (Fig. 72-5). The TSER 2R>3R polymorphism is of clinical significance as patients with metastatic colorectal cancer homozygous for the triple repeat (TSER 3R/3R) had significantly higher intratumoral TS gene expression (Kawakami, 1999; Pullarkat, 2001). The 28 bp TSER tandem repeats contain elements that bind upstream stimulating factor (USF) and thus act to enhance transcriptional activity of the TS gene. The presence of a G>C SNP within the second repeat of the 3R allele results in decreased transcriptional activity by abolishing the binding of USF within the repeat (Mandola, 2003). The 6 bp deletion in the 3'UTR of the TS gene has been associated with decreased TS mRNA stability and lower intratumoral TS mRNA level in patients (Mandola, 2004). The allele frequencies of these three TS polymorphism vary among different ethnic populations (Table 72-7).

It is increasingly apparent that TS polymorphisms are not only prognostic factors of disease-free survival and overall survival but also predictors of chemotherapeutic benefit from 5-FU-based chemotherapy (for review, see Lurje, 2009). Most studies have consistently agreed that high-expression allele or genotype (i.e., TSER-2R/3G, -3C/3G, -3G/3G, 3'-UTR +6bp/+6bp) are generally associated with poor prognosis and worse response to 5-FU-based chemotherapy compared with low-expression group (i.e., TSER-2R/2R, -2R/3C, -3C/3C, 3'-UTR +6bp/-6bp, -6bp/-bp) in patients with colorectal cancer (for review, see Lurje, 2009).

EPIDERMAL GROWTH FACTOR RECEPTOR

The EGFR activation is a key factor in cell proliferation and important for tumor growth, including effects on cell motility, adhesion, invasion, survival, and angiogenesis (Woodburn, 1999; Raymond, 2000). EGFR is a transmembrane cell surface receptor tyrosine kinase that is found in the majority of epithelial tissues. Upon binding of the extracellular ligand (e.g., epidermal growth factor or transforming growth factor- α), the EGFR dimerizes, either homodimerizing with another EGFR or heterodimerizing with other members of the human epidermal growth factor receptor family, leading to the activation of cytoplasmic tyrosine kinase (TK) activity (see Figures 76-1 and 76-2.) The activation of receptor TK leads to the autophosphorylation of the intracellular domain of EGFR, resulting in the activation of downstream signaling pathways (e.g., Ras/mitogen-activated protein kinase pathway and the PI3K/Akt pathway and Janus-activated kinase signal transducers and activator of transcription) that are involved in tumor growth and metastasis (Bokemeyer, 2009; Houtsmma, 2009). Receptor dimerization and signal transduction pathways are discussed further in Chapter 76. The reversible EGFR TK inhibitors, such as gefitinib and erlotinib, target the adenosine-5' triphosphate (ATP) cleft within the EGFR-TK to prevent autophosphorylation of the receptor, thus inhibiting tumor growth and metastasis (Anderson, 2001; Ciardiello, 2001). Treatment with gefitinib or erlotinib results in dramatic clinical response

TABLE 72-7

Functional Polymorphisms of the Thymidylate Synthase (TS) Gene

Polymorphism	ALLELE FREQUENCY*			Functional effect*
	Ca	As	Af	
TSER 2R>3R repeat	52–69	62–82	52	↑TS mRNA for 3R allele
TSER 3R G>C SNP	56	37	28	↓Transcriptional activity of TS for C allele
TS 1494del6b	27–29			↓Stability of TS mRNA for –6bp deletion

Af, African; As, Asian; Ca, Caucasian; mRNA, messenger ribonucleic acid; TSER, TS promoter enhancer region; ↑ indicates increased; ↓ indicates decreased.

*Summarized from Marsh, 2005; Lurje, 2009.

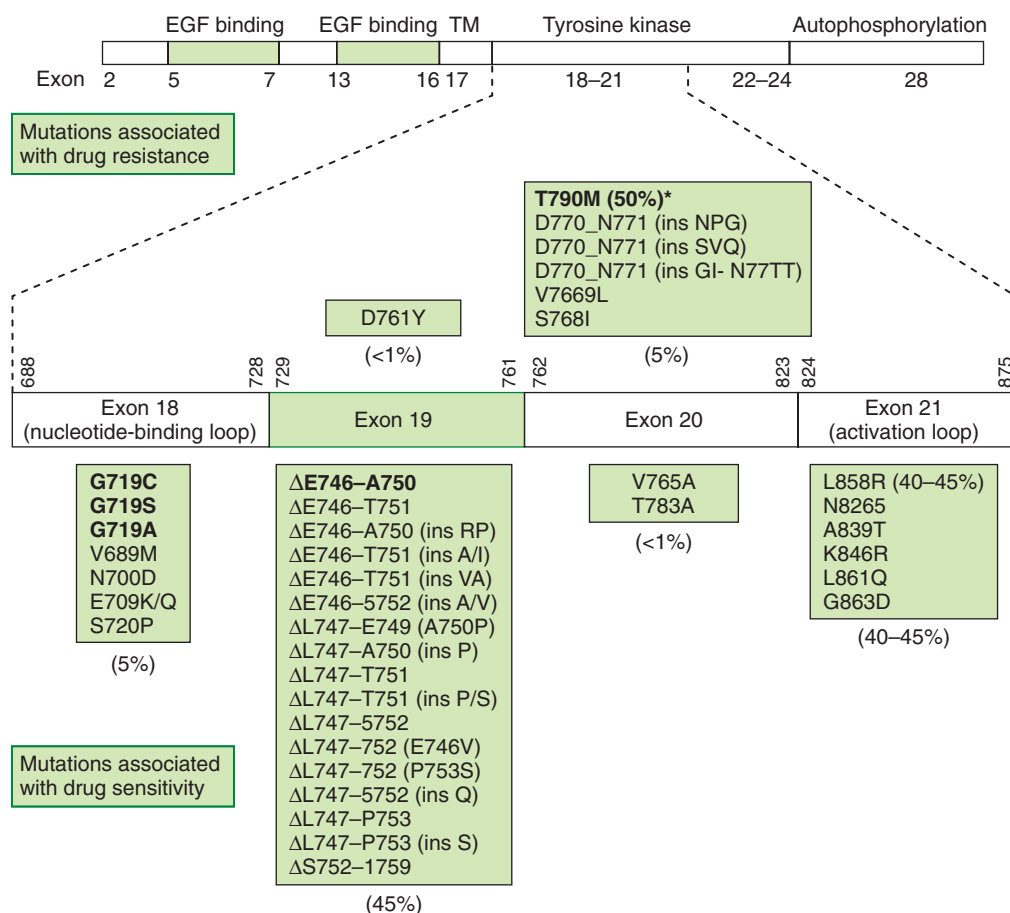

Figure 72-6 Schematic presentation of the epidermal growth factor receptor (EGFR) tyrosine kinase (TK) domain mutations as important determinants of sensitivity or resistance to EGFR TK inhibitors. The most prevalent activating EGFR kinase domain mutations in non-small cell lung cancer (NSCLC) include in-frame deletions in exon 19 (accounting for 45% of EGFR mutations), an L858R substitution in exon 21 (accounting for 40%–45% of EGFR mutations), nucleotide substitutions in exon 18 (e.g., G719C or G719S) (5%), and in-frame insertions in exon 20 (<1%). The most noteworthy clinically relevant mutations associated with resistance to EGFR TK inhibitors include T790M in exon 20, and D761Y, a T790M-like secondary mutation in exon 19. The main mutations in each class are shown in bold type. (Adapted from Sharma SV, Bell DW, Settleman J, Haber DA. Epidermal growth factor receptor mutations in lung cancer. *Nat Rev Cancer* 2007;7[3]:169–81.)

in approximately 10% to 30% patients with non-small cell lung cancer (NSCLC) depending on ethnic origin, sex, and smoking history (Fukuoka, 2003; Kris, 2003; Shepherd, 2005; Thatcher, 2005). It is clear that specific types of somatic mutations of the EGFR gene confer sensitivity or resistance to EGFR TK inhibitors (for reviews, see Kumar, 2008; Gazdar, 2009).

The somatic activating EGFR mutations are found in the first four exons (18 through 21) of the TK domain (Fig. 72-6) (Lynch, 2004; Paez, 2004; Pao, 2004). These mutations fall into three broad classes. Class I mutations are in-frame deletions in exon 19 that almost always include amino acid residues leucine-747 to glutamic acid-749 (ΔLRE) and account for approximately 44% of all EGFR TK activating mutations. Class II mutations are single nucleotide substitutions that cause an amino acid alteration. The most prevalent single-point mutation is L858R (an arginine changed to leucine at codon 858) in exon 21, accounting for about

41% of all EGFR TK activating mutations; other class II mutations include G719 (a glycine changed to serine, alanine, or cysteine) in exon 18 (4% of all EGFR TK activating mutations) and other missense mutations. Class III mutations are in-frame duplications and/or insertions in exon 20, accounting for about 5% of EGFR TK activating mutations. Overall, the frequency of EGFR TK activating mutations is 5%–20%, depending on the population studied. Activating EGFR TK mutations are significantly more common in East Asians, women, never smokers, and patients with adenocarcinoma (Janne, 2006). This mirrors the clinically defined subsets of patients who were most likely to respond to EGFR TK inhibitors. The NSCLC patients who present with EGFR TK activating mutations have not only better response to gefitinib or erlotinib but also significantly longer progression-free survival and overall survival compared with those without these mutations (Gazdar, 2009).

Figure 72-9 Schematic illustration of irinotecan disposition pathway. Irinotecan is activated to 7-ethyl-10-hydroxycamptothecin (SN-38) by human carboxylesterase 1 and 2 (hCE1 and hCE2), and SN-38 is subsequently detoxified by UGT1A1 to a β -glucuronide derivative, SN-38G (Slatter, 1997). In addition, irinotecan undergoes CYP3A4-mediated oxidation to form the inactive metabolites 7-ethyl-10-(4-N-(5-aminopentanoic acid)-1-peperidino) carbonyloxycamptothecin (APC) and 7-ethyl-10-(4-amino-1-peperidino) carbonyloxycamptothecin (NPC), and NPC also undergoes a subsequent conversion by hCE2 to SN-38. Irinotecan and its metabolites (i.e., SN-38 and SN-38G) are also transported by the ABC transporters including ABCB1, ABCC1/2, or ABCG2 or the organic anion transporting polypeptide 1B1 (OATP1B1). (Adapted from van Erp NP, Baker SD, Zhao M, et al. Effect of milk thistle (*Silybum marianum*) on the pharmacokinetics of irinotecan. *Clin Cancer Res* 2005;11[21]:7800–6.)

enzymes and transporters involved in irinotecan disposition. There is definitive evidence that the genetic variant *UGT1A1**28, characterized by the presence of an additional TA repeat in the TATA sequence of the *UGT1A1* promoter ((TA)₇TAA instead of (TA)₆TAA), is associated with reduced SN-38 glucuronidation and greater susceptibility to irinotecan-induced gastrointestinal and hematologic toxicity (Iyer, 2002; Tukey, 2002; Innocenti, 2004). In addition, other polymorphisms in the *UGT1A1* gene have also been associated with irinotecan-related toxicity. Of particular importance to East Asian population is *UGT1A1**6 (Gly71Arg) with an allele frequency of ~12%, which reduces UGT1A1 catalytic activity by 60% in homozygotes (Premawardhena, 2003). This variant allele has been related to higher incidence of toxicity in a population of Korean patients treated with irinotecan and cisplatin for advanced NSCLC (Han, 2006). Additionally, two promoter variants (i.e., *UGT1A1* -3263T>G and -3156G>A), which are in strong linkage disequilibrium with *UGT1A1**28 in Caucasians while less apparent in African-Americans and Asians, have been associated with higher incidence of irinotecan-induced grade 4 neutropenia or diarrhea (Innocenti, 2004; Kitagawa, 2005).

Besides UGT1A1, associations between genetic polymorphisms within the genes encoding the drug transporters such as *ABCB1*, *ABCC1*, *ABCG2*, and *OATP* and irinotecan pharmacokinetics and/or toxicity have been reported even though the data are limited (for review, see de Jong, 2006). For *ABCB1*, *ABCB1* 3435C>T variant allele was related to higher irinotecan plasma concentration in Chinese (Zhou, 2005), and *ABCB1* 1236C>T variant allele resulted in higher AUC of irinotecan and SN-38 but lower AUC of SN-38G in a Caucasian population (Mathijssen, 2003). Nevertheless, the true clinical relevance of a single SNP on *ABCB1* to irinotecan treatment remains to be clarified. A haplotype approach may be more useful to estimate true genetic effects. A haplotype analysis in 49 Japanese patients indicated that the patients carrying the *ABCB1**2 haplotype, containing 1236C>T, 2677G>T, and 3435C>T SNPs, exhibit significantly lower renal clearance of irinotecan, SN-38, and APC (Sai, 2003). With regard to *ABCC2* that is involved in bile excretion of irinotecan, a functional SNP *ABCC2* 3972C>T was found to have significant effect on the AUC of irinotecan, APC, and SN-38G, all being higher in patients carrying homozygous 3972T (Kim, 2002). Irinotecan and SN-38 are good substrates of ABCG2; yet, no significant associations between ABCG2 polymorphisms and irinotecan pharmacokinetics or toxicity were found. OATP1B1 is involved in the transport of SN-38 but not SN-38G;

variants of this transporter including 521T>C, -11187G>A, 388A>G, and *OATP1B1**15 haplotype have been associated with a lower clearance and higher systemic exposure of SN-38 and irinotecan (Xiang, 2006; Han, 2008).

In addition to pharmacogenetic influence of genes involved in irinotecan pharmacokinetics, polymorphisms in the drug target of SN-38, topoisomerase I (TOP1), and cellular downstream effectors leading to DNA repair or cell death may influence patient outcomes to irinotecan treatment. A recent study in 107 advanced colorectal cancer patients showed that *TOP1* and *TDP1* haplotype tagging SNPs (htSNPs) were related to grade 3/4 neutropenia and response, respectively; and a DNA repair gene *XRCC1* haplotype was associated with response (Hoskins, 2008).

Collectively, it is clear that *UGT1A1**28 is associated with greater susceptibility to irinotecan-induced gastrointestinal and hematologic toxicity. It is recommended that the initial dose of irinotecan is reduced for patients homozygous for the *UGT1A1**28 allele. The true clinical significance of polymorphisms within other genes involved in the pharmacokinetics and pharmacodynamics of irinotecan with respect to patient outcome treated with this drug remains to be further clarified.

TAMOXIFEN

Tamoxifen is a well-established drug for use in breast cancer and is within the class of selective estrogen receptor modulators. Despite major strides in the diagnosis and management of breast cancer, the disease will account for an estimated 40,000 deaths in 2008 among women in the United States. Tumors from approximately 75% of women with newly diagnosed breast cancer will express steroid hormone receptors, and those women will likely be recommended endocrine therapy to reduce the risk of recurrence and death. Other endocrine approaches are currently available, including selective estrogen receptor (ER) downregulators (fulvestrant in postmenopausal women), and aromatase inhibitors (e.g., anastrozole, exemestane, and letrozole in postmenopausal women), or ovarian function suppression (by surgery, luteinizing hormone-releasing hormone agonist, or radiation) in premenopausal women (Blackhall, 2006; Bao, 2007; Brauch, 2009). How to apply the various treatment possibilities in order to maximize therapeutic index is controversial. Tamoxifen remains the standard of care in premenopausal women. Most postmenopausal women will be recommended for 5 years of an aromatase inhibitor or 2–3 years of tamoxifen followed

by an aromatase inhibitor for a total of 5 years. Administration of tamoxifen in patients with ER-positive breast cancer as adjuvant therapy for 5 years, following anthracycline-based chemotherapy, reduces the recurrence rate by 50% and the mortality rate by a third in 15-year follow up studies. The most common side effect of tamoxifen is hot flashes, and the most severe adverse effects are thrombotic events in breast cancer patients and endometrial cancer in some patients.

The pharmacology of tamoxifen is thought to be linked to the interaction of the parent drug and its metabolites with the ER in both breast and nonbreast tissues. This interaction induces a specific conformational change of the ER, leading to alteration of downstream signaling pathways and ultimately resulting in transcriptional and posttranscriptional changes in estrogen regulated genes with inhibition of estrogen effects. Tamoxifen is a nonsteroidal agent that has a rather weak affinity for its target the ER. Most of the antiproliferative effects of tamoxifen in breast cancer is mediated by its metabolites. The most important metabolites include 4-hydroxy-tamoxifen (4-OH-tamoxifen) and 4-hydroxy-N-desmethyl tamoxifen (endoxifen). Both metabolites have a much stronger affinity to the ER than does tamoxifen. These metabolites antagonize the effects of estrogen in breast tumors by competing with the hormone at the receptor-binding sites. Endoxifen is prevalent at sixfold to twelvefold higher concentration than tamoxifen. Tamoxifen undergoes extensive phase I and phase II metabolism in the human liver. The bioconversion of tamoxifen includes N-oxidation, N-demethylation, and hydroxylation. There are at least three metabolites of tamoxifen of clinical interest. The major metabolite, N-desmethyl-tamoxifen is roughly equipotent to the parent drug and is produced by the CYP450 3A4/5 mediated demethylation of tamoxifen. In contrast, the other metabolite, 4-hydroxytamoxifen is generated in small quantities compared to tamoxifen by several CYP450 enzymes, including 2D6, but has a greater than 100-fold affinity for the ER and is 30–100 times more potent than tamoxifen in suppressing estrogen-dependent proliferation. The third tamoxifen metabolite, endoxifen, is as potent as 4-hydroxytamoxifen in inhibiting estrogen-mediated proliferation, but it is present at tenfold higher amounts than 4-hydroxytamoxifen. Thus endoxifen is believed to be responsible for the majority of tamoxifen-associated antitumor activity. Endoxifen is primarily generated by CYP450 2D6, and genetic variants of this enzyme as well as drugs that modulate its enzymatic activity could significantly affect the outcome in tamoxifen-treated patients (van Schaik, 2005; Yong, 2007; Ekhardt, 2009; Hoskins, 2009; Zhou, 2009).

Mechanisms of resistance to tamoxifen therapy, as well as predictive markers of susceptibility to resistance, have been widely researched (Ingelman-Sundberg, 2007; Goetz, 2008; Schroth, 2009). Accurate markers would allow prediction of tamoxifen response and personalization of combined therapies. The suggestion has been made that patients with ER-positive breast cancer with inherited nonfunctional alleles of the cytochrome P450 CYP2D6 gene might be poor candidates for adjuvant tamoxifen therapy. The postulation that CYP450 2D6 inhibition might reduce the protection conferred by tamoxifen therapy is based on two lines of evidence. First, women with CYP450 2D6 variant alleles that reduce the enzyme function or who take CYP450 2D6-inhibiting drugs, such as some selective serotonin reuptake inhibitors (SSRIs), have reduced concentration of the tamoxifen metabolites that most strongly bind the ER. Second, in some studies, women with CYP2D6 variant alleles have a higher risk of recurrence than women with two functional alleles. A retrospective study of 223 postmenopausal women examined CYP450 2D6 *4, the most common null allele associated with poor metabolizer status and the outcome of tamoxifen therapy. Women homozygous for CYP450 2D6 *4 had poorer outcomes than women with CYP450 2D6 *4/*1 or *1/*1 genotypes, showing shorter time to relapse and worse disease-free survival. In addition, no women with CYP450 2D6 *4/*4 experienced moderate or severe hot flashes, in contrast to 20% incidence in those women with either one or no *4 alleles (Schroth, 2007). Furthermore, a retrospective study by Schroth and colleagues in a German and US cohort study of 1325 postmenopausal stage I through III breast cancer patients, found that, among women treated with tamoxifen, there was an association between CYP2D6 variation and clinical outcomes, such that the presence of 2 functional CYP2D6 alleles was associated with better clinical outcomes and the presence of nonfunctional or reduced-function alleles with worse outcomes (Schroth, 2009). Similar results were obtained by Borges and associates using an expanded analysis to include other reduced activity alleles such as *4, *5, *10, and *41 (Borges, 2006). All of these studies suggest that CYP450 2D6 poor metabolizers are at higher risk of recurrence of breast cancer or more likely to develop breast cancer when given prophylactic tamoxifen. Based on these studies, there have been efforts to

identify breast cancer patients whose genotypes suggest poor metabolizer phenotypes and offer alternative therapy such as aromatase inhibitors. In opposition to these reports, Wegman and colleagues found a significantly better disease-free survival in 667 tamoxifen-treated postmenopausal breast cancer patients homozygous for CYP450 2D6 *4. Some of the differences seen in the literature might be due to differences in study designs, selection bias, and/or uncontrolled confounders (Wegman, 2007). These and other reports have led to the current controversy both on the clinical validity and utility of CYP450 2D6 genotyping for individuals receiving tamoxifen therapy.

Hot flashes, one of the most common side effects of tamoxifen therapy, are commonly treated with antidepressants such as SSRIs. Certain SSRIs inhibit CYP 450 2D6 enzymatic activity (Van Schaik, 2008). Coadministration of certain SSRIs has been shown to significantly reduce the concentration of one of the most potent metabolites of tamoxifen, endoxifen, even in extensive metabolizer patients. Furthermore, administration of SSRIs that do not inhibit CYP 450 2D6 enzymatic activity has been shown not to diminish the concentration of endoxifen. In a recent prospective study, Goetz and collaborators assessed the influence of genetic and drug-induced reduction in CYP 450 2D6 activity on breast cancer outcomes in 226 patients coadministered potent or weak/moderate CYP 450 2D6 inhibitors with tamoxifen. Patients were stratified by genotype and medication history into subgroups of extensive or decreased metabolizer genotypes (Goetz, 2008). Compared with patients with extensive metabolizer CYP 450 2D6 metabolism genotype, patients with decreased metabolism genotype showed significantly shorter time to recurrence and worse relapse-free survival.

The current evidence regarding CYP 450 2D6 genotype and benefits when selecting a breast cancer treatment is still controversial (Lea, 2007; Li, 2007; Limdi, 2009; Marsh, 2009). An FDA advisory panel suggested that the tamoxifen package insert should alert treating health care providers of concerns that poor metabolizer patients might be at increased risk for recurrence of their breast cancer if treated with tamoxifen and that the coadministration of certain selective SSRIs known to inhibit CYP450 2D6 can affect the metabolism of tamoxifen. On the other hand, the 2009 National Comprehensive Cancer Network of National Institutes of Health breast cancer guidelines do not include any recommendations concerning treatment modification based on CYP 450 2D6 genotyping. In recent years, a great amount of progress has been achieved in the understanding of how genetic makeup of patients might influence the response to breast cancer treatment but much more work needs to be done. Of particular interest would be the development of further studies on postmenopausal patients as well as for premenopausal women to address the relationship between CYP 450 2D6 genotype and success of tamoxifen therapy.

PLATINUM AGENTS

Platinating agents are widely used chemotherapeutic drugs and consist of a number of platinum analogs develop to overcome cellular resistance and reduce toxicity (Furuta, 2009). The chemotherapy drugs cisplatin, carboplatin, and oxaliplatin are commonly used for the treatment of lung, colorectal, ovarian, breast, head and neck, bladder, and testicular cancer. Cisplatin exerts its antitumor activity by binding preferentially to N-7 positions of adenine and guanine of DNA, resulting in the formation of intrastrand and interstrand crosslinks. This cross-linking blocks replication and inhibit transcription. Intrinsic and/or acquired resistance as well as toxicities associated with these agents are the major limitations of these drugs. For example, about 85% of patients with ovarian cancer relapse following initial response. The resistance might be multifactorial, consisting of proteins limiting the formation of DNA adducts and/or operating downstream of the interaction of drug with DNA to promote cell survival. More specifically, nodes of resistance include increased efflux from the cell, drug inactivation, alterations to the drug target, DNA repair, evasion of apoptosis, and drug target alteration. Platinum-induced toxicity can also alter the outcome of treatment by limiting the dose of drug administered, with nephrotoxicity and neuropathy as the main dose-limiting toxicities. Peripheral neuropathy is permanent in approximately 30%–50% of patients receiving treatment. Additionally, ototoxicity and neurotoxicity are difficult to manage and can result in the discontinuation or reduction of treatment. Thus the identification of genetic factors to better predict patients who are at risk of adverse drug reactions associated with cisplatin or relapse is very important (McWhinney, 2009).

The disposition of chemotherapeutic agents is often the key to determining the mechanism by which they cause toxic effects. This disposition

is regulated by the drug metabolism, absorption, distribution, and excretion. Platinum causes interstrand DNA cross-linking, leading to cessation of DNA synthesis and apoptosis, and toxicity due to platinum is modulated by protein involved in DNA repair (ERCC1, ERCC2, and XRCC1), DNA detoxification (GSTP1 and MPO), and transport (SLC31A1, ABCC2, and ABCG2) (Shukla, 2008). However, there are no genetic polymorphisms that are ready for clinical application. In a large study done in Scotland, a randomized clinical trial of carboplatin and taxane in patients with ovarian cancer, genetic polymorphism of genes relevant to the platinum pathway, such as ABCC2, ABCG2, ERCC1, ERCC2, GSTP1, MPO, and XRCC1, were not significantly associated with clinical outcomes or toxicity (Wang, 2008; Caronia, 2009).

DNA repair is an important mechanism for resistance to platinum-based therapy and possibly the development of neurotoxicity. If the cell is able to repair the DNA that is attacked by the platinum agent, then the agent will be unsuccessful in inducing apoptosis. Nucleotide excision repair genes, such as excision repair cross-complementation group 1 (ERCC1), have been hypothesized to play a role in the efficacy of platinum-based drugs. Park and colleagues described the association between the ERCC1 codon 118 polymorphism and the clinical outcome in colorectal cancer patients treated with platinum-based chemotherapy (Park, 2003). This genotype could be a useful predictor of clinical outcome not only for colorectal cancer but also for patients with epithelial ovarian cancer. Today, there has been no association between ERCC1 polymorphism and chemotherapy neurotoxicity. There are many avenues that will need to be pursued to avoid or minimize neurotoxicity caused by platinum drugs.

ANTIBODY THERAPY

Over the past decade, treatment for malignancy such as metastatic colorectal cancer has significantly improved with the approval of several new agents (Jimeno, 2009; Modjtahedi, 2009). In particular two different EGFR inhibitor therapies have emerged as effective treatment for a subset of patients with metastatic colorectal carcinoma: cetuximab and panitumumab (Hamilton, 2008; Garcia-Saenz, 2009; Heinemann, 2009; Siena, 2009; Stintzing, 2009). Because *KRAS* is the downstream effector of EGFR and it is frequently mutated in colorectal cancer, the effectiveness of cetuximab in *KRAS* mutated tumors has become a topic of recent studies (Garcia, 2008; Raponi, 2008; Riely, 2008; Monzon, 2009; Normanno, 2009). Because activating *K* ras mutations lead to EGFR independence, it stands to reason that tumors that harbor *KRAS* activating mutation will not benefit from anti-EGFR therapies. One of the initial reports came from Personeni and colleagues after demonstrating that an increasing copy number of EGFR in colorectal cancer by fluorescent *in situ* hybridization analysis predicted the response to cetuximab (Personeni, 2007). However, tumors with the *KRAS* mutation did not respond to cetuximab therapy. Their observation was further confirmed by several studies that found that *KRAS* mutations precluded tumor response to cetuximab but these studies suffer from a small patient cohort. More recently, Amado and associates examined *KRAS* mutation in 427 patients with metastatic colorectal cancer treated with panitumumab or best supportive care (Amado, 2008). Patients with wild type *KRAS* clearly benefited from this therapy with a significantly longer progression-free survival and overall survival. However, these benefits diminished for those patients harboring a *KRAS* mutation. Furthermore, Van Cutsem and colleagues performed a retrospective study to assess *KRAS* mutational status in patients who participated in the CRYSTAL trial (Van Cutsem, 2007). In this study, 348 patients (64.4%) had a wild type *KRAS* while 192 patients (35.6%) had a mutant *KRAS*. In patients with wild type *KRAS*, cetuximab significantly improved the response rate (43% for FOLFIRI, 59% for cetuximab + FOLFIRI, $P = .00025$) and progression-free survival (8.7 months FOLFIRI, 9.9 months for cetuximab + FOLFIRI, $P = .017$). On the other hand, cetuximab had no effect on tumors bearing the *KRAS* mutation (response rate or RR: 40% without cetuximab vs. 36% with cetuximab, $P = .46$; progression-free survival: 8.1 months without cetuximab vs. 7.6 months for cetuximab, $P = 0.75$). This observation was also confirmed by another large retrospective study presented by Bokemeyer in the OPUS trial (Bokemeyer, 2009). These clinical trials have shown that up to 40% of patients with *KRAS* wild type colorectal cancer show at least a partial response to anti-EGFR therapy, an improvement over the 10% before *KRAS* mutation stratification; whereas patients with *KRAS* mutated tumors gain no benefit from anti-EGFR therapy. The utility of determining *KRAS* mutation status beforehand, therefore, is to determine which patients will not respond to EGFR monoclonal antibody therapy. In light of these results, the National Comprehensive Cancer Network and the American Society of Clinical Oncology have developed

guidelines to recommend that all colorectal tumors with metastases should be tested for mutations in codon 12 and 13 of exon 2 of the *KRAS* gene before initiating anti-EGFR therapy (Pare, 2008; Shankaran, 2008; Allegra, 2009). There are no FDA approved tests in the market and there are no specific technologic recommendations (Weichert, 2010). Unfortunately, at least 60% of *KRAS* wild type patients will derive no benefit from anti-EGFR antibodies, highlighting the need for additional biomarkers to help separate responders from nonresponders. Potential biomarkers include BRAF, *KRAS* codon 61 and 146, PIK3 and PTEN mutation, and EGFR gene copy number (Oikonomou, 2006).

PHARMACOGENOMICS IN OTHER DISEASES

DIABETES

Pharmacogenomic investigations of diabetes mellitus have yielded variations in genomic loci containing common variants with translational consequences of altering disease susceptibility risk, clinical course, and response to standard therapy. This is becoming increasingly important in light of the projected increased prevalence type 2 diabetes (T2D) to more than 300 million cases in the year 2025 (Wei-Jian, 2008; Zimmet, 2001). To this end, polymorphisms in genes related to β cell function, glucose tolerance, insulin uptake and other aspects of glucose metabolism are being actively investigated for effective drug design and personalized responses. One of the many classes of antidiabetic agents are the glitazones (e.g., thiazolidinedione, or TZD) which can be prescribed alone or in combination with sulfonylureas, metformin, or insulin. TZDs pharmacologically act by agonizing the nuclear peroxisome proliferator-activated receptor γ (PPAR- γ) to form heterodimers with the retinoid X receptors, which binds the PPAR-response elements and regulates target gene transcription. Pro-12Ala, polymorphism in the PPAR- γ 2, has a frequency of roughly 12%–15% in the general population, making it the most common PPAR- γ variant. A meta-analysis showed that Ala12 allele displayed a protective effect with regard to developing T2D, reducing the risk in carriers by 19% (Ludovico, 2007). Although one study demonstrated that patients with the Pro12Al genotype receiving rosiglitazone for 12 weeks was significantly better when compared with patients with the homozygous Pro12 (PPAR- γ 2) genotype (86.7% and 43.7%, respectively) (Kang, 2005), other studies have been inconsistent (Blucher, 2003). Polymorphisms in genes associated with glitazone (TZD) toxicity include CYP2C19, CYP2D6, CYP2C8, CYP2C9, and CYP3A4 (Aquilante, 2007); however, the strengths of these relationships vary. Other polymorphisms related to patient responses to antidiabetic agents such as sulfonylureas (tolbutamide [Orinase], glipizide [Glucotrol], glibenclamide [Glyburide], and glimepiride [Amaryl]), biguanides (Metformin), and meglitinides (nateglinide [Starlix] and repaglinide [Prandin]) are reviewed by Avery (2009) and others (Holstein, 2009; Pearson, 2009).

HUMAN IMMUNODEFICIENCY VIRUS

HIV has become increasingly difficult to treat due to the mutational nature of the virus (Wolinski, 1996). Degenerate pathways common to HIV mutants and strains have been targets of drug design such as highly active antiretroviral therapy, which represents a combination of substances directed against various steps in the viral life cycle. Pharmacogenomic approaches are providing additional information toward devising therapies to decrease morbidity and mortality associated with HIV infections. Earlier studies by Liu and colleagues (1996) described resistance to HIV-1 infection in cells, obtained from multiply exposed individuals. Those studies found that such patients were homozygous defective for CC-CKR5 and therefore resistant to infection. Polymorphisms in the cytochrome P450 system, which is involved in drug clearance, has also been shown to be of value. The CYP3A4*20 null allele contains a premature stop codon yielding a truncated protein. Subjects of this genotype might be susceptible to side effects during drug therapy with substrates or inhibitors of CYP3A4, and this may have pharmacokinetic and pharmacodynamic application to antiretroviral drug design (Westlind-Johnsson, 2006; Lakhman, 2009). Adverse effects to antiviral medications have also been linked to polymorphisms. The human leukocyte antigen (HLA)-DRB1*0101 haplotype may determine the susceptibility to nevirapine hypersensitivity and the 3434T allele at the MDR1 gene is associated with a decreased risk of nevirapine-induced hepatotoxicity. Genetic polymorphisms in the HLA haplotypes HLD HLA-B*5701, HLA-DR7, and/or HLA-DQ3 have been correlated

with susceptibility to abacavir allergic reactions. The presence of a TA insertion into the UGT1A1 promoter (Gilbert syndrome) has been associated with increased occurrence of hyperbilirubinemia of atazanavir and indinavir. Polymorphisms in the APOC3 gene have been associated with antiretroviral induced hyperlipidemia; and polymorphisms at the serine protease kinase inhibitor Kazal-1 that encodes a trypsin inhibitor in the cytoplasm of pancreatic acinar cells and the cystic fibrosis transmembrane conductance regulator have been associated with some treatment regimens. Furthermore, many of these responses differ with respect to race (for review, see Clarke, 2009).

OSTEOPOROSIS

Osteoporosis is an increasingly common disorder found in older adults, often resulting from decreased bone mineral density (BMD) with subsequent enhanced bone fragility collectively leading to an increased incidence of fracture. Genetic susceptibility, and hormonal and environmental factors are thought to influence bone mass and as such polymorphisms and their reciprocal effects on therapeutic interventions are actively sought to design the most efficient medications. The VDR gene codes for the vitamin D receptor, which is the target for the active form of vitamin D, 1,25-dihydroxyvitamin D₃ [1,25(OH)₂D₃]. Polymorphisms in the VDR gene can affect stability and expression of the mRNA. Restriction fragment length polymorphism (RFLP) and linkage disequilibrium analysis have highlighted polymorphisms in the VDR gene (TaqI, ApaI, BsmI, FokI), some of which have been correlated with increased BMD measurements in certain patients taking antiresorptive drugs, alendronate, or raloxifene as hormone replacement therapy (Massart, 2008) and that these responses were allele specific (Nguyen, 2008). Bone density regulation, by hormones such as estrogens, are also subject to the effects of genetic polymorphisms and allelic variation. Studies on the ERs, ER α , and ER β , which are coded for by ESR1 and ESR2 genes, respectively, have shown that women with a particular polymorphism (XbaI) had greater spine and hip BMD and that genetic variations of ESR1 relate to bone structure and strength (Ferrari, 2008). The CYP19 gene codes for an enzyme (aromatase) that catalyzes the conversion of androstenedione to estrone and testosterone to estradiol. Mutations in this gene have been found to correlate with decreased BMD. In addition, enzymes involved in the biogenesis of estrone and estradiol have attracted attention as well as polymorphisms in the regulatory region of the type I collagen gene, COL1A1, affecting the binding site for the transcription factor Specificity protein 1 (Sp1) (Thijssen, 2006).

PSYCHIATRIC AND COGNITIVE DISORDERS

Medications prescribed for psychiatric disorders are often administered on a trial-and-error basis (Lin, 2006). Furthermore, although depression and other disorders have been linked to certain genetic predispositions, the multifactorial nature of this disease class is wanting for better understanding of causal relationships. As such clinical correlation studies employing methods such as SNP and linkage studies to facilitate efficiency of antidepressants/antipsychotics with genetic variants have been described (Lin, 2008). As an example, brain-derived neurotrophic factor (BDNF) gene, encodes a protein of the nerve growth factor family that regulates synaptic plasticity and connectivity in the brain. A variation of this gene, which codes for a methionine substitution for valine at codon 66 (Val-66Met), is associated with alterations in brain anatomy and memory (Chen, 2006). Patients with depressive disorder with polymorphisms in this gene have been shown to respond more efficiently to antidepressants such as citalopram, milnacipran, and fluvoxamine in select populations (Choi, 2006; Yoshida, 2007). Furthermore, BDNF stimulates the release of acetylcholine (ACH). Alzheimer's disease (AD) is associated with defective ACH and recent data demonstrates decreased expression BDNF and its receptor, *trk B*, in AD patients. As such, agents that serve to upregulate BDNF and/or *trk B* expression are being investigated with respect to genetic polymorphisms and responses to select drug classes (Fumagalli, 2006). Similarly, in bipolar disorders, genetic factors and polymorphisms have been attributed to efficient response to drugs such as lithium and clozapine. These include variations in serotonin transporter genes and responses to selective serotonin reuptake inhibitors (SSRI), among others (Mansour, 2002). Furthermore, recent studies of Glub and colleagues (2009), examined whether an SNP (rs11042725) in the promoter of the adrenomedullin gene was associated with mood disorders or SSRI antidepressant response. They found that the only significant result was an association of the C/C genotype with a lower likelihood of response to paroxetine (Glub, 2009). Other genes involved in affective disorders that

correlate with selective treatment include variants at the tryptophan hydroxylase gene, 5-HT_{2a} receptor, G-protein β_3 , and inositol polyphosphate 1-phosphatase, among others (Serretti, 2002).

EPIGENOMICS

The term *epigenetics* is defined as follows: *epi-* is Greek for over or above; *-genetics* refers to changes that occur outside the scope of a gene's DNA sequence. These changes result in phenotypic (appearance) or genotypic expression modulation caused by mechanisms other than changes in the underlying DNA sequence (Russo, 1996). Examples of epigenetic phenomenon include DNA methylation status, histone coding, SNPs, copy number variants, and chromatin remodeling, which can affect transcription and subsequent translation of a given gene regardless of its sequence. As such, epigenetics can be used to describe any aspect other than DNA sequence that influences the development of an organism. *Epigenomics* can be considered an extension of this concept to convey overall epigenetic state of a cell across the entire genome. Recent data by Zhang and colleagues (Zhang, 2008) challenge the notion that a drug response is influenced by many different genetic and nongenetic factors; the extent to which each factor contributes to variation in response is not yet fully understood (Fig. 72-10). These concerns make the development of diagnostic tests that could predict an individual's response to a particular drug rather difficult. Profiling the variation in DNA methylation can provide new insights into the regulation of gene expression as well as the mechanisms of individual drug response at a new level of complexity. To this end, the National Institutes of Health have published a roadmap to better understand the relationship of epigenomics to the clinical marketplace (<http://nihroadmap.nih.gov/epigenomics/initiatives.asp>). Their proposition is to study a variety of human cell types, including human embryonic stem cells, differentiating cells, selected differentiated cell lines representative of human disease, and select human primary cells that are relevant to complex human disease. Epigenomes derived from these studies will serve as a reference and resource to identify potential therapeutic targets, to enhance understanding of disease mechanisms, to provide additional insights to genetic susceptibility of disease, to pursue therapeutic opportunities in stem cell based and tissue regeneration strategies, and to understand normal differentiation, development, and aging/senescence. The initiative is intended to elucidate fundamental epigenomic changes or mechanisms underlying specific diseases; conditions of development or aging; or response to exposures (physical, chemical, behavioral, and social factors).

Figure 72-10 DNA methylation status can affect variation in gene expression and drug response. A, For a particular drug response-related gene, there could be people with different epigenetic signatures within a population. Orange, sensitive people; blue, nonresponsive people; white, all others. B, Sensitive people have an epigenetic signature that causes overexpression of the gene. C, In contrast, nonresponsive people have an epigenetic signature that inhibits gene expression. (From Zhang W, Huang RS, Dolan E. Integrating epigenomics into pharmacogenomic studies. *Pharmacogenomics Pers Med* 2008;1:7–14, with permission.)

Epigenomics holds potential to shed light on mental disorders (cognitive decline, AD, and schizophrenia) (Gomase, 2008), drug dependence (Coller, 2009), diabetes (Maier, 2002), and respiratory diseases (Bowman, 2009), among others. As an example with respect to drug dependence, the μ opioid receptor has a clear involvement in mediating the analgesic and rewarding effects of endogenous and exogenous opioids (Glatt, 2007). The most frequently studied of these receptors is the *OPRM1* variant, an SNP A118G (recently renamed 304A/G10) in exon 1 that causes an Asn40Asp substitution at a putative glycosylation site in the extracellular domain and occurs at an allelic frequency of between 10% and 40% depending on ethnicity, and epigenetic studies have elucidated potential differences among ethnicities that may have a role personalizing drug development. Although metaanalyses of such studies may not yield conclusive differences (Coller, 2009), there may be differences in gender or in certain ethnicities (Gelernter, 1999; Hoehe, 2000; Kapur, 2007) that may not be apparent when combined with other studies.

CONCLUSIONS

It is clear that the field of pharmacogenomics has heralded a new way of thinking about the relationship of a disease on the individual and the individual's response to a disease state encompassing the spectrum of disease pathophysiology, diagnosis, prognosis, and treatment. The methodologies employed, such as SNP, RFLP, loss of heterozygosity, and hybridization array based profiling (see Chapter 67), among others, are as important as the study design, patient demographics, characterization, stratification, comorbidities, and data interpretation. Nonetheless, pharmacogenomics provides a unique approach toward investigating, appreciating, and therapeutically serving the individual patient. Continued investigation and adaptation of pharmacogenomics in clinical medicine should likely provide mankind with improved risk vs. benefit ratios with respect to therapeutic efficacy vs. side effect profiles and effective re-evaluation of drug design toward the generation of novel and specific therapies for disease.

KEY POINTS

- This chapter discusses the use of proteins, whose serum levels are often elevated in patients with malignancies, in the diagnosis and management of cancer.
- Many of these are so-called oncofetal antigens, i.e., proteins that are expressed in fetal tissue during development but are not normally found in the tissues of adults. These include α -fetoprotein and carcinoembryonic antigen, whose serum levels are frequently elevated in hepatocellular and colon cancers, respectively.
- Other proteins, such as CA 19-9, CA 125, and CA 15-3, are expressed in epithelial cells and are also often present in the sera of patients with pancreatic, ovarian, and breast cancers, respectively.
- Because these 'tumor marker' proteins are not tissue-specific and can also be expressed in diseases other than cancer, their sensitivities and specificities are not sufficiently high that they can be used as cancer-screening proteins. Their use is predominantly in following patients who are being treated for known malignancies.
- The exception to this is prostate-specific antigen (PSA), a chymotrypsin-like enzyme that is expressed almost exclusively in prostate tissue and is elevated in the sera of most patients with prostate cancer. Elevated serum PSA levels therefore have a high sensitivity for diagnosing prostate cancer; because PSA is also elevated in other prostate diseases, such as benign prostatic hyperplasia, it has a lower specificity but nonetheless can still be used very effectively to screen patients for this disease.

- New developments in the field of early tumor detection using serum markers are also introduced in this chapter. These include use of mitogenic proteins, such as HER2/Neu, known to function as signal transduction proteins whose levels are elevated in many types of cancers; detection of genes encoding these proteins in body fluids; and proteomic approaches involving patterns of expression of multiple proteins that typify specific cancers. These specific approaches are also discussed in depth in the following chapter.
- The identification of circulating tumor cell (CTC) as biomarker is a fast growing area of research. This chapter updates the recent advance on CTC that is or will be applied in clinical application for diagnostic and prognostic values.

Despite the advancement of multidisciplinary treatment modalities, cancer mortality has not been significantly reduced for the past 50 years. In contrast, dramatic decreases in mortality due to cardiovascular and infectious disease have been achieved. Studies have shown that early detection of cancer can lead to superior long-term survival. Thus there is an urgent need to search for cancer biomarkers with high sensitivity and specificity to allow for early cancer detection, effective treatment, and decreased mortality. Therefore much effort has been devoted to the discovery, characterization, and clinical application of tumor markers to detect the presence of cancer at an early stage. As a result, increasing numbers of biomolecules, mainly specific proteins and some specific ribonucleic acids (RNAs) and deoxyribonucleic acids (DNAs), have been identified and

employed as markers potentially for screening purposes and also for prognostic purposes in the daily clinical management of cancer patients. These markers can further be used not only to classify cancers but also to monitor response to neoadjuvant therapy. For example, estrogen receptor (ER), progesterone receptor (PR), and HER2/*neu* oncogene protein are used in the diagnosis and management of breast cancer patients using surgical specimens. ER has been shown to be a prognostic marker for breast cancer and a predictive marker for hormonal treatment (Jensen, 2003). HER2/*neu* amplification and overexpression were shown to be associated with poor prognosis and to be a predictor for therapeutic response in breast cancer (Wilmanns, 2004). PR has been shown to be associated with a good prognosis in ovarian cancer (Munstedt, 2000; Lee, 2005).

Among these markers are a number of tumor markers present in circulating body fluids, including blood. Broadly, body fluid tumor biomarkers (principally serum and urine) are divided into three categories: tumor-associated proteins such as the oncofetal antigens, which seem to be expressed in many cancers but have also been found to be present in other nonneoplastic conditions; oncoproteins, which are involved in the regulation of cell cycle and become overexpressed or mutated almost exclusively in neoplastic conditions; and recently discovered patterns of protein expression in serum that appear to be unique to specific types of cancer (i.e., proteomics). This chapter emphasizes the use of the first two classes of tumor marker. The succeeding chapter discusses oncoproteins and the use of multiple protein profiles on body fluids, or proteomics, as biomarkers for early tumor detection.

SERUM MARKERS AS AN EFFECTIVE TOOL FOR DIAGNOSIS AND MONITORING OF CANCER

Ideally, a tumor marker should become elevated in the serum only of patients with a malignant tumor and should not be elevated in the serum of disease-free individuals or of individuals with nonmalignant diseases such as inflammatory or infectious diseases. Also, a tumor marker protein should become elevated in the serum of cancer patients at an early stage, thereby enabling early tumor detection and the initiation of appropriate therapy. Although no one tumor marker has been found to meet all these characteristics, progress toward the discovery of such markers is continuously being made.

In fact, studies show that one or more cancer biomarkers including DNA, protein, or tumor cells is almost always present in the serum of patients with cancer. These findings provide the rational basis for early detection of cancer using serum samples. Any circulating cell products including DNA, RNA (including microRNA), proteins (enzymes, serum proteins, metabolites, receptors, carcinoembryonic proteins, oncoprotein, and proteins encoded by suppressor genes), and tumor cells can be used as tumor markers if they are associated with events related to tumor formation and/or growth (Fig. 73-1). Such events include malignant

transformation, proliferation, dedifferentiation, and metastasis. The blood levels of serum tumor markers are determined by tumor proliferation, tumor volume, proteolytic activities in the tumor cell, and release from necrotic tumor cells. The recent improvement of instrumentation, especially in consolidation of specialized testing instruments as immunoassay analyzers to a more general chemistry analyzer, facilitated the analysis of a wide range of analytes with the same degree of accuracy, specificity, and precision. The improved sensitivities of the assays made serologic tests far superior to other clinical examinations based on physical methods. An additional advantage of serum testing over tissue-based methods is the noninvasive nature, more accurate quantification, and lack of interobserver difference as opposed to tissue-based methods. Because of these benefits, serum markers are frequently used to screen for, diagnose, and predict the behavior of many cancers.

The clinical value of any given tumor marker will depend on its specificity and sensitivity as well as its intended clinical use. For example, PSA can be used in the screening of prostate cancer, resulting in early detection and treatment. Serum HER2/*neu* is used as marker of prognosis and monitoring therapy for breast cancer. The difference in their usefulness is due to their difference in tissue specificity and cancer sensitivity: PSA is organ-specific but not cancer-specific, whereas HER2/*neu* is cancer-specific but not tissue-specific and is found to be increased in breast cancers, as well as lung and other epithelial cell tumors. The use of tumor markers as prognostic and risk factors has gained more popularity in recent years. Measurement of the level of risk factors has been found to be valuable in the assessment of the aggressiveness of a tumor and is helpful selecting treatment strategies. The utility of tumor markers is adjunctive to medical and surgical management of malignancies, serving to help detect recurrences as well as predict prognosis.

FUNCTIONAL CLASSIFICATION OF TUMOR MARKERS

To learn how to identify, select, and utilize tumor markers for the diagnosis of cancer and the management of cancer patients, it is essential to be familiar with the function of each individual or group of cancer serum markers. This chapter emphasizes the role of three specific classes of tumor marker that are commonly used in the diagnosis of human malignancies: (1) oncofetal antigens, such as α -fetoprotein (AFP) and carcinoembryonic antigen (CEA), which are normally expressed during fetal development but do not occur normally in the tissues or sera of children and adults; (2) proteins occurring in epithelial cells that become elevated in tissue and serum in adenocarcinomas and squamous cell carcinomas, such as the CA 19-9, CA 125, and CA 15-3 proteins; and (3) polypeptide hormones, such as the β chain of human chorionic gonadotropin (β hCG), and specific enzymes, such as the placental isoform of alkaline phosphatase (ALP), that become elevated in the serum of patients with specific tumors. These latter two tumor markers are frequently elevated in the sera of patients with germ cell tumors. Additionally, hormone-like proteins are found in the sera of patients with different cancers, such as parathyroid hormone-like protein that induces hypercalcemia as part of the so-called paraneoplastic syndrome in such cancers as renal cell carcinomas.

Most of these proteins have been discovered on the basis of their having been observed in the sera of cohorts of patients with specific types of cancer. However, many of them are also found in the sera of patients with nonmalignant (e.g., inflammatory) conditions. In addition, they may not occur in significant numbers of patients in whom these cancers have been diagnosed. Thus the sensitivities and specificities of these tumor marker proteins are often low, resulting in their not being useful for screening purposes. On the other hand, all these proteins are quite useful for *monitoring* specific cancers. For example, CEA is often elevated in the sera of patients with colon cancer. Thus if CEA serum levels are found to be elevated in patients who have had a colon cancer resected, this is evidence of tumor recurrence. As discussed later, the one exception is PSA, a chymotrypsin-like enzyme that occurs almost uniquely in the prostate gland and has proved exceptionally useful in screening for prostate cancer and in monitoring patients who are being treated for this disease.

Standard assays for all these proteins are now well-developed and have received approval from the US Food and Drug Administration (FDA) for use in the monitoring of treatment of known cancers but not, except for PSA, for screening for human cancers. Investigations are currently focused on searching for proteins that are expressed only in cancer cells (see

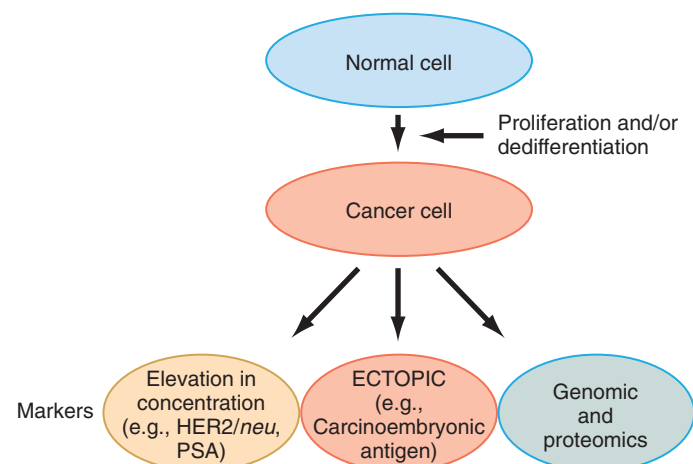

Figure 73-1 Different types of serum tumor marker are used to detect cancer. HER2 and prostate-specific antigen (PSA) reflect increased cellular proliferation. Carcinoembryonic antigen represents dedifferentiation process of cancer. Current genomic and proteomics focus on collective changes in malignant cells.

Chapter 74). This chapter summarizes some of the more recently discovered proteins that are almost always expressed in cancerous but less commonly in non-cancerous diseases and are promising for screening for the occurrence of cancer and for monitoring therapy.

ONCOPROTEINS ARE MARKERS FOR CELL PROLIFERATION

Oncoproteins are proteins that are directly or indirectly involved in the control of mitosis and are altered such that they continuously signal the cell to divide. These proteins either lie on signal transduction pathways carrying mitogenic signals from growth factors at the cell membrane to the nucleus, or are involved in the regulation of transcription, activating the genes ultimately causing cell growth and mitosis (see Chapter 74). For example, as discussed in Chapter 74, HER2/Neu is a transmembrane receptor with an extracellular domain (ECD), a transmembrane domain, and an intracytoplasmic domain containing a tyrosine kinase. Upon binding of extracellular growth factors, the intracellular kinase becomes activated, causing dimerization of the receptor and interaction with a cytosolic adapter protein, Grb-2, to relay the message next to a guanine nucleotide exchange factor, SOS. SOS, in turn, binds to the critically important protein Ras-p21 (Barbacid, 1987). Oncogenic c-Myc is an example of a different type of oncogene transcriptional factor, which functions via the activation of its target genes, inducing synthesis of mitogenic proteins.

Often these proteins can be detected in the serum of patients with abnormal cell growth (i.e., cancer or precancerous states). Extensive testing for the presence of oncoproteins has revealed that many oncoproteins are detected in the serum and/or other body fluids of cancer patients. A detailed discussion of each oncoprotein is found in Chapter 74.

TUMOR SUPPRESSORS/CELL DIFFERENTIATION

Separate from oncogenes but equally important is a group of suppressor genes. Proteins encoded by suppressor genes are responsible for suppressing cell growth, either causing cell growth arrest in cell cycle or apoptosis. Frequently, these suppressor genes undergo deletions or mutations, resulting in the production of inactive gene products. Among the tumor suppressor genes, the antioncogene protein p53 has been widely investigated and best characterized for its role in various cancers. It is involved in apoptosis, cell cycle arrest, cell senescence, and DNA damage response. Deletions or mutations of the p53 gene greatly predispose cells to undergoing malignant transformation. p53 mutations have been identified in nearly 50% of human malignancies (Soussi, 2001). Molecular assays are available to detect mutations in the serum DNA of tumor suppressor genes. In addition, antibodies against the abnormal tumor suppressor proteins can be used as a biomarker for cancer.

Molecular methods such as PCR-SSCP (polymerase chain reaction single strand conformation polymorphism) and DHPLC (denaturing high-performance liquid chromatography) have been described to detect serum p53 mutations in cancer. More significantly, antibodies against the abnormal tumor suppressor p53 proteins have been detected in the serum of cancer patients (Soussi, 2000). Interestingly, the presence of p53 antibodies is correlated with the p53 mutation (Guinee, 1995; Hammel, 1999). In breast cancer, several studies indicated that the presence of p53 Ab in the serum correlated with increased proliferation antigen (Ki-67) and lack of ER expression, indicating that it may serve as a breast cancer prognostic marker (Schlichtholz, 1992; Sangrajang, 2003).

The discovery of two breast cancer susceptibility genes (or tumor-suppressor genes), *BRCA1* and *BRCA2*, have generated tremendous interest. Studies suggest that mutations in *BRCA1* are responsible for approximately half of all cases of inherited breast cancer (Easton, 1993; Miki, 1994; Wooster, 1994). In addition, carriers of *BRCA1* mutations are also at an increased risk for ovarian, colon, and prostate cancer (Futreal, 1994). *BRCA2*, the second susceptibility gene for breast cancer, is thought to account for approximately 70% of cases of inherited breast cancer that are not due to *BRCA1* mutations and is associated with an increased risk of breast cancer in men.

The suppressor genes and their products are potentially useful as tumor markers for the screening and identification of families or high-risk individuals. Development of immunoassays to measure both *BRCA1*- and

BRCA2-encoded proteins are under development and may be useful for the identification of high-risk individuals and their families.

ADHESION MOLECULES AND METASTASIS

Tumor metastases involve several major steps (Liotta, 1987). First, the tumor cells have to penetrate their adjacent surroundings, after which they invade vascular or lymphatic vessels. The tumor cells are then carried to distant sites, until they are lodged in the venous or capillary beds of a distant organ. In this new environment, these tumor cells must again penetrate the vascular walls in order to grow at the distant site. Cell adhesion molecules, including integrins, selectins, cadherins, and cell adhesion molecules of immunoglobulin gene families, regulate many steps of the metastatic process. The changes in their levels of expression reflect the malignant behavior of cancer cells. For example, increased serum levels of E-selectin, intercellular adhesion molecule (ICAM), and vascular cell adhesion molecule (VCAM) are increased, in particular, in late-stage breast cancer patients (O'Hanlon, 2002; Sheen-Chen, 2004). Elevated serum VCAM level may be used to predict a shorter survival. Another study indicated that postchemotherapeutic levels of serum E-selectin and ICAM are associated with a response to treatment of patients with Hodgkin disease (Syrgos, 2004). Furthermore, increased E-selectin, ICAM-1, and VCAM are suggested to be a prognostic factor for patient survival in patients with gastric cancer (Alexiou, 2003). Therefore the appearance of these cell adhesion molecules in blood circulation might indicate the risk or occurrence of metastases or a poor prognosis.

OTHER MARKERS

Many hormones (e.g., hCG, epinephrine, dopamine, and serotonin), serum proteins, enzymes (lactate dehydrogenase, ALP) and their metabolites, such as the metabolites of the neuroendocrine hormones (e.g., vanillylmandelic acid, homovanillic acid, and 5-hydroxyindoleacetic acid), may become elevated in tumors because of the high proliferation rate of tumor cells. Their serum levels rise to even higher levels when a benign tumor becomes malignant and metastasizes. Benign and nonmalignant diseases may also involve elevated levels of markers, so these markers are not suitable for screening or for cancer diagnosis because of the large numbers of false-positive results that would be generated. These markers are more appropriately used for monitoring patient response during treatment.

One exception relates to the enzyme alkaline phosphatase (ALP) discussed in Chapter 20. There are multiple isozymes of this enzyme, one of which is the placental isozyme placental ALP (PLAP). This form becomes elevated in the serum of patients who have germ cell tumors. One particular use of PLAP is in the serum or, more effectively, in the cerebrospinal fluid (CSF) of patients with a mass in the pineal region with a differential diagnosis of germ cell tumor vs. pinealoma. If PLAP is elevated in the CSF of a patient with a mass in the pineal area, a diagnosis of germ cell tumor can be made. As it happens, radiation therapy is curative, obviating the need for surgery.

The enzymatic activities of various tissue-specific glycosyltransferases are altered in tumor cells. Some of the elevated glycosyltransferases have been used as tumor markers. The sugar sequence and composition of the carbohydrate moiety of many serum glycoproteins, including blood group substances and mucins, such as CA 19-9, are tumor markers resulting from altered glycosyltransferase activity. The AFP isolated from patients with primary hepatocellular carcinoma has an additional fucose compared with the AFP from benign liver disease, an example of altered fucosyltransferase in hepatocellular carcinoma cells (Wu, 1990).

Ectopic proteins are often expressed in cancer. Carcinoembryonic proteins, which are detectable in both fetal and tumor tissues but not in normal adult tissues, usually lack any known physiologic function and have blood concentrations at nanogram-per-milliliter levels. Therefore measurements of carcinoembryonic proteins in the circulation must rely on immunoassays. The specificity and sensitivity associated with these proteins, although not 100%, are much higher than those of enzymes and metabolites that have been used as tumor markers in the past. The serum concentration of these carcinoembryonic proteins not only correlates well with tumor activity but can also be used to predict prognosis. However, carcinoembryonic proteins in general are not suitable for screening for the following reasons. First, the polyclonal antibodies directed against these proteins often cross-react with other, normal proteins, and second, these carcinoembryonic proteins do not appear sufficiently early in the blood from cancer patients

to detect the tumors at early stages. However, they have been used as adjunct tests for cancer diagnosis and are extremely useful for monitoring the success of treatment and for detecting recurrence.

MONOCLONAL-ANTIBODY-DEFINED TUMOR MARKERS

The development of hybridoma technology has greatly impacted the identification of tumor markers (Milstein, 1983). Rather than dealing with a whole molecule of known protein structure, it is now possible to focus on only a small surface area, an epitope or antigenic determinant using monoclonal antibodies. It is no longer necessary to purify the antigen for the preparation of polyclonal antibodies in animals. The complete characterization and identification of the molecule carrying the epitope is also no longer needed. A hybridoma can be prepared by injecting a mouse with an enriched fraction of the tumor cell membrane or the whole tumor cell. Hybridomas producing the monoclonal antibodies of interest are selected through the subsequent screening procedure, as described in Section 6. Once a hybridoma is established, there will be an unlimited and consistent supply of monoclonal antibody (MAb) for various uses.

By combining the MAbs with the solid-phase sandwich test design, new assays have been developed that have eliminated many problems associated with polyclonal assays, involving poor reproducibility, lot-to-lot variations, poor specificity, and nonspecific crossreactivity (Diamond, 1981). It also reduces the differences between different kits and widens the linear concentration range for the assay. Whenever an MAb is available, its use is recommended. To achieve higher test sensitivity, the use of a combination of multiple MAbs has been found to improve the affinity between solid-phase-absorbed-multiple MAbs and the soluble antigen.

Tests for the MAb-defined tumor markers have been demonstrated to have a higher sensitivity and specificity than those using polyclonal antibodies. For example, CA 19-9, CA 125, and CA 15-3 are much more sensitive and specific than CEA for pancreatic, ovarian, and breast carcinomas, respectively. These markers are recommended to replace the polyclonal CEA test for the diagnosis and management of patients with the above-mentioned carcinomas. Various tumor markers derived from different tumors also share many tumor-associated epitopes. For example, CA 19-9, CA 15-3, and CA 125 are expressed by almost all carcinomas in varying degrees. In addition to the sharing of any given epitope by more than one carcinoma, it is also possible for a single molecule to express more than one epitope (Yu, 1991). For example, it is likely that CA 15-3 and CA 125 are expressed by the same mucin molecule.

CLINICAL APPLICATIONS

The serum tumor markers are currently used for screening, diagnosing, and predicting prognosis and treatment response. Use of tests for screening of disease, even those with high sensitivity and specificity, should be confined as much as possible to populations at risk for the disease. This is because the positive predictive value depends on the prevalence of the disease. Because most of the tumor markers described in this chapter are expressed both in neoplastic and benign conditions, their use is confined to following possible tumor recurrence in patients being treated for specific types of tumor.

SCREENING

The recommendation of screening for prostate cancer by the measurement of serum PSA in combination with a digital rectal examination (DRE) in men older than age 50 years is due to the high tissue specificity of PSA (Wu, 1994) and the high prevalence of prostate cancer. Combination of the PSA test and DRE provides the least costly approach to the early detection of prostate cancer (Littrup, 1993). PSA screening is especially recommended for African American men because the incidence of prostate cancer for African Americans is nearly twice that of the general population and the death rate is up to three times higher. Screening permits the treatment of organ-confined, potentially curable prostate cancer discovered in men with a life expectancy of longer than 10 years.

Although not approved for screening for hepatocellular carcinoma in the United States, AFP has been used to screen for primary hepatocellular carcinoma in China because of the high incidence of liver cancer in that country. The diagnosis of ovarian cancer has traditionally relied on imaging and discovery at surgery (e.g., exploratory laparotomy). However, in most cases, at the time of detection, the tumor has advanced to a stage at which

the possibility of cure is low. The feasibility of screening for ovarian cancer in women by measuring serum CA 125 is being investigated.

DIAGNOSIS

Several approaches have been suggested recently to improve the diagnostic yield of many tumor markers. The use of multiple markers is one approach that has received wide acceptance. As is also noted in Chapter 74, specific patterns of multiple tumor markers seem to be associated with individual malignant diseases. Another approach to improving both the specificity and sensitivity of a tumor markers, as in the case of serum PSA test, involves the measurement of the velocity (the rate of increase in PSA concentration over time) and the density (e.g., by dividing the serum PSA concentration by the volume of the prostate gland, determined by transrectal ultrasound) (Benson, 1992). These efforts aim at a better discrimination between benign and malignant states. For example, a mildly elevated serum PSA level associated with a small prostate gland may indicate cancer, whereas the same PSA value in a patient with a large gland may indicate benign prostatic hypertrophy (BPH).

PROGNOSIS: RECURRENCE, METASTASIS, AND SURVIVAL

The assessment of tumor aggressiveness and the prognosis for the outcome of a cancer patient has received much attention in recent years. The knowledge of tumor aggressiveness helps in the development of a proper therapy for the patient. For example, the detection of tumor markers, highly associated with malignancy and metastases, will suggest a more rigorous and systemic treatment. Monitoring tumor markers for the detection of recurrence following the surgical removal of the tumor is the secondmost useful application of tumor markers. It is well known that the appearance of most of the circulating tumor markers has a lead time of several months (3–6 months) before the stage at which many of the physical procedures could be used for the detection of cancer. The specificity of tumor markers does not present a problem for this application. The ease of drawing blood and the sensitivity of tumor marker tests make this noninvasive monitoring process now widely accepted.

Most tumor markers become increasingly elevated when the tumor metastasizes. Very few tumor markers have a clear-cut boundary between benign and malignant stages. Proteins that reflect the risk factors associated with the process of tumor metastases, such as proteases and adhesion molecules, are usually better markers for predicting prognosis. However, most of these markers are still measured in tumor tissues and tissue lysates. The finding of the ECD of *c-erbB-2* protein in the serum of cancer patients (Fig. 73-2) and the correlation of the serum ECD with the levels of other

Figure 73-2 HER2/*neu* monoclonal antibodies are used both therapeutically and diagnostically in breast cancer. Humanized HER2 monoclonal antibody trastuzumab (Herceptin), shown with a dark blue complementarity determining region (CDR), reacts with a specific region of HER2 epitope (dark blue), causes the death of malignant breast cells, and is often effective in the treatment of breast cancer. On the other hand, different monoclonal antibodies, which do not crossreact with the trastuzumab determinant, recognize the extracellular domain (ECD) (orange-colored domain in the figure) of HER2/*neu* in serum after it is cleaved off this growth factor receptor by metalloprotease. Because trastuzumab and diagnostic monoclonal antibodies recognize different epitopes of HER2, there is no interference in detecting serum levels of HER2 in trastuzumab-treated patients. M, Cell membrane; MP, metalloprotease; TKD, tyrosine kinase domain

serum tumor markers is encouraging. Another area of intensive study is to explore the use of serum marker surrogates in the prediction of cancer patient survival.

MONITORING TREATMENT RESPONSE

One of the most useful applications of tumor markers involves monitoring the course of the disease, especially during treatment. The serum level of tumor markers reflects the success of surgery or the efficacy of chemotherapy. Detecting elevated levels of a tumor marker after surgery would indicate either incomplete removal of the tumor, recurrence, or the presence of metastases. The measurement of serum tumor markers during chemotherapy also gives an indication of the effectiveness of the antitumor drug used and a guide for the selection of the most effective drug for each individual case.

RECOMMENDATIONS FOR ORDERING TUMOR MARKER TESTS

When ordering tumor markers as an adjunct diagnostic test for managing cancer patients, the following recommendations should be kept in mind in order to avoid misinterpretation of the test results.

1. Never rely on the result of a single test. Because of low specificity associated with most tumor markers, it is difficult to differentiate between malignant and benign diseases on the basis of the result of a single test result. Most tumor marker elevations found in nonmalignant diseases may be transient, whereas with cancer the level often either remains elevated or rises continuously. Ordering serial testing can help detect falsely elevated levels due to transient elevation. For example, elevated serum AFP can be detected in patients with either primary hepatocellular carcinoma or benign liver disease. However, on a subsequent testing 2 weeks later, the serum AFP will remain elevated in patients with cancer, whereas in patients with benign conditions the serum AFP may return to normal levels.
2. When ordering serial testing, be certain to order every test from the same laboratory using the same assay kit. Each different commercial kit may generate different results even though all are designed for the same tumor marker. Ordering from the same laboratory also ensures a more consistent performance. It is important to ensure that any change observed during the monitoring process is due to a change of tumor volume or other tumor activities and not to laboratory variability.
3. Be certain that the tumor marker selected for monitoring recurrence was elevated in the patient before surgery. Because none of the tumor markers are 100% sensitive to the detection of any particular cancer, it is important to be certain that the tumor marker ordered to detect recurrence was elevated before surgery. Otherwise, multiple markers should be measured before the surgery in order to select the tumor marker showing the highest elevation as the marker for monitoring the disease activity. Multiple markers may be used to monitor the therapeutic effects for increased sensitivity.
4. Consider the half-life of the tumor marker when interpreting the test result. Before surgery, estimate the time required for the level to decline to the normal or, in the case of PSA, to an undetectable level, based on the known half-life of the tumor marker. It is important that the success of surgical removal of a tumor as determined by tumor marker concentrations is not assessed earlier than 2 weeks postoperatively. If possible, it is preferable to wait one whole month to allow the preexisting tumor marker in the serum adequate time to decline to lower levels. For example, the half-life of serum PSA is approximately 3–4 days. Therefore it takes 30 days for a serum PSA at 50 ng/mL to drop to an undetectable level following successful surgery.
5. Consider how the tumor marker is removed from or metabolized in the blood circulation. Elevated serum tumor markers are frequently detected in patients with renal or liver disease, depending on whether the tumor marker is removed through the kidney or metabolized by the liver. For example, serum CEA is often elevated in patients with liver disease because the impaired liver fails to remove CEA efficiently from the blood circulation, whereas an elevated serum β_2 -microglobulin (β_2 M) has been frequently found in patients with renal failure in which even the small β_2 M molecule has difficulty passing through the glomerular membrane in a normal fashion.

TABLE 73-1
Monoclonal-Antibody-Defined Tumor Markers

Tumor marker	Major malignant disease
CA125	Ovarian carcinoma
CA19-9	Pancreatic carcinoma
CA15-3	Breast carcinoma
CA72-4	Gastric carcinoma
HER2/neu	Breast carcinoma

6. Consider ordering multiple markers to improve both the sensitivity and the specificity for diagnosis. Tumors are made of heterogeneous types of cells. Some may still be normal while others may be heterogeneous tumor cells as a result of different sequences of multiple mutations. Each type of cell may express a single marker, such as those shown in Table 73-1, or a number of characteristic tumor markers. The same marker may also be produced by different types of cells. Some cells may never produce any unique marker. Certain types of cancer are heterogeneous in their cellular composition. Consequently, more than one tumor marker may be required to provide a high sensitivity of detection. The heterogeneity in cell composition and the percentage cell distribution of each tumor explains why a number of tumor markers may be required to reach a high (>90%) detection sensitivity and the reason that the sensitivity of an individual marker differs among cancer patients. Multiple tumor markers associated with individual malignant diseases are listed in Table 73-2; the appearance of individual tumor markers in various malignancies is listed in Table 73-3. This explains why none of the tumor markers presently employed are 100% sensitive and specific, and why the use of multiple markers will improve the sensitivity of detection. However, a unique pattern of multiple markers may be identified with tumors derived from the same tissues. Therefore ordering multiple tumor markers may also improve the test specificity. For example, a specific pattern seems to be associated with colon, breast, ovarian, and pancreatic carcinomas when all four MAB-defined tumor markers—CEA, CA 19-9, CA 15-3, and CA 125—are measured simultaneously. This information is clinically important, because more than 60% of diagnosed human cancers are epithelial-cell-derived carcinomas (Wu, 1989). Multiple markers were used to develop a more specific screening strategy for ovarian cancer. The use of CA 15-3 and CA72-4 in combination with CA 125 can increase the apparent specificity of the CA 125 assay for distinguishing malignant from benign ovarian disease (Bast, 1991). Another example is the combination of CEA, CA19-9, and CA72-4. Use of this combination improves the diagnostic accuracy of gastrointestinal cancers (Carpelan-Holmstrom, 2002). During the selection of multiple tumor markers, only markers that are complementary to each other should be selected. Many tumor markers, which run parallel to each other when correlated with tumor activities, should not be selected for this purpose.
 7. Be aware of the presence of ectopic tumor markers. The expression of tumor markers is under genetic regulation. For benign tumors, there are often proteins produced by the tumor that are cell-specific and are related to normal cell products at an elevated concentration (see Fig. 73-1). However, if a benign tumor becomes malignant, synthesis of these cell-specific proteins may no longer occur in the malignant cells. Conversely, proteins that are normally found at an early fetal stage and not in normal cells or in benign tumors of these cells may become constitutively expressed in the malignant cells. This is the reason that carcinoembryonic proteins and ectopic tumor markers are usually expressed in malignant cancers, often at advanced stages. Thus, often, the appearance of ectopic tumor markers is associated with poor prognosis or metastasis. For example, elevated serum concentrations of AFP may be detected in patients with cancers of the gastrointestinal tract involving metastases even though the liver function tests are normal. Table 73-4 lists some of the known ectopic markers and their associated malignant diseases.
- One should be aware of the recent guidelines on gastrointestinal and breast cancer marker use published by the American Society of Clinical Oncology (Smith, 1999). They recommend monthly breast self-examination, annual mammography of the preserved and contralateral breast, and a careful history and physical examination every 3–6 months for 3 years, then every 6–12 months for 2 years, and

TABLE 73-2

Serologic Tumor Markers Associated with Individual Malignant Diseases

Malignant disease	Major marker	Other markers
Neuronal Tumors		
Brain tumor	Desmosterol	Polyamines
Neuroblastoma	VMA	HVA, NSE, cystathionine, ferritin, metanephrines
Head and Neck Tumors		
Squamous cell carcinoma	CYFRA 21-1	
Endocrine System		
Pituitary tumors	Growth hormone	IGF-I
Adrenal pituitary tumors	Cortisol	Free catecholamines, DHEA, 17-ketosteroids, prolactin
Cushing syndrome	ACTH	Endorphin, lipotropin
Hypercalcemia of malignancy	PTH-related peptide	
Endocrine pancreatic tumors:	Pancreatic polypeptide:	Chromogranin AC-peptide, IGF-I binding protein I
Gastrinoma	Gastrin	
Glucagonoma	Glucagon	
Insulinoma	Insulin	
Medullary carcinoma of thyroid	Calcitonin	NSE
Microadenomas (pituitary)	Prolactin	
Multiple endocrine neoplasias	Chromogranin A	
Papillary and follicular thyroid cancer	Thyroglobulin	
Parathyroid tumors	PTH-intact	
Zollinger–Ellison syndrome	Gastrin	
Pheochromocytoma	Metanephrine	Chromogranin A, plasma catecholamines
Pituitary tumors	Free β hCG	FSH, LH, prolactin, TSH
Bone and Skeletal Muscle System		
Osteosarcomas	Alkaline phosphatase	
Breast Cancer		
Breast cancer	HER2/ <i>neu</i> , CA 15-3	CYFRA 21-1, CEA, calcitonin
Pulmonary System		
Bronchogenic carcinoma	Prolactin	
Lung cancer (NSC)	CYFRA 21-1, NSE	ACTH, CK-BB, calcitonin, CA 72-4, CEA, AFP, Ferritin, LASA-P, TPA
Carcinoid tumors	Histamine, ADH, bradykinin	
Oat cell cancer	ACTH, ADH, CEA, CK-BB, NSE, bombesin, calcitonin	
Gastrointestinal System		
Colorectal cancer	CEA	CA 19-5, CA 19-9, CA 72-4, NSE
Gastric carcinoma	CA 72-4	CA 19-9, CA 50, CEA, ferritin, CK-BB, hCG, LASA-P, pepsinogen II
Hepatocellular carcinoma	AFP	CEA, ferritin, ALP, TPA, γ -glutamyltranspeptidase (GGT)
Pancreatic carcinoma	CA 19-9	CA 19-5, CA 50, CA 72-4, CEA, CK-BB, ADH, ALP
Vipoma (pancreas)	VIP	
Genitourinary System		
Bladder cancer	T-antigen, urokinase inhibitor, TPA, cytokeratins	Glycosaminoglycans, uroplakins
Nonseminomatous testicular tumor	AFP	hCG
Prostate carcinoma	PSA	PAP, racemase
Renal cell carcinoma	Renin, erythropoietin, IL-4, PGA	
Testicular cancer	hCG	PLAP, Oct3/4
Gynecological Tumors		
Cervical cancer	SCC	CA 125, CEA, TPA
Ovarian carcinoma	CA 125	UGF, inhibin, AFP, amylase isoenzyme, CEA, CK-BB, hCG
Choriocarcinoma	hCG	
Placental tumors	hCG	Free α hCG, CA 15-3, PTH, NSE, prolactin
Uterine cancer	SCC	
Teratoblastoma	AFP	hCG, ferritin
Hematology Malignancies and Lymphomas		
B-cell chronic lymphocytic leukemia	TdT	Serum β_2 M, LASA-P
B-cell malignancies	β_2 M	
Multiple Myeloma	Bence-Jones protein	β_2 M
Chronic myelogenous leukemia	TdT	
Hairy cell leukemia	IL-2 receptor	
Hodgkin disease	LASA-P, ferritin	
Leukemia	TdT	ALP, β_2 M, ferritin, LD, myelin basic protein, adenosine deaminase, PNP

TABLE 73-2

Serologic Tumor Markers Associated with Individual Malignant Diseases—*Cont'd*

Malignant disease	Major marker	Other markers
Lymphoma	β_2 M	TdT, Ki-67, LASA-P
Multiple myeloma	Ig heavy and light chain	Bence-Jones protein, β_2 M, IgA
Waldenström's disease	IgM	β_2 M
Melanoma		
Melanoma antigen	Melanoma-associated LASA-P, L-dopa	C-reactive protein
Endoreticular System		
Spleen tumors	Ferritin	
Other		
Sarcoma	β_2 M	

ACTH, Adrenocorticotrophic hormone; *ADH*, antidiuretic hormone; *AFP*, α -fetoprotein; *ALP*, alkaline phosphatase; β_2 M, β_2 -microglobulin; *CEA*, carcinoembryonic antigen; *CK-BB*, brain isozyme of creatine phosphokinase; *CYFRA 21-1*, cytokeratin subunit 19; *DHEA*, dihydroepiandrosterone; *FSH*, follicle-stimulating hormone; *hCG*, human chorionic gonadotropin; *HVA*, homovanillic acid; *Ig*, immunoglobulin; *IGF*, insulin-like growth factor; *IL*, interleukin; *ki67*, cell proliferation marker; *LASA-P*, lipid-associated sialic acid in plasma; *LD*, lactate dehydrogenase; *LH*, luteinizing hormone; *NSC*, nonsmall cell; *NSE*, neuron-specific enolase; *Oct3/4*, transcription factor in stem cells and germ cells required for pluripotency; *PAP*, prostate acid phosphatase; *PGA*, prostaglandin A; *PLAP*, placental alkaline phosphatase; *PNP*, purine nucleotide phosphorylase; *PTH*, parathyroid hormone; *SCC*, squamous cell carcinoma; *TdT*, terminal deoxynucleotide transferase; *TPA*, tissue plasminogen activator; *TSH*, thyroid-stimulating hormone; *UGF*, uterine growth factor; *VIP*, vasoactive intestinal polypeptide; *VMA*, vanillylmandelic acid.

TABLE 73-3

Malignant Disease Associated with Individual Serologic Tumor Markers

Tumor marker	ASSOCIATED MALIGNANT DISEASE	
	Major disease	Minor disease
α -Fetoprotein	Primary hepatocellular carcinoma	Teratoblastomas of the ovary and testes
β hCG	Pituitary tumors	
β_2 -Microglobulin	B-cell neoplasias	Multiple myeloma, B-cell lymphoma, B-cell chronic lymphocytic leukemia and reticulum cell, sarcoma; Waldenström's macroglobulinemia
β hCG	Choriocarcinoma	Testicular cancers (nonseminomatous), trophoblastic tumors
Bence-Jones protein	Multiple myeloma	
Bombesin	Oat-cell cancer	
C-reactive protein	Melanoma	
CA 15-3	Breast cancer	Various carcinomas
CA 19-9	Pancreatic and gastric carcinoma	Various carcinomas
CA 72-4	Gastric carcinoma	Various carcinomas
CA 125	Ovarian carcinoma	Various carcinomas
CA 549	Breast cancer	
CA M26	Breast cancer	
Calcitonin	Medullary carcinoma	Cancer of the thyroid, liver cancer, renal cancer
Carcinoembryonic antigen	Colorectal carcinoma	Various carcinomas
c-erbB-2 oncoprotein	Breast carcinoma	Various carcinomas
Chromogranin A	Pheochromocytoma, neuroblastoma	Multiple endocrine neoplasias, small cell lung cancer, carcinoid tumors
CYFRA 21-1	Squamous cell carcinoma of the lung	
DHEA	Adrenal/pituitary cancer	
Ferritin	Acute myelocytic leukemia	Hodgkin lymphoma, neuroblastoma and various carcinomas, teratoblastoma
Galactosyltransferase	Ovarian cancer	
Galactosyltransferase isoenzyme II	Pancreatic cancer	
Gastrin	Gastrinoma	Zollinger-Ellison syndrome
Her2/neu	See c-erbB-2 oncoprotein	
Human chorionic gonadotropin	Choriocarcinoma	Gastric, ovarian, and breast carcinoma, trophoblastic or germ cell tumors, testicular cancer
Hyaluronic acid	Mesothelioma	
Immunoglobulin A	Multiple myeloma	
Insulin-like growth factor-I	Pituitary cancer	Insulinoma
Interleukin-2 receptor	Leukemia	
Immunoglobulins	Multiple myeloma	Mediterranean lymphoma, Waldenström's macroglobulinemia, malignant lymphoma
Inhibin	Granulosa-cell tumors	
17-ketosteroids	Adrenal/pituitary cancer	

β hCG, β chain of human chorionic gonadotropin; *CYFRA 21-1*, cytokeratin subunit 19; *DHEA*, dihydroepiandrosterone; *hCG*, human chorionic gonadotropin.

TABLE 73-4

Ectopic Tumor Markers

Marker	Tumor
α -Fetoprotein	Gastrointestinal, renal, bladder, and ovarian carcinoma
Calcitonin	Endocrine tumors (islet cell, carcinoid, medullary thyroid, pheochromocytoma); lung, breast, and ovary carcinoma
Chromogranin A	Endocrine tumors (islet cell, carcinoid, medullary thyroid, pheochromocytoma), prostate cancer
Free α hCG	Colorectal carcinoma and pancreatic endocrine tumors
hCG	Gastric and pancreatic carcinoma, hepatoma, ovarian carcinoma, germ cell tumor of testis
PTH	Renal cell carcinoma; breast; squamous cell carcinoma; bladder and ovarian carcinomas
Thyroglobulin	Differentiated thyroid carcinoma

hCG, Human chorionic gonadotropin; PTH, parathyroid hormone.

annually thereafter. They do not recommend the use of tumor markers (e.g., CEA, CA 15-3, and CA 27.29) for screening, nor do they recommend routine bone scans, chest radiographs, hematologic blood counts, liver ultrasonograms, or computed tomography for screening. The American College of Physicians has also published clinical guidelines concerning the early detection of prostate cancer. They emphasize the importance of both screening PSA and performing DRE for the early detection of prostate cancer. Even though DRE is not as sensitive as PSA screening, it can detect cancer that would otherwise be missed by PSA measurement (Coley, 1997a, 1997b).

- Heterophilic antibody. The use of MAbs in immunoassays and the increasing clinical application of mouse MAbs for targeted imaging and immunotherapy create a new problem. Treated individuals apparently produce heterophilic antibodies against murine antibodies that interfere with many of the immunoassays for tumor markers (Nahm, 1990) although this is not a common encounter. The interference by the heterophilic antibodies in human sera can either increase or decrease the results of an immunoassay. These antibodies react in a way similar to antigens in terms of binding to both solid-phase-associated and signal-labeled antibodies. These heterophilic antibodies may bind to a site other than the analyte-binding site, crosslinking the signal antibody with the capture antibody, and thus generating a false assay response. As many as 15%–40% of individuals may have one or more heterophilic antibodies. The standard approach for reducing heterophilic antibody interference is to include in the assay excess mouse sera or nonspecific mouse immunoglobulins in the immunoassay.

INDIVIDUAL TUMOR MARKERS

α -FETOPROTEIN

AFP is a major fetal serum protein and is also one of the major carcinoembryonic proteins. AFP resembles albumin in many physical and chemical properties. In the fetus, AFP is synthesized by the yolk sac and fetal hepatocytes and to a lesser extent by the fetal gastrointestinal tract and kidneys. Elevated AFP can be found in patients with primary hepatocellular carcinoma and yolk sac–derived germ cell tumors (mainly endodermal sinus tumor) and is the most useful serum marker for these cancers (Lamerz, 1997). However, AFP is also transiently elevated during pregnancy and in many benign liver diseases. Because of the high prevalence of liver cancer in China and other countries in Southeast Asia, AFP testing has been used successfully in screening for hepatocellular carcinoma in that region of the world. Tests for both AFP and hCG are helpful in reducing clinical staging errors in patients with some testicular tumors and aid in the differential diagnosis of various germ cell tumors. Because an increase of fucosylation of AFP (hence the lentil lectin reactivity of serum AFP) has been found in primary hepatocellular carcinoma, the determination of lentil lectin reactivity of serum AFP was found helpful not only to differentiate between primary hepatocellular carcinoma and benign liver diseases but also to provide an early signal indicating that hepatocellular carcinoma may begin to develop in patients with liver disease. Although the necessity for routine AFP screening needs further study, one study indicates that combined screening with AFP and ultrasonography results

in increased sensitivity from 75% to near 100% in detecting hepatocellular carcinoma (hCC) of patients with hepatitis B and C (Izzo, 1998; Gebo, 2002). Lastly, AFP is currently offered for prenatal screening for neural tube defects and, in conjunction with free β hCG and unconjugated estriol, for Down syndrome (Cuckle, 2000; Yamamoto, 2001).

ANGIOGENIC FACTORS

Angiogenesis is the formation of blood vessels *in situ*, involving the orderly migration, proliferation, and differentiation of vascular cells. Blood vessel formation is also important in the pathogenesis of rapid growth and metastasis of solid tumors. Several angiogenic factors have been identified including acidic and basic fibroblast growth factor (bFGF), described in Chapter 74, angiogenin and vascular endothelial growth factor (VEGF) (Folkman, 1992). Both angiogenic and antiangiogenic factors have been found in the serum of patients with malignant disease (Morelli, 1998). Serum levels of bFGF and VEGF reflect their expression in individual tumors (Poon, 2003; Granato, 2004). The significance of elevated serum VEGF in cancer patients has been evaluated in several studies including breast, ovarian, hepatocellular, colorectal, and renal cell carcinomas and soft tissue sarcoma. Elevated serum VEGF values in ovarian cancer patients were correlated with cancer differentiation, metastasis, and, more significantly, shorter average survival time (Alvarez Secord, 2004; Harlozinska, 2004; Li, 2004). Furthermore, elevated serum VEGF has been associated with shorter survival in renal cell carcinoma (Ljungberg, 2003) and colon carcinoma (De Vita, 2004).

β_2 -MICROGLOBULIN

β_2 M is the constant light chain of the human histocompatibility locus antigen expressed on the surface of most nucleated cells. The molecular weight of β_2 M is only 11.8 kDa. β_2 M is shed into the extracellular fluid and is elevated not only in solid tumors but also in lymphoproliferative diseases (including B-cell chronic lymphocytic leukemia, non-Hodgkin lymphoma, and, importantly, multiple myeloma) (Wu, 1986). Serum concentration of β_2 M correlates with lymphocyte activity, making β_2 M a good marker for lymphoid malignancies of the B-cell line. It has been used as an indicator of the patient's response to treatment (Haferlach, 1997). CSF levels of β_2 M are useful for detecting metastases in the central nervous system. It is reported that serum β_2 M level is elevated in 75% of patients with multiple myeloma (Kyle, 2003) and is useful in following the efficacy of the treatment of this disease although currently serum free light chain assay has been found to be more effective in following this disease (see Chapter 46).

CARCINOEMBRYONIC ANTIGEN

CEA is a glycoprotein with a molecular weight of approximately 200 kDa. It is the first of the so-called carcinoembryonic proteins and was discovered by Gold and Freedman in 1965 (Gold, 1965). CEA is still the most widely used tumor marker for gastrointestinal cancer, but most CEA assays have replaced polyclonal with monoclonal anti-CEA antibodies.

CEA was originally thought to be a specific marker for colorectal cancer but turned out to be a nonspecific marker on further studies. CEA levels can be elevated in breast, lung, and liver cancers, among others. CEA studies demonstrated that tumor markers could be used to follow patients during therapy and to detect recurrence after successful surgery. The association between highly elevated serum tumor marker concentration and metastases and poor prognosis was also discovered through CEA studies. Elevated CEA levels before resection of colon cancer may suggest a worse prognosis. Declining levels during therapy suggests response to therapy, whereas increasing levels suggest disease progression. However, clinical decisions regarding management of disease cannot be based on CEA levels alone (Mitchell, 1998). As the liver metabolizes CEA, liver damage can impair CEA clearance and lead to increased levels in the blood circulation. Increased CEA concentrations have been observed in some patients following radiation treatment and chemotherapy. It was recommended that CEA should form part of the American Joint Committee on Cancer staging system (Compton, 2000). CEA can be used as a marker for monitoring colorectal cancer (Bast, 2001). However, a low positive predictive value for diagnosis in asymptomatic patients limits its widespread use in screening.

Other genetic tumor markers are becoming used with increased frequency. For example, transforming growth factor- α , fibroblast growth factor, and Ras oncoprotein are all increased in colorectal cancer and decreased after surgical resection. More recently, mutations of DNA mismatch repair genes (e.g., *bMSH2*, *bMLH1*, and *bMSH6*) are shown to be

associated with hereditary nonpolyposis colorectal cancer. Further clinical studies to correlate the serum levels of expression and mutation in these genes might yield a better diagnostic/prognostic tool.

CA 15-3 AND CA 27.29

These antigens correspond to sequences of mucins called polymorphic epithelial mucins (PEMs), which are often overexpressed on the cell surfaces of malignant glandular cells such as occur in breast cancer, and increasing amounts are shed into the circulation where they can be detected, making them useful as tumor markers. The polypeptide core of PEM contains a 69-amino acid cytoplasmic domain and a much larger ECD, consisting of 20 amino acid tandem repeats that vary between individuals, and different alleles of the human *MUC1* gene may code for between 25 and 100 or more tandem repeats. A large part of the molecule is carbohydrate and the degree of glycosylation is variable, making PEM a very heterogeneous in structure (Klee, 2004).

The CA 15-3 determinant is identified by two distinct monoclonal antibodies. The assay uses a solid-phase conjugated MAb, MAb 115D8, to capture the MAM-6 antigen in human plasma, and a labeled MAb DF3 as detecting antibody. MAb 115D8 was prepared against human defatted milk fat globule and MAb DF3 was prepared against the breast carcinoma cell line MCF-7. The CA 15-3 antigen is present in a variety of adenocarcinomas including breast, colon, lung, ovary, and pancreas.

CA 15-3 is a more sensitive and specific marker for monitoring the clinical course of patients with metastatic breast cancer (Canizares, 2001). CA 15-3 levels increase with higher stages of breast cancer stage (Bast, 2001). In addition, CA 15-3 can be used to predict adverse outcomes in breast cancer patients (Gion, 2002; Kumpulainen, 2002; Duffy, 2004). However, the relative low sensitivity (23%) and specificity (69%) (Chan, 2001) in detecting breast cancer has limited its use. CA 15-3 can also be elevated in chronic hepatitis, liver cirrhosis, sarcoidosis, tuberculosis, and systemic lupus erythematosus, and in patients who smoke (Tondini, 1988). CA 27.29, another mucin marker MUC1-associated antigen, is a slightly more sensitive breast cancer marker than CA 15.3. The FDA has approved both CA 15-3 and CA 27.29 for monitoring therapy of advanced or recurrent breast cancer.

CA 19-9, CA 50, AND CA 19-5

CA 19-9 is the first tumor marker of a group of newer epitopes, including CA 125, CA 15-3, and CEA, defined by monoclonal antibodies. These new monoclonal kits detect more newly discovered epitopes and were designed to replace polyclonal CEA measurements for various carcinomas. The assay for CA 19-9 measures a carbohydrate antigenic determinant expressed on a high molecular weight mucin. CA 19-9 is an epitope, defined as sialylated lacto-*N*-fucopentose II, recognized by the MAb 1116NS-199. The molecule, carrying the CA 19-9 epitope, appears as mucin in the sera of cancer patients but as a ganglioside in tumor cells. CA 19-9 is also related to Lewis blood group substances. Only serum antigen from cancer patients belonging to the Le ($a^{-}b^{+}$) or Le ($a^{+}b^{-}$) blood group will be CA 19-9-positive. In addition to CA 19-9, CA 19-5 and CA50 have also been defined by monoclonal antibodies that are only slightly different from CA 19-9. CA 19-9 can be elevated in patients with colorectal cancer, gastric cancer, and pancreatic cancer. The epitope related to CA 50 is very similar to that of CA 19-9 but lacks a fucose residue, the same epitope found in Lewis-negative Le ($a^{-}b^{-}$) individuals. Serum CA 19-9 concentrations not only are frequently highly elevated in both gastric and pancreatic carcinomas but also are useful for monitoring the success of therapy and for detecting recurrence in these cancer patients. However, it has been reported that CA 19-9 and CA 50 complement each other in pancreatic and other carcinomas: their simultaneous use may improve the sensitivity in detecting these malignant diseases. CA 19-5 is detected by mouse MAb CC3C-195 and reacts with both Le^a and sialyl-Le^a epitopes. CC3C-195 binds with high affinity to the sialylated Le^a blood group antigen but exhibits a lower affinity to the nonsialylated form. Elevated serum levels of CA 50 and CA 19-5 can also be found in patients with colon, pancreatic, and hepatocellular carcinomas. False-positive findings may occur in patients with benign liver disease and may be due to cholestasis in these patients (Wu, 1992).

