Hemolysis is a significant feature in many cases of CRF. There appears to be an extracorporeal factor in uremic plasma that has a detrimental effect on red cell metabolism and results in morphologically deformed cells (echinocytes and spiculated red cells). Numerous irregularly contracted and fragmented cells are seen in the hemolytic-uremic syndrome and in malignant hypertension as a result of traumatic damage incurred by the red cells in traversing damaged small blood vessels. Changes in red cell membrane adenosine triphosphatase (ATPase) and transketolase may render the red cells more sensitive to oxidant drugs or chemicals.

In addition, bleeding is a common problem in chronic renal disease, probably owing to thrombocytopenia, in some patients, or to platelet functional defects, which are present in most patients. Anemia due to iron deficiency from blood loss should always be suspected. Folic acid deficiency may be a problem in patients in a dialysis program, in that folic acid is readily moved into the dialysis bath.

Anemia in Liver Disease

Chronic posthemorrhagic anemia; hypoplastic anemia secondary to viral-induced marrow suppression; folate-deficient megaloblastic anemia due to poor nutrition in alcoholic cirrhosis; and acquired hemolytic anemia associated with Coombs'-positive red cells, congestive splenomegaly, or lipid disturbances may occur in liver disease (Gallagher, 2009). Iron deficiency anemia is the most common in approximately 50% of patients, followed by hypersplenism in approximately 25% of patients (Ozatl, 2000). IFN- α and ribavarin (Rbv) are common therapies for hepatitis C infection. Rbv induces suppression of erythropoiesis, possibly through downregulation of EPO receptors. In addition, Rbv can cause a dose-dependent hemolytic anemia. IFN- α can produce anemia through suppression of hematopoietic progenitor cell proliferation and induction of apoptosis of erythroid progenitor cells (Dieterich, 2003).

In addition to these, an anemia associated with liver disease is characterized by shortened red cell survival and relatively inadequate red cell production. It is exaggerated by an increased blood volume that appears to correlate with the degree of portal hypertension. The red cells are normocytic or macrocytic (thin macrocytes). Frequently, target cells are present, especially in obstructive jaundice; these have increased surface membrane with increased cholesterol and lecithin content. However, the phospholipid/cholesterol ratio is normal. Reticulocytes may be slightly increased, and platelets may be normal or decreased. The bone marrow may be slightly hypercellular, and erythropoiesis is macronormoblastic rather than megaloblastic. Changes in leukocytes, such as those seen in megaloblastic anemias, are not seen, and this type of anemia does not respond to cobalamin (vitamin B₁₂) or folic acid. The anemia is of unknown origin.

A small proportion of patients with severe cirrhosis have a hemolytic anemia associated with "spur cells," which are red cells with thorny projections similar to acanthocytes. As with target cells, the spur cells occur secondary to lipid abnormalities in the plasma; they have increased surface membrane with increased cholesterol, but normal phospholipid content in the membrane. The increased membrane cholesterol tends to associate with the outer membrane leaflet, making it more rigid. The spleen attempts to remodel the membrane, resulting in characteristic membrane projections (Gallagher, 2001).

Anemia in Endocrine Disease

Uncomplicated anemia in hypothyroidism is mild to moderate, with Hb concentration rarely less than 8–9 g/dL; it is normochromic and normocytic without reticulocytosis and with normal red cell survival. It reflects decreased marrow production due to a smaller tissue O₂ requirement and subsequent reduced EPO secretion. Because plasma volume is decreased in hypothyroidism, the apparent degree of anemia may not be proportional to the decrease in red cell mass. Hypothyroidism may be complicated by iron deficiency anemia, producing a microcytic anemia, particularly in

females, as a result of menorrhagia, although in males, it may be caused by achlorhydria and diminished iron absorption. Macrocytosis is frequently observed. Although the incidence of pernicious anemia in patients with hypothyroidism may be increased, most cases of macrocytosis are due to folate deficiency. Approximately 10%–25% of patients with hyperthyroidism have anemia, which is mainly due to increased plasma volume (Greg, 2006).

In adrenal cortical hormone deficiency, a mild normochromic normocytic anemia is present. The cause is unclear, but the condition is corrected by hormone replacement.

Deficient testosterone secretion in men results in a decrease in red cell production of 1–2 g Hb/dL (to a value comparable with that of women). This appears to be due to a stimulatory effect of androgens on EPO secretion and occurs through enhanced EPO action on the marrow, and possibly as a direct effect on a subset of marrow cells, such as stromal cells.

Pituitary deficiency also causes moderately severe normocytic anemia, which is associated with marrow hypoplasia. The mechanism is probably complex and related to loss of function of multiple endocrine glands and possibly loss of growth hormone effect.

A small number of patients with hyperparathyroidism have a normocytic, normochromic anemia. Earlier studies suggested that the parathyroid hormone may suppress normal erythropoiesis. More recent studies failed to support this theory. The cause of the anemia is unknown but is likely related to marrow fibrosis (Greg, 2006).

Anemia Associated With Bone Marrow Infiltration (Myelophthistic Anemia)

This anemia is associated with marrow replacement by (or involvement with) abnormal cells or tissue component, such as metastatic carcinoma, multiple myeloma, leukemia, lymphoma, lipidoses or storage diseases, and certain other conditions.

Normochromic and normocytic (occasionally macrocytic) anemia of varying severity is present. Reticulocytes are often increased, and the number of normoblasts is usually out of proportion to the severity of the anemia. The leukocyte count is normal or reduced (occasionally elevated), and immature neutrophils and even myeloblasts may be found. Platelets are normal or decreased, and bizarre, atypical platelets can sometimes be seen.

Examination of the marrow will usually reveal the condition responsible for this reaction. Mechanical crowding out of the hematopoietic tissue by the pathologic process has been assumed but not proved and probably is not the usual cause. Often the amount of erythropoietic tissue in the marrow as determined by morphologic and kinetic studies is normal or increased. The mechanism described earlier under Anemia of Chronic Disease may often play a role, but the reason for the outpouring of immature cells into the blood is not clear.

In addition to myelophthistic anemias, circulating normoblasts and immature neutrophils can be seen in hemolytic anemias, severe anemias due to other causes, severe infections, and congestive heart failure, but usually the normoblasts are not as numerous.

The **leukoerythroblastic reaction** associated with myelophthistic anemias cannot always be distinguished from the blood picture of primary myelofibrosis, which is one of the myeloproliferative neoplasms. In primary myelofibrosis, enlargement of the spleen and liver is almost always found. In the blood film, more severe red cell abnormalities, leukocytosis, myeloblasts and immature granulocytes of all varieties (not just neutrophils), increased basophils, more atypical platelets, more numerous megakaryocyte fragments, and dwarf megakaryocytes are all findings more characteristic of primary myelofibrosis than of a leukoerythroblastic reaction of some other cause. Examination of the bone marrow biopsy is necessary for the final diagnosis.

Aplastic Anemia

AA usually refers to pancytopenia associated with a severe reduction in the amount of hematopoietic tissue that results in deficient production of blood cells in the absence of a bone marrow infiltrative process or increased reticulatin (Marsh, 2009). Usually two of the following three blood parameters are needed to diagnose AA: Hgb less than 100 g/L, granulocyte count less than $1.5 \times 10^9/L$, and platelet count less than $50 \times 10^9/L$. The marrow, although hypocellular, may have patchy areas of normocellularity, or even hypercellularity. The diagnosis of **severe AA** is made in pancytopenic patients when at least two of the following three peripheral blood values—granulocyte count less than $0.5 \times 10^9/L$, platelet count less than $20 \times 10^9/L$, or reticulocyte count less than $20 \times 10^9/L$, or 1% (corrected for Hct)—are

present and the bone marrow is less than 30% cellular (Young, 2002; Marsh, 2009). The term **very severe AA** is used when granulocyte count is less than $0.2 \times 10^9/L$ (Young, 2002). Otherwise, the AA would be classified as moderate or nonsevere. The incidence of AA is 2 per million per year based on retrospective studies in Europe and North America, and is about 2–3 times higher in East Asia (Marsh, 2009).

Clinical Features

The clinical course may be acute and fulminating, with profound pancytopenia and a rapid progression to death, or the disorder may have an insidious onset and a chronic course. The symptoms and signs depend on the degree of the deficiencies: bleeding from thrombocytopenia, infection from neutropenia, and signs and symptoms of anemia. As a rule, splenomegaly and lymphadenopathy are absent. Bleeding is the most common presentation of AA, occurring in approximately 40% of patients (Young, 2009). Bleeding usually manifests as easy bruisability, gum bleeds, and episodic nosebleeds. Less than 5% of patients present with infection.

Etiology

Aplastic anemias are of diverse origin. Since 1980, in approximately 70% of cases, no specific etiologic agent could be correlated with the disease; such cases are considered idiopathic. Drug- and chemical-related aplastic anemias account for 11%–20%, and those associated with infectious hepatitis account for 2%–9% of cases (Young, 2009).

Pathogenesis

Hematopoietic failure may occur at any level in the differentiation of bone marrow precursor cells. Insufficient stem cells may be assayed as long-term culture-initiating cells, or committed stem cells (progenitor cells) may be insufficient. The CD34+ cells in the bone marrow, which contain most of the stem cells and committed progenitor cells, are markedly decreased in patients with AA. Although in theory AA could result from a defective marrow microenvironment, these defects do not appear to be causative for most patients (Young, 2002).

The mechanism of AA is suggested to fall under two main categories: direct damage and immune-mediated destruction of marrow cells. Direct damage to the hematopoietic stem and progenitor cells could be caused by a known agent, such as cytotoxic drugs, irradiation and viruses, or an unknown agent, which in some way alters the ability of the cell to proliferate or differentiate. Immune-mediated destruction of stem and progenitor cell compartments results from cytotoxic lymphocyte activation, cytokine production, and specific cell elimination. Recent studies favor immune-mediated mechanisms for AA and suggest that chemical and viral antigens may initiate the destructive immune process (Young, 2009). In fact, acquired AA is being viewed now as an immune-mediated disease.

Prognosis

Complications are due to infection, bleeding, and problems of iron overload from repeated transfusions. The prognosis appears to depend on the severity of marrow damage. However, the initial blood count and response to therapy during the first few months of treatment are important prognostic factors (Young, 2009). In a series of 101 patients treated by conventional methods (Williams, 1978), 25% of patients died within 4 months of onset of symptoms, 50% died within 12 months, and 71% within 5 years. Those who died within 4 months had significantly lower reticulocyte, neutrophil, and platelet counts; a lower percentage of myeloid cells in the marrow; and a shorter interval between onset of symptoms and visit to the physician (Lynch, 1975). Other factors that correlated with a poor prognosis included male gender, but not age of the patient or cause of the aplasia (Williams, 1978). Yet, the age of the patient usually influences the decision regarding which therapy the patient should receive. In some survivors, partial recovery is common. With the introduction of modern treatment protocols by immunosuppressive therapy and bone marrow transplantation, long-term survival rates greater than 60% are reported. Survivors have a much higher risk of developing myelodysplastic syndrome, paroxysmal nocturnal hemoglobinuria, acute leukemia, and solid tumors (Young, 2002; Marsh, 2009).

Management

Treatment includes bone marrow transplantation for patients younger than 40 years of age with severe disease if there is an HLA-matched donor. Children and young adults have a much higher survival probability compared with older adults (Young, 2009). Immune suppression using antilymphocyte globulin and cyclosporin A may induce hematologic remission in some patients. Androgens appear to be least helpful in the stimulation of

any residual marrow. Supportive care must be used with caution. Certainly, appropriate antibiotics should be used to combat infection; however, the risk for sensitization should be considered with the administration of blood products. Single-donor platelets or platelets from HLA-matched donors are preferred (Alter, 1998).

Idiopathic Aplastic Anemia

In patients with pancytopenia and a hypocellular marrow, a search should be made for evidence of significant exposure to radiation, drugs, and chemicals of known or possible propensity to injure the marrow, so that further exposure can be eliminated. Nevertheless, in approximately 70% of cases of aplastic anemia, no suspected causal relationship to toxic agents can be found, and it is these that are designated as idiopathic.

The symptoms and signs do not differ, but the onset is commonly more insidious than in toxic or hypersensitive aplastic anemias.

Blood

The red cells are usually normal to increased in size with a varying degree of anisocytosis and poikilocytosis, particularly oval macrocytes. Macrocytosis may be a prominent feature, particularly in response to high levels of EPO. The RDW may be increased, even without transfusion (Elghetany, 1997). Polychromasia, stippling, and normoblasts are most often conspicuously absent. Leukopenia with marked decrease in granulocytes and a relative lymphocytosis are observed. In severe leukopenia, there is often an absolute lymphocytopenia. Neutrophil granules may be larger than normal and may stain dark red (unlike the “toxic” granules found in infections), and the neutrophil alkaline phosphatase may be elevated. However, neutrophil left shift is not seen in the absence of infection (Elghetany, 1997). Thrombocytopenia is part of the picture. Monocytopenia may be present. The serum iron is usually increased, and serum cobalamin and folate levels are usually normal. Although an occasional patient is hypogammaglobulinemic, most patients have normal levels of serum immune globulins.

Bone Marrow. In most cases, the aspirate consists of red cells, lymphocytes, some plasma cells, mast cells, and fatty particles. Marrow sections will show fatty tissue with inconspicuous fibrosis and islands of lymphocytes and plasma cells (Fig. 32-8). Although focal areas of predominantly erythroid normocellularity or hypercellularity (hot spots) may sometimes be present, the overall cellularity is decreased. The hot spots usually show erythroid precursors with delayed nuclear maturation at a high proliferative rate. Storage iron is increased.

Erythrokinetics. The increased serum iron concentration is a valuable early sign of erythroid hypoplasia and reflects decreased plasma iron turnover. In addition, erythrocyte utilization of iron is decreased. Both effective and total erythropoiesis, therefore, are decreased in aplastic anemia.

Aplastic Anemia Associated With Chemical or Physical Agents

Toxic Aplastic Anemias. A number of physical and chemical agents produce marrow damage in all humans and animals exposed to a sufficient dose. Examples include ionizing radiation; mustard compounds; benzene; and antineoplastic agents such as busulfan, urethane, and antimetabolites. Benzene, although strongly linked to AA, is now considered less of a problem than in the past because of reduction in exposure.

Figure 32-8 Section of hypocellular marrow, aplastic anemia. Cellularity is less than 5%.

Ionizing Radiation. Effects depend on the radiosensitivity of the cells and the capacity of the cells to regenerate, as well as the survival rate of cells in the blood. Erythroid cells are most sensitive, granulocytes have intermediate sensitivity, and megakaryocytes are the least sensitive of the three. Stromal cells are relatively insensitive.

After acute exposure to radiation, the reticulocyte count falls, but the red cells decline slowly because of their long survival. Within the first few hours, a neutrophilic leukocytosis occurs as the result of a shift from marginal and probably marrow storage pools. A fall in lymphocytes occurs after the first day and is responsible for the early leukopenia, because lymphocytes are sensitive to irradiation and are directly killed. After 5 days or so, granulocytes begin to fall. The platelets decrease later. Platelets are often the last to return to normal in the recovery phase. Quiescent marrow stem cells are remarkably resistant to a single dose of irradiation. However, chronic exposure to low-dose irradiation, including localized radiation for ankylosing spondylitis, is associated with delayed increased risk for AA because of its impact on the stem cell replicating pool (Young, 2009).

Hypersensitive Aplastic Anemias. A large number of drugs produce marrow damage in some individuals after single or repeated exposures. Effects are not dose related as they are in the previously discussed toxic aplasia. Agents include antimicrobial drugs (salvarsan, chloramphenicol, sulfonamides, chlortetracycline, streptomycin), anticonvulsants (mephentoin, trimethadione), analgesics (phenylbutazone), antithyroid drugs (carbimazole), antihistaminics (tripelennamine), H_2 -histamine receptor antagonists (cimetidine), insecticides (dichlorophenyltrichloroethane [DDT]), and other chemicals—some known (gold compounds, quinacrine, chlorpromazine, hair dyes, bismuth, mercury) and others unknown. The nonsteroidal antiinflammatory medications are becoming more linked to an increased risk for developing AA following marked reduction in the use of chloramphenicol.

Chloramphenicol is an important drug in this category. This antibiotic was considered to be the most common cause of AA at the peak of its use, which began in 1949. Reactions of the marrow to chloramphenicol are of two types, which are possibly unrelated (Alter, 1998).

In about half of patients who receive chloramphenicol, increased serum iron, reticulocytopenia with anemia, neutropenia, and thrombocytopenia are found. The marrow may show decreased erythroid cells and vacuolization of primitive erythroid and granulocyte precursors. These changes are dose related, time dependent, and reversible.

In a very small proportion of persons receiving chloramphenicol, an irreversible AA develops that may be fatal. Pancytopenia occurs 3 weeks to 5 months from the last dosage. No relationship has been established between the reversible erythropoietic lesion and the development of aplastic anemia; it may be that individual susceptibility is responsible for the latter. For this reason, it is essential that restraint be employed in using the drug; monitoring its administration with blood cell counts is not an effective preventive measure.

Aplastic Anemia Associated With Other Disease

Infection. Viral infections are frequently associated with limited marrow suppression, typically neutropenia and less commonly thrombocytopenia. Marrow aplasia has been described as a rare sequela to viral hepatitis, occurring a few months after onset when the hepatitis is resolving. It is estimated at less than 0.07% of hepatitis cases in children and 2% of patients with non-A, non-B hepatitis. Almost all cases are seronegative for hepatitis A, B, C, and G. These patients are usually males younger than age 20; the prognosis is usually grave, and bone marrow transplantation is considered early in the course of the disease (Young, 2002). Parvovirus has been associated with transient erythroid aplastic crisis in patients with chronic hemolytic disorders (Young, 2002). Human immunodeficiency virus and Epstein-Barr virus may also cause hematopoietic depression. The mechanism of virus-induced bone marrow failure may be related to direct cytotoxicity, or, more likely, to immune-mediated mechanisms secondary to molecular mimicry, antigen spread, and danger signals caused by the infection (Young, 2002).

Paroxysmal Nocturnal Hemoglobinuria. This rare hemolytic process (see later discussion) may be followed by aplastic anemia. Usually in paroxysmal nocturnal hemoglobinuria (PNH), a variable degree of marrow hypofunction coexists. Alternatively, in some patients who present with AA, the red cell defect of PNH may be present or may appear during the course of the disease. Recent studies using sensitive techniques, such as

flow cytometry, to detect cells with PNH defect indicate that as many as 40%–50% of patients with AA may have some surface marker evidence of PNH. However, hemolytic disease occurs in approximately one third of these patients. The clonal expansion of PNH cells may have an immunologic background, as evidenced by the strong association of HLA-DR2 and PNH (Young, 2002).

Pregnancy. Pregnancy occurring in a patient with acquired AA may make the pancytopenia more severe. Occasionally, however, AA occurs during pregnancy and remits following delivery. In some such cases, aplasia recurs during a second pregnancy. Infants may be anemic, thrombocytopenic, or leukopenic. Survival rates for AA in pregnancy have been relatively high for the mother (83%) and the baby (75%). Hemorrhage is the most common cause of death in these patients (Young, 2009).

Thymoma. Although thymomas are usually associated with pure red cell aplasias, other bone marrow elements may also become depressed. Pancytopenia, often with hypoplastic bone marrow, occurs in rare cases with thymoma. AA may occur as a late complication after the treatment of thymoma (Ritchie, 2002a).

Immunologic Diseases. AA occurs in approximately 10% of cases of eosinophilic fasciitis. The prognosis of AA in this setting is usually poor. AA may be associated with systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA), although the role of drug therapy in the pathogenesis of AA has been considered (Young, 2009). AA may also complicate multiple sclerosis, congenital immunodeficiency syndromes, and immune thyroid disease.

Inherited Aplastic Anemia

The term **inherited AA** designates individuals with a genetic predisposition to chronic bone marrow failure, which may be associated with other congenital anomalies. Between 30% and 35% of childhood AA cases are inherited. In a study of 134 children with AA, 40 patients were diagnosed with inherited aplastic anemia. Twenty-six had Fanconi's anemia (FA), 10 patients had familial AA without classic signs of FA, and 4 patients presented with amegakaryocytic thrombocytopenia that later developed into complete aplasia (Alter, 1998).

Fanconi's Anemia. FA is an autosomal recessive disorder with a carrier frequency of 1/300 in the United States and Europe (Alter, 2002). Often more than one member of a family is affected. The pancytopenia becomes obvious after infancy and is usually significant by the eighth year of life. The anemia is usually normochromic and may be macrocytic; increased levels of Hb F and i antigen may be observed; the marrow is generally hypocellular. Developmental anomalies are present and may include hyperpigmentation, short stature, hypogonadism, malformations of the extremities (e.g., aplasia of the radius, abnormalities of the thumbs), microcephaly, and malformation of other organs (e.g., heart, kidneys). Chromosomal defects consisting of random breaks and rearrangements characteristically are present in blood lymphocytes, as well as in marrow cells. Chromosomal breakage becomes more evident when the cultured cells are challenged with alkylating and DNA cross-linking agents such as mitomycin C and diepoxybutane. A breakthrough in investigating FA evolved from the observation that hybrid cells from FA and normal cells resulted in correction of the abnormal chromosome fragility, a process known as complementation. More than 13 complementation groups have been distinguished to date (Freedman, 2009). The most common is complementation group A (FANCA), which occurs in approximately 70% of FA patients. Several FA proteins form a nuclear complex that is involved in DNA repair (Alter, 2002). The predicted median survival in FA is 19 years. Patients with FA are at higher risk of developing leukemia and nonhematologic tumors, particularly in the head and neck, liver, lower esophagus, vulva, and anus, with an overall incidence of neoplasia of 15% (Alter, 1998). The median age for all cancers in patients with FA was 16 years (Freedman, 2009).