CA 125

CA 125 is another antigenic determinant defined by a MAb and is also associated with a high-molecular-weight (>200 kDa) mucin-like

glycoprotein. CA 125 is expressed by more than 80% of nonmucinous epithelial ovarian carcinomas and is found in most serous, endometrioid, and clear cell carcinomas of the ovary (Jacobs, 1989). However, patients undergoing chemotherapy may show a false decline of CA 125 antigen and a negative result does not always rule out tumor recurrence. CA 125 is also used clinically for follow-up on uterine tumors (>60% are elevated) and benign tumors, including endometriosis. Recent studies showed greatly improved sensitivity of serum CA 125 in combination with other markers using proteomics techniques (discussed in detail in succeeding chapters) (Jacobs, 2004; Lu, 2004; Zhang, 2004). Studies for the application of serum CA 125 in other cancerous (e.g., non-Hodgkin lymphoma, lung cancer) and nonmalignant (e.g., liver cirrhosis) diseases have been performed (Ando, 2003; Xiao, 2003; Zidan, 2004) and showed increased levels of CA 125 in the sera of these patients.

CA 72-4

The CA 72-4 assay detects a mucin-like human adenocarcinoma-associated antigen, TAG-72, which is a high molecular weight (>10⁶ kDa) mucin-like complex molecule. Because the TAG-72 can be detected in both fetal epithelia and sera from patients with various carcinomas, it is also considered to be a carcinoembryonic protein. However, only moderately elevated serum CA 72-4 are found in most carcinomas. Currently, CA 72-4 is considered to be useful marker for the management of patients with gastric and colorectal carcinoma. CA 72-4 has been proposed as a specific marker for tumor occurrence of resectable gastric cancer (Marrelli, 2001) and a prognostic marker for survival (Gaspar, 2001). CA 72-4 has been reported to be an independent prognostic marker for survival in colorectal cancer (Louhimo, 2002) in multivariate analysis together with β hCG and CEA.

CALCITONIN

Calcitonin is one of the circulating peptide hormones that may become elevated in patients with increased bone turnover rate associated with skeletal metastases. Calcitonin can be ectopically elevated in bronchogenic carcinomas and is also elevated in medullary carcinoma of the thyroid (see Table 73-4).

CHROMOGRANIN A

Chromogranin A is a major soluble protein of the chromaffin granule. Chromogranin A and catecholamines are released from the adrenal medulla upon stimulation of the splanchnic nerve. However, chromogranin A is not confined to chromaffin cells of the adrenal medulla and sympathetic neurons. It is also present in various neuroendocrine organs. Elevated serum chromogranin A levels can be detected in pheochromocytoma (Giovannella, 2002), medullary carcinoma of thyroid, and small cell lung carcinoma (Ma, 2003). Interestingly, increased serum chromogranin A levels are detected in epithelial cancers with neuroendocrine differentiation, including prostate, breast, ovary, pancreas, and colon (Wu, 2000).

Prostate cancer with neuroendocrine differentiation has been an active area of study. Higher levels of serum chromogranin A is associated with poorly differentiated prostate cancer (Isshiki, 2002). It is also increased after androgen blockade therapy and systemic radionuclide therapy (Ferrero-Pous, 2001) for prostate cancer. Furthermore, an association between increased chromogranin A and prostate cancer metastasis has been observed (Tarle, 2002). Intermittent androgen deprivation therapy can reduce the levels of chromogranin A, and thus the neuroendocrine differentiation of prostate cancer (Sciarra, 2003).

CYTOKERATIN 19 FRAGMENT

Cytokeratin 19 fragment (CYFRA 21-1) is a fragment of the cytokeratin 19 intermediate filament found in the serum. It is a subunit of a cytokeratin intermediate filament expressed in simple epithelia and their malignant counterparts. Studies of elevated serum CYFRA 21-1 have concentrated on breast cancer and squamous cell carcinoma of the lung. CYFRA 21-1 was reported to have a sensitivity of 60%, 64.2%, and 89% for the detection of stage IV breast cancer, recurrence, and metastasis, respectively. Probability of survival for primary cancer patients, recurrence after surgery and response after chemotherapy were correlated with elevated preoperative serum CYFRA 21-1 in breast cancer patients (Nakata, 2000, 2004). CYFRA 21-1 was also shown to reflect the tumor mass in multiple studies with correlation to tumor stage, survival, predictive role in surgical treatment for early stage disease and chemotherapy for advanced stage

non-small cell lung cancer (NSCLC). In one study of head and neck squamous cell carcinoma (SCC), increased postradiotherapeutic or chemotherapeutic CYFRA 21-1 has been explored as an early indicator for distant metastasis (Kuropakat, 2002). CYFRA 21-1 is not increased in patients with nonneoplastic lung disease including pneumoconiosis and obstructive airway disease (Schneider, 2003).

HUMAN CHORIONIC GONADOTROPIN

hCG, a member of the glycoprotein hormone family, is synthesized and secreted by trophoblast cells of the placenta and is a heterodimeric hormone composed of noncovalently linked α and β subunits internally linked by disulfide bonds. The current assays using monoclonal antibodies are available to detect intact hCG, "nicked" hCG or hCGn (which is partially degraded hCG missing peptide bonds between amino acids 44 and 45 or 47 and 48), hCG α subunit, hCG β subunit and hCG β core (residual hCG β , residues 6–40 joined by disulfide bond to hCG β , residues 55–92) (Berger, 2002; Birken, 2003). Both malignant and nonmalignant trophoblast cells synthesize and secrete not only the biologically active α and β dimer but also the uncombined (or free) α and β subunits. In addition to the intact dimer, a free β subunit of hCG has been detected in the serum of women during early pregnancy and in patients with malignant tumors (see Chapter 25).

Measurement of the free β subunit is useful for the detection of recurrence or metastasis for choriocarcinoma when the intact hCG may remain normal. Analysis of serum hCG subunits is especially useful for managing patients with germ cell tumors (von Eyben, 2003). However, elevated hCG can be found in trophoblastic tumors, choriocarcinoma, and testicular tumors. More than 60% of patients with nonseminomatous germ cell tumors and 10%–30% with seminomas have elevated free β hCG.

Seminomatous testicular cancer contains both intact hCG and β hCG or free α subunits in equal amounts. Therefore only one assay is needed for monitoring these patients. On the other hand, only hCG or β hCG subunits may be found in patients with nonseminomatous cancers. The measurement of both free subunits and intact hCG will increase the test sensitivity for these patients with nonseminomatous cancers.

Ectopic free β hCG production occurs in approximately 30% of patients with other cancers including urothelial cancer, but only the free β hCG and its respective breakdown product, β core, has been detected in these clinical samples. Ectopic α hCG is a marker of malignancy in pancreatic endocrine tumors (Ma, 2003). Recent efforts in preparation of new World Health Organization reference reagent for hCG (HCG, hCG- α , and hCG- β) and its related molecules may decrease the nonspecific reaction and increased accuracy of clinical hCG testing (Bristow, 2005).

HER2/*neu* (*c-erbB-2*) ONCOPROTEIN

The HER2/*neu* (*c-erbB-2*) oncogene is a 185-kDa transmembrane protein of the tyrosine kinase receptor family and is discussed extensively in Chapter 74. It shows structural and functional homology with the epidermal growth factor receptor (EGFR) containing intracellular, transmembrane, and ECDs (see Fig. 73-2). HER2/*neu* has been found to be elevated in the sera of patients with a number of different epithelial cell cancers, including breast cancer (Mori, 1990; Leitzel, 1992; Ali, 2002; Tsigris, 2002). In patients with breast cancer, serum HER2/*neu* is very important as a prognostic and predictive marker. At the time of initial diagnosis, serum HER2/*neu* is elevated in only 5%–10% of breast cancer patients. Increased serum HER2/*neu* before adjuvant therapy has been shown to be associated with increased tumor size, tumor grade, and positive lymph nodes. The serum HER2/*neu* test is indicated for follow-up and monitoring of patients with metastatic breast cancer whose initial serum HER2/*neu* level is greater than 15 ng/mL. Schippinger and colleagues reported that decrease of elevated Serum HER2/*neu* to levels below 15 ng/mL and levels continuously ≤ 15 ng/mL during the course of disease correlated significantly with longer survival (Schippinger, 2004). The serum HER2 level as assessed by the chemiluminescence immunoassay method is the most sensitive marker of HER2-positive metastatic breast cancer compared with the CEA and CA15-3 levels (Kan, 2009). Prechemotherapy and postchemotherapy HER2/*neu* levels could serve as a prognostic marker for disease-free survival and overall survival (Hayes, 2001; Saghatchian, 2004). In addition, serum HER2/*neu* levels correlate with response to chemotherapy, including chemo- and hormonal- as well as Herceptin (Trastuzumab) treatment; higher levels predict incomplete response while low levels suggest longer or complete treatment responses (Colomer, 2000; Harris, 2001; Lipton, 2002; Bethune-Volters, 2004; Luftner, 2004).

Enzyme-linked immunosorbent assay (ELISA) measures the levels of the circulating *c-erbB-2*, referred to as p105 or serum HER2, constituting the ectodomain (see Fig. 73-2). There are currently three FDA-approved ELISA assays for serum circulating HER2 using monoclonal antibodies, one for microtiter plate assay (Oncogene Science/Siemens) and two for automated instrument, BAYER IMMUNO 1 HER2/*neu* ASSAY (Siemens) and ADVIA Centaur Her2/Neu immunoassay (Siemens). The ADVIA Centaur Her2/Neu immunoassay kit is similar to the Bayer/Siemens Immuno 1 Her2/Neu kit in indication for use, format, performance characteristics and results. The ADVIA differs mainly in the signal system, which is chemiluminogenic instead of the ALP-catalyzed color reaction, in the Siemens/ADVIA immuno-1 assay. More importantly, there is no interference with the serum HER2/*neu* test by heterophile antibodies and more significantly the therapeutic MAb trastuzumab because different antigen epitopes are targeted (see Fig. 73-2).

HER2/*neu* is also overexpressed and/or amplified in oral squamous cell carcinoma (Chen, 2007), NSCLC (Papila, 2009), gastric cancer (Tsigris, 2002b), colorectal cancer (Tsigris, 2002a), urothelial carcinoma (Hussain, 2007), prostate cancer (Kehinde, 2008), and ovarian cancers in association with advanced stage and poor prognosis so it can be used as a therapeutic target in these cancers (Agus, 2000).

p53

p53 (see Chapter 74) is a 53-kDa nuclear phosphoprotein and a negative regulator of cell growth. It functions as a tumor suppressor by inducing the expression of gene products that are responsible for inhibiting or arresting cell growth and proliferation. The ability of p53 protein to regulate transcription of its target genes is based on its sequence-specific DNA binding activity and the presence of a domain that can activate transcription when attached to the DNA-binding domain of p53 target protein. It is the DNA-binding domain that appears to be sensitive to disruption by mutation, and most lesions associated with human cancers occur within this domain. The encoding gene for p53 has been found to be mutated in about half of almost all types of cancer arising from a wide spectrum of tissues. Because of its short half-life (20 minutes), the wild-type p53 protein in the blood circulation is not detectable (Malkin, 1990; Harris, 1993). However, current molecular techniques such as PCR/SSCP (detailed in Part 8) can detect serum p53 gene mutations. The presence of p53 antibody in serum facilitated the detection of abnormal p53 serologically. Significantly, the presence of p53 antibody in serum is associated with expression of p53 mutations and positively correlates with the degree of cancer malignancy (discussed in Chapter 74).

PARATHYROID HORMONE-RELATED PEPTIDE

Plasma concentrations of parathyroid hormone-related peptide (PTH-RP) are elevated in the majority of patients with cancer-associated hypercalcemia. PTH-RP is secreted by tumors associated with hypercalcemia. The circulatory forms of PTH-RP in these patients include both a large amino terminal peptide and a carboxyl terminal peptide with close sequence homology to parathyrin (PTH). The mechanism by which PTH-RP induces hypercalcemia involves binding and activating receptors that also bind PTH. Measuring the concentrations of PTH-RPs may be useful in the differential diagnosis of hypercalcemia related to malignancy and associated either with primary hyperparathyroidism, sarcoidosis, vitamin D toxicity, or various malignancies (including squamous cell, renal, bladder, and ovarian carcinomas). Patients with impaired renal function but without hypercalcemia or cancer may have increased plasma concentrations of PTH-RP (Burtis, 1990).

SERUM AND URINE MARKERS FOR PROSTATE CANCER

Serum Prostate-Specific Antigen

PSA is a member of the kallikrein family of serine proteases that is synthesized uniquely in the epithelial cells of the prostate gland. Its expression in these cells is regulated by the androgen receptor. Because of its high degree of tissue specificity, it is perhaps the most widely used tumor marker discovered thus far. The normal reference range is 0–4 ng/mL. The cancer sensitivity and tissue specificity of PSA makes it the most useful tumor marker available for the screening and management of prostate cancer. Lack of cancer specificity in distinguishing prostate cancer and nonmalignant prostate lesions is the main drawback with PSA. Benign conditions

such as BPH, acute prostatitis, and infarction can also be correlated with elevated serum PSA levels.

PSA serves as an excellent cancer marker in prostate cancer screening, diagnosis, prediction of cancer risk, and recurrence. Since its discovery in prostate cancer serum in 1980 (Papsidero, 1980), PSA has been subjected to intensive research and clinical usage in the screening, detection, and monitoring of prostate cancer. PSA and its various forms are used to guide clinical decisions for further tissue biopsy diagnosis, resulting in increased prostate cancer detection, especially in young men. Use of PSA in prostate cancer detection has also resulted in a reduction in the number of prostate cancers discovered only at late stages in which metastases occurred, from about 30% of all newly diagnosed cases to about 10% of all such cases (Cooperberg, 2004). Annual PSA screening is recommended both by the American Urological Association and the American Cancer Society for all men over the age of 50. The American Urological Association (AUA) issued new guidelines here during its 104th annual meeting (Greene, 2009). The new guidelines have lowered the age for beginning prostate-specific antigen (PSA) screening to 40 years for relatively healthy well-informed men who want to be tested. In addition, because of its tissue specificity, the PSA assay is particularly useful for monitoring the success of surgical prostatectomy. Complete removal of the prostate should result in an undetectable PSA level, while incomplete resection of the gland (not persistent disease) might result in measurable levels of PSA. However, it should remain unchanged on extended follow-up. Any increase in measurable PSA after a successful radical prostatectomy would indicate prostate cancer recurrence or metastasis. A transient and modest increase of PSA may occur during radiation therapy, which should not be misinterpreted as disease progression.

Multiple studies suggest that diagnosis is made in more than 80% (in some studies, >90%, e.g., DeSoto-LaPaix, 2003) of patients with prostate cancer from serum PSA levels that are greater than 4 ng/mL. Because BPH and acute prostatitis also induce elevated serum PSA levels, approximately half of patients with PSA values greater than 4 ng/mL are not found to have prostate cancer on biopsy, even at significantly elevated levels (i.e., >10 ng/mL). These studies therefore suggest that PSA has a sensitivity of a minimum of 80% and a specificity of around 50%. However, it has also been found that about 20% of initially negative biopsies, when repeated over a 3-year period, become positive (DeSoto-LaPaix, 2003). Thus the specificity of PSA may be higher, assuming that the biopsies missed a malignant lesion and that a new malignancy did not occur over the 3-year time period, leading to the current practice of saturation biopsies.

On the other hand, the cutoff value of 4 ng/mL does not sufficiently distinguish patients with and without prostate cancer, including more aggressive cancers (Schroder, 2000; Horninger, 2002; Punglia, 2003; Thompson, 2004). In a review of the Prostate Cancer Prevention Trial, 2950 men who never had a PSA level greater than 4 ng/mL or an abnormal DRE had a final PSA determination and underwent a prostate biopsy after being in the study for 7 years (Thompson, 2004). There was a 15.2% ($n = 449$) biopsy-proven prevalence of prostate cancer in men with PSA levels no greater than 4 ng/mL. High-grade prostate cancer (defined as Gleason score ≥ 7) was seen in 15.8% ($n = 71$) of these men. Size of the tumor was not reported. In the placebo arm of the Prostate Cancer Prevention Trial, there was no cutpoint of PSA with simultaneous high sensitivity and high specificity for detection of prostate cancer in healthy men, but rather a continuum of prostate cancer risk at all values of PSA (Thompson, 2005). These studies appear to confirm the results of other studies that the sensitivity of PSA, using the 4 ng/mL cutoff, in diagnosing prostate cancer is on the order of 80%–85%. The finding that using a cutoff of 4 ng/mL for PSA to diagnose this disease results in 15.2% false-negative results in the patient population subjected to biopsies is compatible with this conclusion (i.e., 84.2% of patients with prostate cancer had serum PSA levels greater than 4 ng/mL).

The issue of using lower cutoffs for serum PSA to identify more patients with prostate cancer has been further explored (Puglia, 2003), especially in view of the development of more sensitive assays for PSA, now commercially available in PSA test kits, that are capable of detecting serum PSA less than 0.1 ng/mL. Based on considerations from a Prostate Cancer Prevention Trial, European guidelines were issued in 2008 recommending a PSA cutoff value of 2.5 ng/mL or, alternatively, a PSA velocity of 0.6 ng/mL per year as a biopsy indication (Heidenreich, 2008).

In addition to the issue of cutoffs for PSA in the diagnosis of prostate cancer, the issue of the efficacy of diagnosis of this disease has been raised because as it has been for a number of other cancers including breast cancer. The question is whether early diagnosis of prostate cancer saves patients' lives. To address this question, a major study by the European

Randomized Study of Screening for Prostate Cancer (ERSPC) was carried out over approximately the past decade, involving 182,000 men between the ages of 50 and 74 in seven European countries who were randomly assigned to a group that was offered PSA screening at an average of once every 4 years or to a control group that was treated according to current practice standards and was not subjected to the regular screening procedure. Most participating centers in this study used a lower PSA cutoff value as an indicator of abnormality than the usual 4 ng/mL (i.e., 3 ng/mL versus 4 ng/mL). Prostate cancer was detected in 8.2% of the men in the screening group while 4.8% was detected in the control group. The absolute death risk difference between the control group and the screening group was 0.71 patient per 1000 patients, implying that 1410 patients must be screened in order to prevent one death from prostate cancer. Overall, this study found that screening resulted in a lower death rate from prostate cancer by 20% (Schroder, 2008, 2009). The study concluded that this significant reduction in the number of deaths from prostate cancer was accompanied by a high risk of overdiagnosis, which, nonetheless, seems to be a small price to pay for the significant number of lives saved.

Contrary to the results of this investigation, another study by the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial on patients assigned to be screened, with PSA and DRE, and control groups found that, whereas 20% more prostate cancer was diagnosed in the screened group than in the control group, the death rate among both groups was the same (Grubb, 2008). The conclusion was that screening for prostate cancer does not save lives but subjects patients to unnecessary procedures that do not affect outcome. However, it was recognized that increasing the length of the study might show differences in death rates between the two groups. Possibly also the lower cutoff value of 3 ng/mL used in many of the centers in the ERSPC study identified more patients with significant disease.

Methods to Improve the Performance of Serum PSA Measurement for the Early Detection of Prostate Cancer

Several approaches have been developed to increase the sensitivity and specificity of PSA in detecting prostate cancer.

First, as noted previously, use of serum PSA in combination with either DRE or transrectal ultrasound of the prostate results in increases in both sensitivity and specificity (Catalona, 1991; Brawer, 1992). In addition, the PSA fractions (i.e., free and bound) have been used to increase the sensitivity and specificity of elevated serum PSA in the diagnosis of prostate cancer.

Free PSA, Complex PSA, and Percentage of Free PSA

PSA is capable of complexing with various endogenous protease inhibitors, including alpha 1-antichymotrypsin (ACT), $\alpha 2$ -macroglobulin (to which it binds covalently) and α -protease inhibitor (API). These stable forms are collectively known as complexed PSA (cPSA). Serum PSA exists in the serum largely (up to 90% of total PSA) (Vessella, 1997) in the form of a PSA-ACT (PSA- $\alpha 1$ -antichymotrypsin) complex (Christensson, 1993), which is readily detectable by most immunoassays, whereas complexes with $\alpha 2$ -macroglobulin escape detection by commercial PSA. The noncomplexed forms, known as free PSA (fPSA), are unreactive with plasma protease inhibitors. In prostate cancer, there is generally an increase in the serum concentration of complexed PSA and a corresponding decrease in unbound or free PSA (Parsons, 2004). On the other hand, the relative amount of free PSA is higher in BPH than in prostate cancer. Thus immunoassays have been developed that quantify either cPSA or fPSA. The epitopes exposed by fPSA but not by cPSA enabled the development of these assays specifically measuring fPSA or cPSA as complements to the conventional PSA assay, which measures total PSA (tPSA) (Lilja, 1991; Stenman, 1991). Based on these assays, it has been found that measuring complex PSA with ACT (PSA-ACT) directly eliminates many technical problems associated with PSA assays and improves the differentiation of BPH from prostate cancer (Wu 1994, 1998), thereby increasing test specificity (Parsons, 2004). The specificity of PSA has been enhanced by using molecular forms of PSA and fPSA, such as percent free PSA (% fPSA), proPSA, intact PSA, or benign prostatic hyperplasia-associated PSA, and/or new serum markers (Stephan, 2009).

Conversely, measurement of fPSA and the calculation of percentage of fPSA (%fPSA = $[fPSA/tPSA] \times 100$), which has an inverse relationship with prostate cancer risk (Polascik, 1999), have been used to help to differentiate BPH from prostate cancer, also increasing test specificity and reducing unnecessary biopsies for BPH patients. More importantly, the free PSA ratio improves the specificity for prostate cancer detection in men

with PSA between 4 and 10 ng/mL, also reducing unnecessary biopsies. In addition, fPSA may be useful as a prostate cancer morbidity predictor (Polascik, 1999; Ito, 2003). Some studies also showed that %fPSA can be used to predict prostate cancer in patients with PSA less than 4 ng/mL (Djavan, 1999; Horninger, 2002). One caveat is that fPSA is subject to quick degradation at 4° C or above. The recommended time interval from sample collection and assay should be less than 3 hours, and the sample should be stored and shipped at -70° C (Woodrum, 1996). Overall, prostate cancer is associated with elevated complexed PSA and low %fPSA (<6%) (Catalona, 1995), and higher ratios of free PSA (>23%) are usually associated with BPH.

The Bayer complexed PSA assay, which measures both PSA-ACT and PSA-API, was initially proposed as a single assay alternative to the free and tPSA assays (Brawer, 1998; Mitchell, 2001). However, only the ratio of complex PSA to total PSA can reach equivalent results compared with %fPSA (Lein, 2003; Roddam, 2005).

fPSA has recently been shown to exist in at least three molecular forms: proPSA (Mikolajczyk, 1997), BPSA (Mikolajczyk, 2000), and inactive "intact" PSA (iPSA). Recently the FDA approved the Dimension FPSA (free PSA) Flex (Dade Behring, Newark, Del.) and AxSYM (Abbott, North Chicago, Ill.) Free Prostate Specific Antigen tests, which are typically performed along with a total prostate specific antigen (tPSA) test and a DRE and helps to determine whether a prostate biopsy is needed to rule out the risk (in percent) of cancer in men 50 years or older with total PSA of 4–10 ng/mL. The smaller the percent fPSA, the more likely the patient is to have prostate cancer.

In 2007, FDA gave approval to a new test Immulite 1000/2000 Free PSA assay (Siemens, Tarrytown, N.Y.), which is a third generation PSA assay based on the solid phase sequential chemiluminescent immunometric method for the quantitative measurement of fPSA, which is used in conjunction with tPSA. The routine sample preparation and refrigerated (2°–8° C) storage of samples for 24 hours or frozen storage at -70° C is acceptable for the measurement of fPSA.

Principles of Measurement. There are several different assays for free and complexed PSA, one of which is summarized in Figure 73-3. When PSA is bound, certain antigenic determinants are "buried" by the protein to which it binds (mainly, ACT). These are exposed on fPSA, so that antibodies to the buried determinants of complexed PSA will detect only fPSA. On the other hand, there are determinants that are exposed on both free and complexed PSA and can be detected by antibodies to these determinants, allowing for determination of total PSA. Finally, antibodies to the buried PSA determinant are available that also block the common exposed determinant. These antibodies react only with free PSA by binding to the buried determinant but also block the exposed common site. Now, in the presence of this blocking antibody, another antibody is added that reacts only with the common exposed determinant. The only available common exposed determinants are on complexed PSA. Thus this double antibody approach, using a blocking antibody and a detection antibody, quantifies the level of complexed PSA.

PSA Doubling Time, Velocity, and Density

Cancer is a growth process, and it seems reasonable to suppose that the rate of change of a tumor marker would be a more sensitive marker of disease aggressiveness than an absolute level, so the concept of PSA doubling time and PSA velocity came forward in the last decade. The time (in months) required for the PSA value to double is known as the *PSA doubling time*. It has been shown that the PSA doubling time can predict recurrence after radical prostatectomy in androgen-independent prostate cancer patients (Lee, 2003; Loberg, 2003).

The rate of PSA increase over time, PSA velocity, or PSAV (Carter, 1992), is the PSA difference divided by the number of years, typically given as nanograms per milliliter per year. It has been shown that a PSA velocity of 0.75 ng/year or greater is a strong predictor of cancer with a specificity of 95% (Carter, 1992). More recently, it has been shown that PSA velocity may be useful in predicting prostate cancer risk when PSA levels are between 2 and 4 ng/mL (Fang, 2002). This is especially useful in predicting the risk of cancer and guiding the necessity of prostate biopsy in patients with low/normal PSA value (2–4 ng/mL). In a recent study (Moul, 2007), it has been suggested that by analogy with serum PSA levels, which are age-dependent, PSA velocity should be age-adjusted. They noted that biopsy-guideline threshold levels (PSA \geq 4 ng/mL, or PSAV \geq 0.75 ng/mL per year) underestimated the cancer risk in men aged 50–59 years, and should therefore be decreased to 2 ng/mL and 0.40 ng/mL per year, respectively. A sharp rise in the PSA level raises the suspicion of a

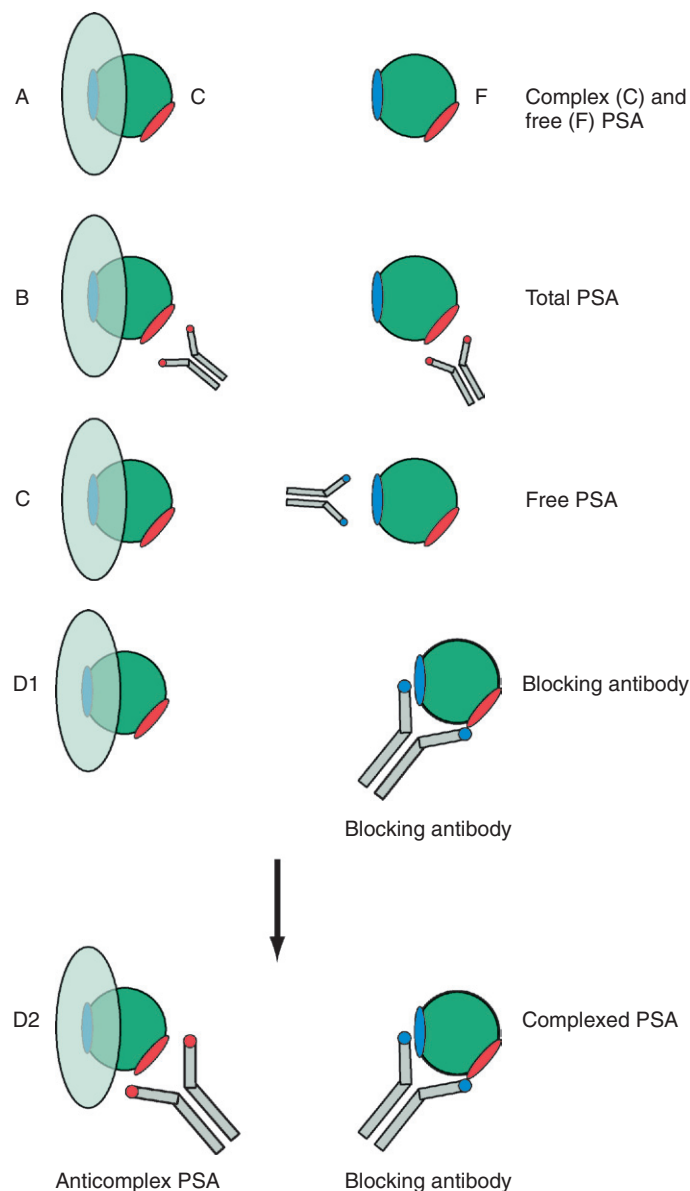

Figure 73-3 Three different assays for prostate-specific antigen (PSA). A, PSA is shown to exist in the free (F) or complexed (C) states. Some of its antigenic determinants (blue in the figure) are buried in the complexed state. These are exposed in the free state. On the other hand, as shown in B, there are common determinants, red in the figure, that are exposed in both complexed and free PSA. Antibodies to these common determinants will detect total PSA (free + complexed). Because the blue determinants are exposed only in free PSA, as shown in C, antibodies to these determinants will detect only free PSA. Finally, as shown in D1, antibodies have been developed against the blue determinant of free PSA that also block the red determinant. Thus antibodies to the red determinant, which is common to both free and complexed PSA, will react only with complexed PSA as shown in D2. This is the basis for the Siemens/Bayer assay for complexed PSA.

fast-growing cancer but another important confounder is prostatitis. Thus a repeat PSA measurement following a trial of antibiotics is a reasonable option. A 2006 study found that men who had a PSA velocity greater than 0.35 ng/mL per year had a higher relative risk of dying of prostate cancer than men who had a PSA velocity less than 0.35 ng/mL per year (Carter, 2006). The National Cancer Center Network 2007 guidelines for prostate cancer detection (National Comprehensive Cancer Network: Prostate cancer detection version 1.2007; National Comprehensive Cancer Network, 2007. <http://www.nccn.org>) include a recommendation that men with a PSA velocity greater than 0.35 ng/mL per year should consider biopsy, even if their PSA level is low. This is a notable finding because prostate cancer causes significant mortality, although a large number of prostate cancer patients die of other causes. Whereas these studies demonstrate a method of identifying aggressive forms of prostate cancer, randomized larger cohort studies are needed to validate these observations. Preoperative PSA velocity is not a good parameter for prostate cancer

grade, stage, or recurrence (Freedland, 2001). PSA density is a measure of the ratio of total PSA to prostate gland volume as measured by transurethral ultrasonography; PSA densities of greater than 0.15 indicate an increased probability of prostate cancer rather than BPH (Polascik, 1999).

PSA is still a gold standard biomarker for prostate cancer. It can be made even more useful diagnostically both by employing it in conjunction with other methods such as DRE and by quantifying its fractions (complexed and free) or various molecular markers in the urine.

Urine Markers

Numerous promising prostate cancer biomarkers have recently been identified. These markers have allowed exploring a new diagnostic approach based on the identification of cancer cells or shed material in the urine obtained after digital examination of the prostate (Fradet, 2009; Ploussard G, 2010).

Urine Prostate Cancer Antigen 3

Prostate cancer antigen 3 (PCA3) is a prostate-specific gene that is an average 66 times overexpressed in prostate cancer cells compared with normal prostate cells (de Kok, 2002). Assays were developed to measure the relative amount of PCA3 RNA over PSA RNA using quantitative reverse transcription-PCR or direct RNA amplification (Hessels, 2003; Fradet, 2004). A commercially available test by GeneProbe Inc. (San Diego), referred to as the *Aptima PCA3 assay*, is based on the principle of target capture followed by transcription-mediated amplification and uses calibrators to quantify PCA3 and PSA RNA copy number to provide a PCA3 score (ratio of PCA3 RNA/PSA RNA) (Groskopf, 2006). In a large European prospective multicenter study, this test clearly demonstrated a greater probability of a positive repeat biopsy with increasing PCA3 scores (Haese, 2008). Indeed, the proportion of patients with positive biopsy went from as low as 10% to as high as 70% in a linear fashion with the increasing PCA3 score. Moreover, using a PCA3 score cutoff of 35 provided similar results in men with serum PSA of 4 or less, 4–10, or more than 10 ng/mL with sensitivities of 50%–61% and specificity of 71%–80% (Hoque, 2005). Furthermore, PCA3 has the advantage compared with PSA that it is independent of prostate volume (Hoque, 2005), is correlated with tumor volume (Nakanishi, 2008, Whitman, 2008), and may even predict extracapsular tumor extension (Roupret, 2007).

Urine Hypermethylated Glutathione S-Transferase pi 1 Gene

DNA hypermethylation has been demonstrated to be one of the most common molecular alterations in prostate cancer, with more than 90% of cancers with hypermethylated promoters in one or more genes (Jeronimao, 2001; Woodson, 2004; Yegnasubramanian, 2004; Bastian, 2005). Cairns and colleagues in 2001 used a DNA-based test to detect the hypermethylation of the glutathione S-transferase pi 1 (GSTP1) gene in urinary sediments after prostatic massage and found an overall sensitivity of 73% and a specificity of 98% in a small cohort of patients (Cairns, 2001). Several groups have evaluated the usefulness of gene hypermethylation as a biomarker by testing for its presence in freely voided urine after prostatic massage, in ejaculates, in directly sampled prostatic secretions, and in serum (Goessl, 2000; Gonzalgo, 2003; Crocitto, 2004; Gonzalgo, 2004; Hoque, 2005; Roupret, 2007). Recently, a study by Woodson and colleagues concluded that the methylation of GSTP1 in urine specimens had 75% sensitivity and 98% specificity for prostate cancer. GSTP1 methylation in the biopsy had 88% specificity and 91% sensitivity. Also an observation of a higher frequency of GSTP1 methylation in the urine of men with stage III vs. II disease (100% vs. 20%, $P = .05$) (Woodson, 2008) suggests increased frequency of hypermethylation with increased stage. This study and other initial studies suggest that GSTP1 methylation and other genes in urine may not have much impact on increasing the sensitivity of PSA screening but it may improve the specificity of PSA and help distinguish men with prostate cancer from those with BPH.

Urine Fusion Gene Variants

A remarkable discovery of a family of new genes resulting from the fusion between the androgen-regulated transmembrane serine protease gene (TMPRSS2) with genes members of the E26 transformation-specific (ETS) family of oncogenes was made using a new biostatistical method called *cancer outlier profile analysis* (Kumar-Sinha, 2008). The TMPRSS2–E26 transformation specific-related gene (ERG) fusion transcripts have been identified in 40%–80% of prostate cancers (see Chapter 76). More recently, TMPRSS2 has been found to be an androgen-regulated gene and

is more commonly associated with Gleason score >7 (41% versus 12%) and more prostate cancer-related deaths and/or metastatic disease development (53% vs. 23%) (Demichelis, 2007). The serine peptidase inhibitor Kazal type 1 gene outlier was identified exclusively in a small subset of ETS fusion transcript negative cancers (Tomlins, 2008).

A combination of the results from individual assays for PCA3 or gene fusion and PSA forms may enable significantly improved management of prostate cancer, including early detection, prognosis, and treatment selection.

FECAL OCCULT BLOOD TESTING AND MUTANT PROTEIN MARKERS IN STOOL

Perhaps the most familiar test to screen for cancer in patients is the fecal occult blood test, which is performed in the physician's office on stool samples obtained from a DRE. It is performed routinely on most patients as part of annual checkups. In the hospital outpatient setting, it is more common to have the patient obtain a stool sample for testing after a bowel movement. The idea is that if blood is discovered in the stool, there is the chance that a colonic tumor is the cause, and further workup, such as colonoscopy, is therefore strongly recommended. The actual test for occult blood is based on the ability of the heme moiety of hemoglobin to catalyze the oxidation of the colorless compound guaiaconic acid (hence the name guaiac test) in the presence of H_2O_2 to a highly conjugated, blue-colored quinone. Usually, the guaiaconic acid is impregnated on a strip or solid support, and the stool specimen is placed on a discrete section of the strip. In this nonspecific test, blood in stool can be caused by a number of non-malignant causes such as hemorrhoids, colitis, diverticulitis, and local trauma to the perianal area, diminishing the specificity of this test. False-positive results for this test are also caused by exogenous factors such as the presence of meat fibers from meat ingestion or of bismuth, which is present in antacid preparations such as Pepto-Bismol. In addition, the ability of this method to detect the presence of colon cancer depends on such factors as whether and to what extent a cancer hemorrhages, its location (the closer to the rectum, the greater the likelihood of detection), and its pattern of growth (e.g., exophytic tumors are more likely to be detected than nonexophytic ones). The sensitivity of the fecal occult blood test is between 15% and 30%. It is much less effective than colonoscopy, the definitive mode of colon cancer detection. However, it offers the advantage of being noninvasive although with “virtual colonoscopy” based on computed tomography scanning of the colon, this advantage is diminished.

As a result, there has been an effort to devise new noninvasive tests on stool specimens that have higher sensitivity and specificity than fecal occult blood tests. As discussed in Chapter 74, several mutant genes that code for proteins that are involved with control of the cell cycle have been strongly implicated as vitally important causative factors of colon cancer. These include mutant *ras* (of the Kirsten or K-variety), mutant p53, the adenomatous polyposis coli (*APC*) gene, and the gene product BAT-26, associated with microsatellite instability. All of these mutant genes are oncogenes in colon cancer. Standardized reverse-transcriptase polymerase chain reaction (RT-PCR) techniques, discussed in Part 8, Chapter 66, are available to detect mutations in any or all of these proteins. In addition, “long” DNA, thought to result from disordered apoptosis of cancer cells in colon cancer, has also been found to occur in a number of colon cancers. If sufficient numbers of cancer cells from a colon cancer are sloughed off into the lumen, one or more of the mutant genes (and/or long DNA) can be discovered, allowing for the noninvasive detection of colon cancer.

Using this approach, a cooperative study, involving the Colorectal Cancer Study Group, was conducted in which more than 5000 patients were entered and more than 2000 were completely evaluated for colon cancer using fecal occult blood testing, multioncogene testing on stool, and colonoscopy (Imperiale, 2004). All patients were 50 years of age or older (mean, 69.5 years). The results showed that the genetic RT-PCR-based methodology results in significantly higher rates of detection than fecal occult blood testing. Overall, the rate of detection of adenocarcinoma was 51.6% for the genetic screening but 12.9% for fecal occult blood screening. Interestingly, advanced adenomas were detected in 15.1% of cases in the genetic screening and 10.7% in the fecal occult blood screening. Because this condition may be regarded as a precursor for frank malignancy, both methods seem to have similar rates of early detection. On the other hand, the rate of detection of TNM stage I colon cancer by genetic screen was 53.3% while that for fecal occult blood screening was 6.7%, suggesting that genetic screening is substantially more effective in detecting true colon cancer in its early stages. Surprisingly, both tests were

found to have similar apparent false-positivity rates in conditions of minor polyps (7.6% vs. 4.8% for genetic and occult blood tests, respectively) and the condition of no polyps found on colonoscopy (5.6% vs. 4.8% for genetic and occult blood tests, respectively). Although this study has certain drawbacks, such as too few patients with cancers and advanced adenomas with high-grade dysplasia, skewing of the age of the population to 65 years of age and older, and lack of information as to appropriate testing intervals for the genetic approach, these results are encouraging and warrant further systematic studies using this approach.

CIRCULATING TUMOR CELLS IN PERIPHERAL BLOOD

Hematogenous spread of cancer cells is the main venue for cancer metastases (Eccles, 2007). Thus the detection of these disseminating primary cancer cells in peripheral blood can not only act as tool for monitoring early metastases but also can predict the prognosis and the treatment outcome of novel therapies.

The major obstacle in successful detection of CTCs is their paucity in peripheral blood, approximately one or fewer CTC cells in 10^5 – 10^6 peripheral blood mononuclear cells. Thus various enrichment techniques are used to capture the circulating tumor cells based on cell size. These include membrane microfilter devices or micro-electro-mechanical system, isolation by size of epithelial tumor, cell density (density-gradient centrifugation) and specific antibodies to the cell surface proteins based on the use of immunomagnetic beads technique (see Chapter 44), and flow-assisted cell sorting (see Chapter 34). The enriched CTC can further be characterized by additional detection techniques. The two main approaches for the detection of CTCs are immunologic assays using monoclonal antibodies directed against specific proteins by using fluorescence microscopy and flow cytometry and by measuring tissue-specific transcripts by using PCR-based molecular assays (e.g., RT-PCR and methylated DNA PCR) (Molnar, 2003). The Cellsearch (Johnson & Johnson) system, the first FDA-approved test based on the immunologic approach, has gained considerable attention because it allows both standardized automated immunomagnetic enrichment using antibodies targeting epithelial cell adhesion molecule (EpCam) and subsequent labeling of CTCs with fluorescent antibodies specific for epithelial cells (cytokeratins 8, 18, and 19) and leukocytes (CD45) (Cristofanilli, 2004; Eccles, 2007; Riethdorf, 2007; Pantel, 2009). This system can provide clinically useful information on the prognosis of patients with metastatic breast, colon, and prostate cancer (Moreno, 2005; Cohen, 2006; Hayes, 2006) and has the potential to evaluate CTCs in pharmacodynamic studies that test new targeted therapies (Moreno, 2005, de Bono, 2007). Recently, a microfluidics microchip technology has been developed that uses a silicon microchip containing thousands of microspots staining with anti-EpCAM (CTC-chip). In this technique, microfluidics are used to pneumatically push whole blood over the surface of the CTC-chip and EpCAM positive CTCs are captured and confirmed as CTC via fluorescence microscopy (Nagrath, 2007; Uhr, 2007). CTC chips identified high numbers of cytokeratin-positive CTCs in nearly all tested patients with lung, prostate, pancreatic, breast, and colon cancer, including those without metastatic disease. Surprisingly, patients with localized prostate cancer had more CTCs than patients with overt metastasis. Future studies are required to test whether these cells are viable CTCs with tumor-specific genomic characteristics (Uhr, 2007).

The amount of EpCAM on tumor cells varies widely based on tumor type (Thurm, 2003). Therefore alternative devices, based on fiber optic array scanning technology, an ultra-speed automated digital microscopy with laser printing techniques, has been developed to circumvent to the rare-cell detection problem (He, 2007). By this method, laser-printing optics has been used to excite 300,000 cells per second, which have been decorated by fluorescent dye-conjugated antibodies directly on the slide. Another completely different antibody-based approach is the EPISPOT assay to detect proteins released by CTCs. Using the EPISPOT method, only viable, protein-excreting cells are detected. Nevertheless, the clinical utility of all of these new approaches needs to be validated in large-scale studies in cancer patients (Alix-Panabieres, 2007a, 2007b).

As summarized, various clinical studies have provided evidence for an association between the presence of CTCs detected at the time of tumor resection and postoperative metastatic relapse in patients with cancers of the breast, prostate, lung, and gastrointestinal tract. The present research data strongly support that CTCs are indicators for cancer progression into metastatic disease and can be used to adjust treatment modality. A recent study indicates that CTC detection predicts the prognosis in clinically

relevant subgroups of early-stage breast cancer patients (Ignatiadis, 2007). Moreover, in other tumor entities such as gastrointestinal cancer, a disease in which overt bone marrow metastases are rare, CTC analyses have generated prognostic information and might therefore become helpful indicators of early systemic tumor cell spread to other distant organs such as lung or liver. Monitoring of bone marrow and peripheral blood during and after systemic adjuvant therapy for CTCs might provide unique information for the clinical management of the individual cancer patient, and allow an early change in therapy years before the appearance of overt metastasis signals incurability. Although large-scale clinical data are still lacking with regard to how molecular characterization of CTCs could be used as a clinical decision making tool, this type of analysis holds tremendous promise for improved stratification of patients and/or the prospective development of tailored, targeted therapy.

CONCLUSIONS AND DIRECTIONS FOR THE FUTURE

In summary, a molecule, almost always a protein, could be used as a tumor marker as long as its changing concentration reflects tumor cell activity. The assessment of clinical utility for an individual tumor marker is based on its sensitivity and specificity. There has been a clear trend toward improving the test specificity and sensitivity by ordering multiple tumor markers. However, controversy exists concerning which and how many tumor markers should be included in a panel for individual malignant diseases. Several new tumor markers, discussed in Chapter 74, are now on the horizon. These tumor markers consist of oncoproteins, suppressor proteins, adhesion molecules, cyclins, and angiogenic factors. They mainly differ from currently used tumor markers in their association with specific known metabolic pathways or physiologic reactions. Most tumor markers employed currently for patient management are not associated with any known specific biological reaction. Conceivably, measuring these new tumor markers will provide information on more specific defects, which will help in the design of better treatments. The best example is the successful use of Herceptin (a humanized MAb against the ectodomain of the *c-erbB-2* receptor) for metastatic breast cancer patients.

SERUM GENOMICS AND PROTEOMICS AS POTENTIAL BIOMARKERS FOR CANCER

Current technology has opened new directions in searching suitable serum markers in early cancer screening, diagnosis, and prognosis and in monitoring treatment response. This active field is applying current genomics and proteomics as well as newer molecular techniques in detecting circulating nucleic acid (DNA and RNA) and tumor cells. Serologic marker profiling with genomics and proteomics (Johann, 2004; Petricoin, 2004; Rai, 2004) has been a very promising area of research. These new advances are described in Chapter 74.

CIRCULATING NUCLEIC ACIDS IN THE DETECTION OF CANCER

Many new techniques have been developed to detect abnormal circulating nucleic acids (DNA, RNA and miRNA) in cancer patients. Among them, PCR-SSCP has been used to detect serum DNA mutations, and fluorescent microsatellite analysis has been used to detect loss of heterozygosity. Fluorescent microsatellite analysis has been frequently used to identify allelic imbalance and loss of heterozygosity as a serologic marker for urothelial carcinoma (von Knobloch, 2004) at the molecular level. These methods might prove to be useful if the specificity and sensitivity are examined in large cohorts of patients.

SERUM PROTEOMICS IN THE DETECTION OF CANCER

Proteomics technology represents a combination of state-of-the-art mass spectrometry and bioinformatics. It includes protein chip surface-enhanced laser desorption ionization (SELDI) and matrix-assisted laser desorption ionization time-of-flight liquid chromatography-mass spectrometry platform as described in Chapter 77. The final use of these challenging techniques will be determined in future clinical trials.

KEY POINTS

- As a result of the vast progress that has been made very recently in sequencing the entire human genome and in illuminating pathways that are involved in tumorigenesis, it has become clear that the malfunctioning of mutant proteins is the central cause of human cancers.
- These proteins—growth factors, growth factor receptors, G-proteins such as ras-p21, the mitogen-activated protein kinases, and nuclear proteins such as Myc, Fos, Jun, and p53—are critical in signal transduction pathways in which proliferation signals from growth factors at the cell membrane are transduced to the nucleus and stimulate cell division.
- The mutations in these proteins result in amino acid substitutions or deletions that cause them to be permanently activated. Mutations in regulatory domains of the genes encoding these proteins can result in protein overexpression, which can also result in continuous mitogenic signaling.

- These proteins and antibodies to them can be used to detect the presence of cancers in patients at early stages—and even to predict their future occurrence.
- Although mutated signal transduction proteins are involved in many different human cancers, it appears that there are patterns of expression of mutated proteins that typify specific cancers.

OVERVIEW

As a result of the vast progress that has been made recently in sequencing the entire human genome and in illuminating pathways that are involved in tumorigenesis, it has become clear that the malfunctioning of mutant proteins is the central cause of human cancers. This has given rise to a whole new field of proteomics, that is, detection of these aberrant proteins in the blood and other body fluids of patients. This chapter explains these new approaches and emphasizes that many of these aberrant proteins are actually involved in the transmission of proliferation signals on signal

transduction pathways, prominent examples of which are discussed. The aim of this chapter is to explain signal transduction pathways in cell proliferation, to illustrate how different mutant proteins on these pathways can cause abnormal, continuous proliferation signaling leading to cell transformation, to demonstrate how these proteins and antibodies to them can be used to detect the presence—and even to predict the future occurrence—of cancers in patients, and to show how new proteins that are strongly associated with different types of cancer have been discovered and can be used to detect these cancers at early stages.

CELL BIOLOGY AND MITOGENESIS

Control of the process of cell division in eukaryotic cells, especially in the higher forms of life, is vital to the processes of cell proliferation and differentiation. The fine balance between these two processes is regulated by numerous proteins that interact in the cell to ensure that this balance is maintained. Virtually all these proteins, many of which are critical in regulating the cell cycle, are encoded by oncogenes. Mutations in oncogenes can result in the production of proteins that become either permanently activated in stimulating cell growth and proliferation (e.g., the ras-gene-encoded p21 protein) or become inactive in inhibiting cell proliferation (e.g., the p53 protein). Both events give rise to malignant tumor cells.

Knowledge not only of the existence of these oncogenes and their encoded oncoproteins but also of the mechanisms by which they exert their effects has resulted in a new series of highly sensitive assays for both mutated oncogenes and their encoded mutant proteins. Assays using amplification methods such as real-time polymerase chain reaction (RT-PCR) for mutated oncogenes are discussed extensively in Part 8 and are further discussed in this chapter. However, the main focus of this chapter is the discussion of how detection of oncogenic *proteins*, or *oncoproteins*, that occur in the serum of patients with malignant tumors enables the diagnosis of malignancy to be made, often at an early stage of tumor development. Because the finding of elevated levels of any of these oncoproteins or mutated forms of these proteins in human serum indicates the likely presence of a malignant tumor, these proteins are also referred to in this chapter as *tumor markers*. Additionally, in view of the enormous strides that have been made in PCR and other molecular technology allowing detection of very few copies of aberrant DNA, we also discuss in this chapter recently developed new detection methods for oncogenic DNA present in the sera and other body fluids of patients with cancer, further allowing early tumor detection.

Oncogenesis, the process by which normal cells become malignant, involves multiple steps, which can be broadly classified into tumor initiation and tumor promotion. Mitogenesis itself is a multistep process that commences at the cell membrane as a result of the activation of a growth factor receptor, which then activates other membrane and cytosolic proteins and second-messenger molecules that transduce the mitogenic “signal” to the nucleus. The pathway in which this orderly progression of activation of successive proteins, mostly kinases, occurs from the cell membrane to the nucleus is referred to as a *signal transduction pathway*.

SIGNAL TRANSDUCTION PATHWAYS

A number of the steps on the signal transduction pathway that are involved in the transduction of the growth factor-initiated signal to the nucleus has become elucidated, but many of the steps that are involved are not fully understood. One well-established pathway, for the ras-oncogene-induced mitogenic signaling pathway, is summarized in Figure 74-1. This figure shows that, when a growth factor receptor is activated by its growth factor, such as epidermal growth factor (EGF), HER2/neu, or insulin, the receptor, in turn, activates several intermediary proteins (Grb-2 and SOS, in Figure 74-1) that activate the all-important G-protein (i.e., guanine triphosphate [GTP]-binding protein), ras-p21. This membrane-bound 21kDa protein, containing 189 amino acids, is activated when the SOS protein induces it to bind GTP in place of guanine diphosphate (GDP). In its activated (GTP-bound) state, ras-p21 directly activates raf (Moody, 1993; Stokoe, 1994), which, in turn, induces a sequential protein kinase cascade beginning with the kinase, MEK (formerly called MAP kinase kinase) and mitogen activated protein (MAP) kinase encoded by the ERK gene, as shown in Figure 74-1.

MAP kinase directly activates nuclear transcription factors, one of these being Fos. This important protein forms a heterodimeric complex with another nuclear transcription factor, Jun, which is directly activated by Jun kinase (JNK). The Fos-Jun complex, also called AP1, binds to specific regions of genomic DNA, inducing the transcription of mitogenic proteins

Figure 74-1 Scheme of some of the known components of the ras signal transduction pathway beginning (top, left) when a growth factor binds to its cell receptor. The remainder of events is explained in the text. DAG, Diacylglycerol; GAP, GTPase-activating protein, which promotes hydrolysis of GTP to GDP bound to p21; grb-2, the adaptor protein that concurrently binds p21 and the guanine nucleotide exchange protein or factor, SOS; PI3K, phosphoinositide-3-hydroxy kinase, an enzyme that induces synthesis of IP₃ and is involved in many aspects of mitogenic signal transduction; IP₃, inositol triphosphate; MAP-2 kinase, mitogen-activated protein kinase or microtubule-associated protein kinase-2 (MAP-2K in the figure, also called ERK); myc, fos, and jun, nuclear oncogenes that code for nuclear proteins; NMP, nuclear matrix proteins; PKC, protein kinase C; PLC, phospholipase C; Raf-1, the oncogene-encoded p74 protein, which functions as a kinase that phosphorylates another kinase of molecular mass 43kDa, called MAP-2 kinase kinase, MEK (as in the figure, or MAP-KK in the figure; ras-p21 protein, ras-p21, defined in the text).

such as the cyclins. Transcription of these proteins is blocked by the anti-oncogene p53 protein (see Fig. 74-1), which further induces the transcription of antimetabolic proteins such as Bax and caspases that are critical to the process apoptosis.

Figure 74-1 shows that there are several other important nuclear oncogene-encoded proteins such as Myc, a 75kDa protein that is overexpressed in Burkitt's lymphoma. This oncogene protein is not directly on the ras signal transduction pathway. Interestingly, there are cell lines that, when transfected with either the ras oncogene or with the myc oncogene, do not undergo cell transformation but, when transfected with both oncogenes simultaneously, do undergo cell transformation. These results indicate that ras and myc may be interdependent and are an excellent prototypical example of the multistage nature of oncogenesis.

Figure 74-1 also illustrates that, in normal mitogenic signal transduction, antiproliferative proteins, also called antioncogene proteins, such as p53, become activated and downregulate mitogenic events. If these proteins become mutated at critical positions in their polypeptide chains, they become inactivated, allowing mitogenic events to occur with less inhibition and regulation. Numerous other antioncogene proteins occur, including p16, mutations in which have been implicated as a major causative factor of bladder cancer; Rb (retinoblastoma antioncogene protein); and APC (adenomatous polyposis coli) protein, mutations of which have been implicated in causing familial adenomatous polyposis and colon cancer.

A central feature of the signal transduction events summarized in Figure 74-1 is that the activation cascades are ordered and are under tight regulatory control. Thus, for example, whereas SOS activates ras-p21,

TABLE 74-1

Mechanisms for Induction of Carcinogenesis by Mitogenic Pathway Elements

Pathway Element	Mechanism of Action
1. Growth factors	a. Overproduction by cell into surroundings b. Interaction of growth factors with high affinity receptors
2. Growth factor receptors	a. Overexpression leading to high concentration of dimers b. Loss of extracellular domain resulting in permanent dimerization of growth factor receptor and continuous signaling c. Amino acid substitutions in transmembrane domain leading to permanent dimerization
3. Cytosolic proteins	a. Overexpression of normal G-proteins and protein kinases b. Amino acid substitutions that permanently change conformation to activated form c. Mutations that remove regulatory domains of kinases
4. Nuclear oncoproteins	a. Overexpression of transcription and replication proteins b. Mutations in antioncogene proteins that inactivate them c. Mutations that remove regulatory domains

GTPase-activating protein induces hydrolysis of GTP bound to Ras-p21, causing its inactivation (see Fig. 74-1). Activated MEK downregulates SOS, diminishing GDP/GTP exchange by Ras-p21 (Holt, 1996).

If one or more proteins on pathways such as the one shown in Figure 74-1 become mutated so that they cannot be downregulated, continuous mitogenic signaling becomes possible, leading ultimately to neoplasia. The more such mutations occur, the more likely it is that the cell will undergo malignant transformation. Thus progressive lesions in a mitogenic pathway or in more than one mitogenic pathways may correspond to the multiple steps in carcinogenesis.

These considerations have critically important practical consequences for both the diagnosis and treatment of cancer. In colon cancer, overexpression of the epidermal growth factor receptor (EGFr) can occur, resulting in continuous mitogenic signaling. In addition, as a second occurrence, the ras gene encoding the ras-p21 protein can become mutated, resulting in expression of oncogenic ras-p21 and also resulting in continuous mitogenic signaling. Note in Figure 74-1 that ras occurs downstream of the growth factor receptor (EGFr in this case). If elevated levels of EGFr are found in the serum and/or tissue of a patient with colorectal cancer, an effective therapy is to treat the patient with anti-EGFr agents such as monoclonal antibodies (e.g., cetuximab and panitumumab). Unfortunately, treatment with EGFr inhibitors has no effect on oncogenic ras-p21 signaling. Therefore, it is necessary, prior to treatment, to ascertain whether oncogenic ras-p21 is present (Normanno, 2009). If it is not present, EGFr inhibitor administration is effective. If oncogenic ras-p21 is present, however, this treatment cannot be employed.

Table 74-1 summarizes the mechanisms by which each type of signal transduction element has been found to induce cell transformation, beginning with growth factors, progressing to growth factor receptors, then to G proteins and the kinase cascades, and finally to nuclear proteins. These mechanisms are discussed in more detail in each section of this chapter devoted to these different signal transduction proteins.

ONCOPROTEINS IN TUMOR DETECTION

Detection of mutated signal transduction proteins or high levels of the wild-type proteins in serum or body fluids is strongly suggestive of neoplasia. Therefore, many assays for different oncoproteins are now available commercially in kit form, including enzyme-linked immunosorbent assay (ELISA) assays for the growth factors, transforming growth factor (TGF)- α and β and fibroblast growth factor (FGF); the growth factor receptor proteins EGFr and HER2/Neu, Ras-p21; and the nuclear proteins p53, Myc, and NMP22 from such companies as Oncogene Science (Cambridge, Mass.) now a division of Siemens; Triton Bioscience (Alameda, Calif.), a division of Berlex; and Matritech (Newton, Mass.), now a member of

Inverness Medical Innovations, Inc. A number of studies also employ the technique of Western blotting or immunoblotting, as described elsewhere in this book.

Numerous studies have documented alterations in oncogene, oncoprotein, or growth factor expression in terms of messenger RNA (mRNA) or protein in tumor tissue compared with normal tissue (Pimentel, 1989; Brandt-Rauf, 1998; Pincus, 2003). Several studies have examined oncoprotein or growth factor expression in biological fluids such as urine or effusions and demonstrated the feasibility of using these peptides and proteins as markers for the presence of neoplasia (Niman, 1985; Yeh, 1989). Succeeding studies have confirmed these initial findings, resulting in the clinical use of these markers to detect the presence of neoplasia.

Recent studies have now revealed that oncogenes themselves can be detected in the body fluids of patients with different types of cancer. With the advent of microarray techniques both for gene expression and for protein detection (see Chapter 67), it is now possible to assay for the presence of multiple oncogenes and oncoproteins in the body fluids, especially serum, of cancer patients. A new, parallel approach for cancer screening has been developed, called *proteomics*, in which serum samples are subjected to mass spectroscopy and pattern analysis to detect the patterns of expression of proteins that are unique to the blood of cancer patients. This type of analysis has recently resulted in the identification of not only oncoproteins but also other proteins that are expressed at abnormally elevated or abnormally low levels in specific types of cancer.

The focus of this chapter is on the identification of different oncoproteins and growth factors, as well as their respective genes, in the serum, plasma, or urine in patients with cancer or who are at risk for the development of cancer. It also focuses on expression of other proteins that occur at abnormally elevated or low levels in specific types of cancer.

Table 74-2 summarizes some of the many (>50) known oncogenes and their functions in the cell. Those for which commercial serum assays are available are labeled with an asterisk.

GROWTH FACTORS

Because various growth factors are believed to play a role in influencing cellular proliferation during tumorigenesis and because growth factors are actively secreted into the extracellular environment, they are attractive targets for detection in blood during cancer development. Several studies have demonstrated differences in blood levels of growth factors in cancer patients and noncancer controls.

Transforming Growth Factors α and β

TGF- α is a polypeptide with 50 amino acids that binds to the EGF receptor, which dimerizes upon binding to TGF- α or to EGF. TGF- β is a family of proteins labeled β_1 - β_5 . TGF- β_1 is a homodimer of two 12 kDa subunits linked together by disulfide bonds. Even though TGF- β has been found to be elaborated by many different types of human malignant tumors, elevated serum levels of this growth factor have been found predominantly in cancers of the liver and bladder. Interestingly, TGF- β has been found to inhibit mitosis in specific cell lines in culture, such as mink bronchial epithelial cells. Thus the serum of patients who have tumors elaborating this growth factor can be assayed for it by measuring the extent of inhibition of cell growth.

TGF- β activity, which is determined using this technique, has been found to be markedly elevated in patients with hepatocellular carcinoma (HCC) but not in age-matched controls (Shirai, 1992). In the sera of patients who have undergone surgical resection of these tumors, the activity of TGF- β is barely detectable, suggesting that the tumor was the source of the elevated levels of growth factor in serum. Interestingly, in many patients with HCC, TGF- β has been found to be elevated in urine (Tsai, 1997). In this regard, in a study on the development of HCC in patients with hepatitis C (see Chapter 21), TGF- β_1 was found to be elevated in the sera of patients with hepatitis C and hepatitis C-induced fibrosis and cirrhosis but was not elevated in the sera of patients in whom HCC subsequently developed resulting from the antecedent disease. Thus TGF- β_1 may be an early marker for HCC, but lower levels may be required for progression of disease (Ali, 2004). However, in other studies, TGF- β_1 was found to be elevated in small (<3 cm) HCC far more frequently than α -fetoprotein (AFP), the classic marker for HCC (see Chapter 73; Song, 2002). Using a cutoff of 800 pg/mL for TGF- β_1 and 200 pg/mL for AFP, where the specificities of both markers were 95% (i.e., few false-positive results), the sensitivity of TGF- β_1 was 68% vs. only 24% for AFP. Thus TGF- β_1 may be a reliable marker for small HCC. The same conclusion

TABLE 74-2

Summary of Some Important Oncogenes and Their Protein Products¹

Oncogene	Protein product	Function
1. erbB*	EGF receptor	Binds to EGF; dimerizes; activates tyrosine kinases in signal transduction. Works through ras.
2. erbB-2*	GF receptor	Very similar to EGF receptor. Works through ras.
3. sis*	β-chain of PDGF	Growth factor receptor. May work through ras.
4. src	Tyrosine kinase	Transduces signal through ras.
5. ras*	p21 proteins; H-, K-, and N-forms	G-proteins; bind to cell membrane and transduce signals through second messengers and raf, GAP(?), JNK, PKC, and PLC.
6. rap-1A	Anti-ras oncogene; in ras family	Blocks ras action in cells.
7. raf*	74 kDa protein	Phosphorylates MAP kinase kinase (MEK), which then phosphorylates MAP kinase.
8. erk-1 and erk-2*	MAP kinase family 43 kDa proteins	Involved in cytoskeletal rearrangements and nuclear signaling.
9. myc*	62/64 kDa nuclear protein	Turns on transcription factors involved in replication.
10. jun	Nuclear protein	Forms complex with fos.
11. fos	Nuclear protein	Forms complex with jun. fos-jun complex activates transcription factors.
12. p53*	53 kDa nuclear anti-oncogene protein	Forms tetramers, then binds DNA segments to block transcription and replication.
13. NMP22*	236 kDa nuclear matrix protein	Involved in mitotic spindle formation.

EGF, Epidermal growth factor; GAP, GTPase activating protein; GF, growth factor; MAP kinase, mitogen-activated protein kinase; NMP22, nuclear matrix protein 22; PKC, protein kinase C; PLC, phospholipase C. The names of the oncogenes are commonly used and relate to the sources from which they were originally discovered. For example, ras is an abbreviation for rat sarcoma viral oncogene.

*Oncogene-encoded proteins for which assays have been performed on human serum. Serum assay kits are commercially available.

¹Only a few of the many (more than 50) oncogenes are listed in this table. The ones that are listed here encode proteins for which assays have been developed or are closely related to these proteins. No growth factors except PDGF are included in this table.

has been reached in a study of HCC in which the sera of 23% of patients with this disease were positive for TGF-β₁ but not for AFP (Sacco, 2000). TGF-β₁ has also been found to be elevated in metastatic prostate cancer (Adler, 1999).

Use of an ELISA with a monoclonal antibody directed against TGF-β₂ has revealed that TGF-β₂ is elevated in a high proportion of patients with invasive bladder cancer but not in patients with noninvasive bladder cancers or in cancer-free patients (Klocker, 1994; Brandt-Rauf, 1998; Pincus, 2003). Recently, a new tumor marker for bladder cancer that appears to be more accurate in diagnosing both noninvasive and invasive bladder cancer is the nuclear matrix protein NMP22, detected in urine.

Thus serum assays for TGF-β are highly useful in diagnosing and following HCC. They are less useful in the diagnosis of carcinoma of the bladder, although for invasive bladder cancer this growth factor has high sensitivity and specificity.

TGF-α has been found to be elevated in a large number of patients with epithelial cell tumors (Katoh, 1990; Chakrabarty, 1994), predominantly breast (almost 100%), lung, stomach, colon, liver, and ovarian. It has been found to be elevated frequently in the sera of patients with gastric carcinoma (Choi, 1999). In contrast, normal individuals have very low serum levels. With respect to liver, TGF-α has been found to be elevated in the sera of patients with HCC but not in patients with cirrhosis. The elevated levels were reduced in patients who had been treated for HCC (Tomiya, 1996).

Recent studies confirm that TGF-α is an effective predictor of the occurrence of malignancies at an early stage. For example, in 36 patients

who had a history of asbestosis and subsequently developed a cancer, mainly adenocarcinoma or squamous cell carcinoma of the lung, more than one third were found to be seropositive for TGF-α. Blood samples from all of these patients were collected and then banked at the time of the diagnosis of asbestosis and before the diagnosis of malignancy. Significantly, all but one of these seropositive patients were found to have elevated TGF-α levels in their banked blood (Brandt-Rauf, 1998).

TGF-α thus appears to be an excellent marker for the presence of malignancy. Unlike the case for TGF-β, these elevations are not tumor-specific. Nonetheless, it is clear that TGF-α is extremely useful in screening patients for the presence of malignant solid tissue tumors.

Platelet-Derived Growth Factor

Platelet-derived growth factor (PDGF), a protein of molecular mass 28 kDa, exists as a dimer of A and B chains, as the A-A, A-B, or B-B dimer forms. Either chain can be glycosylated, increasing the molecular mass to 30 kDa. This growth factor, originally isolated from platelets, binds to a transmembrane growth factor receptor. The B chain is encoded by the *sis* oncogene. It has been found to be a potent mitogen in lymphoid, myeloid, and fibroblastic cell lines. Overexpression of PDGF has been found in both lung and pleural tumors. It has also been examined in the blood of cancer patients. Overall, this growth factor has been found to be significantly elevated in more than 15% of patients with carcinomas, sarcomas, and lymphomas but not at all in normal individuals. In patients with breast cancer, there is an excellent correlation between the stage of the cancer and the serum level of the growth factor (Ariad, 1991). Higher levels predict shorter survivals. In addition, PDGF-B (*Sis*) in breast tissue appears to correlate with increased cellular proliferation as its expression increases with both nonmalignant and malignant states and decreases after menopause. In malignancy, PDGF-B does not correlate with p53 expression, estrogen/progesterone status, or tumor grade (Coltrera, 1995). The role of PDGF-B as a marker in colorectal cancer is less clear (Lindmark, 1993).

As discussed later, not only oncoproteins may be elevated in the sera of patients with cancer but also antibodies to oncoproteins may likewise be elevated. Anti-PDGF antibody (PDGF-Ab) in serum has been found to be potentially diagnostic for pleural mesothelioma in patients with histories of exposure to asbestos. The serum levels of PDGF-Ab correlate positively with severity of the disease and show a significant negative correlation with survival; that is, higher levels correlate with shorter survival times (Filiberti, 2005).

Basic Fibroblast Growth Factor

Basic fibroblast growth factor (bFGF) is a protein containing 155 amino acids. It is a growth factor for mesenchymal cells but has also been found to have relatively high concentrations in the central nervous system (CNS). Interestingly, bFGF has been found to be present in high concentration in the sera of patients with epithelial cell tumors. Prominent among these tumors is renal cell carcinoma. More than 50% of patients with this disease have markedly elevated serum levels of bFGF (Fujimoto, 1991; Li, 1993) as determined either by ELISA or by enhanced chemiluminescent assays. This growth factor is also elevated in the sera of more than 50% of patients with CNS tumors, 90% of patients with lung cancers (Li, 1993), and more than 60% of patients with lymphomas (Kurobe, 1993). It is not elevated, however, in the sera of large populations of normal (control) individuals.

Elevated serum levels of bFGF have been found to be a good prognostic factor in patients with non-small cell carcinomas of the lung (Brattstrom, 1998). Thus TGF-α and TGF-β, PDGF, and bFGF all appear to be elevated in the sera of a significant number of patients with epithelial cell tumors but are not completely tumor specific. TGF-α has some specificity for breast cancer and TGF-β for HCC. bFGF is elevated in a variety of malignancies, including nonepithelial cell tumors, such as CNS tumors and lymphomas. PDGF shows little specificity for tumor type, but high levels in serum indicate the presence of malignancy.

Given the development of protein/antibody and gene arrays, it is possible to assay the sera and other body fluids of cohorts of patients who are at risk for developing cancer due to such factors as occupational exposure for multiple oncogene proteins concurrently. Discovery of the elevation of and/or the presence of oncogenic mutations in one or more of these proteins in a patient's serum or other body fluid identifies the patient as either having a cancer or developing one in the near future. Recently, serial levels of both TGF-β and PDGF were determined by ELISA assay (see Chapter 44) on a cohort of workers with long-term exposure to asbestos. PDGF, but not TGF-β, was found both to predict the development of non-small cell carcinoma of the lung and to predict (1) the radiographically determined

Figure 74-2 Mechanisms for continuous mitogenic signaling by growth factor receptors. Scheme 1 shows that these receptors have three domains: an extracellular, growth factor-binding domain (ECD); a transmembrane domain (TMD), and an intracytoplasmic domain (ICD). A growth factor, GF, binds to the receptor, causing it to dimerize, setting in motion a cascade of intracellular events that are transduced to the nucleus (N) described in Figure 74-1. There are three known ways in which continuous cell signaling by the growth factor receptor can occur, resulting in malignant transformation of cells. Scheme 2 depicts the first of these: overexpression of the receptor that results in many activation processes and continuous signaling to the nucleus. Scheme 3 shows the second mechanism wherein the ECD is either absent or cleaved off by intracellular proteases, leading to spontaneous dimerization. Scheme 4 shows the third mechanism, in which a mutation in the growth factor receptor gene results in an amino acid substitution (X in the figure) in the transmembrane domain leading to formation of α helices that associate (Brandt-Rauf, 1990), resulting in spontaneous dimerization that can occur in the absence or presence of the ligand.

severity of the disease and (2) the levels of PDGF correlating with severity of cancer and with fibrosis of the lung, which may be a predisposing factor (Li, 2009). These studies parallel the results of other studies, such as the study with TGF- α described earlier, in which the sera of patients with occupational and/or environmental risks have been found to be positive for one or more oncogene proteins prior to appearance of a cancer.

Epidermal Growth Factor and Hepatocyte Growth Factor

EGF has been found to be elevated in the serum of some patients with stomach cancer (Pawlikowski, 1989) and cancer of the tongue (Bhatavdekar, 1993) but unchanged or decreased in other cancers (Nedvidkova, 1992). Elevated serum levels of hepatocyte growth factor have been reported in HCC. However, this growth factor appears to be unique in that elevated levels also occur in nonmalignant liver diseases (Hioki, 1993), diminishing its utility as a tumor marker.

GROWTH FACTOR RECEPTORS

Normally, growth factors bind to their growth factor receptors, generally inducing the receptors to dimerize, an event that activates the receptor. At the growth factor receptor level, there are several mechanisms by which uncontrolled mitogenesis may be initiated. These are summarized in Figure 74-2. For both the EGF receptor and the neu (HER2)-oncogene-encoded p185 growth factor receptor protein, strongly associated with breast cancer (Slamon, 1989; Brandt-Rauf, 1998; Pincus, 2003), receptor dimerization results in activation of tyrosine kinases involved in the phosphorylation of proteins that initiate the transduction of the mitogenic signal to the nucleus. There are three known pathologic mechanisms that can result in causing abnormally prolonged receptor dimerization that results in continuous mitogenic signaling. These are loss of the extracellular binding domain (ECD), mutations in the transmembrane domain that promote dimerization (Brandt-Rauf, 1990; Pincus, 2003), and overexpression of the receptor.

Transmembrane growth factor receptors encoded by the *erbB* family of oncogenes (i.e., *erbB*, which encodes the EGF receptor, also called EGFR, and *HER2/neu* [*erbB-2*]), are particularly attractive targets for detection in blood during cancer development because it has been found that, in human cancers induced by these receptors, the mechanism appears to be proteolysis of the extracellular receptor-binding domain (see Fig. 74-2, third illustration). The liberated extracellular domains, termed *ECD*, then enter the circulation and can be readily detected in serum using conventional immunoassay techniques (Brandt-Rauf, 1994a, 1994b, 1998; Pincus, 2003).

Epidermal Growth Factor Receptor

Overexpression of and/or oncogenic amino acid substitutions in the amino acid sequence of EGFR and in the closely related *HER2/neu* receptor are the primary causes of a large number of human epithelial cell tumors. These include colon, breast, lung, and ovarian cancers (Baron, 2009). This observation has been extended to CNS tumors, in particular, glioblastoma multiforme (Quaranta, 2007). As discussed earlier, serum EGFR is not only important for diagnostic purposes but also suggests a therapeutic strategy, that is, administration of EGFR inhibitors, the efficacy of which can be monitored by assaying for serum EGFR.

A particularly important use of serum EGFR is in following patients with known histories of exposure to environmental agents known to cause specific tumors. Elevations of circulating levels of the ECD of this growth factor receptor have been studied in patients with asbestosis (Brandt-Rauf, 1992), which is known to predispose to malignancies. It has been found that patients with ECD serum levels of 636 fmol/mL or higher either have an asbestos-associated malignancy (carcinoma of the lung or mesothelioma) or subsequently develop such a malignancy. Large numbers of normal individuals have been found to have much lower serum ECD levels. Thus EGFR appears to be an excellent marker for asbestos-induced tumors. These results are also of interest because they suggest that the primary effect of asbestos as a carcinogen is to cause mutations in the EGFR gene (Brandt-Rauf, 1998).

As discussed, many colon cancers are treated with EGFR inhibitors. An important indication of efficacy of treatment is to measure circulating levels of EGFR. It was recently found that baseline levels of serum EGFR were strong predictors of outcome, higher values predicting better responses to treatment with EGFR inhibitors than lower values (Zampino, 2008).

Of considerable interest is the recent finding that serum levels of EGFR can detect the presence of prostate cancer (Milanese, 2009). Use of EGFR in detection of prostate cancer was motivated by the finding that overexpression of EGFR or critical amino acid substitutions in the amino acid sequence of prostate EGFR are strongly associated with prostate cancer. It was found that, using a cutoff value of 67.9 ng/mL for serum EGFR, the sensitivity and specificity of serum EGFR was 93.3% and 98%, respectively. In this study it was further found that the best serodiagnostic marker for spread of prostate cancer beyond the prostate (e.g., into the seminal vesicle) was urokinase-type plasminogen activator receptor. These results suggest that both biomarkers may offer a new approach to diagnosis and monitoring of prostate cancer.

HER2/neu Receptor

This protein is discussed in Chapter 73 as a marker for breast cancer and for a number of other cancers. Here we consider its potential as a marker for different stages of this cancer and for other human epithelial neoplasms. Because of the documented strong association between breast cancer and mutations in the *HER2/neu* gene, many studies have examined the p185 *erbB2* ECD in the blood of cancer patients, particularly breast cancer. In prior studies on *neu* oncogene-induced overexpression of the p185 protein (Slamon, 1989), it was found that the level of expression of the *neu* oncogene in breast cancer biopsy tissue correlated with the extent of the tumor and was the best prognostic indicator of survival rates, exceeding even extent of lymph node involvement as a prognostic indicator.

Results on quantitation of p185 ECD in the serum of patients with breast cancer parallel those of the prior genetic results. Between 25% and 50% of patients with stage III or IV breast cancer have been found to have markedly elevated levels of p185 ECD in their sera (40–190-fold higher than in the sera of normal control individuals) (Mori, 1990; Carney, 1991; Kath, 1993). For patients from whom tumor biopsy material is available, there is an excellent correlation between serum ECD levels and tissue level of expression (Breuer, 1993, 1994; Ludovini, 2008). There is also an excellent correlation between levels of serum ECD and recurrent disease (Brandt-Rauf, 1998). ECD levels in serum have also been found to be an excellent prognostic indicator for breast cancer (Molina, 1996). Recently,

in a study of patients with stage I–III breast cancer, it was found that pre-surgical serum ECD level was an independent prognosticator of disease-free survival in early breast cancer (Ludovini, 2008). This is an important finding because it identifies patients with early breast cancer with complete apparent surgical removal who are at significant risk for recurrence.

Because serum levels of p185 ECD correlate with tumor load and stage, detection of incipient breast cancer using serum levels of p185 ECD is less effective for these patients. Overall, the rate of detection of stages I and II breast cancers using serum levels of ECD, based on conventional ELISA techniques, ranges from 10% to 15%. However, use of a sensitive ELISA assay for p185 ECD in breast cancer patients resulted in discovery of carcinoma *in situ* in 43% of patients with this disease (Breuer, 1993). This latter result indicates that use of more sensitive assays for p185 ECD identifies a significant increase in the number of patients with carcinoma *in situ* (i.e., at an early stage of development).

HER2/neu Detects Pulmonary Neoplasms

p185 ECD is also elevated in a high percentage of patients with pulmonary cancers. Elevated serum levels of EGFR in early tumor detection have been employed to screen patients with known predisposition, such as pneumoconioses, for developing these cancers. In 70% of patients with pneumoconioses, elevated serum p185 ECD levels have been found prior to the onset of frank malignancy. In almost 100% of patients with this predisposing factor who have cancer of the lung, serum p185 ECD is markedly elevated (Brandt-Rauf, 1994a). Clearly, this protein is a highly sensitive marker for pulmonary cancers. In contrast, no elevations of p185 ECD have been found in the sera of large numbers of normal individuals (Brandt-Rauf, 1998; Pincus, 2003).

HER2/neu in the Detection of Hepatocellular Carcinomas

It was noted previously that TGF- β is a good marker for HCC. There are now strong indications that p185 ECD is also a sensitive marker for this disease. Serum p185 ECD has been found to be elevated in almost 100% of East Asian people who have known risk factors for developing this disease (Luo, 1993; Yu, 1994a, 1994b). However, tissue expression of *c-erbB-2* in biopsies derived from patients with HCC and adenoma showed neither overexpression nor amplification by FISH or immunohistochemistry (Vlasoff, 2002). Furthermore, no such elevations have been observed in normal individuals of similar age and race or in those with exposure to risk factors for this disease but who did not subsequently develop cancer.

p185*erbB-2* ECD in Other Tumors

Elevated serum *erbB-2* ECD levels have now been found to occur in patients with colorectal, pancreatic, prostatic, hepatic, and ovarian cancers (Wu, 1993) at lower frequencies of detection (15%–20%) and was also found to be significantly higher in patients with nasopharyngeal carcinoma (Yazici, 2001). Excellent correlations between serum levels and tissue levels have been found in many of these cases. There is a direct correlation between serum levels of p185 ECD and tumor size for premalignant adenomas of the colon (Brandt-Rauf, 1994b). Because colonic neoplasia usually progresses through well-defined steps from adenoma to carcinoma with the malignant potential of adenomas increasing with size, serum *erbB-2* ECD levels may be useful in monitoring this progression. Gene amplification and protein overexpression of *c-erbB-2* were also found in adenocarcinoma derived from Barrett esophagus (Gedder, 2002). In addition, pretreatment serum ECD has been found to be a reliable prognosticator of recurrence of metastatic prostate cancer and significantly more reliable than tissue p185 (Tambo, 2009).

G-PROTEINS

ras-p21 Protein

As for growth factor receptors, signaling proteins that occur downstream of the growth factor receptors become oncogenic primarily from overexpression and amino acid substitutions at critical positions in their polypeptide chains. Less commonly, for some proteins, like Raf (see Fig. 74-1; Table 74-2), loss of regulatory domains may also lead to oncogenesis. Amino acid substitutions in signal transducing proteins cause these proteins to undergo conformational changes that result in their becoming permanently activated to stimulate cell division (Pincus, 1992, 2000, 2004, 2007).

This mechanism has been well documented for the ras-oncogene-encoded p21 protein, for which substitutions of most amino acids for glycine 12 or glutamine 61 result in an oncogenic protein. Many p21 proteins with such substitutions have been cloned and directly microinjected into normal cells in culture such as NIH 3T3 cells (Barbacid, 1987). The cells undergo malignant transformation that lasts until the added mutant protein is metabolized and cleared from the cells. Oncogenic mutant forms of the ras gene and of its encoded p21 protein have been found in approximately one of three common human epithelial cell tumors, in more than 90% of human pancreatic tumors, and 75% of human colon cancers (Forester, 1987; Almoguera, 1988).

One of the consequences of amino acid substitutions in p21 and presumably in other signal transducing proteins is the abnormal activation of alternate, unregulated signal transduction pathways. Oncogenic ras-p21 protein (p21 in Figure 74-1) has been found to interact directly with Jun, the nuclear transcription factor, and its activating kinase, Jun kinase (JNK). This binding process results in the direct activation of these nuclear transcription-inducing proteins, thereby bypassing the normal cellular controls. This bypass or short-circuit pathway is shown on the right side of Figure 74-1 for p21 (Adler, 1995; Amar, 1997; Pincus, 2007). In addition, oncogenic ras-p21 protein requires activation of protein kinase C as a downstream event on its signal transduction pathway (Pincus, 1992), as illustrated in Figure 74-1.

As noted previously, the ras-oncogene-encoded p21 proteins are 21 kDa membrane-associated G proteins that have been implicated in the growth signal transduction process from the cell membrane to cytoplasmic kinases. Qualitative (i.e., point mutations) and quantitative (i.e., overexpression) changes in p21 have been identified as contributing to human carcinogenesis (Barbacid, 1987). By as yet undefined mechanisms, p21 proteins gain access to the extracellular environment. Thus increased amounts of p21 or point-mutated forms of p21 can be detected by immunoblotting with monoclonal antibodies in the supernatant of cells in culture known to overexpress p21 or to express mutant p21, respectively (Brandt-Rauf, 1991, 1998; Pincus, 2003).

Similarly, mice bearing tumors that overexpress p21 or express mutant p21 are found by immunoblotting to have increased amounts of p21 or mutant forms of p21 in their serum, respectively (Hamer, 1991). These results suggest that the detection of increased p21 or mutant p21 in blood is possible in humans.

Because of its central role in mitogenic signal transduction, overexpressed and/or mutated p21 protein might be expected to be present in a wide variety of human tumors. Indeed, elevated serum p21 has been identified in the serum of up to 68% of patients with many different cancers, including breast, prostate, colon, lung, and liver cancer. On the other hand, only a small percentage of normal individuals have been found to have detectable serum levels (Weissfeld, 1994). A high incidence of the occurrence of the oncogenic form of the K-ras gene has been found in human pancreatic and colonic cancers. New assays based on reverse-transcriptase (RT)-PCR have detected the ras oncogene in the stool of a high percentage of patients with colonic cancer (Pincus, 2004).

ras-p21 in Lung Cancer

Similarly encouraging results have been obtained using the sputum of patients with lung cancer. Parallel results have now been obtained using the ELISA for the p21 protein using the serum of patients with lung and colonic carcinoma. Elevated levels (five times more than controls) of serum ras-p21 have been found in up to 83% of lung cancer patients, whereas only low levels were found in the sera of normal individuals (Brandt-Rauf, 1991, 1998). In addition, studies have been carried out in which PCR for K-ras mutant genes with base changes at codons 12 and 13 has been performed concurrently on tumor tissue and serum from patients with different stages of colorectal cancer (de Kok, 1997). In more than 90% of the patients with specific mutant ras genes found in tumor tissue, the same mutated ras gene was discovered in their sera, regardless of the stage of the tumor.

In the previous discussion of the HER2/neu-oncogene-encoded p185 protein, it was noted that elevations of the serum levels of this protein were found in patients with pneumoconioses who then progressed to develop frank malignancies. A parallel study has been performed on patients with pneumoconioses in which assays were carried out for ras-p21 in their sera. For patients with this predisposing condition, 39% were found by Western blotting to have elevated serum levels of the ras-p21 protein. Almost all of these patients developed a malignant lung tumor subsequent to the observed elevations of the p21 protein. Thus, like p185 ECD, elevated serum p21 is a biomarker of early malignant disease in patients with a

known predisposition. An obvious study that is yet to be performed is to assay the sera of these patients for both HER2/neu and ras-p21 to increase the sensitivity of the assays.

The aforementioned studies are concerned with detecting elevated serum levels of p21 in serum as an indicator of malignancy. As noted previously, a major mechanism for oncogenesis induced by the ras-p21 protein is amino acid substitutions in its sequence that result in its permanent activation. Identification of mutant ras genes by PCR and direct sequencing of DNA isolated from the serum or plasma of three patients with pancreatic cancer has been described (Sorenson, 1994), but, until recently, the direct detection of mutant p21 protein had not been reported in human blood (de Kok, 1997). Now, however, oncogenic amino acid substitutions in the p21 protein can be identified through the use of monoclonal antibodies that recognize specific oncogenic amino acid substitutions including at positions 12, 13, 59, and 61. Use of these antibodies on the sera of patients with known risk factors for cancer appears to offer much promise for early tumor detection.

ras-p21 in Angiosarcoma

Mutated p21 has been found in the serum of patients with a known history of exposure to the carcinogen, vinyl chloride. This chemical has been shown to predispose individuals to developing angiosarcomas (Brandt-Rauf, 1998). Tissue studies of these angiosarcomas reveal that a mutant ras gene that codes for aspartic acid in place of the normally occurring glycine at position 13 in the polypeptide chain is present in the tumor cells. A monoclonal antibody that recognizes the Asp13 form of the p21 protein has been obtained (Oncogene Science/Siemens). This mutant p21 protein has been identified in the sera of 80% of patients with vinyl chloride-induced angiosarcoma of the liver but not in normal individuals (DeVivo, 1994). There is a direct correlation, moreover, between the degree of exposure of patients to vinyl chloride and the probability of discovering the oncogenic form of the protein in their sera.

ras-p21 in Pancreatic Cancer

In view of the strong causative association of oncogenic k-ras-p21 with pancreatic cancer, it is surprising that there have been no studies using this protein as a marker for this disease. Rather, studies have focused on employing assays for the ras oncogene itself in the sera of patients with this disease. A recent study on patients with pancreatic cancer and a control group of patients with pancreatitis used RT-PCR to detect mutant ras DNA in the sera of these patients together with a serum assay for CA 19-9, a marker for pancreatic cancer as discussed in Chapter 73 (Dabritz, 2009). Using DNA amplification techniques to detect oncogenes in serum is discussed later. In this study, no patients with pancreatitis were found to have oncogenic ras gene in their sera, whereas 36% of patients with pancreatic cancer were found to have detectable serum levels of this oncogene. Overall, using both markers, 91% of the patients with pancreatic cancer were found to have either elevated levels of CA 19-9 or oncogenic ras-p21 or both. Of these, 35% were found to have detectable oncogenic ras but nonelevated or only moderately elevated CA 19-9. Using restriction fragment length polymorphism (RFLP)-PCR on serum samples from patients with pancreatic cancer before and after chemoradiation therapy (CRT), it was found that in patients whose post-CRT sera were negative for oncogenic ras had significantly more favorable survivals (Olsen, 2009).

CYTOSOLIC MITOGENIC KINASES

raf

As shown in Figure 74-1 and Table 74-2, Raf is a 74 kDa protein that is a critical target of ras-p21. It directly activates MEK, which, in turn, activates MAPK (ERK) (see Figure 74-1 and Table 74-2). It is involved in cell growth, proliferation, apoptosis, and differentiation. There are several different isoforms of Raf, such as Raf A and Raf B, which may differ in their exact cellular functions. More than 30 mutations of the B-raf gene associated with human cancers have been identified (Wan, 2004). Western blot analysis showed that activated Raf was overexpressed in tissues obtained from cirrhosis and HCC patients (91.2% and 100%, respectively) (Hwang, 2004). B-raf mutations have also been found in colon cancer, although less frequently than K-ras (Monstein, 2004). However, Raf is found minimally to not at all in tissues from patients with bladder or endometrial carcinoma (Mutch, 2004; Stoehr, 2004). In contrast, mutant raf (V600E) has been found to occur frequently in melanomas although the same mutant raf has also been found in a majority of benign nevi (Wellbrock, 2004). Because raf is immediately downstream of ras-p21 on

the ras signal transduction pathway (Figure 74-1), oncogenic mutations in raf might also be expected to diminish the efficacy of anti-EGFr agents in cancers, especially colorectal cancers. This has been found to be the case for metastatic colon cancer (De Nicolantonio, 2008).

NUCLEAR ONCOPROTEINS

As noted previously, two important nuclear proteins that appear to play critical roles in the regulation of cell growth and division are the tumor suppressor gene protein, p53, and the p62/75 protein encoded by the c-myc oncogene for which serum assays have been developed. Furthermore, nuclear skeletal or matrix proteins are the targets of signal transducing kinases such as MAP kinase, as indicated in Figure 74-1.

p53 and c-myc Proteins

The protein p53 is known to function as a homotetramer and, in this form, binds to specific sequences of DNA. The effect is to repress the mitotic process. In addition, activation of p53 in transformed cells results in apoptosis via activation of pro-apoptotic proteins such as Bax and caspases. Thus p53 is an anti-oncogene protein. Mutations can occur in p53 that inactivate it. This inactivation can itself be oncogenic because the vital control that this protein exerts over mitogenesis is removed. Among the inactivating mutations are deletions of the whole gene, as has been found in a number of colon cancers, and mutations in the gene resulting in amino acid substitutions in the encoded p53 protein. These substitutions cause conformational changes in the protein that result in its inability to perform its antioncogenic function in the cell (Brandt-Rauf, 1996).

Many different point mutations in p53 have been identified in human tumors (Soussi, 1994). The effect of these mutations is to cause a loss of the normal growth-inhibitory function of p53 and, at the same time, some of these mutations result in p53 proteins with considerably increased half-lives so that the mutant proteins accumulate in the transformed cells (Soussi, 1994).

The c-myc oncoprotein is activated to cause cell transformation by overexpression, so it, too, accumulates in transformed cells (Field, 1990). Thus for both p53 and p62/75 myc, increased levels of the proteins can be detected in transformed cells and human tumors (Field, 1990; Soussi, 1994). This overexpression apparently results in leakage of the proteins into the extracellular environment. Not only can these proteins therefore be detected in serum and other body fluids, but these normally sequestered proteins are recognized as foreign, so that some cancer patients develop antibodies to p53 or p62/75 myc. As a result, increased concentrations of p53 or p62/75 or of antibodies to these proteins in blood are excellent markers for tumor detection, for following treatment efficacy and for prognosis.

Detection of Malignancies by Assaying for p53 Protein

Hepatocellular Carcinoma

Increased levels of mutant p53 in serum by ELISA (>0.3 ng/mL, the upper limit of 100 normals) have been found in 20% of patients with HCC and 30% of patients with cirrhosis, a group known to be at increased risk for the development of HCC (Virji, 1992). Because patients with cirrhosis have high levels of p53 in their sera and a known risk factor for developing HCC, the elevated p53 levels may be an early indicator of tumorigenesis.

Breast and Lung Cancers

There have been few studies on p53 as a tumor marker in the sera of patients with breast and lung cancers. Elevated serum mutant p53 levels determined by ELISA have been reported in 8% of breast cancer patients, with levels decreasing following surgical resection of the tumors (Rosanelli, 1993), indicating that the tumors were the source of the elevated p53. Elevations of p53 protein have not been observed in the sera of any normal individuals.

For lung cancer, elevated serum mutant p53 levels determined by ELISA and immunoblotting have been found in up to 34% of lung cancer patients but not in normal individuals (Fontanini, 1994). For these patients, immunohistochemical staining of subsequently obtained biopsy tissue showed elevated p53 levels, correlating with the serum findings.

Colon Cancer

An important mechanism believed to be operative in the development of colonic carcinoma is the deletion of the normal p53 gene or mutation of

the gene leading to a nonfunctional antioncogenic protein. Elevated serum mutant p53 determined by ELISA has been found in about one in five patients with colon carcinomas and in approximately one in 10 patients with colonic adenomas. Normal individuals were found to be negative for serum p53 protein. These results show relatively low sensitivity of this marker for colon cancer, possibly because deletion of the p53 gene occurred in a high percentage of the tumors studied.