Other Inherited Aplastic Anemias. A few children present with bleeding manifestations secondary to amegakaryocytic thrombocytopenia. As their disease progresses, they develop a pancytopenia and a hypocellular marrow. Chromosome breakage studies are usually normal. The mode of inheritance is autosomal recessive. The molecular defect is related to a mutation in the gene for thrombopoietin receptor, *c-mpl*, which maps to 1p35 (Alter, 2002).

Pancytopenia and hypoplastic anemia may develop in a subset of patients with other familial disorders. Some patients with dyskeratosis congenita (reticulated hyperpigmentation of skin, dystrophic nails, and mucous membrane leukoplakia) and Shwachman-Diamond syndrome (exocrine pancreatic insufficiency and neutropenia) develop AA during the course of their disease (Alter, 2002).

Pure Red Cell Aplasia

Transitory Arrest of Erythropoiesis (Transient Aplastic Crises)

This may occur during the course of a hemolytic anemia (often preceded by an infection), and the combination of aplasia and hemolysis becomes a life-threatening situation. Red cell production may occasionally cease during or following rather minor infections in normal children or adults, at which time the marrow will show absence of all but a few of the most immature erythroid precursors. Aplastic episodes in chronic hemolytic anemias often appear to be due to parvovirus B19 infection. This virus inhibits erythropoiesis by infecting mature CFU-Es. The morphologic hallmark of the disease is the presence of scattered giant pronormoblasts in the bone marrow aspirate with marked reduction in the more mature erythroid precursors. Nuclear inclusion may be difficult to identify with Wright's stain. The aplastic crises resulting from parvovirus infection are transient, with erythroid marrow recovery in 1 to 2 weeks after onset (Erslev, 2001c).

Transient Erythroblastopenia of Childhood

Transient erythroblastopenia of childhood (TEC) occurs in previously healthy children, usually younger than 8 years of age, with most affected children between 1 and 3 years of age. It is characterized by a moderate to severe normocytic anemia, severe reticulocytopenia, transient neutropenia (20%), and increased platelet counts (60% of patients). Macrocytosis is usually observed during recovery because of the effects of reticulocytes. A history of a viral infection within the previous 3 months is frequently elicited. The bone marrow is generally normocellular and shows virtual absence of erythroid precursors, except for a few early forms. Granulocytic maturation arrest may occur in some neutropenic patients. Patients recover within 1–2 months without therapy. TEC can occur in siblings simultaneously and in seasonal clusters. Transient neurologic manifestations, such as hemiparesis and seizures, may accompany TEC (Freedman, 2009). In most cases, the pathogenesis involves humoral inhibition of erythropoiesis; cell-mediated immune suppression was identified in about 25% of cases, but parvovirus has not been proven to be the cause of TEC (Alter, 2002; Freedman, 2009).

Congenital Red Cell Aplasia (Diamond-Blackfan Anemia; Congenital Hypoplastic Anemia)

This is a rare, congenital red cell aplasia that usually becomes obvious during the first year of life but may occur as late as 6 years of age. Severe anemia is usually macrocytic, reticulocyte level is low, leukocytes are normal or slightly decreased, platelets are normal or increased, and the marrow usually shows a reduction in all developing erythroid cells, except normal granulocytic and megakaryocytic cell lines. In a small number of cases, residual erythroid precursors are detected. These precursors are mostly pronormoblasts. Hb F is elevated (5%–25%) to a degree not expected for the patient's age, and the antigen i is often present. Red cell adenosine deaminase (ADA) is usually increased. These findings contrast with TEC, in which the red cells are normocytic, the Hb F is normal, the antigen i is absent, and red cell enzymes are at a lower level (characteristic of an older cell population) (Alter, 1998).

Approximately half of cases have an autosomal dominant pattern of inheritance with variable penetrance. The defect appears to be in the erythroid-committed progenitor cells. CFU-Es and BFU-Es are decreased in the marrow, and BFU-Es, which normally circulate, are absent or decreased in the blood. In addition, these progenitor cells exhibit an acceleration in programmed cell death (apoptosis) and fail to respond in vitro culture systems to normal T cells and to usual levels of EPO, suggesting a qualitative defect. A mutation in the *RPS19* gene was detected in 25% of patients. This gene encodes a ribosomal protein subunit of nucleolar localization (Alter, 2002).

About 75% of patients respond at least partially to corticosteroids, and the overall long-term survival is about 65%, although many patients require long-term steroid use (Alter, 1998).

Acquired Pure Red Cell Aplasia

Among middle-aged adults, selective failure of red cell production occurs rarely. Reticulocytopenia and a cellular marrow devoid of all but the most primitive erythroid precursors are characteristic. Leukocyte and platelet production is normal. About half of reported cases have been associated with thymoma, usually a noninvasive spindle cell type. However, only 5%–10% of patients with thymoma have the anemia. Remission of the anemia occurs in about one fourth of cases following surgical removal of the thymoma. Chronic acquired red cell aplasia has also been associated with other conditions, such as drugs, collagen vascular disorders, viral infections such as HIV, lymphoproliferative disorders of granular lymphocytes, or other disorders with immunologic aberrations. Most of these anemias appear to be part of a spectrum of autoimmune cytopenias in which the target cells are erythroid stem cells or normoblasts. In some patients, antibodies that react with these cells have been identified. Corticosteroids and immunosuppressive drugs have been used as therapy, but less than half of patients achieve satisfactory remission (Erslev, 2001c).

Sideroblastic Anemia

Sideroblastic anemia is characterized by hypochromic red cells, which are microcytic in the hereditary forms and often macrocytic in the acquired forms of the disease (Wiley, 2009). The red cells may be mixed with normochromic cells, so that the appearance is dimorphic (see Fig. 30-13). The serum iron concentration is increased, the TIBC is decreased, and the percent saturation of the iron-binding protein is greatly elevated. The marrow shows markedly increased storage iron (see Fig. 32-5), erythroid hyperplasia with evidence of defective hemoglobinization, and increased numbers of sideroblasts. In addition, increased numbers of siderotic granules per cell and granules surround the nucleus (with most authors requiring five or more iron granules encircling at least one third of the circumference), forming “ring sideroblasts” (Swerdlow, 2008) (see Fig. 32-17). In the latter case, iron loading of mitochondria is seen by electron microscopy. These findings are associated with defective synthesis of heme, which may be due to any of several possible enzyme defects. Occasionally, megaloblast-like changes are seen in the erythroid cells, but changes typical of cobalamin or folate deficiency are not seen in granulocytes unless folate deficiency coexists.

Hereditary Sideroblastic Anemias

Hereditary sideroblastic anemias include several modes of inheritance (i.e., X-linked, autosomal dominant, and autosomal recessive). The X-linked forms generally exhibit low levels of δ -aminolevulinic acid synthase (ALAS) enzyme. This occurs in males and may not appear until adolescence. It is rare, but a few family studies have been well documented. In contrast to acquired sideroblastic anemia, the ring sideroblast abnormality is usually found in late, nondividing erythroblasts (Bottomley, 1982). The gene for ALAS-2 isoenzyme (erythroid ALAS) has been localized to the X chromosome, and a point mutation of this gene (*Xp11.21*) seems to occur in most X-linked sideroblastic anemias (Wiley, 2009). Mutations of the *ALAS-2* gene may result in enzyme low affinity for pyridoxal phosphate, structural instability, abnormal catalytic site, or increased susceptibility to mitochondrial proteases. The degree of anemia improves with pyridoxine supplementation when the mutation disrupts the catalytic association between the enzyme and pyridoxal phosphate (Alcindor, 2002). Hereditary sideroblastic anemias may be due to a defect in the mitochondria (i.e., mitochondrial cytopathy). Most of these disorders are produced by deletions in the mitochondrial genome, which may account for as much as 30% of the entire mitochondrial genome (Alcindor, 2002). These rare diseases are usually associated with systemic manifestations such as Pearson's syndrome (pancreatic insufficiency, vacuolation of bone marrow cells, ring sideroblasts, and a variable degree of marrow failure).

Acquired Sideroblastic Anemias

Refractory Anemia With Ring Sideroblasts. Refractory anemia with ring sideroblasts (RARS) is a category of myelodysplastic syndromes (Swerdlow, 2008; see also Chapter 33). The dimorphic anemia has both hypochromic-microcytic and macrocytic red blood cells, and the MCV is usually high (see Fig. 30-15). At least 15% of erythroblasts (early and late forms) in bone marrow are ring sideroblasts. Other manifestation of dysplasia in the erythroid cell line may be seen. When dysplastic features involve myeloid and megakaryocytic cell lines as well, the designation **refractory cytopenia with multilineage dysplasia** is given. Growing evidence suggests that RARS may be caused by mutations of mitochondrial DNA (Swerdlow, 2008).

Secondary (Drug- or Toxin-Induced) Sideroblastic Anemia

This form of sideroblastic anemia is secondary to some agent that interferes with heme synthesis; recognition is important because hematologic improvement occurs if the agent is removed.

The **antituberculosis drugs** isoniazid, cycloserine, and pyrazinamide cause sideroblastic abnormalities in some patients on long-term therapy.

Lead poisoning is an important member of this group because environmental exposure to lead is usually unrecognized and needs to be detected. Lead interferes with heme synthesis by blocking the enzymes ALAS, ALA dehydratase, and heme synthase. These blocks are only partial and of different degrees; ALA and coproporphyrin are increased in the urine. **Chloramphenicol** also results in ring sideroblast formation, probably by inhibiting mitochondrial protein synthesis. **Copper deficiency** or **zinc overload** can produce sideroblastic anemia, vacuolated marrow cells, and neutropenia. Large quantities of ingested zinc interfere with copper absorption and produce manifestations of copper deficiency. Copper chelators in large doses, such as penicillamine, can produce sideroblastic anemia.

Ethanol-induced anemia is perhaps the most common of the reversible sideroblastic anemias. Folate deficiency, hypomagnesemia, and hypokalemia are concomitant findings. Alcohol may produce ring sideroblasts through decreased plasma levels of pyridoxal phosphate, along with decreased activity of ALA dehydratase and ferrochelatase (Wiley, 2009). After withdrawal of alcohol intake, abnormal sideroblasts usually disappear within a few days.

Primary pyridoxine deficiency, often associated with malnutrition, is occasionally associated with sideroblastic anemia. However, other manifestations, such as peripheral neuropathy and dermatitis, dominate the clinical presentation. Sideroblastic anemia as the sole manifestation of pyridoxine deficiency has not been reported in humans, although it occurs in animals (Alcindor, 2002).

Refractory Anemia

An ill-defined group of chronic anemias usually occurs in individuals over the age of 50. Normocytic or macrocytic anemia, reticulocytopenia, often pancytopenia, and a hypercellular marrow showing erythroid hyperplasia with a variable degree of dyserythropoiesis are present. Often the patient has been treated with cobalamin, folic acid, and iron without response. The process is usually unremitting, and in a small proportion of cases additional dysplastic changes in marrow cells and increased blast cells evolve into an acute leukemia. Refractory anemias, therefore, are considered one of the myelodysplastic syndromes (see Chapter 33).

Congenital Dyserythropoietic Anemias

Congenital dyserythropoietic anemias (CDAs) represent a family of inherited refractory anemias characterized by ineffective erythropoiesis and marrow erythroid multinuclearity.

At least three types have thus far been separated on the basis of marrow and serologic findings (Heimpel, 2004). CDA-I has megaloblastic changes with some binuclearity in approximately 5% of marrow erythroblasts, internuclear chromatin bridges, and a macrocytic anemia. Some cases have an abnormality in the *CDAN1* gene located on the long arm of chromosome 15 (Heimpel, 2004). CDA-II is more common than the others and shows binuclearity and multinuclearity of 10%–40% of erythroid precursors with pluripolar mitoses and karyorrhexis. The anemia is normocytic. CDA-II is distinguished from the others in that it has a positive acidified serum test (with some but not all normal sera) and a negative sucrose hemolysis test. It is known as hereditary erythroblastic multinuclearity with positive acidified serum test (HEM-PAS). The red cells have an antigen not present on normal or PNH cells, and about one third of normal sera contain the corresponding immunoglobulin (Ig)M antibody. In addition, red cells in CDA-II react strongly with anti-i and anti-I. Electron microscopy demonstrates an excess of endoplasmic reticulum parallel to the cell membrane, which gives the appearance of a double membrane in late erythroblasts and some erythrocytes. CDA-II is thought to be related to abnormal membrane glycosylation. The gene for CDA-II (*CDAN2*) has not been identified but maps to 20q11.2 (Freedman, 2009). CDA-III has giant erythroid precursors, with more pronounced multinuclearity (gigantoblasts) in 10%–40% of erythroid precursors, along with a macrocytic anemia. A putative gene for CDA-III (*CDAN3*) has been recently localized on chromosome 15 near the *CDAN1* gene (Heimpel, 2004). In contrast to CDA-I and CDA-II, which are autosomal recessive, CDA-III has autosomal dominant inheritance. Other variants have been described in a small number of families.

BLOOD LOSS ANEMIA

Acute Posthemorrhagic Anemia

Blood may be lost from the circulation externally or internally into a tissue space or body cavity. If blood is lost over a short time in amounts sufficient to cause anemia, **acute posthemorrhagic anemia** occurs. Normal healthy individuals are able to compensate for rapid blood loss of up to 20% of circulating blood volume with few symptoms (Hillman, 1996). After a single episode of excessive bleeding, the major manifestations are those due to depletion of blood volume (hypovolemia). After a day or so, blood volume is returned to previous levels by movement of fluid into the circulation, and anemia becomes evident.

The earliest hematologic change is a transient fall in the platelet count, which may rise to elevated levels within an hour. The next development is a moderate neutrophilic leukocytosis with a shift to the left; a maximum leukocyte count of $10\text{--}35 \times 10^9/\text{L}$ may occur in 2–5 hours. Hb and Hct do not fall immediately but only slowly as tissue fluids move into the circulation to compensate for lost blood volume. The fall in Hb and Hct may not reveal the full extent of red cell loss until 2 or 3 days after the hemorrhage.

The anemia that develops at first is normochromic and normocytic, with a normal MCV and mean cell hemoglobin concentration (MCHC) and only minimal anisocytosis and poikilocytosis. Increased EPO secretion stimulates erythroid proliferation in the marrow, and reticulocytes begin to reach the circulation in 3–5 days, reaching a maximum by 10 days or so. During this period, transient macrocytosis (increased MCV), increased polychromasia, and normoblasts may appear in the blood. It takes about 2–4 days after blood loss for the leukocyte count to return to normal, and about 2 weeks for the morphologic changes to disappear. Return of red cell values is slower.

Chronic Posthemorrhagic Anemia

If blood is lost in small amounts over an extended period, both clinical and hematologic features that characterize acute posthemorrhagic anemia are lacking. Regeneration of red cells occurs at a slower rate.

The reticulocyte count may be normal or slightly increased. Significant anemia does not usually develop until after storage iron is depleted; the anemia, therefore, is one of iron deficiency. The anemia is at first normochromic and normocytic, and gradually the newly formed red cells become microcytic, then hypochromic. The leukocyte count is normal or slightly decreased, owing to neutropenia. Platelets are commonly increased, and only later, in severe iron deficiency, are they likely to be decreased.

The cause of blood loss must be identified because a hidden malignancy, particularly of the GI tract, may be the cause of the anemia.

HEMOLYSIS—GENERAL

Anemias that are due primarily to increased red cell destruction are **hemolytic anemias**. A shortened red cell survival, therefore, proves that hemolysis is present; this measurement is usually unnecessary in practice.

Hemolytic anemias may be due to a defect of the red cell itself, an **intrinsic hemolytic anemia**: These are usually hereditary and are commonly grouped as **membrane**, **metabolic**, and **hemoglobin** defects. Alternatively, hemolysis may be due to a factor outside the red cell and acting upon it, an **extrinsic hemolytic anemia**: These are almost always acquired. The terms **intravascular hemolysis** and **extravascular hemolysis** refer to the **site** of destruction of the red cell: within the circulating blood and outside it, respectively.

Erythrocyte Survival Studies

Shortened red cell survival defines hemolysis. If the hemolytic process is moderate or severe, evidence of increased red cell turnover will suffice to show that hemolysis is present. If the hemolytic process is mild or obscure, red cell survival studies may be necessary.

Radioactive chromium (^{51}Cr) is convenient and is widely used for red cell survival studies. Labeled chromate is added to a blood sample in vitro and binds to β -chains of Hb. The chromated red cells are injected intravenously, and their disappearance is measured by counting blood, which is sampled every 1–2 days for 10–14 days. Residual activity is an index of the intravascular life span of the labeled red cells. Because ^{51}Cr emits γ -rays, external scanning can detect sites of red cell destruction.

The erythrocyte life span is usually expressed as the period during which one half of the radioactivity remains in the blood (the $T_{1/2}^{51\text{Cr}}$; Fig. 32-9). Chromium normally elutes from the red cells at a rate of 1% per day. Thus, the half-life of the ^{51}Cr -labeled erythrocytes in normal individuals is 25–32 days instead of 60 days. Blood loss, changes in Hct, and recent blood transfusions significantly complicate the interpretation of survival data; therefore, a steady state is necessary for usable results.

In autoimmune hemolytic anemias, the slope of red cell survival produces a straight line when plotted on semilogarithmic paper (see Fig. 32-9). In other hemolytic anemias, two cell populations may exist. In these situations, the survival curve may be composed of an initial steep slope followed by a flatter component (Fig. 32-10). This type of curve has been seen in hereditary enzyme-deficiency hemolytic anemias, sickle cell anemia, and PNH (Dacie, 1991).

CO production measures heme catabolism immediately before and during the time of the assay. This is the only available method to study short-term fluctuations in red cell destruction (Franco, 2009).

Flow cytometry has been applied in some centers to measure red cell survival. Most techniques use ex vivo labeling of red cells by biotin. The rate of cell disappearance is then measured using fluorochrome-conjugated avidin or streptavidin. With multicolor flow cytometry additional parameters, such as reticulocytes and Hgb F content, may be monitored simultaneously (Franco, 2009).

Hemoglobin Destruction

Laboratory findings differ, depending on the site of blood destruction, the amount of destroyed blood, and the rate of destruction. If the destruction is **intravascular** and the quantity of destroyed blood is large, free Hb and

Figure 32-9 Results of ^{51}Cr erythrocyte survival curve in patients with autoimmune hemolytic anemia. The results are plotted on semilogarithmic graph paper. The mean cell life span (MCL) was 9–10 days and was recorded at a period when 37% of cells were still circulating. The time of 50% survival ($T_{1/2}^{51\text{Cr}}$) was 6–7 days. (From Dacie JV, Lewis SM. *Practical haematology*. 7th ed. Edinburgh: Churchill Livingstone; 1991, p. 386.)

Figure 32-10 Results of radioactive chromium (^{51}Cr) erythrocyte survival curve in a patient with hemolytic anemia containing two cell populations. The percent survival is on the ordinate. By extrapolating the flatter curve to time 0, it can be estimated that 40% of the cells have a mean life span of 100 days. Sixty percent of cells have a mean life span of 5 days. (From Bentley SA. Red cell survival studies reinterpreted. *Clin Haematol* 1977;6:601–23.)

methemalbumin will be present in the plasma (hemoglobinemia and methemalbuminemia). The urine may contain free Hb and also hemosiderin.

Free Hb readily dissociates into $\alpha\beta$ -dimers ($\alpha_2\beta_2 \rightarrow 2\alpha\beta$). These are bound to haptoglobin, an α_2 -globulin, and the Hb-haptoglobin complex is rapidly removed from the circulation and catabolized by the liver parenchymal cells. This process prevents Hb from appearing in the urine. However, when the plasma Hb level exceeds 50–200 mg/dL (8–31 $\mu\text{mol/L}$), which is the capacity of haptoglobin to bind Hb, the free $\alpha\beta$ -dimers of Hb readily pass through the glomerulus of the kidney. Part of the Hb is then absorbed by the proximal tubular cells, where the Hb iron is converted to hemosiderin. When these tubular cells are shed into the urine later, **hemosiderinuria** results. If the amount of Hb in the tubular lumen exceeds the capacity of the tubular cells to absorb it, it reaches the urine (**hemoglobinuria**). In the process, it may be oxidized to methemoglobin (hemiglobin). Plasma Hb not bound to haptoglobin or removed by the kidney is oxidized to hemiglobin. The oxidized heme groups (hemin) are bound to **hemopexin**, a β -globulin, and the complex is rapidly cleared by the hepatic parenchymal cells. If hemopexin is depleted, hemin groups bind to albumin, forming methemalbumin. Once hemopexin again becomes available, it removes the hemin groups from albumin for hepatic clearance (Hillman, 1996).

Lactate dehydrogenase (LD) is released from red cells and is increased in serum in hemolysis, especially in intravascular hemolysis; it is cleared more slowly than Hb. If the upper reference value is 207 IU/L, the LD in hemolytic anemia may be increased by as much as 800 IU/L. In megaloblastic anemia, associated with marked ineffective erythropoiesis, the LD is greatly increased to several thousand units. Serum LD is also increased in other forms of cellular injury. In hemolytic anemias, reversal of the LD isoenzyme pattern is seen, with LD_1 exceeding LD_2 .

The normal plasma Hb level is 0.5–5 mg/dL (0.08–0.78 $\mu\text{mol/L}$). A rise to 10 mg/dL imparts to the plasma a yellow to orange color. With further increase, the color becomes pink. Levels up to 25–30 mg/dL are common in hemolytic anemia. Higher levels usually indicate intravascular hemolysis and are seen in hemolytic transfusion reactions and in paroxysmal cold and nocturnal hemoglobinurias.

If hemolysis is primarily **extravascular**, no hemoglobinemia, hemoglobinuria, or hemosiderinuria is present. Hemolysis is detected by measuring an increase in one of the products of heme catabolism (see Chapter 31):

1. An increase in CO expired, or in the blood carboxyhemoglobin level.
2. An increase in indirect-reacting serum bilirubin; because this is bound to albumin, it will not appear in the urine.

3. An increase in urine urobilinogen or, more consistently, in fecal urobilinogen.

The normal urobilinogen in a 24-hour specimen is 0.5–4 mg (0.8–6.75 μmol) in urine and 40–280 mg (0.068–0.470 mmol) in the stool. Following excessive hemolysis, it may increase to 5–200 mg in the urine and to 300–400 mg in the stool. Examination of feces is more dependable than examination of urine because feces may show an increase when the urine shows none. It may show an increase even when the serum bilirubin concentration is not raised because the normal liver can remove large amounts of (indirectly reacting) bilirubin and of reabsorbed urobilinogen from the blood.

Hemolytic anemia is characterized also by increased red cell production. Because of the availability of maximal amounts of iron for Hb formation, red cell production reaches the maximal degree possible (about eight times normal) in severe chronic hemolytic anemia, if complicating factors such as folate deficiency do not intervene. If red cell destruction exceeds the capacity of the marrow to replace red cells at the same rate, hemolytic anemia occurs. With less severe hemolysis, the marrow may be able to produce enough red cells that anemia does not occur; this is called compensated hemolysis.

Sudden worsening of the degree of anemia may occur in chronic hemolytic anemia and may be due to either of two basic mechanisms. Occasionally, episodes of bone marrow failure (transient arrest of erythropoiesis; see earlier discussion) characterized by erythroid hypoplasia and reticulocytopenia may upset the equilibrium between production and destruction of red cells. In most instances, these **aplastic crises** are probably due to parvoviral infection (Young, 1984). On the other hand, an increased rate of red cell destruction may occur, associated with infection or other illness that increases splenic size. This is not associated with erythroid aplasia and is called a **hemolytic crisis**.

Blood Film

The anemia is normocytic or macrocytic. Macrocytosis is due to the presence of immature red cells, which are larger than normocytes. Polychromasia is usually prominent; it may be excessively basophilic and normoblasts may be present, both of which indicate a “shift” of marrow reticulocytes into the blood. Other red cell abnormalities may give a clue to the nature of the hemolytic process. Spherocytes suggest hereditary spherocytosis (HS) or autoimmune hemolysis (see Fig. 30-12); schistocytes imply microangiopathic hemolytic anemia (see Fig. 30-19); sickle cells, target cells, or crystals suggest a hemoglobinopathy. When hemolytic anemia is acute, increased numbers and younger forms of leukocytes and platelets are often released from the marrow, together with erythrocytes. The result is leukocytosis with a “shift to the left” and thrombocytosis with both normal and giant platelets.

Bone Marrow

Normoblastic hyperplasia is present and may be striking in degree. Storage iron is usually increased and sideroblasts are normal or increased in number, reflecting the abundance of available iron for Hb synthesis.

HEMOLYSIS—MEMBRANE DISORDERS

Hereditary Spherocytosis

HS affects 1 in 5000 of the population, occurring predominantly in those of Northern European ancestry. Prevalence in other ethnic groups is unknown, although HS has been reported worldwide, particularly in Japanese and African populations. The reported prevalence may be an underestimation in that milder forms may be clinically asymptomatic (Gallagher, 2009). HS is characterized by spherocytic red cells that are intrinsically defective, splenomegaly, and familial occurrence (most often autosomal dominant). In about 15%–30% of cases, however, neither parent is affected. The hemolytic process is variable in severity and is corrected by splenectomy, although the spherocytosis remains.

The laboratory findings are those of a chronic extravascular hemolytic process: evidence of increased pigment catabolism, erythroid hyperplasia, and reticulocytosis. The direct antiglobulin test is negative. The red cells characteristically have increased osmotic fragility. On the blood film, spherocytes have a smaller diameter and are more intensely stained than normal cells. They have no central pallor, which if present may be eccentric (see Fig. 30-12). The MCV is low-normal and the MCHC is often increased, reflecting a decrease in cell surface. In compensated cases, reticulocytosis may be a sensitive indicator.

Figure 32-11 Erythrocyte osmotic fragility. **a**, Thalassemia, showing a small fraction of cells with increased fragility (lower left) and a larger fraction of cells with decreased fragility (upper right). **b**, Normal curves fall in the shaded area. **c**, Hereditary spherocytosis, showing increased osmotic fragility.

Figure 32-12 The effect of incubation on erythrocyte osmotic fragility. The change in the osmotic fragility curve from “before incubation” to “after incubation” is illustrated for normal blood (1→1A) and for blood from a patient with hereditary spherocytosis (HS) (2→2A). Blood in HS characteristically shows a greater increase in fragility with incubation than does normal blood or even blood of acquired spherocytosis (e.g., autoimmune hemolytic anemia).

Osmotic Fragility Test

Red cells are suspended in a series of tubes containing hypotonic solutions of NaCl, varying from 0.9%–0.0%, incubated at room temperature for 30 minutes, and centrifuged. The percent hemolysis in the supernatant solutions is measured and plotted for each NaCl concentration. Cells that are more spherical, with a decreased surface/volume ratio, have a limited capacity to expand in hypotonic solutions and lyse at a higher concentration of NaCl than do normal biconcave red cells. They are said to have increased osmotic fragility. Conversely, cells that are hypochromic and flatter have a greater capacity to expand in hypotonic solutions, lyse at a lower concentration than normal cells, and are said to have decreased osmotic fragility (Fig. 32-11).

The osmotic fragility of freshly drawn blood is usually increased in HS but may be normal in mildly affected patients. In blood that is incubated at 37° C for 24 hours before the test is performed, the osmotic fragility is almost always increased (Fig. 32-12).

The increased osmotic fragility of freshly drawn blood is characteristic but not specific; it may occur in acquired spherocytic anemias, such as immune-mediated hemolytic anemia. A greater difference in median

fragility (after incubation from before incubation) occurs in HS cells than in control normal cells; this is an important diagnostic feature in HS. A tail of very fragile cells conditioned by the spleen is usually seen. The tail usually disappears after splenectomy. Cells with increased surface/volume ratio are osmotic resistant. These cells are seen in iron deficiency, thalassemia, liver disease, and reticulocytosis.

Autohemolysis Test

Sterile, defibrinated blood is incubated at 37° C for 48 hours (Dacie, 1991). During this time, red cells undergo a complex series of changes, lose membrane, and become more spherocytic. In normal blood, without added glucose, the amount of autohemolysis at 48 hours is 0.2%–2.0%. In normal blood, incubated with added glucose, the amount of autohemolysis is less—0%–0.9%.

In HS, autohemolysis is virtually always increased; with glucose, the lysis is diminished to a variable extent. This test is being used less frequently and is probably no more sensitive than the incubated osmotic fragility test (Gallagher, 2009).

Red blood cells in HS are characterized by an unstable lipid bilayer, which facilitates the release of lipids from the membrane, resulting in loss of surface area and formation of poorly deformable spherocytes that are selectively retained and damaged in the spleen. The erythrocytes are abnormally permeable to sodium, and there is no defect in energy metabolism, which is, in fact, increased. The increased metabolic activity has been explained as an attempt to compensate for a membrane defect that leaks cations, with degenerative changes and loss of cell membrane accelerated by the metabolic and physical stresses of passage through the spleen.

The genetic defects in HS are heterogeneous but affect the skeletal proteins of the red cell membrane. HS can be divided into the following pathogenetic categories: (1) isolated partial deficiency of spectrin, (2) combined partial deficiency of spectrin and ankyrin, (3) partial deficiency of band 3 protein, (4) deficiency of protein 4.2, and (5) other, less common defects. Most of these abnormalities are related to the synthesis of abnormal protein, mostly through point mutations or frameshift (Gallagher, 2009).

Hereditary Elliptocytosis

This autosomal dominant condition probably includes more than one genetic variant. In the U.S. population, the prevalence is approximately 3–5 per 10,000. It is more common in individuals of African and Mediterranean ancestry. All cases of hereditary elliptocytosis (HE) are associated with weakening of the membrane skeleton and defective association of proteins that hold the skeleton together (Gallagher, 2009). On the basis of red cell morphology, HE can be divided into three groups: (1) common HE (including hereditary pyropoikilocytosis [HPP]), with elliptocytes that may be rod shaped, (2) spherocytic HE, and (3) Southeast Asian ovalocytosis. The most commonly defined abnormality appears to be a defect in spectrin, resulting in impaired association of spectrin dimers into spectrin tetramers and spectrin oligomers. Other abnormalities include a defect in protein 4.1 and deficiency of glycophorin C. HPP is associated with two abnormalities: a mutation in spectrin that disrupts spectrin heterodimer self-association, and a partial deficiency of spectrin that results in a decreased spectrin/band 3 ratio.

Common HE

Most persons with the common form of HE (≈90% of cases) are nonanemic; a minority of this group (perhaps 10%–20%) have mild hemolysis. Nonhypochromic elliptocytes are abundant in the blood film, numbering approximately 15% (see Fig. 30-16), whereas in normal individuals less than 5% of the red cells are elliptical (Gallagher, 2009). The deformity is increased in sealed, moist preparations.

In a subgroup of common HE, especially in black families, affected neonates transiently have moderate poikilocytosis, red cell fragmentation, and budding, with hemolytic anemia; during the first year of life, hemolysis declines and typical HE emerges. Worsening of hemolysis in the neonatal period has been attributed to the presence of fetal hemoglobin, which binds poorly to 2,3-diphosphoglycerate (2,3-DPG). Higher levels of the latter exert a destabilizing effect on spectrin-protein 4.1-actin interaction (Gallagher, 2009).

Hereditary Pyropoikilocytosis

HPP is a severe congenital hemolytic anemia, which is characterized by microcytosis, striking micropoikilocytosis and fragmentation, and autosomal recessive inheritance. HPP represents a subtype of common HE. It occurs primarily in blacks. In contrast to normal red cells, which show

budding and fragmentation when heated to 49° C, HPP red cells fragment at 45°–46° C.

Spherocytic HE

This subgroup accounts for 10% of cases. A mild to moderate hemolytic anemia and splenomegaly are present, with both elliptocytes and spherocytes, along with abnormal osmotic fragility and autohemolysis tests. Poikilocytes and fragments are usually absent. The molecular basis of this subtype is unknown.

Southeast Asian Ovalocytosis

This subgroup occurs with high frequencies (20%–30%) in certain populations of the Far East, particularly Malaysia. Hemolysis is usually absent or mild. The erythrocytes are less elongated, and some have the appearance of stomatocytic ovalocytes. Many cells contain one or two transverse ridges or a longitudinal slit. This condition is associated with increased resistance to malaria. The underlying defect is related to a deletion of 27 bases from the band 3 gene (Gallagher, 2009).

Hereditary Stomatocytosis (Hereditary Hydrocytosis)

This is a rare, autosomally transmitted disorder. Heterozygotic individuals have no anemia, and 1%–25% of stomatocytes are seen on the blood film. In presumed homozygotic individuals, about one third of the red cells are stomatocytes, and there is a mild to moderate hemolytic anemia. The membrane abnormality results in increased permeability of the membrane to Na⁺ and K⁺ (and therefore water), resulting in hydrated, macrocytic red cells. The MCV may be as high as 150 fL. Osmotic fragility and autohemolysis are increased. Although the exact membrane defect is not known, several reports indicate the absence of a membrane protein located in the band 7 region called stomatin. Although stomatin is decreased or absent from red cells of affected individuals, the loss may be maturational in the marrow or circulation rather than causing the disease by itself (Gallagher, 2009). Individuals with Rh deficiency syndrome, either absent (Rh_{null}) or markedly reduced (Rh_{mod}), usually have hemolytic anemia with stomatocytosis.

Paroxysmal Nocturnal Hemoglobinuria

PNH is an acquired clonal stem cell disorder characterized by the production of abnormal erythrocytes, granulocytes, and platelets (Brodsky, 2009). The red cell defect renders them more susceptible to complement-mediated intravascular lysis. Three types of erythrocytes have been described according to their *in vitro* sensitivity: type I with normal sensitivity, type II with medium sensitivity (three to five times normal), and type III with extreme sensitivity (15–25 times normal). Several complement defense proteins are decreased or absent in PNH. These proteins include: decay accelerating factor (DAF, CD55), membrane inhibitor of reactive lysis (MIRL, CD59), and C8-binding protein (a homologous restriction factor). DAF is a glycoprotein that antagonizes the convertase complexes of complement. MIRL is a protein that controls the membrane attack complex, C5b-9. Other proteins that are deficient in PNH include CD58 (leukocyte function antigen 3), CD14 (endotoxin-binding protein receptor), CD24, and CD16a (Fcγ receptor). Membrane-associated enzymes such as acetyl cholinesterase and leukocyte alkaline phosphatase may be deficient as well. Recent work indicates that deficient proteins and enzymes are attached to the cell membrane by a common glycolipid anchor called GPI. Deficiency of GPI results in secondary deficiency of the attached proteins. Therefore, PNH can be redefined as partial or complete lack of GPI-linked proteins on a population of cells of the hematopoietic system.

PNH is a rare disease with an estimated annual incidence of 4 per million (Brodsky, 2009). The disease is characterized by chronic intravascular hemolysis with or without obvious hemoglobinuria. However, hematuria is almost constantly present. Typical nocturnal or sleep-related hemoglobinuria is present in a minority of patients. Bouts of hemolysis could be initiated by infection, surgery, whole blood transfusion, injection of contrast dyes, or even severe exercise. The proposed relationship between mild drop in pH during sleep and nocturnal hemoglobinuria has not been confirmed (Brodsky, 2009).

The blood usually shows a normocytic anemia with a reticulocytosis that is often less than expected for the degree of anemia. Hypochromic microcytic anemia is not uncommon, however, and is due to loss of iron in the urine. Neutropenia occurs in three fifths and thrombocytopenia in two thirds of patients at some time during the course of disease, so that pancytopenia is common. The direct antiglobulin test is usually negative.

The marrow may be hypercellular with erythroid hyperplasia, but it may be hypocellular. In some patients, marrow failure may occur during the course of PNH; in others, AA is the initial diagnosis, with signs of PNH manifesting simultaneously or later. As mentioned earlier, approximately 40% of patients with AA have evidence of PNH clone at diagnosis (Young, 2002).

Thrombotic complications are common, occurring in approximately 40% of patients, and represent a major cause of mortality. Thrombosis commonly occurs in hepatic, cerebral, and abdominal veins. The absence of CD59 on platelets results in externalization of phosphatidylserine, a site for prothrombinase complexes, and thus increases the propensity for thrombosis. The disease may undergo partial remissions and exacerbations. In more than half of patients, both the proportion of abnormal cells and the clinical severity decrease with time. Abnormal cytogenetics can be found in up to 20% of PNH patients. In approximately 3%–5% of PNH patients, the disease progresses to acute leukemia.

Sucrose Hemolysis Test

This test should be performed whenever the diagnosis of PNH is considered, also in hypoplastic anemias and in any hemolytic anemia of obscure origin (Hartmann, 1970). The principle of the test is that sucrose provides a medium of low ionic strength that promotes the binding of complement to the red cells. In PNH, a proportion of red cells are abnormally sensitive to complement-mediated lysis. Suspicious results can be seen in some other hematologic diseases, especially megaloblastic anemia and autoimmune hemolytic anemia. False-negative results occur if the serum lacks complement activity. A simpler screening test, called the sugar water test, applies the same principle of mixing blood with sugar and observing for hemolysis.

Acidified Serum Test (Ham Test)

Definitive diagnosis of PNH used to depend on a positive acidified serum test (Ham, 1939; Dacie, 1991). In acidified serum, complement is activated by the alternate pathway, binds to red cells, and lyses abnormal PNH cells that are unusually susceptible to complement. The patient's washed red cells are mixed with ABO compatible normal serum (fresh or properly stored) and acid; after an hour's incubation at 37° C, the PNH cells are lysed, as indicated in Table 32-3. The patient's own serum may or may not result in lysis, depending on residual complement, and the other tubes provide controls.

In PNH, usually 10%–50% of the cells are lysed. If lysis also occurs with heat-inactivated serum, the test is not positive, as spherocytic or antibody-sensitized cells may be responsible. A positive acidified serum test occurs in congenital dyserythropoietic anemia, type II (CDA-II), or HEM-PAS (see earlier discussion). In this situation, however, lysis does not occur with the patient's own serum, and occurs with only about 30% of normal sera. Also, the sugar water screening test is negative in CDA-II.

Flow cytometry using immunofluorescent staining of red cells with a monoclonal antibody against deficient proteins such as CD55, CD58, and CD59 is gradually becoming the standard method of diagnosing PNH. Granulocytes provide excellent diagnostic targets for flow cytometry. A fluorescein-labeled proaerolysin variant (FLAER) is increasingly being used for the diagnosis of PNH. It binds selectively to the GPI anchor.

The gene responsible for the PNH phenotype has been identified on the X chromosome and designated phosphatidyl inositol glycan A or

PIG-A. More than 120 somatic mutations of the *PIG-A* gene have been described.

HEMOLYSIS—HEMOGLOBIN DISORDERS

There are two main groups of inherited disorders of Hb: (1) structural variants, with defects in the structure, and (2) thalassemias, with defects in the synthesis, of a globin chain. An overlap has been noted between these groups; 44 structural variants also have a thalassemic phenotype with decreased synthesis, and hence, level of the abnormal globin chain. Hereditary persistence of fetal hemoglobin (HPFH) is related to the thalassemias, although the phenotype is not clearly thalassemic. Most thalassemias involve α - or β -globin chains. δ -, γ -, and $\epsilon\gamma\delta\beta$ -thalassemias are known, but are clinically less significant.

Normal Hemoglobins

The heme group is identical in all Hbs. The protein part of the molecule is a tetramer, made up of two dimers; each dimer contains an α -like and a β -like globin. Postnatally, only one α -like globin is present, and this forms three distinct Hb tetramers with the three different β -like globins present. Three additional embryonic Hbs are present only in the first 3 months of gestation (Fig. 32-13).

Hb A ($\alpha_2\beta_2$)

Hemoglobin A is the major normal adult Hb, accounting for about 97% of the total. It consists of two identical α -chains, each with 141 amino acids; and two identical β -chains, with 146 amino acids each. Each chain is linked with one heme group. The molecule is ellipsoidal, with the four heme groups at the surface of the molecule, where they function by combining reversibly with O_2 .

Hb F ($\alpha_2\gamma_2$)

Hemoglobin F is the major Hb of the fetus and the newborn infant. The increased O_2 affinity of fetal blood versus adult blood is due to its lower affinity for 2,3-DPG. The two α -chains are identical to those of Hb A, and the two γ -chains, with 146-amino-acid residues, differ from β -chains. In normal individuals, Hb F has two types of γ -chains, which differ by one amino acid, having either alanine (Ay) or glycine (Gy) at position 136. The ratio of Gy to Ay chains changes from 3:1 at birth to 2:3 by age 12 months (Weatherall, 2001). There is a common polymorphism of the Ay gene, in which threonine replaces isoleucine at position 75. This Hb F variant is called Hb F Sardinia and is without functional abnormalities. Approximately 10% of total Hb F is a negatively charged variant, designated Hb F1, owing to posttranslational acetylation of the amino-terminal ends of the γ -chains.

During fetal life, Hb F predominates, as γ -chain production is high. β -Chain production begins before the 20th week of prenatal life, so that Hb A is 10% of the total between 20 and 35 weeks and between 15% and 40% at the time of birth. Around birth, production of Hb F is turned down; by 6 months, Hb F is usually less than 8%, and by 12 months, it is less than 5%, in about 90% of infants. Between 12 and 24 months of age,

Hb F is usually less than 3% but varies from 3%–10% in about 20% of infants. After the age of 2 years, Hb F is normally less than 2%, and only traces of Hb F (<0.8%) are present in most adults. However, among healthy adults, 5%–10% have slightly raised Hb F level (up to 5%). During fetal life, all red cells produce and contain Hb F, whereas in adults only 3%–5% do so; these are termed F cells (Weatherall, 2001). Adult production of Hb F is regulated by multiple genetic loci, including the Xmn1-HBG2 site in the β -globin locus, the HMIP locus at 6q23, and the bcl11A locus on chromosome 2 (Thein, 2009). Polymorphic variants at these loci cause a modest increase in Hb F in otherwise healthy adults and probably underlie most cases of Swiss-type or heterocellular hereditary persistence of fetal Hb.

F cells may increase in number when reactivation of Hb F synthesis occurs in normal pregnancy and in some disorders of erythropoiesis, particularly chronic bone marrow failure syndromes. In certain acquired hematopoietic disorders, the Hb F level may also be elevated. These include megaloblastic anemia, myelofibrosis, aplastic anemia, paroxysmal nocturnal hemoglobinuria, refractory anemias, leukemias, and solid tumors (up to 5%–10%). In the second trimester of pregnancy, there could be a slight increase, and in hydatidiform moles, a more significant increase—up to 6%. The highest levels of Hb F are found in juvenile myelomonocytic leukemia, Fanconi's anemia, and erythroleukemia (30%–50%). Elevated Hb F is found in a few hemoglobinopathies, in β - and $\delta\beta$ -thalassemias, and in HPFH. The switch from γ -globin to β -globin and the decrease in Hb F are delayed in sickle cell patients, who might not reach their stable Hb F level until adolescence (Huisman, 1980). A similar delay in decline in Hb F is also seen in thalassemia trait (Schroter, 1981).