Bladder Cancer

Studies on the urine of patients with bladder cancer using PCR for p53 on shed cells in urine samples found that the p53 gene was mutated in a high proportion of these patients (Sidransky, 1991), supporting the use of p53 in screening for this disease in a completely noninvasive manner. As discussed later, p53, together with several other promising markers, may result in a set of tests that have a high positive predictive value.

Circulating Anti-p53 Antibodies in Tumor Detection

Serum antibodies against p53 have been reported to be a frequent occurrence in patients with several types of cancer. Production of antibodies to p53 and other oncoproteins has been attributed to their accumulation in necrotic cells and their subsequent release into the circulation, where they are recognized as foreign (Pincus, 2003). There is another cause for the development of antibodies to oncogenic p53. Like oncogenic ras-p21, mutant p53 proteins, containing single amino acid substitutions at critical positions in the polypeptide chain, themselves become oncogenic. These amino acid substitutions induce major changes in the conformation of the p53 protein (Brandt-Rauf, 1996; Adler, 1998). Among these changes is the exposure of specific antigenic determinants that are not normally exposed (Pincus, 2003, 2007). If the protein diffuses into the circulation, antibodies against these determinants often develop.

Antibodies to p53 Are Present in the Sera of Many Patients with Epithelial Cell Tumors and Lymphomas

In several major studies (including a large study of 1392 cancer patients), elevated serum levels of anti-p53 antibodies were found in patients with ovarian and colon cancers (15%); lung cancers, including small cell tumors (up to 25%); and breast cancers, including intraductal carcinoma (up to 15%). Normal individuals did not have elevated serum levels of these antibodies (Angelopoulou, 1994). In a significant number of patients who have been followed for the presence of anti-p53 antibodies in their sera, the appearance of these antibodies has been found to precede the occurrence of malignant tumors. Anti-p53 antibodies are also found to occur in more than 20% of patients with bladder cancer (mostly at more advanced stages), in a high proportion of patients with pancreatic and hepatocellular carcinomas, and in childhood lymphomas.

Anti-p53 in Ovarian Cancer

Further studies on the expression of anti-p53 antibodies in the sera of patients with ovarian cancer have been performed (Tsai-Turton, 2009). Patients with type 2 ovarian cancer, a more aggressive form of this cancer, were found to have anti-p53 antibodies in their sera whereas no patients with less aggressive type 1 cancers were found to have these antibodies in their sera. All of these patients with anti-p53 in their sera were found to have mutant forms of p53 in their cancers; those who did not have mutant p53 in their tumors were not found to have anti-p53 antibodies in their sera, suggesting that mutant p53 is required to provoke this immune response. In all of these seropositive patients, extensive assays for cytokines revealed that interleukin (IL)-4 and 12 were consistently elevated in serum whereas IL-8 was consistently decreased.

Anti-p53 in Hepatocellular Carcinoma

Continuing follow-up studies on anti-p53 antibodies in patients with different cancers reveal that up to half of the patients with HCC, regardless of the size, have markedly elevated serum levels of anti-p53 (Ryder, 1996). These elevated levels correlate with the known elevation of p53 in the sera of patients with this type of cancer.

Anti-p53 in Oral and Esophageal Cancers

Anti-p53 antibodies have likewise been found in the sera of patients with oral lesions, and many of these patients were found to have premalignant lesions (Kaur, 1997), indicating that anti-p53 antibodies are markers for

early detection of oral cancer. Anti-p53 has also been found to be elevated in more than 50% of patients with esophageal squamous cell carcinoma (Shimada, 1998), indicating that anti-p53 may be a very useful one in the diagnosis of this disease.

Anti-p53 in Lung Cancers

In a prospective study of patients with carcinoma of the lung, serum anti-p53 levels were found in 100% of patients with large cell carcinoma, 28% with adenocarcinomas, 55% with squamous cell carcinomas, and 71% with small-cell carcinomas (Segawa, 1998). These results demonstrate that elevated serum anti-p53 levels are tumor-type-specific for carcinoma of the lung, showing high positivity rates for large and small cell lung carcinomas.

Anti-p53 Predicts Cancer Occurrence in Patients with Asbestos Exposure

A retrospective study (Li, 2004) of 103 patients with a known prolonged exposure to asbestos whose serum was banked between the years 1980 and 1988 has been performed. These patients were all followed until the end of 2001. Assays for anti-p53 antibodies were performed on the banked sera. It was found that, of 49 patients who developed cancer, 13 (26.5%) had significantly elevated levels of anti-p53 antibodies in their sera although four of the 54 (7.4%) individuals who did not develop cancer were found to have these antibodies. In all four cases, the antibody levels were found initially to be marginally greater than the cutoff for positivity but, for all four, subsequent banked serum samples were found to be antibody-negative.

In contrast, in all 13 cancer patients for whom multiple samples were available, all samples were positive for these antibodies. Statistical analysis of these results showed that the presence of anti-p53 antibodies is an independent predictor of cancer occurrence and that survival in anti-p53-antibody-free patients is significantly greater than in anti-p53-antibody-positive patients.

Anti-p53 in Colorectal Cancer

Serum anti-p53 antibodies have been found to be reliable indicators of postoperative recurrence of colorectal cancer (Tang, 2009). In patients whose preoperative anti-p53 titers were elevated, elevated postoperative serum anti-p53 antibody titers were found to be better indicators of tumor recurrence than serum elevation of carcinoembryonic antigen (CEA), the classic serum marker for colorectal cancer as discussed in Chapter 73.

myc Oncogene-Encoded Protein in Tumor Detection

The myc gene codes for a protein of molecular mass of 75kDa that functions as a transcription factor. When activated, it derepresses expression of other genes that encode proteins involved in replication. This oncogene is overexpressed in a number of tumors, including Burkitt's lymphoma wherein the myc gene on chromosome 8 is translocated to a long terminal repeat-like region of an immunoglobulin-coding region of chromosome 14. Long terminal repeat regions allow constitutive expression of genes that are adjacent to them.

c-myc-related proteins and antibodies to the c-myc protein, such as p53 and antibodies to it, have been identified in the serum of cancer patients. Detection of this 62/75 kDa protein is hampered by its short half-life in serum. However, it is possible to detect a specific c-myc-related p40 protein in the serum of these patients, using immunoblotting. The highest frequencies of occurrence of myc protein in human serum has been found to occur in breast (about 20%) and colon cancer. Treatment of both types of cancer results in marked diminution in the serum levels of this protein. Recurrences result in elevated levels; c-myc protein is therefore useful in following the course of malignant tumors. It has not been detected in the sera of normal individuals.

Serum Anti-c-myc Protein Antibodies in Tumor Detection in Breast Cancer, Ovarian Cancer, Leukemias, and Lymphomas

High serum levels of anti-c-myc antibodies have been found in the sera of patients with colorectal cancer (55%–65%) and in the sera of patients with both myeloid leukemias and Burkitt's lymphoma. Lower occurrences of elevated antibodies have been reported in patients with breast cancer

(around 10%) and ovarian cancers (10%). Anti-c-myc antibodies have not been found in the sera of normal individuals.

Combined Oncogene Marker Proteins for Detection of Colorectal Cancer

As is discussed later, since the development of gene, mRNA, and protein arrays, it is now possible to screen for multiple oncogene proteins at the same time. Recently, a study was performed in which the peripheral blood leukocytes of patients with colorectal cancer at all stages and of a control group were assayed for overexpression of ras-p21, myc, and p53 proteins. All of the patients with colorectal cancer were found to have marked overexpression of all three oncoproteins compared with the control group (Csontos, 2008). This study is significant both because three oncoproteins were overexpressed consistently in this disease and because it involves the novel use of leukocytes, rather than serum, to assay for oncoprotein expression, pointing to a new diagnostic approach.

Nuclear Matrix Proteins—Detection of Bladder Cancer

Important targets of oncogene-encoded proteins are nuclear matrix proteins (NMPs) (Fig. 74-1), also referred to as *nuclear skeletal proteins*, and nuclear mitotic apparatus proteins. These 236 kDa proteins are vital for correct mitotic spindle formation. They contain a globular head and tail separated by a central rod-like α -helical core domain consisting of heptad repeat sequences. These proteins vary by cell type, stage of differentiation, and cell cycle. Crucially, a number of tumor-associated NMPs has been identified, each specific for one of five tumor types (bladder, prostate, breast, colon, and bone). The best studied is one strongly associated with transitional cell carcinoma of the bladder, NMP22, which functions as a nuclear mitotic apparatus protein, involved with chromosomal separation during mitosis (Hughes, 1999). The amount of this protein in malignant transitional epithelial cells is 10–20 times that in normal cells.

NMP-22 Is an Excellent Biomarker for Bladder and Urothelial Cancers

Antibodies that are specific for this NMP have been developed and are now used in a commercial ELISA on urine (Matritech/Berlex, Newton, MA). Since malignant urothelial cells in patients with bladder cancer are frequently exfoliated into the urine of these patients, this protein from the lysed cancer cells can be detected at elevated levels. Multiple studies of patients who have bladder cancers of a variety of different stages reveal that the sensitivity is close to 90% in malignant, invasive cancer and 75% in carcinoma in situ. The latter result is highly encouraging, since this stage is the earliest detectable one. For malignant papillary, noninvasive carcinoma, the sensitivity is 62%. The overall specificity for this marker ranges from around 73% to as high as 90% depending on the specific study.

Comparison of the sensitivity of NMP22 ELISA with that of cytology reveals that the two methods are about 83% sensitive for invasive carcinoma, but for grade I transitional cell carcinoma, NMP22 is 61% sensitive whereas cytology is only 17% sensitive (Landman, 1998). For grades II and III cancers, the NMP22 ELISA is more sensitive at 78% and 93% than cytologic sensitivities of 50% and 87%, respectively (Landman, 1998).

More recently, studies have compared overall sensitivity and specificity of NMP-22 with the sensitivity and specificity of urine cytology in screening for urothelial cancer of all types and stages. One prospective study of 103 patients found that NMP-22 and cytology gave approximately the same sensitivities and specificities, that is, 69% sensitivity and 76% specificity for NMP-22 and 75% sensitivity and 73% specificity for urine cytology (Hautmann, 2007). On the other hand, another large study of 93 patients with bladder cancer, 42 patients with benign urothelial conditions and 50 normal volunteers found that NMP-22 had a sensitivity of 78% and a specificity of 73% whereas cytology had a sensitivity of 24% and a specificity of 97% (Tsui, 2007). In a study for recurrent bladder cancer in a large cohort of patients it was found that the sensitivity (85.7%), specificity (77.5%), positive predictive value (70.6%), and negative predictive value (89.6%) of NMP-22 alone was almost the same when it was combined with urine cytologic findings, presumably because the sensitivity of NMP-22 is higher than that for urine cytology (Gupta, 2009). These findings again suggest that NMP-22 is more effective overall in screening for bladder cancer than urine cytology.

NMP-22 testing has been approved by the US Food and Drug Administration (FDA), both for screening for the presence of bladder cancer and for the follow-up of bladder cancer in patients who have been treated for this disease. With respect to the latter use of this method, clinical studies have been performed in which the NMP22 ELISA was performed on the urine of patients who have been treated for transitional cell carcinoma, 20–60 days following treatment, who were then subjected to cystoscopy 2–6 months following treatment. Using a cutoff of 10 U/mL, 86% of patients with negative (<10 U/mL) NMP22 values were found to have negative cystoscopic results, and 71% of patients with values greater than 10 U/mL were found to have positive cystoscopic findings. These results, combined with those of other studies, suggest that this methodology may obviate the necessity for performing cystoscopy on many patients who are being followed for tumor recurrence (Miyanaga, 1997).

NMP-22 can be used to monitor the recurrence of bladder cancer after resection. However, because recurrent tumors are smaller than initial tumors, cutoff values should be altered in these cases as the sensitivity of this test increases from 19% to 49% when the cutoff value is reduced to 5.0 U/mL (Miyanaga, 2003).

Bladder Tumor Antigen

Several other biomarkers for bladder cancer are also being used to aid in the diagnosis and follow-up of this disease. Prominent among these is the so-called bladder tumor antigen, which measures a human complement H protein that is produced by malignant but not by normal transitional epithelial cells. This marker has a somewhat lower sensitivity than that for NMP-22 (Tsui, 2007) and also has a lower specificity due to false-positive results from trauma to the urothelial tract. However, use of NMP-22 together with bladder tumor antigen and a number of other markers, including urokinase-type plasminogen activator, can improve the overall sensitivity of bladder cancer detection (Shariat, 2003). It should be further noted that other tests on urine, such as those for mutant or absent p53 discussed previously and for homozygous deletion of the 9p21 chromosome, discussed later, also have high diagnostic yields. Because these tests are relatively simple to perform, it is conceivable that they can be placed on a chip that will allow for simultaneous evaluations. A positive result on one or more test would suggest the occurrence of bladder cancer.

USE OF MULTIPLE ONCOPROTEIN MARKERS IN THE DIAGNOSIS OF CANCER

Early detection of cancer using oncoproteins has been enhanced by two new developments: (1) use of oncoprotein and oncogene arrays (i.e., use of multiple oncoproteins and multiple oncogenes) and (2) proteomics (i.e., identification of differential protein expression in the sera and body fluids of patients with specific cancers compared with expression in the sera and body fluids of control groups). The proteomic approach has been further modified to include the identification of major proteins whose levels are expressed at high or low levels reproducibly in the sera or body fluids of patients with specific cancers but not in those of patients with benign disease or of normal individuals.

MULTIPLE ONCOPROTEIN ASSAY IN PATIENTS AT RISK FOR TUMOR DEVELOPMENT IN PATIENTS WITH PNEUMOCONIOSIS

In a prospective study, 46 patients with a history of exposure to carcinogens and with attendant pneumoconiosis participated in a study in which their sera were assayed for elevated levels of five oncoproteins: ras-p21, Fes, Myb, PDGF, and Int-1. Eighteen of these patients were found to have cancer, including 13 with lung cancer or mesothelioma, at the time the assays were performed. Of these 18 patients, 13 were found to have markedly elevated levels of at least one of the five oncoproteins for which the assays were performed. Eight of these patients were found to have elevations of at least two of these proteins. Another seven patients were found to have elevations of at least two of these oncoproteins but were not found to have cancer. Although some of these latter patients were lost to follow-up, long term follow-up revealed the subsequent development of cancer in all of the remaining patients. Importantly, several of the patients with only one elevated marker were found to have elevations of different

tumor markers in their serum, emphasizing the importance of assaying for as many different oncoproteins as possible (Qin, 2002).

ONCOPROTEIN ARRAYS LIKEWISE HOLD PROMISE IN DETECTING ANTIONCOPROTEIN ANTIBODIES IN SERA

Based on the findings that many patients with cancers are found to have antibodies to a variety of oncoproteins, such as p53 and Myc, studies have been performed to detect one or more such antibodies in patients' sera. In one such study, a miniarray of up to seven full length recombinant oncoproteins was prepared and included such oncoproteins as Myc and p53.

This array was employed to detect antibodies in 527 sera from patients with six different types of cancer (Zhang, 2003). The antibody frequency to any one oncoprotein was on the order of 15%–20%, but inclusion of all seven oncoproteins resulted in detection of up to 68%. Furthermore, distinct patterns of antibody expression were found for patients with breast, lung, and prostate cancer, whereas no discrete patterns were found for patients with gastric, colorectal, or hepatocellular carcinomas. These encouraging results can be enhanced by the inclusion of more oncoproteins. Given the results regarding detection of single oncoproteins, it would seem even more effective to construct arrays with the antibodies to the large number of known oncoproteins in cancer patients to assay for the presence of increased levels of these and/or mutated forms.

PROTEOMIC APPROACHES TO EARLY DETECTION OF CANCER IN SERUM

The aforementioned approaches to tumor detection are based on using known oncoproteins that are expressed in uncontrolled cell proliferation. Alternatively, other approaches, mainly the so-called proteomic approach, described extensively in Chapter 77, have been developed over the past several years to search for the expression of multiple proteins (hence the term *proteomic*) that occur uniquely in human cancers and not in normal and nonmalignant cells. These proteins are then used to detect tumors at an early stage. These techniques involve two-dimensional polyacrylamide gel electrophoresis on protein extracts, from tissue and serum, which are first labeled with different fluorochromes (Wulfschuhle, 2003). The resulting gels from cancer patients are compared with those from normal subjects to detect differences in fluorescent labeling. Bands that differ are eluted and subjected to mass spectrometry to determine molecular weight and fragmentation patterns.

Ultimately, mass spectroscopy, the principles of which are described in Chapters 4, 23, and 77, can be used to obtain sequence information on these proteins. Using this technique, the RS/DI-1 protein that regulates protein–RNA interactions has been identified as a circulating protein in the sera of breast cancer patients but not in normal individuals. Likewise, the protein PGP9.5 has been found to occur in the sera of patients with lung cancer (Wulfschuhle, 2003).

This approach has therefore shown promise in identifying unique markers for different types of cancer. However, it requires high concentrations of proteins to enable detection on the two-dimensional gels and is quite time-consuming. Nonetheless, it is a powerful method for the discovery of proteins that are unique to specific types of tumor.

Another, more direct and more sensitive approach has been designed that enables detection of cancer in the serum of affected patients. In this method the sera of patients is directly applied to a chip, which allows for the partial separation of the proteins in the sample. The chip is then subjected to surface-enhanced laser desorption ionization time of flight (SELDI-TOF) mass spectrometry, as described in Chapters 4 and 77. This produces a complex pattern of protein and protein ion fragments with different mass-to-charge ratios (Wulfschuhle, 2003).

The patterns for the sera of patients with cancer are compared with those from normal individuals using computer pattern-recognition algorithms (some of them based on neural network theory) that can distinguish cancer patterns from normal ones. Importantly, the normal sera provide a “training set” of patterns that defines the normal pattern while a second set of sera from known cancer patients defines the cancer training set (Wulfschuhle, 2003). The idea of profiling patients with different tumor types is consistent with the earlier discussion, in which it was noted that certain patterns of anti-oncoprotein antibody occurrence in serum appear to characterize specific cancers.

APPLICATION OF THE PROTEOMIC APPROACH TO THE DIAGNOSIS OF CANCERS

Ovarian Cancer

The proteomic pattern-recognition approach was applied to 25 patients with ovarian cancers at all stages and a group of unaffected individuals. The sera were analyzed in a blind study. The method resulted in detecting 100% of the patients with ovarian cancer, including 18 who had stage I (early) disease. All the sera from the unaffected patients were identified as being negative for ovarian cancer (Wulfkuhle, 2003). On the other hand, the sera from patients with other types of cancer could not be classified by the algorithm, suggesting that ovarian cancer has a unique protein "profile."

Prostate Cancer

Similar results have been obtained now for patients with breast and prostate cancers. In one study, using an algorithm that incorporated a decision tree classification system, the method had a sensitivity of 83% and a specificity of 97% in distinguishing sera from patients with prostate cancer from sera from patients with non-cancerous conditions like benign prostatic hypertrophy (BPH) or with no disease. The sensitivity could be raised to 100% by incorporation of a more robust algorithm (Wulfkuhle, 2003).

As noted in Chapter 73, prostate specific antigen (PSA) is the marker used in the diagnosis of prostate cancer; the upper limit of normal for PSA is taken to be 4 ng/mL but the 4–10 ng/mL range encompasses many false-positive results. Thus this method was applied to patients found to have serum PSA levels of 4–10 ng/mL. It was found that it could accurately predict the occurrence of cancer in 95% of patients with PSA values in this range and could detect 70% (107 of 153 patients) with benign disease but PSA levels greater than 4 ng/mL (upper reference range) (Wulfkuhle, 2003).

Proteomics Show Promise in Early Tumor Detection

The proteomic approach thus appears to be highly promising. Drawbacks include the absence of identity of many of the proteins in the training sets. In the case of prostate cancer detection, different groups who have analyzed the sera of prostate cancer patients and unaffected individuals have obtained different diagnostic protein patterns in none of which PSA has been identified (Diamandis, 2003). Yet PSA is known to be elevated in more than 90% of patients with prostate cancer. Further questions have been raised as to whether important protein molecules such as PSA are present in sufficiently high concentration in a serum sample to be detected by the method and whether the actual patterns really characterize prostate tissue. With identification of the proteins in the training sets, these questions should be resolved.

PROTEIN ARRAYS FOR SPECIFIC TYPES OF CANCER

Proteomic approaches have been modified so as to identify specific critical proteins whose serum levels reliably increase or decrease in specific cancers. Arrays containing these proteins are then employed to screen patients for the presence of specific cancers as we now describe.

Squamous Cell Carcinomas of the Head and Neck

To identify proteins that, as a group, are expressed in oral squamous cell carcinomas (OSCC), human OSCCs were xenotransplanted into mice. Protein expression in the sera of these mice was compared with that in control sera of non-transplanted mice (Bijian, 2009). It was possible to identify a number of proteins whose expressions exhibited major differences between the two groups. Large increases in expression in the sera of mice transplanted with the OSCCs included EGFr, cytokeratins, a G-protein-coupled receptor, Rab11 GTPase, and several other proteins. Arrays containing antibodies to these proteins are being used to screen for this disease.

In a modification of the proteomic method, a large expression array consisting of multiple oncoproteins, cytokines, chemokines, and tumor markers, such as those discussed in Chapter 73, was used to select the best diagnostic combination of these for head and neck cancers (Linkov, 2007). These cancers can be diagnosed with a sensitivity of 84.5% and a specificity

of 98% if the following combination of biomarkers was used: EGF, EGFr, IL-8, tissue plasminogen activator inhibitor-1, AFP, matrix metalloproteinase-2, matrix metalloproteinase-3, IFN- α , IFN- γ , IFN-inducible protein-10, regulated on activation, normal T-cell expressed and secreted (RANTES) protein, macrophage inflammatory protein-1 α , IL-7, IL-17, IL-1 receptor- α , IL-2 receptor, granulocyte colony-stimulating factor, mesothelin, insulin-like growth factor binding protein 1, E-selectin, cytokeratin-19, vascular cell adhesion molecule, and cancer antigen-125. Using this array on a group of patients with known cancers of the head and neck and a group without this disease, 92% of the patients were correctly diagnosed with this disease.

Breast Cancer

Using a similar approach for breast cancer detection, the sera from 4500 patients with different cancer types including nonmetastatic breast cancer were screened using 50 different protein markers of which 35 were selected (Kim, 2009). When compared with controls, EGF, soluble CD40-ligand, and pro-apolipoprotein A1 were all found to be increased in breast cancer patients while high-molecular-weight kininogen, apolipoprotein A1, soluble vascular cell adhesion molecule-1, plasminogen activator inhibitor-1, vitamin-D binding protein, and fibronectin were decreased in the cancer group. Diagnostic accuracy using these proteins was approximately 90% percent, indicating that the breast cancer array has promise in early detection of this disease.

Lung Cancer

Proteomic methodology has been applied to the sera of a large cohort of patients with squamous cell carcinoma of the lung and a control group (Dowling, 2007). To increase the diagnostic sensitivity of the method, all sera were immunodepleted of all major common serum proteins, such as albumin, and were then subjected to high resolution 2-D electrophoresis and mass spectroscopy. It has been found that a set of proteins—apolipoprotein A-IV precursor, chain F; human complement component C3c; haptoglobin; serum amyloid A protein precursor; and Ras-related protein Rab-7b—is reproducibly elevated. In addition, another set of proteins, α -2-HS glycoprotein, hemopexin precursor, pro-apolipoprotein, anti-thrombin III, and SP40, was reproducibly decreased. This resulting lung cancer array appears to be very useful in screening for this disease.

DETECTION OF ONCOGENES IN SERUM AND OTHER BODY FLUIDS

CELL-FREE NUCLEIC ACID TESTING IN CANCER

Protein tumor markers and histopathologic staging have been the cornerstones of diagnosis and prognosis of malignancy. As mentioned earlier in the G-proteins subsection on ras for detection of pancreatic cancer using amplified ras DNA in serum, the discovery of cell-free nucleic acids in serum, plasma, urine, or other body fluids over the past decade has promoted investigation of oncogenes encoding oncoproteins as an additional means to detect malignancy in a variety of cancers with potentially greater sensitivity (Schmidt, 2004). These studies include melanoma (Kopreski, 1999; Board, 2009), lung (Fleischhacker, 2001; Schmidt, 2004; He, 2009), stomach (Park, 2009), colon (Silva, 2002), breast (Chen, 2000; Gal, 2001), prostate (Goessl, 2001, 2002), ovary (Hickey, 1999), Epstein-Barr virus-positive lymphomas (Lechowicz, 2002; Lei, 2002), leukemia (Schwarz, 2009), intracranial neoplasms (Rhodes, 1994), and bladder (Goessl, 2001, 2002; Utting, 2002; Guo, 2009).

The basic concept is that tumor-derived nucleic acid can be detected in cell-free sources, such as serum, plasma, urine, and lavage fluid, using amplification methods such as RT-PCR or other detection methods (Goldshtein, 2009). Normally, DNA is isolated from tissue through standard procedures using phenol chloroform extraction followed by ethanol precipitation. However, DNA can also be obtained directly from serum, plasma, or other body fluids by centrifugation, separating it from cells and platelets. The methodology of cell-free nucleic-acid-based detection includes detection of gene mutations, microsatellite alterations, and promoter hypermethylation.

GENE MUTATIONS

These normally involve nucleic acid sequencing and can detect single base changes in genomic or mitochondrial DNA (gDNA and mtDNA,

respectively). mtDNA can have 20–200 copies of DNA compared with two copies of gDNA. Mutated mtDNA was detected in three of three patients (100%) with prostate cancer (Jeronimo, 2001), whereas others have reported a lower mtDNA detection rate in patients with colorectal cancer (Anker, 1997; Hibi, 2001). Tumor and plasma DNA of 25 patients with breast or small cell lung cancer were analyzed for the presence of p53 gene mutations. Six patients had detectable mutations in their tissue, and three of these six (50%) had mutations detected in their plasma (Silva, 1999). Furthermore, although gene mutations have been detected in tissue obtained from malignant and healthy patients, the same is not true for plasma. Mutations detected in plasma are very specific for malignancy (Johnson, 2002). To this end recent studies which analyzed plasma DNA of patients with HCC for p53 codon 249 by restriction fragment length polymorphism demonstrated that 6 (7.6%) of 79 samples from the HCC patients had amplifiable plasma DNA whereas none of the 73 samples with amplifiable plasma DNA from the controls had this mutation (Igetei, 2008).

MICROSATELLITE ALTERATIONS

Microsatellites are short sequences of DNA of between 2 and 6 base pairs that repeat multiply across the genome. The simplest of these is the dinucleotide CA. If these microsatellites occur in or near critical genes, they cause frameshifts in coding resulting in functional inactivation of the gene. One set of affected genes is the mismatch repair genes that encode enzymes that correct mismatched bases in DNA. The enzymes are then no longer present to correct mutations that occur in other critical genes, including tumor suppressor genes such as those encoding p53, Rb, and p16. As a result, tumor suppression genes are inactivated, allowing for the possibility of uncontrolled cell proliferation. As long as there is one normal allele of tumor suppressor genes, tumor suppression can still occur. However, if the lesion is extended to the normal allele, a loss of heterozygosity (LOH) occurs, resulting in complete absence of expression of the encoded tumor suppression protein product.

Microsatellite DNA is detectable by microsatellite analysis using PCR. A panel of four to six appropriate markers to detect these microsatellites can be used to profile tumors. LOH requires at least 20% of tumor DNA within normal DNA. Microsatellite instability refers to detection of additional PCR products and requires a ratio of tumor to normal DNA of greater than 0.5% (Goessl, 2001, 2002).

Microsatellite alterations performed on cell-free bronchial lavage specimens from lung cancer patients revealed tumor-associated genes in 47% if DNA was used as the source material ($n = 30$) and in 100% if RNA was used ($n = 25$) (Schmidt, 2004). In addition, four microsatellite loci were detected in the sera of 17 of 34 patients with breast cancer; LOH at various loci was observed in 16 patients, and microsatellite instability was detected in one patient (Schwarzenbach, 2004). However, no correlation was found between circulating tumor DNA and the level of tumor-associated protein marker CA 15–3 (Schwarzenbach, 2004; see Chapter 73 on serodiagnostic tumor markers). Plasma LOH has also been found in patients with recurrent bladder cancer, for which it appears to be a reliable marker (Dominguez, 2002). Recently, microsatellite alterations were detected in plasma DNA obtained from patients with malignant melanoma (Nakamoto, 2008) where metastasis or recurrence was confirmed in three (17.6%) of 17 patients; all of them were found to have LOH at four microsatellite markers, further suggesting the use of such loci markers as a screening tool.

PROMOTER HYPERMETHYLATION

Methylation of CpG islands, located in the promoter region of many genes, is associated with their transcriptional inactivation. Thus aberrant hypermethylation of key tumor suppressor genes can permit expression of otherwise quiescent oncogenes. Promoter hypermethylation can be detected by methylation-specific PCR (MSP), and the reduced protein expression can be determined by immunohistochemistry. MSP requires a ratio of tumor to normal DNA of 0.001%–0.1% (Goessl, 2001, 2002; Bearzatto, 2002). Another method, quantitative methylation analysis of minute DNA amounts after whole bisulfite amplification, (qMAMBA) allows quantitative and sensitive detection of DNA methylation in minute amounts of DNA present in body fluids (Vaissière, 2009). Aberrant methylation of at least one of four tumor suppressor genes was detected in tissue biopsies from 15 of 22 (68%) patients with non-small cell lung cancer. Of the 15 patients with positive non-small cell lung cancer, 11 (73%) also had abnormal methylated DNA in their serum samples (Esteller, 1999). In

addition, 17 of 27 bladder cancer patients (63%) displayed alterations in tumor suppressor genes in cell- and serum-derived DNA (Dominguez, 2002). As noted later, deletion of the p16 tumor suppressor gene is an important causative factor of bladder cancer.

Patterns of gene methylation have been determined for lung cancer (Hsu, 2007). In a study in which methylation of a variety of genes was determined, it was found that methylation of two genes, the p16 anti-oncogene and the Ras-association domain family 1 gene (RASSF1A), occurred with high frequency in lung cancer patients but not in a non-lung cancer control group. Using the methylation status of these two genes for diagnosing lung cancer, the sensitivity was 73% and the specificity 82%. These results appear to support the prior results on methylation of tumor suppressor genes in lung cancer (Esteller, 1999).

Interpretation of results obtained from cell-free testing warrants caution in that results may vary depending on the detection method (promoter hypermethylation, gene rearrangements, microsatellite alterations, PCR, RT-PCR, the sample tested [Lee, 2001], and the nucleic acid source used [RNA, DNA] [Fleishhacker, 2001; Garcia, 2001; Johnson, 2002; Schmidt, 2004]). Nonetheless this remains a promising new modality for early cancer detection (Chan, 2002; Lechowicz, 2002; Board, 2009; Goldshtein, 2009).

GENE ARRAYS DETECTING ONCOPROTEIN ABNORMALITIES

Circulating DNA from mutated oncogenes can be readily detected in the serum of cancer patients (Sorenson, 1994; de Kok, 1997). Use of PCR methodology has successfully identified ras-p21 in the stool of patients with colorectal cancer, altered p53 in the urine of patients with bladder cancer (Sidransky, 1991), and ras, neu/HER2, and PDGF in the bile of patients with biliary tract cancer (Su, 2001). Given the existence now of microchips that contain entire genomes that can be hybridized with the total RNA of cells to detect different levels of gene expression (see Chapter 67), studies using such chips on which different oncogenes are present may be effective in detecting expression of specific oncogenes present in body fluids from patients with different cancers.

That these types of studies are feasible has been demonstrated in a study on the tissue of 20 squamous cell esophageal carcinomas (Arai, 2003). A total of 57 oncogenes were present on the array and included many of the oncogenes discussed here, including FGF, erb-B2 (neu/HER2), and myc. In nine of the 20 specimens, expression of eight oncogenes, including erb-B2 and myc, was two to four times higher than in normal control tissue. Comparison of these results with those obtained using conventional hybridization methods revealed that, frequently, this gene amplification was found not to be due to an increase in copy number. As noted earlier, the p53 gene is frequently overexpressed and/or mutated in squamous cell carcinomas of the esophagus and in head and neck squamous cell carcinomas. Unfortunately, p53 was not included on this array. In addition, this study did not include hybridization assays for mutant genes.

Nonetheless, these studies illustrate that oncogenes are frequently overexpressed in human cancers and can be detected on gene arrays. The earlier PCR studies on body fluids illustrate that gene amplification and mutation can also be readily detected in these body fluids. Therefore gene arrays containing large numbers of different oncogenes, allowing for rapid assays, appear to hold great promise in tumor detection on body fluids.

CELL DNA TESTING FOR CANCER USING FLUORESCENCE IN SITU HYBRIDIZATION

This technique is described in Chapter 68. In brief, fluorophore-labeled DNA oligonucleotide probes containing sequences known to occur uniquely on specific chromosomes are incubated with cells concentrated from body fluids, including blood and urine. These probes are so constructed that they hybridize either to specific normally occurring DNA sequences on specific chromosomes or to known abnormally occurring spliced chromosomal sequences (usually the result of translocations). The latter often produce either overexpressed mitogenic proteins or mutated constitutively activated mitogenic proteins. This methodology has potential application to many disease states including malignancies (Goldshtein, 2009). This technique also detects critical gene deletions that can be identified by the absence of fluorescence of one or both probes in cells.

An example of the application of this technique is in the diagnosis of bladder cancer for which a test, the Vysis-Abbott Urovision detection

system, has been developed and has been FDA-approved. A critical and common chromosomal lesion in this disease is the 9p21 homozygous deletion, perhaps the most constant genetic finding in bladder cancer. This results in deletion of a tumor suppressor gene that codes for the p16 anti-oncogene protein, again resulting in loss of control of mitotic rate (Halling, 2002, 2003).

An oligonucleotide probe, labeled with a gold fluorescent dye, has been developed to a sequence of 9p21. In addition, several other oligonucleotide probes have been prepared, linked to other colored fluorescent dyes, that hybridize to specific sequences in the centromeres of other “control” chromosomes. A mixture of these probes is incubated with cells obtained from the urinary sediments of patients and subjected to fluorescence microscopy. If the cells are normal, duplicate colored spots, from diploid normal chromosomes, appear in these cells.

On the other hand, absence of one or both gold spots for chromosome 9p21 but the presence of duplicate fluorescent spots for the control probes is a strong indication of 9p21 deletion and the presence of urothelial (most probably, bladder) cancer. It should be noted that this hybridization procedure is also capable of detecting malignant aneuploid bladder epithelial cells (with multiple copies of chromosomes) directly.

This method has a sensitivity of 36% for grade 1 cancers, 76% for grade 2, and almost 100% for grade 3 cancers and an overall specificity of 97% (Halling, 2002, 2003). It therefore has great potential in detecting bladder cancer, especially if it is combined with probes for other genetic lesions known to occur in this disease as discussed earlier. In addition, multiple probes for known chromosomal lesions in a variety of lymphomas and leukemias have been prepared and are promising for the detection of these diseases in body fluids and tissue (see Chapter 75).

DIAGNOSTIC EFFICACY OF SERUM ONCOPROTEINS

The results of assays for the different oncoproteins discussed earlier in serum and urine (NMP-22), on several thousand patients, are summarized in Figure 74-3 for different tumor types. The figure shows three-dimensional graphs of tumor type (y-axis), tumor marker (x-axis), and percentage of cases of each tumor type successfully detected by each marker. The results for each marker is given as a specifically colored three-dimensional bar graph. From Figure 74-3, it is clear that, of the proteins studied thus far, positivity rates (sensitivities) vary from less than 30% (myc oncoprotein sensitivity is 8% in breast cancer) to more than 80 percent (e.g., ras in angiosarcoma). However, all of the control groups, given adjacent to each tumor type with an “N” in parenthesis, show very low positivity rates, and are, in most instances, 0. Therefore, whereas the sensitivities of oncoprotein markers vary, *their specificities are exceptionally high*, in the 95%–100% range; that is, there are very few false-positive results. Therefore, if a mutated or overexpressed oncoprotein is detected in the serum or other body fluid of a patient, there is a high probability that the patient has some form of malignancy. Also, the sensitivities and specificities of oncoproteins in diagnosing cancer exceed those of the oncofetal antigens, such as CEA or AFP (see Chapter 73).

How Specific Is Oncoprotein Expression for Different Cancer Types?

Interestingly, although the oncoproteins studied are from signal transduction pathways that are involved in many different types of cells, there seems to be some specificity of expression of particular oncoproteins for certain types of cancer. For example, the growth factor TGF- α is elevated in a large proportion of colorectal, brain, and ovarian cancers, whereas TGF- β is elevated in hepatocellular, lung, and bladder cancers; the p185 ECD (neu) protein is elevated in the sera of many patients with breast (at more advanced stages) carcinomas (Fig. 74-3, B); ras-p21 protein is elevated in colorectal and hepatocellular carcinomas, and angiosarcomas of the liver and lung cancers; p53 is elevated in colorectal and lung cancers and is elevated uniquely in oropharyngeal cancers, although, as discussed earlier, protein arrays designed for diagnosis of these cancers are now available. In addition, it is elevated in a high proportion of lymphomas. Anti-Myc antibody is elevated in many colon cancers and, interestingly, in a high proportion of prostate cancers. This latter finding suggests the need for further investigation. For example, elevated serum anti-Myc may aid in the definitive diagnosis of prostate cancer in patients with elevated serum PSA. In view of the recent findings that the ECD of EGFR is elevated in 93% of patients with prostate cancer in one series

(Milanese, 2009), this oncoprotein may likewise enable definitive diagnosis of prostate cancer.

Sensitivities of Oncoprotein Expression

As noted earlier, the sensitivities of oncoproteins in diagnosing specific cancers vary. Because of the multistep nature of carcinogenesis, there are many potential oncoproteins that may become abnormal. In some types of cancers, pathways may be activated that are not activated in other types of cancers. This phenomenon occurs even within one type of cancer. For example, ras and neu are elevated in the sera of patients with lung cancer but not elevated in patients with lymphomas since different signal transduction proteins are involved in these two different types of cancers. Also, ras and neu do not detect all lung cancers because these cancers differ with respect to affected signal transduction proteins among themselves, and some of them do not involve these two signal transduction proteins.

The next step, therefore, in using these oncoprotein markers in the early diagnosis of cancer is to assay for multiple markers in a given patient's serum, because discovery of at least one aberrant component of the signal transduction pathway is much more likely. If at least one positive result is found, the patient can be followed for signs of the development of a tumor.

As discussed previously, progress has been made in this area. Protein and gene arrays for multiple oncoproteins and oncogenes have been constructed and have succeeded in increasing the rate of positive diagnoses for cancer in patients. Furthermore, the advent of the proteomic/pattern recognition approach to cancer detection is proving to be successful in studies in which it has been thus far tested, that is, in the diagnosis of ovarian, prostate, and breast cancers. Combination of these two methods would result in high diagnostic yields; use of both would be feasible in that each can be performed rapidly.

ORIGINS OF MALIGNANCIES

Figure 74-3 indicates that discovery of an elevated level of an oncoprotein in the serum of a patient does not generally give conclusive information as to the source of the malignancy. For example, although ras-p21 has been found to be elevated with some specificity in colon, lung, and angiosarcomas of the liver; and HER2/neu (c-erbB-2) p185 ECD has been found to be elevated in colon, lung, and breast cancers, elevation of one of these oncoproteins in a patient's serum would not allow identification of exactly the tissue of origin of a malignancy. Because the signal transduction pathways in most cells are remarkably similar to one another, an increase in any oncoprotein can signify malignancy in a number of different cell types. On the other hand, using the proteomic approach, serum protein patterns on SELDI-TOF mass spectrometry are uniquely characteristic of specific tumors so that this approach can identify the tissue of origin of the tumor.

Additionally, many studies on the correlations between the presence of tumors and serum levels of oncoproteins remain to be performed. For example, there are no published data on the occurrence of detectable forms of mutant ras-p21 protein in the serum of patients with pancreatic carcinoma with control groups consisting of age- and sex-matched control individuals and with groups containing patients with pancreatitis but no tumors. This is a vitally needed study, because more than 90% of pancreatic cancers express oncogenic ras-p21 (Almoguera, 1988).

One manner of using serum oncoproteins could be to detect specific tumors at an early stage in tumor progression in populations known to be at risk for developing these cancers. These would include patients with a history of occupational exposure to carcinogens or mutagens as seen from the example of patients with a history of vinyl chloride exposure associated with angiosarcoma of the liver. In addition, patients can be followed who have been exposed chronically to asbestos and silica and who have consequent pneumoconioses associated with lung cancer and mesothelioma. Both conditions are associated with elevated serum levels of ras-p21 protein and/or mutant forms of this protein. Patients with pneumoconioses can also be followed with serum levels of p185neu.

TUMOR SIZE AND ONCOPROTEIN LEVELS

Currently, there is little information on the minimum size of a tumor that gives rise to serum elevations of oncoproteins. However, there are indications that small lesions may give rise to significant levels of certain oncoproteins.

First, in a significant number of patients with known cancer risks, oncoproteins were discovered in their sera before the development of detectable cancer. Thus, in patients with asbestosis, the ECD of the

Figure 74-3 Summary of results of serum assays for different components of mitogenic signaling pathways. These are three-dimensional plots of tumor type on the X axis, pathway component on the Y axis, and the percentage detected or the frequency of finding each of the pathway components elevated in the serum of patients with each tumor type on the perpendicular Z axis. Next to the results for each tumor type, the results for control groups are labeled as "N" for "normals," that is, age- and sex-matched controls who were tumor-free. The controls for patients with each tumor type are abbreviated with a single letter (with "N" in parentheses) for each tumor type, such as "B" for brain. *anti-Myc*, Antibody to the Myc protein; *anti-p53*, anti-p53 antibody; *EGF*, epidermal growth factor; *erbB*, epidermal growth factor (EGF) receptor; *FGF*, fibroblast growth factor; *myc*, a nuclear oncogene that encodes the Myc protein; *Neu*, p185 protein that is similar to the *erbB* protein and is also called *erbB-2* and *HER2*; *NMP-22*, nuclear matrix protein number 22; *p53*, an antioncogene protein *PDGF*, platelet-derived growth factor; *Ras*, p21 protein; *TGF- α* , transforming growth factor- α ; *TGF- β* , transforming growth factor- β .

p185erbB protein became elevated *before* lung tumors were diagnosed. Overexpression of the p185 ECD occurred in a number of patients before the diagnosis of breast cancer. East Asian patients who had high serum levels of p185 ECD went on to develop HCC. Patients with pneumococcoses were found to have elevated levels of p185 ECD and/or ras-p21 protein and subsequently developed lung carcinomas. Mutant (Asp 13-) p21 protein was discovered in the serum of a very high percentage of patients with vinyl chloride exposure who subsequently developed angiosarcoma. Anti-p53 antibodies were found in the sera of individuals who subsequently developed angiosarcomas or lung cancers. All these studies suggest that malignant lesions that are undetectable by conventional techniques may be detected by measuring the serum levels of oncoproteins or antibodies to oncoproteins, especially in patients with known exposures or risk factors for cancer.

Second, carcinomas in situ are known to cause elevated levels of oncoprotein elevated serum as evidenced by elevated serum levels of p185neu protein in incipient breast cancer and NMP-22 in carcinoma in situ of the bladder. These findings suggest that serum oncoprotein levels are effective in detecting the presence of small tumors in individuals at an early stage.

It also seems clear that, as the stage progresses, the tumors elaborate higher levels of oncoproteins so that there appears to be a good correlation, at least in some patients, between serum levels of marker oncoproteins and tumor size and/or level of expression of the marker in the tumor tissue itself. In this regard, some small adenomas (<1 cm) have been found to give rise to elevated levels of p185 ECD or ras-p21 in these patients'

sera. For both ras-p21 protein and p185erbB ECD, there is an excellent correlation between serum level of these markers and the pretreatment and posttreatment clinical status of the patient. Nonetheless, substantially more correlation studies between tumor size and serum level of oncoproteins remain to be performed. One confounding factor may be that a small tumor may produce large amounts of the marker, whereas larger tumors may produce smaller amounts due to such factors as changes in the oncogenic lesions, affecting which oncoproteins are mutated and/or are overexpressed.

EVALUATION AND CONCLUSIONS

Well-defined pathways for mitogenic signal transduction exist between the membrane and the nucleus of cells. These pathways consist mainly of proteins, mutations in or overexpression of which can give rise to uncontrolled mitogenic signaling and cancer. More recently, based on proteomic approaches, other proteins are being discovered that characteristically are either overexpressed or expressed at much lower levels in the sera of patients with specific types of cancers compared with the levels found in the sera of control groups.

Despite the foregoing caveats in interpretations of elevations of serum levels of oncoproteins or the detection of abnormal forms of these proteins in serum and the need for further correlation studies to be performed, assays for the presence of oncoproteins in serum show exceptional promise for detection of malignant tumors at an early stage and for monitoring their progression, response to therapy, remission, and recurrence.

ROLE OF CLINICAL MOLECULAR DIAGNOSTICS IN HEMATOLOGIC CANCERS

The diagnosis of hematolymphoid neoplasms continues to undergo a dramatic transformation with the advent and application of new technologies. Whereas traditional morphologic (light microscopic) evaluation of glass slides still occupies the centerpiece of pathologic diagnosis, the judicious application of ancillary methods, such as special cytochemistry, immunohistochemistry, flow cytometry, cytogenetics (including fluorescence in situ hybridization [FISH]), and molecular genetics, has allowed for much improved diagnostic reproducibility and refinement. Indeed, such elements were formally incorporated into diagnostic hematopathology in the World Health Organization (WHO) classification of hematologic neoplasms (Jaffe, 2001). The rapid pace of research into the molecular underpinnings of hematologic neoplasms necessitated a substantially updated classification in 2008, in which genetic abnormalities continue to assume central importance in our understanding and diagnosis of such processes (Swerdlow, 2008). The relative ease of sampling sites such as the lymph nodes and bone marrow as well as the provision of easily disaggregated viable cell samples for analysis have driven this paradigm of diagnostic evaluation. The nature of the hematolymphoid system is also conducive to relatively easy monitoring of disease status following therapy, which represents another important facet in the management of patients with these illnesses.

Given this plethora of diagnostic tools, what role does molecular genetic evaluation, or molecular diagnostics play? There are perhaps four major scenarios in which molecular diagnostic analysis of a hematolymphoid proliferation is important. First, molecular investigation can establish a diagnosis in situations wherein morphologic details and results of other lab tests are inconclusive for malignancy. The presence of specific genetic abnormalities, or the demonstration of tumor genetic “homogeneity” of a cell population (e.g., by antigen receptor gene rearrangement studies) can establish the presence of a clonal pathologic process. Second, molecular methods are used to subclassify disease entities. To this end, the current WHO classification of hematologic neoplasms includes molecular characterization as a defining feature of many leukemias and lymphomas (Swerdlow, 2008). Next, specific genetic anomalies in hematolymphoid malignancies have important prognostic value, which in turn can influence the initial treatment of certain tumors to produce an optimal clinical outcome. Finally, being potentially of high sensitivity, molecular techniques can be used to assess patients after the onset of therapy, by monitoring for the presence and extent of minimal residual disease (MRD). Table 75-1 summarizes some of the key instances in which molecular diagnostic evaluation is sought in hematopathology practice. As the synergy between

expanding basic biologic information and rapidly progressing technology continues unabated, the future holds promise for many additional applications of molecular diagnostics in the pathology laboratory, including the prediction of disease susceptibility, severity, or treatment response based on polygenic factors; pharmacogenomic profiling of patients to determine drug sensitivity and toxicity profiles; and the assessment of individual responses to increasingly “targeted” therapies.

This chapter focuses on the background, clinical rationale, and fundamental technical considerations underlying the molecular diagnostic evaluation and monitoring of hematologic and lymphoid tumors. As the large majority of these laboratory assays are polymerase chain reaction (PCR) based, the emphasis is accordingly placed on methods concerning either DNA or RNA (i.e., reverse-transcription) PCR techniques. Of note, it is apparent that the detection of tumor-specific genetic abnormalities can be achieved by different analytic means, for example, cytogenetics, FISH, or PCR. Although at first glance these various methods may seem redundant, these laboratory techniques should be considered complementary and the choice of methodology is determined by a number of factors, including knowledge of the detection rates, analytic sensitivity, and limitations of various techniques; understanding of the disease pathobiology; the level of interpretive experience and expertise with these procedures; the type of sample; and the phase of the disease under investigation. Table 75-2 indicates comparative analytic sensitivities of the principal modalities used to detect hematolymphoid tumor-related genetic abnormalities.

The increasingly ubiquitous need for molecular genetic evaluation of hematopoietic cancers has initiated earnest attempts to address and achieve better interlaboratory standardization, and such efforts can be expected to continue to improve the benchmarks of sensitivity and specificity in this field. Nonetheless, in the application and interpretation of molecular diagnostic tests, one caveat that cannot be emphasized enough is that the results of these investigations must never be considered in isolation, but rather, in conjunction with the salient clinical, morphologic, and additional laboratory data concerning the individual patient. Regardless of the remarkable specificity and sensitivity of molecular markers, the evident complexity of hematolymphoid neoplasia mandates such a fully integrated approach, in order to diminish the possibility of diagnostic error.

MOLECULAR DIAGNOSIS OF ACUTE LEUKEMIAS

GENE FUSION CONCEPT IN LEUKEMIA AND THE BASIS FOR REVERSE-TRANSCRIPTION POLYMERASE CHAIN REACTION ANALYSIS

The leukemias are hematologic cancers with a diverse pathogenesis and pathobiology. However, a significant proportion of these tumors is characterized by nonrandom, (usually) balanced chromosomal translocations, resulting in the formation of fusion, or chimeric genes. In general, although two such fusions are created in this abnormal event (i.e., one on each reciprocal translocated chromosome), typically only one of these derivative loci gives rise to a leukemogenic “hybrid” gene. At the molecular level, the intronic breakpoint and fusion sites in the involved genes are highly variable among patients with the same type of leukemia, although there may be evidence of clustered breakpoint “hotspots” in certain types of leukemia-related rearranging genes. Despite the variability in breakpoint sites in both of the involved genes, a consistent feature of the leukemic gene fusions is the production of a chimeric messenger ribonucleic acid (mRNA) molecule. This abnormal transcript is further translated to a fusion protein, presumed to be operative in disrupting many cellular pathways involved in regulating normal proliferative capacity, differentiation, and survival in immature (i.e., precursor) marrow stem or progenitor cells.

Although the formation of a translocation fusion gene, such as the well known *BCR-ABL1* abnormality, is known to be necessary for disease production, results from animal models have suggested that, at least for some types of leukemia, this may not be a sufficient event, requiring in addition secondary incompletely characterized genetic insults as well. This concept has been formalized into a general scheme in which leukemogenic abnormalities are considered to be class I or class II, depending, respectively, on whether they provide a proliferative advantage or disturb the complex processes of hematopoietic differentiation. In this conceptualization, the development of leukemia becomes more likely when both class I and class

TABLE 75-1
Applications of Molecular Diagnostics in Hematologic and Lymphoid Neoplasia

Indication	Examples
Diagnosis and subclassification	<i>JAK2</i> mutations in myeloproliferative neoplasms <i>CCND1-IGH@</i> abnormality in mantle cell lymphoma <i>PML-RARA</i> abnormality in APL <i>FLT3</i> , <i>NPM1</i> , and <i>CEPBA</i> mutations in normal karyotype AML
Determination of tumor clonality	Assessment of abnormal B and T cell lymphoid proliferations
Prognosis and/or therapeutic monitoring	Quantitative PCR monitoring of <i>BCR-ABL1</i> mRNA in CML patients on tyrosine kinase inhibitor therapy (e.g., imatinib) Quantitative PCR monitoring of <i>PML-RARα</i> mRNA in APL Multiparameter cytogenetic and molecular assessment of chronic lymphocytic leukemia Relapse risk prediction in childhood acute lymphoblastic leukemias Outcome prediction of diffuse large B cell lymphoma subtypes by gene expression profiling

TABLE 75-2

Relative Sensitivities of Major Techniques Used to Detect Leukemia or Lymphoma-Associated Abnormalities

Method	Analytic sensitivity (%)*	Notes
Cytogenetics	5	Global genomic assessment Requires fresh, sterile cells Detects numerical and structural chromosome aberrations Difficult or impossible to detect alterations in DNA below band resolution
FISH	1–5	Targeted assessment of relatively large genomic abnormalities Technically straightforward and rapid; can frequently be performed on interphase nuclei Applicable to a variety of tissue sources Requires rigorous quality standards to avoid false positive results at low levels of the abnormality in question
SBH	5–10	Targeted assessment for structural abnormalities in genomic DNA Technically laborious and time-intensive Requires samples with well preserved high-molecular-weight DNA (e.g., fresh or frozen cells)
PCR	10 ⁻² –10 ⁻⁴	Targeted assessment of small genomic or mRNA abnormalities Detection of unique chimeric fusion gene mRNA species is highly sensitive Technically straightforward and rapid but may require post-PCR detection procedures Applicable to a broad range of sample types, including fixed paraffin-embedded tissues Can be optimized for high sensitivity, minimal residual disease monitoring (real-time quantitative PCR), or other specialized applications such as allele-specific discrimination
DNA sequencing (Sanger method)	20–30	Targeted assessment of single nucleotide or small base alterations in template (DNA or RNA) sequences Typically performed on PCR-amplified products Modifications or special methods (e.g., pyrosequencing) can improve sensitivity to 5%

DNA, Deoxyribonucleic acid; FISH, fluorescence in situ hybridization; PCR, polymerase chain reaction; RNA, ribonucleic acid; SBH, Southern blot hybridization.

*Generally attainable with the indicated molecular methods, although several technical or biologic factors may influence the lower limits of detection.

II derangements cooperate to alter the fate of the cell (Ishikawa, 2009). In the molecular hematopathology laboratory, most leukemia-related assays are directed toward chimeric gene fusions that generally fall into the class II category. However, testing for class I mutations (e.g., *FLT3* internal tandem duplication) has more recently become integral to more comprehensive evaluations. The challenge for the molecular hematopathology laboratory is thus to incorporate an adequate spectrum of assays directed to the detection of both class I and class II category genetic abnormalities, according to the (ever-changing) understanding of disease molecular pathogenesis.

One practical aspect of the chimeric gene concept is that regardless of the variable location of the genomic (DNA-level) breakpoints in a given translocation gene fusion, the presence of this abnormality can be confirmed by detecting the corresponding invariant chimeric mRNA species. In the molecular diagnostic laboratory, we can thus utilize the reverse-transcription polymerase chain reaction (RT-PCR) method to first convert the fusion mRNA transcript to its complementary deoxyribonucleic acid (cDNA) and then amplify this specific molecule. The ability to perform RT-PCR analysis obviates the difficulties imposed by the often very large flanking regions of intronic DNA surrounding the genomic breakpoint-fusion loci, which would normally not be amenable to amplification by standard DNA-based PCR approaches. Furthermore, the presence of such an aberrant mRNA species is highly specific for the disease, in that it should not theoretically be present in normal cells. Table 75-3 lists the major leukemia-associated translocations along with their resultant fusion gene and mRNA products. Two related concepts are important in the further understanding of chimeric genes and transcripts. *Breakpoint heterogeneity* refers to the presence of two (or more) common breakpoint loci in a particular gene, which can be targeted by the translocation event. In some examples, different breakpoint sites may be correlated with a presenting disease phenotype or particular clinical features (e.g., the *BCR-ABL1* fusion in chronic myeloid leukemia [CML] versus acute lymphoblastic leukemia [ALL]), but this is not always the case. Second, alternative exon splicing of a single chimeric transcript may occur, such that additional, related mRNA products may be observed during PCR amplification of the principal target (e.g., the *PML-RARA* fusion in acute promyelocytic leukemia). RT-PCR-based assays require fresh bone marrow aspirate or blood cells, although cryopreserved tissue or cells can also be used effectively for RNA isolation. RNA extraction and RT-PCR from paraffin tissue block samples has also been successfully described; however, fixed cellular material is often subjected to degradation or the presence of PCR inhibitors,

and consequently a higher PCR detection failure rate. Finally, given the highly sensitive nature of PCR amplification, these laboratory assays must be carefully controlled to avoid false-positive contamination artifacts. The following sections describe the molecular genetic and diagnostic features of the most common, prognostically important leukemic diseases.

ACUTE MYELOID LEUKEMIAS

The importance of tumor genetic markers is reflected in the present WHO classification (Swerdlow, 2008), in which acute myeloid leukemias (AMLs) are increasingly defined by their characteristic genetic abnormalities in relation to phenotypic features, prognosis, and clinical outcome. The identification of specific genetic markers can thus establish a definitive AML subclassification, provide important prognostic information, guide therapeutic intervention, and reveal insights into tumor biology.

AML can be broadly classified as being of relatively “favorable,” “intermediate,” or “poor” prognosis type, based on the degree of tumor cytogenetic complexity or the nature of specific tumor genetic markers. For example, extensive numerical and structural karyotypic abnormalities, or the presence of “myelodysplasia-background” genetic findings (e.g., abnormalities of chromosomes 5 or 7), are indicative of very aggressive subtypes of AML. Several nonrandom recurring chromosomal translocations characterize another significant subset of AML and can be detected by PCR-based molecular diagnostic techniques. These translocations usually occur without additional cytogenetic findings, often show distinct genotype-phenotype correlations, and many are associated with relatively favorable outcome. In particular, the t(15;17), t(8;21), and inv(16) or related t(16;16) translocations together account for approximately 25%–30% of de novo AML in both adults and children. In addition to these three, the current WHO classification recognizes four additional rare, recurrent cytogenetically defined subtypes of AML: t(9;11)*MLLT3-MLL*, t(6;9)*DEK-NUP214*, inv(3)*RPN1-EVT1*, and t(1;22)*RBM15-MKL1* (Swerdlow 2008).

Historically, consideration of numerical and structural karyotypic abnormalities tended to dominate the discussion of AML subcategorization, because relatively little was known about “cytogenetically normal” cases. Recently, however, characteristic gene mutations have been recognized that appear to carry important etiologic and prognostic information in the latter group of AML. These alterations include mutations of *CEBPA*, *NPM1*, and *FLT3*. Whereas the relevance of these mutations is most pronounced in cases of AML with normal karyotype, some of these

TABLE 75-3

Common Leukemia-Associated Translocations and Gene Mutations in Myeloid Neoplasms

Genetic abnormality	Disease associations	Basic molecular pathogenesis	Diagnostic detection*
t(9;22)/ <i>BCR-ABL1</i>	Chronic myeloid leukemia (100%) Ph+ adult acute lymphoblastic leukemia (20%–25%) Ph+ pediatric acute lymphoblastic leukemia (3%)	Chimeric fusion protein with deregulation of Abl tyrosine kinase; effects on cell proliferation, apoptosis, adhesion	RT-PCR; FISH
<i>JAK2</i> V617F mutations	Polycythemia vera (>95%); primary myelofibrosis (75%); essential thrombocytosis (50%)	Aberrant activation of cell signaling tyrosine kinase; activation of JAK-STAT pathway	DNA PCR
t(15;17)/ <i>PML-RARA</i>	Acute promyelocytic leukemia (100%)	Chimeric fusion protein; interference with myeloid maturation and differentiation	RT-PCR; FISH
t(8;21)/ <i>RUNX1-RUNX1T1</i>	AML (10%)	Chimeric fusion protein affecting the CBF transcriptional pathway	RT-PCR; FISH
inv(16) or t(16;16)/ <i>CBFB-MYH11</i>	Acute myelomonocytic leukemia with abnormal eosinophils (AMML-Eo)		
<i>FLT3</i> mutations	AML with normal karyotype (20%–25%)	ITD or point mutation resulting in constitutive activity of Flt3 tyrosine kinase and cell proliferation	DNA PCR
<i>NPM1</i> mutations	AML with normal karyotype (50%)	Complex effects of mutated NPM1 nuclear/cytoplasmic transport protein	DNA PCR
<i>KIT</i> mutations	Systemic mastocytosis	Aberrant activation of receptor for hematopoietic stem cell factor	DNA PCR
<i>PDGFRα</i> , <i>PDGFRβ</i> , and <i>FGFR1</i> translocations	Myeloid and lymphoid neoplasms with eosinophilia	Deregulation of growth factor receptor tyrosine kinases	FISH > RT-PCR
t(12;21)/ <i>ETV6-RUNX1</i>	Childhood B-precursor acute lymphoblastic leukemia (20%)	Chimeric fusion protein; disruption of CBF transcriptional pathway	RT-PCR; FISH
11q23/ <i>MLL</i> translocations	Childhood (mainly infant) B-lineage ALL (5%) Adult de novo AML, usually monocytic (subset of cases) Subset of secondary AML (after DNA topoisomerase II agent exposure)	Chimeric MLL fusion proteins; disruption of MLL-mediated regulation of normal hematopoiesis	FISH; RT-PCR

ALL, Acute lymphoblastic leukemia; AML, acute myeloid leukemia; CBF, core binding factor; DNA, deoxyribonucleic acid; FISH, fluorescence in situ hybridization; ITD, Internal tandem duplication; MLL, mixed lineage leukemia; PCR, polymerase chain reaction; RT-PCR, reverse-transcriptase polymerase chain reaction.

*PCR includes use of specialized methods (e.g., allele-specific PCR or real-time quantitative platforms) and appropriate postamplification detection techniques (e.g., gel/capillary electrophoresis, melting analysis, sequencing.)

genetic changes (e.g., *FLT3* mutation) may also accompany cases with characteristic translocations, such as the t(15;17), or other cytogenetic abnormalities. Thus, whereas AML with *NPM1* and *CEBPA* mutations have been designated as *provisional entities* in the 2008 WHO classification, *FLT3* alterations, by virtue of their relatively ubiquitous distribution in AML generally, remain an aid to prognostication but not to specific disease subclassification (Swerdlow, 2008).

This section focuses on the common AML-related molecular genetic abnormalities that are currently considered to be the most clinically relevant due to frequency of occurrence and impact on therapy or prognosis. The major abnormalities in AML are summarized in Table 75-3.

Acute Promyelocytic Leukemia: t(15;17)/PML-RARA Abnormality

Acute promyelocytic leukemia (APL), or AML-M3 (according to the previous French-American-British [FAB] classification of AML) accounts for 5%–10% of de novo AML. Patients typically present with symptoms from peripheral blood cytopenias and have a high propensity for life-threatening coagulopathy. Morphologically, APL consists of a proliferation of hypergranular promyelocytes and myeloblasts; however, a microgranular variant form is also frequently encountered (Mantadakis, 2008). APL is genetically defined by the presence of the t(15;17)(q22;q12-21) abnormality, resulting in the fusion of the retinoic acid receptor- α gene, *RARA* [17(q21)] with the *PML* gene [15(q22)] to form a *PML-RARA* chimeric gene on the derivative chromosome 15q (Grignani, 1994; Jurcic, 2007).

The *RARA* gene product is a subunit of a heterodimeric nuclear receptor for the naturally occurring ligand retinoic acid, or vitamin A. The retinoid nuclear receptor pathway is functional in many aspects of normal cell proliferation and differentiation (Chambon, 1996; Collins, 2008; Mark, 2009). *PML* encodes a DNA-binding zinc finger protein and associates with several other proteins in a macromolecular complex, forming discrete nuclear bodies (Dyck, 1994; Weis, 1994; Reineke, 2009). This interesting protein appears to have multiple possible cellular functions, including transcriptional regulation, apoptosis, and possibly immune surveillance

(Quignon, 1998; Wang, 1998; Grimwade, 1999; Zhong, 2000; Borden 2009; Reinecke, 2009). The hybrid *PML-RAR α* protein is clearly involved in disrupting numerous intracellular processes, primarily resulting in a lack of terminal differentiation of neoplastic myeloid precursors beyond the promyelocytic stage. Nonetheless, the significance of APL as a “therapeutic paradigm” for leukemia resides in the ability of pharmacologic doses of *all trans* retinoic acid (atRA) to induce leukemic cell differentiation in vivo. When used in combination with cytotoxic chemotherapy, the synergistic effects of atRA induce complete remission in 90%–98% of patients, and prolonged remission in more than 80% of patients (Tallman, 1997; Tallman, 2002; Clavio, 2009; Licht, 2009; Sanz, 2009). This remarkable finding has intensified efforts to identify other avenues for “cytodifferentiative” therapy in AML. Even though the effect of atRA would seem superficially related to the interaction with the *RAR α* moiety in the abnormal *PML-RAR α* protein, further investigations have unraveled the basic molecular mechanisms underlying the success of this agent. The normal retinoic acid receptor, when not bound to its retinoic acid ligand, associates with histone deacetylase (HDAC) in a nuclear protein co-repressor complex (Guidez, 1998; Melnick, 1999; Lefebvre, 2001; Wei, 2004). This interaction reduces the accessibility of chromatin to transcription factors (and thus locus-specific transcriptional activity), yet is reversible in normal marrow cells upon exposure to physiologic concentrations of retinoic acid. The *PML-RAR α* oncoprotein stabilizes and enhances the state of transcriptional repression by this multiprotein complex; however, therapeutic doses of atRA appear to overcome this abnormal condition and relieve the cellular differentiation block (Melnick, 1999; Hormaeche 2007; Collins 2008; Licht 2009). Whereas some evidence suggests that the *PML-RAR α* oncoprotein may also disrupt the normal pro-apoptotic functions of *PML*, thus potentiating transformation via pathways involving both partners in the translocation, the direct contribution of altered *PML* to leukemogenesis remains controversial (Strudwick, 2002; Collins, 2008; Brown, 2009). Functional haploinsufficiency of one remaining normal *PML* gene may also be important in the pathobiology of APL.

The molecular anatomy of the *PML-RARA* fusion gene and mRNA products in APL is summarized diagrammatically in Figure 75-1, A. The

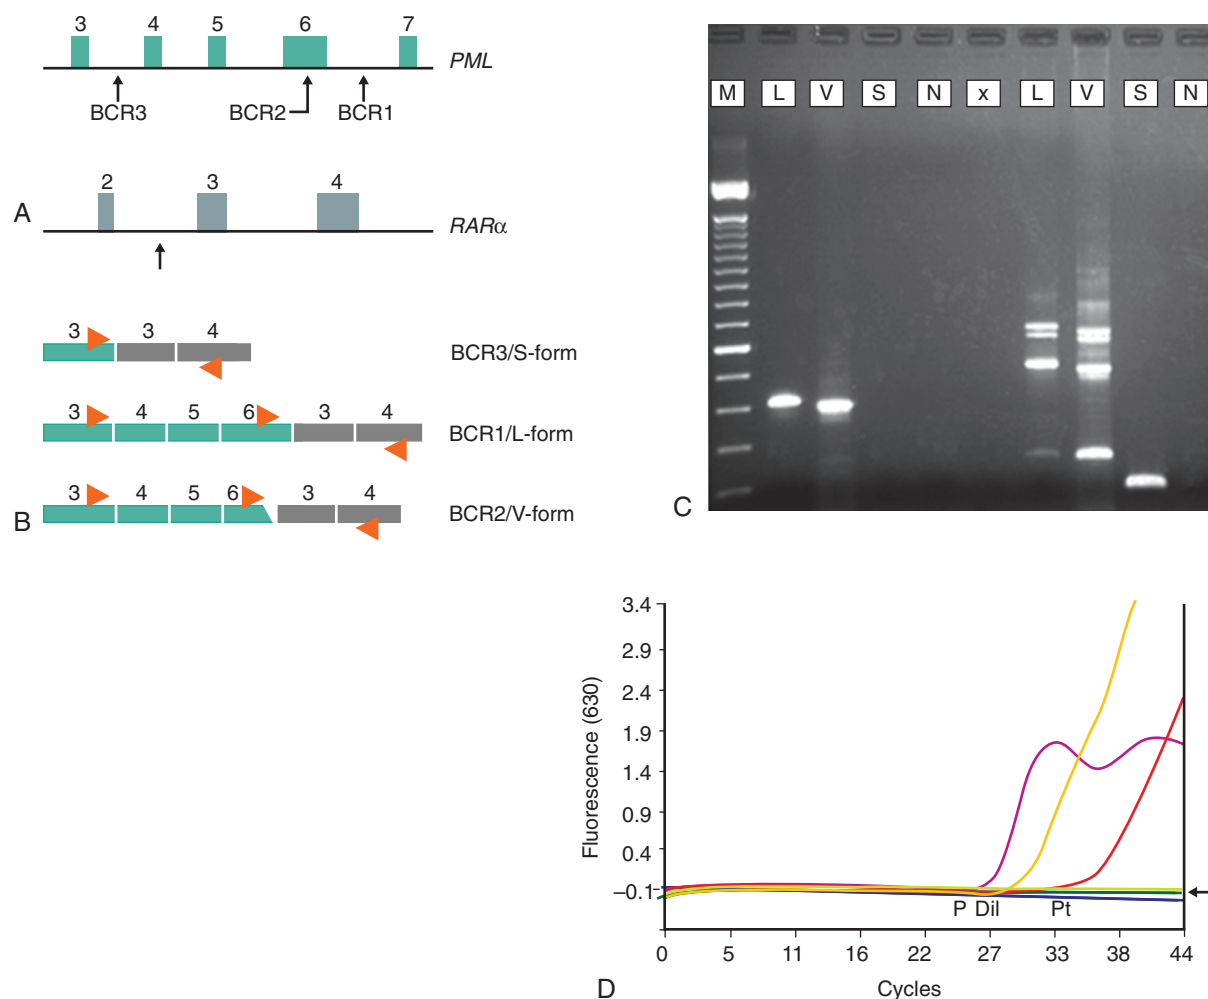

Figure 75-1 t(15;17)/PML-RARA abnormality in acute promyelocytic leukemia. **A**, Partial genomic configurations of *PML* and *RARα* genes. Vertical black arrows indicate the three breakpoint sites in the *PML* gene (BCR1, BCR2, BCR3) and the intron 2 breakpoint region in the *RARα* gene. Note that the BCR2 breakpoint occurs within exon 6 of the *PML* gene. **B**, Representations of various PML-RARα mRNA transcripts derived from the each of the three breakpoint-fusion events. The three transcripts are respectively named according to the length of the chimeric species: long (L)-form for BCR1, short (S)-form for BCR3, and variable (V)-form for BCR2. The BCR2/V-form fusion contains only a portion of PML exon 6, although extra nucleotides may be added or deleted at the junction to maintain an intact PML-RARα reading frame. Orange arrows indicate the relative positions of PCR primers to detect these chimeric transcripts by RT-PCR technique. **C**, Representative results from a qualitative RT-PCR analysis to detect the PML-RARα abnormality. The gel bands on the left side (up to the empty lane x) indicate PCR products for L-form/BCR1 and V-form/BCR2 detected with primers situated in PML exon 6 and RARα exon 4. Because exon 6 is not present in the S-form/BCR3 transcript, no PCR product is generated, as shown in the corresponding lane. Gel bands to the right of empty lane x show results obtained with a PML exon 3 primer and the same RARα primer. In this case, a more complex banding pattern is seen for L-form/BCR1 and V-form/BCR2 products due to alternative splicing out of PML exon 5 and exons 5 and 6 (the middle and lower PCR product bands in these lanes). The S-form/BCR3 fusion is readily detected with this primer set. Note that for the rare V-form/BCR2 type PML-RARα, the PCR products are slightly smaller than the L-form/BCR1 species, due to the absence of some of PML exon 6. **D**, Example of RQ-PCR to monitor for the PML-RARα transcript following therapy. The PML-RARα transcript abundance is normalized to a control transcript amplification (not shown) for each sample. Short arrow indicates negative and no template controls. The most informative testing interval occurs at the end of consolidation therapy when PCR positive results are associated with a high risk for leukemic relapse. Dil, Dilute positive control; L, long form/BCR1; M, molecular size marker (100 bp); N, no template control; P, positive control; Pt, patient sample; RQ-PCR, real-time quantitative PCR methods; RT-PCR, reverse-transcriptase polymerase chain reaction; S, S-form/BCR3; V, V-form/BCR2; x, empty lane.

PML gene exhibits breakpoint heterogeneity in that one of three possible break sites can be encountered in any given patient, involving either intron 3 or intron 6, or occurring within exon 6 (Grignani, 1994; Gallagher, 1995; Reiter, 2003). In contrast, the *RARα* breakpoints are uniformly distributed in intron 2 of the gene. Thus one of three possible PML-RARα chimeric mRNAs can result from this genetic fusion: PML exon 6/RARα exon 3 (long (L)-form, or BCR 1), PML exon 3/RARα exon 3 (Short (S)-form, or BCR 3) and PML exon 6Δ/RARα exon 3 (variable [V]-form, or BCR 2). The V-form transcript is unique in that the *PML* break occurs within exon 6 and a variable proportion of this exon is retained, although additional nucleotides may be added or deleted (Gallagher, 1995; Reiter, 2003). Notably, an in-frame fusion mRNA is produced in each case of APL, underscoring the critical requirement for the PML-RARα protein in leukemogenesis. The L-form (BCR 1) and S-form (BCR 3) PML-RARα fusions are most commonly found in APL (~45%–50% of cases each), whereas the V-form (BCR 2) is only rarely encountered (~5% of APL). The strategy for RT-PCR amplification of these PML-RARα transcripts is depicted in Figure 75-1B, as is a representative diagnostic PCR assay (see Fig. 75-1, C). Of note, the L-form (BCR 1) and V-form (BCR 2) type

transcripts show alternative splicing out of exons 5 and 6, producing three major amplified products when a PML exon 3 primer is employed.

The clinical relevance in detecting the PML-RARα fusion abnormality in cases of suspected APL is evident from the efficacy of administering specific therapy (i.e., chemotherapy + atRA) with a high possibility of long-term remission and survival. To this end, despite the tight correlation between the t(15;17)/PML-RARA and APL morphology, it is recognized that other rare APL-like myeloid leukemias do occur. These morphologic mimics harbor alternative translocations involving the *RARA* gene with fusion partner genes other than *PML*. Examples of these variants include the t(11;17)/ZBTB16(PLZF)-RARA, t(11;17)/NUMA1-RARA, t(5;17)/NPM1-RARA, and the t(17;17)STAT5B-RARA acute myeloid leukemias (Melnick, 1999; Grimwade, 2000; Sainty, 2000; Zelent, 2001; Redner, 2002). Notably, ZBTB16(PLZF)-RARA and STAT5B-RARA positive leukemias in particular are not responsive to the differentiating effects of atRA and are associated with less favorable outcome (Jansen 2001; Redner 2002). Molecular assays specific for the common PML-RARα fusion will not detect these variant transcripts. Other morphologic AML subtypes characterized by increased promyelocytes are similarly atRA

unresponsive and also require distinction from true *PML-RARα* positive APL. Several studies have assessed the possible clinical significance of the *PML-RARα* transcript type in APL patients. Both the S-form (BCR 3) and rare V-form (BCR 2) *PML-RARα* fusions have been associated with adverse features such as higher presentation white blood cell count, poor atRA response, and possibly shorter remission duration (Vahdat, 1994; Gallagher, 1995, 1997; Jurcic, 2001; Gupta, 2004); however, the independent prognostic value of molecular subclassification in APL has not been definitively established.

Finally, the *PML-RARα* transcript serves as a valuable molecular disease marker to follow therapeutic response (see Fig. 75-1, D). Patients with APL treated with combination chemotherapy and atRA have a relatively favorable prognosis, yet disease relapses occur frequently. The use of qualitative RT-PCR methods to detect the *PML-RARα* fusion mRNA (with a typical sensitivity of 10^{-3} – 10^{-4}) was initially found to be a very powerful tool for predicting relapse risk in individual patients (Jurcic, 2001; Grimwade, 2002; Lo Coco, 2002). The timing, or phase of disease therapy, is an important consideration in this leukemia. Patients evaluated for *PML-RARα* at the end of induction are often found to be positive and the predictive value at this timepoint is not significant. By the end of consolidation therapy, however, PCR positivity is strongly predictive of relapse in patients who have apparently achieved clinical complete remission, in that nearly all such patients will progress to hematologic relapse within months. In contrast, a single PCR-negative measurement at this timepoint is not necessarily predictive of favorable outcome, in that a significant number of such patients may also suffer relapse. This has led to recommendations for more frequent posttherapy monitoring using sensitive and precise real-time quantitative PCR methods (RQ-PCR). To this end, several APL study groups have reported results of serial *PML-RARα* monitoring using RQ-PCR techniques and these efforts have shown a benefit for detecting low-level molecular disease and its value in predicting relapse risk (Grimwade, 2002; Gallagher, 2003; Grimwade 2009). Furthermore, several studies have validated the concept of “salvaging” or retreatment of patients with molecular residual disease, with good clinical outcomes. Given an array of additional treatment options for APL, including highly effective second line intervention with arsenic trioxide (As_2O_3) and autologous or allogeneic stem cell transplantation, molecular residual disease assessment thus forms an integral aspect of the management of all APL patients (Santamaria, 2007; Kohno, 2008; Lo Coco, 2008; Grimwade, 2009). Although no formal guidelines have been firmly established for RQ-PCR monitoring of *PML-RARα* in APL, proposed common sampling timepoints for assessment include the end of induction, end of consolidation, then every 2–3 months for the first year after therapy, because this is the window during which most relapses occur. Bone marrow aspirate samples are preferred for MRD assessment, in that the peripheral blood is less sensitive for transcript detection following treatment onset.

Core Binding Factor–Related Acute Myeloid Leukemias: t(8;21)/*RUNX1-RUNX1T1* and Inv(16) or t(16;16)/*CBFB-MYH11* Abnormalities

Acute myeloid leukemias with the t(8;21)(q22;q22) and inv(16)(p13;q22) or related t(16;16)(p13;q22) cytogenetic abnormalities together account for approximately 11%–18% of de novo cases (Schnittger, 2007; Cheng, 2009). Core binding factor (CBF)-related AML cases are roughly evenly distributed between those with the t(8;21) and cases with inv(16)/t(16;16) (Dombret, 2009). Whereas the t(8;21) is generally associated with AML showing maturation (FAB type AML-M2), the inv(16) and t(16;16) are highly correlated with acute myelomonocytic leukemia with abnormal eosinophils (FAB type AML-M4Eo) (Cheng, 2009). Clinically, these genetically defined AML subtypes are responsive to chemotherapy (especially high-dose cytarabine regimens) and are considered to be prognostically favorable compared with AML in general (Appelbaum, 2006; Dombret, 2009).

Although different respective leukemia phenotypes derive from these translocations, a remarkable and common pathobiologic feature of both the t(8;21) and inv(16) or t(16;16) leukemias is disruption of the CBF transcriptional regulatory pathway (Speck, 1999; Paschka, 2008). CBF is a heterodimeric transcription factor that consists of a DNA binding α -subunit (CBF α) and a peptide-interacting β -subunit (CBF β), which acts to stabilize CBF α at sites of DNA interaction (Fig. 75-2). In normal cells, CBF acts at “core” enhancer sequences in a number of genes required for proper myeloid and lymphoid cell differentiation or maturation. The binding of CBF facilitates the access of other transcription factor complexes to these chromatin sites, in part through increased acetylation of

Figure 75-2 Disruption of the CBF transcriptional pathway in leukemogenesis. This schematic illustrates the central role of the core binding factor transcriptional pathway in leukemogenesis. Both components of the heterodimeric CBF are targeted for disruption in a variety of acute lymphoblastic and myeloblastic leukemias. Of these, the t(8;21)/*RUNX1-RUNX1T1* and inv(16) or t(16;16)/*CBFB-MYH11* account for nearly 20% of de novo AML cases, whereas the t(12;21)/*ETV6-RUNX1* is found in 20% of pediatric acute lymphoblastic leukemias. (Alternative gene nomenclature: *RUNX1* = *AML1* = *CBF2*; *RUNX1T1* = *ETO* = *MTG8*; *ETV6* = *TEL*). AML, Acute myeloid leukemia; CBF, core binding factor.

DNA-bound histone proteins by histone acetyltransferases (Lorsbach, 2001; Yamagata, 2005). In human acute myeloid leukemias with the t(8;21), the *RUNX1* gene (formerly designated *AML1*, or *CBF2*) encoding an isoform of CBF α , is joined to a putative transcription factor, *RUNX1T1* (formerly *ETO*, or *MTG8*) to form the *RUNX1-RUNX1T1* fusion (Downing, 1999; Peterson, 2007). In the case of the inv(16) or t(16;16), the gene producing CBF β (i.e., *CBFB*) is juxtaposed to a smooth muscle myosin heavy chain gene *MYH11* to form the hybrid *CBFB-MYH11* (Liu, 1995; Mrózek, 2008). In either case, profound disruption of the normal cellular differentiation program is thought to be central to the causation of acute leukemia. The prominence of CBF pathway alterations in leukemogenesis is additionally emphasized by the finding of *RUNX1* gene translocations in several other types of leukemia and myelodysplasia (see Fig. 75-2), including the t(12;21)/*ETV6-RUNX1* abnormality, the most common single genetic abnormality in pediatric ALL.

From a mechanistic viewpoint, the *RUNX1-RUNX1T1* leukemic fusion protein is thought to act in a dominant negative manner to normal *RUNX1* (i.e., CBF α) by recruiting or stabilizing elements of transcriptional repression, including histone deacetylase complexes, at critical DNA sites (Lorsbach, 2001; Yamagata, 2005). Normal gene expression patterns are also disrupted by the altered affinity of the abnormal fusion protein for specific core enhancer sequences, including an increased propensity to bind sites with such sequences in duplicate (Okumura, 2008). CBF β -MYH11 chimeric protein sequesters normal CBF α protein in the cytosol, thereby abrogating heterodimeric CBF assembly in the nucleus, but may also create an abnormally repressive transcriptional complex in a manner analogous to that of *RUNX1-RUNX1T1* (Shigesada, 2004). In either case, the resultant inhibition of transcription at key genes alters the genetic program for normal proliferation and differentiation in hematolymphoid stem or progenitor cells.

In keeping with the concept outlined previously that an individual genetic aberrancy is of itself not likely sufficient for carcinogenesis, transgenic mice engineered to conditionally express a *RUNX1-RUNX1T1* oncogene develop acute myeloid leukemia only on subsequent exposure to a promoting mutagen (Lorsbach, 2001; Peterson, 2007; Müller, 2008). In CBF leukemias, the pathognomonic translocations create a block in cellular differentiation (class II mutations), but affected cells often acquire secondary class I mutations that endow them with enhanced proliferative capacity. Indeed, there is a particularly strong association in CBF leukemias with secondary mutations to the gene encoding the c-KIT tyrosine kinase (stem cell factor receptor), a potent regulator of cell growth. Up to half of CBF leukemias carry *KIT* mutations; in contrast, approximately 5% of all AML cases show such mutations (Müller, 2008). Many of these *KIT* mutations involve the D816 “hot-spot” amino acid (that is also affected in systemic mastocytosis), but mutations have been described in other exons as well. The presence of *KIT* mutations in CBF leukemias has been associated with increased relapse risk and, in some studies, poorer overall survival, although the latter finding remains somewhat controversial at present (Cairolì, 2006; Paschka, 2006; Mrózek, 2008; Müller, 2008). Thus the routine clinical utility of *KIT* mutation testing in CBF leukemias currently awaits validation by larger trials. Notably, deregulation of c-KIT expression as a consequence of *KIT* mutations in these leukemias may present a rational therapeutic target, given that the 5-year-survival for CBF leukemia patients, albeit better than for AML in general, does not substantially surpass 50%.

The molecular rearrangements underlying the *RUNX1-RUNX1T1* fusion are such that the breakpoint-fusion sites invariably involve the same limited set of intron regions in both genes, resulting in a consistent in-frame *RUNX1-RUNX1T1* mRNA molecule in each patient with this type of AML, although some degree of variant transcripts derived from alternative splicing and differential promoter usage can also be seen (Zhang, 2002; LaFiura, 2007). In contrast, standard RT-PCR detection of the *CBFB-MYH11* chimeric transcript is complicated by the potential for marked breakpoint heterogeneity mainly in the *MYH11* gene, as well as by rare alternate breakage sites described in *CBFB*. In all, more than 10 *CBFB-MYH11* fusion transcript forms have been identified to date (Liu, 1995; Viswanatha, 1998; Kadkol, 2004; Schnittger, 2007). Despite this complexity, the *CBFB-MYH11* gene fusion can be readily detected by RT-PCR, because approximately 90% of these tumors harbor the so-called “type A” chimeric mRNA, characterized by fusion of *CBFB* nucleotide 495 to *MYH11* nucleotide 1921 to form a transcript of relatively short length (Schnittger, 2007). More comprehensive PCR strategies have also emerged to detect the majority of the other rare *CBFB-MYH11* fusion types, each of which account for the remainder of cases of *inv(16)* or *t(16;16)* AML (Kadkol, 2004). RT-PCR analysis for the *CBFB-MYH11* abnormality is often advantageous, in that standard cytogenetic interpretation may be uninformative in some cases (Merchant, 2004; Monma 2007). In this context, it is possible, though unlikely, that a case with a true non-type A *CBFB-MYH11* fusion could be negative by both conventional cytogenetic and molecular analysis, if karyotyping fails to detect a cryptic translocation and RT-PCR technique targets only the type A transcript; this possibility underscores the general importance of maintaining awareness of the limitations of a specific molecular assay, as well as the central role that morphologic assessment must play even in the molecular era. Nevertheless, given the generally more favorable clinical outcome for both of these AML subtypes, molecular diagnosis can play a significant role both in initial identification, as well as in disease monitoring following treatment.

Acute Myeloid Leukemias with *FLT3*, *NPM1*, and *CEBPA* Gene Mutations

The most recent WHO classification of AML has been broadened to include additional entities characterized by specific gene mutations (Swerdlow, 2008). Chief among these with regard to diagnostic and clinical significance are alterations of *FLT3*, *NPM1*, and *CEBPA*. These gene mutations involve relatively small scale modifications to the specific DNA sequences, including short insertions, deletions, or single base pair changes, and therefore cannot be detected by conventional cytogenetic or FISH techniques. AML with gene mutations usually are characterized by the presence of a normal tumor karyotype and are discussed here in this context; however, similar mutations can also accompany AML with recurrent translocations or other cytogenetic abnormalities. Notably, the characteristic “genotype-phenotype” correlations between morphologic, clinical, and genetic findings observed in AML with recurrent translocations are not as obviously encountered in AML with *FLT3*, *NPM1*, or *CEBPA* gene mutations. Among the group of AML with gene mutations, *FLT3* is an adverse prognostic factor, whereas *NPM1* and *CEBPA* mutations indicate an outcome somewhat better than for AML in general. Complicating this scenario is the fact that a significant subset of normal karyotype AML may harbor two or more gene mutations producing variable effects on tumor prognosis. Most significantly, *FLT3* and *NPM1* mutations may occur together, in which case the relative outcome benefit of the *NPM1* mutation is abrogated by the coexisting *FLT3* mutation. Furthermore, if these mutations are detected in the setting of cytogenetic abnormalities, or in other infrequent combinations, the prognostic significance is less clearly established. Whereas testing for *FLT3*, *NPM1*, and *CEBPA* gene mutations is currently indicated in cytogenetically normal AML cases, molecular genetic assays for these mutations should ideally not be considered in isolation. As noted earlier, *FLT3* mutation was not designated as a specific subtype of AML in the 2008 WHO classification, and cases of AML with mutated *NPM1* or *CEBPA* remain only provisional diagnostic entities at present.

FLT3 Mutations in AML

Expression of the *FLT3* gene (Fms-like tyrosine kinase; also known as *FLK2* and *STK1*) produces a membrane-spanning signal transduction protein of the receptor tyrosine kinase (RTK) type III family, whose members also include the platelet-derived growth factor receptor (PDGFR) genes and the *KIT* gene (Agnes, 1994; Small 2008). *FLT3* receptor-ligand

interactions are important for the maintenance and propagation of early progenitor cells in normal myeloid and lymphoid hematopoiesis. Not surprisingly, the wild type receptor protein is also expressed in the majority of AML and B-lineage ALLs, emphasizing its role in the survival and proliferation of immature hematopoietic cells (Gilliland, 2002; Stirewalt, 2003). *FLT3* mutations in AML most frequently take the form of internal tandem duplications (ITD) of part of the coding region for the juxtamembrane portion of this tyrosine kinase, producing an abnormal, constitutively active *FLT3* protein. All ITDs preserve an intact reading frame, despite the introduction of additional nucleotides, consistent with abnormal activation of a largely functional protein. A second type of activating lesion involves point mutation of *FLT3* at amino acid sites D835 or I836 in the “activation loop” of the protein (Yamamoto, 2001; Bacher, 2008). The constitutively active *FLT3* tyrosine kinase initiates increased activity within its downstream signaling cascade, which in turn provides a proliferative stimulus to the myeloid cell. Thus *FLT3* belongs to the “class I” group of AML-related genetic abnormalities. These *FLT3* gene mutations are together estimated to occur in 20%–40% of adult AML (as well as a smaller number of pediatric AML, secondary AML, and myelodysplasias), and appear to be distributed among all morphologic subtypes. *FLT3* is consequently one of the most common recurrent abnormal genetic findings encountered in AML. *FLT3* ITD mutations are most frequently observed in several cytogenetic settings, including *t(15;17)* APL, *t(6;9)* *DEK-NUP214* associated AML, and in many cytogenetically normal cases; this suggests a key role for this genetic aberration in the pathophysiology of these subsets of AML (Schnittger, 2002; Thiede, 2002).

In general, the presence of *FLT3* gene mutations in AML has been associated with poor prognosis, and the prognostic impact of *FLT3* mutations is particularly well-established in cytogenetically normal cases (Kottaridis, 2001; Zwaan, 2003; Schlenk, 2008; also reviewed in Stirewalt, 2003). More refined prognostic information appears to be derived from an assessment of the “gene dosage,” or ratio of *FLT3* ITD relative to wild type allele (*FLT3* ITD:WT), with higher ratios correlated with poorer clinical outcome (Thiede, 2002; Baldus, 2006; Meshinchi, 2006). Elevated *FLT3* ITD:WT ratios could possibly arise from gene amplification of the ITD allele, biallelic mutations, or from the presence of a more prevalent subclone of leukemic cells with the *FLT3* ITD (Stirewalt, 2003). However, some caveats remain notable regarding *FLT3* mutations. Although the prognostic impact of *FLT3*-ITD mutations is well established, the influence of *FLT3*-TKD mutations remains controversial (Fröhling, 2002; Moreno 2003; Yanada 2005; Mead 2007). Recent data suggest that *FLT3*-TKD mutations have no effect on prognosis in AML overall, but may have differential effects on outcomes (i.e., better or worse) in particular subgroups of AML (Bacher, 2008). AML with *FLT3*-ITD and *FLT3*-TKD mutations also have distinct gene expression profiles, suggesting that these two mutations, although within the same gene, may act in biologically and perhaps prognostically dissimilar ways (Neben, 2005). The value of additional screening for *FLT3*-TKD mutations in the molecular hematopathology laboratory therefore awaits a clearer understanding of the clinical significance of this molecular target. Second, the role of cooperating *FLT3* mutations in APL is well recognized and has been associated with proliferative features, such as leukocytosis (Callens, 2005); however, APL patients with *FLT3* mutations do not have a significantly different outcome than those without and mutation analysis is thus not routinely recommended in the setting of APL.

In contrast to the situation for translocation fusion genes with chimeric mRNA transcripts, *FLT3* ITD can be detected by PCR amplification of genomic DNA. Amplification of exons 14 and 15 of *FLT3* can identify the ITD, because these are variably larger in fragment size than expected for this region in the wild type gene. The presence of an ITD is typically established by PCR product sizing, for example using capillary electrophoresis of fluorescent PCR amplicons. Different molecular approaches are employed to detect TKD mutations, including DNA PCR followed by amplicon digestion with informative restriction endonucleases, direct sequencing, or other sequence-specific methods.

NPM1 Mutations in Acute Myeloid Leukemia

NPM1, which encodes the protein nucleophosmin, is mutated in 50%–60% of AML with a normal karyotype (Falini, 2005). Many of these leukemias are characterized by a lack of CD34 antigen expression and features of monocytic differentiation. *NPM1* is also the partner gene in the translocation characteristic of an unrelated hematologic malignancy, anaplastic large cell lymphoma (ALCL), suggesting its broader importance in fundamental hematopoietic signaling pathways. Normal cellular nucleophosmin is largely present within the nucleolus, but the protein operates as a

“shuttle,” escorting proteins, particularly ribosomal subunits, between the nucleus and cytoplasm (Yun, 2003; Yu, 2006). Nucleophosmin also participates in cell cycle regulation, by virtue of its ability to activate, via both direct and indirect mechanisms, p53 and other proteins involved in cell cycle control (Falini, 2007). Yet another task of this multifaceted protein is the control of centrosome duplication before mitosis (Tsou, 2006), and experimental depletion of *NPM1* results in improper chromosome alignment, abnormal centrosomes, and disorganization of mitotic spindles (Amin, 2008). *NPM1* mutations in AML involve small insertions of variable length and sequence in a specific region of the gene, producing a frameshift that alters the amino acid sequence at the C-terminus of the protein. This portion of nucleophosmin carries a nuclear localization signal (NLS) important for nuclear retention. The altered protein, lacking the NLS and incorporating instead a nuclear export signal, is aberrantly retained in the cytoplasm (Chen, 2006). The exact mechanisms by which cytoplasmic nucleophosmin contributes to leukemogenesis remain unclear, but the loss of the usual intranuclear interactions between nucleophosmin and cell cycle control proteins is hypothesized to play an important role in transformation (Falini, 2007). The presence of mutated *NPM1* is significantly associated with a relatively good prognosis in normal karyotype AML, but only if an accompanying *FLT3* mutation is absent (Schlenk, 2008). Nearly 40% of *NPM1* mutated AML cases harbor a concomitant *FLT3* mutation, and these patients have an inferior prognosis, essentially similar to AML with *FLT3* mutations alone (Baldus, 2007).