Hb A₂ ($\alpha_2\delta_2$)

Hemoglobin A₂ accounts for 1.5%–3.5% of normal adult Hb. Its two α -chains are the same as in Hb A; its two δ -chains differ from β -chains in only 10 of their 146 amino acids. Less efficient transcription of the δ -globin gene compared with the β -gene is the result of differences in the promoter area (Delvoye, 1993; Tang, 1997) and the second intron (Kosche, 1985). δ -Chain synthesis begins late in fetal life. The level of Hb A₂ gradually increases during the first year of life, at which time the adult level is reached.

Increased Hb A₂ is seen almost exclusively in β -thalassemias. It rarely reaches 6% and never more than 12%. Hb A₂ is occasionally increased in hyperthyroidism and megaloblastic anemia; it has been reported to be increased in sickle cell trait (Whitten, 1981) and sickle cell disease, but the increase is only modest and the level stays below 4.5%. It may be decreased in iron deficiency anemia and α -thalassemia. If the patient with β -thalassemia trait has concomitant severe iron deficiency, the increase in Hb A₂ might be dampened down and appear equivocal; in these instances, retesting should be performed after the iron deficiency is corrected. Because of its developmental delay, Hb A₂ might not be useful in diagnosing β -thalassemia trait in young infants.

Embryonic Hemoglobins. The zeta (ζ) chain is the embryonic analog of the α -chain and may combine with epsilon (ϵ) chains to form Hb Gower-1 ($\zeta_2\epsilon_2$) or with γ -chains to form Hb Portland ($\zeta_2\gamma_2$). The ϵ -chain is the embryonic counterpart of the γ -, β -, and δ -chains and combines with α -chains to form Hb Gower-2 ($\alpha_2\epsilon_2$). Hb Gower-1, Hb Portland, and Hb Gower-2 are the embryonic Hbs and are found in normal human embryos and fetuses with a gestational age of less than 3 months.

The Globin Gene Clusters. Globin synthesis is controlled by two separate gene clusters. The ζ -gene and two α -genes (α -like globins), together with nonfunctioning pseudogenes, are on chromosome 16. Genes for the ϵ -, δ -, β -chains, and the two γ -chains (β -like globins), and two pseudogenes are located on chromosome 11 (Fig. 32-14). Note that there are two functioning α -genes on a haploid chromosome (balanced by only one β -gene). The different globin genes evolved from a common ancestor by gene duplication. There is considerable polymorphism of regulatory sequences within these clusters, accounting for normal variations and wide phenotypic differences in hemoglobinopathy and thalassemia syndromes.

Glycosylated Hemoglobins. The term glycation or glycosylation implies the linkage of a sugar to a protein. Approximately 5% of Hb A undergoes posttranslational glycosylation, resulting in linkage of sugars to serine, asparagine, and hydroxylysine residues. The glycosylated Hbs have been designated Hb A1a (<1%), Hb A1b (<2%), and Hb A1c (3%). Glycosylation of Hb increases linearly over the 120-day life span of the red cell. Hb A1c contains a molecule of glucose attached nonenzymatically by a

Figure 32-13 Relative proportions of polypeptide chains of hemoglobin present during fetal and neonatal life. (From Bentley SA. Red cell survival studies reinterpreted. *Clin Haematol* 1977;16:601–23.)

Figure 32-14 The α - and β -globin gene clusters on chromosomes 16 and 11, respectively. In the extended α - and β -globin genes, the introns are shaded dark, the 5' and 3' noncoding regions are hatched, and the exons are unshaded. (From Weatherall DJ, Clegg JB. *The thalassemia syndromes*. 4th ed. Oxford: Blackwell Scientific Publications; 2001.)

ketoamine linkage to the amino-terminal amino group of each β -chain. Hb A_{1c} is elevated twofold to threefold in patients with diabetes mellitus. The measurement of Hb A_{1c} has been used as an index of metabolic control of diabetes during the preceding 2–3 months (Bunn, 1994). Hb A_{1c} may be falsely decreased in conditions associated with rapid red cell turnover, such as hemolytic anemia.

Laboratory Investigation of Hemoglobinopathies and Thalassemias

Current recommendations include automated complete blood count (CBC) with accurate MCV, RBC, MCH, and MCHC values; Hb H test; ferritin; and high-performance liquid chromatography (HPLC) for Hb A₂ and Hb F measurement and detection of Hb variants, followed by alkaline and acid electrophoresis when a variant is found and additional studies (Sickledex) as necessary (Clarke, 2000).

Cation-Exchange HPLC. Numerous automated systems have been developed in the last 20 years, and HPLC is now the method of choice for initial screening of Hb variants and for separation and determination of percentages of Hb A, Hb A₂, and Hb F (Wilson, 1983). A cation-exchange HPLC system, Bio-Rad Variant by Bio-Rad Laboratories (Philadelphia, Pa.), emerged as the leading commercial kit. Resolution of this system is claimed to be similar to that of isoelectric focusing, and data banks of retention times are available (Figs. 32-15 and 32-16) (Riou, 1997; Globin Gene Server). Variants detected by HPLC are confirmed by an alternative technique, such as electrophoresis.

Hemoglobin Electrophoresis and Isoelectric Focusing. Hb molecules in an alkaline solution have a net negative charge and move toward the anode in an electrophoretic system. A practical method for routine Hb electrophoresis is cellulose acetate at alkaline pH (Briere, 1965). It is rapid and reproducible and separates the major Hb variants S, D, G, C, and E from Hb A (Figs. 32-17 and 32-18). Quantification of the major bands is easily accomplished. Those with an electrophoretic mobility greater than that of Hb A at pH 8.6 are known as the “fast Hbs”; these include, in order of increasing mobility, Hbs K, J, Bart’s, N, I, and H. Hbs A₂, C, E, and O Arab at the slow end are unresolved from each other, as are S, D, G, and Lepore. Citrate agar electrophoresis at an acidic pH (Milner, 1975) provides ready separation of Hbs that migrate together on cellulose acetate: S from D and G, and C from E and O (Fig. 32-19). Isoelectric focusing separates Hbs based on their isoelectric point along a pH gradient with a high resolution (Fig. 32-20). Capillary electrophoresis is a rapidly developing automated system with a performance similar to that of HPLC (Mario, 1997).

Alkali Denaturation Test for Hb F. Fetal hemoglobin resists alkali denaturation; adult Hb does not (Singer, 1951). A hemolysate is alkalinized and then neutralized, and the denatured adult Hb is precipitated by ammonium sulfate. A filtrate will then contain only alkali-resistant Hb, which is measured and expressed as a percentage of the total. The modification of Betke (1959) is reliable for Hb F less than 15% but underestimates Hb F at higher levels. The reference interval is 0.2%–1.0% for adults. This method has been largely replaced by HPLC or capillary electrophoresis estimation of Hb F.

Acid Elution Slide Test for F Cells. Modification of the original method of Kleihauer and Betke by Shepard (1962) is useful for analyzing the distribution of Hb F among red cells. Hemoglobins other than Hb F are eluted from the red cells on an air-dried blood film by a citric acid-phosphate buffer (pH 3.3). Only Hb F remains in the fixed red cells, and the distribution can be determined after staining. In normal adults, almost all red cells appear as ghosts; 1%–5% of red cells contain residual Hb (F cells). In most types of HPFH, Hb F is distributed evenly among red cells (pancellular distribution). In all other conditions, such as thalassemia or a hemoglobinopathy, and in Swiss-type HPFH, the distribution of Hb F is heterogeneous or uneven among red cells (heterocellular distribution). Flow cytometry is also used to detect F cells.

Hb A₂ Quantitation. Hb A₂ quantitation is challenging for two reasons: (1) Its level is low with a narrow range and only a modest increase in disease, requiring a high degree of precision, and (2) Hb variants with similar charge or retention time interfere with its estimation. Several laboratory methods of varying accuracy and precision are being used. Cation-exchange HPLC (Head, 2004), microcolumn chromatography (Steinberg, 1991), and cellulose acetate electrophoresis with elution are considered to be sufficiently precise. Densitometry of electrophoretic bands on cellulose acetate membrane is unreliable (Schmidt, 1975). Increasingly, cation-exchange HPLC is the method of choice; it provides accurate measurement of Hb F, along with separation of Hb variants. In the presence of Hb S, however, its level is falsely elevated because Hb S adducts have similar retention times (Suh, 1996). In the presence of Hb S, microcolumn chromatography gives an accurate measurement of Hb A₂ (Head, 2004).

Hb A₂ estimation is used principally in diagnosis of β -thalassemia trait, in which it is elevated up to 7%. Hb A₂ values from normal individuals do not overlap with those of individuals with β -thalassemia trait when performed by microchromatography or HPLC; however, there is some overlap with the cellulose acetate electrophoresis method (Huisman, 1986). Reference intervals for Hb A₂ are 1.5%–3.5% of total Hb.

Sickling Test—Metabisulfite Slide Test. Adding sodium metabisulfite, a reducing substance, to blood enhances deoxygenation of Hb and sickling of Hb S (Fig. 32-21). The test does not distinguish sickle cell anemia from sickle trait or other Hb S syndromes because all red cells sickle; however, sickling occurs more rapidly with greater amounts of Hb S in the cells. Positive tests may occur with other rare sickling hemoglobins (Hbs S Travis, C Harlem), Hb I, and high concentrations of Hb Bart’s. Hb I, an α -chain variant, has normal functional properties. False-negative tests may occur if Hb S concentration is less than 10% (as in very young infants), or if deoxygenation is inadequate (e.g., deterioration of reagent).

Sickle Solubility Test. In this nonquantitative test, red cells are lysed with saponin, and Hb is reduced by dithionite (sodium hydrosulfite). Reduced Hb S is insoluble in concentrated inorganic buffer (2.3 M phosphate buffer), and the polymers of deoxy-Hb S obstruct light rays to produce opacity. The test is useful in screening large numbers of people for the presence of Hb S or other sickling Hbs. False-positive reactions (turbid solution) occur also in the presence of many Heinz bodies, as in unstable Hb disorders after splenectomy, and in blood protein disorders due to precipitation of plasma proteins. False-negative reactions (clear

Cation-exchange high-performance liquid chromatography (HPLC) separation by the Bio-Rad Variant system, using the β Thalassemia Short Program. (From Riou J, Godart C, Hurtrel D, et al. Cation-exchange HPLC evaluated for presumptive identification of hemoglobin variants. *Clin Chem* 1997;43:34–9.)

solution) occur if the amount of Hb S is too small, as in severe anemia, or if the reagent has deteriorated.

DNA Analysis (Old, 2001). Gap PCR is used for detection of common deletions in α - or, less often, in the other thalassemia syndromes. In gap PCR, primers bind to the region flanking the deletion. PCR product is obtained only from the affected alleles, as the primers are located far apart in the normal gene. Additional primers that amplify the normal allele are used to assess for heterozygosity/homozygosity. Southern blotting is still used and can assess all alleles and confirm PCR results. PCR-based techniques have been developed to screen for common point mutations in β -thalassemia and Hb variants. In reverse dot blotting or reverse hybridization, mutant oligonucleotides are fixed to a nylon membrane (ViennaLab) or microplate (Bio-Rad), and hybridized with the patient's amplified DNA. In ARMS (amplification refractory mutation system), amplification takes place only when the primer matches perfectly the genomic DNA sequence. ARMS primers are available for the detection of all common β -thalassemia mutations (Old, 1996). PCR-based sequencing is utilized for confirmation of single nucleotide mutations and small deletions.

Structural Hemoglobin Variants

As of 2005, 893 Hb variants had been identified (Huisman, 1998; Globin Gene Server). Ninety percent of these are due to single amino acid

substitutions; in the remaining 10%, the polypeptide chain is abnormally long or short as a result of termination errors, frameshift mutations, insertions, deletions, or fused or hybrid chains.

A majority affect the α - or β -globin chains. Involvement of the γ -chain and the δ -chain occurs, but because of the small amount of Hb involved, their variants are less often detected and are rarely of clinical significance. A large number of Hb variants that do not cause disease have been discovered in surveys.

New Hbs were assigned letters of the alphabet, then geographic names—usually to distinguish different Hbs with similar electrophoretic mobilities. Several variants of Hb D, G, and J, for example, are known. Sometimes, a variant is known by multiple names, based on independent discoveries. Hb M indicates a variant that forms methemoglobin. Amino acid substitutions in some of the known Hb variants are listed and classified by functional characteristics in Table 32-4.

Hbs S, C, E, and D are, by far, the most important variants (Table 32-5). Together with the thalassemias, they reached polymorphic frequencies in regions where falciparum malaria was/is endemic, owing to partial protection against this parasite by mechanisms still not fully understood.

Abnormal Hemoglobin Syndromes

In homozygous β -chain structural variants, both allelic genes for the abnormal β -chains are present, so that no normal β -chains (hence, no Hb

Figure 32-16 Ion-exchange high-performance liquid chromatography (HPLC) separation of hemoglobins (Hbs): patient with sickle cell trait: Hbs F, A, and A₂ and an abnormal Hb in the S window are detected. Hemoglobin A₂ cannot be quantified because of the presence of Hb S. (Bio-Rad Variant Classic Hb Testing System, Bio-Rad Laboratories, Philadelphia.)

Figure 32-17 Electrophoretic separation of hemoglobins at alkaline pH. **1**, Normal adult; **2** and **3**, 17-year-old with sickle cell anemia; **5** and **6**, patient with sickle cell anemia, recently transfused; **4** and **7**, Hbs A/F/S/C standard (Hydragel 7 Hemoglobin/Hydrazys System, Sebia Electrophoresis, Norcross, Ga).

A) are produced. Because α -, γ -, and δ -genes are normal, the Hb F and Hb A₂ are structurally normal, although they may be increased in amount.

In heterozygous β -chain structural variants, the abnormal Hb is present, in addition to Hb A, F, and A₂. Its level depends on its rate of synthesis and stability, but also on its readiness to form dimers with α -chains. This latter process is driven by electrostatic forces between the positively charged α -globin and the negative β -globin. Because most β -globin variants acquire positive charge, their assembly with the positive α -chain is slower. As a result, the percentage of abnormal Hb is usually less than that of Hb A. In the presence of coexistent α -thalassemia, when β -chains compete for an insufficient number of α -globins, these effects are exaggerated and the level of structural variant decreases further. Similar forces influence the levels of Hb A₂. δ -Globin, the subunit of Hb A₂, has a significant positive charge, not favorable for dimer formation. Positively charged β -chain variants also have little affinity for α -chains, leaving excess α -chains for assembly with δ -globin and resulting in a slight increase in Hb A₂. This has been described in Hbs S and C trait, but the increase is so minimal that its existence was always questioned.

TABLE 32-4

Functional Classification of Hemoglobin Variants

- I. Homozygous: hemoglobin (Hb) polymorphisms: the variants that are most common

Hb S	$\alpha_2\beta_2^{6Val}$	Severe hemolytic anemia: sickling
Hb C	$\alpha_2\beta_2^{6Lys}$	Mild hemolytic anemia
Hb D	Punjab $\alpha_2\beta_2^{121Gln}$	No anemia
Hb E	$\alpha_2\beta_2^{26Lys}$	Mild microcytic anemia
- II. Heterozygous: hemoglobin variants causing functional aberrations or hemolytic anemia in the heterozygous state
 - A. Hemoglobins associated with methemoglobinemia and cyanosis

Hb M Boston	$\alpha_2\beta_2^{58Tyr}$
Hb M Iwate	$\alpha_2\beta_2^{87Tyr}$
Hb M Saskatoon	$\alpha_2\beta_2^{63Tyr}$
Hb M Milwaukee	$\alpha_2\beta_2^{67Glu}$
Hb M Hyde Park	$\alpha_2\beta_2^{92Tyr}$
Hb FM Osaka	$\alpha_2\beta_2^{63Tyr}$
Hb FM Fort Ripley	$\alpha_2\beta_2^{92Tyr}$
 - B. Hemoglobins associated with altered oxygen affinity
 1. Increased affinity and polycythemia

Hb Chesapeake	$\alpha_2\beta_2^{92Leu}$
Hb J Capetown	$\alpha_2\beta_2^{92Gln}$
Hb Malmo	$\alpha_2\beta_2^{97Gln}$
Hb Yakima	$\alpha_2\beta_2^{99His}$
Hb Kempsey	$\alpha_2\beta_2^{99Asn}$
Hb Y psi (Ypsilanti)	$\alpha_2\beta_2^{99Tyr}$
Hb Hiroshima	$\alpha_2\beta_2^{146Asp}$
Hb Rainier	$\alpha_2\beta_2^{145Cys}$
Hb Bethesda	$\alpha_2\beta_2^{145His}$
 2. Decreased affinity—may have mild anemia or cyanosis

Hb Kansas	$\alpha_2\beta_2^{102Thr}$
Hb Titusville	$\alpha_2\beta_2^{94Asn}$
Hb Providence	$\alpha_2\beta_2^{82Asn}$
Hb Agenogi	$\alpha_2\beta_2^{90Lys}$
Hb Beth Israel	$\alpha_2\beta_2^{102Ser}$
Hb Yoshizuka	$\alpha_2\beta_2^{108Asp}$
 - C. Unstable hemoglobins
 1. Hb may precipitate as Heinz bodies after splenectomy: “congenital Heinz body anemia”
 - a. Severe hemolysis: no improvement after splenectomy

Hb Bibba	$\alpha_2\beta_2^{136Pro}$
Hb Hammersmith	$\alpha_2\beta_2^{42Ser}$
Hb Bristol	$\alpha_2\beta_2^{67Asp}$
Hb Olmsted	$\alpha_2\beta_2^{141Arg}$
 - b. Severe hemolysis: improvement after splenectomy

Hb Torino	$\alpha_2\beta_2^{43Val}$
Hb Ann Arbor	$\alpha_2\beta_2^{80Arg}$
Hb Genova	$\alpha_2\beta_2^{28Pro}$
Hb Shepherd's Bush	$\alpha_2\beta_2^{74Asp}$
Hb Koln	$\alpha_2\beta_2^{98Met}$
Hb Wein	$\alpha_2\beta_2^{130Asp}$
 - c. Mild hemolysis: intermittent exacerbations

Hb L-Ferrara	$\alpha_2\beta_2^{47Gly}$
Hb Hasharon	$\alpha_2\beta_2^{47His}$
Hb Leiden	$\alpha_2\beta_2^{6 or 7}$ (Glu deleted)
Hb Freiburg	$\alpha_2\beta_2^{23}$ (Val deleted)
Hb Seattle	$\alpha_2\beta_2^{70Asp}$
Hb Louisville	$\alpha_2\beta_2^{42Leu}$
Hb Zürich	$\alpha_2\beta_2^{63Arg}$
Hb Gun Hill	$\alpha_2\beta_2^{91-97}$ (5 a. a. deleted)
 - d. No disease

Hb Etobicoke	$\alpha_2\beta_2^{84Arg}$
Hb Dakar	$\alpha_2\beta_2^{112Gln}$
Hb Sogn	$\alpha_2\beta_2^{14Arg}$
Hb Tacoma	$\alpha_2\beta_2^{30Ser}$
 2. Tetramers of normal chains: appear in thalassemias

Hb Bart's	γ_4
HbH	β_4
Hb α_4	

Data from Winslow RM, Anderson WF. The hemoglobinopathies. In: Stanbury JB, Wyngaarden JB, Fredrickson DS, et al, editors. The metabolic basis of inherited disease. 5th ed. New York: McGraw-Hill; 1983, p. 2281–317.