Although the cytoplasmic localization of nucleophosmin in *NPM1* mutated AML cases presents a potentially attractive target for simple detection via immunohistochemistry, such a technique may be insufficient for accurate prognostication based on the lack of quantitative standards and the problem of tumor heterogeneity (Konoplev, 2009). Therefore molecular analysis is the preferred method for identifying *NPM1* mutations. More than 25 mutations (all heterozygous) have been identified affecting exon 12 (Konoplev, 2009). The most common mutation, labeled type A, is seen in up to 80% of *NPM1* positive cases and involves the insertion of the tetranucleotide sequence TCTG at positions 956 to 959 of the gene (Falini, 2007). Because these *NPM1* exon 12 mutations change the length of the DNA sequence relative to wild type, standard PCR amplification of the genomic region paired with fluorescent product size analysis by capillary electrophoresis suffices to detect the change. A distinct advantage of this strategy is that the same method can be applied to the detection of *FLT3*-ITD mutations, simplifying the technical approach to these genetic abnormalities; as indicated, *NPM1* analysis should always be performed in conjunction with *FLT3* testing to provide accurate prognostic information.

CEBPA Mutations in Acute Myeloid Leukemia

Acute myeloid leukemias with mutations of the CCAAT/enhancer binding protein α (*CEBPA*) gene represent a third distinct group of tumors recently included in the 2008 WHO AML classification. *CEBPA* encodes a transcription factor essential to granulocytic differentiation, such that the production of mature granulocytes does not occur in its absence (Koschmieder, 2009). Corollary functions of normal *CEBPA* protein include transcriptional repression of genes involved in nonhematopoietic programs and the promotion of cell cycle arrest as a component of terminal differentiation. Although mutations of *CEBPA* are thought to promote leukemogenesis by blocking granulocytic differentiation and proliferation control, the exact pathogenetic mechanisms remain to be elucidated. Notably, some families with an inherited predisposition to the development of AML carry germline *CEBPA* mutations (Renneville, 2009a). Approximately 15%–20% of cytogenetically normal cases of AML carry the *CEBPA* mutation (Baldus, 2007). In this setting, *CEBPA* mutations are associated with a relatively favorable prognosis (Fröhling, 2004; Bienz, 2005; Schlenk, 2008). Although the significance of *CEBPA* mutations in other types of AML is not completely clear, recent evidence suggests that the beneficial prognostic effect of *CEBPA* mutations applies only in cases with normal karyotype and without *FLT3*-ITD mutation (Renneville, 2009). Paradoxically, though, coexisting *FLT3*-TKD mutations in particular may not affect the positive impact of mutated *CEBPA* (Bacher, 2008). Furthermore, recent observations suggest that the improved outcome in *CEBPA* mutation-positive AML appears to be limited only to those cases carrying biallelic mutations, underscoring incomplete but evolving understanding of this area (Wouters, 2009a).

Prototypical *CEBPA* mutations are found widely separated within both N- and C-terminal regions of the gene, in contrast to the more clustered localization of mutations in *FLT3* and *NPM1*. The N-terminal mutations prevent translation of the full-length p42 isoform, but an alternative start

site downstream from the mutated N-terminal site permits continued production of a shorter p30 isoform (Wouters, 2009a). In contrast, C-terminal mutations are in frame and are thought to impair protein function. Other mutations have been described throughout the intervening region. Consequently, molecular detection strategies must be capable of detecting many mutations over a potentially wide area. Direct sequencing of RT-PCR amplified *CEBPA* mRNA, both with and without initial screening via high-resolution melting curve analysis, has been successfully employed in this regard (Ahn, 2009; Rázga, 2009).

Other Gene Mutations in Acute Myeloid Leukemias

Mutations involving many other genes, including *WT1*, *MLL*, *NRAS*, and *KRAS*, have been associated with prognostic or biologic importance in AML. In addition, abnormal gene expression patterns of *BAALC*, *ERG*, and *MNI* have also been tied to prognosis (Baldus, 2007). As this list continues to expand, a major challenge for the diagnostician and clinician will be in the rational interpretation of potentially many interacting genetic factors in order to determine appropriate risk stratification and therapy options for individual AML patients. As suggested from the inherent complexity of simultaneously assessing the three relatively common mutations considered previously (*FLT3*, *NPM1*, and *CEBPA*), the impact of multiple cooperating genetic events requires sophisticated bioinformatics analyses applied to well-designed and sufficiently powered clinical studies. The optimal strategy for evaluation of gene mutations in AML will thus continue to evolve as additional clinical data emerge.

ACUTE LYMPHOBLASTIC LEUKEMIA/LYMPHOMA, B AND T CELL LINEAGE

B Cell Lymphoblastic Leukemia/Lymphoma (Precursor B Cell Acute Lymphoblastic Leukemia)

Significant biologic and clinical differences exist between adult and childhood onset ALLs. Comparatively little is known about the pathogenesis of adult ALL, which overall is associated with a relatively unfavorable outcome. As such, cytogenetic and molecular genetic anomalies in adult ALL are incompletely characterized, with the exception of the very poor prognosis t(9;22)/*BCR-ABL1* (i.e., Ph+ ALL). Beyond detection of the *BCR-ABL1* gene fusion, molecular diagnosis is currently of limited utility in the management of adult ALL. In marked contrast, the molecular diagnostic evaluation of pediatric ALL is of substantial value in the stratification of patients to “risk-adapted” treatment strategies. Over the past 20 years, the improvement in therapeutic regimens for these children, coupled with a more profound understanding of ALL tumor biology, has resulted in cure rates of 80% or better overall (Pui, 2004; O’Leary, 2008; Pui, 2008; Vrooman, 2009). In turn, this has led to the concept of tailoring therapy to defined subsets of patients based on a combination of presenting clinical and biologic features, including early treatment response and tumor genetics. The aim in childhood ALL has thus evolved to balance the highest probability of long-term remission with the lowest chance of therapy-related adverse events. Although clinical features (e.g., age, degree of leukocytosis, CNS involvement) are initially used to separate “standard risk” from “high risk” individuals, tumor genetics are also an integral component of the initial (i.e., pretreatment) evaluation of childhood ALL patients. Broadly, both numerical and structural chromosomal abnormalities are considered in this process (Table 75-4). In the former instance, “high hyperdiploidy,” or tumor aneuploidy with a chromosome number in excess of 52, has been associated with more favorable treatment response and outcome, particularly when certain chromosomal trisomies (e.g., +4, +10, +17) are present (Harris, 1992; Heerema, 2000; Moorman, 2003; Sutcliffe, 2005; Schultz, 2007). Conversely, tumor hypodiploidy, especially less than 44 chromosomes, is associated with a very high frequency of treatment failure (Heerema, 1999; Nachman, 2007; Schultz, 2007). Among the structural rearrangements, four chromosomal translocations account for approximately one third of pediatric ALL cases, each with prognostic importance: the t(9;22)/*BCR-ABL1*, t(1;19)/*TCF3-PBX1*, t(12;21)/*ETV6-RUNX1*, and rearrangements involving the 11(q23)/*MLL* locus (Bartolo, 2000; Harrison, 2001; Pui, 2004; Armstrong, 2005). In general, numerical and structural alterations are mutually exclusive in any given case of childhood ALL; however, occasionally, these findings can coexist. Although not dealt with formally in this section, the detection of minimal residual disease at certain posttherapeutic timepoints (e.g., end-of-induction) has also emerged as a highly important component of outcome prediction in

TABLE 75-4

Risk Stratification/Outcome Prediction in Childhood B-lineage Acute Lymphoblastic Leukemia*

Abnormality	Prognostic significance	Notes
High hyperdiploidy (>52 chromosomes)	Favorable	Hyperdiploid tumors with particular trisomic chromosomes (e.g., +4, +10, +17) associated with very favorable outcome
t(12;21)/ETV6-RUNX1	Favorable	Very favorable outcome, but appreciable incidence of late relapses
t(1;19)/TCF3-PBX1	Intermediate	Intensive therapy results in good outcome
t(9;22)/BCR-ABL1	Unfavorable	Very high risk for relapse/refractory disease
11q23/MLL gene rearrangements	Unfavorable	Very high risk for infant ALL; also considered high risk factor for older children
Hypodiploidy (<44 chromosomes)	Unfavorable	Very high risk for relapse/refractory disease
High level molecular MRD at end-induction therapy	Unfavorable	Very high risk of relapse in patients with MRD above 10^{-2} – 10^{-3} , detected by molecular or flow cytometric methods

ALL, Acute lymphoblastic leukemia; MRD, minimal residual disease.

*Tumor genetic features and early MRD are considered in conjunction with clinical and laboratory findings, including age, presenting blast count, and evidence of extramedullary disease. These risk factors therefore modify and refine traditional parameters for predicting therapeutic response.

childhood ALL (Cave, 1998; van Dongen, 1998; Nyvold, 2002; Campana, 2008; Flohr, 2008; Campana, 2009).

Major Translocation Fusion Gene Abnormalities in B Cell ALL

The t(9;22)(q34;q11.2)/*BCR-ABL1* is found in approximately 3%–4% of childhood B-lineage ALL, but occurs in 20%–25% of adult B-ALL (Armstrong, 2005). Typically, these patients present with markedly elevated lymphoblast counts and other adverse clinical features. Of the two common break-fusion events associated with the *BCR-ABL1* fusion gene, the majority of cases of pediatric B-ALL (80%–90%) have *BCR* breakpoints situated in the minor breakpoint cluster region (m-*BCR*), with production of an e1-a2 type chimeric *BCR-ABL1* mRNA. The e1-a2 mRNA type is also found in many adult *BCR-ABL1* positive B-ALL, but approximately one third of adult cases alternatively demonstrate e13-a2 or e14-a2 transcripts, characteristic of major breakpoint cluster region (M-*BCR*) disruption in the *BCR* gene. The structure and molecular diagnostic aspects of the *BCR-ABL1* gene fusion are presented in greater detail in the subsequent section on CML. The presence of the *BCR-ABL1* in childhood ALL is an independently poor prognostic factor, placing these patients among the very highest at risk for primary treatment failure and relapse (Fletcher, 1991; Gaynon, 1997; Jones, 2005; Yanada, 2009). The majority of *BCR-ABL1* positive ALL patients are candidates for more aggressive therapy including early allogeneic hematopoietic stem cell transplantation. The introduction of the tyrosine kinase inhibitor imatinib mesylate may offer additional therapeutic benefit in the treatment of this disease; in adult Ph+ALL, imatinib in combination with conventional chemotherapy results in a very high (95%) rate of initial complete remission, although durable responses are often difficult to maintain (Jones, 2005; Gökbuget, 2009; Ribera, 2009; Vrooman, 2009; Yanada, 2009; reviewed in Gruber, 2009). Studies of the efficacy of imatinib in childhood Ph+ ALL are ongoing (Jones, 2005; Vrooman, 2009). Molecular analysis of the *BCR-ABL1* transcript by RT-PCR technique is critical for risk prediction in childhood ALL, as well as providing a marker for residual disease monitoring. Recently, deletion of *IKZF1*, which codes for the transcription factor Ikaros, has been identified as a genetic change present in many cases of *BCR-ABL1* ALL (Mullighan, 2008; Iacobucci, 2009; Martinelli, 2009; Mullighan, 2009). Although data are still emerging, Ikaros alterations appear to be an important cooperative lesion in this subclass of ALL, strongly influencing the aggressive behavior of *BCR-ABL1* ALL (Martinelli, 2009; Mullighan, 2009).

B-ALL characterized by the t(1;19)(q23;p13.3) abnormality are uncommon, accounting for less than 5% of pediatric cases and only rare occurrences in adults (Armstrong, 2005). This translocation is strongly associated with “pre-B” immunophenotypic features, typified by the presence of cytoplasmic IgM production in the tumor cells. Following its initial recognition in childhood ALL, the t(1;19) was associated with poor outcome. However, it has become apparent that more intensive treatment protocols largely negate the adverse effects of this genotype, resulting in stable remissions for most of these individuals. Recognition of this translocation is thus required for appropriate therapy (Schultz, 2007). The t(1;19) most frequently occurs as an unbalanced form of translocation (with resultant loss of some genetic material) and produces the chimeric *TCF3* (formerly *E2A*)-*PBX1* gene fusion, although balanced translocations with the same fusion product also occur (Hunger, 1991; Paulsson, 2007). The *TCF3* gene encodes a series of basic helix-loop-helix transcription factors, which are involved in myocyte and B-lymphocyte development. *PBX1* is a DNA-binding transcription factor that is not normally expressed in lymphoid cells. The fusion *TCF3-PBX1* protein replaces the DNA binding and protein dimerization motifs of *TCF3* with the DNA binding region of *PBX1*, predisposing the progenitor B cell to neoplastic proliferation. The location of genomic breakpoints within *TCF3* and *PBX1* introns is consistent in essentially all cases, resulting in the formation of a single *TCF3-PBX1* transcript (Hunger, 1991; Wiemels, 2002), with only few reported variants (Paulsson, 2007). This fusion mRNA is readily amenable to RT-PCR detection and can also serve as a disease-specific marker for sensitive detection in the bone marrow. Of note, rare cytogenetically detectable ALL cases with t(1;19) lack the *TCF3-PBX1* fusion and appear to be associated with an inferior outcome (Privitera, 1992; Prima, 2007); these variant t(1;19)(q23;p13.3) translocations instead create reciprocal oncogenic fusion proteins, *DAZAP1/MEF2D* and *MEF2D/DAZAP1* (Prima, 2007).

Overall, 20%–25% of pediatric ALL patients are characterized by the presence of the t(12;21)(p13;q22) abnormality, establishing this lesion as the most common recurrent translocation in this patient group (Armstrong, 2005). This genetic finding is essentially absent among adults with B-ALL. The t(12;21) is cytogenetically cryptic in almost all cases (Karrman, 2006), instead often being suggested by an apparent deletion of the short arm of one chromosome 12. Although patients with t(12;21) ALL are found distributed among different clinical risk groups, in general, these individuals are between the ages of 2 and 7 and have diploid karyotype tumors (Rubnitz, 1997a; Forestier, 2006; Forestier, 2007). The t(12;21) results in the joining of the 12p locus *ETV6* gene (also known as *TEL*) with the *RUNX1* (or *AML1*, *CBEA2*) gene on 21q to form the chimeric gene fusion, *ETV6-RUNX1* on the derivative chromosome 12 (Romana, 1995; Zelent, 2004). Pediatric patients with *ETV6-RUNX1* positive ALL have a favorable outcome, with excellent disease-free remissions approaching 80% (similar to the aforementioned high-hyperdiploid group with specific chromosomal trisomies) (Shurtleff, 1995; Borkhardt, 1997; Rubnitz, 1997a; Rubnitz, 1997b; Forestier, 2008). However, reports of a substantial late relapse rate among some *ETV6-RUNX1* ALL patients have refocused attention on more clearly defining the risk characteristics of this group, even though many such relapsed patients remain responsive to “salvage therapy” protocols (Harbott, 1997; Seeger, 1998; Ford, 2001; Forestier, 2008). The molecular pathology of *ETV6-RUNX1* ALL is related to disruption of normal CBF activity, leading to enhanced transcriptional repression of many target genes, as similarly discussed for the *RUNX1-RUNX1T1* abnormality in AML (Fig. 75-3) (Zelent, 2004). In almost 90% of *ETV6-RUNX1* ALL cases, the remaining *ETV6* allele is partially or completely deleted in a variable proportion of tumor cells, suggesting that this event may be an important secondary event for leukemogenic transformation, through complete loss of normal *ETV6* function (Raynaud, 1996; Tsuzuki, 2007; Wiemels, 2008). At the DNA level, *ETV6* and *RUNX1* breaksites in ALL occur most often in the same genomic regions of *ETV6* intron 5 and *RUNX1* intron 1 (Romana, 1995; von Goessel, 2009), with evidence of some propensity for breakpoint clustering. A second minor variant with breakpoints situated in *RUNX1* intron 2 is also described. The in-frame transcribed *ETV6-RUNX1* mRNA thus encompasses a novel region joining *ETV6* exon 5 to *RUNX1* exon 2 (most cases), or *ETV6* exon 5 to *RUNX1* exon 3 (fewer cases) (Nakao, 1996b; von Goessel, 2009). Additional complexity is present in this gene fusion owing to alternative splicing out of *RUNX1* exons 2 and/or 3, with the possibility of detecting up to four *ETV6-RUNX1* amplified transcript forms by RT-PCR in any given case. Molecular (RT-PCR) or FISH detection of the *ETV6-RUNX1* is frequently employed in pediatric ALL, given the inability to diagnose the t(12;21) by standard cytogenetics. The

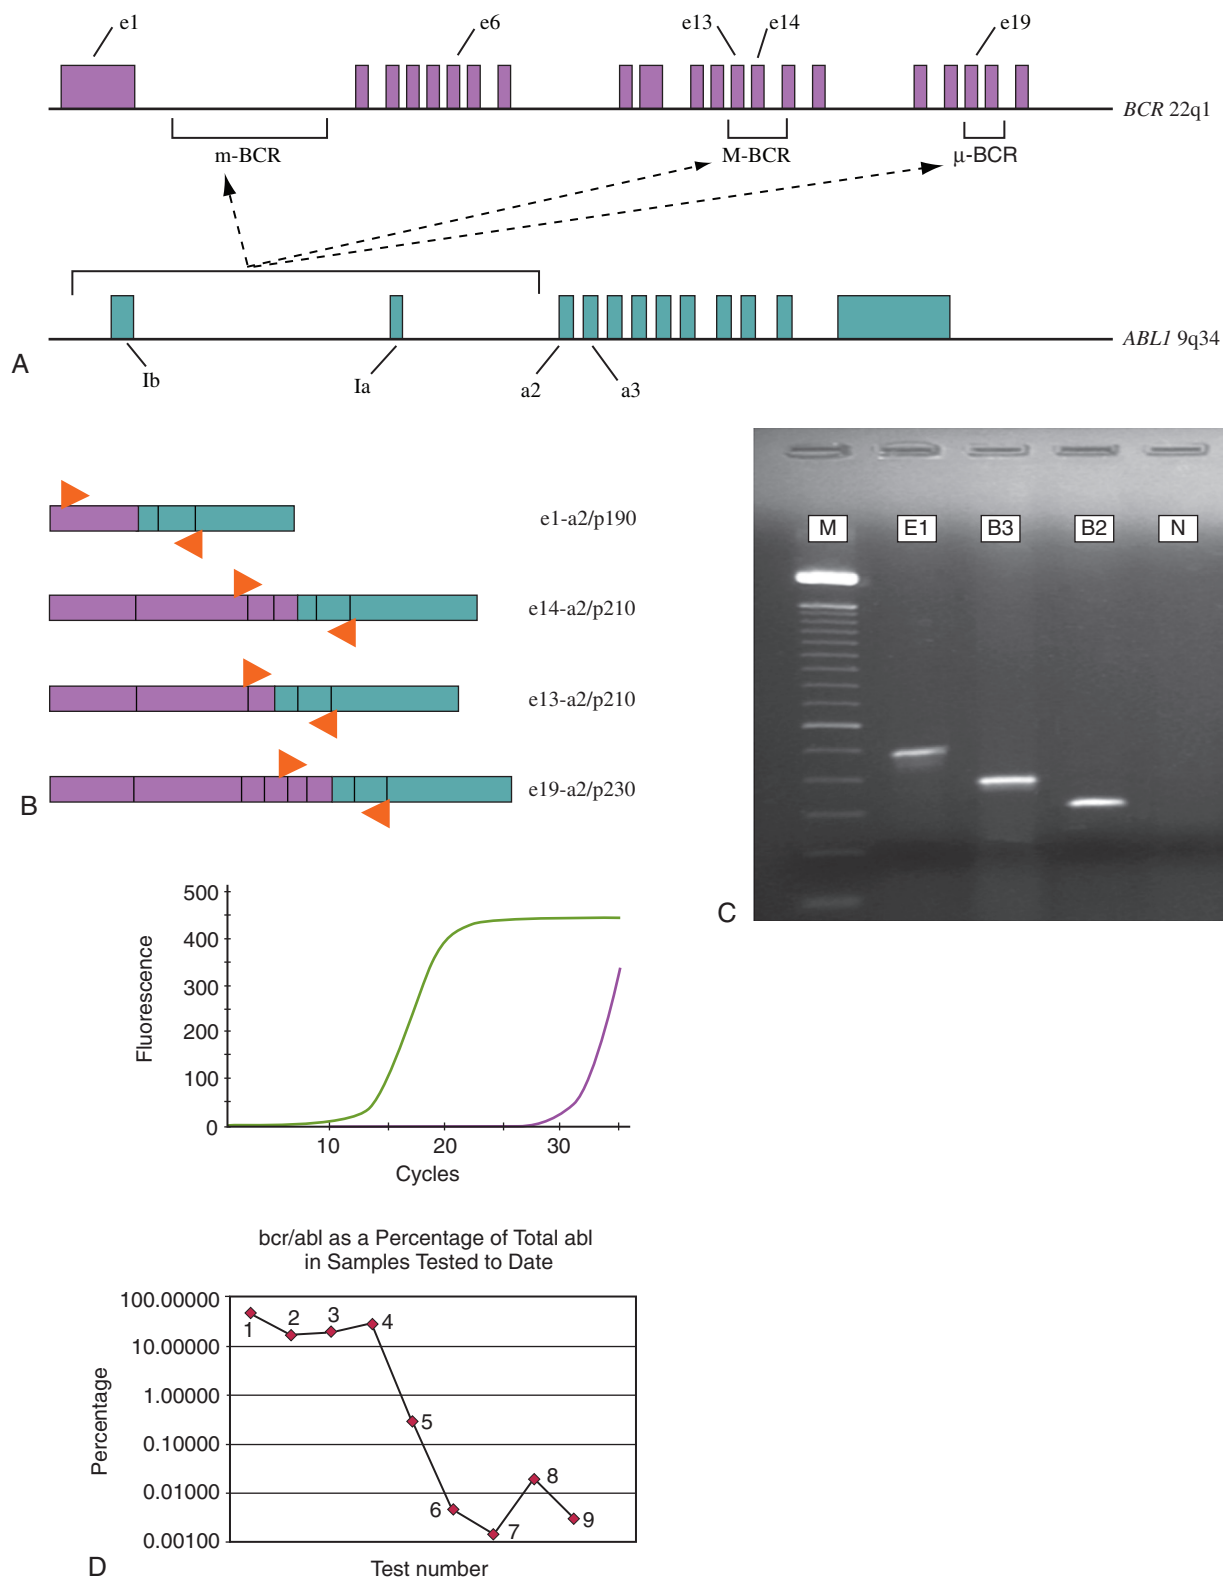

Figure 75-3 *t*(9;22)/*BCR-ABL1* abnormality in chronic myeloid leukemia and Ph+ acute lymphoblastic leukemia. **A**, The partial genomic organization of the *BCR* and *ABL1* genes (not to scale). Three major breakpoint regions are recognized in the *BCR* gene: the minor breakpoint cluster region (m-BCR), the major breakpoint cluster region (M-BCR), and the μ -BCR. The M-BCR is involved in essentially all cases of CML and approximately one third of de novo adult Ph+ acute lymphoblastic leukemias (Ph+ ALL). A small percentage of childhood Ph+ ALL may have BCR breakpoints at this site as well. The m-BCR is typically associated with the vast majority of pediatric Ph+ ALL and most adult Ph+ ALL. Breakpoints at the μ -BCR have been associated with rare cases of CML with essentially complete neutrophilic maturation. For the *ABL1* gene, breakpoints are distributed throughout a large region 5' of exon 2 (a2) encompassing the first exon region. **B**, The principal BCR-ABL1 chimeric transcripts arising from these various translocation fusion gene breakpoints. The exon-exon fusions are indicated for these transcripts and the corresponding chimeric protein product sizes are shown in kilodaltons (e.g., e1-a2/p190). The orange arrows indicate relative positions of PCR primers to detect these various forms in RT-PCR assays. **C**, Typical RT-PCR gel electrophoresis results for detection of the m-BCR and M-BCR transcripts. **D**, Example of RQ-PCR monitoring of BCR-ABL1 mRNA in a CML patient being treated with imatinib mesylate. The upper section displays the RQ-PCR amplification traces for BCR-ABL1 (purple) and ABL1 control (green). The quantity of BCR-ABL1 is expressed as a normalized ratio of BCR-ABL1/ABL1. The lower section indicates a time course of quantitative BCR-ABL1 level measurements over several months for this patient. A therapeutic level of less than 0.1% BCR-ABL1/ABL1 in CML is compatible with an excellent outcome and very low relapse risk. CML, Chronic myeloid leukemia; E1, e1-a2 product; E13, e13-a2 product; E14, e14-a2 product; M, molecular size marker (100 bp); N, no template control; RQ-PCR, real-time quantitative polymerase chain reaction; RT-PCR, reverse-transcriptase polymerase chain reaction.

chimeric mRNA further represents a highly specific molecular marker for residual disease assessment.

Translocations involving the “mixed lineage leukemia” (*MLL*) gene located on chromosome 11q23 are observed in 5%–9% of pediatric ALL cases overall and are disproportionately represented in infants younger than 1 year of age (Bartolo, 2000; Armstrong, 2005; Silverman, 2007; Chowdhury, 2008). The presence of *MLL* gene translocations is associated with a poor outcome for these very young children and is considered an adverse finding in older children as well, particularly in the setting of a poor prednisone response (Pui, 2003; Chowdhury, 2008). Infant *MLL*-positive leukemias are of B-lineage, lack CD10 positivity, and demonstrate aberrant expression of some myeloid-associated markers (Chen, 1993; Burmeister, 2009). Clinically, these patients have high initial leukocyte counts, organomegaly, and a tendency for involvement of the central nervous system. Translocations involving 11q23/*MLL* also occur in de novo AML and secondary (therapy-related) AML and in either case are characterized by monocytic morphologic features (i.e., FAB AML-M4 or M5 types). In de novo adult AML, *MLL* gene rearrangements, specifically the t(9;11) *MLLT3-MLL* abnormality, may not represent a high risk tumor genotype. In contrast, secondary AML arises in subsets of both pediatric and adult patients who have had prior dose intensive chemotherapy with DNA topoisomerase II inhibitors (e.g., epipodophyllotoxins and anthracyclines); these tumors occur abruptly within a few months to years after exposure and have a very aggressive treatment-resistant course (Godley, 2008).

The pathobiology underlying *MLL* gene translocations in these different types of de novo and secondary acute lymphoid and myeloid leukemias is becoming better understood. The *MLL* protein is a large (~430 kD) DNA binding protein, which is characterized by several functional domains, indicating its role as a multifunctional transcriptional factor with histone methyltransferase activity (Hess, 2004; Li, 2005; Krivtsov, 2007; Wang, 2009). *MLL* is known to regulate several *HOX* (homeobox) genes involved in the coordination of proper skeletal development during mammalian embryogenesis (Yu, 1995; Soshnikova, 2008). Several *HOX* genes also appear to be central to the development and maintenance of myeloid and lymphoid progenitor cells, thus establishing a tight link for *MLL* in the genetic control of normal hematopoiesis as well (Hess, 2004; Ernst, 2004a; Ernst, 2004b; McGonigle, 2008). *MLL* gene translocations produce an altered functional form of the protein; in each instance, the N-terminal “A-T hook” DNA binding motif of *MLL* is retained in the chimeric protein, typically with fusion to a portion of another transcription factor (Waring, 1997; Chowdhury, 2008). Accumulating data indicate that abnormal expression of *MLL* fusion proteins can constitutively deregulate certain *HOX* genes, leading to hematopoietic progenitor cell immortalization and predisposition to leukemogenesis (Armstrong, 2003; Hess, 2004; Ono, 2009). Indeed, recent studies using chromatin immunoprecipitation to identify portions of the genome bound by *MLL* have further detected its presence at numerous promoter regions, suggesting a more global role for *MLL* in transcriptional regulation.

Some additional key biologic insights have emerged from the structural analysis of *MLL* gene breakpoints in different subsets of leukemias. The majority of de novo AML with *MLL* translocations have breaksites situated 5' in the *MLL* breakpoint cluster region, whereas the preponderance of secondary AML occur in a more distal (3') segment of this locus (Stissel-Broeker, 1996; Zhang, 2006). Infant ALL cases strikingly also tend to associate with the 3' genomic region, suggesting a commonality in pathogenesis with secondary AML. This 3' “hotspot” area contains a strong consensus binding site for DNA topoisomerase II, as well as an adjacent “scaffold attachment region,” which is highly susceptible to cleavage by endonucleases. Although the presence of the topoisomerase II site presents an attractive explanation for the basis of developing secondary AML (e.g., via double strand break induction by topoisomerase II inhibitors and subsequent *MLL* translocation rearrangements), the hypersensitive 3' scaffold site of the gene has received further attention, since it too appears to be particularly prone to double strand breaks in experimental models (Stissel-Broeker, 1996). The latter *MLL* region is in fact selectively targeted for cleavage during cell death in response to diverse apoptogenic stimuli (e.g., following cellular stress or DNA damage) (Betti, 2001; Sim, 2001; Betti, 2003; Greaves, 2003a; Betti, 2005). These recent investigations imply that exposure to agents that can induce this site-specific *MLL* breakage potentially set the stage for *MLL* gene fusions, leading to the very aggressive forms of leukemia observed in infants and after distinct types of chemotherapy. In turn, because the causal etiology is already identified for secondary AML with *MLL* translocations, current studies in infant ALL seek to discover possible exogenous or naturally occurring transplacental factors

that may predispose developing fetal hematopoietic stem cells to *MLL* gene breakage and illegitimate recombination (Spector, 2005; Pombo-de-Oliveira, 2006).

The *MLL* gene is involved in translocation events with more than 60 known partner genes (Liu, 2009); however, the t(4;11)(q21;q23)/*MLL-AF4* abnormality is the most frequently encountered in infant ALL (75% of cases). *MLL* gene locus breakpoints are distributed over an 8.3 kb region of DNA encompassing exons 5–11 (Chowdhury, 2008). This marked breakpoint heterogeneity may also occur in the translocated gene (e.g., *AF4*), resulting in the possibility of several *MLL* hybrid gene products, typically one of which is expressed in any given patient with this leukemia. RT-PCR method can be used to identify individual *MLL* fusion gene transcripts, such as the *MLL-AF4* chimeric mRNA; however, the combination of multiple rearranging gene partners in these leukemias and the potential for substantial genomic breakpoint variability requires comprehensive and technically challenging laboratory approaches, such as multiplex PCR assays or, in the research setting, techniques such as long-distance inverse PCR (Pallisaard, 1998; Andersson, 2001; Meyer, 2009a, 2009b). *MLL* gene locus rearrangements have also been successfully detected by Southern blot analysis, although FISH technique now provides a rapid and highly efficacious alternative for this purpose (Cuthbert, 2000; Cavazzini, 2006). FISH analysis can provide very rapid confirmation of *MLL* gene breakage, implying a translocation event, but cannot give information regarding the particular translocation present. Thus RT-PCR, even with the limitations described, can serve a useful purpose in the diagnosis and monitoring of these leukemias, especially because the fusion gene type can be specifically and more sensitively identified in contrast to other analytic methods.

Prenatal Origins of Childhood Leukemias

Major advances continue to be made in understanding the molecular basis of the pediatric acute leukemias. These efforts now span the realms of basic science, translational and clinical research, and increasingly, population-based methods. Studies of concordant ALL occurring in monozygotic twins first demonstrated that the leukemias arising in each paired affected individual were genetically identical based on molecular analysis of the genomic breakpoint sequences of involved *MLL*, *ETV6-RUNX1*, or clonotypic immunoglobulin or T cell receptor gene rearrangements (summarized in Greaves, 2003b; Taub, 2004). Notably, the propensity to develop concordant leukemias is variable for different leukemic subtypes in twin studies, approaching 100% for *MLL* translocation ALL and only 10% for *ETV6-RUNX1* ALL. These findings suggest a variable transformation potential for these different gene fusions in vivo, raising the issues of both the nature and timing of secondary genetic insults. The results of these investigations have been corroborated using similar experimental techniques to “back track” leukemia-specific DNA abnormalities to archived neonatal blood samples of individual (nontwin) children of different ages, with genetically defined subtypes of ALL or AML (Gale, 1997; Wiemels, 1999; Fasching, 2000; Yagi, 2000; Wiemels, 2002a; Greaves, 2003a, 2003b; Taub, 2004; Ross, 2008). Together, these data strongly suggest that many pediatric ALL (and some AML) have origins in utero; that is, prenatal acquisition of potentially leukemogenic translocation events, or other genetic abnormalities, can occur during the time of active fetal hematopoiesis, but in most cases additional, later-occurring genetic alterations in susceptible individuals are required in order to produce overt leukemia. The rapid evolution of *MLL*-associated ALL vs. the longer latency (i.e., older age at onset) of *ETV6-RUNX1* ALL indicates that both the biologic effects of the primary (predisposing) genetic lesion, as well as the timing and type of promoting insult(s) are complex, although within defined subtypes of leukemia, it may now be possible to better elucidate the molecular pathways resulting in tumorigenesis. Not all types of pediatric ALL however, can be traced back to a prenatal clonal cell origin. The retrospective neonatal blood data for the t(1;19)/*TCF3-PBX1* ALL subgroup instead support the concept that the majority of these patients develop this genetic aberration in the postnatal period (Wiemels, 2002b).

Prospective RT-PCR and FISH screening of blood samples from healthy newborn children has subsequently revealed a detection frequency of 1% for the *ETV6-RUNX1* abnormality and 0.2% for the *RUNX1-RUNX1T1* fusion transcript, markedly higher than the incidence of either of these leukemia subtypes in childhood (Mori, 2002; Olsen, 2006). These data demonstrate that the occurrence of at least some chromosomal translocation fusion genes is a common event in utero; however the presence of such an abnormality is clearly insufficient to cause overt leukemia in the vast majority of individuals. Although the translocation-type acute leukemias are karyotypically characterized in most instances by an apparent

“single genetic anomaly,” it is becoming evident that these tumors also conform to the “two-hit” hypothesis of Knudson proposed for solid tissue cancers (Knudson, 1992; Schindler, 2009), as discussed in further detail in Chapter 74. In this concept, the initiating translocation event must be stable enough in a long-lived progenitor hematopoietic cell to confer some advantage in survival or proliferation; the acquisition of one or more subsequent genotoxic events in a susceptible individual would then lead to complete malignant transformation. The fate of such silent “translocation positive” cells is thus an important parameter, not only for understanding disease pathogenesis, but also in a practical setting for the appropriate interpretation of molecular diagnostic assays in the context of detecting minimal residual disease.

Intriguingly, recent research using genome-wide association has identified certain low-penetrance germline variants of *IKZF1* (as well as other genes) that may increase susceptibility to the development of childhood ALL (Papaemmanuil, 2009). Even though much research remains directed at the basic molecular and cell biology of childhood acute leukemias, molecular epidemiologic methods will play an increasing role in identifying the interplay between environmental factors and host genetic polymorphisms, which underlie the predisposition to this disease in some individuals (Clavel, 2005; Spector, 2005; La Fiura, 2007; reviewed in Pui 2008). Indeed, the relatively brief period of potential environmental exposure in utero may lend itself to the detection of specific risk factors in a manner impossible for adult-onset leukemias (Kim, 2006; Ross, 2008); mitigation strategies to decrease the risk of childhood leukemia is thus a goal of these efforts.

T Cell Lymphoblastic Leukemia/Lymphoma

In contrast to the relatively well-understood pathobiology of B lineage ALL, the genetic underpinnings of T cell lymphoblastic neoplasms (T-ALL) have historically remained obscure. This may be partially explained by the relative rarity of T-ALL in comparison to B-ALL, with the former accounting for 15% and 25% of pediatric and adult cases of overall lymphoblastic leukemias, respectively (Chiaretti, 2009). Recently, however, molecular genetic techniques have uncovered a surprisingly diverse set of abnormalities seen recurrently in T-ALL. These studies have begun to elucidate what have been previously unknown leukemogenic mechanisms, although currently these investigational findings have not yet been definitively linked with relevant clinical or prognostic subgroups of patients, or with applications to minimal residual disease detection (Baldus, 2009; Mansour, 2009). Translocations involving the T cell receptor genes are identified in up to 35% of T-ALL, juxtaposing TCR regions with a wide array of partner genes that often code for transcription factors, including *HOX11*, *HOX11L2*, *HOXA4*, and *TAL1* (Chiaretti, 2009). The *TAL1* oncogene is also frequently (25% of cases) fused to its neighbor *SIL* following a cryptic interstitial deletion at 1p32 (van der Burg, 2002). More than 50% of cases of T-ALL have activating mutations in *NOTCH1*, which encodes a transmembrane receptor important in the regulation of physiologic T cell development. In a manner analogous to the role played by *FLT3* in some cases of AML, mutations in *NOTCH1* create a constitutively active receptor promoting unchecked downstream signaling, resulting in altered expression of target genes, including the oncogene *MYC* (Pui 2008). In some cases, missense mutations in *FBXW7*, a negative regulator of *NOTCH1*, can achieve the same pathogenic effect (Park, 2009). Abnormal tyrosine kinase activity is also found in subsets of T-ALL. The *NUP214(CAN)-ABL1* gene fusion, which is often found in amplified extra-chromosomal episomes formed from 9q34, is identified in 6% of cases (Graux, 2004). *JAK1* mutations are detectable in 18% of T-ALL and may be associated with an inferior prognosis (Flex 2008).

MOLECULAR DIAGNOSIS OF MYELOPROLIFERATIVE NEOPLASMS

Chronic Myelogenous Leukemia, BCR-ABL1 Positive

Chronic myelogenous (or myeloid) leukemia is a clonal marrow stem cell disease resulting predominantly from excessive proliferation of granulocytic cells at all stages of maturation. The natural course of CML is typified by a protracted chronic phase, often for several years, followed by a rapid transformation to an aggressive acute myeloid or lymphoid blast crisis with fatal outcome. The decades-long investigation and treatment of this disorder has led from the association of a karyotypic abnormality with disease phenotype, to the unraveling of its molecular genetic pathogenesis, and currently, to the widespread use of a highly effective targeted

pharmacologic therapy in the form of imatinib mesylate (Gleevec, Novartis) (Goldman, 2003; Pavlovsky, 2009). CML is characterized by the presence of the t(9;22)(q34;q11.2) chromosomal translocation, initially observed as an abnormal 22q termed the *Philadelphia chromosome* (Ph) (Nowell, 1960; Rowley, 1973). This translocation leads to juxtaposition of the *ABL1* tyrosine kinase gene (9q34) with the *BCR* gene (22q11.2) on the derivative chromosome 22q, formation of the *BCR-ABL1* fusion gene and mRNA, and production of a chimeric BCR-ABL1 protein (Melo, 1996; Deininger, 2000). As noted, the t(9;22)/*BCR-ABL1* is not pathognomonic of CML, in that it also occurs in 20%–25% of adult and approximately 3% of pediatric ALLs (i.e., Ph+ ALL), in both instances associated with highly aggressive disease behavior.

Despite the notably long history of research involving *BCR-ABL1* (the Philadelphia chromosome was the first such translocation associated with a neoplasm), the detailed pathogenesis of CML remains to be fully elucidated. *ABL1* is normally a highly regulated tyrosine kinase that participates in diverse cellular processes pertaining to actin organization, cellular differentiation, apoptosis, and T cell receptor signaling. The function of the normal *BCR* gene product is incompletely understood; it contains several functional domains, including a serine/threonine kinase and has been shown to participate in vascular intimal signaling in response to injury and inflammation (Alexis, 2009). In general, the abnormal genetic fusion disrupts the localization and regulated activity of the *ABL1* tyrosine kinase, producing complex effects on cellular signal transduction pathways, proliferation, apoptosis control, and cell adhesion (Deininger, 2000; Quintás-Cardama, 2009). The reciprocal *ABL1-BCR* fusion gene, long regarded as an inconsequential byproduct of the creation of the *BCR-ABL1* fusion, may also have some independent effects of cellular proliferation (Zheng, 2009). In vivo topographic studies of the *BCR* and *ABL1* genes in cycling normal hematopoietic progenitor cells, as well as the surprising demonstration of very low levels of BCR-ABL1 transcripts in the blood of many healthy subjects, suggest that the t(9;22) may occur relatively frequently in normal human bone marrow cells (Brassensco, 2008). The complex interplay of host response to these abnormal genetic rearrangements and the acquisition of other initiating or potentiating genetic lesions leading to the overt development of CML (or Ph+ ALL) are yet to be determined. Definitive treatment for patients with CML is achieved only by allogeneic bone marrow or stem cell transplantation, although the frontline management of CML has now been significantly altered with the advent of imatinib and other similar tyrosine kinase inhibitors, such that the disease may now be controlled over long periods of time, although not eliminated (Druker, 2001; O'Brien, 2003; Pavlovsky, 2009).

At the DNA level, the *BCR-ABL1* gene fusion exhibits features of breakpoint heterogeneity with three main recognized breakpoint loci in the *BCR* gene, as well as some alternative splice transcript variation (see Fig. 75-3, A and B) (Melo, 1996; Deininger, 2000; Foroni, 2009). In virtually all cases of CML, the *BCR* gene breakpoints are situated in the so-called major breakpoint cluster region, or M-BCR. These breakpoints occur in a relatively small 5.8 kb genomic region spanning *BCR* exons e12–e16 (also known as exons b1–b5), specifically between the e13 and e14, or the e14 and e15 exons. In contrast, the breakpoints in the *ABL1* gene are distributed over a very large region of intronic DNA 5' to exon a2. In CML therefore, two types of BCR-ABL1 fusion mRNA transcripts can arise from M-BCR locus gene fusions, namely the e13–a2, or e14–a2 forms. These two products encode a novel protein of 210 kD (p210). Whereas most cases of CML harbor either a e13–a2 or e14–a2 transcript type, occasional tumors may demonstrate alternative splicing of the latter form to produce both transcripts simultaneously; this occurrence may be attributable to a polymorphism in *BCR* that affects splicing efficiency. In the pre-imatinib era, the type of M-BCR locus *BCR-ABL1* fusion in CML was considered to hold no clinical or prognostic significance; however, recent data suggest the possibility of differential imatinib sensitivity based on the transcript type, requiring further investigation (Lucas, 2009). A second common breakpoint locus is present in the *BCR* gene, designated as the minor breakpoint cluster region, or m-BCR. Translocations involving this locus result in the formation of an e1–a2 BCR-ABL1 fusion transcript, encoding a 190 kD BCR-ABL1 protein (p190). The e1–a2 type BCR-ABL1 is highly characteristic of Ph+ ALL. However, the subdivision of M-BCR and m-BCR fusions as CML-associated and ALL-associated is not so straightforward, despite these general correlations between *BCR-ABL1* breakpoint fusion location and disease phenotype. Whereas the vast majority of pediatric Ph+ ALL cases are of e1–a2 (m-BCR) type, approximately 30%–40% of adult Ph+ ALL patients demonstrate e14–a2 or e13–a2 (M-BCR) BCR-ABL fusions. In the latter situation, distinction of

true de novo Ph+ ALL from CML in lymphoid blast crisis is important. In addition, it is well known that a significant proportion of classic CML with the expected e14-a2 or e13-a2 transcript types will also demonstrate concurrent low abundance e1-a2 mRNA due to a minimal degree of alternative splicing of the longer M-BCR derived transcript (Saglio, 1996; van Rhee 1996). Potentially more confusing is the finding of rare Ph+ chronic leukemias with the e1-a2 fusion that manifest a predominantly monocytic phenotype (rather than the typical myeloid cell predominance of CML). These foregoing observations underscore the pathobiologic variability associated with *BCR-ABL1* expression in different myeloid and lymphoid progenitor cells. The third cluster region for *BCR-ABL1* gene fusions has been called the μ -BCR and results in formation of an e19-a2 transcript. This fusion transcript is predicted to result in translation of a 230 kD size protein (p230) and this type of *BCR-ABL1* event has been associated with a myeloproliferative neoplasm showing exuberant neutrophilia. Historically, these cases have been labeled as *chronic neutrophilic leukemias*, but the current view considers these rare e19-a2 fusion-positive presentations to be bona fide cases of CML (Swerdlow, 2008). Rarely occurring CML and Ph+ ALL cases involving the use of alternate, adjacent BCR or ABL exons have been encountered, generating e13-a3, e1-a3, or e6-a2 transcript forms (Melo, 1996; Deininger, 2000; Foroni, 2009).

Figure 75-3, B, indicates the placement of oligonucleotide PCR primers to specifically amplify the M-BCR (e14-a2, e13-a2), m-BCR (e1-a2), and μ -BCR (e19-a2) fusion transcripts following reverse transcription of total mRNA; these molecular assays can be designed to be either qualitative or quantitative in nature. Qualitative assays for *BCR-ABL1* detection may rely on gel electrophoresis sizing of PCR products as shown in Figure 75-3, C, often with a post-PCR confirmatory assay, such as Southern blot hybridization using a junction-specific labeled oligonucleotide probe or related methods. Given the importance of long-term monitoring of *BCR-ABL1* transcript levels in CML patients (discussed later), many labs also perform RQ-PCR. In one such assay strategy, reverse transcribed *BCR-ABL1* transcript abundance is determined relative to a concurrently generated standard curve, and the results are reported as a normalized ratio of *BCR-ABL1* copies to the copies of a similarly measured normally expressed mRNA (often the normal BCR or ABL1 transcript itself) to correct for variable cellular abundance and RNA quality in different samples (Fig. 75-3) (Foroni, 2009). Although PCR-based methods are highly sensitive, FISH analysis may have some additional utility for identifying concurrent large genomic deletions occurring on the derivative 9q or 22q chromosomes, which have been associated with inferior outcome in this subgroup of CML patients (Sinclair, 2000; Lee, 2006; Vaz de Campos, 2007); however, the impact of these additional findings may be relatively less important in the era of imatinib therapy (Kim, 2008).

Molecular detection of these abnormal *BCR-ABL1* mRNA chimeric transcripts is clearly valuable for establishing a diagnosis of CML and Ph+ ALL. For example, even though approximately 98% of CML cases are *BCR-ABL1* positive, a small number of morphologic mimickers will lack this genetic abnormality. These leukemic disorders fall into an ill-defined subset including atypical CML, chronic myelomonocytic leukemia, or other chronic myeloproliferative or myelodysplastic disorders, and therapeutic options and outcome for such patients will be different than for true CML. Conversely, atypical myeloproliferative presentations of CML are not infrequently encountered and the demonstration of *BCR-ABL1* in these situations is critical for correct diagnosis and management. Similarly, detection of the *BCR-ABL1* abnormality in adult and pediatric ALL identifies these subsets of patients who are at high risk for conventional chemotherapy failure and may benefit from more intensive treatment regimens.

Molecular diagnostic evaluation for *BCR-ABL1* is also important for delineating the specific *BCR-ABL1* fusion mRNA type for subsequent molecular MRD monitoring following allogeneic stem cell transplantation (ASCT), chemoimmunotherapy (e.g., with Ara-C and interferon- α [IFN- α] therapy), or therapy with tyrosine kinase inhibitors, or TKIs (e.g., imatinib mesylate). For example, the quantitative level of *BCR-ABL1* transcript in ASCT patients in the early posttransplant period has been strongly correlated with risk of relapse (Olavarria, 2001; Faderl, 2004). Other data similarly suggested more refined outcome prediction in PCR-positive patients who are further out from transplantation, using RQ-PCR technique (Radich, 2001). RQ-PCR for *BCR-ABL1* has also proven worthwhile in evaluating treatment response to IFN- α , despite the observation that molecular remissions with this agent are very uncommon. However, the largest impact on RQ-PCR monitoring of *BCR-ABL1* in CML has come with the widespread use of targeted therapy with TKIs (e.g., imatinib and related drugs). For CML patients on TKI agents,

therapeutic responses are evaluated in a highly coordinated manner using clinical (i.e., hematologic), cytogenetic, and molecular MRD criteria. Single-agent imatinib (previously called STI-571) was shown to be highly effective in inducing complete hematologic and cytogenetic responses in the majority of treated CML patients within 12 months (Hughes, 2003, 2009). These data were reported in the landmark International Randomized Study of Interferon and STI-571 (IRIS) clinical trial and results were updated recently (Hochhaus, 2008; Hochhaus, 2009).

Importantly, data derived from these and other studies have demonstrated that the kinetics of *BCR-ABL1* reduction is strongly related to progression-free survival. While criteria are continually being refined, several critical thresholds have been defined that indicate optimal response to imatinib. The vast majority of CML patients will achieve complete hematologic remission within 3 months. Subsequently, favorable response to TKI therapy is indicated by the attainment of a complete cytogenetic response (CCyR, defined by the absence of Ph metaphases by cytogenetic analysis), followed by a major molecular response (MMR). The MMR level has been defined by the IRIS group as 3-log reduction from baseline *BCR-ABL1* level, equivalent to 0.1% normalized *BCR-ABL* transcript ratio (i.e., *BCR-ABL1/ABL1*). A significant challenge for molecular hematopathology laboratories lies in the development of standardized RQ-PCR assays for *BCR-ABL1* that can meet the requirements of technical sensitivity and reproducibility for reporting patient results on this international scale (IS). Patients who achieve MMR within a 12- to 18-month window following TKI therapy initiation have an excellent long-term prognosis and a very low relapse risk (see Fig. 75-3, D) (Hughes, 2009). A subset of individuals may also continue to deepen their molecular response and eventually become PCR negative. Similarly, the combination of bone marrow cytogenetics and peripheral blood RQ-PCR for *BCR-ABL1* levels can also be predictive of treatment failure and increased relapse risk. Patients who do not achieve a major cytogenetic response (<35% Ph metaphases) or remain above 10% normalized *BCR-ABL1* transcript level at 6 months, or those failing to become cytogenetically negative (CCyR) for the t(9;22) with *BCR-ABL1/ABL1* >1% at 12 months, are at significantly higher risk of disease progression. These timepoints have been incorporated into a benchmark strategy by the European LeukemiaNet for monitoring suboptimal responses to TKI therapy in CML patients (Baccarani, 2009).

Although more than 80% of CML patients on imatinib will be alive and without adverse events at 6 years (Hochhaus, 2008, 2009; Hughes, 2009), a significant subgroup will manifest resistance to imatinib. Imatinib treatment failures are typically identified by loss of a previously attained CCyR, loss of MMR, or suboptimal responses at timepoints as described earlier. Although resistance to TKI therapy is complex, about 50% of CML patients develop point mutations in the ABL1 kinase domain of the chimeric *BCR-ABL1* gene that confer variable degrees of nonresponsiveness to imatinib or second generation agents. Interestingly, such mutations may be naturally selected in the presence of these drugs, such that cells harboring the ABL1 kinase domain mutations (KDM) gain a survival advantage and expand under the continued pressure of the pharmacologic therapy. Abnormal activity of activation-induced cytidine deaminase (AID), an enzyme important in the somatic hypermutation process in germinal center B cells, may be important in the acquisition of ABL1 KDM in CML patients (Klemm, 2009). For patients being monitored by RQ-PCR, an increase in normalized *BCR-ABL1* transcript level of 0.5 to 1 log, demonstrated in at least two consecutive samples is often indicative of the presence of an acquired ABL1 KDM. The precise quantitative level of change is somewhat controversial and other investigators have suggested an increase of only 2.6-fold as optimal for detection of a KDM when using a highly optimized RQ-PCR assay (Press, 2009). ABL1 mutations can occur anywhere in the kinase domain, but tend to preferentially involve critical amino acids in several regions corresponding to the phosphorylation loop (P-loop), activation loop (A-loop), and drug contact sites. Notably, P-loop and some direct contact site mutations are associated with high-level resistance to imatinib. Examples of common P-loop alterations include Q252H, Y253F/H, E255K/V, and G250E. Nonetheless, a significant number of imatinib resistance mutants can be overcome by increasing the dosage of imatinib or by switching to a second generation TKI, such as dasatinib, nilotinib, or bosutinib. Most problematic of all is the contact site mutation T315I, which is relatively frequently encountered and exhibits marked in vivo and clinical resistance to imatinib and all other currently approved second generation TKI drugs (Quintás-Cardama, 2008a). Molecular diagnostic evaluation for ABL1 KDM is therefore an increasingly integral part of assessment for a subset of CML patients (Jones, 2009). Most commonly, ABL1 KDM are detected by direct sequencing of

the amplified region of ABL1 from the BCR-ABL1 transcript. This approach is relatively insensitive technically, but is successful at mRNA levels of BCR-ABL1/ABL1 at or above the MMR, where acquired drug resistance is likely to be encountered. The scope of ABL1 KDM analysis has progressed to allow predictions of response to the various TKI agents in clinical use, thus giving the managing physician a rational approach to selecting alternative TKI drugs if mutation-based resistance to one agent has developed in a given patient (Branford, 2009). Efforts to refine this type of real-time therapeutic efficacy assessment will continue as newer TKI or related small molecule kinase inhibitors enter the clinical arena. In this regard, overcoming the particularly adverse effects of the pan-resistant T315I is a major goal. Finally, it should be noted that low-level mutations can be identified using very sensitive targeted molecular techniques in chronic phase CML patients who are otherwise initially responsive to imatinib. The predictive value of such small subclonal populations is not well understood and currently there is no rationale for “early” mutation detection in CML patients starting treatment with imatinib; however, the importance of detecting small mutated clones may increase as more data emerge (Quintás-Cardama, 2008b).

Ph-Negative Myeloproliferative Neoplasms: Polycythemia Vera, Essential Thrombocythemia, and Primary Myelofibrosis—JAK2 and MPL Gene Mutations

The non-CML, or Ph-negative myeloproliferative neoplasms (MPN), include polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis (PMF). These diseases are individually characterized by a defined set of clinical, laboratory, and morphologic features, yet show striking overlap in several aspects. Until recently, relatively little was understood about the molecular pathogenesis of the Ph-negative MPN; however, this situation has improved substantially with the discovery of mutations involving the *JAK2* (Janus kinase 2) gene, encoding a tyrosine kinase central to ligand-induced cell signaling in hematopoietic progenitor cells. In 2005, four research groups independently described a novel single point mutation abnormality in *JAK2*, occurring in classically defined chronic MPN exclusive of CML (Baxter, 2005; James, 2005; Kralovics, 2005; Levine, 2005). This mutation produces a V617F amino acid substitution (phenylalanine for valine), and constitutively activates the JAK2 tyrosine kinase. These studies and others have subsequently identified the *JAK2* V617F in 95% of PV, 75% of PMF, and 50% of ET. JAK2 is one member of a family of structurally related tyrosine kinases containing a tyrosine kinase domain and an adjacent “pseudokinase” domain, the latter functioning to inhibit and thus autoregulate activity of the true kinase domain (Ihle, 2007); this juxtaposition of activation and autoregulatory regions thus accounts for the designation of this class of genes after the two-faced Roman god Janus (Fig. 75-4). In normal cellular function, JAK proteins function to initiate cellular signaling pathways between specific cell surface receptors lacking catalytic activity, via interactions with STAT proteins (signal transducers and activators of transcription); activated STAT proteins translocate to the nucleus and differentially regulate target genes in response to the corresponding initial cell surface signal (Pfeifer, 2008). Of note, the V617F mutation so consistently identified in these entities affects the inhibitory pseudokinase domain of the protein, resulting in unchecked ligand-independent tyrosine kinase activity of JAK2 and an increased propensity for cellular proliferation (Ihle, 2007). JAK2 in particular associates with the cell surface erythropoietin receptor (EPO-R) and becomes activated by the binding of EPO, thus accounting in part for the significance of the V617F mutation in the pathogenesis of PV.

The variability of disease phenotypes among the different Ph-negative MPN that otherwise share the presence of a single common gene mutation remains incompletely understood, but several hypotheses have been advanced to explain the apparent centrality of the *JAK2* V617F mutation in the three major MPN subtypes (James, 2008). First, the nature of the hematopoietic progenitor cell in which the *JAK2* mutation occurs may result in specific patterns of disease. For example, a V617F mutation arising in cells fully or partially committed to erythroid or megakaryocytic differentiation might be expected to induce phenotypic features in the progeny of the transformed cells consistent with PV or an ET type processes, respectively. Second, the amount of mutated, activated protein that is produced seems to have some bearing on disease phenotype. Patients with PV and a subset of those with PMF are more likely to be homozygous for the V617F mutation and consequently have a higher mutated “allele burden” than do patients with ET. Interestingly, homozygous mutation status is selected for by the process of uniparental disomy (copy-neutral

Figure 75-4 Role of *JAK2* mutations in myeloproliferative neoplasms, *BCR-ABL1* (Ph) negative. The Janus kinase 2 (*JAK2*) “two headed” protein is illustrated by two circles, corresponding to the JH1 tyrosine kinase domain (green) and the inhibitory JH2 pseudokinase domain (red). **A**, *JAK2* has bound to the erythropoietin receptor (EPOR). In the absence of ligand binding, the JH2 domain prevents activation of the JH1 domain. **B**, The ligand erythropoietin has bound to the receptor, inducing conformational changes that permit activation of the JH1 tyrosine kinase domain. **C**, The *JAK2* V617F mutation (indicated by “X”) prevents proper interaction between the JH2 and JH1 domains, thus allowing tyrosine kinase activity at extremely low concentrations of ligand, or even in the absence of ligand binding. (Adapted from Klipp E and Liebermeister W. Mathematical modeling of intracellular signaling pathways. *BMC Neurosci* 2006;7(Suppl 1):10; Bennett M and Stroncek DF. Recent advances in the *bcx-abl* negative chronic myeloproliferative diseases. *J Transl Med* 2006;4:41.)

loss of heterozygosity), usually through mitotic duplication of the mutated *JAK2* allele (Kralovics, 2002; Vannucchi, 2008). Third, the larger genetic background in which the mutation occurs may to some degree influence the expression of the disease. For example, the introduction of the V617F mutation into different strains of mice yields consistently different disease phenotypes (James, 2008), and some evidence suggests that polymorphisms in such genes as *JAK2* and *EPOR* are associated with certain MPNs but not with others (Pardanani, 2008). Furthermore, despite the major advance represented by the discovery of *JAK2* V617F mutations in MPN, this genetic lesion is clearly not present in all cases and as a corollary, many presentations of MPN (especially ET and some PMF) are not associated with deregulation of this gene. This has led to the suggestion that the *JAK2* mutation may be a relatively late event in transformation (Kralovics, 2006; Nussenzveig, 2007), with earlier mutations in other unknown genes perhaps setting the stage for the development of a specific MPN and the *JAK2* mutation providing only the final element necessary for growth factor-independent proliferation. Nevertheless, the advent of small molecule JAK2 inhibitors for clinical use indicates the importance of this target in both disease biology and management.

Whereas constitutive JAK2 activation is clearly important in the MPN, this relationship is most consistent in PV. It now appears that the small number (approximately 5%) of patients with PV who lack the *JAK2* V617F mutation instead harbor different mutations in *JAK2*, most commonly involving exon 12 (Scott, 2007; Pietra, 2008). Patients with PV with *JAK2* exon 12 mutations do not show the same propensity to thrombocytosis as those with *JAK2* V617F mutations, but otherwise the disease appears clinically similar, despite the alternate localization of the mutation (Kilpivaara, 2008). Finally, in addition to *JAK2* mutations, other genetic abnormalities are also biologically and diagnostically important in this setting. Mutations in the *MPL* gene have been identified in a subset (<10%) of *JAK2*-negative cases of ET and PMF (Pikman, 2006; Tefferi, 2008; Beer, 2008). *MPL* encodes the cell surface receptor for thrombopoietin, and activating mutations thus induce aberrant constitutive signaling effects as observed similarly for mutated *JAK2*. The changes in *MPL* involve several possible amino acid substitutions (W to L, K, or S), all occurring at codon 515.

Although it is apparent that *JAK2* and *MPL* mutations are in general neither necessary nor sufficient for the diagnosis of Ph-negative MPN, the detection of either one can establish the presence of a clonal myeloid

neoplasm and help distinguish potentially overlapping reactive conditions in which cytosols figure prominently. The presence of *JAK2* V617F gene mutations in MPN can be detected by a variety of methods including allele-specific PCR (also referred to as *amplification refractory mutation system*, or ARMS PCR), melting curve analysis of PCR products, allele-specific fluorescent probe hybridization, pyrosequencing, restriction enzymatic digestion of PCR amplicons, and direct sequencing of PCR-amplified DNA. The latter two methods may be of limited analytic sensitivity for detecting small percentages of *JAK2* mutated cells in a given case. The recommended analytic sensitivity of a *JAK2* V617F assay has been proposed as less than or equal to 1% (Wang, 2008). Some studies have shown that small numbers of randomly tested healthy individuals, when analyzed with techniques of this or much higher technical sensitivity, will demonstrate the presence of a low-level *JAK2* mutation (Xu, 2007). The significance of this finding is not certain, although it is likely analogous to the detection of leukemia-associated translocations at low levels in apparently healthy individuals. More significantly, *JAK2* V617F mutations are also detectable in some subtypes of myelodysplastic syndrome, in myelodysplastic/myeloproliferative neoplasms (e.g., chronic myelomonocytic leukemia), and in rare cases of lymphoma and acute leukemia. Thus a positive *JAK2* V617F result must always be correlated with clinical and complete pathologic data; conversely, the detection of this mutation in a patient with clinical and/or morphologic features of a classic myeloproliferative neoplasm may be interpreted as essentially confirmatory of such a process. In order to expand the scope of molecular analysis in MPN, an increasing number of laboratories are complementing *JAK2* V617F assays with additional lab-developed tests to detect mutations in *MPL* or *JAK2* exon 12. *MPL* analysis may be performed using allele-specific PCR, allele-specific fluorescent probe hybridization, or direct sequencing of PCR products (Pancrazzi, 2008; Daly, 2009). In contrast, *JAK2* exon 12 presents a relatively large genomic area across which mutations may be scattered. Screening techniques, including high-resolution melting curve analysis, may be used to triage specimens and distinguish those that are apparently wild type from those deserving of additional scrutiny via direct sequencing (Jones, 2008; Rapado, 2009).

Mastocytosis and the KIT D816V Gene Mutation

Clinical and pathologic manifestations of neoplastic mast cell proliferations are diverse, resulting in a relatively complex system of classification (Swerdlow, 2008). In general, mast cell neoplasms can be considered in two main clinical categories: (1) cutaneous mastocytosis exhibiting predominantly localized involvement of the skin and (2) systemic mastocytosis with widespread involvement of the bone marrow and other organs, and elevations of mast cell-derived serum tryptase (Horny, 2009). Mutations in the tyrosine kinase gene *KIT*, particularly the common codon D816V abnormality, are strongly but not invariably associated with mastocytosis. *KIT* is the cell membrane-associated receptor for stem cell factor, an extracellular ligand important in promoting the proliferative activities essential to stem cell regeneration and the expansion of hematopoietic progeny. *KIT* is also expressed on melanocytes, germ cells, and gastrointestinal pacemaker cells (Metcalf, 2008). Activating *KIT* mutations obviate the normally regulated ligand-receptor mechanism and produce growth factor-independent cell proliferation. Although *KIT* mutations are often detected in mastocytosis, they are not 100% sensitive or specific for this diagnosis. The detection rate is also highly dependent on the assay method used. As many as 30% of cases of systemic mastocytosis may appear to lack the D816V mutation when using moderately sensitive assays on unfractionated bone marrow cells, but the detection rate increases to approximately 95% using higher sensitivity detection methods such as nested PCR and/or enrichment of mast cells via cell sorting or microdissection (Akin, 2006). The proportion of D816V-negative cases is higher in cutaneous mastocytosis (Lanternier, 2008). Importantly, *KIT* mutations are not specific for mastocytosis, in that they are detectable in some cases of CBF acute leukemias (as discussed earlier), gastrointestinal stromal tumors, and a subset of melanomas (Orfao, 2007). The genomic distribution of *KIT* mutations is variable in these different tumors. Nevertheless, detection of a *KIT* D816V mutation fulfils one of four “minor” diagnostic criteria for systemic mastocytosis and is thus often helpful in definitively supporting a diagnosis suspected on clinical, morphologic, or immunophenotypic grounds.

The exon 17 situated D816V is the most common *KIT* mutation in mastocytosis, present in more than 90% of positive cases; this consistency presents an attractive target for molecular diagnostic methodologies amenable to the interrogation of specific sequence changes, including restriction fragment length polymorphism-based analysis, allele-specific PCR, and pyrosequencing. Notably, despite the optimism for using imatinib

mesylate for more broad-spectrum tyrosine kinase inhibition outside the setting of BCR-ABL-positive neoplasms, the D816V mutation is not responsive to this drug (Vega-Ruiz, 2009). Molecular analysis of *KIT* mutations occurring at other locations in the gene (e.g., in many cases of cutaneous mastocytosis, or in non-mast cell malignancies) requires a more comprehensive approach involving post-PCR sequencing of several exon regions.

NEOPLASTIC DISORDERS ASSOCIATED WITH EOSINOPHILIA

The trend to molecular classification of hematologic malignancies is further illustrated by the creation, in the 2008 WHO classification, of a new subcategory of hematopoietic neoplasms defined almost exclusively on molecular grounds. *Myeloid and lymphoid neoplasms with eosinophilia (MLNE) and abnormalities of PDGFRA, PDGFRB or FGFR1* encompasses a heterogeneous group of both myeloid and lymphoid lineage, previously existing as separate entities largely defined by morphologic, clinical, and certain cytogenetic features (Swerdlow, 2008). A unifying feature of these neoplasms is the deregulated activity of specific tyrosine kinase growth factor receptors by aberrant gene rearrangements and a tumor phenotype characterized in part by the production of excess eosinophils and eosinophilic precursors. Hence, these tumors were first broadly and imprecisely classified under *chronic eosinophilic leukemia/idiopathic hypereosinophilic syndrome (CEL/IHES)*; however, the lineage-specific or underlying neoplastic expansion varies according to the now better understood genetically defined disease subsets. Although laboratory testing for these genetic abnormalities is accomplished mainly by FISH and/or conventional karyotypic analysis, a short précis of this new entity is included here, because it represents a good example of the reconfiguration of hematologic malignancies based on molecular characterization.

Rearrangement of the platelet-derived growth factor receptor α (*PDGFRA*) gene is diagnostic of a hematologic malignancy typically characterized by the clonal expansion of eosinophils (i.e., CEL), but may in some cases present with additional findings of AML or T-ALL. The presence of a *PDGFRA* rearrangement thus defines this diagnostic entity at the molecular level, regardless of the cellular component heterogeneity. The most common *PDGFRA* rearrangement is a karyotypically cryptic interstitial deletion at 4q12 that juxtaposes *PDGFRA* with an adjacent gene, *FIP1L1*. The resultant expression of a *FIP1L1*-*PDGFRA* fusion protein disrupts the autoinhibitory domain of *PDGFRA* and leads to its constitutive tyrosine kinase activity (Stover, 2006). An intervening gene called *CHIC2* is deleted in the 4q12 rearrangement; thus assessment of the *CHIC2* locus by FISH technique serves as an effective method to identify the chromosomal microdeletion and establish the presence of a *PDGFRA* rearrangement (Pardanani, 2003; Fink, 2009). Of note, a subset of CEL with *PDGFRA* rearrangements also exhibits abnormal mast cell expansions in the bone marrow, but the *KIT* D816V abnormality is not present in these cases. The overlapping nature of neoplastic myeloid cellular proliferations therefore underscores the comprehensive molecular approach to subclassification of these diseases. Most significantly, patients with *PDGFRA*-positive CEL are remarkably sensitive to treatment with even low doses of imatinib, again emphasizing the potential of molecularly targeted therapy (Pardanani, 2003). Myeloid neoplasms with platelet-derived growth factor receptor β (*PDGFRB*) gene rearrangements are conceptually similar. These neoplasms are typically characterized morphologically as chronic myelomonocytic leukemias with eosinophilia, although variant presentations are recognized. A karyotypic abnormality t(5;12) (q33;p13) is commonly associated with the deregulation of *PDGFRB*, via creation of a chimeric *ETV6(TEL)*-*PDGFRB* fusion gene and protein; however, several other translocation partners with *PDGFRB* have also been described. Alterations of the *PDGFRB* locus can be detected by FISH analysis, although some cases are FISH negative in the face of a submicroscopic *ETV6*-*PDGFRB* gene fusion, indicating that comprehensive detection requires a combination of PCR-based and molecular cytogenetic approaches. *PDGFRB* rearranged neoplasms are also expected to benefit from treatment with imatinib (David, 2007). In contrast to MLNE with rearrangements of *PDGFRA* or *PDGFRB*, patients with tumors overexpressing fibroblast growth factor receptor-1 (*FGFR1*) differ in certain key respects. First, the translocated gene encodes a tyrosine kinase receptor involved in a different cell signaling pathway. Second, these cases are particularly associated with presentations of lymphoblastic (e.g., T-ALL) or mixed phenotype acute leukemias, as well as often prominent neoplastic eosinophilia. And finally, an effective tyrosine kinase inhibitor therapy has

yet to be established in the setting of *FGFR1* rearrangement. Cytogenetic and FISH analyses can be used to diagnose the presence of *FGFR1* gene rearrangements.

MOLECULAR DIAGNOSIS OF NON-HODGKIN LYMPHOMAS

RATIONALE FOR MOLECULAR GENETIC ANALYSIS IN THE LYMPHOID DISORDERS

The non-Hodgkin lymphomas (NHLs) and chronic lymphoid leukemias encompass relatively common adult malignancies, and the incidence of these diseases is increasing (Chiu, 2003; Liu, 2003; Fisher 2004). A central paradigm in the diagnosis of lymphoma is the demonstration of monoclonality, which is highly correlated with the malignant state. In many instances, a monoclonal lymphoid proliferation can be suggested or established with the aid of immunophenotypic studies, for example, by demonstrating light chain restriction in the case of B cell neoplasms, or aberrant antigen expression in the setting of atypical T cell expansions. However, there are several instances in which the foregoing analyses may be insufficient and the determination of clonality in a lymphoid population remains a key diagnostic issue. In these situations, which may include samples with uninformative phenotypic features, small tissue biopsies, or partially degraded specimens and paraffin-embedded tissues, the molecular assessment of antigen receptor gene rearrangements is extremely valuable. Standard molecular clonality detection methods are often employed to resolve the definitive diagnosis of lymphoid neoplasms with features potentially mimicking benign hyperplasias (e.g., follicular lymphomas or extranodal marginal zone B cell lymphomas), to assign cell lineage in undifferentiated hematopoietic tumors (i.e., B vs. T cell), and to aid in the diagnosis of neoplastic T cell lymphoproliferations.

Along with characteristic light microscopic tumor cell features and phenotypic cell marker profiling (e.g., by flow cytometry and immunohistochemistry), the identification of recurrent, nonrandom tumor genetic abnormalities (most commonly produced by chromosomal translocation events) has also fundamentally refined the subclassification of the NHLs. Indeed, cytogenetic and molecular genetic data of this type now form an integral part of the 2008 WHO lymphoma classification (Swerdlow, 2008). The following sections detail the molecular approaches to the determination of B and T cell clonality, and the detection and significance of common recurrent lymphoma translocations. More recent advancements, including research applications of microarray gene expression profiling and array-based genomics studies have begun to further alter the landscape of subclassification and prognostication in the lymphomas and, as such, these efforts will translate into novel molecular targets and even technical platforms for future diagnostic applications. The major implications of these newer developments will also be briefly presented in reference to specific types of NHL.

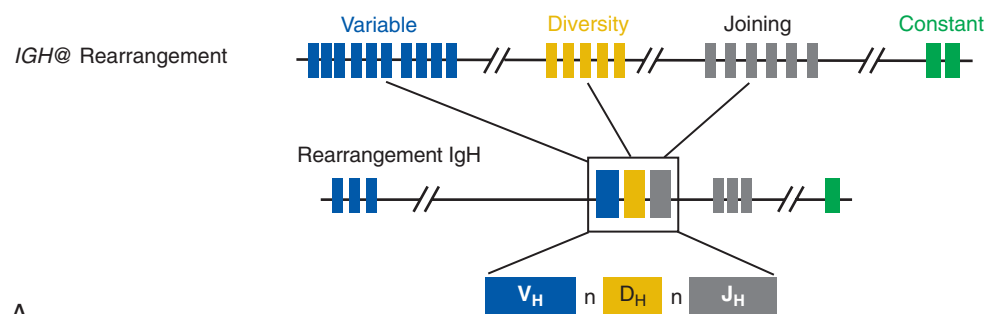

ANTIGEN RECEPTOR GENE REARRANGEMENTS FOR CLONALITY DETERMINATION

Mechanism of Antigen Receptor Gene Rearrangements

The antigen receptor genes are rearranged early in the development of B and T lymphocytes in the bone marrow and thymus, respectively. The process of DNA rearrangement, or genetic recombination, essentially involves the splicing and fusion of one of numerous variable (V) gene segments with a joining (J) exon. At some loci, notably the immunoglobulin heavy chain and T cell receptor β genes, an additional diversity (D) segment is interposed between V and J segments. The assembled V-J or V-D-J segment is subsequently joined with the constant (C) region of the antigen receptor gene to produce an intact coding sequence capable of translation to a functional antigen receptor protein (Fig. 75-5, A and B) (Macintyre, 1999; Bassing, 2002). Immune cells incapable of producing functional receptor proteins undergo deletion by apoptosis. For immature B cells, the immunoglobulin heavy chain gene (*IGH@*) on chromosome 14(q32) is the first to undergo this segmental rearrangement, followed in turn by the κ light chain gene (*IGK@*) on 2(p12). If the latter attempt is nonproductive at both alleles, the λ locus (*IGL@*) on 22(q11) is selected in order to generate the final tetrameric immunoglobulin molecule. For T cells, the T cell receptor δ (*TRD@*) [14(q11)] and γ (*TRG@*) [7(p15)] loci initiate this process in the thymus; however, many of these gene rearrangements fail to produce a functional heterodimeric receptor protein. Thus rearrangement continues essentially simultaneously at the T cell receptor α (*TRA@*) and β (*TRB@*) loci, located on chromosomes 14(q11) and 7(q34), respectively, generating a $\alpha\beta$ receptor in the large majority (>90%) of T cells. As an important point related to molecular analysis (discussed later), nearly all mature $\alpha\beta$ cells still retain a γ (*TRG@*) locus gene rearrangement.

Enormous diversity exists among the immunoglobulin and T cell receptors, arising in part from the potential for genetic recombination between numerous V-, (D-), and J-gene segments at these loci. In addition, the activity of the enzyme terminal deoxynucleotidyl transferase (TdT) adds nontemplated ("N") nucleic acid bases at the junctions of the rearranged gene segments in immature B and T cells, further increasing sequence diversity (see Fig. 75-5, A and B). As a result of the largely random nature of this process, individual B and T lymphocytes harbor specific gene rearrangement sequences and express correspondingly unique antigen receptor immune proteins on their cell surfaces. In a polyclonal lymphoid expansion, therefore, a highly variable distribution of antigen receptor gene rearrangements is generally found, whereas a monoclonal population is characterized by a single identical gene rearrangement in each progeny cell. This concept is exploited by both Southern blot hybridization (SBH) analysis and PCR technique, to distinguish polyclonal ("benign") from monoclonal ("malignant") lymphocytic proliferations.

Figure 75-5 Immunoglobulin and T cell receptor gene rearrangements: concept and application of Southern blot hybridization (SBH) and polymerase chain reaction techniques for clonality determination in lymphoid populations. **A**, Schematic demonstration of the basic process of somatic rearrangement of the immunoglobulin heavy chain (*IGH@*) locus on chromosome 14q32 occurring early in developing B cells. Selection and rearrangement of *IGH@* diversity (D_H) and joining (J_H) gene segments first occurs over a large region of intervening DNA, followed by the recruitment of a variable region (V_H) exon to complete a VDJ coding cassette. Substantial diversity is generated at the nucleotide level because of the recombination potential of the many V, D, and J segments, as well as by the activity of the enzyme terminal deoxynucleotidyl transferase (TdT), which inserts a random number of "nontemplated" (n) nucleotides at the rearranged junctions. The T cell receptor gamma gene (*TRG@*) located at chromosome 7p15, depicted in panel **B**, shares similar structural and rearrangement features, with the exception that there are no D-segments. The *TRG@* gene is less complex having only 11 functional V_γ segments capable of functional rearrangements, although there are two J-segment loci (J_γ and J_γ') and two constant regions. **C**, Schematic of the J-region of the immunoglobulin heavy chain gene (*IGH@*) locus on chromosome 14q32. J_H exons are shown as boxes. The intact, or germline J_H region is flanked by EcoRI restriction endonuclease sites, which, upon DNA digestion, will render a fragment of approximately 16 kilobases (kb) in size. This large DNA fragment can be detected by SBH using a cloned or PCR generated radioisotope-labeled probe (in this case, a 2.2 kb genomic fragment is depicted as the probe). In contrast, when the J_H region is altered by the somatic gene rearrangement process in a B cell, a change in restriction enzyme sites is introduced, such that digestion produces a DNA fragment of altered size from the expected germline size. In the diagram, this is shown as a new 12 kb J_H fragment. In a monoclonal B cell population, all B cells will harbor the same rearrangement and this can be detected by SBH technique as a new band distinct from the germline location. **D**, Typical results of SBH for detection of *IGH@* locus gene rearrangements. Lanes "P" and "T" indicate placental and tonsil DNA samples digested with EcoRI and analyzed by SBH, indicating the presence of germline (16 kb) bands only (single asterisk). The lane "NHL" is a B cell lymphoma sample showing clonally rearranged bands which clearly differ in size from the germline configuration. The presence of two new bands in the NHL sample (double asterisks) is indicative of biallelic *IGH@* locus rearrangements. **E**, The "micro-locus" features of a rearranged *IGH@* gene, showing the joined VDJ exon coding region. The V_H segment encodes much of the variable component of the immunoglobulin heavy chain. Three framework regions (FRI-III) are identified in the V-segment, as well as two complementary determining regions (CDRI and II). The third and most variable region of nucleotide sequence is comprised of the junction between V-, D-, and J-segments, along with inserted nontemplated (n) nucleotides (mediated by the enzyme TdT); this region is termed CDRIII and represents a highly unique nucleotide sequence in each B cell. The presence of shared sequence homology among many of the V-region segments in the antigen receptor gene loci, along with the highly homologous nature of the J-segments, permits the detection of most gene rearrangements occurring in B or T cell lymphocytes by PCR methods employing flanking "consensus" oligonucleotide primers. This concept is depicted by the orange arrows. The use of multiple primer sets covering the region of interest and targeting of different antigen receptor loci increases the chance of detecting even rare immunoglobulin or T cell gene rearrangements in a lymphoid population. **F**, Typical results of *IGH@* PCR using fluorescently labeled consensus primers and analysis by capillary electrophoresis. In a polyclonal B cell population, a range of VDJ rearrangement sizes exists, delimited both by the nature of V-, D-, and J-segments used and the finite number of inserted n-nucleotides. This fragment size range is normally distributed, as shown in the left side panel. In contrast, a monoclonal B cell population is characterized by a single (or dual, if biallelic) rearrangement(s), as demonstrated in the right-hand panel.

Techniques to Detect Antigen Receptor Gene Rearrangements: Southern Blot Hybridization

Genomic SBH technique can be considered a relatively “large-scale” molecular approach, involving restriction endonuclease enzyme digestions of a high molecular weight DNA sample, followed by fragment separation, immobilization on a nylon or nitrocellulose membrane, and specific radioisotope (or nonisotopic) labeled probe detection of one or more relatively large target DNA fragments (Cossman, 1988; Beishuizen, 1993; Langerak, 1999; Macintyre, 1999; Medeiros, 1999; Arber, 2000). A schematic summary and example of genomic SBH as applied to the diagnosis of lymphoma is shown in [Figure 75-5C](#). To briefly summarize, for a structurally unaltered (nonrearranged) region of the target DNA, Southern hybridization analysis will reveal a certain pattern of fragment sizes or bands, termed a *germline* configuration, based on the distribution of particular restriction enzyme sites flanking or within the locus in question. If this region of DNA is rearranged, as in the case of the B and T cell antigen receptor loci, a different banding pattern will be produced (as a result of shifts in the locations of germline restriction enzyme sites) and these changes can be readily recognized by hybridization with a specific probe. The sensitivity of SBH is such that at least 5%–10% of a population of cells must contain the same nongermline rearrangement in order to be detected (see [Table 75-2](#)). In a polyclonal lymphocyte population, individual B or T cells carry unique rearrangements of their antigen receptor genes and would theoretically be expected to generate a “ladder” or broad distribution of rearrangements when analyzed by SBH with the appropriate probes. In practice, however, no such rearrangement pattern is seen in polyclonal proliferations, because even highly selected and expanded groups of reactive lymphoid cells do not typically constitute up to 5% of the total cells in these situations. In contrast, each cell in a monoclonal population contains an identical antigen receptor gene rearrangement, and SBH will identify distinct, rearranged (nongermline) bands (see [Fig. 75-5, D](#)). The successful application of SBH technique to detect lymphoid clonality is dependent on several factors. First, the locus being interrogated must be structurally favorable for study by enzyme digestion and probe hybridization. Certain loci, such as the *TRA@* gene, are very large and difficult to adequately assess with high sensitivity using a practical number of restriction enzyme digests and probes. Conversely, the *TRG@* locus, as discussed further below, is relatively small and of limited diversity, resulting in poor specificity and generally precluding its use for SBH. Second, hybridization probes must be easily available for use in the clinical diagnostic setting. Probes may be produced from either cloned genomic DNA or cDNA complementary to the region of interest, and several are available commercially. Finally, SBH method requires the use of high-molecular-weight, nondegraded DNA from fresh or frozen tissue sources. Of note, because a known amount of genomic DNA is used per enzymatic digest (e.g., 5 µg), the relative proportion of clonal cells in a given sample can be estimated by relative band intensities using SBH analysis.

For determination of B cell clonality by SBH, both the immunoglobulin heavy chain (*IGH@*) and the light chain genes have been used. The *IGH@* gene is frequently assessed with a J-region probe (Cossman, 1988; Beishuizen, 1993; Medeiros, 1999). The *IGH@* J-region (*J_H*) is highly informative, because this locus is relatively compact, is easily defined by restriction enzyme digestions, and is always involved in recombination events in B cells (see [Fig. 75-5, D and E](#)). With the use of a *J_k* probe, the *κ* light chain gene (*IGK@*) can also be targeted for SBH analysis, although a minority of lymphoma cases (mainly those with *λ* light chain rearrangements) may be missed due to site-specific deletions of the rearranged *κ* loci encompassing the C_k and sometimes the J_k regions (Cossman 1988; Medeiros 1999). Rearrangements of the *λ* light chain gene (*IGL@*) can be assessed with a constant region (C_λ) probe; however, this locus is highly polymorphic with typically used restriction enzyme digests and banding results are more difficult to interpret (Saueracker, 1992).

The T cell *β* locus (*TRB@*) has proven to be most useful for detection of T cell clonality by SBH, and this region shares structural genomic features similar to the *IGH@* gene. The complexity of the *TRB@* locus is notably greater due to the presence at both alleles of two D_β, J_β, and C_β regions available for recombination with a relatively large repertoire of V_β region segments. However, because the two C_β regions are nearly identical in sequence, *TRB@* gene rearrangements can be identified by SBH using a common C_β genomic probe and appropriate restriction digests of the target DNA (Langerak, 1999; Medeiros, 1999). The use of two specific J_β region probes has also been described to detect clonality at the *TRB@* locus and may offer some advantages in conjunction with C_β probes (Langerak,

1999). The *γ* T cell (*TRG@*) locus is generally less favorable for SBH analysis due to the relatively small number of rearranging V_γ and J_γ region segments. This limited capacity for segmental recombination creates a relatively small pool of functional *TRG@* gene rearrangements, from which germline and true rearranged bands may not be confidently distinguished by SBH (Cossman, 1988; Medeiros, 1999).

Techniques to Detect Antigen Receptor Gene Rearrangements: Polymerase Chain Reaction

Rearrangements of the immunoglobulin and T cell receptor genes can be identified by PCR methods as well. In contrast to SBH, which detects relatively large structural genomic alterations based on changes in restriction enzyme sites, PCR is designed to amplify short regions of DNA encompassing the immediate area of V-(D)-J gene segment fusion in the rearranged antigen receptor genes. Under standard PCR conditions, a germline antigen receptor gene configuration is amplified poorly or not at all, due to the very large intervening areas of DNA between primer sites. However, when coding V-, (D-), and J-segments are juxtaposed in a rearranged gene, amplification of the region between the now closely apposed primers is readily accomplished by PCR. The most widely used loci for PCR determination of lymphoid clonality are the *IGH@*, *IGK@*, *TRG@*, and *TRB@* genes. In 2003, the BIOMED-2 consortium published a series of landmark articles detailing comprehensive, multilocus, and multiplex PCR-based strategies for determining clonality in B and T cell lymphoproliferations (van Dongen, 2003). These studies represented the culmination of prior investigative efforts and authoritatively established the efficacy, interpretive pitfalls, and utility of PCR methods for routine molecular diagnosis in this area. The BIOMED-2 approach has been validated independently (McClure, 2006; Liu, 2007) and was recently updated in a series of articles attempting to codify a more standardized laboratory approach to lymphoid clonality detection by PCR technique (Bruggemann, 2007; Evans, 2007; van Krieken, 2007).

A schematic of PCR strategy directed at the *IGH@* locus is shown in [Figure 75-5, E](#), and this depiction is illustrative in general of the approaches used for comprehensive clonality evaluation by PCR methods targeting several antigen receptor gene loci. The *IGH@* V_H gene region comprises approximately 70–80 discrete coding or functional V-segments that can be grouped into six “families” based on sequence similarities. The D region includes approximately 20–30 gene segments and the J region includes approximately six gene segments. Successful recombination of V-, D- and J-segment elements, along with random “N”-nucleotide insertions at junctional sites by TdT, create a unique DNA “fingerprint” in an individual B cell, and these markers can potentially be used in the determination of clonality by PCR. Although V-D-J recombination is by nature extensively variable among individual B lymphocytes, PCR methods targeting this region are fortunately simplified by the use of “consensus” sequence primers. Both the 5′ DNA region flanking the V-D-J junction (i.e., framework regions, FR), as well as the *IGH@*-J_H region, contain nucleotide sequences that are highly conserved. Complementary FR and J_H sequence PCR primers can thus be designed that amplify these unique V-D-J rearrangements in most B cells. [Figure 75-5, E](#), for example, demonstrates the relative placement of consensus primers to provide comprehensive coverage for detecting *IGH@* gene rearrangements; FR1-directed primers typically include six or seven different oligonucleotides recognizing essentially all major V_H family gene segments based on germline sequence similarities.

The use of multiple primers for the *IGH@* locus is important to circumvent potential PCR failures; such failed amplifications are potentially common in B cells that have experienced a lymphoid follicle germinal center environment, in turn acquiring somatic hypermutation sequence changes involving the CDRs and immediately flanking framework DNA regions. Somatic hypermutations can inhibit efficient consensus primer binding and amplification. To further enhance the successful analysis of B cell clonality using PCR-based methods, consensus primers can also be employed to analyze the light chain genes, most commonly *IGK@*. The *IGK@* locus is very informative in this regard because in addition to V-J segmental recombinations, B cells that fail to make a productive *κ* gene rearrangement go on to delete the allelic region in a site-specific manner, before undergoing rearrangement of the other *κ* gene, or the *λ* light chain loci. *κ* Deletions are carried out by recombinations between the so-called *κ*-deleting element (KDE) and the upstream V-region, or the KDE and an intron recombination signal sequence (IRSS) situated 5′ of the C_k region (van Dongen, 2003). In either case, the *κ* allele is subtotally deleted,

or rendered nonfunctional; however, the molecular mechanisms governing κ deletions operate similarly as for V-J recombination, and these “signatures” at the DNA level can also serve as relatively specific rearrangement markers for clonality analysis.

The *TRG@* locus, although not well suited for SBH, has nonetheless been very successfully used for the determination of T cell clonality by PCR (Beaubier, 2000; Greiner, 2002; Lawnicki, 2003). *TRG@* gene rearrangement occurs early in developing thymic T lymphocytes and this genetic event is retained at the DNA level, even though the vast majority of developing T cells continues to rearrange the *TRA@* and *TRB@* loci and ultimately develop an α - β receptor phenotype. The *TRG@* locus encompasses 11 coding V γ region segments, grouped into four families based on sequence similarities. Five J γ region segments are present, including the highly conserved J γ 1 and J γ 2 exons as well as J γ p, J γ p1, and J γ p2 exons (see Fig. 75-5, B) (Greiner, 2002). Consensus primers complementary to sequences of shared homology in the T cell gamma V- and J-segments can similarly be used to simplify the PCR procedure. *TRG@* PCR also relies on the unique nature of V-J junctional rearrangements in individual T lymphocytes; the technique is analytically informative despite the limited segmental diversity of this locus, keeping some caveats in mind (discussed in the following section). Despite the far greater degree of gene segment complexity at the *TRB@* locus, successful PCR protocols have been developed in a manner similar to that for *IGH@*, relying on the use of multiple V- and J-region consensus primers.

Amplified antigen receptor gene rearrangements can be visualized by agarose or polyacrylamide gel electrophoresis with or without prior “heteroduplex” manipulation, or more commonly now by capillary electrophoresis following PCR amplification with fluorescently labeled primers (Beaubier, 2000; Greiner, 2002,). In a polyclonal B or T cell proliferation, many hundreds or thousands of individual V-(D)-J rearrangements can be expected in a given DNA sample. Because none of these reactive lymphocyte subpopulations is typically present above the sensitivity threshold of standard PCR analysis (discussed later), a polyclonal smear or faint multiple-band ladder pattern is visualized by gel electrophoresis or rendered as a series of normally distributed peaks by capillary electrophoresis (Fig. 75-5, F). In a monoclonal B or T cell process, all cells harbor identical immunoglobulin or T cell receptor gene rearrangements that are preferentially amplified during the PCR, producing one or sometimes two (i.e., biallelic) distinct clonal bands or peak profiles during post-PCR analysis.

Advantages and Shortcomings Southern Blot Hybridization and Polymerase Chain Reaction for Lymphoid Clonality Assessment

The decision to use PCR versus SBH requires knowledge of several factors such as tissue source, type of lymphoproliferative disorder being investigated, sensitivity of the respective assays, and false-positive and negative rates. The advantages and disadvantages of the respective techniques are summarized in Table 75-5. In general, PCR technique has gained wide popularity for clonality determination, principally due to its relative ease of performance and rapidity. SBH method is, in contrast, labor intensive and costly; it may involve the use of radioactive probes and requires approximately 1–2 weeks to complete. Further disadvantages of SBH include the requirement for fresh or frozen tissue of good quality (for high molecular weight DNA) and a relatively low sensitivity, in the range of 5%–10%. PCR is advantageous in that the turnaround time is within 2–3 days, it is cheaper, and it requires far less starting DNA quantity (e.g., 0.5–1 μ g) compared with SBH. Moreover, PCR can be performed from fresh samples or fixed paraffinized tissue sources, although certain fixatives (e.g., B5), or substances commonly used in lymph node or bone marrow processing, may inhibit the PCR. Clonality assessment by PCR has a nominal sensitivity of 1%–5%, although a prominent polyclonal B or T cell background can significantly reduce the ability of the technique to detect a coexistent monoclonal lymphocyte population.

Although PCR methods seemingly offer advantages relative to SBH, the technique is occasionally subject to false-negative assay results, because it is not possible to design consensus type primers to capture all possible antigen receptor gene rearrangements; the issue of somatic hypermutation in B cells is one example, although this can be largely overcome with multiple primer strategies and inclusion of the *IGK@* locus. More significantly, the problem of false positivity is a risk encountered not uncommonly in interpretation of T cell gene rearrangements by PCR. This situation is most aptly seen at the *TRG@* locus, which, as a result of limited overall V- and J-gene segment recombination potential, can lead

TABLE 75-5

Southern Blot Hybridization versus Polymerase Chain Reaction Method for Lymphoid Clonality Analysis

	Advantages	Disadvantages
Southern blot	Essentially no false-negative results Can detect nature of uncommon rearrangements (e.g., partial D-J) Can detect presence of oligoclonal gene rearrangement patterns	Cost, labor, technical difficulty Time-intensive (requires 1–2 weeks) Possible use of radionuclide labeled probes Requirement for high molecular weight DNA Large amount of DNA required (5 μ g per enzymatic digestion) Limited analytic sensitivity (can detect 5%–10% of a monoclonal population in background cells)
PCR	Rapid (24–48 hours), inexpensive, technically straightforward Use of DNA from many sources, including fixed, paraffin-embedded tissues Requires minimal DNA (0.5–1 μ g per reaction) Sensitive (nominally 1%–5%, can be augmented) Can combine different PCR locus strategies to increase clonality detection rate	False-positive risk (contamination, skewed T cell gene rearrangements) False-negative risk (detection rate not 100%) May miss oligoclonal populations Analytic sensitivity can be adversely affected by presence of polyclonal lymphocyte background when using consensus primers

DNA, Deoxyribonucleic acid; PCR, polymerase chain reaction.

to aspecific (“pseudoclonal”) amplification products in prominent reactive T cell proliferations. Skewed T cell populations can be encountered in several situations, including autoimmune disorders, after allogeneic organ transplantation, or as a consequence of normal aging. Therefore, diagnostic interpretation of T cell clonality studies by PCR is occasionally more problematic, with the propensity for encountering “equivocal” results. Furthermore, the presence of “promiscuous” locus rearrangements (e.g., *TRG* rearrangements in B cells and vice versa) are well described, particularly in cases of lymphoblastic leukemia/lymphoma, indicating that lineage specificity for antigen receptor gene rearrangements is not strictly followed in some lymphoid neoplasias (Szczepanski, 2002).

To summarize, PCR and SBH are complementary techniques for the determination of clonality in B and T cell lymphoid proliferations. The current status of PCR-based methods provides a rapid and effective alternative to SBH for interrogating both B and T cell loci, although the detection rate for optimized PCR assays is slightly less than 100%, and conversely, the risk of false-positive results (especially involving T cell receptor gene rearrangements), requires vigilance. It is clear that PCR analysis of antigen receptor gene rearrangements must always be interpreted alongside clinical and relevant pathologic or other laboratory data. Improvements to PCR-based methodology, including expansive coverage of multiple antigen receptor loci, have largely led to the replacement of SBH for lymphoid clonality determination; however, some diagnostic laboratories still retain expertise in SBH practice in order to resolve difficult cases. Finally, PCR analysis provides an additional benefit accruing from its analytic sensitivity under certain circumstances. Because clonal antigen receptor gene rearrangements in individual lymphoid neoplasms are unique, these DNA markers can also be used for highly sensitive (e.g., 10^{-3} – 10^{-5}) and specific detection of MRD in blood or bone marrow following therapy (Szczepanski, 2002; van der Velden, 2003; Szczepanski, 2007; van der Velden, 2007). As a primary example, quantitative MRD levels at the end of induction therapy have been shown to be strongly related to event-free and overall survival in childhood lymphoblastic leukemias (Cave, 1998; van Dongen, 1998; Nyvold, 2002; Campana, 2008; Flohr, 2008; Campana, 2009), these data are now being employed in conjunction with other tumor-associated molecular genetic features (as described previously) to augment individual risk assessment and treatment options for these patients.

TABLE 75-6
Lymphoma-Associated Translocations and Resultant Gene Rearrangements

Genetic abnormality	Disease associations	Basic molecular pathogenesis	Diagnostic detection*
t(14;18)/ <i>BCL2-IGH</i> @	90% of FL 20%–30% of DLBCL	Overexpression of anti-apoptotic Bcl2 protein in FL; not clear for DLBCL	FISH > PCR
t(11;14)/ <i>CCND1-IGH</i> @	100% of mantle cell lymphoma	Overexpression of G1-phase cell cycle protein cyclin D1	FISH >> PCR
3q27/ <i>BCL6</i>	30% of DLBCL	Disruption of normal Bcl6 regulation of germinal center B cell maturation	FISH
t(8;14)/ <i>MYC-IGH</i> @ and variant <i>MYC</i> translocations	100% of BL; 5%–10% of DLBCL; rare cases of high-grade B cell lymphoma with concurrent <i>BCL2</i> or <i>BCL6</i> rearrangements	Overexpression of potent early response mitogenic transcriptional factor Myc	FISH
t(11;18)/ <i>API2-MALT1</i> t(14;18)/ <i>MALT1-IGH</i> @ t(1;14)/ <i>BCL10-IGH</i> @ t(3;14)/ <i>FOXP1-IGH</i> @	Extranodal marginal zone lymphomas (~20%–30%)	Upregulation of NFκB signal transduction pathway activity	FISH; RT-PCR (for <i>API2-MALT1</i> mRNA)
t(2;5)/ <i>NPM1-ALK</i> and variant <i>ALK</i> translocations	T cell anaplastic large cell lymphoma (~80%–90%); rare cases of ALK positive large B cell lymphoma	Constitutive activation and abnormal localization of Alk tyrosine kinase	FISH (all variants); RT-PCR (for <i>NPM1-ALK</i> mRNA)
14q32/ <i>TCL1A</i>	T cell prolymphocytic leukemia (T-PLL)	Overexpression of transcription factor	FISH

BL, Burkitt lymphoma; DLBCL, diffuse large B cell lymphoma; FISH, fluorescence in situ hybridization; FL, follicular lymphoma; PCR, polymerase chain reaction; RT-PCR, reverse-transcriptase polymerase chain reaction.

*Detection by molecular techniques indicated; specific diagnosis can also be established in some tumors by detecting specific protein overexpression (e.g., cyclin D1 in mantle cell lymphoma, Alk in anaplastic large T cell lymphoma). PCR includes use of appropriate postamplification detection techniques (e.g., gel/capillary electrophoresis, melting analysis, and sequencing.)

MOLECULAR DETECTION AND SIGNIFICANCE OF COMMON LYMPHOMA-ASSOCIATED CHROMOSOMAL TRANSLOCATIONS

Our growing understanding of NHL biology has been substantially furthered by the identification of recurrent chromosomal translocations associated with particular neoplasms (Table 75-6) (Vega, 2003). Identification of these genetic abnormalities is not only highly useful for diagnosis, but also often provides prognostic information or a specific tumor marker for residual disease detection. In general, chromosome translocations are more prevalent in B cell NHLs and result in the fusion of two genetic loci, most commonly involving the *IGH*@ locus. In this pathogenetic process, a normally highly regulated proto-oncogene becomes constitutively activated by juxtaposition to the immunoglobulin gene, leading to marked oncoprotein overexpression, as typified by the *MYC-IGH*@ gene fusion in Burkitt lymphoma (BL) and some large B cell lymphomas. In a minority of examples, a chimeric fusion gene is produced and expressed as a hybrid mRNA and protein; this situation is found in ALCL of T cell lineage, characterized by the t(2;5)/*NPM1-ALK* abnormality. In either case, interference with normal lymphoid cell growth, homeostasis, or cell death (i.e., apoptosis) is thought to play a central role in lymphomagenesis. Lymphoma-associated translocation events are thought in many tumors to be linked to aberrant consequences of the recombinase activating gene (RAG) and DNA breakage-repair enzyme systems that are active during the time of normal antigen receptor gene rearrangement, or through germinal center processes like somatic hypermutation (SHM) and class switch recombination, which also require the enzyme AID (Pasqualucci, 2008). The exact mechanisms underlying translocation events in leukemias and lymphomas are incompletely understood, but may involve nonrandom spatial proximity of genes during cell cycling, fragile sites such as single-stranded intermediates of DNA prone to breakage and recombination, as well as others (Roix, 2003; Raghavan, 2004). Whereas most acute leukemia-associated translocations are best identified by the presence of their fusion corresponding chimeric mRNA species, gene fusion abnormalities in the lymphomas require a different molecular diagnostic strategy. A proportion of lymphoma-associated translocations can be detected by PCR methods using genomic DNA because of substantial breakpoint clustering in both partner genes; however, many are not amenable to PCR detection due to large regions of genomic breakpoint heterogeneity and additional analyses, such as FISH or immunohistochemistry (to detect overexpressed proteins), playing vital roles in the specific diagnosis and subclassification of the NHLs. New investigative techniques evaluating global gene expression or regulation are providing a more comprehensive, though complicated,

picture of the pathways of genetic deregulation in NHLs, with and without recurrent translocations (see later). These next generation platforms have already begun to further influence the subclassification and prognostication of lymphoid neoplasms; disease-specific examples are briefly discussed here.

t(14;18)/*BCL2-IGH*@ Abnormality in Follicular and Diffuse Large B Cell Lymphomas

The t(14;18)(q21;q32) abnormality is a common translocation encountered in B-lineage lymphomas. At the molecular level, this translocation results in the juxtaposition of the *BCL2* gene with the J-region of the immunoglobulin heavy chain locus (*IGH*@). As a consequence, the *BCL2* gene on 18q21 is brought under the control of the highly active *IGH*@ enhancer element on the derivative 14q32, leading to marked overexpression of Bcl2 protein. The Bcl2 gene product is a prototypic antiapoptotic protein capable of abrogating the process of programmed cell death in cells exposed to genotoxic or metabolic stress. As such, Bcl2 overexpression can protect neoplastic cells from a variety of otherwise lethal cytotoxic events and promote a milieu favoring acquisition of additional progression-related genetic abnormalities (Cory, 2002; Reed, 2008). *BCL2* gene rearrangements are present in 85%–90% of follicular lymphomas, approximately 20%–25% of diffuse large B cell lymphomas (DLBCL), and rarely in other B cell lymphoproliferative disorders. The partial genomic structure of the *BCL2* gene locus is illustrated in Figure 75-6. The largest proportion (50%–65%) of break-fusion sites in the *BCL2* gene occurs in a tightly clustered area of approximately 150 bp in the 3′ noncoding segment of exon 3 known as the major breakpoint region (MBR). Additional loosely clustered breakpoint regions in *BCL2* have been described, including the minor cluster (mcr), intermediate cluster (icr), and areas 3′ of the MBR and 5′ of the mcr (Akasaka, 1998; Albinger-Hegyi, 2002).

BCL2 gene rearrangements involving the MBR can be readily detected by PCR methods using genomic DNA and consensus primers situated near the MBR and in the *IGH*@-J_H region (Aster, 2002; Hsi, 2002; Iqbal, 2004; Gu, 2008). Other *BCL2* breaksite areas are more difficult to target by PCR because of heterogeneity in distribution; some investigators have described the use of specialized long distance DNA PCR techniques (requiring the use of high molecular weight DNA template), or RQ-PCR with multiple primer sets to extend coverage for detecting *BCL2* rearrangements (Akasaka, 1998; Albinger-Hegyi, 2002; Weinberg, 2007). Ultimately though, these expanded PCR approaches do not achieve complete detection sensitivity, particularly when compared with highly reliable FISH analysis using *BCL2* and *IGH*@ dual color locus-specific probes (Vega, 2003; Einerson, 2005). FISH is a versatile approach and can be performed

Figure 75-6 The t(14;18)/*BCL2*-*IGH@* abnormality in non-Hodgkin lymphomas. The *BCL2* gene is rearranged by translocation to the *IGH@* locus in most follicular lymphomas and a subset of large B cell lymphomas. Most genomic breakpoints are relatively tightly clustered in the 3' aspect of the noncoding third exon of the *BCL2* gene, in a region termed the major breakpoint region (MBR). Up to four additional *BCL2* breakpoint clusters have been described: the minor cluster region (mcr), the intermediate cluster region (icr), and two areas near distal and proximal to the MBR and mcr respectively (i.e., 3' MBR and 5' mcr). For the *IGH@* gene, breakpoints occur within the *J_H* segment region. Because of the clustered nature of breakpoints and the relatively short intervening distances between *BCL2* and *J_H* in the rearranged configuration, consensus *BCL2* and *J_H* PCR primers (orange arrows) can be used to detect many *BCL2*-*IGH@* gene fusions arising from the t(14;18)(q21;q32). Nevertheless, the widespread distribution of breakpoints in *BCL2* precludes the identification of a significant number of rearrangements by PCR, such that fluorescence in situ hybridization analysis has emerged as the method of choice for detection. A closely related t(14;18) variant occurs in low-grade extranodal marginal zone B cell ("MALT") lymphomas resulting in a *MALT1*-*IGH@* gene fusion. Even though they are karyotypically identical, FISH probe analyses can readily distinguish this entity from the *BCL2*-*IGH@* abnormality.

on nuclei extracted from fresh or paraffin-embedded tissues. A number of molecular diagnostic laboratories nonetheless continue to offer *BCL2*-*IGH@* translocation detection by PCR technique, although knowledge of the clinical assay (i.e., detection) sensitivity is important when interpreting these results.

The identification of *BCL2* gene rearrangements in neoplastic lymphoid proliferations is very useful in several clinical contexts including diagnosis and disease subclassification. Cases of atypical or florid but benign follicular hyperplasia can be histologically and phenotypically difficult to differentiate from follicular lymphoma and in this situation, the presence of clonal immunoglobulin gene rearrangements and/or the *BCL2*-*IGH@* abnormality definitively establishes the latter diagnosis. Furthermore, identification of the *BCL2*-*IGH@* fusion can be used to specifically distinguish low-grade follicular lymphomas from other small B cell lymphomas with potentially overlapping morphologic patterns, such as mantle cell or marginal zone types. As a footnote, the presence of *BCL2* gene rearrangements is relatively specific for follicular lymphoma and is almost always correlated with Bcl2 protein overexpression. Conversely, it is important to realize that many B cell lymphomas and lymphoid leukemias are also associated with deregulated Bcl2 protein expression in the absence of structural *BCL2* gene translocations (e.g., via gene amplification or possibly epigenetic mechanisms), indicating that the protein expression itself cannot be used for specific lymphoma subtyping. As noted, a small proportion of follicular lymphomas lacks the t(14;18)/*BCL2*-*IGH@*. Some of these *BCL2*-rearrangement negative follicular lymphomas demonstrate higher cytologic grade (e.g., grade 3B) and are associated with translocations involving the *BCL6* proto-oncogene (Katzenberger, 2004; Gu, 2009). No significant survival differences have been observed between "*BCL2*-positive" and "*BCL2*-negative" follicular lymphomas, but recent high-resolution genomics and gene expression profiling studies have suggested distinct molecular pathways for these entities (Leich, 2009).

Among DLBCL, the presence of the t(14;18)/*BCL2*-*IGH@* has been associated with a "germinal center" phenotype. While increasing evidence supports the concept that germinal center type DLBCL has a relatively favorable clinical outcome, the prognostic value of the (14;18) itself in DLBCL remains controversial (Gascoyne, 1997; Barrans, 2003).

Rearrangements or genomic gains at the *BCL2* locus have been more recently associated with adverse prognosis in some cases of DLBCL with a "nongerminal center" phenotype (Obermann, 2009a). More significantly, as discussed later, the presence of the *BCL2*-*IGH@* in conjunction with *MYC* gene alterations identifies a subgroup of very aggressive B cell lymphomas.

t(11;14)/*CCND1*-*IGH@* Abnormality in Mantle Cell Lymphoma

The t(11;14)(q13;q32) is essentially pathognomonic for the diagnosis of mantle cell lymphoma (MCL), when considering the differential diagnosis of small B cell neoplasms. This abnormality is also detected in a subset of multiple myelomas. Although previously thought to be present in some cases of B cell prolymphocytic leukemia, splenic marginal zone lymphoma

(also referred to as splenic lymphoma with "villous lymphocytes"), and chronic lymphocytic leukemia (CLL), critical reappraisal of the clinical and pathologic spectrum of MCL has led to the conclusion that these occurrences are in fact atypical presentations of MCL. The t(11;14) places a genomic region on 11q13 called *BCL1* in proximity to the *J_H* region of the *IGH@* gene. The gene encoding cyclin D1 (*CCND1*) is located telomeric to the majority of *BCL1* breaksites, but nonetheless is the consistent target of transcriptional deregulation by the *IGH@* as a result of the translocation. Cyclin D1 is an early G₁-phase cell cycle protein normally required for the activity of cyclin-dependent kinases 4 and 6 (cdk4, cdk6); these holoenzyme complexes promote progression through the G₁/S transition of the cell cycle in proliferating cells principally through phosphorylation of the retinoblastoma protein (Sherr, 2000). Cyclin D1 (in contrast to other related proteins cyclins D2 and D3) is not expressed by normal B cells. Oncogenic overexpression of the D1 type cyclin is thus thought to play a key role in the pathogenesis of MCL and is supported by the overall "proliferative" transcriptional signature in MCL cells as identified by more recent gene expression profiling studies (Rosenwald, 2003; Bertoni, 2004; Pedro Jares, 2008). This propensity to a proliferative and antiapoptotic tumor phenotype underlies the relatively poor prognosis of MCL among other "small B-lymphocyte" neoplasms.

Identification of the t(11;14) or *CCND1* genetic rearrangements in MCL is variable depending on the methodology employed. The *BCL1* breakpoint region encompasses a large area of 11q13. Approximately one half of *BCL1* locus breakpoints occur over a small, well-defined site, referred to as the major translocation cluster region (MTC) (Chibbar, 1998; Williams, 1993a; Williams, 1991). The MTC is located nearly 120 kilobases (kb) centromeric of the *CCND1* gene. Other breakpoints have been defined by Southern blot analyses and are either more distal to the MTC or located in the immediate 5' region of the *CCND1* (Williams, 1991, 1993a, 1993b). SBH methods using probes targeting the MTC and other genomic regions were historically described to detect *BCL1* alterations in up to 70% of MCL cases; however, the technical complexity, as well as the lack of commonly available genomic probes for the multiple *BCL1* regions, renders SBH impractical for routine diagnostic purposes. DNA-based PCR technique has been successfully used to identify the subset of *BCL1*-*IGH@* fusions involving the MTC region, accounting for an overall translocation detection rate of approximately 40% (Pinyol, 1996; Chibbar, 1998). It is thus evident that the large and widely distributed breakpoint region encompassed by the *BCL1* locus presents substantial difficulties for these molecular diagnostic approaches. To this end, FISH assays have subsequently emerged as the method of choice for resolving t(11;14)/*CCND1*-*IGH@* genomic abnormalities in MCL, capable of detecting essentially 100% of rearrangements (Remstein, 2000a; Belaud-Rotureau, 2002). Some investigators have also described using RQ-PCR evaluation of cyclin D1 mRNA levels to assist in the diagnosis of MCL, although this is not notably more advantageous over genomic FISH (Elenitoba-Johnson, 2002; Thomazy, 2002; Jones, 2004). Finally, cyclin D1 protein overexpression can be readily detected by immunohistochemical technique in fixed, paraffin-embedded tissues, providing an additional rapid, widely applicable and complementary method in the diagnosis of MCL (Belaud-Rotureau, 2002). Immunohistochemical detection can occasionally be complicated by the finding of acquired cyclin D1 expression in other B cell neoplasms, in the absence of the *CCND1*-*IGH@* gene fusion; examples include a subset of hairy cell leukemia and rare cases of chronic lymphocytic leukemia and large B cell lymphoma. In this regard, correlation with clinical presentation, morphology and immunophenotypic profile is critical, and molecular or FISH studies for the genomic t(11;14)/*CCND1*-*IGH@* remain an important diagnostic adjunct.

Data derived from gene expression studies of MCL also identified rare cases of morphologically and phenotypically classical MCL that nonetheless lack the t(11;14) and cyclin D1 overexpression (Rosenwald, 2003). Transcriptional profiling studies reveal similar features in these lymphomas to those found in cyclin D1-positive MCL (Fu, 2005). At least some of these uncommon types of MCL have been associated with translocations involving the *CCND2* or *CCND3* genes, or overexpression of D2 or D3 type cyclins (Wlodarska, 2008); however, it is currently not possible to distinguish this subgroup of cyclin D1-negative MCL using standard clinical diagnostic lab methods.

MALT1, BCL10, and FOXP1 Gene Abnormalities in Extranodal Marginal Zone B Cell Lymphomas

Extranodal marginal zone B cell lymphomas (EN-MZL), also referred to as mucosa associated lymphoid tissue (MALT) lymphomas, are uncommon

and biologically unusual lymphoid tumors. In addition to neoplastic growth in many diverse extranodal tissue sites (e.g., stomach, lung, salivary gland, thyroid), these tumors are often characterized by the presence of predisposing infectious or autoimmune conditions and a preceding or coexistent reactive lymphoid component. Gastric EN-MZL is a prototypic example: a significant subset of these lymphomas arises in the presence of *Helicobacter pylori* infection, which appears to play a key role in early disease pathogenesis (Zucca, 2000; Isaacson, 2004). In addition to underlying conditions, several recurrent genetic abnormalities have been associated with, or in some cases are defining of EN-MZL. A proportion of these lymphomas may have a normal karyotype or minimal numerical chromosomal changes (e.g., trisomies of 3 or 18); however, specific translocation abnormalities have recently been identified among subsets of EN-MZL, with variable frequency and tissue site distributions (Du, 2007). The t(11;18)(q21;q21)/*API2-MALT1* abnormality was the first to be described and is characterized by fusion of an inhibitor-of-apoptosis gene (*API2*, or *IAP2*) to a gene encoding a paracaspase-like protein (*MALT1*, previously *MLT1*) (Dierlamm, 1999; Rosenwald, 1999; Baens, 2000; Motegi, 2000; Remstein, 2000b; Yonezumi, 2001; Ye, 2003a, 2003b). *API2-MALT1* positive tumors have a predilection for gastric and lung sites, with infrequent occurrences elsewhere. A second translocation event occurring in EN-MZL is characterized by the t(14;18)(q21;q32) derived *MALT1-IGH@* gene fusion (Murga Penas, 2003; Sanchez-Izquierdo, 2003; Streubel, 2003; Remstein, 2004; Streubel, 2004; Ye, 2005). Notably, the *MALT1* gene is situated slightly centromeric to the *BCL2* locus on chromosome 18q and as such these two t(14;18)-associated gene fusions are indistinguishable by standard cytogenetics, requiring instead FISH analysis for accurate diagnosis. *MALT1-IGH@* positive lymphomas are distributed in orbital, parotid, lung, and cutaneous sites and are very uncommonly encountered in the stomach. Other rare translocations described sporadically in EN-MZL are the t(1;14)(p22;q32)/*BCL10-IGH@* and t(3;14)(p14.1;q32)/*FOXP1-IGH@* abnormalities (Wotherspoon, 1990; Willis, 1999; Streubel, 2005). Significantly, some of the reported tissue site distributions for *API2-MALT1* and *MALT1-IGH@* in EN-MZL may be reflective of other factors, such as geographic differences, recurrences of MALT lymphomas in organs distinct from the primary presentation, or other pathogenic influences (Remstein, 2006). Despite the apparent complexity of translocation genotypes and tissue distribution, a fundamental pathogenesis links these events in the development of EN-MZL. Through overexpression of either *MALT1* or *Bcl10* proteins, or by expression of an abnormally active chimeric *MALT1* moiety (i.e., as a result of the *API2-MALT1* gene fusion), constitutive activation of the NF- κ B signal transduction pathway is induced, leading to profoundly altered effects on cell growth, immunity and apoptosis regulation (Isaacson, 2004; Du, 2007). The centrality of the NF- κ B pathway also suggests attractive targets for the development of small molecule inhibitor therapies. Results from gene expression profiling studies continue to add to our understanding of pathway deregulation in MALT lymphomas (Chng, 2009).

Detection of these translocation events is generally best accomplished by FISH techniques (Remstein, 2006). RT-PCR analysis for the *API2-MALT1* transcript has been described and represents an alternative method for detecting the t(11;18) (Zhang, 2006); however, owing to substantial breakpoint heterogeneity in both genes, comprehensive primers are necessary and sufficient, good quality RNA is required, the latter often being a limiting factor in small tissue or paraffin-embedded biopsies. The diagnosis of a MALT lymphoma may not necessarily require additional investigations to detect these specific translocations. Conversely, in some situations, the detection of EN-MZL-related translocations by FISH methods can be very useful to establish the diagnosis of lymphoma in morphologically difficult cases with intermixed reactive or hyperplastic features, or to differentiate a true MALT lymphoma from another subtype of low-grade B cell lymphoma. More specifically, detection of the *API2-MALT1* lesion in gastric EN-MZL is potentially important for therapeutic management. Broad-spectrum antibiotic eradication of *H. pylori* can induce tumor regression in a significant subset of translocation-negative gastric EN-MZL, whereas the presence of the *API2-MALT1* gene fusion implies a distinct pathogenesis that is refractory to this nonchemotherapeutic option (Liu, 2001, 2002).

Standard PCR analysis for immunoglobulin gene rearrangements is frequently pursued at diagnosis in EN-MZL, to confirm the presence of a monoclonal B cell process. The use of PCR for assessing minimal residual disease following therapy can be more problematic. The significance of detecting clonal B cells using PCR technique in posttreatment biopsies from patients with gastric EN-MZL has been controversial, with some reports suggesting prolonged persistence of monoclonality after histologic

eradication of lymphoma, and others paradoxically showing the presence of clonotypic B cell populations in benign gastric lymphoid proliferations (Bertonio, 2002; Wundisch, 2003). Whereas many of these studies have employed PCR techniques with differing sensitivities, it appears that the decrease in PCR-detected clonotypic B cells generally lags behind the histologic normalization of gastric tissue in successfully treated patients. These findings suggest caution in the interpretation of molecular clonality investigations and careful correlation with morphologic findings in this clinical setting.

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma: Molecular and Cytogenetic Prognostic Markers

Chronic lymphocytic leukemia and its nodal manifestation small lymphocytic lymphoma (CLL/SLL) is overall an indolent form of B cell lymphoproliferative disorder, often not requiring early therapeutic intervention. Yet, advances in the last decade have defined more distinct prognostic subgroups independent of clinical staging, in turn identifying those patients at risk for early progressive disease and adverse outcome (Seiler, 2006; Zent, 2006; Hamblin, 2007; Moreno, 2008). This area of malignant hematology is illustrative of the convergence of phenotypic, cytogenetic, and molecular genetic tumor features in order to produce a more sophisticated approach to outcome prediction for these patients. Well-known phenotypic adverse factors include high expression of cell surface CD38 antigen and the overexpression of the signaling kinase ZAP-70. Several recurrent cytogenetic anomalies have been identified in CLL/SLL, none of which are disease-specific. These abnormalities include deletions of chromosome 13 or 13q; deletions of 11q; deletions of 17p; and trisomy 12. The cytogenetic changes are most reliably identified by targeted DNA probes using FISH technique. The presence of isolated 13q- has been associated with relatively favorable outcome. In contrast, 11q- and 17p- confer a more aggressive disease course with early requirement for chemotherapy. In the latter two situations, minimally deleted regions of these chromosomal loci include the *ATM* and *TP53* genes, respectively. In most cases of CLL with loss of 17p, the remaining allele shows mutation of *TP53*, indicating biallelic loss of tumor suppressor p53 expression (Dicker 2008; Fabris, 2008). Although 17p- CLL cases account for 10% or less of all patients, these individuals suffer a disproportionate share of disease complications and furthermore, are refractory to commonly used purine nucleoside analog chemotherapeutic agents. A major advance in CLL/SLL biology also occurred with the identification of tumors with SHM of the *IGH@* V-region. Previously, CLL/SLL was considered to be a malignant counterpart of "naïve" or pregerminal center B cells; the discovery of SHM involving the immunoglobulin genes indicate that these tumor cells have experienced antigenic stimulation in a germinal center environment and are functionally more related to memory type B cells. Prognostically, a significant difference in clinical outcome has been shown for CLL/SLL patients with mutated (defined as >2% nucleotide deviation from germline DNA sequence) vs. unmutated *IGH@* V-region status (Hamblin 1999; Oscier, 2002). Mutational analysis of *IGH@* V-region alleles is currently performed in some molecular hematopathology laboratories and though technically involved, this process has been greatly facilitated by the development of comprehensive antigen receptor gene databases (e.g., Immunogenetics; <http://imgt.cines.fr>). These various predictive genetic and phenotypic parameters can obviously coexist in any given case of CLL/SLL, resulting in a complex set of (often) conflicting data for an individual patient. One exception is the presence of the 17p- alteration, for which FISH and molecular screening of *TP53* mutations (e.g., by PCR and sequencing) appears very important to identify these high-risk CLL/SLL patients who may benefit from alternative and earlier treatment interventions (Rossi, 2009; Zent, 2008).

Diffuse Large B Cell Lymphomas: Role of BCL6 and MYC Gene Abnormalities and Classification Based on Gene Expression Profiling

The diffuse large B cell lymphomas (DLBCL) are characterized by moderate cytologic variability, but a relatively pronounced range of clinical outcome and biologic heterogeneity. Although nearly 50% of patients with de novo DLBCL are clinically "cured" of disease in the era of chemoinmunotherapy (e.g., "CHOP" + rituximab, or R-CHOP), prognostic factors to recognize those individuals with excellent versus poor outcome have not been easily identified. Cytogenetic studies of DLBCL have revealed a range of findings including normal karyotype, complex karyotype and the

presence of recurrent gene rearrangement abnormalities. Among the latter, translocations involving the *BCL2*, *BCL6* and *MYC* genes are the most frequent or clinically important. Cytogenetic aberrations of chromosome 3q27 and the *BCL6* gene have been characterized in approximately 20%–40% of DLBCL and a smaller proportion of follicular lymphomas. In contrast to most other lymphoma-associated translocations, gene fusions with *BCL6* can involve a large number of partner genes, many of which are unrelated to the antigen receptor genes (Chen, 1998; Ohno, 2004, 2006). However, a subset of cases will harbor the t(3;14)(q27;q32) abnormality, joining the *BCL6* gene to the *IGH@* locus, while others may involve the immunoglobulin light chain gene loci. In addition, 60%–70% of DLBCL demonstrate acquired somatic mutations in the 5' noncoding regulatory region of *BCL6*, with or without accompanying translocation events.

Bcl6 is expressed by normal germinal center lymphocytes (centroblasts and centrocytes) and this gene product is in fact vital for the formation of the normal germinal center reaction, for T cell-dependent antibody responses, and for control of Th2-type cytokine-induced inflammatory responses (Dent, 1997; Ye, 1997; Polo, 2004). The Bcl6 transcriptional program has been shown to be active in repressing proto-oncogene expression in normal B cells, but it is deregulated in large B cell lymphoma cells (Ci, 2009). Bcl6 has also been shown to functionally down-regulate the p53 and Atr tumor suppressor proteins (Phan, 2004; Jardin, 2007; Ranuncolo, 2007); in this capacity, Bcl6 functions to protect normal germinal center B cells from apoptotic signaling induced by physiologic DNA double strand breakage during the somatic hypermutation process, supporting affinity maturation of immunoglobulins. As a consequence of this environment, some normal germinal center-experienced B cells acquire somatic mutations in the 5' noncoding region of the *BCL6* gene process (Shen, 1998); however, the 5' *BCL6* mutations found in DLBCL are often distributed differentially to mutations in normal B cells, implying that the regions targeted in lymphoma have pathologic effects on gene regulation (Pasqualucci, 2003; Jardin, 2005; Saito, 2007). Importantly, Bcl6 protein is not expressed in normal pregerminal center (naïve) B cells and it is rapidly down-regulated in B cells exiting the germinal center, conferring some relative specificity of this marker for the normal germinal center environment. Accordingly, the presence of Bcl6 protein expression is observed in many large B cell lymphomas, most follicular lymphomas, and BLs, but not in other B cell lymphoma subtypes (Cattoretti, 1995; Onizuka, 1995; Pittaluga, 1996; Falini, 1997).

The detection of *BCL6* gene rearrangements is most sensitively accomplished by FISH technique. Selection of probes is important, in that *BCL6* breaksites include both a major breakpoint region (MBR) and an alternate breakpoint region (ABR) (Iqbal, 2007). The clinical significance of *BCL6* gene alterations in DLBCL, whether present as translocation rearrangement events or somatic 5' regulatory mutations, is still not clearly defined. Some studies have implied an adverse prognosis for large B cell lymphomas with *BCL6* gene rearrangements, perhaps pertaining more to tumors with nonimmunoglobulin gene translocations (Akasaka, 2000; Barrans, 2002), whereas other investigations have shown either opposite findings, or no convincing prognostic effect (Jerkeman, 2002). The effect of *BCL6* translocations in nodal DLBCL may also be associated with other adverse tumor biologic factors (Shustik, 2009). Primary central nervous system DLBCL with *BCL6* structural changes do appear to have a significantly worse outcome (Cady, 2008). As noted earlier, *BCL6* alterations may also be related to the pathogenesis of a distinct subset of high-grade follicular lymphomas, in the absence of the t(14;18)/*BCL2*-IgH (Katzenberger, 2004; Gu, 2009). Abnormalities of *BCL6* have also been described in high-grade B cell lymphomas with concurrent *MYC* gene abnormalities (see later), in posttransplant large B cell lymphomas, and in some of the aggressive lymphomas arising in the setting of human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS). Although the exact molecular mechanisms predisposing to the development of large B cell lymphomas continue to be defined, it is evident that deregulation of *BCL6* creates a cellular environment conducive to additional lymphomagenic genetic derangements.

The *MYC* gene on 8q24 is rearranged in approximately 5%–10% of DLBCL, representing translocations to the *IGH@*, immunoglobulin light chain, or nonimmunoglobulin gene loci. *MyC* is a potent cellular growth factor and classic proto-oncogene. A more detailed molecular description of *MYC* gene translocation events and function is presented in the later discussion on BL. Several large clinical studies have shown that unselected de novo DLBCL patients with *MYC* gene rearrangements have a significantly worse overall outcome (Klapper, 2008; Obermann, 2009b; Savage, 2009). Because no distinctive phenotypic or presenting clinical features can

reliably identify *MYC* rearrangements in morphologically typical DLBCL cases, some investigators have suggested routine diagnostic assessment of the *MYC* locus by FISH analysis, despite its relatively low prevalence. Patients with so-called double hit genetics (e.g., *MYC* plus concurrent *BCL2* or *BCL6* rearrangements) have very aggressive disease, but are often characterized by variant cytomorphology akin to BL rather than usual type centroblastic features, and so are considered separately (see following discussion on BL).

Recent years have witnessed a paradigm shift in the classification of DLBCL based on gene expression signatures. One landmark publication using microarray-based analysis of global tumor mRNA expression revealed two major DLBCL subgroups designated as *germinal center-like B cell* (GCB) and *activated B cell like* (ABC) (Alizadeh, 2000; Rosenwald, 2002). Strikingly, GCB-classified patients had a much superior survival outcome relative to ABC type patients (summarized in de Leval, 2009). The validity of this approach has been confirmed by other studies, including evaluation of smaller gene sets characteristic of either GCB or ABC type tumors (Lossos, 2004). For example, a subset of overexpressed genes, including *BCL6*, *LMO2*, *HGAL*, and *CD10*, are strongly related to GCB phenotype, whereas *MUM1/IRF4*, *CD44*, *XBPI*, and several others are preferentially seen in ABC DLBCL. Certain cytogenetic features also appear to segregate between these subtypes, such that the t(14;18)/*BCL2*-*IGH@* is identified among GCB tumors and, interestingly, *BCL6* gene translocations are more prevalent in ABC lymphomas. The latter findings suggest that Bcl6 protein overexpression is important in the pathogenesis of GCB DLBCL, but structural rearrangements of the *BCL6* gene are reflective of a different pathogenesis and adverse features as seen in ABC DLBCL. Most intriguingly, ABC tumors consistently demonstrate deregulation of the NF- κ B pathway, via abnormalities in upstream pathway proteins such as CARD11, BCL10, and MALT1; selective targeting of this pathway holds therapeutic promise for better managing these relatively refractory cases of DLBCL. Currently, determination of GCB versus ABC DLBCL types using microarray-scale gene expression methods remains outside the realm of routine clinical molecular diagnostics, although promising technologic developments may make this approach more feasible in smaller and more targeted platforms. Attempts to reproduce this classification using immunohistochemistry have not been rigorously successful because of a lack of strict gene expression level-to-protein correlation, overlapping expression patterns in many DLBCL for some protein markers, and the lack of reproducible standards for a nonquantitative technique. Finally, it should be noted that gene expression studies by other groups have revealed different functional subsets of DLBCL (Shipp, 2002; Monti, 2005) and a challenge for the development of a new biologic and clinically relevant classification in this disease will require a thorough understanding of these large and complex datasets.

MYC Gene Translocations in Burkitt Lymphomas and "High-Grade" B Cell Lymphomas, Unclassifiable

Genetic alterations of the *MYC* locus, situated on chromosome 8q24, are classically associated with BL; however, this gene is also implicated in the pathogenesis of several other aggressive lymphoid tumors including high-grade (secondary) transformations of indolent lymphomas, HIV/AIDS-associated lymphomas, and monomorphic B cell posttransplant lymphoproliferative disorders. Most commonly, the *MYC* gene is translocated to the *IGH@* locus as a result of the t(8;14)(q24;q32) abnormality. In other instances, *MYC* may be brought adjacent to the *IGK* [2(p12)] or *IGL* [22(q11)] light chain genes. In each case, *MYC* is placed under the strong transcriptional influence of an immunoglobulin enhancer element, leading to overexpression of the gene. *MyC* (or *cMyC*) is normally a highly regulated transcription factor involved in coordinating early cell cycle and DNA replication nuclear responses to mitogenic signaling pathways. *MYC* translocation and deregulation in lymphoma thus leads to transactivation of multiple cognate target genes, ultimately driving uncontrolled cell proliferation, in a permissive cellular context (Hecht, 2000). The simultaneous abrogation of proapoptotic mechanisms is synergistic with rapid *MyC*-induced transformation (Beverly, 2009). The molecular anatomy of *MYC* region breakpoints has been well studied in BL with the t(8;14) (Hecht, 2000; Blum, 2004). In so-called endemic BL, which is strongly associated with chronic Epstein-Barr virus (EBV) infection, *MYC* breaksites occur far upstream of the gene and primarily involve the *IGH@* J_H region. In contrast, sporadic type BL demonstrate *MYC* breaks that are situated closer to the 5' region of the gene and are typically associated with fusion to the *IGH@* isotype switch regions, located upstream of the respective constant

region (C-) exons. The enzyme AID is critical to the process of class switch recombination and SHM in normal germinal center B cells, and *MYC-IGH* translocation breaks in BL have been shown to be AID-dependent (Robbiani, 2008). Sporadic BL is far less frequently associated with EBV (20% of cases). These data suggest that translocation events involving *MYC* in these epidemiologic BL variants may occur at slightly different stages of maturation in a developing B cell; clinically, however, these differences appear to be insignificant.

In routine practice, the diagnosis of BL can usually be established with a high degree of probability using a combination of clinical, morphologic, and targeted immunohistochemical studies (Brazier, 2001). Definitive diagnosis however, requires detection of a *MYC* gene rearrangement. *MYC* translocations cannot be identified by standard PCR approaches due to the pronounced breakpoint heterogeneity in the *MYC* gene; FISH or karyotype analysis thus currently remains the best option for identifying these abnormalities. FISH strategies can include initial targeting of the *MYC* gene locus using a break-apart probe strategy, followed by locus-specific probes to identify *MYC-IGH* fusions. Novel probes to detect translocations with the immunoglobulin light chain genes have also been described (Einerson, 2006).

An uncommon type of lymphoid tumor with cytomorphologic features reminiscent, but atypical, of BL has been described with highly aggressive clinical behavior (Haralambieva, 2005; McClure, 2005). Notably, these B cell lymphomas are often associated with *MYC* gene rearrangements, as well coexisting translocations involving the *BCL2* or *BCL6* genes. These lesions have been termed *double hit* lymphomas and are presently classified as “B cell lymphomas, unclassifiable, with features intermediate between diffuse large B cell lymphoma and Burkitt lymphoma” in the 2008 WHO classification of lymphomas. This group of B cell lymphomas is considered heterogeneous, and includes de novo double hit cases, transformed follicular lymphomas with both *BCL2* and secondary *MYC* rearrangements, and *MYC*-negative cases with complex karyotype. Recognition of these high-grade B cell lymphomas by morphologic and molecular genetic criteria is important given the inadequate response to DLBCL therapy. In this regard, FISH studies to identify double hit genetic abnormalities of *MYC* and *BCL2* or *BCL6* are often pursued.

ALK Gene Abnormalities in Anaplastic Large Cell Lymphomas

ALCL is a unique subtype of peripheral T cell NHL that may present as a primary cutaneous disease, or more commonly as a systemic form involving lymph nodes, visceral organs and skin. A phenotypic hallmark in nearly all cases of ALCL is strong uniform expression of the CD30 (Ki-1) antigen, an activation marker and member of the tumor necrosis factor family. Although classic ALCL tumors are known to be of T cell lineage, some examples fail to express lineage associated T cell markers (“null” cell phenotype), but these cases can usually be confirmed as being of T cell origin based on T cell receptor gene clonality studies. A major subset of ALCL is characterized by translocations involving the anaplastic lymphoma kinase (*ALK*) gene located on chromosome 2p23. *ALK* encodes a novel tyrosine kinase that is not normally expressed in lymphoid cells. Approximately 90% of *ALK*-rearranged ALCL harbor the t(2;5)(p23;q35) abnormality, leading to a fusion of the *ALK* gene with the *NPM1* gene (Stein, 2000). The *NPM1* gene is also mutated in many normal karyotype acute myeloid leukemias as described previously. As a result of the *NPM1-ALK* gene fusion, the tyrosine kinase activity and intracellular location of *ALK* becomes deregulated, contributing to lymphomagenesis through increased target protein phosphorylation and signal transduction (Falini, 2001; Chiarle, 2008). Unlike the more typical gene overexpression consequences of most lymphoma-associated translocations, the *NPM1-ALK* fusion differs in that a chimeric mRNA and protein are produced, although overproduction of the normally silent *ALK* gene in a T-lymphocyte appears to be the principal mechanism involved in malignant transformation. Investigative efforts have shown that *ALK* deregulation can involve down-regulation of T cell associated antigens, NF- κ B target gene activation, functional inactivation of normal p53 tumor suppression, and immunosuppressive effects mediated through STAT3 signaling (Cui, 2009; Eckerle, 2009; Wasik, 2009). In addition to *NPM1-ALK*, several less common variant genetic rearrangements of *ALK* are also described in this type of lymphoma, including the t(1;2)(q25;p23)/*TPM3-ALK*, t(2;3)(p23;q35)/*TFG-ALK*, and inv(2)(p23q35)/*ATIC-ALK* abnormalities, all giving rise to *ALK* gene deregulation (Swerdlow, 2008). Importantly, the abnormal cellular sublocalization of constitutive *ALK* kinase activity is

mediated by the fusion partner protein moiety. Thus *NPM1-ALK* oncoproteins are situated in both a nuclear and cytosolic pattern, whereas *TPM3-ALK* products show diffuse cytoplasmic distribution, in accordance with the usual site of the *TPM3* gene product, tropomyosin-3. Several clinical studies have demonstrated a relatively favorable prognosis for *ALK*-positive ALCL, regardless of the actual translocation present. *ALK*-positive ALCL are more prevalently seen in younger patients (e.g., less than 50 years) and in the pediatric population. In contrast, another group of T cell lymphomas sharing the same morphologic features and expression of CD30 antigen do not have *ALK* gene rearrangements or deregulation of *ALK* protein expression. These *ALK*-negative tumors also appear to differ in global gene expression profiles, indicating distinct pathways of malignant transformation. Most significantly, *ALK*-negative ALCL are associated with more aggressive disease behavior typical of peripheral T cell lymphoma unspecified, justifying the recognition of the *ALK*-positive subtype by molecular or immunophenotypic methods (Falini, 1999a; Gascoyne, 1999; de Leval, 2009; Fornari, 2009; Savage, 2008). In addition to distinguishing the two major systemic subtypes of ALCL, the presence of an *ALK* gene rearrangement can help in the differential diagnosis between ALCL and Hodgkin lymphoma, and rare cases of phenotypically indeterminate large cell lymphoma. An unusual and rare complication of silicone breast prostheses is the development of implantation-site ALCL in some patients, which are also *ALK* negative (de Jong, 2008). Of note, the primary cutaneous type of ALCL is not associated with *ALK* gene abnormalities or aberrant *ALK* expression and has a very favorable outcome.

Genomic breakpoints in cases of t(2;5) positive ALCL lie consistently within the same intron regions in both *NPM1* and *ALK* genes, resulting in the generation of a single, unique *NPM1-ALK* chimeric mRNA. As a result, RT-PCR technique can be used to detect the fusion transcript with high specificity and sensitivity (Ladanyi, 1994; Lamant, 1996; Weiss, 1995; Wellmann, 1995; Yee, 1996). In addition, long distance DNA PCR has also been successfully employed to identify the genomic *NPM1-ALK* abnormality (Ladanyi, 1996; Sarris, 1998). The latter approach requires high molecular weight DNA, but obviates the need for RNA isolation and reverse transcription. FISH methodology is nevertheless the most widely employed diagnostic modality to detect *ALK* gene rearrangements. Essentially all translocation-associated alterations can be detected using a break-apart probe method directed to the *ALK* locus; elucidation of the specific translocation gene partner is not required because of its limited clinical value. As with other gene overexpression phenomena in the NHLs, *ALK*-positive ALCL can also be readily diagnosed using monoclonal antibodies against the *ALK* portion of the oncoprotein. The immunohistochemical cellular localization of abnormal *ALK*, as suggested previously, also correlates to some extent with the type of translocation event, reflecting the effects of the fusion partner segment (Falini, 1999b; Stein, 2000).

To complete the discussion of *ALK*-positive lymphomas, several reports have recently documented the presence of the t(2;17)(p23;q23)/*CLTC-ALK* or *NPM1-ALK* gene fusions in very rare and unusual occurrences of IgA heavy chain-positive diffuse large B cell lymphoma with plasmablastic features (de Paepe, 2003; Gascoyne, 2003). These tumors are also recognized by the presence of plasmacytic cell markers but lack of CD20 expression and CD30 negativity (compared with T cell ALCL). The *CLTC* gene encodes clathrin and the chimeric *CLTC-ALK* protein has a unique cellular distribution of granular membrane positivity, corresponding to localization to clathrin-coated pits. *ALK*-positive large B cell lymphomas are associated with a particularly poor outcome (Laurent, 2009).

TCL1A Gene Abnormalities in T Cell Prolymphocytic Leukemia

T cell prolymphocytic leukemia (T-PLL) is a mature T cell leukemia most often characterized by expression of CD4, although phenotypic variants are well known. T-PLL is often suspected by cytology and immunophenotype, but can share overlapping features with other T cell neoplasms showing blood and bone marrow involvement. T-PLL cases are, however, definitively diagnosed by the presence of a *TCL1A* gene rearrangement (Pekarsky, 2001; Krishnan, 2006). *Tcl1a* is a transcription factor that is not completely understood, but is expressed in a subset of normal B cells, but not normal mature T cells. As a result of *TCL1A* rearrangement in a candidate T-lymphocyte, the gene becomes aberrantly active, leading to the pathogenesis of T-PLL. Rearrangements of *TCL1A* are not identified in other major subgroups of peripheral T cell lymphoma. The *TCL1A*

gene is situated on chromosome 14q32 and in 80% of T-PLL cases are juxtaposed with the *TRA* gene locus, either through an inversion [inv14(q11;q32)], or reciprocal translocation event [t(14;14)(q11;q32)]. A small number of T-PLL will have alternate translocations t(X;14)(q28;q11) or t(X;7)(q28;q35) involving a fusion of the *TCL1A*-related gene, *MTCPI1*, to either the *TRA* or *TRB* gene loci, respectively (De Schouwer, 2000). The diagnosis of T-PLL is thus greatly facilitated and confirmed by FISH analysis for *TCL1A* rearrangements or chromosome studies for *MTCPI1*-related translocations. In tissue sections, Tc1a immunohistochemistry can be used to identify the overexpressed protein in suspected cases.

EMERGING TECHNOLOGIES IMPACTING MOLECULAR DIAGNOSIS AND PROGNOSIS PREDICTION IN HEMATOLYMPHOID NEOPLASIA

The practice of hematopathology remains integrally tied to the rapid pace of development in molecular genetics: advancements in molecular discovery and application have transformed the diagnosis and management of hematolymphoid neoplasms and, in turn, these same diseases have provided fertile and easily accessible biologic material for the advancement of the technologies themselves. Several new molecular applications are currently poised to enter clinical practice, an event that may have effects as profound as the advent of the polymerase chain reaction. As always with platform shifts and paradigmatic change, the clinical molecular diagnostic laboratory will need to be flexible when adopting these developments, while maintaining its primary focus on the high standards of quality, reproducibility and cost effectiveness.

Chief among these promising new techniques is what has been called “deep sequencing,” “high throughput sequencing,” and “next generation sequencing” (Tucker, 2009). Although there are several such sequencing platforms that vary in technical approach, many of them share the same general approach: multiple copies of large genomic targets are fragmented at random into short segments, which are then randomly immobilized and simultaneously sequenced. This apparently disjointed data can be reorganized by sophisticated computer software programs, using the principle that each randomly generated fragment of the sequence will share some degree of overlap with many other fragments from the same genomic region (Flicek, 2009). This technology, an offshoot of the human genome project, has been called “massively parallel sequencing,” and it is capable of generating hundreds of megabases of sequence data per day. Entire genomes can be sequenced in this manner, but for the purposes of molecular hematopathology in the near term, genes of diagnostic importance can be either preselected by hybridizing the genomic DNA to complementary capture probes, or enriched using other techniques. The technology can also be applied to other species of ribonucleic acid, including messenger RNA and microRNA, yielding large scale analysis of the transcriptome and “miRnome,” respectively. When coupled with techniques such as chromatin immunoprecipitation and bisulfite treatment, next generation sequencing can analyze protein-gene interactions and methylation patterns on a genome-wide scale. Thus instead of assaying for mutations or changes in a handful of genes (e.g., *NPM1*, *CEBPA*, and *FLT3* in AML), the diagnostician of the near future may be able to screen cases for mutations or other alterations involving any of dozens to many hundreds of genes. As complex as the computer algorithms at the heart of next generation sequencing are, they pale in comparison to the bioinformatic and interpretive challenges presented by this comparative avalanche of data (ten Bosch, 2008). Therefore, routine clinical laboratory applications of high throughput sequencing will first require many clinical correlative studies to identify valid associations between large sets of potential nucleic acid biomarkers, and parameters such as disease predisposition, prognosis, or therapeutic efficacy (McPherson, 2009). In this regard, it is worth bearing in mind that the state-of-the-art 2008 WHO classification struggles to document all facets of even the few genes of currently recognized significance in AML (Swerdlow, 2008). Close collaboration between the diagnostic, clinical, bioinformatic, and basic research communities will be necessary in the coming years to employ this powerful new technology in a rational manner tied to improved patient outcomes.

A similarly ground-breaking advance in diagnostic capability will likely arise from the growing convergence of molecular diagnostics and cytogenetics, as demonstrated by array comparative genomic hybridization

(aCGH) and the genotyping of single nucleotide polymorphisms (SNPs) via microarray. These techniques permit genome-wide analysis on a scale of resolution intermediate between the base pair level of molecular diagnostics and the gross overview afforded by conventional cytogenetics and even FISH methods. aCGH is performed by fragmenting and labeling sample and control genomic DNA with different fluorescent colors, then competitively hybridizing a mixture of the labeled fragments to a microarray containing millions of oligonucleotide probes in a predetermined arrangement. The ratio of sample to control fluorescence for each probe location conveys information about the “copy number” of the sample relative to the control at that locus. An alternative strategy to gain knowledge of copy number takes advantage of the existence of SNPs, locations in DNA at which a significant proportion of randomly selected individuals will differ in their genetic sequence by a single base change. SNP arrays hybridize labeled genomic DNA from the sample to microarrays spotted with pairs of probes designed to preferentially bind sequences containing one or the other version of the SNP. The total fluorescent intensity arising from both probes of a given pair yields the copy number at that location, while the relative intensity of one probe to the other reflects the individual’s genotype (heterozygous or homozygous) at the SNP. This genotype information can be used to detect uniparental disomy or copy number neutral loss of heterozygosity (UPD/CN-LOH), situations in which the expected two copies of each sequence are present, but each copy is identical throughout a region of DNA, indicating in neoplasms, a duplication of a segmental genomic abnormality; aCGH does not detect this UPD/CN-LOH, which is an important mechanism of tumor suppressor silencing in tumorigenesis. Already these technologies have revolutionized clinical genetic testing for inherited dysmorphism syndromes and developmental delay, in addition to documenting a previously unsuspected degree of human genetic diversity (Redon, 2006; Edelmann, 2009; Zhang, 2009). Among hematolymphoid neoplasms, CLL has thus far received the most attention from investigators using these techniques (Gunn, 2008; Higgins, 2008; Patel, 2008; Sargent, 2009).

In contrast to next-generation sequencing and molecular karyotyping, gene expression profiling (GEP) by microarray is a technique that has by now compiled a lengthy track record as a tool for biomedical research. Although microarray analysis is not as yet routinely used in the clinical laboratory, it is a powerful technology from which a number of clinically important observations have been made in acute leukemias and lymphomas (Levene, 2003; Hubank, 2004; Winter, 2007; Wouters, 2009b). Microarrays contain oligonucleotide or cDNA targets on a “chip” surface. These targets represent a large component of the expressed genome or the entire genome and are designed to specifically represent the mRNA levels of genes in parallel from a single sample. Detailed overviews of the various options available for array-based expression analyses as well as their techniques related to their analysis and interpretation are discussed elsewhere in this book. Studies on hematopoietic neoplasms have provided insights into “class prediction” (prediction of a tumor type based on specific gene expression profiles of selected informative genes) as well as “class discovery” (discovery of new sub-entities within tumor groups formerly regarded as a homogenous entity). Class discovery is not solely limited to identification of new subtypes of leukemia, for instance, but includes definition of prognostically differing groups, which are anticipated to influence therapeutic strategies. The application of GEP to diffuse large B cell lymphoma (DLBCL) has been described earlier and is one example of class discovery (Dybkaer, 2004). Similar studies in follicular lymphoma have revealed two multigene expression signatures, allowing separation of patients into subsets independent of currently available clinical prognostic variables (Dave, 2004). Most intriguingly, the length of survival among these follicular lymphoma patients correlated with the molecular profile of the non-malignant tumor infiltrating immune cells, revealing the contribution of host background to neoplastic growth. Gene expression microarray studies of CLL were also important to uncover the expression of the *ZAP-70* gene as a strong surrogate marker of adverse outcome (Rosenwald, 2001). The protein level of ZAP-70, as assessed by flow cytometry, has since become an accepted prognostic marker in CLL, despite the technical problems inherent in performing this assay. As microarray technology matures and becomes more cost effective, it is apparent that variations of this methodology will have application in the clinical laboratory.

The future for diagnostic hematopathology therefore appears challenging, yet exciting in this new era of genome-wide analysis and targeted therapies, with the goal of optimizing individual care for patients and realizing the potential of “personalized medicine.”

KEY POINTS

- Solid tissue (mainly epithelial cell) tumors are mainly caused by genetic lesions of three types: deletion or inactivation of tumor suppressor genes, mutation in or overexpression of oncogenes (i.e., genes encoding proteins that are vital in control of the cell cycle), and hypermethylation of the promoter regions.
- These genetic lesions can be detected using the techniques described in Part 8 of this textbook involving real-time polymerase chain reaction, fluorescent *in situ* hybridization, immunohistochemistry, enzyme-linked immunosorbent assay, etc.
- Detection of genetic lesions in solid tissue tumors is of great value for the diagnosis of specific types, for classification of the tumor, and for determining prognosis for a patient with a specific type of cancer, and for classification of the tumor. A common mutation in several of these cancers is overexpression of the epidermal growth factor receptor (EGFR). Discovery of this lesion allows for implementation of anti-EGFR therapy. However, because *ras-p21* is a downstream target of EGFR, and because it is commonly mutated in many human cancers, it is necessary to test for oncogenic mutations in the *ras* gene. If these are found, the efficacy of anti-EGFR agents is diminished.
- Less commonly, oncogenic mutations can be found in downstream targets of *ras-p21*, such as *BRAF*, which makes treatment with anti-EGFR agents less effective.

- Many solid tissue tumors express the same oncogenes, such as *BRAF*, in melanoma and thyroid cancer, but other cancers have genetic lesions that appear to be specific for that type of cancer, such as *RET* in medullary thyroid carcinoma.
- Although not formally classified as solid tissue tumors, sarcomas often behave in a manner identical to that of solid tissue tumors. These cancers have been found to be caused by reciprocal translocations resulting in oncogenic fusion transcripts (accounting for 15%–20% of cases) and by specific oncogenic mutations (e.g., *KIT* and *PDGFRA* mutations in gastrointestinal stromal tumors). Both types of genetic alterations are often specific to certain types of sarcomas.
- Because the genetic alterations or changes that underlie many familial types of cancers are known, it is possible to screen for these in the children and close relatives of patients known to have a form of familial cancer, so as to detect the presence of these cancers as rapidly as possible.

Cancer is largely a genetically encoded disease. Recent research on cancer molecular genetics, epigenetics, and genomics, as well as their application, has vastly changed the practice of cancer diagnosis, classification, prognosis, and treatment. Application of molecular genetics to solid tumors is a major milestone in diagnostic pathology. The molecular diagnosis was initially introduced for accurate diagnosis of solid tumors, based on the

unique genetics. Now the utility of molecular diagnosis is far beyond its original intention, and it is no longer just an adjunct method. It has become an indispensable tool that is widely used to predict clinical outcome, including disease prognosis, selection of optimal therapeutic regimens, and anticipation in response to treatment. It has not only revolutionized the concept and practice of diagnostic pathology for solid tumors, it has also become the basis for personalized medicine.

The principles and method in molecular diagnostics of solid tumors are similar to those used in other fields of molecular diagnosis. Techniques commonly used in cancer molecular pathology include detection or identification of specific sequences of genes (DNA and/or its transcribed RNA) or gene product (protein) alterations. They include amplification-based techniques (i.e., polymerase chain reaction [PCR], RT-PCR, branched DNA testing), hybridization methods (i.e., in situ hybridization, or fluorescent in situ hybridization [FISH]), microarray-based approaches (i.e., comparative genomic hybridization [CGH], DNA, RNA, microRNA microarray), and sequencing. PCR and FISH are among the most commonly used methods, whereas array-based techniques have a promising future, but have not been used widely in clinical settings to this point. Each method is described in Part 8 of this text.

Tissue sources of diagnostic materials of molecular pathology for solid tumor include paraffin-embedded tissue, fresh tissue, and cytologic specimens. Fresh tissue is a preferred choice for preservation of DNA, RNA, or protein. In most cases, only fresh tissue is usable in array-based methods; however, it is usually not readily available or accessible. Thus, paraffin-embedded tissue is used most commonly because of its availability and ease of access; it also allows use of the corresponding hematoxylin and eosin-stained slides for morphologic study. However, exposure of nucleic acid to formalin is associated with the major inherent problems of increased nucleic acid fragmentation and low integrity of DNA, RNA, and protein. Tissue fixation in formalin for longer than 24 hours will likely reduce the yield of high molecular weight nucleic acid. Thus, longer formalin fixation, paraffin embedding, and long storage at room temperatures can lead to false-negative results. A second problem is impurity of tumor cells, which usually are mixed with normal cells and stromal cells. Relatively pure tumor cells can be achieved by employing microdissection that isolates the tumor cells, even a single tumor cell, by a manual or instrument-assisted method. Cytologic specimens, including cells from fine-needle aspiration (FNA), urine, and blood, and swabs for molecular pathology, are used most often to assist in accurate diagnosis of superficial solid tumor, such as human epidermal growth factor receptor (*Her*)-2/*neu* (*ERBB2*) for breast cancer, human papillomavirus (HPV) testing for cervical cancer, and UroVysion (Abbott Laboratories, Abbott Park, Ill.) for bladder cancer.

Molecular diagnoses of solid tumors rely on our understanding of the molecular mechanism involved in carcinogenesis of solid tumors. Genetic alterations can be inherited or can result from carcinogenesis, as described in Chapter 74. In several tumors, polygenic mutations occur, but often in these cases, some unique or specific genetic alterations lead to carcinogenesis. Those genetic or epigenetic components mainly belong to the following:

1. Tumor suppressor genes (TSGs) (*Rb*, *SMAD*, adenomatous polyposis coli [*APC*], etc).
2. Oncogenes (*EWS*, *cKIT*, *Her2/neu*, *KRAS*, *BRAF*, etc).
3. Promoter regions with methylation/inactivation activity.

Application of molecular diagnosis of solid tumors has been used clinically as follows:

1. **Assistance in disease diagnosis and classification:** For example, small “blue cell” tumors encompassing Ewing’s sarcoma, lymphoma, rhabdomyosarcoma, and so forth, can be diagnosed by identification of specifically altered genes (e.g., Ewing’s sarcoma-specific gene translocations). In cervical cancer, detection of HPV assists in the diagnosis of neoplastic change on cervical biopsies or smears. Moreover, in the future, DNA microarray of the tumor may detect gene signatures.
2. **Determination of prognosis:** With better understanding of the molecular genetics of solid tumors, a greater number of prognostic markers can be identified. Thus detection of those markers in some cases has become a routine practice. For example, detection of overexpression/amplification of *Her2/neu* in breast cancer and 1p19q deletion in brain tumor has been used to predict prognosis or clinical outcome.
3. **Determination of therapeutic options:** Many drugs have been developed to target certain genes and gene products (i.e., proteins) and related pathways. Examples include tyrosine kinase inhibitors

(TKIs) and monoclonal antibodies to EGFRs in lung and colon cancer. Moreover, only certain groups of patients with unique genetic profiles can respond to these treatments. Thus, providing the right management not only will increase the chances for cure, but also will improve patient quality of life by avoiding unnecessary side effects.

4. **Combination of the above:** In most cases, detection of molecular markers may provide both diagnostic and prognostic information such as *cKIT* mutations and chromosomal abnormalities detected by UroVysion, and amplification of *Her2/neu*.

This chapter focuses on the clinical application of molecular pathology in cancer diagnosis, prognosis, and predicting treatment response in common solid tumors. The major genetic findings in each tumor type are summarized in Table 76-1.

MOLECULAR GENETIC PATHOLOGY OF SPECIFIC SOLID TUMORS BY MAJOR ORGAN

BRAIN TUMOR

Primary central nervous system (CNS) gliomas, originating exclusively from brain cells such as astrocytes, oligodendrocytes, and ependymal cells, account for only about 1.35% of all cancers, but rank second among the causes of death from neurologic disease. Glioblastomas are the most common primary CNS tumor and are categorized as World Health Organization (WHO) grades I–IV, based on histologic characteristics. With the advent of new treatment modalities, the use of microscopic examination alone is insufficient for the histologic classification and grading of gliomas.

Glioblastoma Multiforme

Glioblastoma multiforme (GBM) consists of anaplastic malignant astrocytic tumors characterized by predominant microvascular and endothelial proliferation. The current standard of care for GBM is surgical resection, followed by radiation therapy. However, the association of specific molecular genetics not only assists in diagnosis and prognosis but also leads to the development of new adjuvant chemotherapy (e.g., temozolomide) (Stupp, 2005). Glioblastomas (WHO grade IV) may develop de novo (primary glioblastomas) or through progression from low-grade astrocytomas (secondary glioblastomas). The two types show similar histologic features; however, they differ in terms of molecular alterations, with primary glioblastomas showing activation of the EGFR pathway, whereas secondary glioblastomas are more commonly associated with *TP53* mutations. Thus, the molecular genetics of these tumors demonstrates that they are distinct diseases and therefore may exhibit different prognoses and responsiveness to therapy (Ohgaki, 2007). Tyrosine kinase inhibitors, such as erlotinib and gefitinib, may offer a therapeutic option for primary tumors in which EGFR signaling is upregulated (Ohgaki, 2007).

Recent comprehensive genetic screens of GBM (Parsons, 2008) have confirmed that genetic loss is scattered across the entire genome, affecting numerous chromosomes. **Loss of heterozygosity (LOH) on chromosome 10 is the most frequent genetic loss in GBM**, occurring in 60%–80% of cases. Allelic losses on 1p and 7q have also been seen in GBM, but at lower frequencies. Loss of 1p occurs in 6%–20% of GBMs, and in combination with 19q loss may indicate a better prognosis and improved responsiveness to therapy; however, the combined loss of 1p/19q is a rare event in GBM (Kanu, 2009).

Gains in gene expression have also been demonstrated in GBM in the form of duplication of entire chromosomes, intrachromosomal amplification of specific alleles, or extrachromosomal amplification (often in the form of double minutes) and activating mutations. Many genes have been shown to be amplified in glioma; these include *EGFR*, *CDK4*, *SAS*, *MDM2*, *GLI*, *PDGFRA*, *MYC*, *N-MYC*, *MYCL1*, *MET*, *GADD153*, and *cKIT*. The most commonly amplified genes in glioblastoma are *EGFR* on chromosome 7 (in approximately 40% of cases), *CDK4*, and *SAS* (in approximately 15%).

Other molecular mechanisms of gliomagenesis include loss of the DNA repair enzyme, O(6)-methyl guanine DNA methyltransferase (MGMT), which specifically removes pro-mutagenic alkyl groups from the O6-position of guanine in DNA (Kanu, 2009). Expression of MGMT protects normal cells from carcinogens; however, it can also protect cancer cells from chemotherapeutic alkylating agents. This has been implicated as an important mechanism of drug resistance because it reduces the

TABLE 76-1

Most Common Genetic Alterations in Solid Tissue Tumors

Tumor type	Major molecular targets*	Main methods of detection	Clinical application
Solid Tissue Tumors			
Glioblastoma	<i>EGFR</i> , <i>TP53</i> , 10q, MGMT, mutations in <i>TP53</i> and <i>PTEN</i> , <i>P16INK4a</i> deletions	RT-PCR, methylation-specific PCR, FISH	Prognosis, treatment response
Oligodendroglioma	1p and 19q deletions, <i>EGFR</i> , <i>TP53</i>	FISH, RT-PCR, LOH	Diagnosis, prognosis, treatment response
Sporadic, nonhereditary breast cancer	<i>Her2/neu</i> , multiplex genes	FISH, IHC, RT-PCR, Oncotype, MammaPrint	Molecular classification, prognosis, treatment response
Hereditary breast cancer	<i>BRCA1</i> , <i>BRCA2</i> , <i>EGFR</i>	High-throughput sequencing, multiplex PCR, genetic counseling	Diagnosis, genetic counseling
Papillary thyroid cancer	<i>BRAF</i> , <i>RET</i> , <i>PTC1</i> , <i>PTC3</i>	FISH, RT-PCR, direct sequencing	Diagnosis, prognosis, therapeutic option
Follicular thyroid cancer	<i>PAX8-PPARγ</i>	IHC, FISH, RT-PCR	Diagnosis, prognosis
Medullary thyroid carcinoma	<i>RET</i>	Sequencing, PCR	Diagnosis, screening, surveillance
Non-small cell cancers of the lung	<i>EGFR</i> , <i>RAS</i>	PCR, sequencing, FISH	Prognosis, treatment response
Liver (hepatocellular)	<i>EEGFR</i> , <i>VEGFR</i> , glypican-3, <i>p53</i> , β -catenin, microRNA (miR-122a), multiple genes	FISH, PCR, sequencing, microarray	Diagnosis, prognosis, targeted therapy
Gastric cancer, intestinal type	<i>p73</i> mutations, <i>MSI</i> (<i>MLH1</i> and <i>MSH2</i>), LOH/mutations of <i>APC</i> genes, and <i>Her2/neu</i>	FISH, PCR, IHC	Diagnosis, prognosis
Gastric cancer, diffuse type	<i>CDH1</i>	FISH, PCR, IHC	Diagnosis, prognosis
Colon cancer	1. Mutated oncogenes: mainly <i>EGFR</i> , <i>KRAS</i> , <i>BRAF</i> , and <i>P13K</i> . 2. Mutated or deleted antioncogenes: <i>p53</i> , <i>APC</i> , <i>TGFBRI</i> , <i>SMAD2</i> , <i>SMAD4</i> 3. Microsatellite instability (MSI) genes and CpG island methylator (CIMP) genes	FISH, PCR, microarray, methylation-specific PCR, sequencing, array technology	Diagnosis, prognosis
Pancreatic cancer	Most pancreatic cancers: <i>KRAS</i> mutations Inactivating mutation or deletion or methylation of genes encoding <i>TP53</i> , <i>SMAD4</i> , <i>p16/CDKN2A</i> miRNAs (miR-196a, 217, 221, 376a, and 301)	PCR, sequencing PCR, methylation-specific PCR RT-PCR	Diagnosis Diagnosis (rarely), prognosis Diagnosis, prognosis
Renal cell carcinoma (RCC)	Chromosome 3p deletion, von Hippel-Lindau (<i>VHL</i>) gene deletion; hypoxia-inducible factor (<i>HIF</i>) overexpression	Sequencing, FISH (for <i>VHL</i>)	Diagnosis
Translocation-associated RCC	t(X;17)(p11.2;q25); <i>ASPL-TFE3</i> and <i>PRCC-TFE3</i> fusion genes	RT-PCR, FISH, IHC for the C-terminal domain of nuclear TFE3	Diagnosis, classification
RCC, clear cell	1. Carbonic anhydrase IX 2. Genes of immune response and angiogenesis 3. Proximal nephron markers: megalin, cubilin, adipophilin	Gene expression arrays, IHC	Diagnosis, prognosis, classification
RCC, papillary	1. Proximal nephron marker α -methylacyl-coA racemase	Gene expression arrays, IHC	Diagnosis, prognosis, classification
RCC, chromophobe	1. Abundant mitochondria 2. Distal nephron markers: β -defensin, parvalbumin, chloride channel Kb, claudin 7 and 8, and EGF	Gene expression arrays, IHC	Diagnosis, prognosis, classification
RCC, oncocytoma	1. Abundant mitochondria 2. Distal nephron markers: β -defensin, parvalbumin, chloride channel Kb, claudin 7 and 8, EGF	Gene expression arrays, IHC	Diagnosis, prognosis, classification
Bladder cancer	Aneuploidy of chromosomes 3, 7, and 17 and/or deletion of the 9p21 (encoding p16); <i>NMP 22</i>	FISH	Diagnosis
Prostate cancer	<i>TMPS2</i> (21q22.3) to transcripts of the ETS family member genes: overexpression of ETS proteins (e.g., <i>ERG</i> , <i>ETV1</i> , <i>ETV4</i> , <i>ETV5</i>)	FISH, ELISA, RT-PCR, gene expression arrays	Diagnosis, classification
Cervical cancer	HPV-6 and -18	Hybrid capture DNA assay, RT-PCR, Southern blotting, dot blot	Diagnosis, follow-up of abnormal PAP smears

TABLE 76-1

Most Common Genetic Alterations in Solid Tissue Tumors—Cont'd

Tumor type	Major molecular targets*	Main methods of detection	Clinical application
Ovarian Cancer			
Low-grade serous	<i>KRAS</i> , <i>BRAF</i>	PCR, Southern blotting	Diagnosis, classification
High-grade serous	<i>p53</i> deletion/mutation; Wnt/ β -catenin or PI3K/PTEN signaling pathway defects	PCR, Southern blotting	Diagnosis, classification
Mucinous	<i>KRAS</i> , <i>BRAF</i>	PCR, Southern blotting	Diagnosis, classification
Clear cell	<i>PI3K/PTEN</i> mutations	PCR, Southern blotting	Diagnosis, classification
Endometrioid	Mutations of <i>CTNNB1</i> (β -catenin)	PCR, Southern blotting	Diagnosis, classification
Melanoma	<i>CDKN2A</i> , <i>p14</i> , and <i>p16</i> inactivation; <i>NRAS</i> (G12V) and <i>BRAF</i> oncogenic mutations (V600E)	PCR, sequencing	Diagnosis, classification, therapy
Sarcoma			
Sarcoma with fusion genes involving the <i>TET</i> gene: Ewing's sarcoma	t(11;22)(q24;q12) translocation; fusion of <i>EWSR1</i> and an <i>ETS</i> family gene, mainly <i>FLI1</i>	RT-PCR, FISH, Southern blot	Diagnosis Prognosis
Sarcoma with fusion genes involving receptor tyrosine kinase: congenital fibrosarcoma	t(12;15)(p13;q25) translocation, resulting in fusion of <i>ETS</i> gene, <i>ETV6</i> with neurotrophin receptor (that has tyrosine kinase activity), <i>NTRK3</i> gene	RT-PCR, FISH, Southern blot	Diagnosis
Sarcoma with fusion genes involving chromatin remodeling: synovial sarcoma (SS)	t(X;18)(p11.2;q11.2) translocation resulting in fusion of <i>SS18(SYT)</i> gene with one of the <i>SSX</i> genes on the X chromosome, creating <i>SS18-SSX1</i> , <i>SS18-SSX2</i> , or <i>SS18-SSX4</i> chimeric genes Downstream targets of above fusion proteins: <i>CCND1</i> (cyclin D1) and <i>TLE1</i> that encodes a transcriptional corepressor	FISH, RT-PCR IHC	Diagnosis, classification Diagnosis
Sarcoma with fusion genes involving growth factors: dermatofibrosarcoma protuberans (DFSP) and giant cell fibroblastoma (GCF)	t(17;22)(q11;q13.1) translocation resulting in fusion of the <i>COL1A1</i> gene on chromosome 17 with the <i>PDGFRB</i> gene on chromosome 22, leading to <i>PDGFRB</i> overexpression	RT-PCR	Diagnosis, classification
Sarcoma with other types of fusion genes: alveolar rhabdomyosarcoma (ARMS)	t(2;13)(q35;q14) translocation that results in fusion of <i>PAX3</i> with <i>FOXO1A</i>	FISH	Diagnosis
Sarcoma with oncogenic mutations: gastrointestinal stromal tumor (GIST)	<i>cKIT/PDGFR</i>	PCR, sequencing, Southern blotting	Diagnosis
Sarcoma with no consistent genetic lesions: leiomyosarcoma (LMS)	Loss of 1p12-pter, 2p, 13q14-q21 (targeting the Rb pathway), 10q (targeting <i>PTEN</i>), 16q. Gains of 17p, 8q, and 5p14 pter. Activation of the PI3K-AKT pathway and mTOR	FISH	Diagnosis
Syndromic Cancers			
Familial adenomatous polyposis syndrome	Adenomatous polyposis coli (<i>APC</i>) (long arm of chromosome 5) or MutY human homologue (<i>MYH</i>) gene involved in repair of oxidative damage to DNA	PCR, sequencing, Southern blot	Diagnosis
Hereditary nonpolyposis colorectal cancer (HNPCC): Lynch syndrome	Microsatellite instability (MSI) in mismatch repair (<i>MMR</i>) genes, including <i>MLH1</i> , <i>MSH2</i> , <i>MSH6</i> , <i>MLH3</i> , and <i>PMS2</i>	IHC, PCR, sequencing	Diagnosis, classification, genetic counseling
Familial juvenile polyposis syndrome	Germline mutations of <i>SMAD4</i> , <i>BMPR1A</i> , and <i>ENG</i> ; also, mutations in kinase, <i>BMPR1A</i> (bone morphogenetic protein receptor Type IA), on chromosome 10q22.3. Involvement of TGF- β signal transduction pathway	PCR, sequencing	Diagnosis, classification
Peutz-Jeghers syndrome (PJS): melanotic mucocutaneous hyperpigmentation and GI hamartomas, which occur anywhere from the stomach to the anus; multiple polyps in small bowel	<i>STK11/LKB1</i> gene	PCR, sequencing	Diagnosis, classification
Multiple endocrine neoplasia (MEN)			

TABLE 76-1

Most Common Genetic Alterations in Solid Tissue Tumors—Cont'd

Tumor type	Major molecular targets*	Main methods of detection	Clinical application
MEN type 1: tumors in the parathyroid glands, in the stomach, pancreas and intestinal tract, anterior pituitary, endocrine pancreas, and duodenum, and by the presence of other, nonendocrine tumors such as hemangioma, ependymoma, and leiomyoma, often at a young age	MEN 1 tumor suppressor gene, <i>MEN 1</i>	PCR	Diagnosis, classification
MEN type 2: medullary thyroid carcinoma (MTC) and associated pheochromocytoma and hyperparathyroidism	<i>RET</i> (chromosome 10q11.2) (encoding a tyrosine kinase) mutations	PCR, sequencing	Diagnosis, classification
von Hippel–Lindau syndrome (VHL): neoplasia syndrome characterized by hemangioblastomas in the central nervous system and retina, pheochromocytomas, renal cysts and clear cell renal cell carcinoma, pancreatic cysts and islet cell tumors, endolymphatic sac tumors, and papillary cystadenomas of the epididymis and broad ligament	<i>VHL</i> tumor suppressor gene (three exons) on chromosome 3p25. Encodes VHL protein, critical in regulating hypoxia-inducible factor (HIF- α and - β)	PCR, sequencing	Diagnosis, classification
Familial paraganglioma syndromes	Mutation of three genes encoding subunits of mitochondrial succinate dehydrogenase (SDH complex): <i>SDHB</i> at 1p36.1 (PGL4), <i>SDHC</i> at 1q21 (PGL3), and <i>SDHD</i> at 11q23 (PGL1)	PCR	Diagnosis, classification
Cowden syndrome (CS); breast, thyroid, and endometrial cancers and other benign conditions, including multiple hamartomas in the colon, lipomas, fibromas	<i>PTEN</i> mutations	PCR	Diagnosis, classification
Li-Fraumeni syndrome; soft tissue sarcomas, breast cancer, osteosarcoma, brain tumors, childhood leukemias, and adrenocortical carcinoma	<i>p53</i> gene mutations	PCR, IHC	Diagnosis, classification
Neurofibromatosis 1 (NF1); neurofibroma and, less commonly, gliomas and other abnormalities (learning disability, vasculopathy, and bony abnormalities)	<i>NF1</i> , located on chromosome 17q11.2; diminished GTPase activating (GAP) activity activating the ras signal transduction pathway	FISH, direct sequencing, long-range PCR with Southern blot analysis, and/or cytogenetic analysis	Diagnosis, classification
Neurofibromatosis (NF2) and schwannomatosis. NF2 involves schwannomas, meningiomas, and ependymomas	<i>NF2</i> gene (chromosome 22)	Sequencing, mutation scanning, duplication/deletion testing, PCR, quantitative PCR, microarray, comparative genomic hybridization, or combination	Diagnosis, classification

ELISA, Enzyme-linked immunosorbent assay; FISH, fluorescent in situ hybridization; IHC, immunohistochemistry; LOH, loss of heterozygosity; PCR, polymerase chain reaction; RT-PCR, real-time PCR.

*Full names and functions of molecular targets (i.e., oncogenes and oncoproteins) listed in the second column may be found in the corresponding sections of this chapter describing these targets and the corresponding references.

cytotoxicity of alkylating chemotherapeutic agents. Loss of MGMT expression may be caused by methylation of promoter CpG islands, which have been detected in 75% of secondary GBMs—much more frequently than in primary GBMs (36%). Immunohistochemical staining for MGMT does not offer a reliable way to stratify GBM (Kanu, 2009), and PCR assay is therefore necessary. *TP53* is one of the more commonly studied TSGs in GBM. Loss of normal *TP53* function due to mutation occurs more frequently in secondary GBM. Thus, the major molecular targets of glioblastomas are EGFR, *TP53*, 10q LOH, and deletion of the *MGMT* gene. These can be detected using RT-PCR, methylation-specific PCR, and FISH. The main clinical applications are related to prognosis and treatment response. These findings are summarized in Table 76-1 and, in greater detail, in Table 76-2.

Oligodendroglioma

Oligodendroglioma is an infiltrating glioma of the cerebral cortex diagnostically characterized by a triad of uniformly round to ovoid nuclei, perinuclear halos, and an even distribution of cells, together with a delicate chicken wire-type of vasculature. However, in a significant number of these lesions, the microscopic morphology is not so clear cut, and distinction from other diffuse glial lesions may be difficult. Combined loss of 1p and 19q (Fig. 76-1, A through C) is typical in oligodendroglioma (Aldape, 2007), and loss of 19q occurs in astrocytoma and mixed oligoastrocytoma (Aldape, 2007). The incidence of 1p/19q loss varies from 50%–80% in oligodendroglioma in different studies, and it is 1%–10% in other gliomas, which indicates its utility in differentiating the diagnosis. Recent studies suggest that the combined loss of 1p/19q may follow a (1; 19)(q10; p10)

Figure 76-1 Examples of fluorescent in situ hybridization in cancer diagnosis. Oligodendroglioma with **A**, 1p and **B**, 19q deletions compared with **C**, normal cells. Green color in **A**, 1q probe; red color in **A**, 1p probe; green color in **B**, 19p probe; red color in **B**, 19q probe. **D**, Her2/neu amplification compared with **E**, normal cells. TABLE 76-2 Common Genetic Alterations in Glioblastoma Multiforme		
	Primary GBM	Secondary GBM
LOH 10q	70%	63%
EGFR amplification	36%	8%
P16INK4a deletion	31%	19%
TP53 mutation	28%	65%
PTEN mutation	25%	4%

Data from Ohgaki H, Kleihues P. Genetic pathways to primary and secondary glioblastoma. *Am J Pathol* 2007;170:1445–53.
EGFR, Epidermal growth factor receptor; *GBM*, glioblastoma multiforme; *LOH*, loss of heterozygosity; *PTEN*, phosphate and tensin homologue deleted on chromosome ten.

translocation, with subsequent loss of the derivative chromosome der(1;19) (q10; p10) (Aldape, 2007). Identification of 1p/19q loss is associated with two unique features of tumor biology with clinical indications: first, they grow slowly, even those that are anaplastic in nature; second, they correlate with better prognosis and response to chemotherapy (Kuo, 2009). In terms of treatment response, initial studies suggested that 1p/19q loss is a marker of response to PCV (procarbazine, lomustine/CCNU, and vincristine) or temozolomide chemotherapy (Kuo, 2009). Thus, the 1p/19q status has become an important part of diagnosis, prognosis, and predicted therapeutic response of oligodendrogliomas. In addition to 1p/19q alteration, LOH mutations in *p53* and *p16* may be associated with poor survival or tumor progression (Kuo, 2009).

BREAST CANCER

Breast cancer is the most common cancer in women and the second most common cause of cancer death in women in the United States. Until recently, breast cancer was characterized according to tumor type (ductal vs. lobular carcinoma), histologic grade (I–III), steroid hormone receptors (ER and PR), and *Her2/neu* status (positive vs. negative), along with metastasis to lymph nodes and distant organs, for its prognosis and treatment. Gene expression profiling has recently been introduced as a potentially useful adjunct for the management of recently diagnosed breast cancer.

Sporadic, Nonhereditary Breast Cancer

Various genetic, epigenetic, and genomic changes have been associated with breast cancer. Traditionally, estrogen receptor (ER) and progesterone receptor (PR) status is used as a prognostic and predictive marker for breast cancer. *Her2/neu* (detailed in Chapter 74) status has been added in the past decade as a breast cancer prognostic and predictive marker. The FISH method has been used primarily to determine the copy number of the *Her2/neu* gene (Fig. 76-1, **D** and **E**) for the purpose of selecting Her2-targeted therapies such as trastuzumab and lapatinib in both adjuvant and neoadjuvant settings. Enumeration of 20 interphase nuclei from tumor cells on a given case is reported as the ratio of average *Her2/neu* copy number to that of chromosome enumeration probe 17 for centromere, CEP17. Specimens with amplification showed a *Her2/neu*:CEP17 signal ratio ≥ 2.0 as abnormal, and a ratio < 2.0 as normal. A three-color FISH assay has been commercialized recently for assessment of standalone prognosis in ER-positive and ER-negative stage I breast cancers (Ross, 2009).

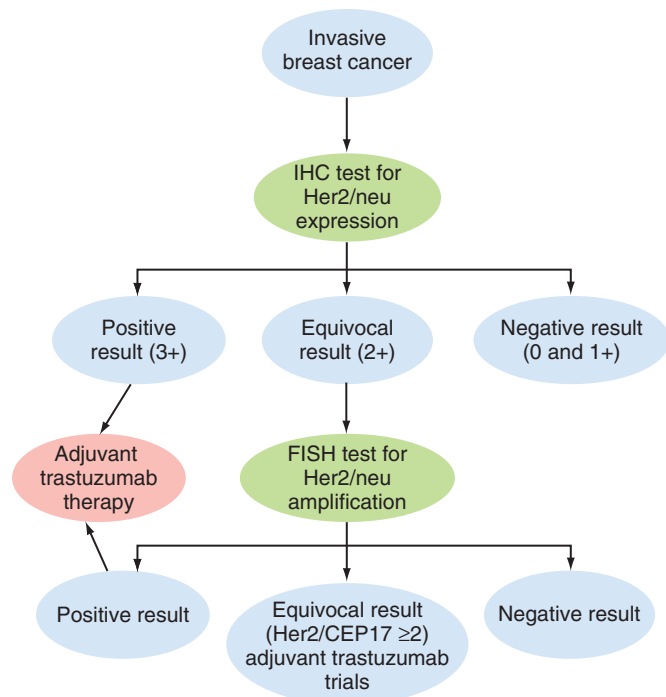

Figure 76-2 Algorithm using Her2/neu status in diagnosis and treatment of breast cancer.

In addition, HercepTest (Dako Corp, Carpinteria, Calif.), an immunohistochemistry (IHC) for *Her2/neu* using a polyclonal antibody, was the first U.S. Food and Drug Administration (FDA)-approved test; subsequently, Pathway (Ventana Medical Systems, Tucson, Ariz.) produced a monoclonal antibody (CB11) for *Her2/neu* for the same response indication that has also been approved by the FDA and is used in combination with FISH (Fig. 76-2). IHC is widely used to measure prognostic factors, including ER, PR, Her2/neu, and the proliferation marker, Ki-67, and to predict response to hormonal and Her2-targeted therapies (Ross, 2009).

Concerns associated with IHC-based assays for multiple markers include the nonlinear nature of IHC staining, the different subcellular localization of different markers, and the impact of different slide scoring thresholds for different antibodies. The introduction of whole genome profiling technologies has greatly expanded our knowledge of the genomic pathways associated with the development and progression of breast cancer (Bao, 2008). These research results have led to the development of several commercialized tests with multigenes/proteins as prognostic and predictive tools for clinical application using IHC, FISH, RT-PCR, and genomic microarray technologies with integrated bioinformatic/statistical algorithms designed to calculate the disease recurrence and survival of the patient (Ross, 2008).

Microarray-based gene expression profiling is now extensively used to define cellular functions and regulatory mechanisms, including the evaluation of breast cancer. Microarray platforms commonly used include Affymetrix GeneChip (Affymetrix Corporation, Santa Clara, Calif.) and the Agilent custom microarrays (Agilent Technologies, Santa Clara, Calif.). These technologies require the use of fresh or frozen tissue for messenger ribonucleic acid (mRNA) extracts and have not been fully adapted for use in formalin-fixed, paraffin-embedded (FFPE) tissue. Molecular classification of breast cancer has been proposed, based on gene expression profiling, to include luminal-like, normal-like, Her2-positive, and basal-like subtypes of invasive breast cancer (Ross, 2008). It is important to note that all of the luminal groups of breast cancers are ER positive, and nearly two thirds of them are of low or intermediate histologic grade, whereas 95% of all (Ross, 2009) basal-like cancers are ER negative, and 91% of these tumors are of high grade (Bao, 2008). Studies of clinical outcomes based on molecular subtypes have shown that luminal A is more sensitive to antiestrogen than is luminal B. Her2-positive responds to trastuzumab, an anti-Her2 antibody, whereas basal is more aggressive (but is especially sensitive to anthracycline-based neoadjuvant chemotherapy) than are the luminal breast cancers (Ross, 2009). Basal-like and Her2-positive subgroups are associated with the highest rates of pathologic complete response to neoadjuvant multiagent chemotherapy (Ross, 2009).

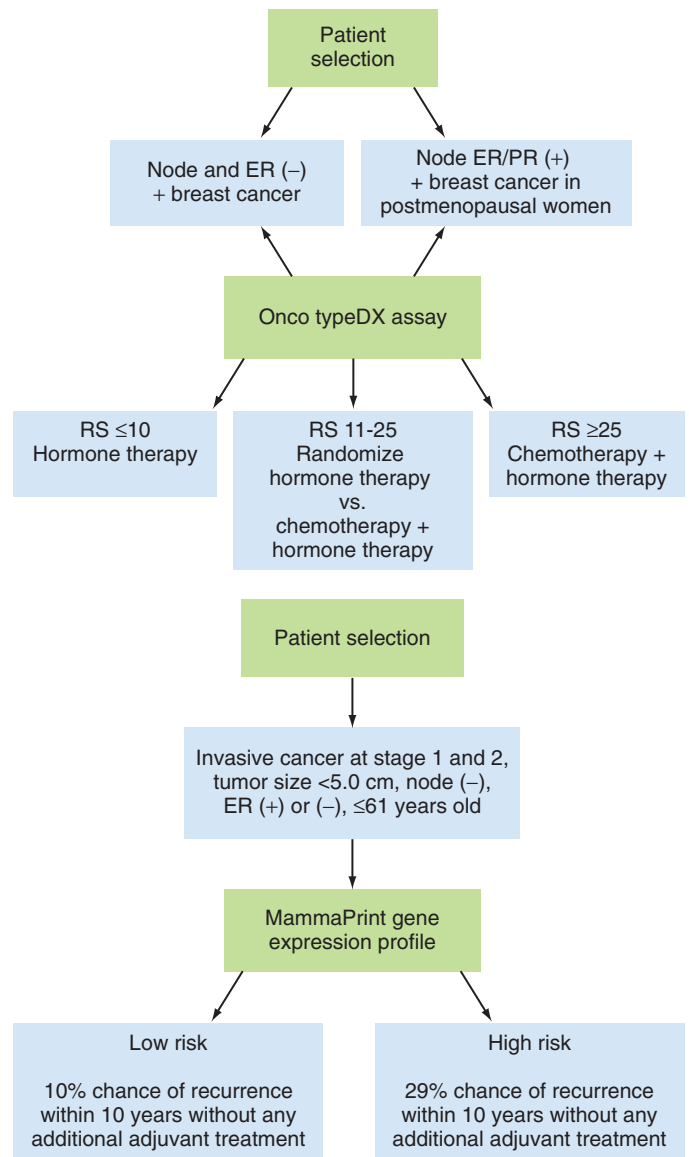

Figure 76-3 Algorithm of A, OncotypeDx and B, MammaPrint assays in breast cancer management.

The two prototypes of gene microarray-based clinical tests are the OncotypeDx and MammaPrint assays (Fig. 76-3) (Kato, 2009; Oakman, 2009). OncotypeDx (Genomic Health, Inc., Redwood City, Calif.) is a 21-gene multiplex prognostic and predictive RT-PCR assay performed on primary FFPE breast cancer samples. The original 16 informative genes (Paik, 2004) that calculate the recurrence score (RS) were discovered on archived FFPE samples by transcriptional profiling and then were converted to the FFPE RT-PCR assay (Ross, 2008). OncotypeDx determines the 10-year risk for disease recurrence in patients with ER-positive, lymph node-negative tumors by using a continuous variable algorithm and assigning a tripartite RS (17, low risk; 18–30, intermediate risk; >30, high risk). Of the multiple pathways assessed by this assay, the proliferation and ER pathways are the most influential in RS calculation, followed by the Her2 pathway. High relative levels of ER mRNA and low levels of Ki-67 proliferation gene mRNA have a low RS. Low levels of ER mRNA and high levels of Ki-67 mRNA have a high RS. The other 14 informative mRNA levels play their greatest roles in determining the RS in tumors with intermediate ER and Ki-67 mRNA levels. It should also be noted that OncotypeDx is best suited for detecting breast cancers with a low potential for recurrence. The MammaPrint assay (Agendia BV, Amsterdam, The Netherlands) was the first fully commercialized microarray-based multi-gene assay for breast cancer. This test is currently designed as a pure prognostic assay, has received 510 (k) clearances from the FDA, and is offered as a prognostic test for lymph node-negative breast cancer in women younger than age 61 with ER-positive or ER-negative tumor. This test was also the first assay to be approved by the FDA's new in vitro

diagnostic multivariate index assay classification. Unlike OncotypeDx, this test cannot currently be performed on FFPE tissues but requires fresh-frozen tumor samples or tissues collected into an RNA preservative solution. The 70 genes that make up the MammaPrint assay are focused primarily on proliferation; additional genes are associated with invasion, metastasis, stromal integrity, and angiogenesis. Of note, the OncotypeDx and MammaPrint assays have only one individual gene in common—the *SCUBE2* gene, which is a member of the ER pathway. Unlike the OncotypeDx test, which features a continuous RS result, the MammaPrint test uses a dichotomous “high risk versus low risk” result format. The MammaPrint test does not include ER, PR, or Her2 in the 70-gene microarray. A new assay, TargetPrint (Agendia BV), has recently been launched that measures the mRNA of these three genes on the Agilent microarray system.

Multigene testing procedures such as disease classifiers and prognostic and predictive markers have been introduced with the use of slide-based methods (e.g., IHC, FISH) or molecular platform-based methods such as quantitative multiplex PCR and genomic array profiling. Morphologically based mRNA extraction performed with the use of tissue macrodissection or microdissection is recommended for analysis, as it is highly enriched for invasive carcinoma and is not diluted with cells from benign tissues and in situ carcinoma areas (Ross, 2008). The heterogeneous expression of important mRNAs, such as ER, Her2, and Ki-67, often reflected in the varying histologic grades seen in larger tumors, can influence the predictive accuracy of transcriptional profiling measurements. One caveat is that, although the number of genes that can be simultaneously assessed by multiplex qRT-PCR is significantly greater than that for IHC, multiplex qRT-PCR requires a more complex statistical evaluation of the gene expression profiles. Nevertheless, the RT-PCR technique has been used to predict overall prognosis and response to both hormonal and cytotoxic therapies.