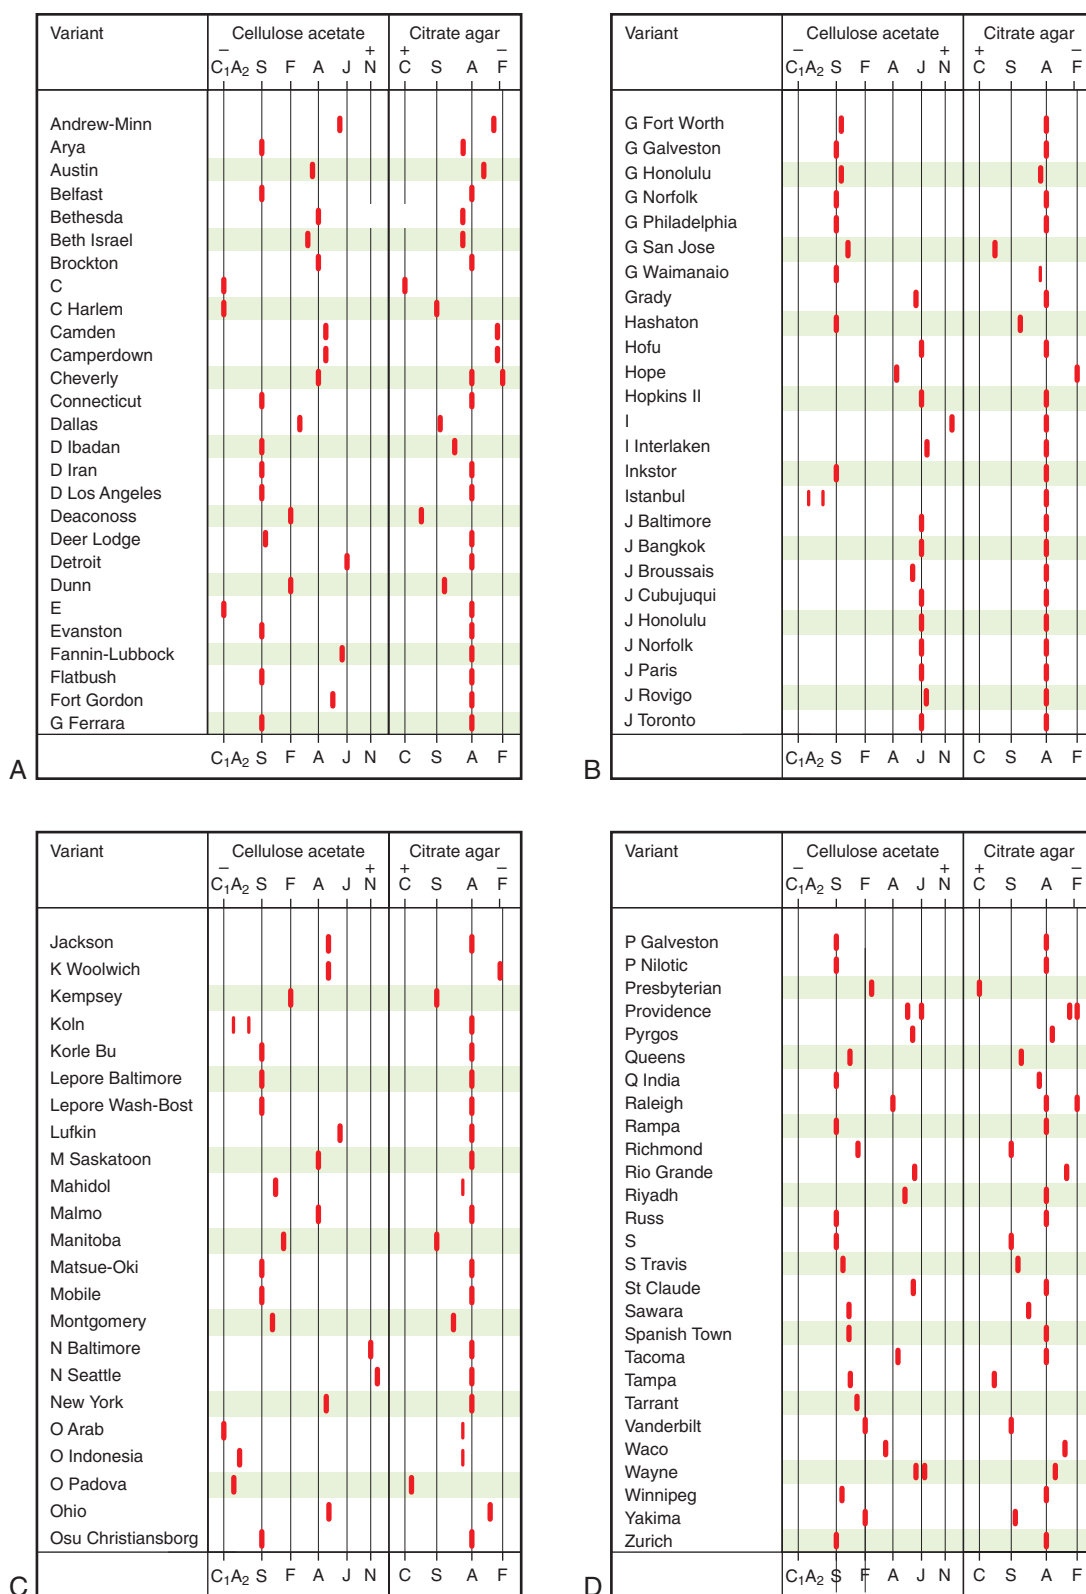

Figure 32-18 Electrophoretic mobility of 102 hemoglobin variants at alkaline (cellulose acetate) and acidic (citrate agar) pH. (Courtesy of Winston Moo-Penn and Danny Jue.)

Figure 32-19 Hemoglobin (Hb) electrophoresis. Comparison of various Hb samples on cellulose acetate (at pH 8.4) and citrate agar (at pH 6), showing relative mobilities. The control is a composite sample. The relative amounts of Hb are not necessarily proportional to the size of the band. (From Schmidt RM, Brosious EF. *Basic laboratory methods of hemoglobinopathy detection*. 6th ed. Atlanta: U.S. Department of Health, Education and Welfare, Centers of Disease Control; 1976. HEW Publ. No. CDC 77-8266.)

Double heterozygotes for a β -chain structural variant and β^+ -thalassemia are well known. Here, the quantity of abnormal Hb exceeds that of Hb A, in contrast to the heterozygous β -structural hemoglobinopathies, in which the reverse is true.

In heterozygous α -chain structural variants, the abnormality in the α -chain will affect all three Hb types. Therefore, six different hemoglobins are found—the three normal hemoglobins and the three abnormal forms. Examples are Hb D Baltimore, Hb Ann Arbor, and Hb M Boston.

Double heterozygotes for two β -chain abnormalities produce two different abnormal β -chains; therefore, there are two abnormal Hbs and no Hb A. An example of this is Hb SC disease. Double heterozygotes for β - and δ -chain abnormalities and for α - and β -chain abnormalities are rare but have provided important information. The latter will have four major Hb types on electrophoresis.

Sickling Disorders

Sickle Cell Trait (Hb AS)

The heterozygous state for Hb S is the most common hemoglobinopathy in the United States. It is present in about 8% of African Americans (Schneider, 1976) and in as many as 45% of the population in certain areas of West Africa. The gene is found throughout sub-Saharan Africa and, at a much lower frequency, in the Mediterranean, Middle East, and India. Hb S trait is a completely benign condition without clinical symptoms or hematologic abnormalities. Added risk associated with sickle cell trait is minimal, at the most, and is seen only in very rare circumstances. Extreme low O_2 tensions can trigger sickling, and a few people have sustained splenic infarction when flying at very high altitude in unpressurized airplanes. Slightly increased incidences of hematuria, impaired ability to concentrate urine, and bacteriuria in women have been reported. Sickle cell trait confers protection to children from the lethal effects of falciparum malaria, which accounts for the major distribution of Hb S in central Africa.

The stained blood film appears normal, except perhaps for a few target cells. Blood cell counts are normal. The sickle cell slide preparation is positive, and almost all red cells eventually sickle. The solubility test is positive.

TABLE 32-5

Prevalence of Common Hemoglobin Disorders Among African Americans

	%
Traits	
Silent α -thalassemia ($\alpha\alpha/-\alpha$)	24
Hb AS	8.6
α -Thalassemia trait ($-\alpha/-\alpha$)	5.7
Hb AC	2.4
β -Thalassemia trait	1.5
HPFH	0.1
Hbs D and G	0.026
All others	0.3
Sickling Disorders	
Hb SS	0.16
Hb S/C	0.13
Hb S/thal	0.06
Hb S/HPFH	0.004
Other Disorders	
Hb CC	0.02
Hb C/ β -thalassemia	0.02
Homozygous β -thalassemia	0.005

Data from Motulsky (1973), Schneider (1976), and Pierce (1977).

Hb, Hemoglobin; HPFH, hereditary persistence of fetal hemoglobin.

Hemoglobin separation shows 60% Hb A, 40% Hb S, normal Hb F, and normal to slightly increased Hb A₂, up to 4.5%.

The proportion of Hb S is decreased in the presence of α -thalassemia; Hb S is less than 35% when one α -gene is deleted, and less than 29% when two genes are lost (Head, 2004). In the latter, cells are hypochromic and microcytic. Because 27% of African Americans carry the α^+ -thalassemia gene, it is not surprising that this diagnostic dilemma is quite common. Hb S level may also be diminished in iron and folate deficiency. Clinically, the combination of sickle cell trait and α -thalassemia trait is benign, with possible mild microcytic anemia due to the thalassemia trait.

Sickle Cell Disease (Hb SS)

Homozygous Hb S disease is a serious chronic hemolytic anemia, first manifested in early childhood and often fatal before the age of 30 years. With modern medical care, many patients live longer, but the median age of death in the United States is still only in the 40s. Hb S is found mostly in the black population; 1 of every 600 black persons in the United States has sickle cell anemia (Steinberg, 1999).

In Hb S ($\beta^6 \text{ glu} \rightarrow \text{val}$), the glutamic acid in the sixth position on the β -chain is replaced by valine. Hb S is freely soluble when fully oxygenated; when O_2 is removed, Hb S polymerizes, with formation of tactoids (fluid crystals) that are rigid and deform the cell into the shape that gave the cell its name. A strong interaction between the side chain of β^6 valine and the hydrophobic pocket of β^{85} phenylalanine and 88 leucine of another Hb S molecule is probably the basis of polymer formation. In homozygous Hb S disease, sickling occurs at physiologic O_2 tensions, and the rigidity of the red cells is responsible for the hemolysis, as well as for most of the complications. These irreversibly sickled cells result from membrane reorganization during repeated episodes of sickling and unsickling, in addition to cell dehydration that markedly reduces cellular deformability. Sick cells contain high calcium levels, which stimulate potassium and water loss (Gardos effect) and exaggerate cell dehydration (Weatherall, 1999). The hemolytic component is mostly extracellular and is caused by clustering of band 3 of the cell membrane, with the consequence of increased IgG binding and recognition by macrophages. Integrins ($\alpha_4\beta_1$) on the sickle cell surface attach to fibronectin and adhesion molecules expressed on endothelial cells; this is enhanced by inflammatory cytokines, von Willebrand factor, and platelet activation, and together these interactions cause vaso-occlusion.

Complications. In early childhood, bilateral painful swelling of the dorsa of the hands or feet occurs as a result of sickling and capillary stasis; this is known as the **hand-foot syndrome**, or sickle cell dactylitis. It lasts about 2 weeks, is accompanied by changes of periostitis as observed by X-ray, and does not occur after the age of 4.

The spleen is central to three complications: A **sequestration crisis** refers to sudden pooling of blood and rapid enlargement of the spleen, resulting in hypovolemic shock. This may occur in early childhood when

Figure 32-20 Comparison of 57 hemoglobin variants by isoelectric focusing. Asterisk denotes α -chain variants. (From Basset P, Braconnier F, Rosa J. An update on electrophoretic and chromatographic methods in the diagnosis of hemoglobinopathies. *J Chromatogr Biomed Appl* 1982;227:267–304.)

splenomegaly is present and is often preceded by infection. **Functional asplenia** (Pearson, 1969) consists of inadequate antibody responses under some conditions and an impaired ability of the reticuloendothelial system to clear bacteria and particulate material from the blood, probably owing to reticuloendothelial blockade. This may explain in part the increased risk of infection in children with the disease. Salmonellal and pneumococcal infections are unusually prevalent in children with sickle cell anemia. Vaso-occlusive episodes result in progressive infarction, fibrosis, and contraction of the spleen—so-called **autosplenectomy**. Although splenomegaly is present in childhood, a small fibrotic remnant is the rule in the adult.

From early childhood, patients cannot produce concentrated urine, apparently as a result of anoxic damage in the medullae of the kidneys. Hematuria as a result of papillary necrosis is common. Renal insufficiency occurs in 5%–20% of adults (Steinberg, 1999).

Vaso-occlusive crises are debilitating episodes of abdominal and bone or joint pain, accompanied by fever, which are probably due to plugging of small blood vessels by masses of sickled cells. Bone necrosis occurs in 10%–50% of patients and may be a focus for salmonellal osteomyelitis. Acute chest syndrome represents episodes of acute chest pain often associated with a new infiltrate in the chest film. Approximately 40% of patients

Figure 32-21 Sickle cell preparation, in sodium metabisulfate; sickle cell anemia. Even in sickle cell trait, all cells eventually sickle.

Figure 32-22 Blood film, sickle cell anemia. The erythrocytes are far from one another, suggesting a severe anemia. Numerous pointed sickle cells and target cells are present. Close to the nucleated red blood cell, elliptical cells are seen. These cells have a dense center, instead of the usual central pallor, suggesting that they are incipient sickle cells (500 \times).

experience at least one episode of acute chest syndrome. Although an infectious origin has been suspected in earlier studies, fat embolism is now considered to play a major role in this syndrome. The various complications that result from recurring vaso-occlusive crises involve many body organs (Steinberg, 1999).

Aplastic crises occasionally can afflict any patient with chronic hemolytic anemia. Temporary failure of red cell production that would not be noticed in a person with a normal red cell life span will cause a serious fall in Hb concentration in chronic hemolytic anemia. This may be the result of infection, particularly parvovirus B19, exposure to toxic drugs, or folic acid deficiency; sometimes no cause can be found. Hemolytic crises due to a further increase in hemolysis are rare.

Diagnosis. The anemia is normochromic and normocytic; polychromasia is increased, and nucleated red blood cells are present. Sick cells are almost always found in the stained smear (Fig. 32-22). Target cells are numerous, and Howell-Jolly and Pappenheimer bodies are regularly seen in older children and adults as a result of asplenia. The microhematocrit as an estimate of degree of anemia is unreliable because of excessive plasma trapping. Neutrophilia and thrombocytosis are usual. The marrow shows normoblastic hyperplasia.

No Hb A is found if the patient has not been transfused recently; more than 80% of the hemoglobin is Hb S, 1%–20% Hb F, and 2%–4.5% Hb A₂ (Wrightstone, 1974). The fetal hemoglobin is distributed unevenly among the red cells. Hb S and several D and G hemoglobins have the same electrophoretic mobility at alkaline pH, but of these, only Hb S gives a positive sickling test.

Hemoglobin SC Disease

The frequency of Hb SC disease is almost the same as that of Hb SS disease in African Americans. It causes a mild hemolytic anemia. Crises are less frequent and less painful than in sickle cell anemia. Onset is usually in childhood, but the disease might be undetected until later in life. The life expectancy is only modestly shortened. The body habitus is normal or stocky in contrast to the asthenic features in sickle cell anemia. Splenomegaly might be the only finding on physical examination. Fatigue, dyspnea on effort, frequent upper respiratory infections, attacks of mild jaundice, and arthralgias are seen. Constant hip and low back pain may be present with aseptic necrosis of the head of the femur. Hematuria from

renal medullary infarction and splenic infarcts has been described. In pregnancy, crises are more frequent and there is an increase in thrombotic tendency, which can cause massive thromboembolism and sudden death following childbirth. A higher incidence of retinopathy is seen in Hb SC disease than in SS disease.

Anemia varies from moderate to very mild and is normochromic-normocytic. Anisocytosis and poikilocytosis are mild to severe, and target cells are numerous—up to 85% of the erythrocytes. Plump and angulated sickled cells are often present on the film. The sickling test is positive. Hb S is 50% and Hb C is slightly less. Hb F is usually under 2%. The proportions of Hbs are the same in patients with coexistent α -thalassemia (Steinberg, 1983).

Hb S/ β^0 -Thalassemia

This is the third most common sickling disorder after Hb SS and Hb SC in African Americans, and the most common one in people from the Mediterranean. It usually runs a milder course in black people (usually S/ β^+ -thalassemia) but causes a severe sickling disorder with manifestations similar to those of sickle cell anemia in people of Italian, Turkish, or Greek descent.

In Hb S/ β^0 -thalassemia, Hb A is absent; Hb S is 75%–90%, Hb F is 5%–20%, and Hb A₂ is 4%–6%. This disorder clinically and hematologically resembles sickle cell disease, except for the spleen, which remains enlarged after childhood and into adult life. The main difference is that in Hb S/ β^0 -thalassemia, the MCV and MCH are decreased, and the Hb A₂ might be significantly increased. Family study is often necessary for a clear distinction (Wrightstone, 1974; Lehmann, 1977). On the blood smear, pronounced microcytosis, variable hypochromia, and many target cells are present. As a consequence of reduced cellular hemoglobin, Hb S polymers are formed more slowly, and fewer sickled cells are present on the smear.

In Hb S/ β^+ -thalassemia, Hb A is 15%–30%; Hb S is over 50%, Hb F is 1%–20%, and Hb A₂ is 4%–6%. Although these individuals clinically may resemble those with sickle trait (Hb AS), in S/ β^+ -thalassemia, the amount of Hb S always exceeds Hb A, and in Hb AS, Hb A always exceeds Hb S.

Hb SS/ α -Thalassemia

Thirty to forty percent of patients with sickle cell anemia are heterozygous, and 2%–3% are homozygous for α^+ -thalassemia (Higgs, 1982). MCV (83 fL in heterozygotes and 72 fL in homozygotes) and MCH are decreased. Hb level is higher and reticulocyte count is significantly lower, as compared with sickle cell anemia. On the smear, sickled cells are uncommon similarly to Hb S/ β^0 -thalassemia. Although anemia is less severe, the vaso-occlusive disease is not, and some studies even show increased morbidity and mortality. As described earlier, δ -chains successfully compete with positively charged S-chains for a limited number of α -chains, and Hb A₂ levels increase. Hematologically, this cannot be separated from Hb S/ β^0 -thalassemia (Table 32-6). Whenever microcytosis and increased Hb A₂ are present in sickle cell anemia, family or molecular studies are to be done to differentiate these entities.

Hemoglobin SD Disease

(Hb S/D-Los Angeles). SD disease simulates but is less severe than sickle cell anemia, and thus may also resemble SC disease. It is occasionally seen in the African American population. On routine (alkaline) electrophoresis, the pattern is indistinguishable from sickle cell anemia because Hb S and Hb D cannot be separated. Agar gel electrophoresis at pH 6.2 will separate Hb S and Hb D.

Hb S/O Arab. Compound heterozygotes of Hb S and Hb O Arab (β^{121} glu \rightarrow lys) have a severe sickling disorder. Hb O Arab is found in black and Arabic people. Hb E and a few other, less frequent β -variants also cause sickling disorders with Hb S. Coexistence of an α -chain variant and a sickle cell trait does not cause a sickling disorder.

Other Common β -Chain Variants

Hb C Trait (β^6 glu \rightarrow lys). Hemoglobin C is prevalent in West Africans and in about 2%–3% of black people. The heterozygous state (Hb AC) is asymptomatic, without anemia, with normal or minimally reduced MCV and normal red cell life span. The MCHC might be slightly elevated. Target cells are present on blood film. Hb C makes up about 40% of the total hemoglobin. When significant microcytosis is present, it is usually caused by coexistent α -thalassemia, and Hb C is reduced to 38%, 32%, and 24% in patients with three, two, and one α -gene, respectively (Huisman, 1977).

TABLE 32-6

Differential Diagnosis of Sickle Cell/Thalassemia Syndromes

Genotype	Clinical expression	Hb	MCV	Hb F	Hb A ₂	Hb A
SS	Severe	7–8	85–95	2–20	2–4	
S/β ⁰ thal	Moderate to severe	8–10	65–75	5–20	4–6	
SS/α thal	Moderate to severe	8–10	70–85	2–20	3–5	
S/HPFH	Asymptomatic to mild	13–14	75–85	20–30	1–3	
S/β ⁺ thal	Mild to moderate	11–12	70–80	1–13	3–6	10–30

Data from Bunn (1986) and Steinberg (2001).

Hb, Hemoglobin; Hb A, accounts for 97% of normal adult hemoglobin; Hb A₂, accounts for the remaining 3% of normal adult hemoglobin; Hb F, fetal hemoglobin; HPFH, hereditary persistence of fetal hemoglobin; MCV, mean corpuscular volume.

Figure 32-23 Hemoglobin (Hb) C disease, after splenectomy. Before splenectomy, the only morphologic abnormality was the presence of target cells. After splenectomy, Howell-Jolly bodies and Hb crystals, such as those in the center, were present. Note that almost all of the Hb in this particular cell is in the dark bar, and the membrane is still visible. Some such crystals are distinctly hexagonal (1000×).

Hb C Disease. Homozygous Hb C disease is a mild hemolytic anemia with splenomegaly that is often asymptomatic but occasionally results in jaundice and abdominal discomfort. Life expectancy is normal. In the United States, 0.02% of black people have Hb C disease (Schneider, 1976). Reticulocytosis is low for the degree of anemia. The anemia is largely a consequence of low O₂ affinity of Hb C (Bunn, 1986) and should not be treated. The MCV is normal or decreased, and the MCHC is normal or increased. Numerous target cells with an admixture of microspherocytes and minimal polychromasia are seen in the blood. Osmotic fragility is biphasic, with both increased and decreased fragility, but is not used in the diagnosis today. Hexagonal or rod-shaped crystals may be seen in erythrocytes in the stained smear, especially after splenectomy or after slow drying of the smear (Fig. 32-23). As opposed to Hb S, crystals of Hb C tend to melt at low partial pressure of oxygen (pO₂) and do not cause vaso-occlusive disease. The red cells are dehydrated (causing the increased MCHC), owing to loss of cations and water as a result of interaction of Hb C with the red cell membrane. As a consequence, the cells are more rigid and less deformable than normal, increasing their likelihood of being trapped and destroyed in the spleen. Hb F is elevated at 2%–4%, and Hb A₂, when measured by HPLC, might be slightly increased; the remainder of hemoglobin is Hb C.

Hb C/β⁺-Thalassemia. This occurs mainly in black people, in whom it tends to result in little disability, except for anemia in pregnancy. Red cell indices are typical of β-thalassemia trait, but there is anisocytosis and 20%–50% target cells. Usual values are 65%–80% for Hb C, 16%–30% for Hb A, and 2%–5% for Hb F.

Hb C/β⁰-thalassemia. People of Mediterranean extraction usually have a moderately severe hemolytic anemia with β⁰ or a severe β⁺ genotype. This combination is extremely rare in the African population. Hb C/β⁰-thalassemia may be difficult to distinguish from Hb C disease in that Hb A is absent in both, and there is an overlap in Hbs A₂ and F levels. Hb A₂ is elevated to about twice normal, and Hb F is elevated at 3%–10%.

Hb E (β 26 glu→lys). This is probably the most prevalent hemoglobin variant worldwide and the third most common in the United States, behind S and C. It is found primarily in Southeast Asia, especially in people of Thai and Burmese extraction, but is also found in blacks and Caucasians.