Hereditary Breast Cancer

Hereditary breast cancer (HBC) accounts for approximately 10% of all breast cancers. Positive family history is the strongest risk factor, as it is present in about 20% of breast cancer cases. Population-based studies indicate that 15% of familial risk can be attributed to *BRCA* gene mutations, and that a further 10% involve *TP53*, phosphate and tensin homologue (*PTEN*), *ATM*, and *CHEK2*; the rest may be explained by a polygenic model. A significant number of HBC-prone families are characterized by the more common hereditary breast-ovarian cancer syndrome. The *BRCA* genes operate as TSGs, and germline mutations affecting one allele of *BRCA1* or *BRCA2* confer susceptibility to breast and ovarian cancers. The cumulative risks of developing breast cancer by the age of 70 years approach 50%–70% in *BRCA1*-mutation carriers, and ovarian cancer, 30%–40% (Venkitaraman, 2009). For *BRCA2*-mutation carriers, the risk is 40%–50% for breast cancer and 10%–15% for ovarian. However, individuals who carry *BRCA2* mutations also have an increased risk of other cancers, including those of the male breast (≈seventy-fivefold relative risk), pancreas (fourfold to eightfold), and prostate (twofold to fourfold) (Venkitaraman, 2009). The spontaneous instability of chromosome structure and number is a hallmark of *BRCA*-deficient cells and arises from the distinct cellular functions performed by the *BRCA1* and *BRCA2* proteins in DNA repair and mitotic control. Since the discovery of *BRCA* genes and the development of methods for mutation screening, identification of *BRCA*-mutation carriers during the clinical management of familial cancer cases has become widespread. Gene expression profiling has revealed that tumors from patients who are *BRCA1*-mutated segregate within the basal subgroup of breast cancers (Venkitaraman, 2009) of the five different molecular groups, as discussed earlier. Tumors from *BRCA1*-mutation carriers are likely to stain positive for basal cytokeratins 5/6 and 14, and to exhibit negative estrogen receptor staining. These breast carcinomas also commonly stain for EGFR. *BRCA1*-associated tumors are commonly of high grade and are *p53*-mutated. They have a tendency to occur in younger women and carry a poor prognosis (Venkitaraman, 2009).

THYROID CANCER

Thyroid cancer is the most common endocrine neoplastic condition. The two most frequent types of thyroid malignancy derived from follicular cells are papillary and follicular carcinomas, which constitute approximately 80% and 15%, respectively, of all thyroid cancers. These follicular cell-derived tumors are well differentiated, in contrast to poorly differentiated and anaplastic carcinomas, which constitute about 2% of cases. Another malignancy in thyroid is medullary carcinoma, which originates from parafollicular C cells and accounts for approximately 3% of cases. Several

genetic alterations in various thyroid tumors have been well documented, including translocations and point mutations. The genetic alteration in thyroid cancer involves *RET*, *BRAF*, *RAS*, and *PAX8*.

Papillary Thyroid Carcinoma

RET/PTC rearrangement and point mutations of *RAF*, in particular, the *BRAF* form, and *RAS* genes are found in more than 70% of cases of papillary thyroid carcinoma (PTC) (Nikiforova, 2008). *RAF* is a direct target of ras-p21. The *BRAF* gene mutation is the most common known genetic alteration in papillary carcinoma and is found in approximately 45% of these tumors (Nikiforova, 2008). A majority of mutations involve T1799A transversion mutation in exon 15 of the gene, which causes amino acid change from valine to glutamine at amino acid residue 600 (V600E), leading to constitutive activation of BRAF kinase, subsequent phosphorylation of MEK and ERK protein kinases (see Chapter 74), and downstream effectors of the mitogen-activated protein kinase (MAPK) pathway, as is summarized in Chapter 74 (see Fig. 74-1). Other mechanisms of *BRAF* activation, although rare, include K601E point mutation, small in-frame insertions or deletions surrounding codon 600, and *AKAP9-BRAF* rearrangement, which is more commonly associated with radiation exposure papillary carcinoma. *BRAF V600E* mutation is highly prevalent in papillary carcinoma with classical histology and in the tall cell variant. It has been correlated with aggressive features such as extrathyroid extension, advanced tumor stage at presentation, recurrence, and lymph node involvement and/or distant spread (Xing, 2005). Cancers with these mutations have decreased ability to trap radioiodine and lead to treatment failure and more aggressive behavior (Nikiforova, 2008). Detection of *BRAF* mutation can be achieved by direct sequencing, colorimetric mutation detection assay based on shifted terminal assay (Xing, 2004), real-time PCR, and allele-specific SYBR green PCR on an FNA sample, which is virtually diagnostic of papillary carcinoma. *BRAF* mutation represents an attractive therapeutic target for papillary carcinoma with the advent of various BRAF inhibitors (e.g., BAY43-9006) (Wan, 2004; Wilhelm, 2004).

The *RET/PTC* gene rearrangement is another prominent genetic alteration that plays a role in the pathogenesis of up to 20% of sporadic PTCs (Nikiforova, 2008). The *RET* gene, located on chromosome 10q11.2, encodes the tyrosine kinase receptor consisting of an extracellular ligand binding domain for the glial-derived neurotrophic factor family of growth factors, a cysteine-rich region, a transmembrane domain, and an intracellular tyrosine kinase domain. *RET* is highly expressed in parafollicular C cells and at very low levels in thyroid follicular cells (Nikiforov, 2008). *RET/PTC* rearrangements are a very early event in thyroid cancer development; this would explain their high prevalence in occult or microscopic PTC. Twelve forms of *RET/PTC* rearrangements have been reported to date, linking the 3' portion of the *RET* gene with the 5' portion of various different genes of the PTC family (Nikiforova, 2008). Of remaining genes, the two most common are *PTC1* (*H4*) and *PTC3* (*ELF1*, *ARA70*, *NCOR4*), which account for up to 70% and 30% of rearrangements in sporadic PTC, respectively (Nikiforova, 2008). In particular, *RET/PTC* rearrangements are more frequent in individuals exposed to ionizing radiation (50%–80%) (Nikiforova, 2008), with the exception of *ELKS-RET* and *HOOK3RET* fusion. *RET/PTC* rearrangements are also more frequent in children (40%–70%) (Nikiforova, 2008) as compared with the general population (15%–30%). Papillary carcinomas with *RET/PTC* gene rearrangements typically present in younger individuals and exhibit a high rate of lymph node metastasis with classical papillary histology and lower stage at presentation, particularly in cases harboring *RET/PTC1* (Nikiforova, 2008). In tumors arising after radiation exposure, *RET/PTC1* was found to be associated with classic papillary histology, whereas the *RET/PTC3* type was more common among solid variants (Nikiforova, 2008).

Activated RET kinase has been explored as a target of therapy using TKIs such as ZD6474 (Nikiforova, 2008). The distribution of *RET/PTC* rearrangements within each tumor may vary from involving almost all neoplastic cells (clonal *RET/PTC*) to being detected only in a small fraction of tumor cells (nonclonal *RET/PTC*) (Nikiforov, 2008). This heterogeneity is a potential problem in RET receptor-targeted therapy.

Other point mutations involving several specific sites (codons 12, 13, and 61) in *NRAS*, *HRAS*, and *KRAS* genes are found in 10%–20% of cases of papillary carcinoma. These mutations are almost always found in the follicular variant of papillary carcinoma (Nikiforova, 2008).

Follicular Carcinoma

Most of the frequent genetic alterations in follicular carcinoma are *RAS* point mutations and *PAX8-PPAR γ* rearrangements, altering the PI3K/AKT signal pathway. Several studies have reported the utility of

Figure 76-4 Clinically significant mutations of epidermal growth factor receptor mutation in cancer.

molecular testing in diagnosing this type of thyroid cancer preoperatively on FNA specimens.

A *RAS* mutation is found in 40%–50% of conventional follicular carcinomas and in 20%–40% of adenomas. It is interesting to note that the most common *ras* mutations, instead of occurring at codon 12, as in most other cancers, occur at codon 61 for *NRAS* and *HRAS* (Nikiforova, 2008). These mutations are associated with tumor dedifferentiation, a less favorable prognosis, and metastasis to bone (Nikiforova, 2008).

The *PAX8-PPARγ* gene rearrangement is a result of the translocation t(2;3)(q13;p25). It leads to a fusion between the *PAX8* gene, which encodes a thyroid-specific paired domain transcription factor, and the *PPARγ* gene. It occurs in 35% of conventional follicular carcinomas and has a lower prevalence in oncocytic (Hürthle cell) carcinomas (Nikiforova, 2008). Detection of *PAX8-PPARγ* rearrangement is almost always diagnostic of follicular carcinoma. Tumors harboring *PAX8-PPARγ* rearrangements tend to present in a younger age group, are smaller, and exhibit solid or nested patterns and more frequent vascular invasion. This rearrangement results in overexpression of the *PPARγ* protein that is detectable on IHC (Nikiforova, 2003).

Medullary Carcinoma

Medullary carcinoma of the thyroid (MTC) is a sporadic malignancy in a majority of cases (75%), with the remainder spanning three familial syndromes, including multiple endocrine neoplasia (MEN 2A and MEN 2B) and familial MTC (FMTC). In MTC, *RET* is activated by point mutations, in contrast to its activation by chromosomal rearrangement in PTC. In sporadic medullary carcinomas, somatic mutations of *RET* are found in 20%–80% of cases without a germline mutation. Germline mutations in *RET* are found in almost all patients with familial forms of medullary carcinoma; this correlates with the aggressiveness of MTC.

LUNG CANCER

Lung cancer remains the most common cause of cancer-related death among men and women worldwide. Epithelial tumors of the lung are of four principal types: squamous cell carcinoma, adenocarcinoma, large cell carcinoma, and small cell carcinoma. Clinically, the most important distinction is noted between small cell carcinoma and the others, which can be grouped together as non-small cell carcinoma. Small cell cancers

respond to chemotherapy, whereas non-small cell carcinomas (NSCLCs) are removed surgically if possible. *EGFR* mutations have been identified in certain NSCLCs, among other types of cancer (e.g., colon, glioma, squamous cell carcinoma, Wilms' tumor). *EGFR* is a **membranous oncoprotein** that induces cell proliferation upon activation. Binding of a ligand to receptor activates its tyrosine kinase activity, which phosphorylates several substrates on a number of signal transduction pathways, leading to DNA synthesis and expression of oncogenes such as *fos* and *jun* and finally cell growth (see Chapter 74). Increased *EGFR* signaling can be the result of *EGFR* gene amplification, protein overexpression, or specific activation mutations in the *EGFR* gene, as described in detail in Chapter 74.

It has been shown that a subset of patients with NSCLC (10%–40%) (Coate, 2009) have specific activating mutations in the *EGFR* gene (Fig. 76-4) that are associated with increased sensitivity to TKIs, such as gefitinib (Iressa) or erlotinib (Tarceva), targeting *EGFR* in lung cancer. Common activating *EGFR* mutations occur most often in exons 18 to 21 and cluster in two major hot spots. The prototype mutation *L858R* in exon 21 (40% of *EGFR* mutations) encoding the tyrosine kinase domain and small in-frame deletions in exon 19 (>50%) are reportedly most often associated with responses to *EGFR* TKI therapy. Mutations in exons 18 and 20 account for the remaining 10% of *EGFR* mutations in NSCLC (Sholl, 2009). Recent studies have reported that *EGFR* gene mutations are more common among females, Asians, and nonsmokers with adenocarcinoma; these are the same groups that have the highest response rates to TKIs (Sequist, 2008). Furthermore, increased gene copy numbers detected by FISH and protein overexpression by IHC of *EGFR* have emerged as predictors of efficacy of *EGFR* TKIs. Therefore, these predictors are used in the selection of patients for anti-*EGFR* therapies (El-Zammar, 2009). Overall, it appears that the FISH test is the first step, followed by PCR for FISH-negative cases; this is the most effective method (El-Zammar, 2009). Recent studies have demonstrated that in patients with *EGFR* mutations, the *EGFR* locus is often concurrently amplified.

Mutations in *KRAS*, frequently in codons 12 and 13, have been reported in up to 30% of cases of lung adenocarcinoma (Coate, 2009). These mutations are usually found in cancers of smokers and are more common in adenocarcinoma (30%–50%) than in NSCLC (15%–20%). Conversely, activating mutations in the *KRAS* gene were reportedly associated with resistance to *EGFR*-TKIs and have an adverse effect/poor outcome in NSCLC patient survival on *EGFR*-TKI therapy (Mascaux,

2005). Thus, the recommended molecular workup for NSCLC includes *EGFR* mutation screening by restriction fragment length polymorphism (RFLP) analysis, *EGFR* gene copy number using two color probes with FISH, and screening for *KRAS* mutations. The latter is important because *EGFR*-TKI therapy is less effective if oncogenic K-ras mutations occur since ras occurs downstream of *EGFR* (see Chapter 74) (Mascaux, 2005).

HEPATOCELLULAR CARCINOMA

Hepatocellular carcinoma (HCC) is the sixth most common malignancy and the third most common cause of cancer death worldwide. Major risk factors include chronic viral infection (hepatitis B virus [HBV] and hepatitis C virus [HCV]), alcoholic/nonalcoholic liver disease, environmental carcinogens (e.g., aflatoxin B1), and inherited genetic disorders (e.g., Wilson's, hemochromatosis, α_1 -antitrypsin deficiency, tyrosinemia) (McGlynn, 2005; Parkin, 2005; Clark, 2006; Motola-Kuba, 2006). The development of HCC is a multistep process, comprising of hyperplastic change, dysplasia, early HCC, and well-developed HCC in the setting of chronic hepatitis or cirrhosis (Takayama, 1990; Theise, 2002), or in a small percentage of patients without cirrhosis.

The genomic abnormality of HCC is heterogeneous, largely as the result of various molecular mechanisms of carcinogenesis related to different causes and multifactorial processes (Jain, 2010a). HCV-related HCC has an exclusive gain at 10q, and loss of 4q and 16q and gain of 11q are seen preferentially in HBV-positive cases (Kusano, 1999; Nishida, 2003). Most HCCs are aneuploid and harbor multiple different chromosomal abnormalities, including nonrandom, recurrent DNA copy number losses on multiple chromosomal arms 1p, 4p, 5q, 6q, 8p, 9p, 13q, 16p, 16q, and 17p, and gains on 1q, 6p, 8q, and 17q, detected by conventional cytogenetic studies and CGH. Chromosome 1q is the most common aberration in several geographic locations (Guan, 2001; Chang, 2002; Terracciano, 2003). Frequently deleted chromosome regions by LOH in HCCs contain many TSGs, including *p53*, *Rb*, *p16*, *PTEN*, and *DLG1*, and oncogenes such as insulin-like growth factor-2 receptor *IGF2R* (Hsia, 1994; Edamoto, 2003; Matsuda, 2003). LOH at chromosome 1p usually is seen in early, small, or well-differentiated HCC (Kuroki, 1995), whereas LOH at chromosomes 16p and 17p is more frequently associated with aggressiveness of HCC, including advanced stage and poor prognosis (Tamura, 1997). By CGH, abnormalities in chromosomes 8p, 17p, and 19p are associated with metastasis of HCC (Zhang, 2003).

Dysregulation of the major signal transduction pathways is found in all HCCs, but differs with various associated causes. Abnormal activities of Wnt/ β -catenin, hedgehog, transforming growth factor (TGF)- β , ras-p21 and MEK/ERK, IGF, and *PTEN* signaling pathways, as well as apoptosis, *p53*, *Rb*, and microsatellite stability, are commonly found in HCCs, irrespective of etiology, reflecting common pathogenetic mechanisms (e.g., chronic liver injury, cirrhosis) (Edamoto, 2003; Zucman-Rossi, 2006; Aravalli, 2008). However, HCC resulting from different causes may predominantly affect certain pathways. HCV-associated HCC shows significant abnormality in both Wnt/ β -catenin and MAPK pathways (Bai, 2003; Colnot, 2004). Dysfunction of Wnt/ β -catenin, *p53*, *pRb*, and MAPK (Budhu, 2006) and cytokine signaling are more commonly seen HBV-related HCCs (Azechi, 2001; Bai, 2003; Colnot, 2004; Yoshida, 2006). Tumors associated with alcoholism have more frequent alterations in the *Rb1* and *p53* pathways than those caused by HCV infection (Marchio, 2000). The "aflatoxin-associated" codon 249 mutation of *p53* is identified only in samples from areas with high aflatoxin content (Asia and Africa) (Kirk, 2000; Huang, 2003).

Molecular approaches have been advocated to classify and predict clinical outcome and facilitate target molecular therapies using gene expression microarray and single-nucleotide polymorphism arrays (Boyault, 2007; Katoh, 2007; Chiang, 2008; Hoshida, 2008). Using global gene expression profiling, analyses of 91 human HCCs employing DNA microarrays containing 21,329 unique genes could subclassify HCC into two distinctive groups: (1) low survival subclass (class A, overall survival time 30.3 ± 8.02 months), which show strong cell proliferation and antiapoptosis gene expression signatures (such as *PCNA* and cell cycle regulators such as *CDK4*, *CCNB1*, *CCNA2*, and *CKS2*), as well as genes involving ubiquitination and sumoylation; and (2) high survival subclass (class B, overall survival time 83.7 ± 0.3 months) without the above expression signature (Lee, 2004a). Similarly, whole genomic array CGH analysis of 87 HCCs revealed two groups of tumors (clusters A and B) based on differences in chromosomal alteration profiles. Cluster A showed significant association with clinical features, such as HBV infection, higher serum α -fetoprotein levels, and a higher incidence of intrahepatic metastasis, along with shorter

overall patient survival and poor clinical outcome (Katoh, 2007). Gene expression profiles could also subclassify patients with HCC into different survival groups on the basis of paraffin-embedded surrounding nontumoral liver tissue, not tumor tissue (Hoshida, 2008). A genome-wide transcriptomic analysis of 60 HCC tumors found a 16-gene signature to classify HCC tumors into six robust subgroups of HCC, labeled G1–G6. Each group has unique clinical and genetic characteristics that are based on chromosome stability status: chromosome unstable (groups G1–G3) and chromosome stable (G4–G5). Because each group of tumors has specific pathways of activation (i.e., protein kinase B [AKT or PKB] in G1–G2 and Wnt pathways in G5–G6), this molecular classification not only provides prognostic information, but also helps in the development of targeted therapies for HCC (Boyault, 2007).

Current treatment modalities usually are not effective because patients with HCC generally are diagnosed at an advanced stage. Treatment effects are also influenced by significant clinical and genetic heterogeneity among HCCs associated with different causes. Therefore, standard treatments may not work for all HCCs. Molecular target therapies specific for a group of HCCs with similar genetics recently have been introduced. The target therapy aims to inactivate the activated oncogene and recover the tumor's suppressor and/or repair genes and other genes or molecules related to the development of HCC, thereby correcting abnormal genes or their functions, as well as biological behavior. Many candidate genome-based drug targets have been discovered recently by microarray technology, promoter arrays for whole genome epigenetic aberration analysis, chromatin immunoprecipitation-on-chip analysis, and high-throughput sequencing systems. Examples of target genes or molecules include VEGFR, *EGFR*, *DDEFL*, *VANGLI*, *WDRPUH*, *Ephrin-A1*, *glypican-3*, number gain 7q, PFTAIRES protein kinase 1 and paternally expressed 10, and miR-122a (Yagyu, 2002; Okabe, 2003; Okabe, 2004; Zender, 2008). Moreover, some reagents or drugs that work against these candidate target genes or molecules such as monoclonal antibodies, small molecules, and antisense have been on phase II and III clinical trials for therapeutic use; many have been shown to be effective. Sorafenib, an oral multikinase inhibitor of the vascular endothelial growth factor receptor, and Ras kinase have been approved by the FDA as molecularly targeted anticancer agents (Midorikawa, 2009; Thomas, 2009). Some of the other agents targeting similar genes are being tested in preclinical and clinical trials for HCC. These include *EGFR* inhibitors (anti-*EGFR*, gefitinib, and erlotinib), vascular endothelial growth factor (VEGF) vascularization inhibitors (antiangiogenesis, sorafenib, bevacizumab), and multikinase targets in patients who are unresectable or have metastatic HCCs (Huynh, 2009).

GASTRIC CANCER

Gastric cancer (GC) is the fourth most common cancer and is second only to lung cancer as the leading cause of cancer-related death worldwide (Ferlay, 2004). A majority of GCs are adenocarcinomas, histologically classified into two major groups by Laurén's classification: intestinal type with glandular pattern, and diffuse or poorly differentiated type with a signet ring cell morphology in some cases (Laurén, 1965). These two types of GCs have a distinct molecular basis of carcinogenesis, and clinical and genetic characteristics. The main causes of the intestinal type include dietary habits, environmental factors, and *Helicobacter pylori* infection (Kelley, 2003). Gastric cancer risk is also associated with hereditary tumor syndromes such as hereditary diffuse-type gastric cancer syndrome, hereditary nonpolyposis colorectal cancer (HNPCC), Li-Fraumeni syndrome, Peutz-Jeghers syndrome (i.e., familial adenomatous polyposis [FAP] and juvenile polyposis) (Traverso, 2002; Napieralski, 2005).

The development of intestinal-type GC is a multistep process that proceeds from gastritis (chronic or atrophic) and related changes (pernicious anemia, etc) to intestinal metaplasia, dysplasia, and eventually carcinoma (Oberhuber, 2000; Kelley, 2003). These processes are accompanied by a series of genetic alterations. The inactivation mutation of the TSG *p53* (see Chapter 74) occurs in an early stage of carcinogenesis (i.e., intestinal metaplasia [38%] and dysplasia [58%]), and is also seen in 38%–71% of GCs (Joypaul, 1993; Shiao, 1994; Xiangming, 2000). Mutation in *p73*, a member of the *p53* family, is indicated in the development of GC associated with *H. pylori* infection in mouse mode. High-level of microsatellite instability (MSI-H) is frequently seen in intestinal-type GC, largely caused by hypermethylation of the promoter regions of mismatch repair genes (most commonly, *MLH1* and *MSH2*) or gene mutations (in a small percentage of GCs) (Lee, 2004b; Gu, 2009; Seo, 2009). The CpG island methylator phenotype, originally found in colorectal cancer, has been detected in 24%–47% of GCs (Toyota, 1999; Oue, 2003; Lee, 2004b).

LOH or mutation of *APC* genes may occur in up to 60% of intestinal-type GC and in approximately 25% of the precursors—adenomas (Hori, 1992; Nakatsuru, 1992; Nakatsuru, 1993). LOH at the *bcl-2* locus and amplification of cyclin D1 and E are also associated with intestinal-type GC tumors (Ayhan, 1994; Muller, 1999). The oncogene product *Her2/neu* is frequently amplified in intestinal-type GC (Wang, 2002). In contrast to the diffuse cell type, *E-cadherin* gene (*CDH1*) mutations are infrequently present in intestinal-type GC (Machado, 2001; Mingchao, 2001).

The molecular pathogenesis of diffuse-type GC is less clear. *H. pylori* infection seems not to be related to the diffuse type of GC, according to epidemiologic studies. It can be part of a hereditary gastric cancer predisposition syndrome (Guilford, 1998). The unique molecular abnormality of diffuse-type GC distinct from intestinal-type GC is deficiency in cell-cell adhesion caused by loss or downregulation of the *E-cadherin* gene (*CDH1*) as a result of genetic or epigenetic alterations. The abnormality in *CDH1* can be found in the early stages of diffuse GC development. Decreased *CDH1* expression is detected in 50% of diffuse-type GCs, and more than 70% of those somatic *CDH1* mutations consist of complete or partial deletion of exons (Berx, 1998; Napieralski, 2005). The unique molecular genetics of GC might be useful for diagnosis in that *CDH1* mutations can be detected by polymerase chain reaction on paraffin-embedded tissue. Detection of the germline mutation in *CDH1* may help in identification of carriers of asymptomatic mutations involved in the GC family syndrome, and may offer an opportunity for prophylactic total gastrectomy in patients carrying the *CDH1* mutation (Fitzgerald, 2002). Other frequently altered genes or gene products in diffuse-type GC include the met proto-oncogene, encoding the hepatocyte growth factor receptor, and the SC-1 antigen, an apoptosis receptor (Kuniyasu, 1992; Vollmers, 1998a, 1998b).

Currently, the most valuable predictive and prognostic factor for GC is clinical staging independent of cancer type, but it does not reflect the heterogeneity of tumor biology. Molecular biomarkers have been investigated as alternatives or supplements to the current system and have shown very promising results in predicting prognosis and therapeutic response. For example, MSI-H is usually associated with intestinal-type GC, commonly seen in the distal stomach or antrum, and is associated with less frequent local lymph node metastasis. However, whether patients with MSI-H GC have more favorable long-term survival than those with MSH-L (novel tumor bands with one marker/ microsatellite stable (MSS) (no novel tumor bands) GC remains controversial (Hayden, 1997; Wirtz, 1998). Expression in tumor tissue of caudal-type homeobox transcription factor 2 (*CDX2*), in combination with normal *E-cadherin* and nonexpression of the transmembrane protein mucin 1 (*MUC1*), is a favorable prognostic factor for patients with GC (Tanaka, 2003; Fondevila, 2004).

Abnormal gene profiling on *RBP4*, *OCT2*, *IGF2*, *PFN2*, *KLA1093*, and *PCOLCW* and overexpression of three genes in the primary tumor (*BIK*, *Aurora kinase B*, and *eIF5A2*) are related to node metastasis (Hippo, 2002; Marchet, 2007). Matrix metalloproteinase-1 (MMP-1)—overexpressing GCs have a worse prognosis in terms of tumor invasion and metastasis than MMP-negative tumors (Noel, 2008). *VEGF* overexpression enhances tumor angiogenesis and thus is associated with lymph node metastasis, hepatic metastasis, and shorter survival time. As with breast cancer (see earlier), amplification/overexpression of the *Her2/neu* oncogene has been shown to be a potential independent unfavorable prognostic factor (Allgayer, 2000; Park, 2006). Overexpression of *EGFR* and β -*catenin* appears also to herald decreased survival and a less favorable prognosis (Jonjic, 1997; Zhou, 2002; Gamboa-Dominguez, 2004). In addition, mutation or abnormal expression of *p53* may predict a reduced cumulative survival and is associated with lymph node metastasis and lower chemosensitivity (Fondevila, 2004; Pinto-de-Sousa, 2004; Oh, 2008).

Treatment of GC, especially late-stage tumor, usually requires a multidisciplinary approach that includes chemotherapy in combination with surgical resection. Molecular markers for predicting therapeutic response have been studied, and several of them have been shown to be potentially useful clinically. These are discussed at length in Chapter 72.

COLORECTAL CANCER

Colorectal cancer (CRC) is the third most common malignancy worldwide (Ferlay, 2004). Prognostication of newly diagnosed CRC predominantly relies on stage or anatomic extent of disease based on the International Union Against Cancer and the American Joint Committee on Cancer staging classifications. However, CRC should be regarded as a heterogeneous, multipathway disease—an observation substantiated by the fact that histologically identical tumors may have neither similar prognosis nor

similar response to therapy (Umar, 2004). Mutations and/or epigenetic alterations in TSGs (e.g., *APC*, *DCC*, *SMAD-2*, *SMAD-4*, *p53*) and oncogenes (e.g., *KRAS*, *p53*) are molecular determinants during the development of sporadic colorectal cancer, which was first summarized in the adenoma–carcinoma sequence described by Vogelstein and coworkers (Fearon, 1990). Based on genetic background, sporadic CRCs can be subclassified into two major types: (1) chromosomal and (2) unstable microsatellite, and an additional group with CpG island methylator phenotypes. Various genetic syndromes are known to predispose to colorectal carcinoma and to have specific inherited gene defects (see “Molecular Genetic Pathology of Syndromic Cancers” section later for details). These molecular markers are currently being investigated as a means of improving the identification of patients likely to have poor clinical outcomes, and therefore more possibly benefiting from adjuvant treatment (Eschrich, 2005; Ghadimi, 2005; Liang, 2009).

EGFR, a receptor tyrosine kinase, overexpression is detected in up to 80% of colorectal cancers (Messa, 1998). Tumors with a high level of EGFR expression usually have a poor prognosis (Ghadimi, 2005; Liang, 2009). These data have led to the clinical use of EGFR blockade in the treatment of colorectal cancers with anti-EGFR monoclonal antibodies such as cetuximab or panitumumab (see also Chapter 74). Cetuximab is a mouse–human hybrid monoclonal antibody used as second-line treatment of colorectal cancer and approved by the FDA in 2004. Panitumumab is a fully human immunoglobulin G₂ monoclonal antibody approved by the FDA in 2007 as third-line monoclonal antibody therapy of refractory colorectal cancer. Both of these drugs are expensive and have significant side effects. Thus, it is imperative to use a biomarker to predicate the therapeutic response. However, use of EGFR as a biomarker to predict response to EGFR monoclonal antibodies has had limited success. Only detection of increased EGFR copy number by FISH has predictive value (Liang, 2009), and it has been proven that EGFR expression levels detected by IHC are not so useful. In contrast to *EGFR* mutation in lung cancer, *EGFR* mutation in CRC is a rare event that occurs in less than 1% of cases (Plesce, 2009). Current studies are focused on finding the downstream effectors of the EGFR pathway that may serve as biomarkers for predicting the effectiveness of anti-EGFR therapy.

As summarized in Chapter 74, Ras-p21 proteins are guanosine triphosphate (GTP)-coupled proteins that are important in many receptor tyrosine kinases that utilize signaling on the Ras/Raf/Erk/Map kinase signal transduction pathway. Mutations that result in single amino acid substitutions at critical positions in the amino acid sequence of this protein, such as Gly 12, Gly 13, and Gln 61, occur in the Ras protein and cause its constitutive activation. This leads to a series of oncogenic events that activate downstream signaling pathways, promoting tumor initiation and tumor growth and progression, including local invasion, angiogenesis, metastasis, and even immune response (Rowinsky, 1999; Smakman, 2005).

KRAS mutation occurs in at least 35%–45% of cases and, in some series, in up to 75% of cases of CRC. Mutations of this gene occur almost exclusively in three hot spots (codons 12, 13, and 61) and rarely in others, including codon 146 (Ogino, 2005; Smakman, 2005). Because KRAS is the downstream effector of EGFR and is frequently mutated in CRC, the mutation status of *KRAS* has become an important predictive marker for the effectiveness of cetuximab or panitumumab on metastatic CRCs. The American Society of Clinical Oncology (ASCO) has recommended that patients with diagnosed metastatic colon cancer who are candidates for anti-EGFR therapy should be tested for *KRAS* mutations in a Clinical Laboratory Improvement Amendments (CLIA)-accredited laboratory. If negative for *KRAS* mutations, these patients are deemed suitable for treatment with anti-EGFR antibody (cetuximab or panitumumab) therapy. This recommendation is based on the results of phase II and III clinical trials. Retrospective subset analyses of these trial data suggest that patients who have *KRAS* mutations detected in codon 12 or 13 do not benefit from this therapy. This was further confirmed by five randomized controlled trials of cetuximab or panitumumab response in relation to *KRAS* mutational status (no mutation [wild type] and mutated [abnormal]) and another five single-arm retrospective studies undertaken to evaluate tumor response according to *KRAS* mutation status.

According to the College of American Pathologist (CAP) Perspectives on Emerging Technology (POET) report, acceptable samples for *KRAS* mutation include fresh, frozen, and FFPE tissues. Acceptable assay types are RT-PCR and direct sequencing analysis; however, other methods such as pyrosequencing or microarray (chip)-based tests have also been developed (Pajkos, 2000; Ogino, 2005). As of the time of this writing, no type of *KRAS* testing has been approved by the FDA. Although recommended testing is limited to codons 12 and 13 of exon 2, which make up

the vast majority of cases with *KRAS* mutations, many laboratories and commercial kits also include testing for other mutations, such as for codons 61 and 146.

BRAF is an immediate downstream effector of *RAS* in the Ras/Raf/Map kinase pathway (see Fig. 76-1). Mutation of *BRAF* has been identified in approximately 10% of CRCs (Di Nicolantonio, 2008). A vast majority of the point mutations are V600E, a mutational hot spot at nucleotide 1796 within exon 15, accounting for a T:A transversion mutation and a valine-to-glutamic acid substitution. All point mutations occur within the kinase domain of B-Raf protein, leading to constitutive activation of B-raf kinase (Davies, 2002). *BRAF* mutation is almost mutually exclusive with *KRAS* mutations. Unlike the *KRAS* mutation, mutations in *BRAF* frequently occur in female patients older than 75 years of age with proximal lesions. The tumors exhibit MSI with higher frequency (Barault, 2008) than those in other patients with colon cancer, which appear to be due to epigenetic effects involving hypermethylation of the promoter regions of mismatch repair genes. *BRAF* mutations in tumors have been characteristically associated with a worse survival than those without and resistance to treatment with anti-EGFR monoclonal antibodies, cetuximab, or panitumumab for metastatic CRCs. Currently, molecular testing for *BRAF* mutation V600E has been performed in many clinical laboratories as a therapeutic indicator for anti-EGFR treatment, in combination with *KRAS* mutation analysis (Siena, 2009).

PI3KCA is a membrane lipid kinase that phosphorylates the 3-hydroxyl group of phosphatidylinositol. This critical enzyme, which binds directly to ras-p21 protein, can be activated by EGFR-mediated signaling, in parallel with the K-ras/B-raf/MAP kinase pathway. Activation of PI3KCA counteracts PTEN, an antioncogene protein, and promotes AKT1 phosphorylation, stimulating cell proliferation, survival, and angiogenesis in cooperation with other pathways. The *PI3KCA* gene is mutated in about 20% of CRCs (Sartore-Bianchi, 2009). The mutation of *PI3KCA* usually occurs in the hot spots in exon 9 (E542K, E545K) and exon 20 (H1047R), both of which are oncogenic in CRC cellular models. Unlike *BRAF* mutation, *PI3KCA* and *KRAS* mutations may coexist. In addition to their association with poor prognosis (i.e., local recurrence and increased mortality of CRCs), *PI3KCA* mutations can independently predict resistance to anti-EGFR therapy with panitumumab or cetuximab for metastatic CRCs (Ogino, 2009a; Sartore-Bianchi, 2009; Siena, 2009). Testing for combinations of the *PI3KCA/PTEN* and *KRAS* mutations can detect up to 70% of patients who are unlikely to respond to anti-EGFR therapy, although more validation is required for clinical practice (Siena, 2009).

The **APC gene**, a tumor necrosis factor-stimulated gene (TSG), encodes a 2843-amino acid protein and is located on chromosome 5q21-22, regulating Wnt/ β -catenin signaling (Phelps, 2009). Mutations of this gene can be point mutations or small deletions or insertions. The latter cause frameshifts that generate stop codons. Germline mutations of this gene are responsible for FAP, whereas somatic mutations occur in the majority of sporadic CRCs. Somatic mutations of this gene may initiate and promote carcinogenesis of sporadic CRCs, and can be found in early neoplastic stages, even in dysplastic cryptic foci (Varesco, 2004; Phelps, 2009; Sweeney, 2009). CRCs with *APC* mutation usually are those with chromosomal instability or MSS (Luceri, 2002). The *APC* gene can serve as a biomarker for early detection, or as a risk factor for familial polyposis syndrome. Detection methods include various types of PCR, LOH, and others (Varesco, 2004). Screening for *APC* mutations may detect patients with relatively early CRC by purified DNA from routinely collected stool samples (Traverso, 2002).

p53 or TP53 is a tumor suppressor that regulates the cell cycle and is involved in apoptosis and DNA repair. This protein is discussed at length in Chapters 73 and 74. It is located on the short arm of chromosome 17 (17p13.1) (Isobe, 1986). Mutation or homozygous deletion of *TP53* is found in 40%–50% of CRCs. Loss of wild-type *p53* activity is thought to be a major predictor of failure to respond to radiotherapy and chemotherapy in various human cancers, including CRCs, and predicts lower survival (Weller, 1998; Zlobec, 2008). Although *TP53* mutation analysis has shown promising prognostic value, the American Society of Clinical Oncology Tumor Markers Expert Panel does not currently recommend its use in routine practice.

TGFBRI, SMAD2, and SMAD4 are proteins involved in the transforming growth factor-beta (TGF- β) signaling pathway (see also Chapter 74). SMAD proteins are the principal components mediating the TGF- β signaling pathway, which negatively regulates the growth of epithelial cells (Kouvidou, 2006). It has been found that germline allele-specific expression (ASE) of the gene encoding TGF- β type I receptor, *TGFBRI*, occurs in 10%–20% of CRCs in both familial (dominantly inherited and

segregated) and sporadic forms (Valle, 2008). The presence of multiple-mutated TGF- β has been linked with poor prognosis in a subset of CRC patients. Approximately 50%–60% of CRCs have been found to harbor *SMAD4* mutations (Woodford-Richens, 2001), but, in contrast, only a few have been found to have *SMAD2* mutations. Both *SMAD2* and *SMAD4* are mapped to chromosome 18q21 (Woodford-Richens, 2001; Miyaki, 2003). Most mutations of *SMAD2* and *SMAD4* occur in their so-called MH2 domain. Inactivation of the *SMAD4* gene through germline mutation and loss of the unaffected wild-type allele are responsible for familial juvenile polyposis, whereas inactivation of the *SMAD4* gene through homozygous deletion or intragenic mutation occurs frequently in CRC and pancreatic cancer. *SMAD4* mutation occurs at a later stage of colorectal carcinogenesis and is an indicator of advanced phenotypes. Loss or low levels of *SMAD4* expression in CRCs are found to be associated with poor prognosis following surgery and 5-fluorouracil (5-FU)-based adjuvant therapy; however, the predictive value of *SMAD4* mutation/inactivation is controversial (Miyaki, 2003; Alhopuro, 2005). Chromosomal loss at 18q encompassing both *SMAD2* and *SMAD4* has been reported in up to 70% of CRCs (Alhopuro, 2005). Patients with locally advanced stage II or stage III disease appear to demonstrate a significantly poorer prognosis with loss of 18q (Popat, 2005).

MSI is involved in approximately 75%–85% of CRCs, characterized by aneuploidy, allelic losses, amplifications, translocations, and mutations of *APC*, *KRAS*, and *TP53* (Jones, 2008). Although the prognosis of patients with MSI CRC is stage and grade dependent, tumors with identical morphologic features display considerable heterogeneity in terms of clinical outcome. The remaining 15%–20% of CRCs have MSI-H characterized by inactivation of mismatch repair (*MMR*) genes (Umar, 2004), as discussed in Chapter 74. Sporadic *MSI-H* cases have been shown to arise predominantly through promoter hypermethylation and silencing of the *hMLH1* gene, in contrast to a hereditary form of *MSI-H* CRC, HNPCC, which typically shows germline mutations in one of the DNA *MMR* genes (Weisenberger, 2006). Tumors with *MSI-H* tend to be more proximally located, poorly differentiated, and of mucinous histologic type, and to show considerable lymphocytic infiltration; they have been linked with *TGFBRII* and *BRAF* mutations (Zlobec, 2008). Patients with colon cancers demonstrating MSI-H have a stage-independent improved survival compared with patients with MSS tumors in most, although not all studies, but they do not benefit from treatment with 5-FU in randomized adjuvant therapy trials (Ribic, 2003).

The **CpG island methylator phenotype (CIMP+)**, or simultaneous hypermethylation of the promoter regions of a number of TSGs, is one of the principal mechanisms of colorectal carcinogenesis, independent of chromosomal instability or MSI. CIMP+ is found in approximately 20% of patients with CRCs. These patients usually are female and of more advanced age with a history of cigarette smoking. These cancers occur predominantly in the proximal colon and are associated with MSI, wild-type *TP53*, *BRAF* mutation, and β -catenin activation (Grady, 2007; Ogino, 2009b). The association between CIMP status and prognosis is controversial, however, and later studies suggest that the occurrence of CIMP appears to be an independent predictor of a low colon cancer-specific mortality and survival advantage and a high responsive rate to 5-FU-based treatment (Iacopetta, 2008; Ogino, 2009b). Additional studies including randomized clinical trials are required to confirm the value of CIMP+ and associated molecular features for the prediction of clinical outcomes of CRCs.

PANCREATIC CANCER (NON-NEUROENDOCRINE TUMOR)

Pancreatic cancer is one of the lead causes of cancer-related death worldwide (Parkin, 2001) and ranks as the fourth most common cause of cancer death in the United States (Jemal, 2008). Most pancreatic cancer is of exocrine origin, and most cases involve invasive ductal adenocarcinoma (PDAC) and its variants (Hruban, 2007; Ranganathan, 2009). Other nonendocrine, nonductal carcinomas such as acinar cell carcinoma, solid-pseudopapillary neoplasm, and pancreatoblastoma are uncommon (Hruban, 2009). It should be noted, however, that the actual cell of origin of certain pancreatic carcinomas is not known, and much debate continues regarding this issue.

Pancreatic ductal adenocarcinoma is the result of accumulation of inherited (germline) or acquired (somatic or epigenetic) mutations of genes, or both, including oncogenes such as, most prominently, mutated (Val-for-Gly 12) *K-RAS*-p21; TSGs such as *p53*, *p16*, and *SMAD4*; and

genome maintenance genes such as *BRCA2*, telomerase, and MSI (Su, 2000; Ranganathan, 2009). Oncogenic ras-p21 protein has been identified in more than 90% of human pancreatic cancers and therefore is considered a major causative factor in this disease (see Chapter 74).

The genetic alterations that have been observed in pancreatic cancer may be reflected by chromosome gain, loss, or copy number changes. PDACs frequently have loss of chromosomes 18, 17, 6, 21, 22, Y, 10, 4, 15p, 14p, 5, 13p, 9p, 21p, and 17p (Johansson, 1992; Ranganathan, 2009). Among them, allelic loss of chromosome 18 is the most common event, and about a third of pancreatic carcinomas have a consensus region of homozygous deletion at 18q21 (Hahn, 1996a). More specific genetic alterations or mutations have been identified by many studies using different molecular approaches. One study by Jones et al (2008) identified more than 1500 somatic mutations affecting 1007 genes in pancreatic cancers. Among these are the most frequent and well-known gene mutations, including activation of *KRAS* (95%), inactivation of *p16/CDKN2A* (75%–80% mutation and 15% hypermethylation), *TP53* (80%), and inactivation of *SMAD4* (95%) (Hruban, 1993; Caldas, 1994; Redston, 1994; Hahn, 1996b; Jones, 2008). Activating point mutation of *KRAS* occurs commonly in codon 12 and much less frequently in codons 13 and 61. Germline mutations in *BRCA2*, a predisposing factor to pancreatic cancer, are frequently detected in the Ashkenazi Jewish population (Ranganathan, 2009). Inactivation of genes by hypermethylation is also important in the development of pancreatic cancer. Aberrant methylation has been identified in the promoter regions of *p16/CDKN2A*, *APC*, *TSLC1/IGSF4*, *SOCS-1*, *cyclin D2*, *RASSF1A*, *WWOX*, *RUNX3*, *CDH13*, *DUSP6*, *HHIP*, and *SLC5A8*, and in pancreatic cancer and precancerous lesions (Sato, 2002; Ranganathan, 2009). Those gene mutations or genetic alterations may affect one or more signaling pathways and MSI. As stated earlier, the most commonly affected signaling pathways include the EGFR/RAS/MAPK pathway and, in addition, the PI3K/AKT pathway, VEGF, the WNT/ β -catenin pathway, and TGF- β signaling (Buchholz, 2009; Hruban, 2009). MicroRNAs are also associated with pancreatic carcinogenesis. miR-216, miR-196a, miR-217, and miR-210 were identified specifically for or were frequently associated with PDAC (Bloomston, 2007; Szafranska, 2007; Hoimes, 2009).

Pre-cancerous lesions including pancreatic intraductal neoplasia (PanIN) and intraductal papillary-mucinous neoplasms (IPMNs) may also have mutations of *KRAS*, *TP53*, *SMAD4*, and *p16/CDKN2A* genes, as seen in PDACs (Hruban, 2009; Ranganathan, 2009). However, intestinal-type IPMNs, a precursor to invasive colloid carcinomas, always have intact *SMAD4/DPC4* and harbor *PIK3CA* mutations in 10% of cases; this usually does not occur in PDACs (Hruban, 2009; Ranganathan, 2009).

Pancreatic cancer other than PDACs shows different molecular genetics. The major genetic alteration of medullary carcinoma is characterized by MSI (Hruban, 2009). Colloid carcinoma frequently shows CDX2/*MUC2* expression (Hruban, 2009). Undifferentiated carcinoma may have loss of e-cadherin. Acinar carcinomas are, on the basis of some studies, thought not to have activation of *KRAS* and inactivation of *TP53*, *p16/CDKN2A*, or *SMAD4*, as seen in PDACs, but may have loss of chromosome 11p and *APC/ β -catenin* gene mutations in some cases (Hoorens, 1993; Abraham, 2002; Hruban, 2009). On the other hand, nontransformed pancreatic acinar cells in culture are readily and stably transformed into malignant pancreatic cancer cells by transfection of oncogenic K-ras or by exposure to carcinogens present in cigarette smoke, a known major risk factor for developing this disease. A common finding in these transformed acinar cells is oncogenic ras-p21.

Solid-pseudopapillary neoplasms commonly have abnormal expression of β -catenin (Hruban, 2009). The most common genetic abnormality in pancreatoblastomas is loss of one copy of the short arm of chromosome 11 near the *WT-2* locus (11p15.5) (Abraham, 2001; Kerr, 2002). Those genetic differences may dictate their different morphology and clinical/biological behaviors in different types of pancreatic exocrine carcinomas.

A vast majority of pancreatic cancers are sporadic; however, familial forms have also been reported. Familial pancreatic cancers most often are associated with many genetic cancer syndromes, including hereditary breast and ovarian cancer syndrome, Peutz-Jeghers syndrome, HNPCC syndrome, FAP, familial pancreatic cancer, and hereditary pancreatitis (associated with mutations of *PRSS1* and *SPINK1*) (see respective sections, later).

The molecular changes noted in pancreatic cancer, as described previously, may serve as diagnostic markers. Detection of mutations of *KRAS*, telomerase (*bTERT*), and others has been used or proposed for the diagnosis of pancreatic carcinoma, which can be potentially applied in surgically resected pancreatic specimens and pancreatic fluid samples (Seki, 2001; Mishra, 2006), although the usefulness of these techniques requires

further evaluation (Fry, 2008). The levels of *bTERT* expression could differentiate PDACs from adenoma and pancreatitis (Nakashima, 2009). Although deletion/inactivation of *SMAD4* is also a relatively highly frequent event in pancreatic cancer, it is not specific. Thus, its utility in molecular diagnosis requires further evaluation (Hruban, 2009; Ranganathan, 2009). Aberrant methylation of certain genes may also have diagnostic utility (Matsubayashi, 2006; Ranganathan, 2009). Yan and colleagues showed that a panel of molecular markers (methylated *p16*, *p53* mutations, and *KRAS* mutations) could stratify patients in high-risk groups from negligible risk to greater than 50% probability of an early cancer (Yan, 2005). In addition, the expression pattern of a group of 112 miRNAs could correctly distinguish pancreatic cancer tissue from adjacent normal and benign tissues, including pancreatitis. Three of the top differentially expressed miRNAs (miR-221, -376a, and -301) were specifically localized to pancreatic carcinoma, but not to the stroma or to normal acini or ducts (Lee, 2007; Liang, 2009). Other potentially useful diagnostic markers for pancreatic cancers include miR-217 and miR-196a (Szafranska, 2007).

Amplification of *KRAS2* and *CMYC* and loss of *TP53* genes are found to be correlated with tumor grade and survival (Ranganathan, 2009). Alterations of *p16* and *bTERT* may also be a prognostic indicator of pancreatic cancer, which conferred a worse outcome by univariate and multivariate analysis (Kumari, 2009). Giovannetti found that patients with high levels of human equilibrative nucleoside transporter-1 (hENT1) mRNA had significantly longer overall survival than patients with a low level of hENT1 expression, suggesting that hENT1 levels may be a predictor of survival (Giovannetti, 2006; Liang, 2009). Iacobuzio-Donahue found that *SMAD4/DPC4* loss is usually associated with death related to multiple metastases, whereas patients found to have intact *SMAD4* genes are more likely to have localized disease, although many of these cancers are also fatal (Hruban, 2009; Iacobuzio-Donahue, 2009). The presence of microRNAs, miR-21, and miR-196a-2 has been found to be a significant predictor of poor survival (Bloomston, 2007; Dillhoff, 2008). *BRCA2* gene mutation, seen in 7% of PDACs and in more cases of familial disease, is a predicting marker for responsiveness to poly-(adenosine diphosphate [ADP]-ribose) polymerase-1 (PARP) inhibitors and to DNA cross-linking agents such as mitomycin C (Helleday, 2005; van der Heijden, 2005; McCabe, 2006).

KIDNEY TUMOR

Renal Cell Carcinoma: Clear Cell Carcinoma

Clear cell renal cell carcinoma (RCC), the most common subtype (50%–70%) of renal cancer, is characterized by an encapsulated solid mass with alveolar or acinar arrangement of clear polygonal cells. Chromosome 3p deletion is seen in 70%–90% of cases (Crossey, 1994; Lonser, 2003), and TSG von Hippel-Lindau (VHL) located on 3p25 is consistently inactivated in 100% of familial renal cancer syndromes and 57% of sporadic cases (Gnarra, 1994). VHL protein regulates expression of the transcription factor, hypoxia-inducible factor (HIF), implicated in tumor growth and angiogenesis. VHL syndrome–associated clear cell carcinoma is caused by a germline mutation at birth in one copy of the *VHL* gene, and a second hit can result from deletion, nonsense mutations, allelic loss, or hypermethylation of the VHL promoter region. Loss of both VHL genes leads to tumorigenesis.

Translocation-Associated RCC

Renal cell carcinoma with Xp11 translocation is a recently recognized entity with unique morphology and genetic characteristics. The most common translocations associated with these tumors are t(X;17)(p11.2;q25), the same cytogenetic abnormality (with identical breakpoints) observed in alveolar soft part sarcomas, which gives rise to the *ASPL-TFE3* fusion gene, and t(X;1)(p11.2;q21), which results in the *PRCC-TFE3* fusion gene.

In this entity, translocation fuses the *TFE3* transcription factor gene at Xp11.2 to *ASPL*, a novel gene at 17q25, or 1q21, which results in the fusion protein ASPL-TFE3 or PRCC-TFE3, respectively (Tomlinson, 1991; Meloni, 1992, 1993; Hernandez-Marti, 1995; Sidhar, 1996; Carcao, 1998; Heimann, 1998; Argani, 2001; Heimann, 2001; Ladanyi, 2001; Argani, 2002, 2003a). Both the *ASPL-TFE3* and *PRCC-TFE3* fusion genes encode chimeric gene products that retain the ability of the TFE3 protein to migrate to the nucleus and participate in transcriptional activation of target genes (Weternan, 2000; Skalsky, 2001). Originally described to affect the pediatric age group and now recognized in both pediatric and adult populations, the age at diagnosis for Xp11 renal tumor ranges from 17 months to 78 years (Argani, 2001, 2006, 2007). It is interesting to note

that pediatric tumors show no particular sex preference, whereas adult tumors demonstrate a strong female predilection (Argani, 2002, 2007).

Grossly, the tumors resemble clear cell RCCs (Argani, 2001). The histopathologic appearance is that of papillary carcinoma (Argani, 2003b). ASPL-TFE3 renal carcinomas are characterized by cells with voluminous, clear to eosinophilic cytoplasm, discrete cell borders, vesicular nuclear chromatin, and prominent nucleoli (Argani, 2001). Psammoma bodies are constant and sometimes extensive, often arising within characteristic hyaline nodules. In contrast, PRCC-TFE3 renal carcinomas generally feature less abundant cytoplasm, fewer psammoma bodies, fewer hyaline nodules, and a more nested, compact architecture (Argani, 2002). Renal carcinomas with Xp11.2-associated translocations characteristically under-express cytokeratin, epithelial membrane, and vimentin antigen by immunohistochemistry. The tumors, however, consistently label for the RCC marker antigen and CD10, similar to conventional renal carcinomas. The most distinctive immunohistochemical feature of these tumors is the nuclear pattern for TFE3 protein using an antibody to the C-terminal portion of TFE3, which is retained in the gene fusions (Argani, 2003a)—a common feature in all Xp11.2-associated carcinomas and ASPS, and not in other adult-type renal carcinomas (Argani, 2003a).

Gene Expression Profiling by Affymetrix in RCC

Genome-wide gene expression studies have demonstrated distinct molecular signatures for distinct variants of RCC, including clear cell RCC, papillary RCC, chromophobe RCC, oncocytoma, and angiomyolipoma using Affymetrix oligonucleotide microarrays (Affymetrix Inc., Santa Clara, Calif) (Schuetz, 2005). Clear cell RCC showed increased expression in genes of the immune response and in angiogenesis genes, related to rich tumor vascularity, whereas chromophobe RCCs and oncocytomas overexpress energy pathway genes, correlated with abundant mitochondria in chromophobe RCC and oncocytoma (Moch, 1996). Another study demonstrated that clear cell RCC overexpressed the proximal nephron markers megalin and cubilin; papillary RCC strongly overexpressed the proximal nephron marker α -methylacyl coenzyme A (CoA) racemase; and chromophobe RCC and oncocytoma overexpressed the distal nephron markers β -defensin-1, parvalbumin, chloride channel Kb, claudin-7, claudin-8, and epidermal growth factor (Young, 2008). These results of Affymetrix profiling lead to molecular classification of renal tumors (Tickoo, 2000; Higgins, 2003). They also have proved useful in prognosis and therapeutic selection by discovery of novel immunohistochemical markers (Yao, 2005; Rohan, 2006; Cifola, 2008).

Several RCC biomarkers have been verified as potential prognostic markers using immunohistochemistry. For example, adipophilin, which was discovered as a clear cell RCC biomarker using gene expression microarrays, was subsequently associated with favorable outcome by immunohistochemistry (Yao, 2005). Many genes overexpressed in RCC are therapeutically significant. Angiogenesis genes are overexpressed in clear cell RCC, likely related to VHL and HIF1A dysregulation, both of which result in activation of multiple angiogenic tyrosine kinase molecules (e.g., vascular endothelial growth factor [VEGF], platelet-derived growth factor [PDGF]). Tyrosine kinase inhibitors (e.g., sunitinib, sorafenib) proved to have a significant role in metastatic RCC. Angiogenic and immune response regulators both increase expression of carbonic anhydrase IX, which is the target of G250 monoclonal antibody therapy for RCC. Affymetrix profiling may be used in the near future in personalized medicine for tumor classification and prognosis.

BLADDER CANCER

Bladder cancer is the second most common malignancy affecting the urinary system. Urothelial carcinoma (i.e., transitional cell carcinoma) is the most common form of bladder cancer, accounting for about 90% of cases. Remaining forms include squamous cell carcinoma (about 5%), most commonly provoked by *Schistosoma hematobium*, adenocarcinoma, and small cell carcinoma. Serum and urine markers used for early detection of bladder cancer, including genetic tests for *p16* tumor suppressor gene deletion (UroVysion), NMP22, and others, are discussed in Chapter 74.

For diagnosis of bladder cancer, invasive urethrocystoscopy and urinary cytology with low sensitivity for low-grade cancer have generated interest in other noninvasive and more sensitive diagnostic tools. The diagnosis of urothelial carcinoma (UC) is further compounded by the need for accurate pathologic staging, with one of the most critical challenges arising in identification of muscularis propria (detrusor muscle) invasion, which ultimately drives patient management. About 25% of patients with bladder cancer have advanced disease (muscle-invasive or metastatic disease) at

presentation and are candidates for systemic chemotherapy. On the basis of the pivotal importance of diagnosing and staging bladder cancer, numerous recent studies have examined novel markers to aid diagnosis, prognosis, and treatment. Molecular and genetic changes in UC of the bladder can be broadly classified into three interrelated processes: (1) chromosomal alteration, triggering the initial carcinogenic event; (2) cancer cell proliferation, caused by loss of cell cycle regulation and derangements in normal apoptotic turnover; and (3) metastasis, in which the initial tumor spreads and brings into play processes such as angiogenesis and loss of cell adhesions (Quek, 2003).

Recent work has focused on molecular changes that occur in noninvasive low-grade papillary UCs, which only rarely progress to muscle-invasive disease (Holmang, 1999; Holmang, 2001). Activating mutations in the *HRAS* oncogene, discussed previously in Chapter 74, are one of the best characterized alterations in this population and have been associated with progression from urothelial hyperplasia to low-grade noninvasive papillary carcinoma (Spruck, 1994; Fitzgerald, 1995). Activating mutations in fibroblast growth factor receptor-3 (FGFR3), a tyrosine kinase receptor, have been documented in 70%–80% of noninvasive low-grade papillary UCs, in contrast to only approximately 20% of invasive carcinomas (Billerey, 2001; van Rhijn, 2001). High-grade papillary UC and flat carcinoma in situ (CIS) share common molecular alterations with invasive UC, the most commonly studied of which include *TP53* and *RB* gene mutations. Invasive UCs commonly demonstrate immunoreactivity for cytokeratins 7 and 20, p63, and high molecular weight cytokeratins such as CK903. Benign urothelial tissue, however, demonstrates at least focal reactivity for these immunomarkers, including CK7 expression within the urothelial mucosa, CK20 expression in the umbrella cell layer, and p63 nuclear expression in the basal and parabasal cell layers.

Genetic studies of flat (and papillary) urothelial hyperplasia in patients with papillary low-grade UC showed frequent genetic alterations in chromosome 9, whereas chromosomal changes more specifically associated with aggressive bladder cancer (loss of 17p, 2q, 4, 11p) were uncommon (Obermann, 2003). With the FISH technique, chromosomal anomalies can be detected in exfoliated bladder cells from the patient's voided urine. A currently commercially available test, the UroVysion Bladder Cancer Kit (UroVysion) (Fig. 76-1, F through H) is intended to detect aneuploidy for chromosomes 3, 7, and 17, and loss of the 9p21 locus, encoding the p16 tumor suppressor protein, using FISH. The indication for UroVysion includes hematuria and monitoring for tumor recurrence in patients previously diagnosed with urothelial carcinoma. A minimum of 25 morphologically abnormal cells should be analyzed. The abnormal profile for chromosomes 3, 7, and 17 and the 9p21 locus includes aneuploidy of chromosomes 3 (red color), 7 (green color), and 17 (aqua color) and/or deletion of the 9p21 (yellow/gold) locus. Criteria for abnormal results include 4 aneuploid cells, 12 cells with deletion of the 9p21 locus, or 10 cells with a tetraploid or near-tetraploid profile.

Genetic changes can precede appearance of the lesions. Positive results include UC of renal pelvis, ureter, urethra, and urinary bladder (Halling, 2008). Negative UroVysion results could occur with a positive diagnosis of UC by cytopathology or biopsy because certain UCs do not have the cytogenetic change of UroVysion. However, many of these cancers can be detected using the marker NMP22 in voided urine specimens, as described in Chapter 74.

PROSTATE CANCER

Prostate cancer is the most common noncutaneous cancer among males. Almost all cancers of the prostate are adenocarcinomas that occur in more than one site (multifocal) in more than 85% of cases. Adenocarcinomas of the prostate are graded according to the Gleason grading system to predict their prognosis and overall aggressiveness. The most common biomarker in serum that is used in diagnosing prostate cancer is prostate-specific antigen (PSA), as was discussed in detail in Chapter 73. This chapter focuses on new genetic markers in tissue that are diagnostic for this condition.

It has been shown that approximately 70% (Hermans, 2006; Perner, 2006; Soller, 2006; Nam, 2007; Rajput, 2007) of prostate cancers harbor a recurrent chromosomal rearrangement, resulting in the fusion of androgen-regulated *TMPRSS2* (21q22.3) to erythroblastosis virus E26 transforming sequence (ETS) family of transcription factors. The latter is a group of genes that encode transcription factors. *TMPRSS2* is regulated by androgen (Afar, 2001) and estrogen (Setlur, 2008). Fusion leads to overexpression of the ETS family of genes (Petrovics, 2005), including *ERG* (21q22.2), *ETV1* (7q21.2), or *ETV4* (17q21) (Tomlins, 2005; Cerveira,

TABLE 76-3

Oncogenicity of HPV

Oncogenicity	HPV types
High-risk HPV types	16, 18, 31, 33, 35, 39, 45, 52, 56, 58, 59, 67, 68
Low-risk HPV types	6, 11, 40, 42, 43, 44, 54, 61, 70, 72, 74, 81, 83, 84
Probable high-risk types	26, 51, 53, 56, 66, 69, 82

HPV, Human papillomavirus.

2006; Perner, 2006; Wang, 2006; Yoshimoto, 2006; Clark, 2007). In about two thirds of cases resulting in the fusion protein, fusion is the result of genomic deletion (Liu, 2006; Perner, 2006) of the intervening DNA sequence, but fusion may also occur by a more complex rearrangement, such as a translocation (Tomlins, 2005; Hermans, 2006). The most common variant is fusion between the 5'-untranslated region of *TMPRSS2* and the 3' region of *ERG* (Perner, 2006; Mehra, 2007a; Tu, 2007). However, more than 20 other fusion variants have now been described (involving more than 10 different genes [e.g., *ETV1*, *ETV4*, *ETV5*]).

Much diversity is also observed in the transcripts derived from these fusion genes. Multiple *TMPRSS2-ERG* splice variant transcripts have been found both within individual cancers and in comparisons of different cancer samples. Although likely to be an early event in prostate cancer, expression of *ETS* gene fusions can be maintained in advanced disease. High-level *ERG* and *ETV1* gene expression has been reported in metastatic prostate cancer. Moreover, the heterogeneity of *TMPRSS2:ERG* gene fusion at different foci of cancer that arise within a multifocal prostate cancer suggested that they have different origins and represent different malignant clones, which made clinical interpretation of this biomarker more complex (Barry, 2007; Mehra, 2007b; Zhu, 2007).

Five histologic features are associated with the presence of gene fusion: the presence of blue-tinged mucin, a cribriform growth pattern, macro-nucleoli, intraductal tumor spread, and signet ring cell features. These features are also associated with an aggressive clinical course of prostate cancer, but neither Gleason grade nor stage was found to correlate with presence of the fusion gene (Perner, 2006; Nam, 2007; Rajput, 2007; Tu, 2007). Results to date have been inconsistent, but most studies suggest that presence of the fusion protein is not correlated with other markers of risk.

Fusion products can be identified by several techniques, including FISH, RT-PCR, and expression profiling using exon arrays. *TMPRSS2:ERG* gene fusion is specific for prostate cancer, and the ability to identify this DNA rearrangement could be used as a screening test for prostate cancer in serum, prostatic fluid, or urine. The clinical significance of the presence of the *TMPRSS2:ERG* gene fusion product for prostate cancer presentation and progression is not fully understood, but studies to date suggest that this may be a biomarker of risk.

CERVICAL CANCER

Cervical carcinoma is the second most prevalent cancer in women worldwide (Parkin, 2001). The primary cause of cervical cancer is human papillomavirus (HPV) infection. HPV infection initiates and promotes the development of cervical neoplasia from the precancerous lesion, cervical intraepithelial neoplasia (CIN) I or low-grade squamous intraepithelial lesion (LSIL), to in situ cancer III or high-grade squamous intraepithelial lesion (HSIL) and invasive cancer (Kisseljov, 2008; Herrington, 2009). Other cellular or environmental factors, such as genetic and immune disorders, hormonal contraception, high parity, tobacco smoking, coinfection with other microorganisms, such as HIV, and dietary deficiencies, are also implicated in the cervical carcinogenesis. These factors are important for the progression from cervical HPV infection to cervical intraepithelial lesions and cancer (Munoz, 2006).

HPVs are double-stranded circular DNA viruses that contain seven early (*E1-E7*) and two late (*L1-L2*) genes necessary for viral replication. Among them, two genes (*E6* and *E7*) play a pivotal role in the initiation of cervical carcinogenesis and maintain the transformed phenotype (Mantovani, 2001; Munger, 2001). The *E7* protein binds to the retinoblastoma TSG product pRB, preferably the underphosphorylated or "active" form of pRB. HPV *E6* proteins can also associate with the p53 tumor suppressor protein. Inactivation of pRB and p53 by the HPV oncoproteins *E7* and *E6* likely represents major steps in cervical carcinogenesis. HPV may also be integrated with the human genome, which is important in the progression of HPV-associated neoplasia. This integration may cause upregulation of HPV *E6* and *E7* expression and other genetic abnormalities, including telomerase activation and chromosomal alterations leading to the development of high-grade intraepithelial and invasive squamous carcinoma. In addition, HPV infection can induce many epigenetic changes, including methylation of the promoter of TSGs involved in cell proliferation and differentiation (Kisseljov, 2008; Gupta, 2009; Herrington, 2009).

Although more than 100 HPV types have been identified, studies show that HPV-16 and, to a lesser extent, HPV-18 play a dominant role in cervical carcinogenesis and are jointly responsible for 70% of the world's cervical cancer cases. Based on their capability for tumorigenicity, HPVs are classified into high- and low-risk groups (Table 76-3), with high-risk HPV types causing high-grade cervical intraepithelial lesions (CIN2/3 or HSIL),

and with low-risk HPV types leading to low-grade cervical intraepithelial lesions (CIN1 or LSIL) (Kisseljov, 2008; Herrington, 2009).

Because a strong causative association has been observed between HPV infection and cervical cancer, identification of HPVs in tissue or cytologic specimens has become a routine practice, not only for screening purposes, but also for the diagnosis of cervical cancer and for follow-up of abnormal changes detected by a cervical Pap smear. The combination of HPV testing and Pap smear evaluation has significantly improved the sensitivity and specificity of the diagnosis of precancerous lesions and cancer (Cuzick, 2008). Among various platforms for HPV infection detection, Hybrid Capture (Digene, Gaithersburg, Md.) is an in vitro, solution hybridization, signal-amplified test used to detect HPV DNA targets. First introduced by Digene in 1995, it was designed to detect 14 HPV types, including the high-risk types HPV 16, 18, 31, 33, 35, 45, 51, 52, and 56; and the low-risk types HPV 6, 11, 42, 43, and 44. The Hybrid Capture test is performed on the residual liquid portion of the patient's Pap smear specimen, such as the thin preparation containing HPV DNA. This reacted viral DNA is combined with viral-specific RNA probes, creating hybrids. These RNA:DNA hybrids are then combined onto a solid phase coat, with subsequent capture by universal antibodies that are specific for that particular RNA:DNA nucleic acid hybrid. In turn, the RNA:DNA antibody is detected by a signaling antibody conjugated to alkaline phosphatase, resulting in chemiluminescence, which, when amplified, can be measured in relative light units (RLUs). The second generation of the hybrid capture assay, Hybrid Capture 2, replaces the tubes with microtiter plates to improve performance and suitability for automation. It is the first FDA-approved form of HPV testing for high-risk groups for HPV.

Two HPV tests have been approved by the FDA, both of which utilize an isothermal enzymatic DNA amplification process with a fluorescent readout used with ThinPrep samples (Hologic Inc., Marlborough, Mass.). One of these tests, Cervista HPV HR (Hologic Inc.), is designed to identify 14 high-risk types of HPV. These include the 13 types detected by the Hybrid Capture 2 HPV DNA assay (16, 18, 31, 33, 35, 39, 45, 51, 52, and 56, as well as 58, 59, and 68) and HPV 66. The other test, Cervista HPV 16/18, is designed to specifically detect HPV 16 and HPV 18. Other technologies are also used by some laboratories, including PCR, DNA microarray, dot blot, Southern blot, and genotyping such as TaqMan PCR genotyping assay, GenProbe (GenProbe Inc., San Diego), and APTIMA1 HPV assay (Aptima Inc., Woburn, Mass.).

OVARIAN CANCER

Ovarian cancer is one of the most common gynecologic malignancies and is the fifth leading cause of cancer mortality in women in the United States (Jemal, 2009). Ovarian epithelial cancers are classified on the basis of morphology, depending upon invasiveness (tumor grade) and type of differentiation (e.g., serous, mucinous, endometrioid, clear cell, and transitional type).

Studies on the molecular pathology of ovarian cancer show that each of the four major histopathologic types of ovarian carcinoma is characterized by rather distinctive, although not necessarily unique, genetic abnormalities. For example, *TP53* gene mutations are extremely common in high grade serous carcinomas, low grade serous, and mucinous adenocarcinomas have a high prevalence of *KRAS* and *B-RAF* mutations (75% in primary mucinous adenocarcinomas) (Cho, 2009). Mutations of *CTNNB1*, the gene encoding β -catenin and *PTEN*, are common in endometrioid adenocarcinoma but are rare in serous, mucinous, and clear cell carcinomas. Mutations of *PIK3CA*, which encodes the catalytic subunit of PI3K (phosphoinositide 3-kinase), are observed most frequently in clear cell carcinoma. In addition, genetic differences exist within a given type of ovarian cancer.

Molecular subgroups of endometrioid adenocarcinomas correlate with tumor grade, stage of disease, and clinical outcome. Serous carcinomas can be subdivided into low-grade serous carcinoma (LGSC) and high-grade serous carcinoma (HGSC).

Histologic Subtypes of Serous Carcinoma

LGSC, also called International Federation of Gynecology and Obstetrics (FIGO) stage I, is defined as malignancy of one (Ia) or both (Ib) ovaries. These carcinomas characteristically have mutations of *KRAS* or *BRAF*, but lack *TP53* mutations (Gills, 2009). Mutations of *KRAS* or *BRAF* lead to constitutive activation of the MAPK (mitogen-activated protein kinase) signaling pathway. Low-grade tumors have also been found to contain mutations that deregulate the canonical Wnt/ β -catenin and PI3K/PTEN signaling pathways and typically lack *TP53* mutations (Cho, 2009).

On the other hand, HGSCs are characterized by high-grade nuclei, have short latent precursor lesions, and have rapid tumor progression into invasive carcinoma. HGSCs are often identified in advanced stage and have a high prevalence (50–70%) of *TP53* gene mutations (Wen, 1999), but unlike in LGSC, mutations of *KRAS* and *BRAF* are rare. Most HGSC cancers further lack Wnt/ β -catenin or PI3K/PTEN signaling pathway defects (Kolasa, 2006), which are common in the LGSC cancers. Moreover, it is important to note that most HGSCs have genetic and somatic alterations of *BRCA1* and *BRCA2* (germline or somatic mutation or promoter methylation and loss of expression) (Kobel, 2008). These changes occur early during oncogenesis and result in loss of ability to repair DNA double-strand breaks, which, in turn, leads to chromosomal instability.

Molecular Classification of Ovarian Cancer

Molecular studies led to the proposal of a new model for classifying ovarian carcinomas, in which surface epithelial tumors can be divided into two broad categories designated Type I and Type II, based on their pattern of tumor progression and molecular genetic changes (Landen, 2008; Levanon, 2008). Type I tumors include low-grade serous carcinoma, low-grade endometrioid carcinoma, mucinous carcinoma, and a subset of clear cell carcinomas that develop in a stepwise fashion from well-recognized precursors, in most cases, borderline tumors, which generally are large and often are confined to the ovary at diagnosis. In contrast, Type II tumors are of high grade and almost always have spread beyond the ovaries at presentation; these include high-grade serous carcinoma, undifferentiated carcinoma, some clear cell carcinomas, and malignant mixed müllerian tumor. Type I and Type II tumors also differ in their molecular profiles. Type I tumors often harbor somatic mutations of genes encoding protein kinases, including *KRAS*, *BRAF*, *PIK3CA*, and *ERB-2* (*Her2/neu*), and other signaling molecules, including CTNNB1 and PTEN. In contrast, Type II tumors generally lack these mutations but are characterized by a high frequency of *TP53* mutations, which are rare in Type I tumors. Chromosomal instability levels, as reflected by genome-wide changes in DNA copy number, are much higher in Type II tumors than in Type I tumors (Mayr, 2006).

Clear Cell Ovarian Carcinoma

Mutations in *KRAS*, *BRAF*, and *TP53* are present in some clear cell carcinomas, but their frequency is generally low. Mutations predicted to deregulate PI3K/PTEN signaling are more common in clear cell carcinomas, with *PIK3CA* mutations reported in 20%–25%, and *PTEN* mutations in 8% of tumors (Cho, 2009).

BRCA1 and BRCA2 in Ovarian Cancer

These genes encode proteins that are required for DNA double-strand break repair by homologous recombination. Cells lacking *BRCA1*- or *BRCA2*-dependent DNA repair tend to develop chromosomal rearrangements and genomic instability. Inheritance of DNA repair defects involving *BRCA1* and *BRCA2* contributes to as many as 10%–15% of ovarian cancers (Lancaster, 1996). The lifetime risk of developing ovarian cancer in mutation carriers varies with the genetic defect (for *BRCA1*, 30%–60%, and for *BRCA2*, 15%–30%). *BRCA*-related familial ovarian cancers are more frequently multifocal and progress faster. Carcinomas arising in patients with germline *BRCA1* or *BRCA2* mutations are almost invariably of the high-grade serous type discussed previously. Fortunately, however, ovarian cancers that contain mutations affecting *BRCA1* and *BRCA2* are more sensitive to DNA damage induced by chemotherapeutic agents such as platinum drugs and PARP inhibitors because they are less able to repair the DNA damage caused by these agents. Thus, these drugs are particularly

effective in the presence of defects in homologous recombination repair, and clinical trials with these agents are under way in ovarian cancer patients with inherited *BRCA1* and *BRCA2* mutations (Yap, 2009).

Although *BRCA1* and *BRCA2* genes have been thought to be mutated only rarely in sporadic ovarian cancers, somatic mutations have recently been documented in approximately 10% of nonfamilial cases, particularly in high-grade serous epithelial ovarian cancers, and expression of *BRCA1* and *BRCA2* can be silenced by methylation in additional cancers. This contributes to their sensitivity to platinum-containing therapies in HGSC. PARP inhibitors might also find broader clinical application in these sporadic cancers, in which these pathways are also defective. Thus, in some regions, all patients presenting with an HGSC are referred for genetic counseling and screening for *BRCA* mutations (Risch, 2001).

MELANOMA

Malignant melanoma is an aggressive tumor that originates from pigment-producing melanocytes, mainly in skin. About 80% of melanomas are diagnosed early and can be cured by surgical excision (Gray-Schopfer, 2007). However, metastatic melanomas are refractory to current chemotherapy or radiotherapy and have a very poor prognosis, with a median survival of 6 months (Miller, 2006). A majority (90%) of melanoma cases are sporadic, and 10% are familial melanomas, also known as dysplastic nevus syndrome. Four melanoma-predisposing genes have been identified in familial melanoma based on the discovery of germline mutations in multiple-case families; three are high penetrance, and one is low penetrance. The best characterized high-penetrance gene is cyclin-dependent kinase inhibitor 2A. It is located on chromosome 9p21 and encodes two distinct melanoma-predisposing genes: *p16* (discussed previously in the bladder cancer section) and *p14* (Mehra, 2007b). The protein product of *p16* is INK4a, and the protein product of *p14* is ARF. Twenty-five percent to 40% of familial melanoma cases harbor an inactivating mutation in *CDKN2A* (Miller, 2006; Gray-Schopfer, 2007). Cyclin-dependent kinase 4 (*CDK4*), located on 12q14, is the third high-penetrance melanoma susceptibility gene (Zuo, 1996). Finally, melanocortin-1 receptor (*MC1R*) is a low-penetrance gene implicated in melanomagenesis.

The RAS/RAF/MEK/ERK signaling pathway has emerged as a major player in the induction and maintenance of sporadic melanoma. Among *RAS* family members, mutations in *NRAS* occur most frequently in melanocytes, with rates approaching 56% in congenital nevi (Demunter, 2001), 33% in primary melanomas, and 26% in metastatic melanomas (Garnett, 2005).

However, as in papillary thyroid carcinoma and in some forms of colorectal cancer, the most important signaling molecule in melanoma downstream of RAS is BRAF. *BRAF* somatic missense mutations are found in 66% of malignant melanomas, of which 80% involve a single base substitution of valine by glutamic acid at position 600 (V600E). Most of these mutations activate BRAF kinase activity from 1.5- to 700-fold, although a small number actually are inactivating mutations. However, even these inactive mutants can stimulate cellular signaling through the MEK-ERK pathway because they activate the related family member *C-RAF* (Garnett, 2005).

It is interesting to note that genetic alterations in *NRAS* and *BRAF* rarely coexist in melanoma (Zuo, 1996; Tsao, 2004; Miller, 2006), suggesting that mutant *BRAF* or *NRAS* alone is able to activate the pathway. Recent studies have revealed deregulation of PI3K signaling in a high proportion of melanomas. Indeed, in about 45% of melanomas, *PTEN* is deleted and the downstream *AKT* gene is amplified (Zhou, 2003; Stahl, 2004). Additionally, RAS binds and activates PI3K, thereby activating the AKT pathway and preventing apoptosis (Sekulic, 2008). These data suggest that loss of *PTEN* and oncogenic activation of RAS are equivalent (Zhou, 2003).

The high mutation rate of *BRAF* in melanoma makes it an attractive therapeutic target. Investigators have focused much attention on agents that specifically target BRAF, such as sorafenib, as well as on molecules that function both upstream and downstream of BRAF. A nonspecific inhibitor of BRAF, sorafenib is not effective as a single agent in advanced-stage melanoma patients (Sekulic, 2008). Of interest downstream of BRAF is the direct inhibition of ERK and MEK. Although no mutations have been documented in either molecule, inhibition of MEK has proved effective in the presence of a mutated *BRAF* (Sekulic, 2008). Several MEK inhibitors are currently in clinical trials. Upstream of BRAF, RAS is an attractive target for inhibition. Farnesyltransferase inhibitors (FTIs) interfere with posttranslational processing of RAS, and thereby inhibit the downstream effects of RAS.

MOLECULAR GENETIC PATHOLOGY OF SARCOMA

Sarcomas are malignant neoplasms arising in connective tissue, fat, muscle, blood vessels, deep skin tissues, nerves, bones, and cartilage. These types of cancers often are not considered classical “solid tissue tumors,” although often their biological behavior is similar to that of the types of solid tissue tumors discussed previously. However, because major advances have been made in the area of the molecular biology of sarcomas, and because these advances have illuminated the nature of specific genetic lesions that cause cell transformation, we describe them in this section. This section is meant to show the principles that have been discovered in sarcomatous cell transformation and is not meant to be a detailed discussion of specific genetic lesions in each of the myriad of different sarcomas that have been described. Rather, we present specific examples of each type of genetic lesion that has been discovered. The reader is referred to other texts that describe the genetic lesions in each sarcoma type.

Many sarcomas harbor specific translocations or other characteristic genetic defects that aid in the diagnosis of each tumor type and, in some cases, impart prognostic or predictive information influencing clinical management (Jain, 2010b). Recent molecular cytogenetic analysis has demonstrated that the sarcomas can be divided into two main categories:

1. Sarcomas with specific genetic alterations. These can be subclassified further into sarcomas that harbor reciprocal translocations resulting in oncogenic fusion transcripts (accounting for 15%–20% of cases [e.g., SS18-SSX in synovial sarcoma]) and sarcomas that harbor specific oncogenic mutations (e.g., *KIT* and *PDGFRA* mutations in gastrointestinal stromal tumors) (Hirota, 1998; Miettinen, 2006).
2. Sarcomas displaying multiple complex karyotypic abnormalities with no specific pattern, including malignant fibrous histiocytoma (MFH) and leiomyosarcoma (LMS).

SARCOMAS WITH FUSION GENES

Fusion Genes Involving *TET* Genes

Nearly half of the fusion proteins believed to participate in initiation and development of sarcoma contain a portion of the so-called *TET* gene family products, including *EWSR1*, *TLS/FUS*, and *TAFII68*. TET family proteins contain a characteristic 87 amino acid RNA recognition motif that is thought to be implicated in protein–RNA binding and to participate in transcription and RNA metabolism.

Ewing’s Sarcoma/Primitive Peripheral Neuroectodermal Tumor

This is a prime example of a fusion gene-induced sarcoma. The tumor itself is a small blue cell tumor that primarily affects long bones or the vertebral area in young adults and children. Histologically, it is characterized by sheets of small round cells that may form what are called Homer-Wright rosettes. Ewing’s sarcoma family tumors (ESFTs) can be subclassified into Ewing’s sarcomas or primitive peripheral neuroectodermal tumor (PNET), the latter showing evidence of neuroendocrine differentiation immunohistochemically (Olsen, 2006). However, the distinction between them is no longer considered critical for clinical management, as prognosis and therapy are similar.

ESFTs characteristically harbor a recurring t(11;22)(q24;q12) that juxtaposes the *FLI1* and *EWSR1* genes to encode a chimeric RNA and protein. About 10% of Ewing family tumors have an alternate translocation involving the *EWSR1* gene, implying that disruption of *EWSR1* is the critical molecular event underlying tumorigenesis. Except for *FUS-ERG*, all fusion transcripts identified so far in ESFTs consist of *EWSR1* and an ETS family transcription factor, including *FLI1*, *ERG*, *ETV1*, *ETV4*, and *FEV* genes (de Alava, 2000). Approximately 85%–90% of ESFTs are associated with the *EWSR1-FLI1* fusion gene, 9%–14% with *EWRI-ERG*, and the remaining 1%–5% with other rare variants (de Alava, 2000).

Karyotype is the analytic method used for the initial workup of a suspected Ewing family tumor because the characteristic t(11;22) is evident in approximately 90% of these tumors. However, in a case of strong suspicion of Ewing’s sarcoma/PNET with normal karyotype, FISH should be considered as an additional test for the genetic defects. FISH, using a break-apart probe targeting the *EWSR1* gene, is an excellent method to identify or exclude a *EWSR1* gene rearrangement. FISH may be carried

out on metaphase cells (requiring fresh tissue) or on interphase cells (feasible on a wide variety of sample types, including fine-needle aspirates, touch preparations, smears, or paraffin-embedded tissue) (Kilpatrick, 2006). An advantage unique to RT-PCR is its ability to define which of two prognostically relevant transcript structures is present: type 1 fusion transcripts (*EWSR1-FLI1*) are not transcribed as actively and carry a good prognosis compared with alternative fusions. Another advantage of RT-PCR is its ability to detect minimal residual disease after therapy (Vermeulen, 2006). Immunohistochemical analyses of *CD99* and *FLI1* reveal overexpression in most Ewing’s/PNET tumors harboring a t(11;22) (Hameed, 2007).

Fusion Genes Involving Receptor Tyrosine Kinase Genes

Congenital fibrosarcoma (CFS) is a low-grade pediatric soft tissue sarcoma, principally arising in the extremities, generally in the first year of life. Recently, CFSs were shown to contain a novel t(12;15)(p13;q25) translocation, resulting in *ETV6-NTRK3* gene fusion. *ETV6* is a member of the ETS family of transcription factors containing a basic helix-loop-helix (bHLH) dimerization domain, which was originally found at the breakpoint in translocations in leukemia and myeloproliferative syndromes. NTRK3 is the cell surface receptor for neurotrophin 3 expressed primarily in the CNS. The ETV6-NTRK3 fusion protein forms a homodimer or heterodimer with wild-type NTRK3, which displays receptor tyrosine kinase (RTK) activity and undergoes autophosphorylation at tyrosine residues (Knezevich, 1998). Cytogenetic t(12;15) translocations may not be identified in several cases (CMN4, CFS1, and CFS5), but RT-PCR and FISH analyses revealed ETV6-region rearrangements in those same cases. Detection of *ETV6-NTRK3* fusion transcripts in most CFSs using RT-PCR methods with archival, formalin-fixed, paraffin-embedded tissues, therefore, is a useful diagnostic adjunct.

Fusion Genes Involving Chromatin Remodeling Genes

Synovial sarcomas (SSs) often arise deep in the soft tissue near a joint in the extremity of a young adult patient. Most SSs are characterized by t(X;18)(p11.2;q11.2), resulting in a fusion between the *SS18(SYT)* gene on chromosome 18 and one of the *SSX* genes on the X chromosome, creating *SS18-SSX1*, *SS18-SSX2*, or *SS18-SSX4* chimeric genes (Skytting, 1999; Nishio, 2001, 2002a, 2002b, 2005; Kanemitsu, 2007). Two common histologic and genetic variants of synovial sarcoma are known: a monophasic variant comprising vimentin-expressing spindle cells usually carrying *SS18-SSX2* translocation, and a biphasic variant that consists of a mixture of vimentin-expressing spindle cells and keratin-expressing glandular epithelial cells harboring the *SS18-SSX1* or *SS18-SSX2* translocation (Ladanyi, 2002). The biphasic variant may resemble adenocarcinoma or more typically carcinosarcoma and carries a worse prognosis, at least in early-stage patients. Karyotype is helpful when it is positive, but negative results could reflect failure of the tumor cells to divide sufficiently in culture, or other mechanisms of false-negative results. FISH using an SS18 break-apart probe is helpful for demonstrating t(X;18), but it cannot distinguish which partner gene is involved for prognostic purposes. RNA from frozen or paraffin-embedded tissue is suitable for RT-PCR to detect and to distinguish the two common translocation variants (Sieber, 2003). From a mechanistic standpoint, the translocation creates a chimeric gene encoding a fusion protein that redirects the transcription factor function of SS18. Relevant downstream targets include *CCND1* (cyclin D1), which enhances cell cycle progression. *TLE1* encodes a transcriptional corepressor that is overexpressed in synovial sarcomas. Gene and tissue microarray studies have identified TLE1 as an excellent biomarker for distinguishing synovial sarcoma from other soft tissue malignancies on immunohistochemistry (Jagdis, 2009).

Fusion Genes Involving Growth Factors

Dermatofibrosarcoma protuberance (DFSP) is a rare skin tumor of low-grade malignancy that shows local recurrence. The reciprocal chromosomal translocation t(17;22)(q11;q13.1) or a supernumerary ring chromosome derived from t(17;22) is found in this type of tumor, which results in fusion of the *COL1A1* gene on chromosome 17 with the *PDGFB* gene on chromosome 22 (Simon, 1997). Because the point of fusion is highly specific for *PDGFB* but is spread over almost the entire locus for *COL1A1*, the role of the *COL1A1* gene may be simply to upregulate the expression of the platelet-derived growth factor receptor (PDGFR). Imatinib

mesylate is an inhibitor of tyrosine kinases, including PDGFR, and has shown a dramatic response to treatment in adults. The use of other PDGFR inhibitors such as sunitinib and sorafenib has recently commenced in patients with metastatic DFSP (McArthur, 2006).

Giant cell fibroblastoma (GCF) represents the juvenile form of DFSP, which shows local recurrence. Although histologically different, these two diseases share several features, including CD34 positivity and, most important, the genetic alteration t(17;22)(q11;q13.1), involving the *COL1A1* gene as found in DFSP (Simon, 1997).

Other Types of Fusion Genes

Rhabdomyosarcoma (RMS), a malignant tumor of skeletal muscle cells, is the most common soft tissue sarcoma in children and young adults, often arising from extremities, paranasal sinus, or retroperitoneum. The main histologic subtypes are alveolar (ARMS) (20%), embryonal (ERMS) (60%), and pleomorphic (PRMS); survival rates for these subtypes vary from <25%–>95%, respectively (Breneman, 2003). Histologically, striated muscle differentiation is noted with concomitant expression of vimentin, muscle-specific actin, desmin, myogenin, and MyoD1.

In ARMS, 70% of cases harbor the translocation t(2;13)(q35;q14), which fuses the 5' end of *PAX3* with the 3' end of the *FOXO1A* gene. A further 10% of ARMS are associated with fusion of *PAX7* to the *FOXO1A* gene. The remaining 20% of cases of ARMS do not have these fusion genes detectable by routine RT-PCR and constitute cases with very low expression of a fusion gene or a rare variant fusion gene, or with no detectable fusion gene. FISH using a break-apart probe identifies rearrangement of the *FOXO1A* gene (Matsumura, 2008; Mehra, 2008). The karyotype typically reveals t(2;13)(q35;q14) *PAX3-FOXO1A* or t(1;13)(p36;q14) *PAX7-FOXO1A*, with the latter being less common but imparting a better prognosis (Davicioni, 2006). It should be noted that ARMS tend to have a poor prognosis overall, especially when presenting with disseminated disease, so genetic testing may be moot in stage IV patients. Testing is most useful when the histologic features are not classic (e.g., mixed alveolar and embryonal patterns).

SARCOMAS WITH ONCOGENIC MUTATIONS

KIT and *PDGFRA* in Gastrointestinal Stromal Tumor

Gastrointestinal stromal tumor (GIST) is the most common mesenchymal tumor in the gastrointestinal tract. Activating mutations of the *cKIT* gene were found in 75%–80% of cases and of *PDGFRA* in 5%–10%; cases with no mutation in either of these are extremely rare. The *cKIT* protein, which encodes a TKR for stem cell/PDGFR, comprises a long extracellular domain, a transmembrane segment, and an intracellular domain. In all cases, mutated receptors transmit growth signals in a ligand-independent manner, inducing dysregulated cell proliferation, as described in Chapter 74. Mutations generally occur in exon 11, encoding the intracellular receptor domain, but can also occur in exons 9 and (rarely) 13, and 1 in GIST. Mutations in *cKIT* and *PDGFRA* are mutually exclusive. Detection of overexpression or mutation of *cKIT/PDGFRA* has become a standard diagnostic tool for GIST. Drugs targeting the activating tyrosine kinase, such as imatinib mesylate (Gleevec/Gleevec), have been used successfully to treat patients with metastatic GIST showing the previously described mutations. D816V point mutations in *cKIT* exon 17 are responsible for resistance to targeted therapy drugs such as imatinib mesylate (Miettinen, 2006).

SARCOMAS WITH VARIABLE COMPLEX GENETIC ALTERATIONS WITH NO SPECIFIC PATTERN

Tumors in this group are characterized by pleomorphic/spindle cell morphology, including MFH, LMS, and malignant peripheral nerve sheath tumor (MPNST). Chromosomal breakpoints in these tumors are widely scattered, with no predilection for any of the recurrent breakpoints and no losses to any of the morphologic subtypes. A prime example of this type of sarcoma is LMS, a malignant tumor of smooth muscle.

Leiomyosarcomas are adult soft tissue sarcomas that show varying degrees of smooth muscle differentiation and can develop anywhere in the body. LMSs usually show complex karyotypic alterations in the form of gains, losses, and amplifications in chromosomes. Some gains and losses of chromosomal material tend to correlate with poor outcome, large tumor

size, and metastatic dissemination, and include loss of 1p12-pter, loss of 2p, loss of 13q14-q21 (targeting the Rb pathway), loss of 10q (targeting PTEN), and loss of 16q, as well as gains of 17p, 8q, and 5p14 pter. Activation of the *PI3K-AKT* pathway through different mechanisms (e.g., activation of insulin-like growth factor receptor [IGFR]; inactivation of PTEN, a negative regulator of *PI3K-AKT*) also plays a crucial role in the development and maintenance of LMS. This activation leads to the concomitant activation of downstream effectors such as mTOR (target of rapamycin protein; discussed in Chapter 23, see Fig. 23-15) and its targets (β -catenin, pS6, p4E-BP1, etc.), as well as to stabilization of a particularly important promitotic protein, HDM-2 (human double minute-binding protein). Clinical trials have showed that analogs of rapamycin such as everolimus (RAD001), an mTOR inhibitor, have some efficacy in patients with LMS. It is known that the more differentiated retroperitoneal LMSs tend to behave more aggressively as the result of amplification/overexpression of myocardin. This protein is a transcriptional cofactor for regulating smooth muscle differentiation, and its inactivation is associated with less differentiated histology. Myocardin might constitute a promising therapeutic target.

CANCERS OF UNKNOWN ORIGIN

Cancer of unknown primary (CUP) is defined by the presence of cytologically or histologically proven metastases, for which no primary tumor can be identified despite standardized and extensive diagnostic workup. It constitutes approximately 4% of all malignancies, of which 80% are adenocarcinoma (50% well to moderately differentiated and 30% poorly differentiated), 15% squamous cell carcinoma, and 5% undifferentiated neoplasm on light microscopy (Horlings, 2008). Accordingly, failure to identify the primary tumor theoretically incurs the risk of failure to administer appropriate systemic combination chemotherapy, as well as targeted molecular therapy. Although the metastatic pattern in these patients is often atypical, no direct evidence indicates that molecular genetic abnormalities in these tumors differ from those seen in metastatic cancers of known primary site. With expansion of tissue-specific targeted therapy, it is believed that patient prognosis can be better predicted when the primary site of metastatic tumors is assigned.

This has increased the need for identification of the tissue of origin, which further makes the immunohistochemical analysis a crucial component of clinical workup. However, the current success rate of the diagnostic workup, including clinical, radiologic, and extensive pathologic methods, varies between 20% and 30% (Horlings, 2008). Therefore, new methods are required to increase diagnostic accuracy.