Hb E is associated with a β-thalassemia phenotype, as well as with a structurally abnormal globin chain. The mutation that causes amino acid substitution also activates a cryptic splice site that competes with the normal RNA splice donor site, and normally processed RNA is decreased. In the laboratory, Hb E can be demonstrated to be unstable. It precipitates abnormally in the heat denaturation test and with isopropanol, yet this has no in vivo significance; the red cell survival is normal (Fairbanks, 1980).

Hb E Trait (Hb AE). Hb AE is asymptomatic, with borderline microcytosis (MCV = 84 ± 5) and no anemia. Hb A is 65%–70% of the total hemoglobin, Hb E is 30%, and Hb F is normal. Coexistence of one α-thalassemia gene does not change any of the above parameters and can be proven only by DNA analysis. If two or three α-thalassemia genes are also present, the proportion of Hb E decreases to 21% and 14%, respectively. The proportion of Hb E is also significantly lower in iron deficiency.

Hemoglobin E Disease. This is also asymptomatic; it resembles a thalassemia trait, with microcytosis (average MCV = 70 fL), erythrocytosis, normal MCHC, and slight anemia. Thus, Hb E behaves as an extremely mild thalassemia. The reticulocyte count is normal, but 20%–80% target cells are evident on the blood film. Hb E accounts for more than 90% of the hemoglobin, with Hb F from 1%–10% and no Hb A.

Hb E/β-Thalassemia. In sharp contrast with Hb E disease, this is a severe condition. It is one of the most important thalassemia syndromes and is most common in Southeast Asia. Clinical variability is marked; rarely, there are very few symptoms, but the usual picture is that of thalassemia intermedia or thalassemia major. Most of the thalassemia alleles are of the β⁰ or severe β⁺ variety. Ineffective erythropoiesis, a consequence of excess α-globins, red cell indices, red cell morphology, and clinical manifestations are similar to those in homozygous β-thalassemia. Hbs E, F, and A₂ are present. Hb F shows extreme variation, from 5%–85%; the mean Hb F is 42%, and Hb E is 58% (Steinberg, 2001).

Hb D Los Angeles (Punjab) (β121 glu→gln). This constitutes the most common D variant in African Americans (<0.02%). In the Punjab region of India, heterozygosity reaches 3%. Homozygotes have normal red cell indices, no evidence of hemolysis, and 95% Hb D with normal Hbs F and A₂ (Bunn, 1986). Double heterozygotes for Hb D Punjab/β⁰-thalassemia have a mild hemolytic anemia with thalassemic red cell indices and increased Hbs F and A₂.

The significance of Hb D Punjab is that compound heterozygosity with Hb S produces a moderately severe sickling disorder (see Hb SD Disease earlier). Other, less frequent D hemoglobins (D Iran, D Ibadan) and G hemoglobins do not cause sickling—a major difference for genetic counseling. D and G hemoglobins migrate with Hb S on alkaline electrophoresis but are separated from S at acidic pH, migrating with Hb A. It is more difficult to separate them from each other. Careful analysis of isoelectric focusing and HPLC are helpful in most cases.

Common α-Chain Variants

Hb G Philadelphia (α 68asn→lys). This is the most common α-chain variant in black people (Schneider, 1976). Almost invariably, the linked α-gene is deleted (–α^G). Simple heterozygotes (–α^G/αα) have 30% Hb G and normal red cell indices, but double heterozygotes with α-gene deletion on the other chromosome as well (–α^G/–α) have 45% Hb G and a thalassemia trait phenotype. As with other α-chain variants, a minor hemoglobin, a combination of α^G with δ, is present close to Hb A₂ and

helps to differentiate Hb G Philadelphia from β -chain variant G and D hemoglobins.

Disorders of Hemoglobin Function and Stability

A number of amino acid substitutions occur in the heme pocket, where they may increase the stability of the methemoglobin form (Hb M) or alter the affinity of the heme for O_2 ; the latter usually alters the stability of the molecule as well. Other substitutions affect the $\alpha\beta$ contact sites; these also can change stability and O_2 affinity of the molecule (Bunn, 1994).

These functionally significant hemoglobinopathies are heterozygous; usually, the concentration of the abnormal Hb is less than 50%. Generally, Hbs with abnormal α -chains form a smaller proportion of the total (10%–25%) than those with abnormal β -chains (35%–50%).

Hemoglobins Associated With High Oxygen Affinity and Polycythemia

Eighty-six abnormal Hbs with high O_2 affinity that are associated with familial erythrocytosis are known today (Globin Gene Server). Some are listed in Table 32-4. The O_2 dissociation curve is shifted to the left. The p_{50} , the pO_2 at which Hb is 50% saturated, is decreased. Under physiologic conditions, the normal p_{50} of whole blood is 26 mm Hg; in this disorder, it has ranged from 5–23 mm Hg. Because the Hb has high affinity for O_2 , the tissues are relatively hypoxic at any given p_{50} , resulting in increased EPO production and polycythemia. These disorders are autosomal dominant; only heterozygotes have been described. The Hb concentration has ranged from 15–23.8 g/dL. Measurement of O_2 affinity is required to establish the diagnosis (Bunn, 1986). Because the amino acid substitution is inside the molecule, often the abnormal hemoglobin is indistinguishable from Hb A on electrophoresis or HPLC.

Hemoglobins Associated With Low Oxygen Affinity

There are far fewer variants with decreased O_2 affinity (see Table 32-4; Bunn, 1986). The Hb– O_2 dissociation curve is shifted to the right (increased p_{50}). These individuals have mild “anemia,” as they can unload more O_2 to the tissues and they simply do not need that much Hb. A handful of variants with markedly decreased affinity are associated with cyanosis. In these, O_2 uptake is impaired in the lung and the level of deoxyhemoglobin is more than 5 g/dL, causing cyanosis. These patients have a slate gray color to their skin and mucous membranes. They have no anemia. Many of the unstable Hbs also have decreased O_2 affinity; however, the hemolytic state dominates the clinical picture.

M Hemoglobins: Pseudocyanosis

Nine abnormal Hbs are associated with clinical methemoglobinemia and cyanosis that do not respond to methylthioninium chloride (methylene blue) (Globin Gene Server; Bunn, 1994). The color is similar to cyanosis—a brownish color, caused by methemoglobin. The common feature is that all have an amino acid substitution at or near the heme group, so that methemoglobin is unusually stable, and reduction to ferrous heme and hence reversible binding of O_2 are prevented. Methemoglobin constitutes no more than 3% of the total Hb in normal humans.

Cyanosis from birth is seen in Hb M disease with α -chain abnormalities, or in fetal Hb M (Hb FM Osaka). In the latter, cyanosis will disappear after the γ -chains have been replaced by β -chains by 6 months of age. Cyanosis does not appear until nearly 6 months of age in Hb M variants with β -chain abnormalities, for the same reason (Bunn, 1994). Of course, the cyanosis is not associated with enzyme abnormalities in the red cell, toxic drugs, or cyanotic heart disease—conditions that must be considered in the differential diagnosis. Patients usually have no other symptoms.

All Hb M disorders thus far discovered have been reported in heterozygotes, probably because homozygosity is lethal. Some types of Hb M will not separate from Hb A on alkaline electrophoresis. If the hemolysate is first converted to methemoglobin, the Hb M will migrate differently from normal methemoglobin at pH 7.1. The absorption spectra of the eluted Hb M, which may be distinctive, can be compared with those of normal methemoglobin (Bunn, 1994).

Unstable Hemoglobins (Bunn, 1998)

More than 100 Hb variants have been described in which the Hb precipitates within the red cell as Heinz bodies. Some are listed in Table 32-4. About 75% of the abnormalities are β -chain. Rare unstable hemoglobins such as Hb F Poole are related to unstable γ -chain variants. Amino acid substitution or deletion renders the Hb molecule unstable. Precipitated Hb attaches to the cell membrane and shortens its survival; the cells are

inflexible. Heinz bodies are removed by the spleen, and further damaged cells have a shortened survival. The O_2 affinity is usually abnormal and may be increased or decreased. Some of these unstable Hbs cause “congenital Heinz body hemolytic anemias.”

All patients have been heterozygous. Clinical features have shown considerable variation, from severe hemolytic anemia in the first year of life (e.g., Hb Hammersmith, Hb Bristol) to a very mild chronic hemolytic anemia (e.g., Hb Louisville, Hb Hasharon) that may be exacerbated by drugs (e.g., Hb Zurich). A few unstable Hbs have been discovered incidentally in clinically normal individuals (e.g., Hb Tacoma, Hb Sogn).

Jaundice and splenomegaly are common, as in other hemolytic anemias. More distinctive in some cases is the excretion of darkly pigmented urine (only during hemolytic crises in mild variants). The urine pigment appears to be dipyrrole, probably a breakdown product of heme molecules after separation from globin (Dacie, 1991). Cyanosis is present in some patients and is due to methemoglobinuria and sulfhemoglobinemia or to low O_2 affinity.

The anemia is normocytic and normochromic to hypochromic, the latter because of the removal of precipitated Hb from aging red cells by macrophages of the spleen and other reticuloendothelial organs. Prominent basophilic stippling, probably related to excessive clumping of ribosomes, is a common feature. Occasional “bite cells” may be seen. Patients with relatively high Hb concentrations in the steady state usually have Hb variants with a high O_2 affinity and an unexpectedly high reticulocyte count (e.g., Hb Köln, Hb Gun Hill). On the other hand, patients with rather low Hb concentrations may be relatively asymptomatic if their Hb has a low O_2 affinity; their reticulocyte counts are unexpectedly low for the Hb concentration (e.g., Hb Hammersmith). Heinz bodies are rarely seen in circulating red cells before splenectomy, although sometimes they may be generated by incubating the red cells with brilliant cresyl blue or new methylene blue. After splenectomy, Heinz bodies are readily demonstrable in a large proportion of cells; the blood film shows irregularly contracted cells and basophilic stippling that may be pronounced.

In splenectomized patients, the Heinz bodies may interfere with Hb determinations and with electronic platelet and white cell counts. Before the absorbance of the hemolysate is measured, it should be centrifuged to remove the Heinz bodies. Platelet and leukocyte counts should be performed by visual methods. Hb electrophoresis is normal in about one fourth of patients. Hb A₂ may be elevated in β -chain variants because of the loss of abnormal Hb from the cells; this phenotype may resemble thalassemia intermedia. Hb F may be increased to a level of 10%–15%. Key laboratory determinations include heat instability and isopropanol precipitation tests.

Heat Instability Test. Most unstable Hbs precipitate more rapidly than normal Hbs when incubated at 50° C (Dacie, 1991). Both normal and unstable Hbs precipitate more rapidly in Tris-buffer than in phosphate buffers. In a hemolysate in tris-buffer, an easily visible precipitate forms within an hour if unstable Hb is present; the control sample is clear or slightly cloudy. Slight precipitation is equivocal; the test should be repeated and the isopropanol precipitation test performed as well. Precipitates accounting for 10%–40% of the total Hb are found in unstable Hb disorders.

Isopropanol Precipitation Test. A relatively nonpolar solvent weakens the internal bonds of Hb and decreases its stability (Carrell, 1972). An unstable Hb precipitates within 20 minutes in the nonpolar solvent isopropanol, whereas a normal hemolysate remains clear for 30–40 minutes. False-positive results occur with high levels of Hb F.

THALASSEMIAS

In thalassemias, globin chains, usually of normal structure, are produced at a decreased rate. β -Thalassemia refers to decreased production of β -chains; α -thalassemia and $\delta\beta$ -, δ -, and $\gamma\delta\beta$ -thalassemias refer to reduced synthesis of the respective polypeptide chains. As a result, there is an overall deficit of Hb tetramers in the red cells, and MCV and MCH are reduced. However, it is not the lack of the affected globin chain, but the accumulation of the unaffected one, that causes hemolysis and, primarily in β -thalassemia, ineffective hematopoiesis in severe forms of the disease.

Thalassemia occurs predominantly in persons of Mediterranean, African, and Asian ancestry as, similarly to Hb variants or glucose-6-phosphate dehydrogenase (G6PD) deficiency, thalassemia genes are under selective pressure by malaria. In Greece and Southern Italy, the prevalence of β -thalassemia is around 10%, and that of α -thalassemia is 5%.

Figure 32-24 Deletions that cause α^+ thalassemia. The homologous boxes (X, Y, and Z) are interrupted by nonhomologous segments (I, II, and III). Black bars show the extent of each deletion and thin bars show the breakpoint areas. In each case, only one α -gene is deleted.

Twenty-five to 30% of black people and 20% of Thai people carry an α -thalassemia gene. Because structural variants and thalassemias occur in the same population, a wide variety of diseases emerge from their interactions.

Several classifications are used. The clinical classification defines thalassemia major, a severe and transfusion-dependent form; thalassemia intermedia, with less severe symptoms; and thalassemia minor (carrier state or trait), without clinical symptoms, but with hematologic abnormalities. The genetic classification is based on gene(s) affected by the mutation, heterozygous/homozygous state, absent/reduced rate of globin synthesis, and so forth. Finally, specific mutations cause well-defined syndromes and can be used for classification.

Molecular Defects

In β -thalassemia, considerable heterogeneity in molecular defects is noted. One hundred ninety-seven different mutations have been identified as the cause of β -thalassemia. Most are associated with single base substitutions that produce defects in promoter activity, RNA processing/splicing, or translation, resulting in decreased or unstable mRNA. Large deletions are uncommon. In rare structural variants, the production of highly unstable β -chains results in the phenotype of β -thalassemia (Bunn, 1998). Despite this diversity, 20 common mutations account for 80% of β -thalassemia alleles in the world population (Weatherall, 1999). In β^0 -thalassemia, β -chain synthesis is absent on the affected chromosome. Messenger RNA (mRNA) is absent or may be present but nonfunctional. In β^+ -thalassemia, β -globin chains are present but reduced in quantity because molecular defects have resulted in the production of unstable or decreased amounts of mRNA.

In $\delta\beta^0$ -thalassemia, large deletions involve the $\delta\beta$ - or $\Lambda\gamma\delta\beta$ -gene complex. As a result, no Hb A or Hb A₂ synthesis is supported from the affected chromosome, but the γ -gene is upregulated and Hb F production is increased. Lepore Hbs have $\delta\beta$ -fusion globins that are the result of unequal crossover between δ - and β -globin genes during meiosis.

The α -thalassemias are generally due to gene deletion of various lengths. Two α -globin genes are present on each chromosome 16, surrounded by two highly homologous duplication units, each containing three homologous segments (Z, X, and Y). Unequal crossing over between the Z segments produces a chromosome with one α -gene ($-\alpha^{3.7}$) and another with three ($\alpha\alpha\alpha$). Similar nonreciprocal crossing over between X boxes causes another common deletion ($-\alpha^{+2}$) (Fig. 32-24). This recombination has a high probability, and chromosomes with missing or extra α -genes are found in every civilization; nonetheless, only the thalassemic

Figure 32-25 Large deletions of the α -gene complex cause α^0 -thalassemia. No α -chain synthesis is directed from the chromosome. MED (Mediterranean) and SEA (South East Asian) deletions are the most frequent.

alleles became frequent in certain populations, under pressure from malaria. These defects, affecting only one of the genes, are called α^+ -thalassemia. The heterozygous genotype can be written ($-\alpha/\alpha$). Nondeletion defects are less common ($\alpha^T\alpha/\alpha\alpha$). α^0 -Thalassemia results from deletion of both α -globin genes on the chromosome (Fig. 32-25), which leads to no α -chain synthesis ($---/\alpha\alpha$).

Hb Constant Spring is due to an abnormal termination codon in an α -globin gene that results in an elongated α -chain with 31 extra amino acids. Because of marked reduction in mRNA stability, the clinical phenotype of α -thalassemia is seen (Orkin, 1998).

β -Thalassemias

Clinical and Hb findings in the β -thalassemias are summarized in Tables 32-7 and 32-8. The disorders are very heterogeneous phenotypically, as well as at the level of the molecular defects. The terms thalassemia major, thalassemia intermedia, and thalassemia minor refer to clinical severity and are not genetic designations.

Homozygous β -Thalassemia (Thalassemia Major; Cooley's Anemia)

With absence of (β^0) or a marked decrease in (β^+) β -chain production, there is an excess of α -chains. Aggregates of α -chains are unstable and precipitate in the normoblast or red cell and damage the cells. Excess α -chains and their degradation products—heme, hemin, and iron, which serve as foci for the generation of reactive O₂ species—result in the partial oxidation of band 4.1 and a reduced spectrin/band 3 ratio in red blood cell precursors. Precipitates and cells are removed, causing ineffective erythropoiesis and severe hemolytic anemia. Furthermore, clustering of band 3 in the membrane may be followed by opsonization with autologous IgG and complement and removal by macrophages (Weatherall, 1999).

Clinical findings include jaundice and splenomegaly, which become evident early in childhood. Prominent frontal bones, cheekbones, and jaws impart a mongoloid appearance. These changes and X-ray findings of a

TABLE 32-8

Major Categories of β -Thalassemia Syndromes

Syndrome	Genotype	Clinical features	Hemoglobin pattern
Homozygous States			
β^+ -thalassemia	β^+/β^+	Thalassemia major or intermedia	$\downarrow\downarrow$ Hb A, $\uparrow\uparrow$ Hb F, variable Hb A ₂
β^0 -thalassemia	β^0/β^0	Thalassemia major	>95% Hb F, rest Hb A ₂
$\delta\beta^0$ -thalassemia	$\delta\beta^0/\delta\beta^0$	Thalassemia intermedia	100% Hb F
Hb Lepore	Lepore/Lepore	Thalassemia major	85% Hb F, 15% Hb Lepore
Heterozygous States			
β^+ -Thalassemia	β^+/β	Thalassemia minor	Hb A, \uparrow Hb A ₂ , $\pm\uparrow$ Hb F
β^0 -Thalassemia	β^0/β	Thalassemia minor	Hb A, \uparrow Hb A ₂ , $\pm\uparrow$ Hb F
$\delta\beta^0$ -Thalassemia	$\delta\beta^0/\delta\beta$	Thalassemia minor	Hb A, 5%–20% Hb F, $\pm\downarrow$ Hb A ₂
Hb Lepore	Lepore/ β	Thalassemia minor	Hb A, \uparrow Hb F, \downarrow Hb A ₂ , 10% Hb Lepore

Modified from Orkin SH, Nathan DG. The thalassemias. *N Engl J Med* 1976;295:710–4.

Hb, Hemoglobin.

Figure 32-26 Homozygous β -thalassemia. A few cells contain hardly any hemoglobin (Hb), and the Hb is often precipitated at the membrane. Bizarre target cells, Howell-Jolly bodies, and poorly hemoglobinized nucleated red blood cells are seen.

thinned cortex of the long and flat bones and thickening of the skull with osteoporosis (“hair-on-end” appearance) reflect extreme bone marrow hyperplasia. Growth is stunted and puberty is delayed. Most patients require regular transfusions and develop problems caused by iron loading. Iron overload commonly develops, and the major cause of death is cardiac failure due to myocardial siderosis by the end of the third decade.

Unlike most hemolytic diseases, the anemia is hypochromic and microcytic. Extreme poikilocytosis with bizarre shapes, target cells, ovalocytosis, Cabot rings, Howell-Jolly bodies, nuclear fragments, siderocytes, anisochromia, anisocytosis, and often extreme normoblastosis are present (Fig. 32-26). Poikilocytosis is more striking in patients with an intact spleen; normoblastosis is more severe after splenectomy. Normoblasts have hypochromic cytoplasm and, especially after splenectomy, aggregates of densely staining Hb, which probably represent precipitated α -chains. Incubation of the blood with methyl violet stains these precipitates in both red cells and normoblasts. The reticulocyte count is less elevated than expected for the degree of anemia because of destruction of erythroid precursors in the marrow. Osmotic resistance of the red cells, serum iron, and indirect-reacting bilirubin are increased.

In the marrow, marked normoblastic hyperplasia is present. Many late normoblasts show inclusion bodies as in the blood. Gaucher-like cells are present. Storage iron and sideroblasts are increased.

In β^0 -thalassemia, Hb A is absent, Hb F is as high as 98%, and Hb A₂ is about 2%. In β^+ -thalassemias (Mediterranean), Hb F is 60%–95%, with Hb A present. Although Hb A₂ may or may not be increased, the ratio of A₂ to A is always increased. In black people with β^+ -thalassemia, the clinical features are less severe (thalassemia intermedia), and transfusion is usually unnecessary; Hb F is 20%–40%, Hb A₂ is 2%–5%, and the rest is Hb A (Table 32-8).

Heterozygous β -Thalassemia (β -Thalassemia Trait; Thalassemia Minor; Cooley’s Trait)

This is caused by the β^0 -thalassemia gene with absent, or the β^+ -thalassemia gene with reduced, β -globin chain synthesis. There are usually no symptoms or abnormal physical signs. The only clinical presentation might be a refractory anemia of pregnancy (Weatherall, 2001).

Most β -thalassemia heterozygotes have a mild anemia, but occasionally, Hct and Hb might be normal. Those of African origin have higher Hb levels than people from the Mediterranean region, reflecting their milder genotype. Characteristically, the RBC is elevated (5–7 M/ μ L), the MCH is low (usually less than 22 pg), and the MCV is low (between 55 and 70 fL). The MCHC is sometimes low but often normal. The reticulocyte count is twice the normal value. On stained films, the cells have a moderate degree of microcytosis, hypochromia, anisocytosis, and poikilocytosis; target cells and basophilic stippling are often, but not always, present (Fig. 32-27). Osmotic fragility is decreased. In the marrow, there is mild normoblastic hyperplasia with ragged cytoplasmic borders—a sign of defective hemoglobinization.