The development of molecular technology that allows gene expression profiling of tumors provides an opportunity for improved diagnosis of patients with CUP. Quantitative reverse transcriptase polymerase chain reaction (RT-PCR) is a technique that allows gene expression profiling of FFPE tissue specimens, and therefore is a potential diagnostic tool with broad applicability. These techniques have enabled researchers to develop expression profiles unique to a wide variety of well-characterized primary cancers. The accuracy of diagnosis of primary site obtained by comparing these known unique signatures with those from unknown primary cancers is 80%–90%. This is based on the finding that metastatic cancers retain at least the basic genetic signature found in their respective primary cancers. Gene expression profiling has also shown important potential diagnostic and therapeutic implications in CUP. The CUP colon cancer profile can be identified, and patients appear to respond well to current regimens for metastatic CRC (Varadhachary, 2008). Expression profiling of certain genes (e.g., *Her/2neu*, *RAS*, *EGFR*, *VEGF*, *COX-2*, *cKIT*) for CUP will benefit patients by revealing therapies that can be used to target these molecules (Pentheroudakis, 2007).

To date, several gene expression–based tests have demonstrated an increase in overall accuracy for the primary site of origin to 78%–88% (Horlings, 2008). Ramaswamy (2001) demonstrated 78% classification accuracy in classifying 10 carcinomas and 4 noncarcinoma types by using oligonucleotide microarray gene expression analysis, whereas Tothill (2005) achieved 89% accuracy with 12 carcinomas and 1 noncarcinoma after reducing the gene classifier from thousands to 79 genes by converting microarray gene expression to RT-qPCR (Tothill, 2005). Ma (2006) used data from a 22,000-gene microarray and devised a 92-gene RT-PCR assay that classified 119 tumors of unknown origin to 32 primary site/histologic types with 87% accuracy. A molecular assay (CUP assay) was developed (Veridex, La Jolla, Calif) that evaluates the expression of 10 tissue type–specific gene markers using quantitative RT-PCR technology and is designed to detect tumors originating from six specific sites: lung (HUMPB,

TTF1, DSG3), breast (MGB, PDEF), colon (CDH17), ovary (WT1), pancreas (PSCA, F5), and prostate (PSA) (Varadhachary, 2008). Another diagnostic gene expression-based classifier (CupPrint, Agendia, Amsterdam, The Netherlands) was developed using 495 genes to classify 48 tumor types. Similar to these, a gene expression-based breast cancer prognosis assay (Genomic Health OncotypeDx Breast Cancer Assay, Redwood City, Calif; MammaPrint, Amsterdam, The Netherlands) has been one of the few gene panels to achieve FDA approval. The FDA has also cleared the Pathwork tissue-of-origin test, developed by Pathwork Diagnostics (Redwood City, Calif.). This is a gene expression microarray-based test of 2029 genes that quantifies the molecular similarity of tumor specimens, improving the identification of primary sites from 60% by IHC alone (Anderson, 2010) to 80%, though the test is limited to only 15 tumor types (Pillai, 2011).

Although a microarray-based gene expression profiling test will not obviate the need for thorough clinical investigation, it may facilitate more focused testing, which would result in reduced cost, lower patient morbidity, and improved outcome.

MOLECULAR GENETIC PATHOLOGY OF SYNDROMATIC CANCERS

HEREDITARY COLONIC CANCER SYNDROME

Approximately 5%–10% of CRCs are hereditary, predominantly in a form of autosomal dominant transmission. Genetic polyposis syndrome accounts for less than 0.5% of all CRCs, whereas nonpolyposis forms of hereditary CRC are seen in a much higher percentage in overall hereditary CRCs (Lynch, 2003; Kievit, 2004).

FAMILIAL ADENOMATOUS POLYPOSIS SYNDROME

FAP is a rare disease that is characterized by numerous colorectal polyps (usually more than 100) (Winawer, 2003). Diagnosis of FAP is based on clinical and endoscopic findings. Three variants of FAP have been described on the basis of clinical manifestations:

1. Gardner syndrome associated with skin, soft tissue, and bone tumors.
2. Turcot syndrome associated with brain tumors.
3. Attenuated FAP with fewer than 100 polyps in the colorectum.

Classic FAP is an autosomal dominant inheritable disease, with nearly 100% penetrance. It is mainly attributable to the mutation/deletion of the *APC* gene, located at the long arm of chromosome 5. So far, more than 500 different germline *APC* mutations have been identified in FAP families (Varesco, 2004). About one third of patients are found to harbor de novo mutations. However, 5%–30% of FAP patients show no *APC* mutations on current genetic testing. Among those patients with *APC*-negative FAP, biallelic mutations in a different gene, the *MutY human homologue* (*MYH*) gene, may be found. The *MYH* gene encodes a member of the base excision repair pathway that is involved in repairing oxidative damage to DNA. Those *APC*-negative FAP patients may have a family history compatible with recessive inheritance (Sieber, 2003; Varesco, 2004), indicating that this may be a different disease. Genetic testing may be helpful in screening and diagnosis of atypical FAP cases and in the management of affected patients. PCR-based methods have been developed to detect *APC* germline mutations (Varesco, 2004).

HEREDITARY NONPOLYPOSIS COLORECTAL CANCER (LYNCH SYNDROME)

Hereditary nonpolyposis colorectal cancer is an autosomal dominant genetic condition, characterized by high predisposition to CRC and other cancers outside of the colorectum, including the genitourinary and female reproduction systems, the upper gastrointestinal tract, the hepatobiliary tract, brain, and skin. Approximately 3% of all diagnosed cases of CRC belong to HNPCC, which makes it the most common hereditary CRC-predisposing syndrome (Lynch, 2003, 2009). It has been found to have lifetime risks of approximately 80% for CRC and 40%–60% for endometrial disease. Colorectal cancer develops in younger patients (average age, 45 years), and two thirds of these cancers occur in the proximal colon. Histologically, HNPCC is not associated with a large number of colorectal

TABLE 76-4

Molecular Genetics of Hereditary Nonpolyposis Colorectal Cancer

MMR gene	OMIM name	Chromosomal locus	% of HNPCC with mutation
<i>MLH1</i>	HNPCC2	3p21	50
<i>MSH2</i>	HNPCC1	2p16	40
<i>MSH6</i>	HNPCC5	2p15	≈7–10
<i>PMS2</i>	HNPCC4	7p22	1–2
<i>MLH3</i>	HNPCC7	14q24.3	1
<i>PMS1a</i>	HNPCC3	7p22	Unclear

HNPCC, Hereditary nonpolyposis colorectal cancer; MMR, mismatch repair; OMIM, Online Mendelian Inheritance in Man (database).

polyps as seen in FAP, rather it forms a large nonpolypoid malignant lesion. Compared with sporadic CRC of equivalent staging, patients with HNPCC may have a better response to chemotherapy and better clinical outcomes (Lynch, 2009).

The molecular basis for the development of HNPCC is due to MSI, which is a consequence of inherited or germline mutations of DNA *MMR* genes. Among nine *MMR* genes discovered, mutations in *MLH1*, *MSH2*, *MSH6*, *MLH3*, and *PMS2* are associated with the development of HNPCC (Peltomaki, 2005). The significance of mutations in two other *MMR* genes, *TGFBR2* and *PMS1*, is less clear (Table 76-4). Among those identifiable mutations associated with HNPCC, 90% occur in *MLH1* or *MSH2* (Chung, 2003), 7%–10% in *MSH6*, and 1%–2% in *PMS2* or *MLH3* (Lawes, 2005). Most germline mutations in *MSH2* lead to complete loss of gene expression, and usually are accompanied by loss of expression of *MSH6*. CRC with *MLH1* mutation is frequently caused by missense mutations. Mutations of *MMR* genes cause abnormal mismatch repair function, failing to correct a larger number of insertions and deletions, eventually leading to frameshift within the microsatellites or MSI (Jacob, 2002; de Vos, 2005). However, approximately 50% of all HNPCCs have no identifiable mutations in *MMR* genes according to current methods of detection (Umar, 2004).

Two rare but distinct variants of HNPCC are known: (1) Muir-Torre syndrome, resulting from mutations in the *MSH2* gene and showing coexisting sebaceous skin tumors with small and large intestinal, gastric, kidney, endometrial, and ovarian cancer (Lynch, 2009); and (2) Turcot's syndrome, resulting from mutations in the *MLH1* and *PMS2* genes and showing coexistent glioblastoma with colorectal CRCs (Abdel-Rahman, 2004).

The diagnosis of HNPCC is based mainly on clinical information and familial history. Genetic testing has been introduced for diagnostic purposes. A testing kit for germline mutations is commercially available for blood samples. *MMR* dysfunction can be analyzed by immunohistochemistry on paraffin-embedded tissues. PCR and sequencing are methods commonly used to detect MSI. According to the Bethesda Guidelines, five microsatellite markers are to be tested. Of these, three are dinucleotide repeats, and two mononucleotide repeats. MSI-H is defined as LOH in two or more of five markers in tumor tissue compared with a normal tissue control. However, although it is a sensitive test, MSI testing is not specific for HNPCC, as HNPCC can be MSI-low and MSI-stable in some cases, and sporadic CRCs may also show MSI-H. Thus, genetic testing may be useful only after patients at risk for HNPCC are identified by the Amsterdam or Bethesda clinical criteria (Abdel-Rahman, 2004; Umar, 2004; Lynch, 2009).

FAMILIAL JUVENILE POLYPOSIS SYNDROME

Familial juvenile polyposis syndrome (JPS) is a rare disorder inherited in an autosomal dominant fashion in at least 30% of patients. The incidence of JPS is approximately 1 per 100,000 births, and it is the most common of the hamartomatous syndromes (Schreibman, 2005). The diagnosis of JPS is made when any of the following three criteria are met (Schreibman, 2005):

1. Multiple (three to ten) hamartomatous polyps in the colorectum.
2. Any number of hamartomatous polyps in a patient with a family history of JPS.

3. Extracolonic hamartomatous polyps (e.g., in the stomach or small intestine).

Germline mutations of *SMAD4*, *BMPRI1A*, and *ENG* have all been described in patients with JPS. *SMAD4* is located on chromosome 18q21.1 and is found to be mutated in approximately 15% of cases of JPS (Mishra, 2006). *BMPRI1A* (bone morphogenetic protein receptor type 1A), located on chromosome 10q22.3, is a serine threonine kinase that is a mediator of the bone morphogenetic protein intracellular signaling pathway (Zbuk, 2007). It has been identified as mutated in about 25% of affected patients with JPS. Both genes mentioned previously encode proteins that are involved in the TGF- β signaling pathway, which is an important modulator of many cellular processes (e.g., cell growth, apoptosis, growth arrest) (Zhou, 2003).

The lifetime risk of CRC is about 70%, and the risk of pancreatic, gastric, and duodenal carcinoma is increased in these patients (Gatalica, 2008). Molecular screening of individuals at risk within a JPS family for a known genetic mutation would allow clinicians to make the diagnosis at an earlier age, and would lead to closer endoscopic screening and follow-up. Individuals without the mutation would need less frequent endoscopic screening and perhaps endoscopy only after age 50, as is provided in the normal population. Therefore, genetic testing can help to define the recommended interval for screening and surveillance; it is hoped that it will help to prevent malignancy by early polypectomy and heightened surveillance (Mishra, 2006).

PEUTZ-JEGHERS SYNDROME

Peutz-Jeghers syndrome (PJS) is an autosomal dominant hamartomatous polyposis syndrome characterized by melanotic mucocutaneous hyperpigmentation and gastrointestinal hamartomas, which occur anywhere from the stomach to the anus, with a prevalence of approximately 1 in 200,000. Polyps usually are fewer than 20 in number and are most prevalent in the small intestine (Bourke, 2006). The only identifiable germline mutation causing PJS is seen in the *STK11/LKB1* gene. PJS patients have increased risk of esophageal, gastrointestinal, and pancreatic cancer, and the risk for these cancers markedly increases with age. By the age of 65 years, the risk of CRC is about 39% (Gatalica, 2008). In women with PJS, the risk for breast cancer is also reported to be substantially increased. PJS patients need to be educated as to the resources available for genetic testing, which can be very helpful, although the diagnosis can be made clinically in most cases when the family history is positive. A positive *LKB1* mutation test will confirm that individuals need careful screening and follow-up and a negative test will allow individuals to be spared of unnecessary screening procedures (Schreibman, 2005).

MULTIPLE ENDOCRINE NEOPLASIA

Multiple endocrine neoplasia (MEN) syndromes consist of a group of benign and malignant tumors in the pituitary, thyroid, parathyroids, adrenals, endocrine pancreas, paraganglia, or nonendocrine organs. Currently, the well-recognized MEN syndrome includes type 1 MEN and type 2 MEN. Some hereditary diseases are not classical for, but should be included in, the MEN syndromes, such as VHL syndrome, familial paraganglioma syndromes, Cowden syndrome, Carney complex, and hyperparathyroidism jaw tumor syndrome, and other uncommon conditions (Callender, 2008).

Multiple endocrine neoplasia type 1, also known as Wermer syndrome, is characterized by tumors in the parathyroid glands, stomach, pancreas and intestinal tract, anterior pituitary, endocrine pancreas, and duodenum, and by the presence of other, nonendocrine tumors such as hemangioma, ependymoma, and leiomyoma, often at a young age (Callender, 2008; Dreijerink, 2009). The syndrome is caused by inactivating germline mutations of the MEN 1 TSG, *MEN1*, encoding a gene product that is involved in the regulation of gene transcription, DNA replication and repair, and chromatin modification (Dreijerink, 2009). Approximately 10% of patients are the first affected person in their family, or the index patient. By age 50 years, approximately 80% of patients with mutations in the *MEN1* TSG will have the disease, and 90%–95% of these patients will have abnormal biochemical screening results (Trump, 1996; Chandrasekharappa, 2001; Callender, 2008). Genetic testing is complicated, as it may detect hundreds of disease-causing mutations (e.g., *MEN1*), as well as polymorphisms. It may potentially identify those with early asymptomatic hyperparathyroidism, allowing for early nonsurgical intervention to avoid invasive surgery (Chew, 2009).

Multiple endocrine neoplasia type 2 is characterized by strong penetrance of the MTC and associated pheochromocytoma and hyperparathyroidism. It can be further categorized into MEN 2A, MEN 2B, and FMTC, based on the risk of pheochromocytoma or hyperparathyroidism, and the presence or absence of characteristic physical features (Callender, 2008; Raue, 2009). MEN 2 is caused by germline activating mutations of the *RET* proto-oncogene due to missense mutations, predominantly in exons 10, 11, or 13 through 16, and rarely in exons 5 and 8 (Da Silva, 2003; Dvorakova, 2005). *RET* is located on chromosome 10q11.2 and encodes a TKR that appears to transduce growth and differentiation signals in several developing tissues, including those derived from the neural crest. Constitutive activation of *RET* leads to uncontrolled cell growth and survival. Genetic testing for germline *RET* mutations is available for a definitive diagnosis of MEN 2 in patients who have an equivocal presentation or family history.

Close genotype-phenotype correlations have been noted in MEN 2. Certain specific *RET* mutations (genotype) are associated with age at onset, aggressiveness of MTC, and the presence or absence of other endocrine neoplasms (phenotype) (Eng, 1996; Yip, 2003). MEN 2A, the most common subtype, has a detectable *RET* mutation in at least 95% of patients (Mulligan, 1994; Schuffenecker, 1994). Among those mutations, codon 634 (exon 11) and codons 609, 611, 618, and 620 are found to be mutated in 85% of patients with MEN 2A and in 10%–15% of patients with MEN 2B. MEN 2B, the rarest subtype of MEN 2, has *RET* mutations in codon 918 (exon 16) in more than 95% of patients, and rarely in codon 883 of exon 15 (A883F in the encoded protein) (Mulligan, 1995; Gimm, 1997). Patients with FMTC who develop only MTC with its germline mutations have these mutations from exons 13 through 15 of *RET* (Brauckhoff, 2002). Based on the mutation sites and numbers, MEN 2 can be stratified into three different levels of risk for MTC development (Brandi, 2001; Frank-Raue, 2006): high-risk group with mutations (codons 609, 768, 790, 791, 804, and 891), higher-risk group with mutations (codons 611, 618, 620, and 634), and highest-risk group with mutations (codons 883 and 918). Genetic testing may help to determine appropriate treatment options for individual patients, including prophylactic thyroidectomy, as well as the extent of surgery.

von Hippel-Lindau syndrome is an autosomal dominant inheritable neoplasia syndrome characterized by hemangioblastomas in the CNS and retina, pheochromocytomas, renal cysts and clear cell RCC, pancreatic cysts and islet cell tumors, endolymphatic sac tumors, and papillary cystadenomas of the epididymis and broad ligament (Maher, 1991). It has a strong penetrance, and more than 90% of affected individuals have the disease by the age of 65 years. As discussed in the earlier section on renal tumors, VHL disease is caused by inactivating germline mutations of the VHL TSG, which contains three exons and is located on chromosome 3p25. VHL is critical in the process of regulating HIF- α and - β , which participate in the cell's response to hypoxia, as discussed earlier. Similar to MEN 2, a clear relationship has been noted between the type of genetic mutation of *VHL* (the genotype) and the pattern of tumors that developed in that particular family (the phenotype) (Crossey, 1994; Maher, 1996; Webster, 1998). The syndrome is associated with an increased risk of a variety of tumors in an allele-specific manner. Genetic testing is available for definite diagnosis of VHL syndrome in patients with equivocal disease and apparently sporadic *VHL*-related disease (Stolle, 1998).

Familial paraganglioma syndromes are inherited in an autosomal dominant manner and are characterized by multiple head and neck, thoracic, and abdominal paragangliomas and/or pheochromocytomas. Four familial paraganglioma syndromes have been described: PGL 1, PGL 2, PGL 3, and PGL 4 (Callender, 2008; Myssiorek, 2008). Most familial cases of paraganglioma have been found to be associated with the mutation of three genes encoding subunits of the mitochondrial II/succinate dehydrogenase (SDH) complex: *SDHB* at 1p36.1 (PGL4), *SDHC* at 1q21 (PGL3), and *SDHD* at 11q23 (PGL1) (most common) by linkage and candidate gene studies (Myssiorek, 2008). Individuals with *SDHB* mutation usually have paragangliomas in the abdomen and less frequently in the head and neck, the chest, and the adrenal gland, and are associated with an increased risk of malignancy. Individuals with *SDHD* mutation develop paragangliomas most often in the head and neck (Neumann, 2004; Benn, 2006). *SDHD* mutation is usually associated with low risk of malignancy of paragangliomas (Neumann, 2004; Dreijerink, 2009). Individuals with *SDHC* mutations are rare, and paragangliomas usually present in the head and neck, with a benign course (Schiavi, 2005).

The genetic screening method is very useful for predicting risk for malignancy, because so far the biological behavior of all neuroendocrine

tumors cannot be determined by conventional histologic examination alone. Genetic screening for the three genes previously discussed has been offered for familial paraganglioma (Oosterwijk, 1996). This test can identify individuals with mutations, allowing earlier detection and earlier intervention.

Cowden syndrome is a rare autosomal dominant, cancer-predisposing condition characterized by increased risk of breast, thyroid, and endometrial cancers and other benign conditions, including multiple hamartomas in the colon, lipomas, and fibromas (Callender, 2008; Hobert, 2009). It is caused by germline mutations in the TSG **phosphate and tensin homologue deleted on chromosome 10**. *PTEN* encodes a tumor suppressor promoting G1 cell cycle arrest or apoptosis by downregulating *P13K* and *AKT* and, concurrently, the raf-MEK-ERK pathway (Waite, 2002; Hobert, 2009).

Genetic testing for this condition is commercially available to identify mutations and/or deletions within *PTEN* (Marsh, 1998; Zhou, 2003). Approximately 85% of patients with Cowden syndrome have an identifiable *PTEN* mutation or deletion (Marsh, 1998; Eng, 2003; Zhou, 2003). This method includes multiplex ligation-dependent probe amplification (the preferred method), Southern blotting, monochromosomal hybrid analysis, real-time polymerase chain reaction, and semiquantitative multiplex PCR. Promoter analysis is also used for genetic testing in the research setting. Identification of *PTEN* mutations not only can confirm the clinical diagnosis, but also can help in prenatal diagnosis and prediction of mutations in affected families (Callender, 2008; Hobert, 2009).

Li-Fraumeni syndrome is a rare autosomal dominant disorder characterized by increased risk of soft tissue sarcoma, breast cancer, and osteosarcoma, as well as brain tumor, childhood leukemia, and adrenocortical carcinoma (Moule, 2006; Callender, 2008).

Most individuals or families with Li-Fraumeni syndrome have the germline mutation in the TSG encoding the *p53* protein on chromosome 17p13.1. Unlike other TSGs, such as *RB* and *p16*, germline mutations in only one copy of *p53* can result in cancer development (Yoon, 2002). Most *p53* germline mutations are missense mutations, and only 10% are due to deletions (Olivier, 2003). A few cases of Li-Fraumeni syndrome and Li-Fraumeni-like syndrome show mutations in another TSG, *CHEK2*, without *p53* mutation (Bell, 1999).

Certain genotypes of *p53* mutations have prognostic significance. Cancers harboring missense *p53* mutations are associated with more aggressive behavior; these mutations therefore suggest poorer prognoses. Missense mutations within the DNA binding region of the *p53* gene are more likely predisposed to early onset of breast cancer and brain tumor, whereas mutations outside the DNA binding region are more commonly seen in adrenocortical carcinoma. Mutations leading to a *p53* null phenotype are associated with earlier onset of brain tumor (Olivier, 2003).

Genetic testing for a mutation of *p53* in a patient with Li-Fraumeni or Li-Fraumeni-like syndrome can confirm the clinical diagnosis and screen family members at risk. However, it should also be noted that inactivating *p53* mutations and homozygous deletions of this gene are observed in a significant number of other types of cancer, including colon, breast, and bladder.

Neurofibromatoses are a group of genetically distinct disorders with predisposition to induce nerve sheath tumor. They include neurofibromatosis 1 (NF1), neurofibromatosis 2 (NF2), and schwannomatosis.

Neurofibromatosis 1 (also referred to as von Recklinghausen's disease), the most common type, is an autosomal dominant multisystem disorder with 100% penetrance and variable expression. It predisposes to the development of benign and malignant tumors, typically neurofibroma, and less commonly glioma and other abnormalities (learning disability, vasculopathy, and bony abnormalities) (Arun, 2004; Boyd, 2009). Patients with this condition often are observed to have multiple tumors and café-au-lait spots on their body surfaces.

NF1 results from a mutation in the *NF1* gene, *NF1*, located on chromosome 17q11.2, and encodes for the large protein, neurofibromin. Of major importance, neurofibromin contains at least one domain that has GTPase-activating (GAP) activity with the ras-p21 protein. As discussed in Chapter 74, wild-type ras-p21 is activated by exchanging guanosine diphosphate for GTP. GAP inactivates wild-type ras-p21 by promoting the hydrolysis of ras-p21-bound GTP. Mutations in *NF1* result in loss of function of neurofibromin, leading to increase Ras activity, particularly in neurocutaneous tissues, as well as to increase proliferation and tumorigenesis (Boyd, 2009). The mutations are near evenly split between the sporadic and the inherited. Types of mutations of *NF1* include complete gene deletions, insertions, stop codons, splicing mutations, amino acid substitutions, and chromosomal rearrangements (Messiaen, 2000).

Molecular testing for *NF1* is clinically available. Because of the large gene size and lack of hot spots of *NF1* mutations, comprehensive screening approaches have been established to detect all or most mutations and may detect 95% of *NF1* mutations (Messiaen, 2000). These approaches include the optimized protein truncation test (an in vitro coupled transcription/translation synthesis assay designed as a tool to detect mutations that lead to premature translational termination), FISH, direct sequencing, RT-PCR with Southern blot analysis, and/or cytogenetic analysis (Messiaen, 2000; Boyd, 2009).

Molecular testing of *NF1* mutations is used mainly for definitive diagnosis in suspicious cases, and for prenatal or preimplantation genetic diagnosis. However, it is not indicated for the routine clinical care of patients with NF1. Because of the lack of genotype-phenotype correlations, genetic testing, although useful for confirming the diagnosis of NF1, does not predict disease severity or outcome.

Neurofibromatosis 2 is also a dominantly inherited tumor predisposition syndrome characterized by the development of multiple schwannomas, meningiomas, and ependymomas. Most patients present with hearing loss due to inevitable development of schwannomas affecting both vestibulocochlear (8th) nerves (Evans, 2009a, 2009b).

NF2 is caused by mutations in the *NF2* gene on chromosome 22. More than 50% of patients have new mutations, and about one third are mosaic for the underlying disease. Germline mutations are most frequently truncating mutations (nonsense and frameshifts) that are associated with the most severe disease. However, single and multiple exon deletions may cause mild disease. Most mutations in *NF2* found on sequence analysis are pathogenic. Some missense mutations or in-frame deletions may be harmless (Evans, 2009b). Diagnosis of NF2 is based on clinical criteria; molecular genetic testing for *NF2* mutations can confirm the diagnosis because *NF2* is the only gene known to be associated with this disease. Methods of genetic testing for *NF2* include sequence analysis, mutation scanning, duplication/deletion testing, RT-PCR, real-time PCR, array comparative genomic hybridization, and combinations of these. Large deletions encompassing *NF2*, ring chromosome 22, and translocation disrupting *NF2* can be detected by cytogenetic analysis, and smaller deletions can be identified by FISH. Molecular testing may also be used for appropriate surveillance, earlier detection, and early intervention of disease among relatives at risk (Evans, 2009a, 2009b).

Schwannomatosis is a recently recognized third major form of NF, characterized by multiple nonvestibular schwannomas in the absence of meningiomas, intraspinal ependymomas, and other clinical signs of NF2. Schwannomatosis and NF2 are clinically and molecularly distinct (MacCollin, 2003), but their phenotypes frequently overlap. In contrast to patients with NF2, multiple tumors from the same individual with schwannomatosis do not share a constitutional mutation (Jacoby, 1997; Kaufman, 2003). Schwannomatosis-derived schwannomas have been shown to have truncating mutations of the *NF2* gene (Jacoby, 1997). Commercially available *NF2* mutational analysis does not help differentiate between schwannomatosis and NF2 (MacCollin, 1994; Moyhuddin, 2003). Definitive diagnosis of schwannomatosis and its distinction from NF2 await identification of the schwannomatosis locus or gene.

KEY POINTS

- Completion of the human genome project has provided scientists with a detailed map of the human genome and predicted coding regions that have facilitated the emergence of high-throughput genomic and proteomic technologies.
- A number of mature platforms exist for high-throughput profiling of gene expression in human tissue, including serial analysis of gene expression (SAGE), DNA microarrays, and real competitive polymerase chain reaction.
- Proteomic technologies, including mass spectrometry and protein arrays, have begun to explore the dynamic and complex protein composition of healthy and diseased human tissue.
- DNA microarray and SAGE technologies have identified diagnostic gene expression signatures for a number of hematologic and solid malignancies that are often difficult to distinguish using traditional histologic analysis.
- Prognostic gene and protein expression profiles have been identified in a large number of cancer settings, including lymphoma, lung cancer, breast cancer, and acute myeloid leukemia, among others.
- Validation in large clinical trials, standardization of techniques and controls, and inclusion of analytic standards are needed before widespread clinical implementation of these technologies can be achieved.

OVERVIEW

With the complete sequence of human and other genomes recently elucidated, we have witnessed an explosion of information and high-throughput tools that are profoundly altering biomedical research and the culture of science. This revolution, which began in the mid-1980s, emerged from developments in three areas: (1) molecular biology, most notably, breakthroughs in rapid DNA sequencing; (2) information technology, in particular, the ability to store and analyze unprecedented quantities of data; and, most important, (3) progress in human genetics, especially the identification of thousands of single-gene human disorders. The convergence of these technological and scientific advances raises promise for the rapid identification of disease-related genes, leading to improved diagnostic tests and more effective therapies.

Detailed maps of human and other genomes provide the information needed to chart a course toward understanding and treating many diseases, but this course remains a long and difficult one. Although progress will come most readily for disorders following Mendelian patterns of inheritance, even these disorders will pose significant difficulties. For example, although the biology and genetics of sickle cell anemia have been reasonably well understood for more than half a century—a single valine replaces glutamic acid at position 6 in the β -hemoglobin chain—effective treatment has been slow to develop. The penetrance of genetic diseases thought to be due to single mutations often relies on more complex interactions between the mutation and a variety of concurrent gene polymorphisms, such as those seen in the genes encoding surface proteins on postcapillary venule endothelial cells, which, in part, account for sickle cell disease severity.

Many common diseases, in particular, cardiovascular disease, mental illness, and almost all cancers, stem from multigenic causes. In addition, these diseases invariably have strong environmental components, presenting a substantial challenge to the development of effective and economical diagnostic and prognostic tests. Even in the absence of a confounding environmental influence, linking the quantifiable phenotype of a disease to a set of distinct alleles is a complex undertaking. Further complicating matters, many disorders do not have sharply defined, quantifiable phenotypes.

In a chapter filled with information on promising technologies, we make these sobering remarks to emphasize that greater understanding never guarantees cures or therapies. However, greater understanding does aid the development of rational strategies to detect and control disease. The reference genome allows us to rapidly characterize polymorphisms across the human population; it also enables molecular fingerprinting technologies that permit identification of the precursors and consequences of normal and pathologic changes in gene and protein expression. We can feel confident that the power of genomic technologies is well beyond anything previously available, and that it will make possible during the next several decades a host of new diagnostics and therapeutics for cancer and other common diseases, profoundly altering the practice of medicine. As discussed in Chapter 72, genomic technologies have already made an impact in the area of pharmacogenomics, in which drug protocols are being designed from the cytochrome P450 genetic profiles of patients, allowing for maximally effective therapeutic regimens for each patient.

This chapter focuses on several high-throughput genomic and proteomic technologies that have the potential to influence disease classification and prognostication (Fig. 77-1). These molecular tools have affected virtually all forms of human pathology; however, given the public health implications and the preponderance of recent publications in the field, we will concentrate on diagnostic and prognostic applications related to

cancer, although other salient disease states will be mentioned where applicable. After presenting a brief overview of the human genome project and resultant high-throughput technologies, we discuss examples of applications in the setting of several hematologic and solid malignancies. The scope of the chapter has been constrained to focus on high-throughput technologies; therefore, this chapter does not represent a comprehensive overview of all technologies being used in clinical genomic and proteomic studies. In addition, among the technologies presented, some are highlighted in greater detail because of their widespread use. As more data are produced using these technologies, strategies combining data sets may become powerful approaches to developing accurate clinical tools. Along with measuring gene and protein expression levels, understanding human genetic variation in DNA will be important in elucidating disease markers and mechanisms. A discussion of high-throughput genotyping technologies to assay single-nucleotide polymorphisms is, however, beyond the scope of this chapter (for reviews, see Ding and Jin, 2009; Syvanen, 2001).

THE HUMAN GENOME PROJECT

PUBLIC SEQUENCING EFFORT (HIERARCHICAL SHOTGUN SEQUENCING)

Sequencing of the human genome was a 15-year, \$3 billion project, initiated in 1990 as a joint effort between the U.S. Department of Energy and the National Institutes of Health (Collins, 2003). From the time of the project's inception through 1995, genetic and physical maps of human and mouse genomes were constructed, and yeast and worm genomes were sequenced. These initial projects, coupled with advances in sequencing technology and sequence data analysis, outlined cost-effective strategies

Figure 77-1 High-throughput platforms and the central dogma of biology. The three major technologies responsible for rapid analysis of biological systems include mass spectrometry, sequencing, and microarrays. Examples of each technology have been listed as applied to each broad stage of biological information, that is, DNA, RNA, and protein. ICAT, Isotope-coded affinity tags; MS, mass spectroscopy; SELDI-TOF-MS, surface-enhanced laser desorption/ionization, time-of-flight mass spectroscopy. (Adapted with permission from Kufe DW, Holland JF. *Cancer medicine*. 6th ed. Hamilton, Ontario: BC Decker; 2003; Wilson J, Hunt T. *Molecular biology of the cell*. 4th ed. New York: Garland Science; 2003; Brown TA. *Genomes*. 2nd ed. New York: John Wiley & Sons; 2002.)

and techniques, while demonstrating the feasibility of sequencing the human genome. In March of 1999, the effort to sequence the human genome commenced in earnest, and sequencing was set to be completed in two phases: the first phase would include completion of a draft sequence, and the second would be a finishing phase for resolution of misassembled regions and filling in of sequence gaps. By June of 2000, centers involved in the project were producing raw sequence data at a rate of about 1000 nucleotides per second, 24 hours a day, 7 days a week (Lander, 2001).

The first phase of the Human Genome Project, a collaborative endeavor of 20 groups in six countries, was completed and published in February of 2001 in the journal *Nature* (Genome International Sequencing Consortium, 2001; Lander, 2001). The draft sequence covered about 96% of the euchromatic part (gene-rich) of the human genome and 94% of the entire genome, with an average of fourfold coverage (i.e., each base sequenced an average of four times). The International Human Genome Sequencing Consortium employed a sequencing strategy referred to as hierarchical shotgun sequencing (also known as map-based, bacterial artificial chromosome (BAC)-based, or clone-by-clone sequencing) (Olson, 2001). Genomic DNA obtained from volunteers from a variety of racial and ethnic backgrounds was partially digested with restriction endonucleases. Fragments of 1–2Mb in length were cloned into BACs. Eight DNA libraries containing overlapping insert clones were created, representing 65-fold coverage of the genome (each base is represented on average 65 times, as seen on examination of all eight libraries).

BACs containing fragments of the human genome are inserted into bacteria and are replicated as the bacteria grow and divide. Each BAC clone is completely digested with a restriction enzyme to produce a unique pattern of DNA fragments, known as a fingerprint. The fingerprints from different BAC clones can be compared to allow selection of a set of overlapping BAC clones that cover a portion of the genome (a large region of the genome covered by overlapping clones is called a contig). Contigs can be positioned along the chromosome by using known markers from previously constructed genetic and physical maps of the human genome. Selected BAC clones are sheared into smaller overlapping fragments, subcloned, and sequenced. Subcloning is necessary because each sequencing reaction can reliably read only about 500 base pairs (bp). The sequence of the BAC clone can be reconstructed from the set of sequences obtained from the subclones, and BAC fingerprints guide the assembly of several BAC clones into contigs.

Draft sequences were required to obtain an average of fourfold coverage with 99% accuracy as determined by software (i.e., PHRED, PHRAP; CodonCode Corporation, Dedham, Mass.) that assigns base quality scores and assembles sequences according to the scores. Throughout the duration of the project, sequences longer than 2 kb were required to be deposited in public databases within 24 hours (data are available from the Genome Browser of the University of California at Santa Cruz, www.genome.ucsc.edu; the GenBank of the National Center for Biotechnology Information, www.ncbi.nih.gov; and Ensembl of the European Bioinformatics Institute and the Sanger Centre, www.ensembl.org). Assembly of the draft sequence was a three-part process that involved filtering the sequence data to eliminate bacterial and mitochondrial sequences, constructing a layout of clones along the genome, and merging overlapping clones to produce a draft sequence.

The hierarchical shotgun sequencing approach was chosen by the public consortium for several reasons. Dividing up the work among sequencing centers was straightforward with the use of clones. Also, the assembly of clones to produce a draft sequence probably would enhance accuracy because approximately 46% of the human genome comprises repeat sequences and exhibits widespread individual sequence variation. In addition, this approach could address cloning bias, and underrepresented sequences could be targeted for sequencing.

PRIVATE SEQUENCING EFFORT (WHOLE-GENOME SHOTGUN SEQUENCING)

In 1998, a private company, Celera Genomics (Alameda, Calif.), led by Craig Venter, announced its intention of sequencing the human genome in 3 years using a different approach, known as whole-genome shotgun sequencing. Celera's draft of the human genome sequence was reported in the February 2001 issue of *Science* (Venter, 2001). Celera generated 14.8 billion bp of DNA sequence in 9 months to produce a 2.91 billion bp consensus sequence of the euchromatic part of the human genome with an average of fivefold coverage. The company used genomic DNA obtained from three females and two males of the following ethnogeographic

groups: African American, Asian-Chinese, Hispanic-Mexican, and Caucasian. A total of 16 different DNA libraries were constructed with three different insert sizes: 2 kb, 10 kb, and 50 kb. Both ends of the insert from clones chosen at random were sequenced to produce "mate pair" sequencing reads. The average distance between mate pairs was known because the range of insert sizes for a clone taken from a particular library could be characterized by calculating the distance between mate pairs in previously sequenced stretches of the genome. Celera generated a set of 27.26 million reads with an average length of 543 bp.

Celera combined its sequence data with all data from the publicly funded efforts available up to September of 2000 in GenBank and pursued two different assembly strategies. The whole-genome assembly strategy involved "shredding" the publicly funded sequences into small fragments, combining these fragments with Celera's reads, identifying overlapping sequences, and joining them to produce long, continuous consensus sequences. These contigs were ordered and gaps between contigs were quantified using information obtained from the mate pair reads. A variant of the process described previously, known as compartmentalized shotgun assembly, yielded slightly better results because sequences were first clustered, based on mapping information, to a region of the chromosome, before the process already described was performed.

Analyses of draft sequences performed by the two groups yielded similar results. Some genes were derived from bacteria or transposable elements, and large segmental duplications were apparent throughout the genome. The distribution of genes, CpG islands, recombination sites, and repeats was found to be highly variable across the genome. Widespread genetic variation was apparent, and about 2.1 million single-nucleotide polymorphisms—1 per 1250 bp—were discovered. One of the most surprising results revealed by completion of the draft sequence was the estimate that the genome contained about 30,000 protein-coding genes, considerably fewer than the 100,000 or more that had been postulated. The number is only one-third greater than that of the worm; however, probably a much larger number of different proteins were noted because of alternative splicing (Claverie, 2001). Scientists used many gene prediction methods to arrive at the gene estimate of 30,000. Gene prediction algorithms predict the location of unknown genes in the genome using sequence characteristics learned from known genes, including codon and nucleotide composition within coding regions and conserved sequences at exon/intron boundaries and within promoter regions. The human genome sequence has a low signal-to-noise ratio because the coding regions represent only about 3% of the genome; therefore, algorithms produce a large number of false-positives. Most algorithms, however, use two other important sources of information: similarity to known human proteins and expressed transcripts, and homology to proteins and sequences characterized in other organisms (for a review of gene prediction algorithms, see Mathe, 2002).

FINISHING THE SEQUENCE OF THE HUMAN GENOME

In October of 2004, in the journal *Nature*, the International Human Genome Sequencing Consortium published an article entitled, "Finishing the Euchromatic Sequence of the Human Genome" (International Human Genome Sequencing Consortium, 2004). This article reported that the draft sequence was missing about 10% of the euchromatic portion of the genome, contained about 150,000 gaps, and had many sequence segments that had not been assigned an order or orientation. The current sequence contains 2.35 billion nucleotides, covers about 99% of the genome, and has only 341 gaps (with an error rate of 1 mistake every 100,000 bases). The sequence revision predicts between 20,000 and 25,000 protein-coding genes; this discrepancy in numbers is due to differences in gene prediction algorithms. The newly published sequence reveals that segmental duplications cover about 5.3% of the euchromatic portion, providing insight into the evolution of the human genome and aiding the study of diseases caused by deletions and rearrangements of these regions (e.g., DiGeorge syndrome) (Stankiewicz, 2002). This latest sequence also makes it possible to trace the birth and death of genes—genes recently born as a result of gene duplication, and genes lost as a result of mutation.

Sequencing of the human genome is a monumental achievement that "holds an extraordinary trove of information about human development, physiology, medicine, and evolution" (Lander, 2001). It has provided the infrastructure for sequencing other genomes and for understanding the structure and complexity of human genetic variation. This detailed map of the human genome and predicted coding regions has facilitated the

emergence of several high-throughput technologies, through which scientists have begun to explore the complete set of gene and protein expressions in healthy and diseased human tissue. These technologies promise to revolutionize the classification of human disease and to usher in an era of individualized molecular medicine.

HIGH-THROUGHPUT TECHNOLOGIES GENOMIC

An intimate understanding of cellular machinery represents the first step toward unraveling the complexity of human disease. Important insights into the function of a gene can be deduced by determining the cell type and conditions under which a gene is expressed, and by quantifying the level of message transcribed. A technique commonly used to assay the level of expression of a single gene (represented by messenger RNA [mRNA]) across a few different conditions is a Northern blot. This “gene-by-gene” approach began to change in the early 1990s as a result of the success of the Human Genome Project and various technological advances that enabled the development of high-throughput gene expression analyses whereby several genes could be assayed simultaneously. Three different genomic high-throughput technologies are discussed here. SAGE (Velculescu, 1995) and DNA microarrays (Schna, 1995; Lockhart, 1996) were both developed in the 1990s and are currently in widespread use; real competitive polymerase chain reaction (PCR) using matrix-assisted laser desorption ionization time-of-flight mass spectroscopy (MALDI-TOF-MS) was first published in 2003 (Ding, 2003). The basic principles underlying DNA microarrays are discussed in Chapter 67; those underlying real competitive PCR are discussed in Chapter 66.

Depending on the experimental design, samples are obtained from cell cultures or surgical tissues, and total RNA is isolated. Techniques such as laser capture microdissection (Emmert-Buck, 1996) are often used before RNA isolation to obtain a homogeneous population of cells from tissue specimens. After total RNA or mRNA is obtained and is reverse transcribed to make complementary DNA (cDNA), each technology uses a different protocol to rapidly measure the transcript levels of the genes in each sample. The principles of each method, as well as corresponding advantages and disadvantages, are outlined in the following sections.

Serial Analysis of Gene Expression

SAGE measures the expression level of genes in a sample by isolating and sequencing several thousand short 10–14-bp tags isolated from cDNA. Two important pieces of information can be deduced from the output: the sequences of the tags usually allow identification of their corresponding genes, and the number of times a particular tag is sequenced is a measure of transcript abundance. The ability to uniquely identify a transcript using as short a sequence as 9bp resides in the probability of defining this sequence from others. Such a sequence can distinguish 262,144 transcripts (4^9)—a number greater than current estimates of the number of transcripts in the human genome (Velculescu, 1995; Pennisi, 2000).

The SAGE protocol involves isolating RNA from a sample of interest. RNA is converted to double-stranded cDNA using a biotinylated oligo primer for first-strand synthesis. SAGE then uses two types of restriction enzymes. The first one, called an anchoring enzyme, recognizes a specific 4-bp sequence (e.g., *Nla*III). Any 4-bp-recognizing enzyme may be used because, on average, enzymes cleave every 256 bp (4^8). The anchoring enzyme leaves a short, overhanging, single-stranded piece of DNA at the 5′ end of the site of cleavage. The biotinylated fragment, which represents the 3′ end of the gene, then is bound to streptavidin beads, capturing only digested cDNA fragments that contain a portion of the poly(A⁺) tail. Captured fragments are purified and are randomly split equally into two pools. The second enzyme, called the tagging enzyme, behaves differently and cleaves DNA 14–15 bp immediately 3′ of its recognition sequence (e.g., *Bsm*FI). The recognition sequence for the tagging enzyme is engineered into the sequence of linkers described in the next section.

After the purified fragments are split into two pools, two different oligonucleotide linkers, each containing a different PCR primer sequence (for purposes of discussion, the linkers will be labeled A and B)—the tagging enzyme recognition sequence and a single-stranded DNA overhang that is part of the anchoring enzyme recognition sequence—are designed and synthesized. Linker A is ligated to the 5′ ends of cDNA fragments in one pool, and linker B is ligated to the 5′ ends of cDNA fragments in the other pool. Ligation proceeds by means of base pairing between complementary single-stranded overhanging DNA ends on both cDNA fragments and linkers, creating an intact anchoring enzyme

recognition sequence. The cDNA fragments in each pool are then cut with the tagging enzyme, resulting in a new fragment that contains the linker plus a short, 10-bp region of cDNA, known as a tag (the remaining cDNA fragment and the poly(A⁺) portion of the tail are removed). The two pools of cDNA fragments are ligated together, creating ditags (the new sequences are as follows: linker A–tag–tag–linker B). Ditags are amplified by PCR using primers designed on the basis of sequences in linkers A and B.

Creation of the ditags is important for several reasons. First, ditags can be amplified by PCR for subsequent cloning steps. Second, each tag within a ditag is linked tail to tail and is flanked by anchoring enzyme recognition sequences, providing important orientation information used to identify the genes corresponding to each tag. Finally, even if tags are highly abundant, the probability of creating identical ditags is extremely low. As a result, the occurrence of identical ditags indicates PCR bias, and these ditags are excluded from the final analysis to ensure accurate quantification of transcript abundance (Velculescu, 1995; Yamamoto, 2001).

After amplification, the anchoring enzyme is used to cleave the linkers from the ditags. Ditags from different reactions are ligated together end to end to form strings of 10–50 tags. The concatenated strings of ditags are cloned into plasmids and are sequenced. Typically, about 50,000 tags are sequenced for each sample of interest, using a high-throughput sequencer (for additional details on the method, see the review by Madden, 2000). The absolute expression levels of genes in the sample are quantified by counting the number of sequenced tags that corresponds with each gene. Figure 77-2 provides a visual scheme of the procedure.

SAGE technology has continued to mature, and technologies have been used to refine this technology toward its application, including an increase in sequencing efficiency (deepSAGE), improved tag-to-transcript mapping of SAGE tags (longSAGE), and reduction of the amount of required input RNA (microSAGE). The expansion of SAGE application from solely transcriptosome-based analysis to genomic analysis has given rise to Serial Analysis of Chromatin Occupancy, which identifies genomic signature tags that pinpoint transcription factor binding sites. Because of the advent of microSAGE, small amounts of material obtained from needle biopsies and from specific cell types (obtained via fluorescence-activated cell sorting or laser microdissection) are sufficient to allow characterization of global gene expression (Datson, 2008).

The Cancer Genome Anatomy Project of the National Cancer Institute has chosen SAGE technology to sequence more than 5 million tags across more than 100 different human cell types. Data are stored in a public database known as SAGEmap (Lal, 1999; Lash, 2000), and several tools such as SAGE Genie (Boon, 2002) are available for reliably assigning tags to genes and for performing data analysis and visualization. Additional information and details can be obtained at <http://cgap.nci.nih.gov/SAGE> or <http://www.sagenet.org>.

SAGE differs from microarray in that the former employs a sequence-based sampling technique that is not contingent on hybridization and does not require well-defined known genes or sequences. Through this approach, novel genes or gene variants can be elucidated. Furthermore, SAGE provides better gene quantification because it directly counts the number of gene transcripts and is less subject to background “noise” of the microarray; however, it is more expensive. Modifications of SAGE, such as longSAGE, utilize different restriction endonucleases as the tagging enzyme that cuts 17 bp 3′ from the anchoring site, generating a tag with a uniqueness probability of >99% and providing the ability to tag a greater proportion of the unannotated genome. Other modifications that require minimal quantities of mRNA for library construction (SAGE-Lite and Micro-SAGE) have also been described (Patino, 2002).

Microarray

DNA microarrays are orderly arrays of spots, each composed of DNA representing a single gene and immobilized onto a solid support such as a glass slide, as described in Chapter 67. DNA microarrays take advantage of Watson-Crick base pairing; therefore, only strands of DNA that are complementary will hybridize and produce a signal that can be used as a measure of gene expression. Production and use of microarrays requires several steps, including creation of probes, array fabrication, target hybridization, fluorescence scanning, and image processing to produce a numeric readout of gene expression. Throughout the chapter, a probe will refer to a nucleic acid sequence that is attached to a solid support, and the target will be a complementary free sequence of nucleic acids measured for its abundance with the use of microarrays. A detailed description regarding the fabrication of cDNA and oligonucleotide arrays, along with how the RNA is prepared and hybridized to these platforms, can be found in Chapter 67.

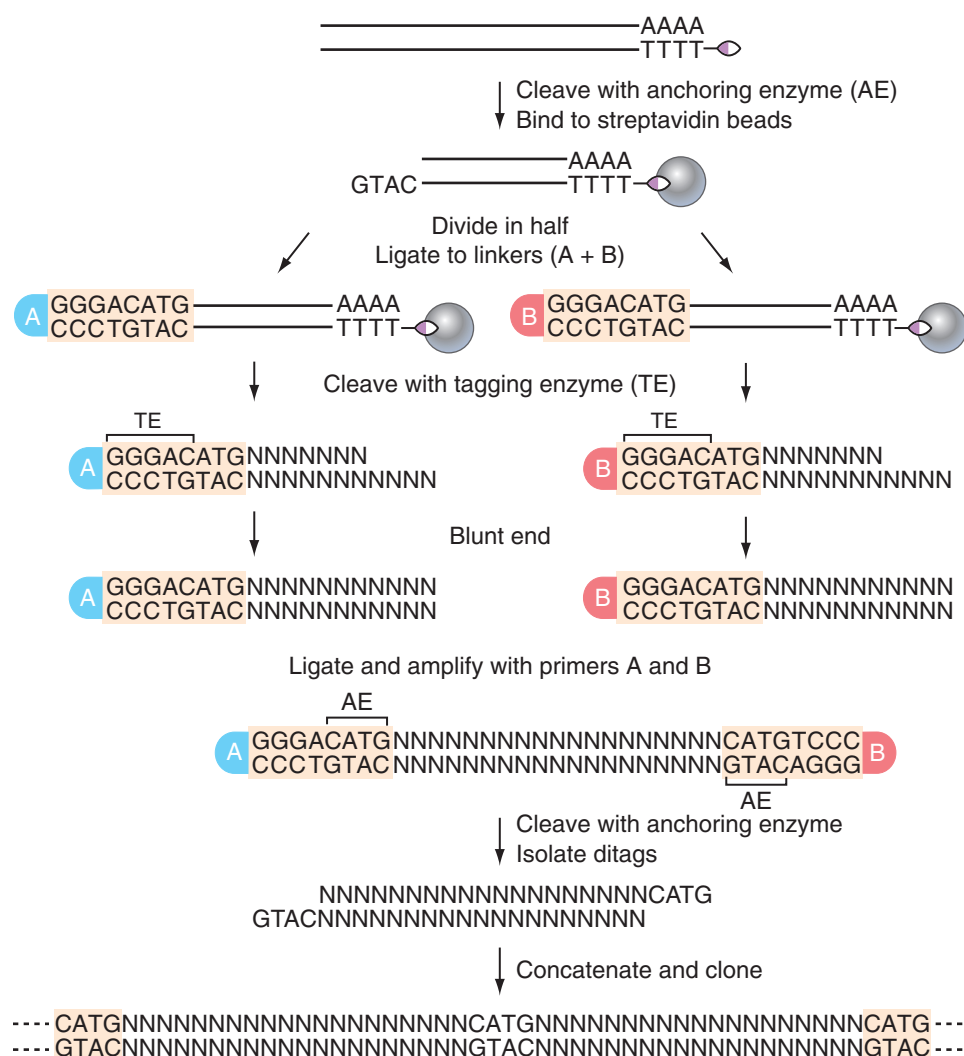

Figure 77-2 Serial analysis of gene expression (SAGE) is a technique that measures the expression levels of genes in a sample of interest. RNA is isolated from the sample, complementary DNA (cDNA) is synthesized, and several thousand short base pair (bp) tags are isolated. SAGE uses two types of restriction enzyme: one, called an anchoring enzyme (i.e., NlaIII), recognizes a specific 4-bp sequence and cleaves DNA every 256 bp, immediately 5' of the sequence tag. The second enzyme, called the tagging enzyme (i.e., BsmFI), behaves differently and cleaves DNA 14–15 bp immediately 3' of its recognition sequence. First, cDNA fragments are cut with the anchoring enzyme, captured using streptavidin–biotin affinity chromatography, purified, and split into two pools—A and B. Second, two different linkers (A and B) are ligated to the 5' ends of the cDNA fragments in their respective pools. The cDNA fragments in each pool are then cut with the tagging enzyme, resulting in a new fragment that contains the linker plus a short 10-bp region of the cDNA, known as a tag. The two pools of cDNA fragments are ligated together, creating ditags, which are amplified by polymerase chain reaction (PCR) using primers designed on the basis of sequences in linkers A and B. After amplification, the anchoring enzyme is used to cleave the linkers off the ends of the ditags. Ditags from different reactions are ligated together to form strings of 10–50 tags. The concatenated strings of ditags are cloned into plasmids and sequenced. Sequences of the tags are used to identify the corresponding genes and represent a measure of transcript abundance. (*Adapted with permission from Yamamoto M, Wakatsuki T, Hada A, Ryo A. Use of serial analysis of gene expression [SAGE] technology. J Immunol Methods 2001;250:45–66.*)

DNA microarray experiments can produce millions of data points; this requires a suite of data processing steps to select relevant genes. Although no standard protocol is available, the following steps usually are included in analysis of a DNA microarray experiment (Fig. 77-3). Image files are converted to numeric values that are normalized and summarized using a software program (both free and commercially available programs such as Affymetrix [Affymetrix Inc., Santa Clara, Calif.] and Agilent [Agilent Technologies, Wilmington, Del.], among others, may be used) (Li, 2001; Irizarry, 2003); poor-quality arrays are removed from the analysis; genes that are not accurately detected by the array and genes that show little variation across samples are filtered out; and a variety of computational and statistical analyses are performed. Exploratory data analyses, including classification and identification of differentially expressed genes, can be divided into two categories: supervised and unsupervised methods. Supervised methods, such as class prediction algorithms, use predefined groups of samples (referred to as the training set) to identify genes that can distinguish between groups to accurately classify unknown samples (referred to as the test set). A large number of supervised class prediction algorithms have been applied to microarray data, including linear or quadratic discriminant analysis (Dudoit, 2002), k-nearest neighbors (Simon, 2004), weighted voting (Golub, 1999), artificial neural networks (Khan, 2001), support vector machines (Brown, 2000), and shrunken

centroids (Tibshirani, 2002). Supervised algorithms such as significance analysis of microarrays (SAM) (Tusher, 2001), as well as parametric and nonparametric statistical tests between groups of samples, can be used to identify differentially expressed genes. Unsupervised methods, also known as class discovery methods, can be used to find previously unknown classes, such as novel cancer subtypes, within a dataset. Various clustering techniques, such as hierarchical clustering (Eisen, 1998) and self-organizing maps, are commonly used class discovery algorithms (see Kaminski, 2002, for a general review; see Leung, 2003, for a cDNA array analysis review; and see Tumor Analysis Best Practices Working Group, 2004, for an oligonucleotide array analysis review).

The Gene Expression Omnibus database (GEO; available at <http://www.ncbi.nlm.nih.gov/geo>) is a central repository for high-throughput gene expression data, through which a wide range of microarray data from published experiments is publicly available. All microarray data deposited in GEO adhere to the Minimum Information About a Microarray Experiment guidelines established to provide basic information about experimental designs, samples, and types of technology used. In addition to GEO, a wide range of bioinformatics tools is available for microarray data analysis (Quackenbush, 2001; Zhang, 2009). No standards for analyzing microarray data have been established, and various methods can often produce different results (for a discussion, see Tumor Analysis Best Practices

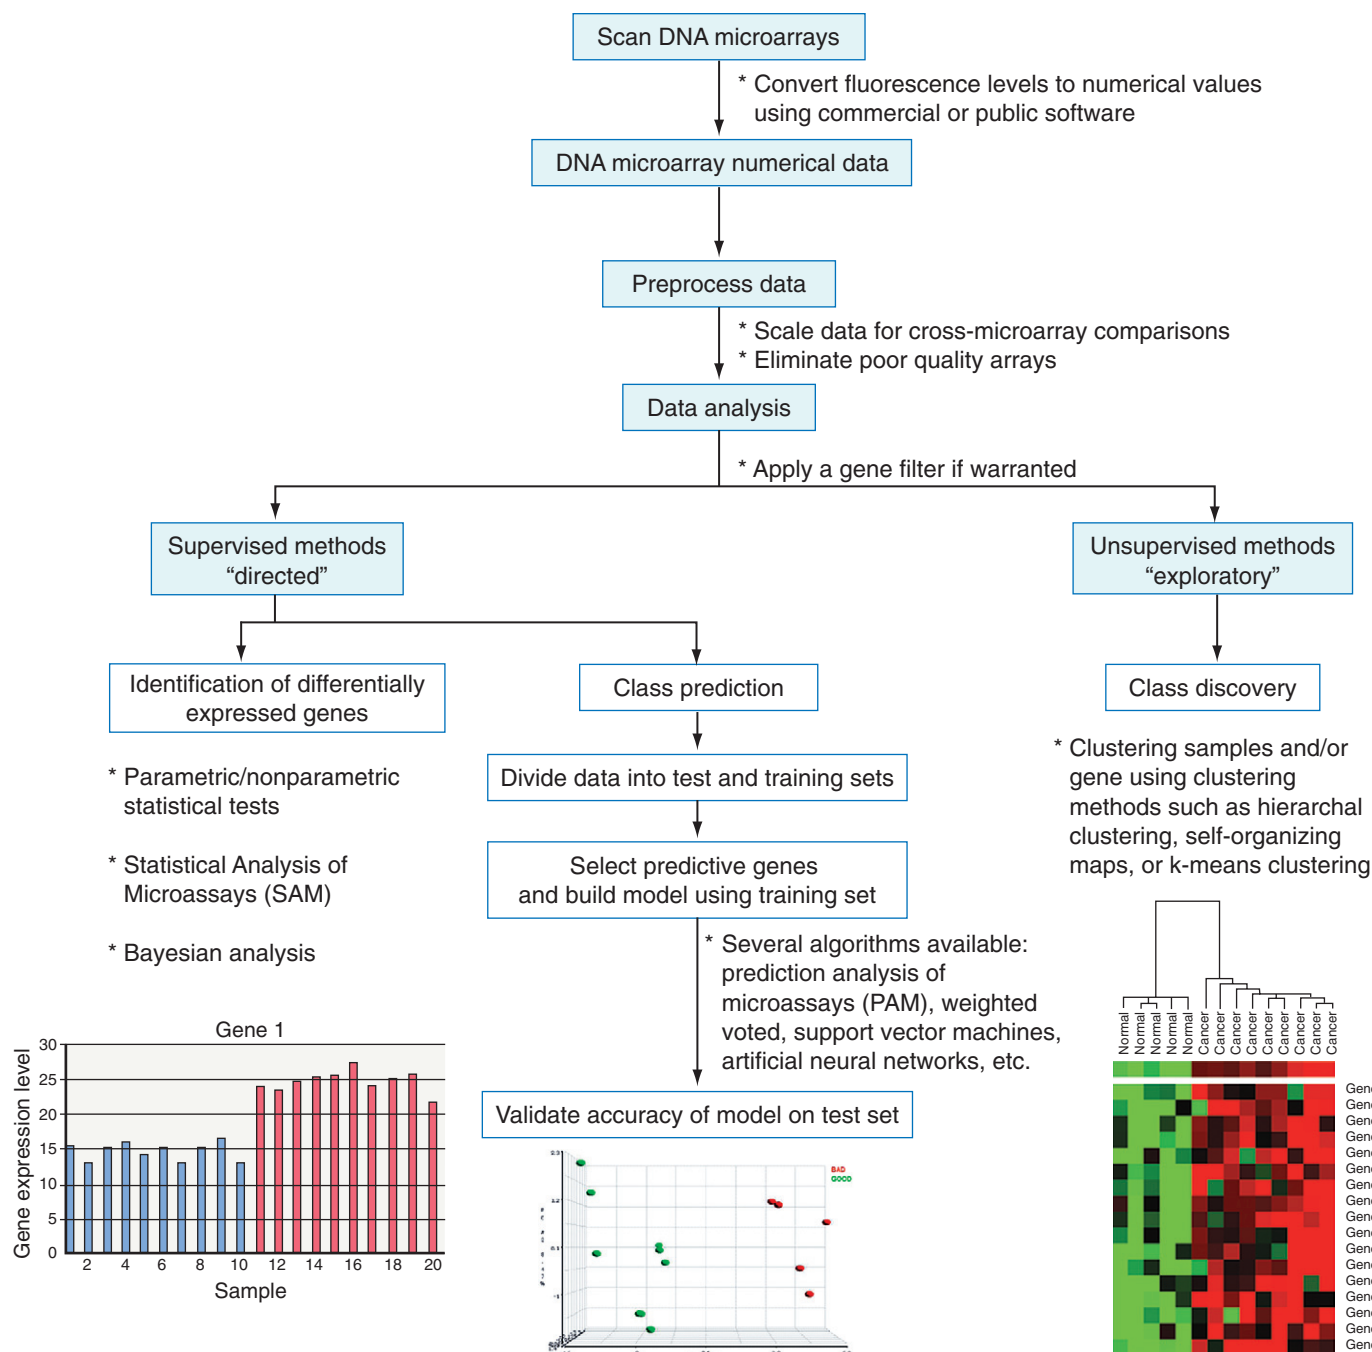

Figure 77-3 Analysis of DNA microarray data. The schematic diagram outlines the various steps required in the analysis of DNA microarray data. Image files are converted to numeric values and normalized, poor-quality arrays are removed from the analysis, and genes that are not accurately detected by the array and genes that show little variation across samples are filtered out. Downstream computational and statistical analysis of the data can be divided into two categories: supervised and unsupervised methods. Supervised methods, such as class prediction algorithms, use predefined groups of samples to identify genes that can distinguish between groups and can accurately classify unknown samples. Unsupervised methods, also known as class discovery methods, try to find previously unknown classes, such as novel cancer subtypes, within a data set.

Working Group, 2004). Validation studies with larger sample sizes or using a different technology are usually necessary to confirm significant findings.

Real Competitive Polymerase Chain Reaction

Real competitive PCR combines conventional competitive PCR techniques with single base extension and MALDI-TOF-MS to measure gene expression levels. The principles of mass spectroscopy are discussed in Chapters 4 and 23, and the use of mass spectroscopy in proteomics in cancer detection is discussed in Chapter 74. The use of MALDI-TOF-MS in high-throughput genomic studies is a recent innovation that is capable of absolute gene quantification with extremely high sensitivity and produces results consistent with real-time PCR and DNA microarrays. The basic principles underlying real-time PCR are discussed in Chapter 66.

Analogous to real-time PCR, use of this technique requires previous knowledge of the sequences of the genes of interest. Through this approach (Figs. 77-4 and 77-5), total RNA from a sample is reverse-transcribed using random hexamers or gene-specific primers. An 80–100-bp region is selected from the gene of interest, and primers are designed to amplify this region in a PCR reaction. A known concentration of an 80–100-bp DNA oligonucleotide of the same length and sequence, except for a single point mutation (known as the competitor), is added to the PCR reaction for amplification with the gene of interest. The competitor and the gene of interest will be amplified with the same kinetics because their sequences are almost identical; as a result, the concentration of the gene of interest can be calculated on the basis of the amount of competitor present in the PCR reaction. A series of PCR reactions are performed with different concentrations of the oligonucleotide competitor to accurately titrate the final concentration of the candidate gene. Next, each PCR reaction is

Figure 77-4 Real competitive polymerase chain reaction (PCR) coupled with matrix-assisted laser desorption/ionization time-of-flight mass spectroscopy (MALDI-TOF-MS) is a technique used to measure the transcript abundance of a gene in a sample of interest. RNA is isolated, complementary DNA (cDNA) is synthesized from a sample, and a region (~80 bp) of the gene of interest is selected for PCR amplification. A known concentration of an oligonucleotide competitor of the same length and sequence except for a single point mutation is added to the PCR reaction for amplification. A short base extension primer (~23 bp) is designed to anneal to both amplified products adjacent to the site of the single point mutation. A base extension reaction is then carried out with three dideoxynucleotide-triphosphates (ddNTPs) and one deoxynucleotide-triphosphate (dNTP) to produce two extension products that differ in their length by one base. As a result of this difference of one nucleotide, MALDI-TOF-MS is able to identify and quantify the two products on the basis of their different molecular weights. (Adapted with permission from Ding C, Cantor CR. A high-throughput gene expression analysis technique using competitive PCR and matrix-assisted laser desorption/ionization time-of-flight MS. *Proc Natl Acad Sci U S A* 2003;100:3059–64.)

subjected to a base extension reaction. A short base extension primer (approximately 23 nucleotides long) is designed to anneal to both 80-bp amplified PCR products adjacent to the site of the single point mutation. A base extension reaction is then carried out with three dideoxynucleotide-triphosphates and one deoxynucleotide-triphosphate to produce two extension products that differ in their terminal nucleotide. As a result of this one-nucleotide difference, MALDI-TOF-MS is able to identify and quantify the two products on the basis of their different molecular weights. The throughput of the assay can be increased by a technique known as multiplexing, whereby several genes are quantified in a single PCR and primer extension reaction using unique primers, competitors, and extension oligonucleotides for each gene.

This system, initially developed for high-throughput genotyping, was adapted for gene expression analysis in 2003 (Ding, 2003) and was

marketed by a California-based company (Sequenom, Inc., San Diego); thus public data and analysis resources are in the process of development. Applications of the technique include measurement of expression levels for three genes in RNA isolated from buccal mucosal cells obtained from smokers versus nonsmokers (Spira, 2004) and measurement of allele-specific expression of *ABCD1*, a gene involved in X-linked adrenoleukodystrophy (Ding, 2004).

The three genomic high-throughput technologies highlighted previously use very different techniques to measure the abundance of gene transcripts; each technique has a unique set of advantages and disadvantages. A brief overview comparing the three different platforms can be found in Table 77-1. The major limitation of SAGE is that it requires many laborious PCR and sequencing reactions per sample and thus is high-throughput in terms of genes, not samples. Another drawback of SAGE is

TABLE 77-1

Comparison of High-Throughput Genomic Technologies

	SAGE	DNA microarray	Real competitive PCR
Equipment needed	Sequencer	Arrayer (cDNA only), array scanner	Nanodispenser, MALDI-TOF-MS
Throughput			
Genes	Medium, ≈2000–20,000 tags/day, depending on sequencer	Highest, ≈40,000/array	Medium, ≈100/day
Samples	Low, ≈1/week	Medium, ≈10–20/day	High, ≈100/day
Cost	\$1500–\$2500/sample if between 50,000 and 100,000 tags are sequenced	\$500–\$1000/chip	\$1–\$2/gene/sample
Amount of starting material required	500–1000 µg total RNA/sample	1–15 µg total RNA/sample, as little as 10–100 ng total RNA/sample can be used with a modified protocol	5 ng total RNA/gene/sample
Gene sequences need to be known a priori	No	Yes	Yes
Absolute gene quantification	Yes	No	Yes

cDNA, Complementary DNA; MALDI-TOF-MS, matrix-assisted laser desorption ionization time-of-flight mass spectroscopy; PCR, polymerase chain reaction; SAGE, serial analysis of gene expression.

Figure 77-5 Matrix-assisted laser desorption ionization time-of-flight mass spectroscopy (MALDI-TOF-MS). A laser pulse provides energy for the matrix solution to ionize peptides and oligonucleotides, which travel downstream to the mass analyzer. (Redrawn from Kintner M, Sherman NE. *Protein sequencing and identification using tandem mass spectrometry*. New York: John Wiley & Sons; 2000.)

that it requires a large amount of starting RNA. However, as noted earlier, several modifications have been made to the protocol, and a new technique known as microSAGE requires only 1–5 ng of poly(A⁺) RNA (Datson, 2008). Advantages of the technology include that it is not based on prior sequence information, and that it is capable of discovering novel transcripts. The output from SAGE consists of sequence data that allow direct transcript identification with the use of public sequence databases.

DNA microarrays, on the other hand, are higher-throughput than SAGE in terms of genes and samples. DNA microarrays are practical for studies assaying clinical samples for which high throughput of samples is required and only small amounts of starting RNA can be obtained. The gene expression levels obtained from DNA microarrays are only relative transcript levels (in contrast to absolute levels with SAGE) that are dependent on probe selection, consequently making cross-platform comparisons difficult.

Finally, with the use of real competitive PCR, it is difficult to assay several thousand genes, because each gene requires the design of specific primers for the PCR and base extension reactions. Once the assay has been

designed, however, the technique can be high-throughput in terms of samples. As a result, real competitive PCR probably will not be used as a discovery platform in the way that SAGE and DNA microarrays are used; rather, it will serve as a validation tool and a potential clinical tool for assaying relatively small numbers of genes across large numbers of individual samples. Continuously evolving Ultra High-throughput genomic technologies offered by various vendors (Illumina/Solexa, San Diego; ABI/SOLiD, Foster City, Calif.; 454/Roche, Branford, Conn.; and Helicos, Cambridge, Mass.) will likely be able to provide even greater throughput at reduced costs.

PROTEOMIC

Current proteomic technology offers a variety of promising high-throughput approaches to the investigation of cellular biology. As one moves from the slowly changing, relatively static genome to RNA transcription, and ultimately to protein translation and additional downstream modifications, the information becomes increasingly more dynamic. An estimated 30,000 genes (Lander, 2001) are present in the human genome and are translated into more than a million proteins (Anderson, 2002); the complexity of this system belies simple global analysis (Oh, 2004). Inability to amplify proteins often necessitates working with small quantities of biological samples. In addition, the range of protein concentrations, spanning several log units, can obscure signals of clinical utility.

Mass Spectrometry

Mass spectrometry (MS) is the tool used most often to investigate the protein composition of complex biological samples. (The principles of mass spectroscopy are discussed in Chapters 4 and 23, and the use of MS for detection of cancer-related proteins is discussed in Chapter 74.) Before the discoveries that made MS protein analysis feasible, protein identification depended on more labor-intensive techniques such as Edman sequencing or antibody-based assays. The major obstacle to high-throughput protein analysis using MS has been the technical difficulty of ionizing proteins. The innovations of John Fenn, working with electrospray ionization, and of Koichi Tanaka, who developed laser desorption ionization, opened the door to the field of proteomics. For their contributions to the field, both scientists shared half of the 2002 Nobel Prize in Chemistry. Electrospray ionization creates small, charged droplets of protein in solution. As the droplets move toward a vacuum chamber, the liquid evaporates, leaving behind a charged protein moiety. In laser desorption, a protein is placed in a chemical solution (called a matrix) in which high-energy electron beams are focused on the protein, resulting in its ionization. Once ionized, the mass-to-charge (m/z) ratio can be determined by migration of the protein in an electrical field.

Additional analytic problems arise from the elaborate structure of proteins and from the sheer abundance seen in most biological samples. With its secondary, tertiary, and quaternary structures, as well as its posttranslational modifications, protein structure is much more complex and is less predictable than that of DNA or RNA. Advances in protein analysis have allowed more rapid identification; however, many of these methods are

subject to variation because of the context in which the protein is found, in particular, its shape and the protein environment in which it is analyzed. Separation remains an important step in reducing complex biological specimens into more manageable samples. Most of proteomic experiments rely on separation of constituent proteins over a two-dimensional gel, a time- and labor-intensive method that slows the discovery process and requires relatively large amounts of starting sample. Other techniques used to improve the resolution of data include proteomic analysis of whole-cell lysate, usually separated by high-pressure liquid chromatography, and multidimensional liquid chromatography.

Although the quantity of a peptide in a sample can increase the amplitude of the m/z spike seen on MS, other factors such as propensity of a peptide to ionize or surrounding ions at the time of measurement can also affect amplitude, making it difficult to comparatively quantify similar samples from different experimental conditions. The use of isotope-coded affinity tags allows quantitative comparison of samples. The tag consists of a biotin marker and a link, which contains eight hydrogens or eight deuteriums. To compare the amount of a single protein present in two different samples, one would label one sample with a light marker, the other with a heavy marker. This is done before MS analysis is performed, which would then show a series of paired peaks for individual peptide fragments, with heavy tag samples having an m/z 8 units greater than light tag samples. One can then compare the relative amplitude of the two samples.

Multidimensional protein identification technology allows identification of proteins in a digested sample. Protein fragments are introduced through high-pressure liquid chromatography into a tandem mass spectrometer. The m/z ratio for each peptide is measured in the first MS chamber, after which the peptide is fragmented. By comparing the relative weights of these fragments, one can determine the amino acid responsible for the change, in effect, sequencing the peptide. Measured peptide sequences are then matched to predicted fragments of known proteins, generating the identity of a large number of proteins from a complex biological sample.

Protein Arrays

Tissue microarrays produce a compact arrangement of sections from frozen or paraffin-embedded tissue, combining samples onto a single platform. Before the sampling advances described by Kononen, the number of sections that could be arranged in parallel limited the simultaneous investigation of multiple tissue sections. Currently, a tissue microarray can hold up to a thousand samples, which can be tagged and labeled via *in situ* hybridization or immunohistochemical assays (Kononen, 1998; Russo, 2003). Such large-scale parallel inquiry may provide a more rapid means of answering questions about the biological mechanisms involved in progression from normal tissue to neoplasia (Kononen, 1998), or the pathways related to variable prognoses among tumors of similar histology (Bubendorf, 1999), providing a ready means of validating results from other genomic or proteomic experiments (Chen, 2003), as well as tumor classification (Djidja, 2010).

Pawletz and associates pioneered the development of reverse-phase protein microarrays. Rather than spotting small sections of tissue, these slides hold arrays of whole-cell lysate from a specific cellular portion of tissue (Pawletz, 2001). Under the microscope, scientists can “hand pick” those cells of interest, capturing them with a small, focused laser that binds cells to an overlying transfer film.

In contrast to arrays containing tissue or cells of interest, other arrays can hold material designed to bind proteins from a sample applied to the surface of the array. Antibodies, DNA, RNA, and ribosomes—any substance with an affinity for a protein—can be used as a probe on the surface of the array. Manufacturing of these slides uses spotting technology similar to that described for oligonucleotide arrays (see earlier).

MOLECULAR MARKERS FOR THE DIAGNOSIS OF HUMAN NEOPLASIA GENOMIC

One clinically relevant application of genomic high-throughput technologies is the identification of diagnostic molecular markers for human diseases such as cancer. Histologic analysis complemented by immunohistochemistry, electron microscopy, and molecular analysis of chromosomal abnormalities is frequently used to classify cancers. Definitive diagnoses can be difficult to determine but are important because they often

influence patient treatment, response, and prognosis. The first paper to use DNA microarrays in clinical samples to develop gene expression profiles for cancer classification was published in 1999 by Todd Golub (1999). Since that time, DNA microarrays have been used extensively across a wide range of malignant and normal tissue specimens in an attempt to develop diagnostic and prognostic tests.

As mentioned in Chapter 75, a pioneering study has been performed using DNA microarrays to distinguish acute myeloid leukemia (AML) from acute lymphoblastic leukemia (ALL). In this study, Affymetrix GeneChips containing approximately 6800 human genes were employed to measure gene expression of bone marrow mononuclear cells obtained from patients with either of these diseases (Golub, 1999). In this study, the choice of acute leukemia, a hematologic malignancy, was important for several reasons. Previous DNA microarray experiments had obtained reproducible results on cell lines; however, clinical specimens introduce additional noise that may obscure differences. Mononuclear cells reduce noise because they are a relatively homogeneous cancer cell population, in contrast to biopsies of solid tumors that exhibit varying quantities of surrounding stromal cells. In addition, distinction between acute leukemia subtypes is difficult with existing techniques, and the discovery of additional molecular markers would enhance the accuracy of diagnosis, ultimately influencing the choice of a therapeutic regimen.

To explore whether differences in gene expression could be detected between 27 ALL and 11 AML samples in this study, a method called **neighborhood analysis** was used. This method ranks genes whose expression patterns across patients are highly correlated with the class of the sample (ALL or AML). A gene that is expressed at high levels across all ALL patients but at low levels in AML patients, for example, would be highly ranked. Significance, or how likely the correlation is by chance, was assessed by randomly assigning class labels to each of the samples and repeating the analysis. Approximately 1100 genes were significantly correlated with class labels, and the top 50 genes were subsequently used in a weighted-vote class prediction algorithm that predicts the class of unknown samples. Each of these 50 genes casts a vote indicating the class of the new sample. Each gene’s “vote”—AML or ALL—was determined by calculating whether the expression value for the gene in the unknown sample was closer to the mean expression value for the gene across all ALL or all AML patients. Votes were then weighted according to the strength of the correlation between gene expression levels and class vector. The votes for each class were summed, and the unknown sample was assigned to the class with the larger total vote. An additional metric, known as prediction strength, can be calculated to determine the margin of victory (for additional details, see <http://www.broad.mit.edu/cancer/software/genecluster2/gc2.html>, and Reich, 2004). The accuracy of this prediction method was evaluated by “leave one out” cross-validation, wherein one of the 38 samples is withheld, the analysis is repeated, and the class of the left out sample is predicted. Using this approach, this study found that 36 of the 38 samples were classified correctly, and 2 were classified as uncertain on cross-validation. The predictor was tested on an independent set of 34 additional samples and was correctly classified in 29 of the 34 samples. The committee of 50 genes contained known markers of lymphoid versus myeloid cell lineage, as well as genes related to carcinogenesis.

In addition to identifying markers capable of distinguishing AML and ALL, Golub and colleagues used an unsupervised clustering method known as self-organizing maps (SOM) to evaluate whether the two subtypes of leukemia could be found within the gene expression data without prior knowledge of the two leukemia classes. SOM group samples were divided into a user-defined number of clusters based on gene expression pattern similarities. Two-cluster SOM produced one cluster containing 24 of the 25 ALL samples and another cluster with 10 of the 13 AML samples. A four-cluster SOM was capable of distinguishing among T-lineage ALL, B-lineage ALL, and AML. The success of this initial experiment and its exciting implications, as well as improvements in DNA microarray technology, analysis, and availability, have resulted in an exponential increase in the number of clinical studies using microarrays. Additional information can be found in Chapter 75.

PROTEOMIC

In Chapter 74, a new approach to the early detection of several different types of cancer based on patterns of protein expression, called proteomics, is discussed as showing great potential. This approach does not search for specific known proteins but rather searches for differences in patterns of protein expression (the identity of many of these proteins is unknown)

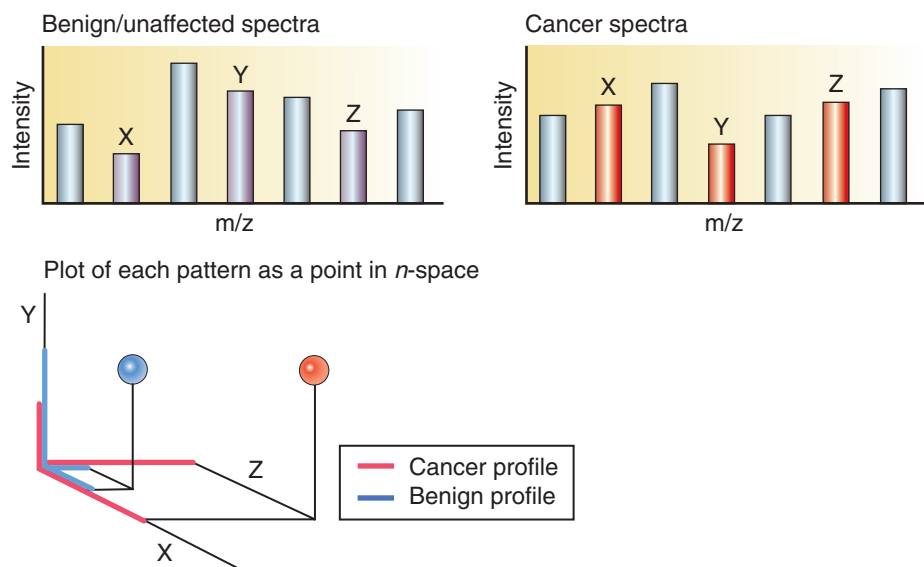

Figure 77-6 Proteomic pattern diagnostics. Pattern analysis identifies m/z ratios with the “most fit” combination of proteins for distinguishing between clinical states of interest. (Redrawn from Petricoin EF, Zoon KC, Kohn EC, Barrett JC, Liotta LA. Clinical proteomics: translating benchside promise into bedside reality. *Nat Rev Drug Discov* 2002;1:683–95.)

based on the use of MS. We discuss this approach further here to illustrate the power of high-throughput postgenomic methods in cancer detection. As noted, this approach does not identify the proteins involved but instead relies on the varying amplitudes of several different m/z ratios present across samples (Fig. 77-6). Given the more favorable prognosis seen with malignancies diagnosed at earlier stages, a great deal of interest has been expressed in using proteomic tools to search for diagnostic markers in readily available biological samples such as blood, urine, or saliva.

Patients with ovarian cancer frequently suffer a worse prognosis than those with other malignancies, in part because of the advanced stage of disease at diagnosis. In an attempt to develop a screening test for high-risk women, Liotta and colleagues used an MS-based platform to analyze serum samples of patients with ovarian cancer compared with controls and found that their model was able to distinguish between sera of women with and without ovarian cancer with a remarkably high degree of accuracy (Petricoin, 2002).

Their method utilizes SELDI-TOF-MS: surface-enhanced laser desorption ionization (SELDI) coupled with a mass spectrometer that measures the time of flight of ionized proteins from laser to detector. Serum samples are placed on a chip with embedded weak cations, which provide the “surface enhancement” of SELDI. Excess serum is washed off, and proteins bound to weak cations remain on the chip, where they are combined with a matrix solution and ionized when exposed to a laser.

Each serum sample results in approximately 15,000 m/z values of varying amplitude. The bioinformatic tools used to parse through such a complicated data set rely on class prediction based on a genetic algorithm. Class prediction involves a “training” set of known cancer and noncancer samples. The genetic algorithm selects a panel of m/z values and tests its ability to differentiate between cancer and control. The “genetics” of a genetic algorithm represents a biological analogy describing repeated mixing and matching of the most successful m/z values, allowing “survival of the fittest” values in successive generations of testing, ultimately producing the most discriminatory panels, which are then tested on a “masked” group of patients and controls (i.e., the condition of each patient is withheld before the test result is obtained).

Although the panel used in this study resulted in a test with 100% sensitivity and 95% specificity, validation in a more realistic clinical setting remains to be done. The idea of studying a group of markers in parallel would seem appropriate, given the complexity of tumor biology and its interaction with the host. The absence of protein identification with this technique constrains the test. It is not clear whether the values included represent participants in tumor biology shed into the bloodstream or nonspecific markers of inflammation. With 15,000 data points to choose from in each serum sample, the risk of overfitting any model so that it would have little clinical utility in a practical setting is significant. In addition, array-based assessments may not correlate with classical diagnostic approaches (immunohistochemistry) or with survival (Dahl Steffensen, 2010) and may differ depending on the choice of specimen interrogated (Sanchez-Carbayo, 2010).

DIAGNOSTIC CANCER APPLICATIONS

SMALL, ROUND BLUE CELL TUMORS

(See also Chapter 76.)

Another cancer that is difficult to accurately diagnose using a variety of histologic and specialized molecular analyses is small, round blue cell tumor (SRBT) of childhood, which includes neuroblastoma, rhabdomyosarcoma, non-Hodgkin lymphoma, and the Ewing family of tumors (EWS). Ewing’s sarcomas are discussed in Chapter 76, where we noted that the most common characteristic finding is the $t(11;22)$ translocation, which juxtaposes the *FLI1* and *EWSR1* genes, giving rise to chimeric (*EWSR1-FLI1*) mRNAs and protein.

Khan and colleagues were among the first to identify molecular markers predictive of SRBT subtypes (Khan, 2001). Predictive genes were chosen using artificial neural networks (ANNs), which are pattern recognition computer programs modeled after the neural structure and behavior of the human brain. Similar to the human brain, ANNs are capable of learning from experience. A neuron can accept many inputs but has only one output, and, in an analogous manner, artificial neurons output a signal based on several inputs. ANNs consist of several connected artificial neurons that can recognize patterns in training data through optimization of several parameters (weights assigned to the links between neurons) to accurately predict the tumor type of unknown samples.

Khan and colleagues used cDNA microarray containing 6567 genes to measure the gene expression of 63 samples, which included both tumor biopsies (13 EWS and 10 rhabdomyosarcoma) and cell lines (10 EWS, 10 rhabdomyosarcoma, 12 neuroblastoma, and 8 Burkitt lymphoma, a subset of non-Hodgkin lymphoma). Using a filtered set of 2308 genes, the 63 samples representing four SRBT diagnostic categories were used to train linear ANN models. A total of 96 probes corresponding to 93 genes were selected on the basis of ANN models because they minimized the misclassification error rate to 0%. The algorithm was validated on a test set of 25 samples that consisted of a mixture of cell lines, tumor biopsies, and five non-SRBTs. In all, 17 SRBT test samples were classified correctly, and the remaining three SRBTs, along with the five non-SRBTs, could not be assigned a subtype. It is interesting to note that even though only data from neuroblastoma cell lines were used in the training set, the model accurately predicted neuroblastoma tumor biopsy specimens in the test set. Results suggest that the use of cell lines may be beneficial in reducing noise created by stromal contamination of tumor specimens.

Many of the 96 predictive genes reported in the study just discussed were expressed at high levels in one, two, or three of the four diagnostic categories. One marker, *MIC2*, is currently used to diagnose EWS, although this is not so specific as the (*EWSR1-FLI1*) fusion genes and their products. Also, *MIC2* was highly expressed in EWS and in some rhabdomyosarcomas, suggesting that the marker may lack specificity when used alone. Another molecular marker, *FGFR4*, a tyrosine kinase receptor related to myogenesis and upregulated only in rhabdomyosarcoma samples,

was investigated by immunostaining across a variety of tissues. FGFR4 was found to be upregulated in some other cancers and normal tissues, providing clues to its potential biological importance, while reducing its potential as a specific molecular marker. This finding illustrates that a compendium of genes, instead of a single molecular marker, may increase diagnostic sensitivity and specificity. This complements the conclusions of Chapter 74 on oncoproteins in tumor diagnosis: arrays of oncoproteins are more effective than individual oncoproteins in early tumor detection.

BARRETT'S ESOPHAGUS

In addition to these studies, several other DNA microarray and SAGE experiments have been conducted to develop diagnostic tests for human cancers that are difficult to classify using conventional histologic methods. Barrett's esophagus, in which the lining of the esophagus is replaced with a metaplastic columnar lining, is a condition associated with gastroesophageal reflux disease that can lead to the development of squamous cell carcinoma or adenocarcinoma. Esophageal cancer is usually difficult to detect at an early stage and has a high mortality rate. Hierarchical clustering and ANNs were used to discover gene expression profiles measured by cDNA microarrays that could distinguish between esophageal cancer and Barrett's metaplasia specimens (Selaru, 2002; Xu, 2002). The expression levels of a small subset of predictor genes were quantified with Taqman quantitative reverse-transcriptase (RT)-PCR (Applied Biosystems, Inc., Carlsbad, Calif.) in 39 patients with Barrett's metaplasia or esophageal cancer to assess their clinical usefulness (Brabender, 2004). Other studies have demonstrated the utility of micro-RNA expression in prognosticating patients with Barrett's esophagitis (Mathe, 2009). In those studies, miR-21, miR-223, miR-192, and miR-194 expression was elevated, whereas miR-203 expression was reduced, in cancerous compared with noncancerous tissue obtained from the same patient (tissue pairs), and reduced levels of miR-375 were strongly correlated with worse prognosis in Barrett's patients. Collectively, these studies illustrate the potential of array-based interrogation toward diagnostic and prognostic application.

THYROID

In Chapter 76, we discuss the most common genetic lesions that have been found in thyroid carcinomas. About half of follicular thyroid carcinomas contain oncogenic ras, and many also express the *PAX8-PPAR γ* fusion gene and its products. A high percentage of papillary thyroid carcinomas express mutant *BRAF* and *RET/PTC* gene rearrangements. Medullary thyroid carcinomas express mutant forms of *RET* (as opposed to fusion gene products).

Distinguishing Follicular Thyroid Carcinoma from Adenoma

New diagnostic molecular markers are needed to distinguish between follicular-patterned thyroid lesions as to whether they are benign or malignant. Papillary thyroid carcinoma is usually diagnosed with fine-needle aspiration (FNA) after detection of a thyroid nodule and can be further characterized by its expression of the markers noted previously and in Chapter 76; however, FNA cannot differentiate between follicular thyroid adenoma (FTA) and follicular thyroid carcinoma (FTC); a more invasive surgical biopsy is usually warranted. Cerutti and colleagues have attempted to develop a preoperative diagnostic test by constructing and analyzing three SAGE libraries using an FTA, an FTC, and a normal thyroid specimen (Cerutti, 2004). More than 360,000 tags were sequenced among the three libraries, and 305 genes were significantly differentially expressed between the three groups. A subset of these genes was chosen for validation with RT-PCR on independent samples that included 10 FTAs, 13 FTCs, and 8 patient-matched normal thyroid tissues. RT-PCR was performed on a subset of the 305 genes: 12 of the most highly expressed genes in FTC and 5 of the most highly expressed genes in FTA/normal thyroid were chosen for validation with RT-PCR. Four genes (*DDIT3*, *ARG2*, *ITM1*, and *Ctorf24*) validated the SAGE results and were able to predict 19 of the 23 samples correctly on leave-one-out cross-validation. In addition, immunohistochemistry was performed on 32 FTA and 27 FTC paraffin-embedded tissues using antibodies against two of the four genes, *DDIT3* and *ARG2*. *DDIT3* and *ARG2* showed staining for FTCs and negative staining for *ARG2* in most samples, suggesting that these markers might improve the preoperative diagnosis of thyroid nodules. Thus these four genes, in addition to expression of oncogenic *ras*, are promising for use in the diagnosis of FTC.

ADENOCARCINOMA

Histologic identification of the primary tumor site in patients presenting with metastatic adenocarcinoma can also be difficult. SAGE data sets suggest that primary and metastatic adenocarcinomas clustered together according to their site of origin. A variety of RNA quantification methods, including DNA microarrays and SAGE, as well as the literature, were used to select tumor- and site-specific molecular markers (Dennis, 2002). Buckhaults and colleagues analyzed a set of 11 SAGE libraries of ovarian, breast, pancreatic, and colon adenocarcinomas to select five genes that could discriminate among these carcinomas of different tissue origins (Buckhaults, 2003). A class prediction algorithm, known as a two-dimensional gene expression-based classification map, was able to correctly classify tissue origin in 81% of 62 independent samples of ovarian, breast, pancreatic, and colorectal carcinomas based on RT-PCR data from the five genes. A related study, aimed at identifying molecular markers of metastasis in primary tumors, compared gene expression profiles of unpaired primary adenocarcinomas and metastatic nodules from different individuals across a broad spectrum of tumor types. A total of 128 genes were identified whose expression patterns could distinguish primary from metastatic adenocarcinoma (Ramaswamy, 2003). Ramaswamy and colleagues demonstrated that a subset of the 128 genes was associated with metastasis in independent data sets from primary lung, breast, and prostate adenocarcinomas, as well as from medulloblastomas and large B-cell lymphomas. These findings challenge the hypothesis that metastatic potential arises in a few cells in the primary tumor, and suggest that the ability to metastasize is preexistent in the primary tumor. If this is correct, gene expression patterns in primary tumors could potentially predict future risks for distant metastasis.

PANCREATIC CANCER

In Chapters 74 and 76, it was noted that more than 90% of pancreatic cancers express oncogenic *k-ras* gene and its ras-p21 protein product. Other common genetic lesions include aberrant methylations of a series of genes, including *p16/CDKN2A*, *APC*, *TSLC/IGSF4*, *SOCS-1*, *cyclin D2*, *RASSF1A*, *WWOX*, *RUNX3*, *CDH13*, *DUSP6*, *HHIP*, and *SLC5A8*. In addition, mutations in *SMAD4*, *PI3K*, and *p53* genes have been found in these cancers.

Microarray, semiquantitative PCR, and SAGE methods have been further applied to identify differentially expressed genes in pancreatic cancer (Iacobuzio-Donahue, 2002; Hustinx, 2004; Watanabe, 2005). Such prostate stem cell antigens as mesothelin and osteopontin were identified as overexpressed in pancreatic carcinoma, the latter of which demonstrated a sensitivity of 80% and a specificity of 97% for pancreatic cancer (Koopmann, 2004). Nonagaki and colleagues developed a three-dimensional microarray technology to assess RNA from endoscopic ultrasound-guided FNA (EUS-FNA) samples obtained from patients with pancreatic cancer (Nonagaki, 2010). They found that *CDK2A*, *CD44*, *S100A4*, and *MUC1* were differentially expressed between cancer and noncancer groups subsequent to two orders of hierarchical clustering analysis. Furthermore, cDNA microarray analysis identified that the secreted protein acidic and rich in cysteine (*SPARC*) gene (also known as osteonectin, or BM-40) and its ligand (*SPARCL1*) are overexpressed in pancreatic cancer tissues, but not in their noncancerous counterparts (Jinawath, 2004). Specific *SPARC* protein antigens are now being evaluated as candidates for immunotherapy for pancreatic and other cancers (Inoue, 2010). These genes may therefore be important in the diagnosis of pancreatic carcinoma.

OTHER

High-throughput genomic technologies have been used in a variety of other diseases, including bladder carcinoma (Dyrskjot, 2003) (see Chapter 74), central nervous system embryonal tumor (Pomeroy, 2002), ovarian cancer (Sawiris, 2002; Tinelli, 2009), breast cancer (Perou, 2000; Porter, 2001, 2003a; Vera-Ramirez, 2010), lung cancer (Bhattacharjee, 2001; Ocaik, 2009), hepatocellular carcinoma (Zender, 2010), and colorectal cancer (Buckhaults, 2001), to aid in disease diagnosis and identification of novel disease subtypes. The use of high-throughput genomic technologies to develop disease diagnostics is an inherently difficult problem because predictive genes identified by a training set are based on histopathologic diagnoses. The histologic methods used for classification of certain cancers, however, may be imperfect, making it difficult to assess the true accuracy of the molecular markers. In addition, it is difficult to verify the existence of novel disease subtypes found in DNA microarray experiments if no complementary histologic evidence is available. In the future, pathologists

probably will use high-throughput genomic technology to facilitate accurate diagnosis in difficult cases. A majority of studies using genomic high-throughput methods have chosen, therefore, to focus on identifying gene expression profiles predictive of disease prognosis, given the limited number of histologic or clinical indicators of disease outcome (see later).