Hb A₂ is elevated in the 3.5%–7% range; Hb F is slightly elevated (1%–3%) in about half of cases. In the few cases where Hb F exceeds 4%, it is likely that a gene for HPFH is also present (Mazza, 1976). Relatively rare deletional forms tend to have higher levels of Hb F (up to 9%), and in a few families, in which the deletion included the promoter region, Hb F was found to be unusually high (up to 14%) (Weatherall, 2001). In infants, a slower than normal decline in Hb F level is observed, and the adult steady-state level is not reached until adolescence. This is a particularly important consideration in double heterozygosity for β -thalassemia and Hb S, when Hb F level is used to predict prognosis.

In a few cases, both Hb A₂ and F are normal. These are difficult to distinguish from the α -thalassemia trait, and only molecular studies might be definitive. Studies indicate that the bulk of these cases result from the coinheritance of β - and δ -thalassemia (Weatherall, 1994), either in *trans* or

Figure 32-27 β -Thalassemia trait. Hypochromic, microcytic red blood cells with frequent targeting. Mild anemia.

in *cis*, to the β -thalassemia gene. In other patients with normal Hb pattern, only minimal hematologic changes are noted (the “silent” β -thalassemia gene), and only a more severe β -thalassemia syndrome in a family member suggests the presence of a very mild β -thalassemia mutation.

Iron studies are little different from normal (Weatherall, 2001), although iron deficiency often complicates thalassemia trait in childhood and during pregnancy. In severe iron deficiency, the level of Hb A_2 may fall into the normal range, thus obscuring the diagnosis of β -thalassemia trait, but this is unusual. Most often, although the level of A_2 falls, it remains elevated above the normal range (Weatherall, 2001). Nevertheless, when iron deficiency is present, repeat measurement of Hb A_2 is recommended after replenishment of iron.

The differential diagnosis between iron deficiency and β - or α -thalassemia trait can be difficult. Increased RBCs in the presence of decreased MCV is the hallmark of thalassemia trait. An MCV/RBC ratio <13 suggests thalassemia trait; a ratio >13 is more consistent with iron deficiency, but this and other formulas are not conclusive enough for diagnosis.

$\delta\beta^0$ -Thalassemia

This is sometimes called F-thalassemia, a helpful name, as you have to think of it when there are thalassemic indices and significantly increased levels of Hb F. β - and δ -chains are not produced; this is nearly, although not completely, compensated for by increased output of γ -chains. The heterozygous state is similar to a mild β -thalassemia trait, except that Hb A_2 is not increased or is even slightly reduced (mean level is 2.4%), and Hb F is significantly increased (5.4%–20%). In the homozygous state, hemoglobin consists of only Hb F.

Clinically, $(\delta\beta)^0$ -thalassemia behaves as a mild form of β -thalassemia. In the heterozygous state, the Hb is normal or slightly reduced, the MCH is between 21 and 26 pg, and the MCV is 65–79 fL. There are no clinical symptoms. Homozygotes have a mild form of thalassemia intermedia with a Hb level of 10–13 g/dL, mildly thalassemic red cell indices, and only minimal hepatosplenomegaly. It is most common in the Mediterranean population. The mild phenotype is the result of increased production of γ -chains, which compensate to some degree for the lack of β -chains.

The molecular defect is a long deletion involving the β - and δ - and often also the $A\gamma$ -gene. Twenty-one different deletions have been described (Globin Gene Server), but the hematologic findings are essentially the same. When the $A\gamma$ -gene is also deleted, the accurate nomenclature is $(A\gamma\delta\beta)^0$ -thalassemia; homozygotes have a somewhat more severe phenotype.

$\delta\beta^+$ -Thalassemia: Lepore Hemoglobins

In the Lepore hemoglobins, an abnormal $\delta\beta$ -fusion chain is produced, a result of chromosome crossing-over and fusion of genetic material at the $\delta\beta$ -genes. No δ - or β -chain synthesis is directed from the affected chromosome. Because Hb F production is only slightly increased and the composite $\delta\beta$ -chain is synthesized at a very slow rate, a severe thalassemic phenotype is produced. Hematologic abnormalities are similar to those seen in β^0 -thalassemia. Hb Lepore migrates slightly faster than Hb S on alkaline electrophoresis and usually constitutes about 10% of total Hb in the heterozygotes; Hb A_2 averages 2%, and Hb F is 2%–3% (Efremov, 1978). In homozygotes, Hb Lepore is 10%–15%, and the rest is Hb F. Different Hb Lepores have been described, depending on the point of fusion, but they behave similarly. This is a much more severe thalassemia gene than the $(\delta\beta)^0$ form and causes transfusion-dependent thalassemia major in the homozygous state.

Hereditary Persistence of Fetal Hemoglobin

A group of conditions with persistence of fetal hemoglobin production beyond infancy, but without significant hematologic abnormalities, is known as HPFH. There are two major types: pancellular and heterocellular (or Swiss) HPFH.

The pancellular form of HPFH is closely related to β - and $\delta\beta$ -thalassemias, with which it forms a continuous spectrum. At one end of the spectrum is minimal γ -chain production with no compensation for deficiency of β -chains in β -thalassemia; at the other end, Hb F production is up and almost entirely compensates for the deficit in HPFH (Weatherall, 2001). As a result, at least in heterozygotes, there is no clear evidence of thalassemia (except maybe borderline microcytosis in a few cases), and this serves as a criterion in diagnosis. In clinical practice, a patient with significantly elevated Hb F and reduced Hb A_2 is suspected to have HPFH if red cell indices are normal but is diagnosed with $\delta\beta^0$ -thalassemia if the indices are thalassemic. Nevertheless, there is a slight α /non- α -chain imbalance, and HPFH could be considered a mild form of $\delta\beta^0$ -thalassemia. Hb F is homogeneously (evenly) distributed among the red cells (pancellular). This is in contrast to β - or $\delta\beta$ -thalassemia, in which the distribution is heterocellular. Pancellular HPFH is rare. It is found in about 0.1% of African Americans and even less frequently in other ethnic groups.

Deletional Pancellular HPFH. In the six deletional forms, the $\delta\beta$ -gene complex is deleted. The black and Ghanaian forms are the most common, but Indian, Italian, and Southeast Asian forms are also well documented. Homozygotes have slightly microcytic, hypochromic red cells, but no anemia. Hb F is 100%; no Hb A or Hb A_2 is present. The Hct can even be high—a result of high O_2 affinity of Hb F. In the heterozygote, no hematologic abnormalities are found. Hb F is 15%–30%, and Hb A_2 is decreased at 1%–2.1%.

Hb Kenya. This is a Hb analogous to the Lepore Hbs, which is associated with an HPFH phenotype. It contains an $A\gamma\beta$ -fusion gene. In the heterozygote, Hb Kenya is around 10%, F is 7%, and A_2 is reduced.

Nondeletional Pancellular HPFH. A mutation in the promoter region of one of the γ -genes results in increased synthesis of Hb F. Output from the δ - and β -genes in *cis* is reduced. Levels of Hb F range from 3%–31% in the different forms, Hb A_2 is invariably low, and the red cell indices are close to normal. There are two particulars to keep in mind. First, β -chain synthesis is decreased, but not absent from the affected chromosome, and compound heterozygotes of this form of HPFH and Hb S on the other chromosome do have Hb A ($\approx 30\%$). The hemoglobin composition is similar to that seen in Hb S/ β^+ -thalassemia, except that Hb A_2 is reduced. Second, it is not rare to find it together with an α -thalassemia gene, which is highly prevalent in African Americans.

Heterocellular or Swiss-type HPFH has less Hb F, ranging from 2%–5%. The distribution of Hb F is uneven (heterocellular): F cells and erythrocytes without Hb F are present. It was first described among healthy Swiss army recruits but is present in other populations and is quite common. It is caused by polymorphic variations at three well-known and other lesser known loci that regulate adult Hb F production (Thein, 2009). In normals or in carriers of β -thalassemia or Hb S, there is only a minimal increase in Hb F. When inherited with Hb SS or homozygous β -thalassemia, however, the result could be an unusually high level of Hb F and milder disease.

α -Thalassemias

α -Thalassemia is probably the most common single-gene disorder in humans. Its distribution is largely limited to tropical and subtropical regions of Asia and Africa and the Mediterranean (Higgs, 1989), where it reaches extremely high frequencies.

Two α -globin genes are present on each chromosome 16. α -Thalassemias are classified according to the total output of these two linked α -globin genes. In α^0 -thalassemia, both genes are inactive ($-/-$), but in α^+ -thalassemia, only one gene is defective as the result of deletion ($-/\alpha$) or, less frequently, of mutation (α^T/α). Nondeletional forms usually result in less globin output from the linked α -gene and more severe phenotypes. Rarely, the chromosome has a deletion and a separate mutation ($\alpha^T/-$). Previously, α^0 and α^+ were called α -thalassemia 1 and 2. This was rather confusing, as the milder defect with one affected gene was called α -thalassemia 2, and the more severe genotype with two defective genes, α -thalassemia 1. Alternatively, these terms were also used to describe clinical phenotypes.

TABLE 32-9

 α -Thalassemia Syndromes

Syndrome	Defective genes	Genotype	Clinical features	Newborn	After first year
Hydrops fetalis	4	—/—	Fetal or neonatal death with severe anemia	Hb Bart's >80% Hb H, Hb Portland	
Hb H disease	3	—/— α (—/ $\alpha\alpha^{CS}$)	Chronic hemolytic anemia	Hb Bart's 20%–40% (Hb CS)	Hb H 5%–30% (Hb CS 2%–3%)
Thalassemia minor	2	—/ $\alpha\alpha$ α^- / α $\alpha^T\alpha^-$ / α	Asymptomatic, mild anemia, thalassemic indices	Hb Bart's 5%–10%	None
Silent carrier	1	α^- / $\alpha\alpha$ ($\alpha\alpha$ / $\alpha\alpha^{CS}$)	No clinical or hematologic abnormality	Hb Bart's \pm 1%–2% (Hb CS)	None (Hb CS 1%)

Modified from Wintrobe MM, Lee GR, Boggs DR, et al. Clinical hematology. 8th ed. Philadelphia: Lea & Febiger; 1981.

Hb, Hemoglobin.

Figure 32-28 Hemoglobin H disease. Mild anemia and target cells.

Unlike the extremely unstable α -chains in β -thalassemia, excess β - and γ -chains can form stable tetramers, hemoglobin H (β_4), and Bart's (γ_4). These precipitate in aging red cells and, through interaction with the cell membrane, cause hemolysis. This is mostly a hemolytic anemia, whereas in β -thalassemia, ineffective erythropoiesis predominates.

α -Thalassemia Syndromes

Four α -thalassemia syndromes result from the combination of these genotypes (Bunn, 1986), which roughly correspond to a loss of 4, 3, 2, or 1 genes from the normal complement ($\alpha\alpha/\alpha\alpha$) (see Table 32-9). In the following discussion, nondeletion forms are not always depicted separately, for the sake of simplicity.

Hemoglobin Bart's Hydrops Fetalis (—/—). Complete absence of α -chains is incompatible with life. Infants are stillborn with severe edema, marked anemia, and marked hepatosplenomegaly. The blood shows marked anisocytosis, poikilocytosis, microcytosis, and erythroblastosis. ABO or Rh incompatibility is absent. Because of the absence of α -chains, no Hb A or Hb F is present. Large quantities of Hb Bart's (γ_4), a variable amount of Hb Portland, and traces of Hb H (β_4) are present; all of these migrate faster than Hb A on alkaline electrophoresis. Hb Bart's is functionally useless for O_2 transfer, causing extreme intrauterine hypoxia.

Hemoglobin H Disease (— α /—). Three of the four α -genes are absent. A chronic hemolytic anemia occurs with the clinical picture of thalassemia intermedia in a minority of cases, although the severity varies, and most patients do well. Hb H disease is very common in Southeast Asia but is also seen in the Mediterranean and the Middle East; it is very rare, however, in black people, as α^0 -thalassemia is uncommon in this group. Splenomegaly and sometimes hepatomegaly are present. Hb values average 3 g/dL less than in age- and sex-matched controls. Transfusion is rarely needed. Anemia may become more severe during pregnancy, but the Hb rarely falls below 7 g/dL. The MCV (60–70 fL) and MCH (17–21 pg) are decreased (Higgs, 1989), and RBC is increased (6–6.2 M/ μ L). The blood film shows hypochromia, basophilic stippling, and anisopoikilocytosis with target cells (Fig. 32-28). Reticulocytes range from 4%–5%.

Hemoglobin electrophoresis shows a rapidly migrating band of Hb H (β_4), accounting for approximately 9% (from 1%–40%) of the hemoglobin, and the slightly less rapidly migrating Hb Bart's in half of cases. Hb

Figure 32-29 Hemoglobin H preparation. Film made after incubation of blood with brilliant cresyl blue. Several red cells contain multiple small pale blue inclusions.

H can be precipitated in vitro and lost from the hemolysate by careless handling or prolonged storage. In old hemolysates, a series of bands migrates as Hb H. Hb Bart's is alkali resistant and may be measured with Hb F (which is not increased in Hb H disease). The percentage of Hb Bart's is 2%–40% at birth; it gradually falls thereafter, averaging 4.8%, but the level in adults is variable. As in other α -thalassemia syndromes, more Hb Bart's is present at birth than Hb H in adult life. Hb A₂ is diminished.

Hemoglobin H Preparation. Vital staining of the blood with an oxidizing dye such as brilliant cresyl blue induces inclusion bodies (Hb H precipitates) in many of the red cells. During incubation of two parts of blood in one part of 1% brilliant cresyl blue stain, the unstable Hb H (β_4) gradually precipitates as multiple small pale blue inclusions uniformly distributed on the red cell membrane (Fig. 32-29) (Jones, 1981). Hb H inclusions must be distinguished from (1) the granules and reticular networks in reticulocytes, which are darker blue in color; and (2) pre-formed Heinz bodies, which are larger, also darker blue, and often are attached to the membrane. After 20 minutes of incubation at room temperature, Hb H inclusions are present in at least half of the red cells in Hb H disease, and in a very rare red cell in α -thalassemia trait. The larger, single Heinz bodies may be found after splenectomy in Hb H disease.

α -Thalassemia Trait: Heterozygous α^+ -Thalassemia (—/ α) or Homozygous α^+ -Thalassemia (— α /— α).

Absence of two α -genes results in clinical features similar to β -thalassemia minor with very mild anemia and thalassemic indices, with MCV ranging from 65–75 fL (Higgs, 1989). The α -chain/ β -chain synthesis ratio is decreased (\approx 0.6). Diagnosis is best made by finding 5%–10% Hb Bart's in cord blood; normally, only trace amounts (<0.5%) are found. In adults, Hb Bart's is undetectable, and Hb studies are perfectly normal, except that Hb A₂ might be slightly reduced. Hb H inclusions are found in α^+ -thalassemia, but rarely in heterozygous or homozygous α^+ -thalassemia, and only in a very small percentage of red cells, if exhaustively sought after (Wasi, 1974), and if the sample is enriched for Hb H-containing red cells (Jones, 1981). Otherwise, no evidence of Hb imbalance is detectable by standard techniques, and the diagnosis is one of excluding iron deficiency, anemia of chronic disease, and β -thalassemia trait. In contrast to β -thalassemia, Hb F is normal, and Hb A₂ is normal or decreased. This condition is absolutely benign, and most patients are diagnosed on routine screening. Hematologic findings are

identical in the two distinct genotypes found in different populations: ($-\alpha/\alpha$), common in Southeast Asia and the Mediterranean and exceedingly rare in black people; and ($-\alpha-\alpha$), most common in those of African descent.

Silent Carrier α -Thalassemia (Heterozygous α^+ -Thalassemia) ($\alpha\alpha^-/-\alpha$). In this condition, one of four α -globin genes is absent. Hematologic findings are normal, except that the MCV might be slightly reduced, with a mean value of 81 fL and a range of 75–85 fL, and the MCH might be minimally decreased; many times, however, the red cell indices are perfectly normal. During the neonatal period, heterozygous α^+ -thalassemia can be diagnosed by a raised level of Hb Bart's (1%–2%) in the cord blood. Hb Bart's disappears by the age of 6 months, and the diagnosis can be made only by molecular or globin chain synthesis studies. Because only 40% of newborns with the heterozygous α^+ -thalassemia genotype have detectable Hb Bart's in their cord blood (Higgs, 1982), failure to detect Hb Bart's in the newborn does not rule out silent carrier α -thalassemia, and newborn screening should not be used to rule out this entity.

From large studies comparing hematologic findings of different genotypes, it became apparent that there is a continuum between normal, silent carrier, and α -thalassemia trait. Because there is no clear separation between one- and two-gene defects, some authors group these together as milder α -thalassemia phenotypes. None of the α -thalassemia genes or their combinations can be identified with certainty without molecular studies.

Hemoglobin Constant Spring (α CS α /). Hb Constant Spring is due to an abnormal termination codon in an α -gene that results in an elongated α -chain with 31 extra amino acids. It is by far the most common of the elongated α -chain variants. Because of marked reduction in mRNA stability, the clinical phenotype of α -thalassemia is seen (Orkin, 1998). Similar to other nondeletional α^+ -thalassemia genes, it causes a more severe phenotype. The homozygous state appears as an asymptomatic, mild hemolytic anemia, with a Hb level of 9–11 g/dL. The red cell indices are unusual for thalassemia: The MCV is normal (88 fL) and the RBC is low (3.9 M/ μ L). Hemoglobin consists of 5%–8% Hb CS, normal Hb A₂, trace amounts of Hb Bart's, and the rest Hb A (Weatherall, 1994). Heterozygotes have a silent carrier phenotype with no hematologic abnormality and about 1% Hb CS. Abnormal Hb migrates more slowly than Hb A₂ at alkaline pH and is easily missed. Hb CS is common in Southeast Asia, where it is found in about 50% of cases of Hb H disease (α CS α /—).

Screening and Prenatal Diagnosis of Hemoglobin Disorders

In populations in which there is a significant incidence of severe forms of thalassemia or sickle cell anemia, women should be screened early in pregnancy for thalassemia and the sickle cell trait (Weatherall, 1985, 1994; Alter, 1988). If both parents are carriers, prevention of severe disease is possible through genetic counseling and offering prenatal diagnosis with the option of therapeutic abortion. In high-frequency regions, screening of school children or premarital counseling has been implemented. Initial tests include MCV (<80 fL), MCH (<27 pg), and HPLC to estimate Hb A₂ (>3.5%) and to detect common Hb variants (cutoff values are in parentheses). In prenatal diagnosis, fetal DNA analysis of chorionic villi replaced fetal blood analysis by the early 1990s.

HEMOLYSIS—METABOLIC DISORDERS

Deficient enzyme activity in the erythrocyte may result in abnormalities that lead to premature destruction and hemolytic anemia; these disorders are usually inherited. However, interference with, or oxidative stress on, erythrocyte metabolism can sometimes result in hemolysis in individuals who have normal erythrocytes.

Erythrocyte Metabolism

The mature red cell lacks mitochondria and, therefore, lacks oxidative phosphorylation and Krebs cycle activity. Energy production is mainly glycolytic, 90% of which occurs through the Embden-Meyerhof pathway, as glucose goes to lactic acid with the net production of 2 mol of adenosine triphosphate (ATP) (Fig. 32-30). ATP is needed for energy-requiring reactions in the cell: for active cation transport across the membrane, for maintaining membrane deformability, and for preserving the cell's biconcave shape. Glucose uptake by red cells is independent of insulin.

Approximately 90% of glucose is consumed in the glycolytic pathway, while 10% is utilized in the pentose phosphate pathway (hexose monophosphate [HMP] shunt). One step of the glycolytic pathway replenishes NADH (reducing agent derived from nicotinamide adenine dinucleotide [NAD]), which plays a major role in protecting Hb from oxidative stress. Most of the hemoglobin (methemoglobin) produced in the normal cell (about 3% of the total per day) is reduced by NAD-linked methemoglobin (Met Hb) reductase. The HMP shunt generates nicotinamide adenine dinucleotide phosphate (NADPH) in the first two steps through the enzymes G6PD and 6-phosphogluconate. NADPH production is linked to glutathione reduction and, through this mechanism, to preservation of vital enzymes and Hb from oxidation. Small amounts of oxidized hemoglobin (methemoglobin) are reduced by glutathione (GSH). The activity of the HMP shunt increases when the cell is exposed to an oxidant drug, probably as a result of increased NADP production. If an enzyme in this pathway lacks activity, GSH cannot be produced, and Hb will be oxidized by the oxidant stress. Oxidation in the red cells is mediated by high-energy derivatives of O₂, referred to collectively as activated O₂ (Prchal, 2000). Oxidized globin chains denature and precipitate as Heinz bodies, which adhere to the membrane, inducing rigidity and a tendency to lyse. Moderate enzyme deficiencies in this pathway (e.g., in G6PD) may not be associated with anemia under normal conditions; however, an acute hemolytic episode occurs if the cells are challenged by oxidant stress (e.g., drugs, infection).

Deficiencies in the Embden-Meyerhof pathway result in impaired ATP generation and a chronic hemolytic anemia. The mechanism of red cell destruction here is less clear. Heinz bodies are not formed. Lack of cell deformability and impaired cation pumping are important in the hemolytic process. However, ATP deficiency is difficult to demonstrate in many patients, and other disorders associated with more severe ATP deficiency are not associated with significant hemolysis (Prchal, 2000).