Application of proteomics in the search for a clinically useful biomarker has been reported in patients with breast (Kuerer, 2002), prostate (Ornstein, 2004), colorectal (Zhou, 2010), and lung cancers (Chen, 2003), among others (Djidja, 2010). When these techniques of detection and analysis are applied to prostate cancer, preliminary data from men with an indeterminate elevation of prostate-specific antigen (PSA) suggest that an “ion signature” is present (see Chapter 74) that distinguishes between men with prostate cancer and those with benign prostatic hyperplasia with 100% sensitivity and 67% specificity (Ornstein, 2004).

Because the serum represents a particularly complicated specimen for two-dimensional polyacrylamide gel electrophoresis (2D-PAGE)-based proteomic analysis, other specimens in proximity to the tissue in question may be more readily available and simpler to work with. Nipple aspirate fluid is easily obtained and, in the case of unilateral disease, allows for a simple paired sample from the unaffected breast. Kuerer and colleagues used 2D-PAGE in an initial descriptive study comparing protein expression in the nipple aspirate from both breasts in patients with unilateral breast cancer and a healthy volunteer (Kuerer, 2002). Their results showed highly concordant protein electrophoresis patterns when nipple aspirate fluid was compared from each breast in the control subject, as opposed to samples obtained from patients with breast cancer, which exhibited a larger number of proteins unique to the affected breast compared with the unaffected breast in the same patient. This finding suggests that localized breast malignancy significantly alters protein expression in nipple aspirate fluid, raising the possibility of a diagnostic marker pattern.

PROGNOSTIC MOLECULAR MARKERS OF DISEASE

GENOMIC

Patients diagnosed with the same type of cancer and treated using similar protocols often respond differently and have varying survival rates. Several clinical and histologic variables such as age, serum protein levels, and stage or grade of tumor can be used to assess a patient's prognosis with variable accuracy. Many studies have utilized genomic high-throughput technologies, especially DNA microarrays, as described at length in Chapter 67, to identify gene expression signatures that predict patient survival or relapse rates. Instead of comparing two different disease states, as detailed earlier in the diagnostics section, the experimental design for the development of molecular prognostic indicators usually attempts to stratify a particular cancer into subtypes according to outcome, using unsupervised or supervised computational approaches (see Fig. 77-3). The marker associated with poor prognosis may provide clues about the biological mechanisms underlying resistance to chemotherapeutics and may aid in the identification of new drug targets.

Diffuse Large B-Cell Lymphoma

(See also Chapter 75.)

Identifying molecular markers that predict patient survival involves distinguishing subtle differences between specimens; as previously noted in the diagnostics section, many studies have been conducted on hematologic malignancies in which a homogeneous population of cells can be isolated easily. Diffuse large B-cell lymphoma (DLBCL), the most common adult lymphoid neoplasm, accounts for 30%–40% of all non-Hodgkin lymphomas. DLBCLs commonly contain *BCL6* gene fusions, as discussed in Chapter 75. Response to chemotherapy is highly variable, and less than half of treated patients achieve long-term remission. Currently, the International Prognostic Index (IPI) is used to approximate the outcome of patients diagnosed with DLBCL based on several clinical factors such as serum lactate dehydrogenase and stage.

As noted in Chapter 75, a paradigm shift has occurred in the classification of DLBCLs based on the use of gene arrays. Here we discuss this approach further. Alizadeh and colleagues constructed a specialized cDNA microarray, known as the lymphochip, which included 17,856 probes chosen from germinal center B-cells, DLBCLs, and other lymphoma cDNA libraries (Alizadeh, 2000). In all, 128 lymphochips were used to assay 96 normal and malignant samples from leukemia and lymphoma cell lines and from patients with DLBCL, follicular lymphoma, and chronic

lymphocytic leukemia. Hierarchical clustering of the microarrays revealed three subgroups of DLBCL samples based on genes related to proliferation: T-cells, lymph node biology, and germinal center B-cells. DLBCLs are thought to arise at different stages of B-cell differentiation, and hierarchical clustering of just DLBCL samples across the genes related to germinal center B-cells separated the sample into two distinct clusters: germinal center B-cell-like DLBCLs and activated B-cell-like DLBCLs, as discussed in Chapter 75. The two subtypes were shown to have statistically different overall survival (72% of germinal cell B-cell-like DLBCL subjects were alive after 5 years in comparison with 16% of activated B-cell-like DLBCL subjects), and the two classes could be used to further stratify patients identified as low risk by the IPI. This study was one of the first to relate tumor subtypes identified by global gene expression profiling to patient outcome. Use of DNA microarray in diagnosing this condition and further subtyping it into the germinal center B-cell-like group and the activated B-cell-like group is discussed in Chapter 75.

A follow-up study by Shipp and colleagues tested whether a gene expression profile could be identified, without prior discovery of subtypes, which predicted survival in DLBCL patients (Shipp, 2002). Affymetrix HuGeneFL microarrays containing approximately 6800 probes were used to measure global gene expression profiles across 58 patients with DLBCL (32 patients with cured disease, 26 patients with refractory/fatal disease). The weighted vote class prediction algorithm with cross-validation was used to identify a gene expression signature of 13 genes capable of distinguishing between patients with cured and those with fatal disease. The prediction model was also able to stratify patients into good and poor prognosis groups within categories defined by the IPI. As additional validation, results of the current study were compared with previous findings reported by Alizadeh's group. The studies used microarray platforms that interrogated two different but overlapping sets of genes. Genes used to distinguish the two subtypes of DLBCL in the Alizadeh study that were also present on the HuGeneFL microarray separated the 58 DLBCLs into two groups, but the groups did not correlate with overall survival rates. However, of 13 predictive genes identified by Shipp and colleagues, 3 were present on the lymphochip and correlated with survival across patients in the Alizadeh study.

In a related study, Rosenwald and colleagues used the lymphochip to study 240 patients with untreated DLBCL who subsequently received anthracycline-based chemotherapy (Rosenwald, 2002). Using a training set of 160 samples, gene expression levels were correlated with survival times using the Cox proportional hazards model. A total of 670 genes had expression patterns that were significantly correlated with prognosis, and these genes were clustered to identify sets of genes with similar expression patterns. Highly correlated genes were involved in similar biological processes, and four sets of correlated genes related to proliferation, major histocompatibility complex class II, lymph node biology, and germinal center B cells were used to develop a class prediction model. The gene expression levels of genes within each set were averaged, and these composite values were used to build a multivariate prediction model. The model was capable of assigning each sample in the test set a score related to the risk of succumbing to the disease. Scores assigned by the model to the entire set of samples were stratified into quartiles, with a 5-year survival of 73% in the first group compared with 15% in the fourth group.

Follicular Lymphoma

A similar survival prediction model was used to predict the prognosis of patients with follicular lymphoma, a cancer similarly arising from germinal center B-cells (Dave, 2004). Treatment may involve chemotherapy, immunologic therapy, or hematopoietic stem cell transplantation; however, no consensus has been reached as to which regimen is superior, and outcome is highly variable. Tumor biopsies from 191 patients with follicular lymphoma were divided into training and test sets. With use of the Cox proportional hazards model to correlate genes with survival, two highly correlated sets of genes were chosen to build a multivariate predictive model. The set associated with a favorable prognosis contained genes highly expressed in T-cells and macrophages, whereas the set associated with poor prognosis contained genes expressed in macrophages and dendritic cells. In additional experiments on biopsy specimens separated into malignant and nonmalignant fractions, two sets of gene signatures culled from the initial 10 set gene signature patterns were highly predictive of survival. These findings support the notion that immune-related responses by way of gene signatures reflect biological characteristics that may predict the length of survival.

The lymphoma studies already discussed demonstrate that microarrays may be successful in accurately predicting patient prognosis and may

complement currently used methods such as the IPI. Results imply that biopsies obtained at the time of diagnosis can be used to predict prognosis and could influence treatment decisions. As noted earlier, however, disagreement between studies has resulted from several factors, including the DNA microarray platform used, patient population, differences in treatment regimens, sample size, the variable quality of long-term follow-up data, and choice of prediction methods (see Pitfalls section, later). The follicular lymphoma study also shows the importance of the tumor microenvironment—something that is not typically explored in DNA microarray studies.

Acute Myeloid Leukemia

In Chapter 75, patterns of oncogene expression in different phenotypes of AML that are currently used for therapeutic and prognostic purposes are discussed. Certain patterns of expression of these oncogenes suggest not only possible effective therapeutic regimens but also prognosis. For example, oncogenes found frequently in promyelocytic leukemia include the retinoic acid receptor- α (PML-RAR α) fusion genes, whose presence suggests a favorable prognosis and indicates that treatment with all-*trans* retinoic acid (aTR) will be of therapeutic benefit. However, the presence of RAR fusion genes with other, non-PML genes, including ZBTB16(PLZF)-RARA, t(11;17)/NUMA1-RARA, t(5;17)/NPM1-RARA, and t(17;17)STAT5B-RARA, is a strong indicator that aTR will not be so effective, and that the prognosis is not favorable. In addition, core-binding domain fusion genes such as RUNX1-RUNX1T1 and CBF β -MYH11 are expressed in other AMLs (such as myelomonocytic leukemia) and correlate with specific chromosomal abnormalities. The presence of these fusion genes suggests susceptibility of the tumor to high-dose cytarabine regimens and often indicates a favorable prognosis. On the other hand, the presence of the FLT3 oncogene alone or together with these other fusion genes suggests a less favorable prognosis, despite the suggested chemotherapeutic regimen. Additional aspects of gene mutations that affect therapeutic responses can be found in Chapter 72.

Overall, the presence of specific fusion genes in AML does not always reflect the molecular heterogeneity of the disease because the presence or absence of other fusion oncogenes or mutations in proto-oncogenes may not be detected, and other genes, not thus far identified, may also be involved in the cell transformation process. To attempt to identify which genes may be involved in cell transformation in AML and to detect patterns of gene expression in AML that correlate with prognosis and suggest effective therapies, several studies using gene expression microarrays from patients with AML have been carried out. Despite potential problems with this type of approach, discussed in the preceding section, two studies published in the *New England Journal of Medicine* identified gene expression profiles that can be used as prognostic indicators in AML (Bullinger, 2004; Valk, 2004).

Bullinger's group used cDNA microarrays ($\approx 39,000$ probes) to obtain global gene expression profiles for 116 patients with AML, and Valk's group used Affymetrix human U133A microarrays ($\approx 22,000$ probes) to assay 285 patients with AML. Unsupervised hierarchical clustering in both studies revealed clusters that correlated with cytogenetic and molecular abnormalities present in the tumors. Using the Cox proportional hazards model implemented in SAM software (Tusher, 2001), Bullinger and colleagues identified gene expression patterns that correlated with survival. K-means clustering was used to divide the training samples into two groups, representing good and bad outcomes, based on genes selected by SAM. The prediction analysis of microarrays (PAM) algorithm was used to develop an outcome predictor using 133 genes based on the two identified groups in the training set. PAM was applied to the test samples and was able to separate them into two groups that differed significantly in terms of survival times. In this study, it was found that expression of so-called "forkhead" genes such as the forkhead box O1A gene (FOXO1A, also known as FKHR) in AML is associated with a favorable prognosis. On the other hand, expression of such genes as MAP7, GUCY1A3, TCF4, and MSI prognosticates a less favorable prognosis. Overexpression of genes involved in homeobox regulation such as HOXB2, HOXB5, PBX3, HOXA, and HOXA10 has occurred in multiple different phenotypic AMLs, suggesting their importance in leukemogenesis. Expression of mutant or overexpressed FLT3 was associated with a poor outcome, as discussed in Chapter 75.

Valk's group used similar methods to identify genes that could classify samples into disease subgroups previously identified by clustering analysis. These subgroups were associated with cytogenetic and molecular abnormalities, as well as with patient prognosis. Both studies demonstrated the usefulness of global gene expression analysis in dissecting the

heterogeneity that exists within tumors of the same type. The high degree of overlapping results between these two studies shows the potential that microarray technology has to distinguish between subtle tumor subtypes and to add prognostic information to current clinical practice.

Breast Cancer

Although similar prognostic biomarker studies have been carried out in prostate cancer (Dhanasekaran, 2001), lung adenocarcinoma (Beer, 2002), and multiple myeloma (Tian, 2003), identification of prognostic biomarkers in breast cancer best demonstrates how successful high-throughput genomic studies can translate into important clinical tools. In Chapter 76, we discuss how the use of gene arrays has been successful in enabling prognosis and treatment of different breast cancers. The most important markers for these purposes are estrogen receptor (ER), progesterone receptor (PR), the proliferation marker protein, Ki67, and the HER2/*neu* oncogene.

Additional prognostic molecular markers were identified from gene expression studies using primary breast cancer biopsies from patients younger than 55 years of age with sporadic node-negative disease that did and did not develop metastases within 5 years. The predictive power of these molecular markers was deemed to be greater than that of other clinical and histologic factors such as tumor grade, size, angioinvasion, or ER status (van't Veer, 2002). Similar studies on breast cancer were subsequently conducted (van de Vijver, 2002; Huang, 2003; Sotiriou, 2003), and a recent paper describes the development of a predictive model that uses gene expression, clinical, and histologic data to more accurately estimate prognosis (Pittman, 2004).

One bottleneck to performing DNA microarray studies is the dearth of snap-frozen tissues obtained from patients with long-term follow-up. Snap-freezing tissue preserves the integrity of the RNA and is ideal for DNA microarray experiments; however, most tissue banks and clinical trials have collected paraffin-embedded tissue. Paraffin-embedded tissue contains partially degraded RNA that usually is insufficient to allow high-quality DNA microarray results (although advances in this area are ongoing; Drury, 2010). Technologies such as real competitive PCR and real-time PCR are being used to measure gene expression levels in these tissues, but the amount of RNA obtained from tissue blocks often limits assays to a few hundred genes. Using RT-PCR, Paik and colleagues studied 21 genes (16 cancer-related and 5 reference genes for normalization) chosen from the breast cancer DNA microarray studies outlined previously. Samples included 675 paraffin-embedded tissue blocks obtained from patients enrolled in the National Surgical Adjuvant Breast and Bowel Project B-14 trials (Paik, 2004). All tissue blocks were obtained from tamoxifen-treated patients who had node-negative, ER-positive primary breast cancer. Expression levels of the 16 cancer-related genes were used to calculate a score representing the risk of cancer recurrence at a distant site. Patients were stratified into low-, intermediate-, and high-risk groups based on the recurrence score. The recurrence score provided significant predictive information beyond tumor grade, age, and tumor size. The simplified 21-gene assay can be translated easily into a clinical prognostic test designed to help physicians decide which tamoxifen-treated, node-negative, ER-positive breast cancer patients should receive additional chemotherapy.

Prognostic molecular markers for breast cancer have been identified using SAGE technology. SAGE, unlike DNA microarrays, cannot be used to assay hundreds of clinical samples; however, it is not restricted to known genes, nor is it limited by the selection of probes on a microarray. SAGE is capable of identifying novel transcripts that have not been described previously, possibly because of their tissue-specific expression (an advantage in developing therapeutics). Two studies using SAGE libraries obtained from normal tissue, as well as from ductal carcinoma in situ (DCIS), invasive, and metastatic breast tumors, were used to identify transcripts that changed between disease states (Porter, 2001, 2003a). Several DCIS or invasive/metastatic "specific" genes were assayed by mRNA in situ hybridization using 18 frozen DCIS and invasive breast cancer samples, and by immunohistochemistry using 769 DCIS, invasive, and metastatic breast tumor samples. S100A7, a member of the S100 family of calcium-binding proteins, was preferentially expressed in DCIS (with highest levels restricted to high-grade comedo DCIS) versus normal or invasive/metastatic tumors. Although S100A7 is expressed less strongly in invasive tumors, its levels are higher in ER-negative, poorly differentiated, lymph node-positive tumors, suggesting that its expression in DCIS may be a useful prognostic indicator. In a follow-up study, Porter et al. further characterized dermcidin, identified in previous studies as preferentially expressed in invasive and metastatic tumors. Dermcidin is a 110

amino acid-containing protein that is expressed mainly in sweat glands and the pons of the brain (Porter, 2003b) and is proteolyzed to a 47 amino acid-containing peptide. The marker was expressed in a subset of invasive tumors by immunohistochemistry, and its expression correlated with larger tumor size and the presence of metastatic lymph nodes. In a subset of cases, higher expression levels were attributable to gene amplification at the gene locus on chromosome 12. Dermcidin was shown to enhance cell growth and survival and may be a promising prognostic indicator of overall and distant metastatic-free survival.

INTEGRATING GENOMICS AND PROTEOMICS

The development of high-throughput technology allows one not only to look at how multiple genes or proteins might predict a clinical feature of interest, but also to study overlap in transcriptional activity and protein translation. Chen and colleagues looked at the ability of genetic profiling and protein translation in lung adenocarcinoma to predict survival (Chen, 2003). After filtering low-abundance genes, they found approximately 5000 genes consistently expressed across a cohort of 86 adenocarcinoma samples and 10 normal tissue samples. Hierarchical clustering and leave-one-out cross-validation generated a list of the 50 genes that were most effective in dividing patients into high- and low-risk groups for mortality over several years of follow-up. Of particular interest was the observation that stage I patients, those most likely to experience a surgical cure of their disease, could also be divided into high- and low-risk groups, potentially identifying a novel group that would benefit from adjuvant chemotherapy.

A total of 76 tumor samples underwent both microarray and proteomic analysis. In the examples of genes found along with their corresponding protein products, correlation peaked at 0.39. Although statistically significant, the low degree of correlation underlines the point that the oversimplified model of transcription and translation is in reality a much more elaborate system of translational regulation, glycosylation, phosphorylation, and additional downstream modifications. As the authors conclude, many of the transcripts probably do not correlate well with their protein counterparts as a result of this continued posttranslational development. Extension of their investigation to include genomics and proteomics uncovered a significant cohort of genes and proteins involved in the glycolytic pathway and upregulated among patients with a high risk of mortality, suggesting that this integration of genomics and proteomics has particular value in shedding light on the molecular pathogenesis of disease states.

PITFALLS OF MOLECULAR MARKERS FOR BOTH PROGNOSTICS AND DIAGNOSTICS

MICROARRAY DATA SETS

Diffuse large B-cell lymphoma studies conducted by Alizadeh and Shipp (2000) identified subsets of genes that specified two subtypes of DLBCL patients who differed in terms of survival. Shipp and colleagues also identified two subtypes of DLBCL patients; however, these types did not correlate with survival. The example presented earlier illustrates one of many DNA microarray studies in which little or no overlap of results is evident. Several potential causes seen in the experimental design and analysis of DNA microarray results may account for the widespread discrepancies (Simon, 2003). Two different studies performed using similar tissue samples may involve slightly different patient populations and sample sizes. Tissue heterogeneity is also a problem. Biopsies obtained from different locations have varying numbers of normal cells contaminating the tumor samples. Additionally, no "standard" is used for preprocessing and analyzing microarray data. New computational approaches are continually emerging, and two groups analyzing the same data set will often produce disparate gene lists. Finally, methods used to compare data sets generated using different DNA microarray platforms are currently being developed, and similar studies with nonoverlapping results may have employed inadequate methods of comparison.

"OVERFITTING" THE PREDICTOR

Traditionally, clinical studies aim to associate a handful of variables across several hundred patients, whereas DNA microarray studies contain

thousands of variables (gene expression levels) across relatively small numbers of patients (typically, 20–200 patients). Many class prediction algorithms yield accurate results for samples in the study from which they were derived, but when they are applied to an independent patient sample, performance drops significantly—a phenomenon known as overfitting (Ransohoff, 2004). Results of DNA microarray studies therefore are most robust when the data are divided into a training set and a test or validation set (Ntzani, 2003). In addition to the need for independent sample validation, it is important for investigators to validate gene expression levels using different technology. To realize the true promise of these technologies, it is critical to develop methods that combine several gene expression studies to identify markers that are consistently correlated with disease class or outcome, and then to validate these markers using different technology and a different cohort of patients.

THE "BYSTANDER" EFFECT

Miklos and colleagues compared DNA microarray studies measuring prefrontal cortex gene expression in patients with and without schizophrenia versus nonmicroarray studies that included genetic, RNA, and protein measurements obtained through a variety of approaches (Miklos, 2004). Little overlap was noted between DNA microarray and nonmicroarray experiments. One reason for this may be that genes identified using DNA microarray studies are "bystander," that is, not involved in the pathogenesis of the disease state. Genes identified by genetic linkage studies are usually causally related to a disease; however, expression levels of these genes may remain constant because the genetic alteration affects only mRNA splicing or posttranscriptional regulation. Also, DNA microarray technologies may not be sensitive enough to accurately measure gene expression changes in genes expressed at low levels.

Despite the suggested cautions, DNA microarray studies in the recent literature have begun to explore the biological significance and therapeutic potential of promising genes in greater depth using *in vitro* and *in vivo* models. For example, using DNA microarrays, Tian and colleagues (2003) identified a gene, *DKK1*, which was differentially expressed in multiple myeloma patients with and without focal bone lesions. Patients with bone lesions expressed higher levels of *DKK1* RNA and protein. *DKK1* is involved in bone formation through the Wnt signaling pathway, and marrow plasma from patients with bone lesions was shown to block osteoblast differentiation *in vitro*, indicating a causal role in disease progression and a potential therapeutic target. Another study, using cDNA microarrays to study liver samples from patients with hepatitis B–positive hepatocellular carcinomas with and without intrahepatic metastases, found that paired primary and metastatic tumors had similar gene expression patterns (Ye, 2003). Many differentially expressed genes, however, were identified between primary carcinomas that did and did not metastasize. Osteopontin, a glycosylated phosphoprotein that acts as a cytokine, was overexpressed in primary tumors with metastasis. Additional experimental studies showed that cellular invasiveness was reduced in hepatoma-derived cell lines treated with neutralizing osteopontin antibody. In addition, nude mice injected with hepatocellular carcinoma cells had a reduced incidence of metastasis when treated with osteopontin-specific antibody.

LIMITATIONS OF PROTEOMIC TECHNIQUES

Proteomic studies suffer from problems similar to those outlined previously for DNA microarrays, including tissue heterogeneity, overfitting of predictive models, and identification of causative disease proteins. Specific criticism of proteomic techniques for the diagnosis of cancer focuses largely on the SELDI-TOF-MS technique. Diamandis (2004a, 2004b), the most widely published critic of this approach, has outlined several shortcomings of the technology. Although several papers have published impressive diagnostic yields using a panel of mass spectra, or "ion signatures," few positive identifications of proteins responsible for those peaks have occurred. Some of the proteins identified have been studied previously as tumor markers but were dismissed as acute phase reactants. The absence of more positive protein identification limits the interpretation of published results, which potentially record differences attributable to something other than the underlying cancer, such as generalized inflammation.

The narrow dynamic detection range of MS technology also limits proteomic studies. In the case of serum samples, minimal preprocessing generally occurs prior to MS analysis; this involves surface enhancement attained through incubation on a weakly cationic protein chip—a nonspecific process that would likely bind only to the most abundant proteins in

the sample, failing to detect potentially informative low-abundance proteins. One would likely not expect the proteins shed from a malignancy such as prostate cancer to be the most abundant proteins in a serum sample. By some estimates, SELDI-TOF-MS could not detect proteins at less than 1 µg/dL—a concentration many times higher than that of most known tumor markers (Diamandis, 2003).

CONCLUSIONS AND FUTURE CHALLENGES

The recent completion of the Human Genome Project and advances within the biotechnology sector offer unprecedented opportunities for identification of biomarkers associated with cancer and other pathologies. Genome sequence data combined with high-throughput biomarker discovery will facilitate the correlation of genetic variation with disease diagnosis and biological outcomes. The emerging fields of functional genomics and functional proteomics offer the opportunity to translate these advances into a full comprehension of the pathophysiology of cancer and other complex multigenic diseases.

High-throughput genomic and proteomic technologies have the potential to transform clinical practice and are likely to lead to the supplementation or replacement of traditional diagnostic and prognostic biomarkers. Many of the studies detailed in this chapter have demonstrated the utility of gene expression profiles for the classification of tumors into distinct, clinically relevant subtypes and for the prediction of clinical

outcomes. In addition, emerging proteomics platforms have just begun to add another layer of molecular information to the study of human disease. These technologies should lead to a new era of individualized molecular medicine, whereby all patients will be treated on the basis of genetic changes in their tumors and their own genetic makeup, resulting in more effective and less toxic therapy.

These high-throughput platforms offer the promise of influencing the practice of medicine. However, a number of obstacles to widespread clinical implementation of these technologies remain. Genomic and proteomic biomarkers are an emerging class of laboratory tests that present special implementation challenges for the clinical laboratory, including analytic, bioinformatics, and bioethical issues. Considerable efforts are required to provide the necessary clinical laboratory infrastructure for standard high-throughput analyzers capable of detecting genomic and proteomic alterations within a variety of biological samples and within various high-performance computing and advanced data management capabilities. Significant improvements in analytic tools are needed, as are efforts to standardize techniques, controls, and reference standards. The application of such information to medical diagnosis and treatment will require considerable changes in the training of physicians. The most pressing need, however, is for extensive independent validation of the profiles described in the previous sections using large, statistically powered data sets. Inclusion of genomic- and proteomic-based molecular profiling techniques into clinical trial protocols will be needed to realize the potential of this technology to improve diagnosis and to tailor treatment of human disease.

APPENDIX

1

PHYSIOLOGIC SOLUTIONS, BUFFERS, ACID-BASE INDICATORS, STANDARD REFERENCE MATERIALS, AND TEMPERATURE CONVERSIONS

PHYSIOLOGIC SOLUTIONS

A physiologic solution is one that contains various salts in concentrations that closely approximate the composition of fluids in the human body. The simplest of these is physiologic saline, which has the same osmotic pressure as the blood. There are more elaborate solutions, for example, to maintain tissues in a metabolically active state for longer periods of time. Table A1-1 lists formulas of some solutions that are isotonic with respect to blood.

BUFFERS*

Buffers have the ability to resist changes in pH. Buffers usually consist of a weak acid and its salt or a weak base and its salt. The Henderson-Hasselbalch equation is useful in calculating the acid (or base) to salt ratio required to establish a desired pH from a buffer system:

$$\text{pH} = \text{pK} + \log[\text{salt}]/[\text{acid}] \quad (\text{A1-1})$$

EXAMPLE 1

If the pH of a 0.1M acetate buffer is known to be 4.90, calculate the concentration of acetic acid and sodium acetate in the buffer (pK for acetic acid = 4.76).

Substituting values of pH and pK in Equation A1-1:

$$\log[\text{acetate}]/[\text{acetic acid}] = 4.90 - 4.76 = 0.14$$

$$[\text{acetate}]/[\text{acetic acid}] = 1.38$$

$$[\text{acetate}] = 1.38[\text{acetic acid}]$$

Because the total buffer/L concentrations is 0.1M,

$$[\text{acetate}] + [\text{acetic acid}] = 0.1 \text{ M} \quad (\text{A1-2})$$

Substituting the value of acetate in Equation A1-2:

$$1.38[\text{acetic acid}] + [\text{acetic acid}] = 0.1 \text{ M}$$

Hence,

$$[\text{acetic acid}] = 0.042 \text{ M}$$

$$[\text{acetic acid}] = 2.52 \text{ g/L}$$

$$[\text{acetate}] = 0.058 \text{ M} \\ = 4.76 \text{ g/L}$$

EXAMPLE 2

If 648 mL of 0.025 molar diethylbarbituric acid and 10 mL of 0.5 molar sodium diethylbarbiturate are mixed and diluted to 1L, calculate the pH of the solution (pK for diethylbarbituric acid = 7.98 and molar concentration = moles/liter).

The following relationship exists between molarity and volume of a solution:

$$M_1V_1 = M_2V_2 \quad (\text{A1-3})$$

where, M1 = molarity of the initial solution, V1 = volume of the initial solution, M2 = molarity of the final solution, V2 = volume of the final solution.

Use Equation A1-3 to calculate changes in salt and acid concentrations after dilution to 1L:

$$[\text{Sodium diethylbarbiturate}] = 0.025 \times 0.648 \\ = 0.0162 \text{ mol/L}$$

$$[\text{Diethylbarbituric acid}] = 0.5 \times 0.01 \\ = 0.005 \text{ mol/L}$$

Calculate pH of the solution using Equation A1-1:

$$\text{pH} = 7.98 - \log(0.0162/0.005) \\ = 7.98 - \log 3.24 \\ = 7.98 - 0.51 \\ = 7.47$$

The maximum buffering capacity is at the pK value of the weak acid or base. For instance, for acetic acid with a pH value of 4.76, more acid is required to change the pH of an acetate buffer from 4.76 to 4.66 than from

TABLE A1-1
Physiologic Solutions

TABLE A1-2

Sorensen's Table of Buffer Mixtures

Na ₂ HPO ₄ solution (mL)	KH ₂ PO ₄ solution (mL)	pH
0.25	9.75	5.288
0.5	9.5	5.589
1.0	9.0	5.906
2.0	8.0	6.239
3.0	7.0	6.468
4.0	6.0	6.643
5.0	5.0	6.813
6.0	4.0	6.979
7.0	3.0	7.168
8.0	2.0	7.381
9.0	1.0	7.731
9.5	0.5	8.043

TABLE A1-3

Tris(hydroxymethyl)aminomethane Buffer

mL 0.1N HCl added	Resulting pH at 23° C	Resulting pH at 37° C
5.0	9.10	8.95
7.5	8.92	8.78
10.0	8.74	8.60
12.5	8.62	8.48
15.0	8.50	8.37
17.5	8.40	8.27
20.0	8.32	8.18
22.5	8.23	8.10
25.0	8.14	8.00
27.5	8.05	7.90
30.0	7.96	7.82
32.5	7.87	7.73
35.0	7.77	7.63
37.5	7.66	7.52
40.0	7.54	7.40
42.5	7.36	7.22
45.0	7.20	7.05

4.20 to 4.10. Efficient buffering capacity covers a pH range of about 1 unit on either side of the pK value of the weak acid or base. For acetic acid, this would be from about pH 3.8 to 5.8.

SORENSEN'S PHOSPHATE BUFFERS

These buffer solutions are generally useful, because the range of the mixtures is from pH 5 to 8.

Prepare 0.1 molar solutions of monobasic potassium phosphate (13.6 g/L) and dibasic sodium phosphate (14.2 g/L). Mix solutions in the ratio indicated in Table A1-2 to obtain the buffer of desired pH.

TRIS(HYDROXYMETHYL)AMINOMETHANE BUFFER*

Tris(hydroxymethyl)aminomethane buffer can be used for a pH range between 7.0 and 9.0, but its best buffer capacity is between 7.5 and 8.5. It

*If buffers of a higher molarity are desired, the 0.1N HCl may have to be replaced by 1.0N HCl.

TABLE A1-4

Acid-Base Indicators

Indicator	pH range	Quantity of indicator per 10 mL	Color acid	Alkaline
Thymol blue (A) [†]	1.2–2.8	1–2 drops 0.1% solution in aqueous	Red	Yellow
Methyl orange (B)	3.1–4.4	1 drop 0.1% solution in aqueous	Red	Orange
Bromphenol blue (A) [†]	3.0–4.6	1 drop 0.1% solution in aqueous	Yellow	Blue-violet
Bromcresol green (A) [†]	4.0–5.6	1 drop 0.1% solution in aqueous	Yellow	Blue
Methyl red (A) [†]	4.4–6.2	1 drop 0.1% solution in aqueous.	Red	Yellow
Bromcresol purple (A) [†]	5.2–6.8	1 drop 0.1% solution in aqueous	Yellow	Purple
Bromthymol blue (A) [†]	6.2–7.6	1 drop 0.1% solution in aqueous	Yellow	Blue
Phenol red (A) [†]	6.4–8.0	1 drop 0.1% solution in aqueous	Yellow	Red
Neutral red (B)	6.8–8.0	1 drop 0.1% solution in 70% alcohol	Red	Yellow
Thymol blue (A) ^{†‡}	8.0–9.6	1–5 drops 0.1% solution in aqueous	Yellow	Blue
Phenolphthalein (A)	8.0–10.0	1–5 drops 0.1% solution in 70% alcohol	Colorless	Red
Thymolphthalein (A)	9.4–10.6	1 drop 0.1% solution in 90% alcohol	Colorless	Blue

is practically ineffective below pH 7.0 and above pH 9.0. One advantage of the buffer is its excellent stability. The buffer can be prepared by weighing the desired amount of tris(hydroxymethyl)aminomethane, dissolving it in water, and adjusting the pH to the desired value with HCl. For example, if 100 mL of 0.05 M buffer is desired, place 0.6057 g of tris(hydroxymethyl)aminomethane into a 100-mL volumetric flask. This is dissolved in approximately 50 mL of distilled water. Add 0.1N HCl, as indicated in Table A1-3, and fill up to the mark with distilled water. The table shows the pH values obtained when 0.6057 g of tris(hydroxymethyl)aminomethane dissolved in water is mixed with the indicated amounts of 0.1N HCl and diluted to 100 mL.

ACID-BASE INDICATORS*

An acid-base indicator is a weak acid or a weak base, the undissociated form of which has a color and constitution other than the ionic form. Color change takes place over a certain narrow range of hydrogen ion concentrations. This range is called the *color change interval* and is expressed in terms of pH (the negative logarithm of the hydrogen ion concentration). A great number of substances show indicator properties, although relatively few of them are practically applied for neutralization reactions and pH determinations. Commonly used acid-base indicators are listed in Table A1-4. In general, weak acids should be titrated in the presence of indicators that change in slightly alkaline solutions. Weak bases should be titrated in the presence of indicators that change in slightly acid solutions. commonly used acids and alkalis are listed in Table A1-5.

The availability of precision pH meters allows titration to a selected end point (pH) and may replace use of indicators for several applications.

42	107.6	10	50
41	105.8	+5	41
40.5	104.9	0	32
40	104	-5	23
39.5	103.1	-10	14
39	102.2	-15	+5
38.5	101.3	-20	-4

1° F = -17.2° C.

1° C = 33.8° F.

To convert Fahrenheit into centigrade, subtract 32 and multiply by 0.555.

To convert centigrade to Fahrenheit, multiply by 1.8 and add 32.

STANDARD REFERENCE MATERIALS

Standard reference materials (SRM) are available for many substances with defined identities and concentrations in solutions or as other materials such as thermometers or optical filters with specified transmission wavelengths (Table A1-6). SRMs are used as standards or controls against which assays may be calibrated with high certainty of accuracy in both identity and concentration of the substance or other property.

TEMPERATURE CONVERSION

Temperature is expressed in either Fahrenheit (F) or centigrade (C) scale according to the convention of the country, editorial policy of journals, and local practices. The simple relationship between these two temperature scales is:

Temperature in degrees Fahrenheit

$$= 1.8 \times \text{temperature in degrees centigrade} + 32$$

Often it is more convenient to look up corresponding values for these two temperature scales in a list of values (Table A1-7). A unique value occurs at -40° where the two scales intersect and the values coincide (i.e., -40° F = -40° C).

Source: http://www.nhlbi.nih.gov/guidelines/obesity/bmi_tbl.htm.

Figure A2-1 Nomogram for the determination of body surface area of children and adults. (From Boothby WM, Sandiford RB. Nomographic charts for the calculation of the metabolic rate by the gasometer method. *Boston Med Surg J* 1921;185:337, with permission.)

Figure A2-2 Nomogram for the determination of body surface area of children. (From DuBois EF. *Basal metabolism in health and disease*. Philadelphia: Lea & Febiger; 1936.)

The formula for calculating BMI is:

$$\text{BMI} = \text{Weight (kg)} / \text{Height (m}^2\text{)}$$

Or

$$\text{BMI} = 703 \times \text{Weight (lb)} / (\text{Height (in)}^2)$$

Interpretation of BMI for adults 20 years old and older:

<18.5 is underweight

18.5–24.9 is normal

25–29.9 is overweight

30 and above is obese.

(From Centers for Disease Control and Prevention. About BMI for adults. http://www.cdc.gov/healthyweight/assessing/bmi/adult_bmi/index.html.)

APPENDIX

3

APPROXIMATIONS OF TOTAL BLOOD VOLUME

When estimating a patient's total blood volume (TBV), a commonly used approximation is 70 mL of TBV per kilogram body weight. While useful in many patients, in others, particularly children and overweight or thin adults, this figure offers only a poor approximation of actual TBV. In these patients, other methods of estimation of TBV are more appropriate.

ADULTS

The COBE Spectra uses the Nadler and Allen formula to calculate approximate TBV for patients (COBE Spectra Apheresis System Operator's Manual, 1997). This formula uses patient height, weight, and sex to calculate TBV. Specifically, the formula is:

$$\text{Males: TBV (mL)} = 604 + [367 \times \text{height}^3 (\text{m})] + [32.2 \times \text{weight (kg)}]$$

$$\text{Females: TBV (mL)} = 183 + [356 \times \text{height}^3 (\text{m})] + [33.1 \times \text{weight (kg)}]$$

TBV can also be approximated using the patient's calculated body surface area (Shoemaker, 1989):

$$\text{Males: TBV} = 2740 \text{ mL/m}^2$$

$$\text{Females: TBV} = 2370 \text{ mL/m}^2$$

Another relatively simple approximation uses Gilcher's so-called rule of fives, reproduced here, as an estimate of blood volume, which is more tailored to the individual patient than the 70 mL/kg rule (Gilcher, 1996).

	Fat	Thin	Normal	Muscular
Males	60	65	70	75
Females	55	60	65	70

CHILDREN

The Nadler and Allen calculation can be particularly inaccurate in children, especially prepubertal boys, in whom it has been recommended that the female gender be entered to improve the estimation (Kim, 2000). The following values for TBV per kilogram body weight can be used (Oski, 1993):

Premature infants	89–105 mL/kg
Term newborns	82–86 mL/kg
Infants and preschoolers	73–82 mL/kg

SI UNITS

The Standard International (SI) consists of seven dimensionally independent base units, which are listed in Table A5-1, along with the symbols to be used to denote these units. Table A5-2 lists a number of derived units of the SI that are used in the clinical laboratory. There are two kinds of derived units: (1) coherent units, which are derived directly from the base units without the use of conversion factors, and (2) noncoherent units, which are constructed from the base units and contain a numerical factor to make the numbers more convenient to use. The prefixes to denote fractions or multiples of base and derived SI units are given in Table A5-3. A complete description of the SI and its application in medicine may be found in the World Health Organization publication *The SI for the Health Professions* (World Health Organization, 1977). See Tietz (1995) for a comprehensive list of quantities and their internationally recommended SI units.

In making the conversion to recommend SI units (Tables A5-4 through A5-13), the following guidelines were followed:

1. All reference intervals have been converted to SI units except in cases in which the measurements are not quantitative.
2. Chemical names have not been changed; for example, urea is retained instead of changing to carbamide.
3. Factors are those published by the American National Metric Council (Lundberg, 1986; Beeler, 1987; Young, 1987), based on the Metric Commission of Canada (1981) factors.
4. Factors are calculated to the base unit for volume of 1 L.
5. The order of magnitude of the factors is calculated to make the values in SI units convenient numbers, that is, with prefixes, a number not greater than 1000 or smaller than 0.001.
6. The number in recommended SI units is equal to the number in conventional units times the factor.
7. For compounds for which relative molecular masses are not definitely known (e.g., proteins), reference intervals are converted to mass amounts per liter.
8. For mixtures of indeterminate composition (e.g., phospholipids), reference intervals are converted to mass amounts per liter or are based on a given standard, for example, DHEA for 17-ketosteroids.
9. Quantities of a relative nature that are usually expressed as percentages, for example, fractions of LD isoenzymes, are given as fractions.
10. Enzyme units are given as the international unit per liter (U/L). Although the coherent SI unit for catalytic activity (including enzymes), the katal, has been defined as the number of moles of substrate converted per second under defined conditions, its adoption is limited.
11. The pH scale is retained for measurement of hydrogen ion concentrations.
12. It is recommended that the unit millimeters of mercury (mm Hg) be retained for pressure (P_{CO_2} , P_{O_2}) at the present time.

13. Percentages are expressed as fractions in the SI, where a fraction is a dimensionless quantity given by the number of defined particles constituting a specified component divided by the total number of defined particles in the system.

TABLE A5-2
SI Derived Units

Quantity	Unit name	Unit symbol
Area	square meter*	m ²
Volume	cubic meter*	m ³
	liter†	L = dm ^{3‡}
Concentration		
Mass	kilogram/liter†	kg/L
Substance	mole/liter†	mol/L
Molality	mole/kilogram	mol/kg
Density	kilogram/liter†	kg/L
Mass fraction	kilogram/kilogram	kg/kg
Mole fraction	mole/mole	mol/mol
Number concentration	number/liter	L ⁻¹
Temperature	degree celsius*	°C = °K – 273.15
Pressure	pascal*	Pa = kg/m ²
Frequency	hertz*	Hz = 1 cycle/s
Clearance	liter/second†	L/s
Electrical potential	volt*	V = kgm ² /s ³ A
Energy	joule*	J = kgm ² /s ²

*Derived coherent unit.

†Derived noncoherent unit.

‡Both "L" and "l" are symbols for the liter.

TABLE A5-3
Prefixes

Prefix	Prefix symbol	Factor
exa	E	10 ¹⁸
peta	P	10 ¹⁵
tera	T	10 ¹²
giga	G	10 ⁹
mega	M	10 ⁶
kilo	k	10 ³
hecto	h	10 ²
deca	da	10 ¹
deci	d	10 ⁻¹
centi	c	10 ⁻²
milli	m	10 ⁻³
micro	μ	10 ⁻⁶
nano	n	10 ⁻⁹
pico	p	10 ⁻¹²
femto	f	10 ⁻¹⁵
atto	a	10 ⁻¹⁸
zepto	z	10 ⁻²¹
yocto	y	10 ⁻²⁴

TABLE A5-1

SI Base Units

Quantity	Name	Symbol
Length	meter	m
Mass	kilogram	kg
Time	second	s
Electric current	ampere	A
Thermodynamic temperature	kelvin	K
Luminous intensity	candela	cd
Amount of substance	mole	mol

TABLE A5-4

Whole Blood, Serum, and Plasma Chemistry

Component	System	TYPICAL REFERENCE INTERVALS		
		Conventional units	Factor*	Recommended SI units†
Acetoacetic acid				
Qualitative	Serum	Negative	—	Negative
Quantitative	Serum	0.2–1 mg/dL	97.95	20–100 µmol/L
Acetone				
Qualitative	Serum	Negative	—	Negative
Quantitative	Serum	0.3–2 mg/dL	172.95	20–340 µmol/L
Albumin				
Qualitative	Serum	3.2–4.5 g/dL (salt fractionation)	10	32–45 g/L
		3.2–5.6 g/dL (electrophoresis)		32–56 g/L
		3.8–5 g/dL (eye binding)		38–50 g/L
Alcohol, ethyl	Serum or whole blood	Negative—but presented as mg/dL	0.2171	Negative—but presented as mmol/L
Aldolase	Serum			
	Adults	3–8 Sibley-Lehninger U/dL at 37° C	7.4	22–59 mU/L at 37° C
	Children	Approximately 2× adult levels	—	Approximately 2× adult levels
	Newborn	Approximately 4× adult levels	—	Approximately 4× adult levels
α-Amino acid nitrogen	Serum	3.6–7 mg/dL	0.7139	2.6–5 mmol/L
δ-Aminolevulinic acid	Serum	0.01–0.03 mg/dL	76.26	0.8–2.3 µmol/L
Ammonia	Plasma	20–120 µg/dL (diffusion)	0.5872	12–70 µmol/L
		40–80 µg/dL (enzymatic method)		23–47 µmol/L
		12–48 µg/dL (resin method)		7–28 µmol/L
Amylase	Serum	16–120 Somogyi units/dL	1.85	30–220 U/L
Argininosuccinate lyase	Serum	0–4 U/dL	10	0–40 U/L
Arsenic‡	Whole blood	<7 µg/dL	0.05055	<0.4 µmol/L
Ascorbic acid (vitamin C)	Plasma	0.6–1.6 mg/dL	56.78	34–91 µmol/L
	Whole blood	0.7–2 mg/dL		40–114 µmol/L
Barbiturates	Serum, plasma, or whole blood	Negative	—	Negative
Base excess	Whole blood			
	Male	–3.3 to +1.2 mEq/L	1	–3.3 to +1.2 mmol/L
	Female	–2.4 to +2.3 mEq/L		–2.4 to +2.3 mmol/L
Base, total	Serum	145–160 mEq/L	1	145–160 mmol/L
Bicarbonate	Plasma	21–28 mmol/L	1	21–28 mmol/L
Bile acids	Serum	0.3–3 mg/dL	10	3–30 mg/L
Bilirubin				
Direct (conjugated)	Serum	<0.3 mg/dL	17.10	<5 µmol/L
Indirect (unconjugated)	Serum	0.1–1 mg/dL		2–17 µmol/L
Total	Serum	0.1–1.2 mg/dL		2–21 µmol/L
Newborns total	Serum	1–12 mg/dL		17–205 µmol/L
Blood gases (see Chapter 14)				
pH	Whole blood	7.38–7.44 (arterial)	1	7.38–7.44
		7.36–7.41 (venous)		7.36–7.41
PCO ₂	Whole blood	35–40 mm Hg (arterial)	0.1333	4.7–5.3 kPa
		40–45 mm Hg (venous)		5.3–6 kPa
PO ₂	Whole blood	95–100 mm Hg (arterial)	0.1333	12.7–13.3 kPa
Bromide	Serum	<5 mg/dL	0.125	<0.63 mmol/L
Calcium				
Ionized	Serum	4–4.8 mg/dL	0.2500	1–1.2 mmol/L
		2–2.4 mEq/L	0.5000	
		30–58% of total	0.01	0.30–1.58 of total
Total	Serum	9.2–11.0 mg/dL	0.2500	2.30–2.74 mmol/L
		4.6–5.5 mEq/L	0.5000	
Carbon dioxide (CO ₂ content)	Whole blood (arterial)	19–24 mmol/L	1	19–24 mmol/L
	Plasma or serum (arterial)	21–28 mmol/L		21–28 mmol/L
Carbon dioxide	Whole blood (venous)	22–26 mmol/L	1	22–26 mmol/L
	Plasma or serum (venous)	24–30 mmol/L		24–30 mmol/L
CO ₂ combining power	Plasma or serum (venous)	24–30 mmol/L	1	24–30 mmol/L
CO ₂ partial pressure (PCO ₂)	Whole blood (arterial)	35–40 mm Hg	0.1333	4.7–5.3 kPa
	Whole blood (venous)	40–45 mm Hg		5.3–6 kPa

TABLE A5-4

Whole Blood, Serum, and Plasma Chemistry—Cont'd

Component	System	TYPICAL REFERENCE INTERVALS		
		Conventional units	Factor*	Recommended SI units†
Carbonic acid (H ₂ CO ₃)	Whole blood (arterial)	1.05–1.45 mmol/L	1	1.05–1.45 mmol/L
	Whole blood (venous)	1.15–1.50 mmol/L		1.15–1.50 mmol/L
	Plasma (venous)	1.02–1.38 mmol/L		1.02–1.38 mmol/L
Carboxyhemoglobin (carbon monoxide hemoglobin)	Whole blood suburban	<1.5% saturation of hemoglobin	0.01	Fraction hemoglobin saturated: <0.015
	Nonsmokers			
	Smokers	1.5%–5% saturation		0.015–0.050
	Heavy smokers	5%–9% saturation		0.050–0.090
Carotene, β	Serum	40–200 μg/dL	0.01863	0.7–3.7 μmol/L
Ceruloplasmin	Serum	23–50 mg/dL	10	230–500 mg/L
Chloride	Serum	95–103 mEq/L	1	95–103 mmol/L
Cholesterol				
Total (see Chapter 17)	Serum	150–250 mg/dL (varies with diet, sex, and age)	0.02586	3.88–6.47 mmol/L
Esters	Serum	65%–75% of total cholesterol	0.01	Fraction of total cholesterol: 0.65–0.75
Cholinesterase (pseudocholinesterase)	Erythrocytes	0.65–1.3 pH units	1	0.65–1.3 units [§]
	Plasma	0.5–1.3 pH units 8–18 U/L at 37° C	1	0.5–1.3 units
Citrate	Serum or plasma	1.7–3 mg/dL	52.05	88–156 μmol/L
Copper	Serum, plasma			
	Male	70–140 μg/dL	0.1574	11–22 μmol/L
	Female	80–155 μg/dL		13–24 μmol/L
Cortisol	Plasma			
	8 AM–10 AM	5–23 μg/dL	27.59	138–635 nmol/L
	4 PM–6 PM	3–13 μg/dL		83–359 nmol/L
Creatine	Serum or plasma			
	Male	0.1–0.4 mg/dL	76.25	8–31 μmol/L
	Female	0.2–0.7 mg/dL		15–53 μmol/L
Creatine kinase (CK)	Serum			
	Male	55–170 U/L at 37° C	1	55–170 U/L at 37° C
	Female	30–135 U/L at 37° C	1	30–135 U/L at 37° C
Creatinine (see Chapter 14)	Serum or plasma	0.6–1.2 mg/dL (adult)	88.40	53–106 μmol/L
		0.3–0.6 mg/dL (children <2 yr)		27–53 μmol/L
Creatinine clearance (endogenous) (see Chapter 14)	Serum or plasma and urine			
	Male	107–139 mL/min	0.01667	1.78–2.32 mL/sec
	Female	87–107 mL/min		1.45–1.78 mL/sec
Cryoglobulins	Serum	Negative	—	Negative
Electrophoresis, protein	Serum			
Albumin		52%–65% of total protein	0.01	Fraction of total protein: 0.52–0.65
α-1		2.5%–5% of total protein	0.01	0.025–0.05
α-2		7%–13% of total protein	0.01	0.07–0.13
β		8%–14% of total protein	0.1	0.08–0.14
γ		12%–22% of total protein	0.01	0.12–0.22
	Serum	Concentration		
Albumin		3.2–5.6 g/dL	10	32–56 g/L
α-1		0.1–0.4 g/dL		1–4 g/L
α-2		0.4–1.2 g/dL		4–12 g/L
β		0.5–1.1 g/dL		5–11 g/L
γ		0.5–1.6 g/dL		5–16 g/L
Fats, neutral (see Triglycerides)				
Fatty acids				
Total (free and esterified)	Serum	9–15 mmol/L	1	9–15 mmol/L
Free (nonesterified)	Plasma	300–480 μEq/L	1	300–480 μmol/L
Ferritin	Serum			
	Male	15–200 ng/mL	1	15–200 μg/L
	Female	12–150 ng/mL	1	15–150 μg/L
Fibrinogen	Plasma	200–400 mg/dL	0.01	2–4 g/L

Whole Blood, Serum, and Plasma Chemistry—Cont'd

Component	System	TYPICAL REFERENCE INTERVALS		
		Conventional units	Factor*	Recommended SI units†
Fluoride	Whole blood	<0.05 mg/dL	0.5263	<0.027 mmol/L
Folate	Serum			11–57 nmol/L
		≥3.5 ng/mL (radioassay)	2.266	>5 nmol/L
	Erythrocytes	166–640 ng/mL (bioassay)		376–1450 nmol/L
		>140 ng/mL (radioassay)		>317 nmol/L
Galactose	Whole blood			
	Adults	None	—	None
	Children	<20 mg/dL	0.05551	<1.11 mmol/L
Gamma globulin	Serum	0.5–1.6 g/dL	10	5–16 g/L
Globulins, total	Serum	2.3–3.5 g/dL	10	23–35 g/L
Glucose, fasting	Serum or plasma	70–110 mg/dL	0.05551	3.9–6.1 mmol/L
	Whole blood	60–100 mg/dL		3.3–5.6 mmol/L
Glucose tolerance	Serum or plasma			
Oral	Fasting	70–110 mg/dL	0.05551	3.9–6.1 mmol/L
	30 min	30–60 mg/dL above fasting		1.7–3.3 mmol/L above fasting
	60 min	20–50 mg/dL above fasting		1.1–2.8 mmol/L above fasting
	120 min	5–15 mg/dL above fasting		0.3–0.8 mmol/L above fasting
	180 min	Fasting level or below	—	Fasting level or below
Intravenous	Serum or plasma			
	Fasting	70–110 mg/dL	0.05551	3.9–6.1 mmol/L
	5 min	Maximum of 250 mg/dL		Maximum of 13.9 mmol/L
	60 min	Significant decrease	—	Significant decrease
	120 min	Below 120 mg/dL	0.05551	Below 6.7 mmol/L
	180 min	Fasting level	—	Fasting level
Glucose-6-phosphate dehydrogenase (G6PD)	Erythrocytes	250–5000 units/10 ⁶ cells	1	250–5000 μunits/cell
		1200–2000 mU/mL packed erythrocytes	1	1200–2000 U/L packed erythrocytes
γ-Glutamyltransferase	Serum	5–40 U/L	1	5–40 U/L at 37° C
Glutathione	Whole blood	24–37 mg/dL	0.03254	0.78–1.20 mmol/L
Growth hormone	Serum	<10 ng/mL	1	<10 μg/L
Guanase	Serum	<3 nmol/mL/min	1	<3 U/L at 37° C
Haptoglobin	Serum	60–270 mg/dL	0.01	0.6–2.7 g/L
Hemoglobin	Serum or plasma			
	Qualitative	Negative	—	Negative
	Quantitative	0.5–5 mg/dL	10	5–50 mg/L
	Whole blood			
	Female	12–16 g/dL	10	120–160 g/L
	Male	13.5–18 g/dL		135–180 g/L
α-Hydroxybutyrate dehydrogenase	Serum	140–350 U/mL	1	140–350 kU/L
17-Hydroxycorticosteroids	Plasma			
	Male	7–19 μg/dL	25.59 [§]	193–524 mmol/L
	Female	9–21 μg/dL		248–579 mmol/L
	After 24 USP units of ACTH intramuscularly	35–55 μg/dL		966–1517 nmol/L
Immunoglobulins:	Serum			
IgG		800–1801 mg/dL	0.01	8–18 g/L
IgA		113–563 mg/dL		1.1–5.6 g/L
IgM		54–222 mg/dL		0.5–2.2 g/L
IgD		0.5–3 mg/dL	10	5–30 mg/L
IgE		0.01–0.04 mg/dL		0.1–0.4 mg/L
Insulin	Plasma bioassay	11–240 μU/mL	7.175	79–1722 pmol/L
	Radioimmunoassay	4–24 μU/mL		29–172 pmol/L
Insulin tolerance (0.1 unit/kg)	Serum			
	Fasting	Glucose of 70–110 mg/dL	0.05551	Glucose of 3.9–6.1 mmol/L
	30 min	Fall to 50% of fasting level	0.01	Fall to 0.5 of fasting level
	90 min	Fasting level	—	Fasting level
Iron, total	Serum	60–150 μg/dL	0.1791	10.7–26.9 μmol/L

TABLE A5-4

Whole Blood, Serum, and Plasma Chemistry—Cont'd

Component	System	TYPICAL REFERENCE INTERVALS		
		Conventional units	Factor*	Recommended SI units†
Iron-binding capacity	Serum	250–400 µg/dL	0.1791	44.8–71.6 µmol/L
Iron saturation	Serum	20–55%	0.01	Fraction of total iron-binding capacity: 0.20–0.55
Isocitric dehydrogenase	Serum	50–240 U/mL at 25° C (Wolfson-WilliamsAshman units)	0.0166	0.83–4.18 U/L at 25° C
Ketone bodies	Serum	Negative	—	Negative
17-Ketosteroids	Plasma	25–125 µg/dL	34.67**	866–4334 nmol/L
Lactic acid (as lactate)	Whole blood			
	Venous	5–20 mg/dL	0.1110	0.6–2.2 mmol/L
	Arterial	3–7 mg/dL		0.3–0.8 mmol/L
Lactate dehydrogenase (LD)	Serum	(lactate → pyruvate) 80–120 units at 30° C	0.48	38–62 U/L at 30° C
		(pyruvate → lactate) 185–640 units at 30° C	0.48	90–310 U/L at 30° C
		(lactate → pyruvate) 100–190 U/L at 37° C	1	100–190 U/L at 37° C
Lactate dehydrogenase isoenzymes	Serum			Fraction of total LD
LD ₁ (anode)		17%–27%	0.01	0.17–0.27
LD ₂		27%–37%		0.27–0.37
LD ₃		18%–25%		0.18–0.25
LD ₄		3%–8%		0.03–0.08
LD ₅ (cathode)		0%–5%		0.00–0.05
Lactate dehydrogenase (heat stable)	Serum	30%–60% of total	0.01	Fraction of total LD: 0.30–0.6
Lactose tolerance	Serum	Serum glucose changes similar to glucose tolerance test	—	Serum glucose changes similar to glucose tolerance test
Lead	Whole blood	<50 µg/dL	0.04826	<2.41 µmol/L
Leucine aminopeptidase (LAP)	Serum			
	Male	80–200 U/mL (Goldbarg–Rutenberg)	0.24	19.2–48 U/L
	Female	75–185 U/mL (Goldbarg–Rutenberg)		18–44.4 U/L
Lipase	Serum	0–1.5 U/mL (Cherry–Crandall)	278	0–417 U/L
		14–280 mU/mL	1	14–280 U/L
Lipids, total	Serum	400–800 mg/dL	0.01	4–8 g/L
Cholesterol (see Chapter 17)		150–250 mg/dL	0.02586	3.88–6.47 mmol/L
Triglycerides (see Chapter 17)		10–90 mg/dL	0.01129††	0.11–2.15 mmol/L
Phospholipids		150–380 mg/dL	0.01	1.50–3.80 g/L
Fatty acids (free)		9–15 mmol/L	1	9–15 mmol/L
Phospholipid phosphorus		8–11 mg/dL	0.3229	2.58–3.55 mmol/L
Lithium	Serum	Negative	—	Negative
Therapeutic interval		0.5–1.4 mEq/L	1	0.5–1.4 mmol/L
Long-acting thyroid-stimulating hormone (LATS)	Serum	None detected	—	None detected
Luteinizing hormone (LH)	Serum			
	Male	6–30 mU/mL	1	6–30 U/L
	Female	Midcycle peak: 3× baseline value	—	Midcycle peak: 3× baseline value
		Premenopausal <30 mU/mL	1	Premenopausal <30 U/L
		Postmenopausal >35 mU/mL		Postmenopausal >35 U/L
Macroglobulins, total	Serum	70–430 mg/dL	0.01	0.7–4.3 g/L
Magnesium	Serum	1.3–2.1 mEq/L	0.5000	0.65–1.05 mmol/L
		1.8–3 mg/dL	0.4114	0.74–1.23 mmol/L
Methemoglobin	Whole blood	<0.24 g/dL	10	<2.4 g/L
		<1% of total hemoglobin	0.01	Fraction of total hemoglobin <0.01
Mucoprotein	Serum	80–200 mg/dL	0.01	0.8–2 g/L
Muramidase	Serum	4–13 mg/L	1	4–13 mg/L
Myoglobin	Serum	<90 µg/L	1	<90 µg/L
Nonprotein nitrogen (NPN)	Serum or plasma	20–35 mg/dL	0.7139	14.3–25 mmol/L
	Whole blood	25–50 mg/dL		17.8–35.7 mmol/L

TABLE A5-4

Whole Blood, Serum, and Plasma Chemistry—Cont'd

Component	System	TYPICAL REFERENCE INTERVALS		
		Conventional units	Factor*	Recommended SI units†
5'-Nucleotidase	Serum	0–1.6 units at 37° C	1	0–1.6 units at 37° C
Ornithine carbamyl transferase	Serum	8–20 mU/mL at 37° C	1	8–20 U/L at 37° C
Osmolality	Serum	280–295 mOsm/kg	1	280–295 mmol/kg
Oxygen (see Chapter 14)				
Pressure (PO ₂)	Whole blood (arterial)	95–100 mmHg	0.1333	2.7–13.3 kPa
Content	Whole blood (arterial)	15–23 volume	0.01	Volume fraction: 0.15–0.23
Saturation	Whole blood (arterial)	94–100%	0.01	Fraction saturated: 0.94–1
pH	Whole blood (arterial)	7.38–7.44	1	7.38–7.44
	Whole blood (venous)	7.36–7.41		7.36–7.41
	Serum or plasma (venous)	7.35–7.45		7.35–7.45
Phenylalanine	Serum			
	Adults	<3 mg/dL	60.54	<182 μmol/L
	Newborns (term)	1.2–3.5 mg/dL		73–212 μmol/L
Phosphatase				
Acid phosphatase	Serum	0.13–0.63 U/L at 37° C (<i>p</i> -nitrophenylphosphate)	16.67	2.2–10.5 U/L at 37° C
Alkaline phosphatase	Serum	20–130 U/L at 37° C (<i>p</i> -nitrophenylphosphate in AMP buffer)	1	20–130 U/L at 37° C
Phospholipid phosphorus (see Lipids, total)		M		
Phospholipids (see Lipids, total)				
Phosphorus, inorganic	Serum			
	Adults	2.3–4.7 mg/dL	0.3229	0.74–1.52 mmol/L
	Children	4–7 mg/dL		1.29–2.26 mmol/L
Potassium	Plasma	3.8–5 mEq/L	1	3.8–5 mmol/L
Prolactin	Serum			
	Female	1–25 ng/mL	1	1–25 μg/L
	Male	1–20 ng/mL		1–20 μg/L
Proteins (see Chapter 19)	Serum			
Total		6–7.8 g/dL	10	60–78 g/L
Albumin		3.2–4.5 g/dL		32–45 g/L
Globulin		2.3–3.5 g/dL		23–35 g/L
Protein fractionation, see Electrophoresis				
Protoporphyrin	Erythrocytes	15–50 mg/dL	0.01777	0.27–0.89 μmol/L
Pyruvate	Whole blood	0.3–0.9 mg/dL	113.6	34–102 μmol/L
Salicylates	Serum	Negative	—	Negative
Therapeutic interval		15–30 mg/dL	0.07240	1.08–2.17 mmol/L
Sodium	Plasma	136–142 mEq/L	1	136–142 mmol/L
Sulfate, inorganic	Serum	0.2–1.3 mEq/L	0.5	0.10–0.65 mmol/L
		0.9–6 in mg/dL as SO ₄ ²⁻	0.1042	0.09–0.63 mmol/L as SO ₄ ²⁻
Sulfhemoglobin	Whole blood	Negative	—	Negative
Sulfonamides	Serum or whole blood	Negative	—	Negative
Testosterone	Serum or plasma			
	Male	300–1200 ng/dL	0.03467	10.4–41.6 nmol/L
	Female	30–95 ng/dL		1–3.3 nmol/L
Thiocyanate	Serum	Negative	—	Negative
Thyroid hormone tests (see Chapter 24)	Serum			
thyroxine, total (T4)		5.5–12.5 μg/dL	12.87	71–161 nmol/L
thyroxine, free (FT4)		0.9–2.3 ng/dL	12.87	12–30 pmol/L
T3 resin uptake		25–38 relative % uptake	0.01	Relative uptake fraction: 0.25–0.38
Thyroxine-binding globulin (TBG)	Serum	10–26 μg/dL	10	100–260 μg/L
Thyrotropin (TSH)	Serum	0.5–5 μU/mL	1	0.5–5 μU/L
Triiodothyronine (T3)		80–200 mg/dL	0.0154	1.23–3 of nmol/L
Transferases				
Aspartate amino transferase (AST or SGOT)	Serum	8–33 U/L at 37° C	1	8–33 U/L at 37° C
Alanine amino transferase (ALT or SGPT)	Serum	4–36 U/L at 37° C	1	4–36 U/L at 37° C

TABLE A5-4

Whole Blood, Serum, and Plasma Chemistry—Cont'd

Component	System	TYPICAL REFERENCE INTERVALS		
		Conventional units	Factor*	Recommended SI units†
γ Glutamyl transferase (GGT)		5–40 U/L at 37° C	1	5–40 U/L at 37° C
Triglycerides (see Chapter 17)	Serum	10–190 mg/dL	0.01129††	0.11–2.15 mmol/L
Troponin I	Serum	<2 mg/mL		0–0.6 µg/L 0–0.1 µg/L
Urea nitrogen	Serum	8–23 mg/dL	0.357	2.9–8.2 mmol/L
Urea clearance	Serum and urine			
Maximum clearance		64–99 mL/min	0.01667	1.07–1.65 L/s
Standard clearance		41–65 mL/min, or more than 75% of normal clearance		0.68–1.08 L/s or more than 0.75 of normal clearance
Uric acid	Serum			
	Male	4–8.5 mg/dL	0.05948	0.24–0.51 mmol/L
	Female	2.7–7.3 mg/dL		0.16–0.43 mmol/L
Vitamin A	Serum	15–60 µg/dL	0.03491	0.52–2.09 µmol/L
Vitamin A tolerance	Serum	15–60 µg/dL	0.03491	0.52–2.09 µmol/L
	Fasting 3 hr or 6 hr after 5000 units vitamin A/kg	200–600 µg/dL	0.03491	6.98–20.95 µmol/L
	24 hr	Fasting values or slightly above	—	Fasting values or slightly above
Vitamin B ₁₂	Serum	160–950 pg/mL	0.7378	118–701 pmol/L
Unsaturated vitamin B ₁₂ -binding capacity	Serum	1000–2000 pg/mL	0.7378	738–1475 pmol/L
Vitamin C	Plasma	0.6–1.6 mg/dL	56.78	34–91 µmol/L
Xylose absorption	Serum normal in malabsorption	25–40 mg/dL 1–2 hr Maximum ≈10 mg/dL Dose: adult 25 g D-xylose; children 0.5 g D-xylose/kg	0.06661	1.67–2.66 mmol/L 1–2 h Maximum ≈0.67 mmol/L
Zinc	Serum	50–150 µg/dL	0.1530	7.7–23 µmol/L

*Factor = number factor (note that units are not presented).

†Value in SI units = value in conventional units × factor.

‡Usually not measured in blood (preferred specimen is urine, hair, or nails except in acute cases, when gastric contents are used).

§Unit based on hydrogen ion concentration.

¶As cortisol.

||1 International unit of insulin corresponds to 0.04167 mg of the 4th International Standard (a mixture of 52% beef insulin and 48% pig insulin).

**As DHEA.

††As triolein.

TABLE A5-9

Hematology—Cont'd

Component	TYPICAL REFERENCE INTERVALS		
	Conventional units	Factor	Recommended SI units
Platelet count	150,000–450,000/ μ L	10^6	150–450 $\times 10^9$ /L
Reticulocyte count	0.5%–1.5%	0.01	Number fraction: 0.005–0.015
	25,000–75,000 cells/ μ L	10^6	25–75 $\times 10^9$ /L
Sedimentation rate (ESR) (Westergren)			
Men younger than 50 yr	<15 mm/hr		
Men 50–85 yr	<20 mm/hr		
Men older than 85 yr	<30 mm/hr		
Women younger than 50 yr	<20 mm/hr		
Women 50–85 yr	<30 mm/hr		
Women older than 85 yr	<42 mm/hr		
Viscosity	1.4–1.8 times water	1	1.4–1.8 times water
Zeta sedimentation ratio	41%–54%	0.01	Fraction: 0.41–0.54

*All percentages are multiplied by 0.01 to give fraction.

TABLE A5-10

Amniotic Fluid

Component	TYPICAL REFERENCE INTERVALS		
	Conventional units	Factor	Recommended SI units
Appearance			
Early gestation	Clear	—	Clear
Term	Clear or slightly opalescent	—	Clear or slightly opalescent
Albumin			
Early gestation	0.39 g/dL	10	3.9 g/L
Term	0.19 g/dL		1.9 g/L
Bilirubin			
Early gestation	<0.075 mg/dL	17.10	<1.3 μ mol/L
Term	<0.025 mg/dL		<0.41 μ mol/L
Chloride			
Early gestation	Approximately equal to serum chloride	—	Approximately equal to serum chloride
Term	Generally 1–3 mEq/L lower than serum chloride	1	Generally 1–3 mmol/L lower than serum chloride
Creatinine			
Early gestation	0.8–1.1 mg/dL	88.40	71–97 μ mol/L
Term	1.8–4 mg/dL (generally >2 mg/dL)		159–354 μ mol/L (generally >177 μ mol/L)
Estriol			
Early gestation	<10 μ g/dL	3.468	<347 nmol/L
Term	<60 μ g/dL		>2081 nmol/L
Lecithin: sphingomyelin			
Early (immature)	<1:1	1	<1:1
Term (mature)	>2:1		>2:1
Osmolality			
Early gestation	Approximately equal to serum osmolality	—	Approximately equal to serum osmolality
Term	230–270 mOsm/kg	1	230–270 mmol/kg
P _{CO} ₂			
Early gestation	33–55 mm Hg	0.1333	4.4–7.3 kPa
Term	42–55 mm Hg (increases toward term)		5.6–7.3 kPa (increases toward term)
pH			
Early gestation	7.12–7.38	1	7.12–7.38
Term	6.91–7.43 (decreases toward term)		6.91–7.43

TABLE A5-10

Amniotic Fluid—Cont'd

Component	TYPICAL REFERENCE INTERVALS		
	Conventional units	Factor	Recommended SI units
Protein, total			
Early gestation	0.60 ± 0.24 g/dL	10	60 ± 2.4 g/L
Term	0.26 ± 0.19 g/dL		2.6 ± 1.9 g/L
Sodium			
Early gestation	Approximately equal to serum sodium	—	Approximately equal to serum sodium
Term	7–10 mEq/L lower than serum sodium	1	7–10 mmol/L lower than serum sodium
Staining, cytologic			
Oil Red O			
Early gestation	Stained fraction: <10%	0.01	Stained fraction: <0.1
Term	Stained fraction: >50%		>0.5
Nile blue sulfate			
Early gestation	Stained fraction: 0	0.01	Stained fraction: <0.0
Term	Stained fraction: >20%		>0.2
Urea			
Early gestation	18 ± 5.9 mg/dL	0.1665	3.00 ± 0.98 mmol/L
Term	30.3 ± 11.4 mg/dL		5.04 ± 1.90 mmol/L
Uric acid			
Early gestation	3.72 ± 0.96 mg/dL	59.48	221 ± 57 μmol/L
Term	9.90 ± 2.23 mg/dL		589 ± 133 μmol/L
Volume			
Early gestation	450–1200 mL	0.001	0.45–1.2 L
Term	500–1400 mL (increases toward term)		0.5–1.4 L (increases toward term)

TABLE A5-11

Cerebrospinal Fluid

Component	TYPICAL REFERENCE INTERVALS		
	Conventional units	Factor	Recommended SI units
Albumin	<10–30 mg/dL	10	100–300 mg/L
Cell count	<5 cells/μL	10 ⁶	<5 × 10 ⁶ /L
Glucose	40–80 mg/dL	0.05551	2.8–4.4 mmol/L
Lactate dehydrogenase (LD)	Approximately 10% of serum level	—	Activity fraction: approximately 0.1 of serum level
Proteins	12–60 mg/dL	10	120–600 mg/L
Protein electrophoresis			Fraction:
Prealbumin	2%–7%	0.01	0.2–0.07
Albumin	56%–76%		0.56–0.76
α-1 Globulin	2%–7%		0.02–0.07
α-2 Globulin	4%–12%		0.04–0.12
β Globulin	8%–18%		0.08–0.18
γ Globulin	3%–12%		0.03–0.12
Xanthochromia	Negative	—	Negative

COMMON CHIMERIC GENES IDENTIFIED IN HUMAN MALIGNANCIES

Peng Lee, Naif Z. Abraham Jr, Matthew R. Pincus

Tables A6-1 and A6-2 give well-known examples of common recurrent translocations identified in a number of malignancies. Table A6-1 correlates the specific translocation and genes involved with the respective malignancy. For example, in chronic myelogenous leukemia (CML), the typical chromosomal translocation present is t(9;22)(q34;q11), where typically the long arms of chromosome 22 and 9 are involved in a reciprocal translocation or genetic fusion. The *bcr* gene is located on chromosome 22q11, whereas the *abl* oncogene resides on chromosome 9q34. This translocation produces an abnormal *bcr/abl* fusion gene. This gene, in turn, is transcribed into an abnormal *bcr/abl* fusion mRNA, which in turn is translated into the leukemia-producing *bcr/abl* protein molecule. This fusion protein possesses an abnormally increased tyrosine kinase activity which is involved in malignant transformation of hematopoietic cells to produce CML.

Table A6-2 indicates the genes and their chromosomal locations, their apparent protein product, and the abbreviation or nomenclature used in the research and medical literature to identify them. For example, in transformation to CML, key genes involved are *bcr* and *abl*, where the nomenclature *bcr* stands for “breakpoint cluster region” and *abl* refers to the human homologue of the oncogene of the Abelson murine leukemia virus or *v-abl*.

These tables and their “explanations” of the gene nomenclature are intended to help clarify to the student of molecular and clinical pathology the function and/or particular research history of these genes and protein products. All information in these tables are derived from references listed here:

TABLE A6-1

Common Recurrent Chromosome Changes with Common Chimeric Genes and Protein Fusions Identified in Malignancies

Malignancy	Translocation, genes/proteins involved
Hematopoietic malignancies	
Chronic myelogenous leukemia	t(9;22)(q34;q11), BCR/ABL
Acute myeloid leukemia	t(8;21)(q22;q22), AML1/ETO
Acute promyelocytic leukemia	t(15;17)(q22;q12), PML/RAR α
AML with abnormal eosinophils	t(16;16)(p13;q22) or inv(16)(p13q22), CBFb/MYH11
Burkitt lymphoma	t(8;14)(q24;q32), c-MYC/Ig heavy chain locus
Precursor B ALL/lymphoma	t(9;22)(q34;q11.2), BCR/ABL
	t(4;11)(q21;q23), AF4/MLL
	t(1;19)(q23;p13.3), PBX/E2A
	t(12;21)(p13;q22), TEL/AML1
Mantle cell lymphoma	t(11;14)(q13;q32), Ig heavy chain locus/BCL1
Follicular lymphoma	t(14;18)(q32;q21), BCL2 rearranged
MALT lymphoma	t(11;18)(q21;q21), API2/MLT
Anaplastic large cell lymphoma	t(2;5)(p23;q35), ALK/NPM
T cell prolymphocytic leukemia	t(14;14)(q11;q32), TCR α /TCL1
	inv14q(q11;q32), TCR α /TCL1
Mesenchymal malignancies	
Alveolar soft part sarcoma	t(X;17)(p11;q25), ASPL/TFE3
Alveolar rhabdomyosarcoma	t(2;13)(q35;q14), PAX3/FKHR
	t(1;13)(q36;q14), PAX7-FOXO1A
Congenital fibrosarcoma	t(12;15)(p13;q25), ETV6/NTRK3
Clear cell sarcoma	t(12;22)(q13;q12), EWSR1-ATF1
	t(2;22)(q33;q12), EWSR1-CREB1
Dermatofibrosarcoma protuberans	t(17;22)(q22;q13), COL1A1/PDGFB
Desmoplastic small round cell tumor	t(11;22)(p13;q12), EWS/WT1
	t(21;22)(q22;q12), EWSR1-ERG*
Ewing's sarcoma/peripheral primitive neuroectodermal tumor	t(11;22)(q24;q12), EWS/FLI1
Extraskelatal myxoid chondrosarcoma	t(9;22)(q22;q12), EWS/TEC
Malignant melanoma of soft parts/clear cell sarcoma	t(12;22)(q13;q12), EWS/ATF1

TABLE A6-1

Common Recurrent Chromosome Changes with Common Chimeric Genes and Protein Fusions Identified in Malignancies—Cont'd

Malignancy	Translocation, genes/proteins involved
Myxoid/round cell liposarcoma	t(12;16)(q13;p11), TLS/CHOP
Synovial sarcoma	t(X;18)(p11.23;q11), SYT/SSX1 t(X;18)(p11;q11), SS18-SSX2
Carcinomas	
Renal cell carcinoma, papillary type	t(X;1)(p11;q21), TFE3/PRCC t(X;1)(p11;p34), TFE3/PSF
Papillary carcinoma of thyroid	2 protooncogenes identified in some cancers: RET and NTRK1 fused to the amino-terminus of different gene products
Prostate cancer	Deletion of TMPRSS2 with fusion to ETS family proteins including: TMPRSS2/ERG TMPRSS2/ETV1 TMPRSS2/ETV4
Follicular carcinoma of thyroid	T(2;3)(q13;p25), PAX8-PPAR γ

TABLE A6-2

Genes and Proteins Involved in Malignancies

HEMATOPOIETIC MALIGNANCIES	
BCR	Breakpoint cluster region gene, codes for a putative serine/threonine kinase, maps to chromosome 22q11
ABL	Human homologue of the oncogene of the Abelson murine leukemia virus, or v-abl, codes for a non-receptor tyrosine kinase, maps to chromosome 9q34
AML1	Acute myelogenous leukemia-1 gene, codes for a transcription factor, maps to chromosome 21q22; also known as core binding factor α 2 or CBF α 2, RUNX1, PEBP2 α B
ETO	Eight-twenty-one gene, codes for a transcription factor, maps to chromosome 21q22
PML	Promyelocytic leukemia gene, codes for a nuclear factor which may influence transcription, maps to chromosome 15q22
RAR α	Retinoic acid receptor α gene, codes for a ligand-dependent nuclear retinoic acid receptor with transcription factor activity, maps to chromosome 17q21
CBF β	Core binding factor β , codes for a transcription factor, maps to chromosome 16q22; also known as PEBP2B or polyoma enhancer binding protein
MYH11	Myosin heavy chain 11 gene, codes for smooth muscle myosin heavy chain, maps to chromosome 16p13
c-MYC	Cellular homologue of the v-myc oncogene from the avian myelocytomatosis retrovirus, codes for a transcription factor, maps to chromosome 8q24
Ig heavy chain locus	Codes for the principal constituent (i.e., the heavy or H chain) of the immunoglobulin molecule and determines the class (IgA, IgD, IgE, IgG, IgM) of the molecule, maps to chromosome 14q32
AF4	ALL-1 fused gene on chromosome 4, codes for a putative transcription factor, maps to chromosome 4q21; also known as FEL
MLL	Mixed lineage leukemia or myeloid/lymphoid leukemia gene, codes for a transcriptional regulator, maps to chromosome 11q23; also known as HRX and ALL-1
PBX1	Pre-B cell leukemic homeobox 1 gene, codes for a transcriptional activator, maps to chromosome 1q23
E2A	Enhancer binding A gene (encoding two proteins that bind to the kappa E2 site in the enhancer region of the kappa light chain gene), codes for a transcription factor required in B cell development, maps to chromosome 19p13.3
TEL	Translocated ETS (E26-transformation specific) leukemia gene, codes for a transcription factor, maps to chromosome 12p13; also known as ETV6
BCL1	B cell leukemia/lymphoma 1 gene, codes for a growth factor sensor protein involved in regulation of cell cycle division, maps to chromosome 11q13; also known as PRAD1/CCND1 or cyclin D1
BCL2	B cell leukemia/lymphoma 2 gene, codes for BCL-2 protein which inhibits apoptosis (programmed cell death), maps to chromosome 18q21.3
API2	Apoptosis inhibitor 2 gene, codes for an inhibitor of apoptosis, maps to chromosome 11q21; also known as c-IAP2, HIAP1, MIHC
MLT	MALT (mucosa-associated lymphoid tissue) lymphoma-associated translocation, codes for protein of unknown function, maps to chromosome 18q21
ALK	Anaplastic lymphoma kinase gene, codes for a receptor tyrosine kinase (expressed in neural tissue), maps to chromosome 2p23
NPM	Nucleophosmin (a nonribosomal nucleolar phosphoprotein involved in transporting ribosomal components between the nucleus and the cytoplasm for ribosomal assembly), coded by the NPM gene, maps to chromosome 5q35
TCR	T cell antigen receptor, a T cell membrane/surface receptor for antigen, composed of polypeptide chains from the α/δ (chromosome 14q11), β (chromosome 7q34), and/or γ (chromosome 7p) gene sets
TCL1	T cell leukemia/lymphoma 1 gene, codes for a protein of unknown function, but may be involved in lymphoid cell proliferation and/or survival, maps to chromosome 14q32.1

TABLE A6-2

Genes and Proteins Involved in Malignancies—Cont'd

MESENCHYMAL MALIGNANCIES	
ASPL	Alveolar soft part sarcoma locus, function unknown, maps to chromosome 17q25
c-Kit	Mast/stem cell growth factor receptor gene encodes a tyrosine-protein kinase, maps to chromosome 4q11-q12
TFE3	Gene codes for a transcription factor which binds to the IgH intronic enhancer muE3 DNA region, maps to chromosome Xp11.2
PAX3	Paired box transcription factor 3 gene, codes for a transcription factor, maps to chromosome 2q35
FKHR	Forkhead-related gene, codes for a transcription factor, maps to chromosome 13q14; also known as FOXO1A
ETV6	Ets variant 6 gene, codes for a transcription factor, maps to chromosome 12p13; also known as TEL
NTRK3	Neurotrophin transmembrane receptor tyrosine kinase 3 gene, codes for a receptor that induces the release of neurotrophins, maps to chromosome 15q25; also known as TRKC or transmembrane receptor tyrosine kinase C
COL1A1	Collagen type 1 α 1 chain gene, codes for an extracellular matrix protein, maps to chromosome 17q22
PDGFB	Platelet-derived growth factor β chain gene, codes for a growth factor or mitogen, maps to chromosome 22q13; a human homologue of v-sis (simian sarcoma virus) oncogene
EWS	Ewing sarcoma gene, a putative nuclear RNA binding protein, maps to chromosome 22q12
WT1	Wilms' tumor protein 1 gene, codes for a transcription factor, maps to chromosome 11p13
FLI1	Freund's leukemia integration site 1 gene and an ETS family gene, codes for a transcriptional regulator protein, maps to chromosome 11q
TEC	Translocated in extraskeletal chondrosarcoma, codes for a steroid nuclear receptor/transcription factor thought to be involved in control of cellular proliferation and apoptosis, maps to chromosome 9q22; also known as CHN (chondrosarcoma), NOR1 (neuron derived orphan receptor 1)—a receptor is termed an orphan when its ligand has not been isolated
ATF1	Activating transcription factor 1 gene, codes for a transcription factor, maps to chromosome 12q13
TLS	Translocated in liposarcoma gene, a putative nuclear RNA binding protein, maps to chromosome 16p11; also known as FUS or fusion
CHOP	C/EBP homologous protein—where C/EBP refers to CCAAT/enhancer-binding protein—codes for a transcription factor, maps to chromosome 12q13; also known as GADD153, DDIT3
SYT	Synovial sarcoma translocation gene, a putative transcriptional activator, maps to chromosome 18q11
SSX1	Synovial sarcoma X chromosome breakpoint gene 1, a putative transcriptional repressor/DNA binding factor, maps to chromosome Xp11
CARCINOMAS	
BRCA1/ BRCA2	Breast and ovarian cancer susceptibility proteins, BRCA1 maps to chromosome 17q21 and BRCA2 maps to chromosome 13q12.3
BRAF	B-Raf proto-oncogene encoding serine/threonine-protein kinase, maps to chromosome 7q34
EGFR	Epidermal growth factor receptor encodes transmembrane tyrosine-protein kinase, maps to chromosome 7p12
HER2/neu	Human epidermal growth factor receptor 2, maps to chromosome 17q11.2-q12
TFE3	Gene codes for a transcription factor which binds to the IgH intronic enhancer muE3 DNA region, maps to chromosome Xp11.2
PRCC	Papillary renal cell carcinoma gene, a ubiquitously expressed nuclear protein, maps to chromosome 1q21.2
PSF	PTB-associated splicing factor gene where PTB = polypyrimidine tract-binding protein, codes for a ubiquitously expressed, putative multifunctional, nuclear protein possibly involved in transcription, maps to chromosome 1p34
RAS	Rat sarcoma oncogene encodes ras p21 protein (protein of molecular mass 21 kD), a membrane-bound G-protein that is the target of different activated growth factor receptors. Mutations that cause amino acid substitutions at critical positions, such as Val-for-Gly 12, are oncogenic. There are three major ras types: Harvey (Ha), Kirsten (K) and N.K-ras with the Val-for Gly 12 substitution has been found in over 90 percent of pancreatic cancers and over 50 percent of colon cancers and occurs in about 1 in every three common solid tissue tumors. K-ras maps to chromosome 12p12.1
RET	Rearranged during transfection, codes for a tyrosine kinase receptor, maps to chromosome 10q11
NTRK1	Neurotrophin transmembrane receptor tyrosine kinase 1 gene, codes for a tyrosine kinase receptor for nerve growth factor, maps to chromosome 1q21-22; also known as TRKA or transmembrane receptor tyrosine kinase A

GUIDELINES FOR ORDERING BLOOD FOR ELECTIVE SURGERY

ALSO REFERRED TO AS MAXIMUM SURGICAL BLOOD ORDER SCHEDULE (MSBOS)

These guidelines present a range in numbers of units of blood to be ordered as practiced at three different institutions: University Hospital State University of New York Upstate Medical Center at Syracuse, N.Y.; Virginia Commonwealth University Medical Center, Richmond, Va.; and University of Michigan Hospitals, Ann Arbor, Mich. Each institution should set its own guidelines for ordering blood products to take into account varying medical needs and practices in collaboration with the hospital medical and surgical staff.

KEY:

- 0 = no testing required
- T&S = type & screen
- 1-6 = number of units crossmatched
- AO = as ordered
- * = varies with purpose

Hemicolectomy.....	T&S
Hemorrhoidectomy.....	0
Hepatic lobectomy.....	4
Hernia repair, inguinal.....	0
Ileostomy.....	T&S
Iliac profunda bypass.....	2
Jejunostomy tube placement.....	0
Lumpectomy, breast mass.....	0
Mastectomy, simple.....	0
Mastectomy, modified radical.....	0
Mastectomy, radical.....	T&S
Mediastinoscopy.....	0
Myotomy (pyloric).....	0
Parotidectomy.....	0
Pilonidal cyst.....	0
Portocaval shunt.....	4 to 6
Pseudoaneurysm repair.....	4 to 6
Rib resection.....	0
Sigmoidectomy.....	T&S
Sigmoidoscopy.....	0
Small bowel resection.....	T&S
Splenectomy.....	T&S to 2
Sympathectomy.....	T&S
Thyroidectomy.....	0
Total colon resection.....	T&S
Transjugular intrahepatic portosystemic shunt (TIPS).....	T&S
Vagotomy.....	0
Vein stripping.....	T&S
Whipple's procedure.....	2 to 4

GYNECOLOGY

Anterior-posterior repair.....	0
Cone biopsy (CO ₂ laser).....	0
Dilation and curettage (D&C).....	0 to 2
Ectopic pregnancy.....	T&S
Endometrium ablation.....	0
Examine under anesthesia (EUA).....	0
Exploratory laparotomy.....	T&S to 2
Exenteration procedure.....	4
Hysterectomy, total abdominal.....	T&S
Hysteroscopy.....	0
Laparoscopy.....	0
Laser vaporization.....	0
Neosalpingostomy.....	0

Oophorectomy.....	0
Ovarian wedge resection.....	0
Salpingo-oophorectomy.....	0
Uterine suspension.....	0
Tubal ligation.....	0
Tuboplasty.....	0
Vaginectomy.....	T&S to 2
Vulvectomy.....	T&S to 2

NEUROSURGERY

Aneurysm clipping.....	2
Biopsy (cervical/brain).....	T&S
Burr hole.....	T&S
Carpal tunnel release.....	0 or T&S
Cervical decompression	
1-2 level.....	0
>2 level.....	T&S
Cervical discectomy.....	T&S
Cordotomy.....	T&S
Corpectomy.....	1
Craniectomy.....	2
Cranioplasty.....	T&S
Craniotomy.....	2
Endarterectomy, carotid.....	T&S
Hypophysectomy.....	T&S to 1
Laminectomy	
1-2 level.....	0
>2 level.....	T&S
Lobectomy.....	2
Neuroma removal.....	T&S
Nerve repair.....	T&S
Pituitary tumor resection.....	1
Spinal fusion.....	T&S
Stereotactic brain biopsy.....	T&S
Stereotactic hematoma.....	T&S
Ulnar nerve transplant.....	0
Ventricular-peritoneal shunt insertion.....	0 or T&S

ORTHOPEDICS

Acromioplasty.....	0
Amputation.....	T&S
Arthroscopy.....	0
Arthroplasty.....	0
Arthrotomy.....	0
Biopsy, excisional.....	0
Bipolar transfer.....	T&S
Carpal tunnel release.....	0
Closed reduction.....	0
Debridement.....	AO
Decompression laminectomy	
1-2 level.....	0
>2 level.....	T&S
Discectomy.....	T&S
Fractures.....	0
*Fusions, other.....	T&S to 2
Hardware removal.....	0
Hip revision.....	T&S to 2
Hip screw and nailing.....	T&S to 2
Lumbar laminectomy	
1-2 level.....	0
>2 level.....	T&S

Menisectomy.....	0
Nerve transposition.....	0
Neuroma excision.....	0
Open reduction	
Femur, pelvis, acetabulum.....	T&S to 2
Hand, foot.....	0
Radius, humerus, elbow.....	0 or T&S
Osteotomy.....	0
Posterior rod fusion.....	2
Prosthesis removal.....	0
Releases.....	0
Revascularization and exploration.....	T&S
Rodding (Grosse and Kempf).....	T&S
Rotator cuff repair.....	T&S
Shoulder replacement.....	T&S
Shoulder repair.....	0
Spinal fusions.....	2 to 4
Tendon repair.....	0
Total elbow.....	0
Total hip.....	T&S
Total knee.....	T&S

OTORHINOLARYNGOLOGY/ HEAD AND NECK SURGERY

Antrotomy.....	0
Atticoantrotomy.....	0
Bronchoscopy.....	0
Caldwell-Luc.....	0 or T&S
Cochlear implant.....	0
Composite resection.....	4
Craniofacial resection.....	T&S
Dissecting laryngoscopy.....	0
Endoscopy.....	0
Esophageal reconstruction.....	T&S
Esophagoscopy.....	0
Ethmoid artery ligation.....	4
Ethmoidectomy.....	T&S
Excisional biopsy.....	0
Frontal sinus exploration.....	T&S
Glossectomy.....	T&S
Labyrinthectomy.....	0
Laryngectomy.....	T&S
Laryngoscopy.....	0
Mandibulectomy.....	T&S

Mastoidectomy.....	0
Maxillary fixation.....	T&S
Maxillectomy.....	T&S
Myringotomy.....	0
Nasopharyngoscopy.....	0
Neck dissection.....	T&S
Neurectomy.....	0 or T&S
Panendoscopy.....	0
Parotidectomy.....	0
Plate removal.....	0
Septoplasty.....	0 or T&S
Septorhinoplasty.....	0 or T&S
Sphenoethmoidectomy.....	T&S
Sphenoidectomy.....	T&S
Stapedectomy.....	0
Thyroidectomy.....	0
Tonsillectomy.....	0
Tracheoscopy.....	0
Tracheostomy tube insertion.....	0
Tracheotomy.....	T&S
Tympanomastoidectomy.....	0 or T&S
Tympanoplasty.....	0

PLASTIC SURGERY

Millard's repair.....	T&S
Orbitotomy.....	T&S
Reduction mammoplasty.....	0
Septorhinoplasty.....	0

RENAL TRANSPLANTATION

Arteriovenous fistula.....	0
Donor nephrectomy.....	T&S
Pancreas transplant.....	4
Renal artery-vein patch.....	3
Renal transplant.....	T&S to 2
Vascular catheter insertion/removal (Tenckhoff).....	T&S

UROLOGY

Adrenalectomy.....	2
Bladder resection.....	T&S
Circumcision.....	0

Cystectomy	
Simple.....	0
Radical.....	2
Cystoscopy.....	0
Cystotomy.....	0
Fulguration, bleeding bladder.....	T&S
Hydrocelectomy.....	0
Ileal conduit.....	1
Lithotomy, ureteral.....	T&S
Lithotripsy, shock wave.....	0
Meatotomy.....	T&S
Needle biopsy of prostate.....	0
Nephrectomy, donor.....	T&S
Nephrectomy, radical.....	T&S
Nephrolithotripsy.....	1
Nephrostomy.....	T&S
Orchiopexy.....	0
Orchiectomy.....	0
Penectomy.....	2
Penile prosthesis insertion.....	0
Prostatectomy.....	T&S
Pyelolithotomy.....	T&S
Reimplantation of ureter.....	T&S
Stamey's procedure.....	0 or T&S
Transurethral resection of the prostate.....	0
Ureterectomy.....	0
Ureterolithotomy.....	T&S
Ureteroscopy.....	0
Urethral fistula excision.....	T&S
Vasectomy.....	0
Vasovasotomy.....	0

VASCULAR SURGERY

Abdominal aortic surgery.....	4
Aneurysm repair.....	2
Aortoiliac bypass.....	2
Arteriofemoral bypass.....	2
Arteriovenous fistula.....	0
Carotid endarterectomy.....	T&S
Catheter insertion/removal.....	0
Femoral bypass.....	T&S
Iliac profunda bypass.....	2
Renal artery repair.....	3
Splenorenal artery bypass.....	T&S