The Rapoport-Luebering shunt provides for the conversion of 1,3-diphosphoglycerate (1,3-DPG) to 2,3-DPG instead of directly to 3-phosphoglycerate (3-PG) (see Fig. 32-30). If this shunt is operating, generation of 2 mol of ATP (per mole of glucose) is bypassed; the result is no net energy production in glycolysis. However, 2,3-DPG combines with the β -chain of Hb and decreases the affinity of Hb for O₂. At a given pO₂, therefore, increased 2,3-DPG allows more O₂ to leave Hb and go to the tissues; the O₂ dissociation curve is shifted to the right. Increased activity of this shunt is apparently stimulated by hypoxia.

Glucose-6-Phosphate Dehydrogenase Deficiency

About 10% of male American blacks who were given the antimalarial drug primaquine during the Korean War developed a self-limited, acute hemolytic anemia (Beutler, 1994; Prchal, 2000). The relationship between antimalarial drugs and hemolysis had been observed earlier in the 1920s (Beutler, 1999). Only the older red cells were destroyed, and it was eventually determined that the deficiency in susceptible red cells was in G6PD. Reticulocytes have five times higher enzyme activity than the oldest erythrocyte population (Prchal, 2000). It has since been found that G6PD deficiency is widespread throughout the world. Among whites, the highest incidence is in Kurdish Jews; the deficiency is common in the Middle East, in Mediterranean countries, and in Asia. G6PD deficiency is the most common human enzyme defect and is present in more than 400 million people worldwide (Cappellini, 2008).

G6PD is present in all cells; however, its concentration varies in different tissues. In healthy red cells, the enzyme operates at only 1%–2% of its maximal potential, allowing for a large reserve of reductive potential (Cappellini, 2008). Because G6PD is determined by a gene on the X chromosome, full expression of the deficiency is found in the male hemizygote. Partial expression may be found in the heterozygous female, who has two populations of red cells—one normal and one deficient. The deficiency of G6PD limits the regeneration of NADPH, which renders the cell vulnerable to oxidative denaturation of Hb. Because, normally, G6PD is highest in young cells and decreases as the cell ages, in persons with G6PD deficiency, the older cells are preferentially destroyed.

Hemolytic susceptibility in affected persons can increase greatly during intercurrent illness or upon exposure to various drugs that have oxidant properties (Table 32-10).

The genetic heterogeneity is great, and approximately 400 biochemical variants have been defined. This genetic heterogeneity is expressed as variations in stability and the electrophoretic and catalytic properties of the enzymes, in the degree of deficiency, in the types of cells in the body affected, in the types of drugs that will produce hemolysis, and in susceptibility to chronic hemolysis or to neonatal jaundice. The most common

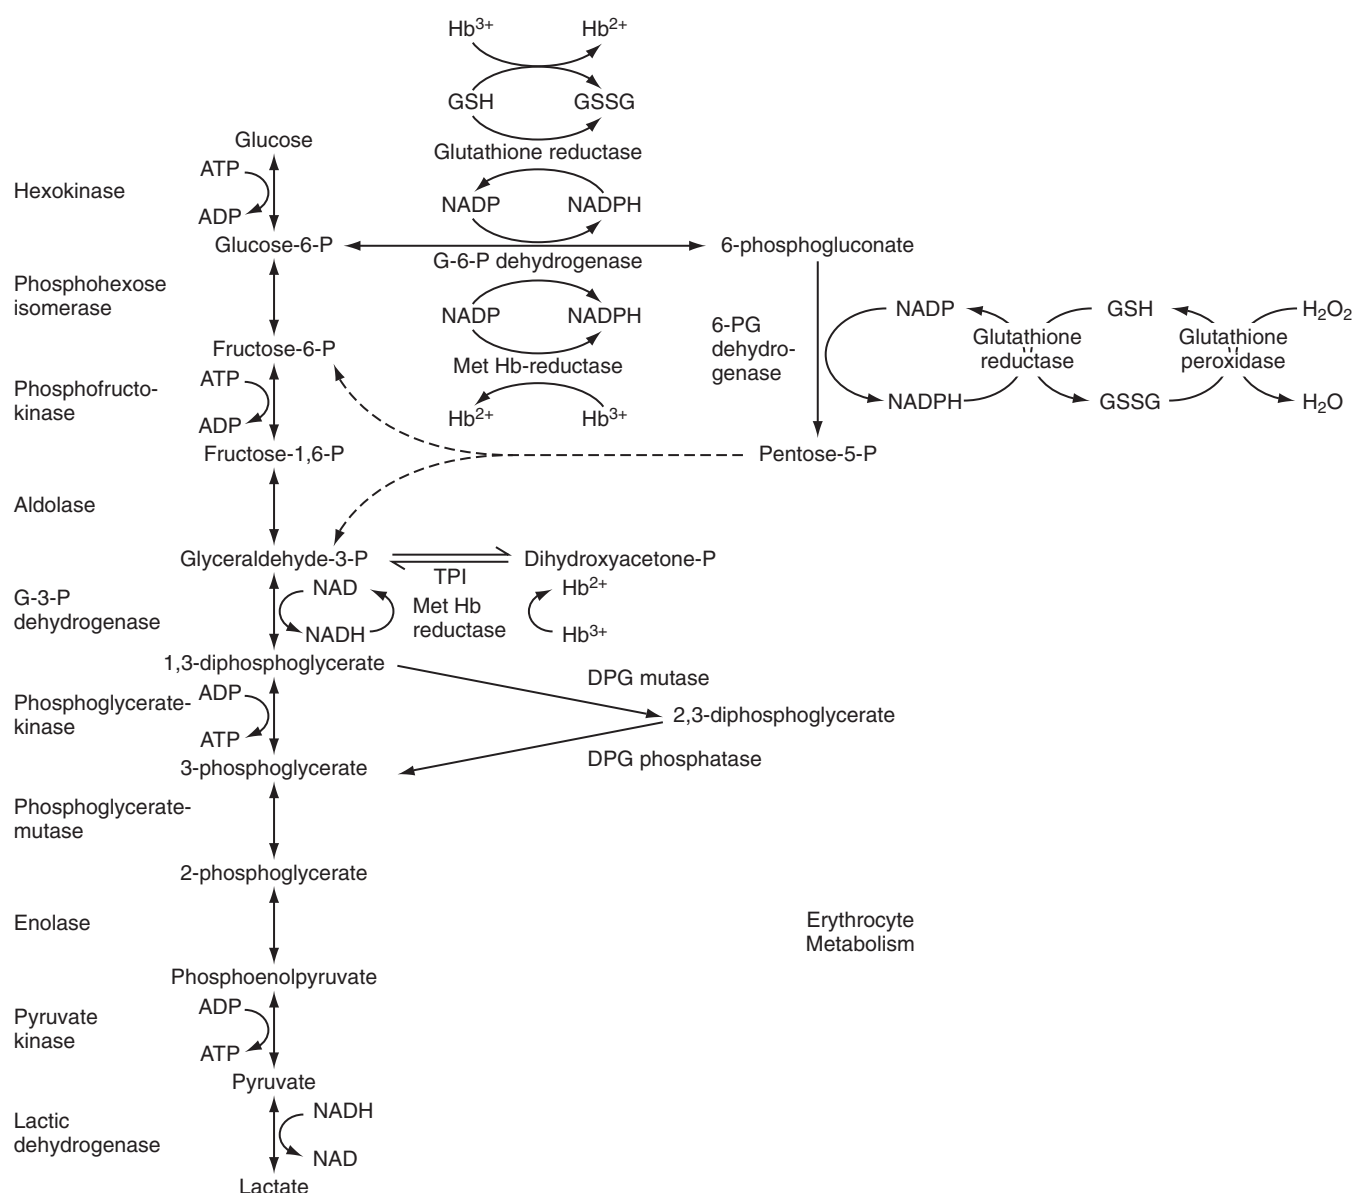

Figure 32-30 Erythrocyte metabolism is discussed in the text. Normally, most hemoglobin (methemoglobin, Hb³⁺) is reduced to hemoglobin (Hb²⁺) by nicotinamide adenine dinucleotide-linked methemoglobin reductase (NAD, Met Hb reductase). Nicotinamide adenine dinucleotide phosphate (NADP)-linked methemoglobin reductase requires methylene blue for activation and is more effective in drug-induced methemoglobinemia than the normal cell mechanism. GSH, Reduced glutathione; GSSG, oxidized glutathione.

("normal") G6PD isoenzyme in all population groups is designated as B. In blacks, an electrophoretically more rapid variant, A, is prevalent and has almost the same activity; 20% of black males have this variant. Eleven percent of black males have the A type of G6PD, which involves only 5%–15% of normal enzyme activity; it is these individuals who are susceptible to hemolysis after ingesting oxidant drugs or during infection. The most common variant in whites is G6PD-Mediterranean, found in Mediterranean populations; the level of enzyme activity in affected males is low—often less than 1%. These individuals usually are not anemic but may have somewhat more severe and non-self-limited hemolytic anemia with infection, and with a wider variety of drugs than the black variant. In a subgroup of G6PD-deficient subjects, severe hemolysis may occur within hours after eating fava beans ("favism"). Although the vast majority of G6PD-deficient subjects worldwide are not anemic, a small proportion of persons with G6PD-Mediterranean (and persons with some rarer variants) have a chronic nonspherocytic hemolytic anemia. G6PD deficiency is a common cause of neonatal jaundice, occurring in approximately one third of all male neonates with jaundice (Cappellini, 2008). Jaundice is usually evident by 1–4 days of age and is more severe in premature babies than in full-term infants.

Laboratory findings during active hemolysis are those of hemolytic anemia in general. In the blood film, one finds poikilocytes, some

spherocytes, bite cells, and irregularly contracted cells that stain densely and have contraction of Hb from a part of the cell membrane. These probably are cells from which Heinz bodies have been removed by the spleen. After supravital staining with methyl violet, Heinz bodies may be present early in an acute hemolytic episode. G6PD deficiency may be detected by one of the screening tests: the dye reduction test, the ascorbate cyanide test, or a fluorescent spot test. Confirmation is made with a quantitative assay.

Heinz Bodies

When a globin chain denatures, it forms precipitates that are known as Heinz bodies (Dacie, 1991). These precipitates cannot be detected in Romanowsky's-stained, air-dried blood films, but after vital staining with methyl violet or crystal violet, Heinz bodies stain deep purple. They vary from 1 to 4 μ m in diameter and often attach to the red cell membrane. They also stain, but less intensely, as pale blue inclusions in reticulocyte stains (e.g., new methylene blue) (Fig. 32-31).

The presence of Heinz bodies in freshly drawn blood indicates that (1) an oxidizing drug or chemical (e.g., phenylhydrazine, chlorate, naphthalene, dapsone) has been ingested in sufficient amount to overwhelm the normal protective mechanisms of the red cell and denature Hb; (2) a drug such as primaquine has been ingested by an individual with

TABLE 32-10

Drugs and Chemicals That Have Clearly Been Shown to Cause Clinically Significant Hemolytic Anemia in G6PD Deficiency

Acetanilid
Methylene blue
Nalidixic acid (NegGram)
Naphthalene
Niridazole (Ambilhar)
Nitrofurantoin (Furadantin)
Pamaquine
Pentaquine
Phenylhydrazine
Primaquine
Sulfacetamide
Sulfanilamide
Sulfamethoxazole (Gantanol)
Sulfapyridine
Thiazolesulfone
Toluidine blue
Trinitrotoluene (TNT)

G6PD, Glucose-6-phosphate dehydrogenase.

Figure 32-31 Heinz bodies. Normal red cells incubated with an oxidant drug and stained while in suspension with methyl violet; finally, an air-dried film was made and stained with Wright's stain. Purple-staining Heinz bodies are precipitates of denatured hemoglobin that tend to attach to the cell membrane.

G6PD deficiency (or another defect resulting in a deficiency of reduced glutathione), so that Hb is not protected from oxidative denaturation; or (3) the subject has an unstable Hb.

Ascorbate Cyanide Test

When blood is incubated with a solution of sodium cyanide and sodium ascorbate, hydrogen peroxide is generated from the coupled oxidation of ascorbate and oxyhemoglobin (Dacie, 1991). Cyanide inhibits catalase, hydrogen peroxide is available to oxidize Hb, and the brown color of methemoglobin is discernible. This occurs more rapidly in G6PD-deficient cells than in normal cells.

The ascorbate cyanide test is not specific, in that abnormalities in the glutathione synthesis or maintenance pathways can produce positive results.

Fluorescent Spot Test

Whole blood is added to a mixture of glucose-6-phosphate (G6P), NADP, saponin, and buffer, and a spot of this mixture is placed on filter paper and is observed for fluorescence with ultraviolet light. If G6PD is present, NADP is converted to NADPH. Because phosphogluconate dehydrogenase is present in most hemolysates, further NADP is converted to NADPH (see Fig. 32-30). NADPH fluoresces, but NADP does not. The normal control sample fluoresces brightly, and lack of fluorescence indicates G6PD deficiency. By reoxidizing any small amounts of NADPH formed, oxidized glutathione (GSSG) enhances the ability of the test to detect mild G6PD deficiency. This is the recommended screening test for G6PD deficiency (Beutler, 1979b).

Quantitative Assay of G6PD. For G6PD, most assays are based on the rate of reduction of NADP to NADPH, measured spectrometrically at 340 nm, when a hemolysate is incubated with G6P (Beutler, 1984). In heterozygotes or in acute hemolysis in black subjects with G6PD deficiency, the diagnosis may be obscured even with the assay, because of increased levels of G6PD in reticulocytes and younger erythrocytes. Usually, however, the ascorbate cyanide screening test will be positive in these instances.

Pyruvate Kinase (PK) Deficiency

The most common red cell enzyme deficiency involving the Embden-Meyerhof glycolytic pathway, PK deficiency results in mild to moderately severe nonspherocytic chronic hemolytic anemia with splenomegaly. The prevalence of PK deficiency is estimated to be 1:20,000 in the general white population (Zanella, 2005). The anemia may be detected in infancy, or not until adult life in milder cases. Neonatal jaundice occurs in more than half of cases, which may require exchange transfusion. Patients tend to tolerate the anemia rather well because of high levels of 2,3-DPG, which occur as a result of the block in glycolysis. The blood film may show no notable red cell abnormalities until after splenectomy, when echinocytes, irregularly contracted cells, and crenated red cells may be prominent. Reticulocyte counts are elevated and increase further after splenectomy.

PK isoenzymes are produced by two separate genes: one on chromosome 15, encoding the M (muscle) isoforms, and the other on chromosome 1, encoding the L (liver) and R (red cell) isoforms. The complexity of PK isoforms is further complicated by the fact that functional enzyme is a tetramer. Inheritance is autosomal recessive, but this is probably true only in consanguineous families. PK mutants are numerous and are not detected in phenotypically normal heterozygotes that have one half the normal PK activity. Most individuals with PK-deficient hemolytic anemias are therefore probably double heterozygotes for two mutant genes (Valentine, 1979). Acquired PK deficiency occurs occasionally in myelodysplastic disorders and leukemias (Valentine, 1979; Miwa, 1981).

The autohemolysis test gives variable results. Some patients show only a mild increase in autohemolysis that is partially prevented by glucose (type I), and others have a greater increase that is not prevented by glucose (type II). Heinz bodies are not found. The diagnosis is made by a specific screening test or enzyme assay.

The reticulocyte count in unsplenectomized patients is usually increased, although not proportional to the degree of anemia, because younger PK-deficient erythrocytes are selectively sequestered in the spleen (Zanella, 2005). Splenectomy is indicated in cases requiring transfusions. After splenectomy, the Hb concentration usually increases by 1–2 g/dL and the reticulocytes increase sharply, although hemolysis persists (Miwa, 1981).

Fluorescent Spot Test. Pyruvate kinase catalyzes the phosphorylation of adenosine diphosphate (ADP) to ATP by phosphoenolpyruvate (PEP) with the formation of pyruvate (Beutler, 1984). Pyruvate then reduces any NADH present to NAD with the formation of lactate (see Fig. 32-30). Loss of fluorescence of NADH under ultraviolet light is observed as evidence of the presence of PK.

Leukocytes must be removed from the sample because they normally contain about 300 times as much PK as red cells do, and in PK deficiency, the red cells but not the leukocytes are deficient.

Quantitative Assay of PK. The same principle is employed as in the screening test, but the rate of decrease of absorbance at 340 nm is measured. A negative screening test or a normal PK assay (using the standard high substrate [PEP] concentrations) does not rule out PK-deficient hemolytic anemia. Because mutant PK enzymes may have normal activity at high PEP concentrations and decreased activity at low PEP concentrations, it is necessary to perform the assay both ways (Beutler, 1984).

Other Glycolytic Enzyme Deficiencies

Other enzyme deficiencies in the **Embden-Meyerhof pathway** are rarer (Beutler, 1994; Prchal, 2000). When severe, they produce hemolytic anemia, with two exceptions: (1) LD deficiency has no clinical manifestations; and (2) deficiencies of 2,3-DPG mutase and 2,3-DPG phosphatase activities occur together and result in erythrocytosis as a result of lack of 2,3-DPG, shifting the O₂ dissociation curve of Hb to the left.

Other enzyme deficiencies in the **hexose monophosphate shunt** are rare. They include the two enzymes involved in glutathione synthesis: γ -glutamyl cysteine synthase and glutathione synthetase. As in G6PD deficiency, hemolysis increases with oxidant drug exposure or infection.

No good evidence is available, however, for the causation of chronic hemolytic anemia by 6-phosphogluconate deficiency, glutathione reductase (GR) deficiency, or glutathione peroxidase (GP_x) deficiency (Beutler, 1994). GR contains flavine-adenine dinucleotide and is often partially deficient because of dietary riboflavin deficiency. GP_x is one-half normal in about 30% of the Jewish population as a result of homozygosity for a gene with low GP_x activity; in addition, GP_x activity is dependent on selenium intake in the diet. In neither case is there an association with a hematologic disorder.

Pyrimidine-5'-Nucleotidase Deficiency

When RNA is degraded in the reticulocyte, pyrimidine nucleotides must be dephosphorylated by pyrimidine-5'-nucleotidase (PN) to cross the red cell membrane (Paglia, 1981). Autosomal recessive PN deficiency results in accumulation of pyrimidines, and the impaired degradation of RNA results in pronounced basophilic stippling in red cells on the blood film. This is probably one of the more common enzyme deficiencies responsible for nonspherocytic hereditary hemolytic anemia, once G6PD and PK deficiencies are excluded (Rees, 2003).

The disorder is characterized by mild to moderate chronic hemolysis, jaundice, reticulocytosis (≈10%), marked basophilic stippling (about 5% of the red cells), and splenomegaly without notable improvement after splenectomy. However, no cases of transfusion dependency associated with PN deficiency have been reported (Rees, 2003). A screening test compares the ultraviolet absorption of deproteinized extracts of red cells at 260 nm with that at 280 nm. In PN deficiency, the major absorption peak is shifted from the normal 260 nm to 280 nm, which is the maximum for the pyrimidines uridine diphosphate and cytidine diphosphate. Confirmation requires an assay showing decreased nucleotidase activity (Beutler, 1984).

Acquired PN deficiency occurs in lead poisoning and is probably responsible for the basophilic stippling in that condition. It has been also reported in β-thalassemia trait, acute leukemias, chronic myeloid leukemia, chronic lymphocytic leukemia, and lymphomas (Rees, 2003).

HEMOLYSIS—ACQUIRED; EXTRINSIC

Chemical Agents

Agents Hemolytic to Normal Cells

The action of chemical agents depends on the dose and on other factors, many of which are known only vaguely. They range from simple substances, such as water, to some that are highly complex. When used as irrigating fluid, distilled water may be found responsible for acute hemolytic anemia as a result of entry into venous channels during transurethral resection. Also, drowning in fresh water may be associated with red cell hemolysis, particularly in the lungs, although drowning in salt water could cause profound red cell hydration (Schrier, 2009).

In addition to anemia, some chemicals produce methemoglobinemia, which can manifest as cyanosis (toluene, trinitrotoluene, nitrobenzene, acetanilide, and phenacetin). Some may lead to AA (toluene and trinitrotoluene). Promin, a sulfone derivative, makes blood turn chocolate brown because of the formation of sulfhemoglobins. As mentioned earlier, ribavirin, a drug used in the treatment of hepatitis C virus infection, may produce a dose-dependent hemolytic anemia in about one third of patients.

Lead toxicity may produce progressive anemia, with basophilic stippling, reticulocytosis, normoblastemia, Cabot rings, Howell-Jolly bodies, and leukocytosis. Lead not only causes damage to the red cell and hemolysis, but also produces defects in the heme synthetic pathway. In cases of chronic exposure to lead, basophilic stippling, more in the marrow than in the peripheral blood, and coproporphyrinuria are the characteristic findings. These changes produce defective erythrocytes, which are removed by the spleen.

Agents Hemolytic to Abnormal Cells

Certain drugs and chemicals that have oxidizing activity may produce hemolytic anemia in individuals with G6PD deficiency or other defects resulting in glutathione deficiency. In addition, unstable hemoglobins, such as Hb Zürich, have a propensity for drug-induced hemolytic anemia. Premature infants, although they have high levels of G6PD, have glutathione instability and low levels of glutathione and may develop hemolytic anemia when given large doses of synthetic water-soluble analogs of vitamin K.

It must be remembered that, if exposure to these oxidant substances is great enough, acute hemolytic anemia may be produced in normal individuals.

During the acute hemolytic episode, Heinz bodies can be demonstrated frequently by direct staining of blood with methyl violet. Red cells with Heinz bodies are removed from the circulation by the spleen, or the Heinz bodies are extracted from the red cells by splenic action. Therefore, Heinz bodies may not be found in the blood if the spleen is effectively removing them, or after the acute hemolytic process has abated.

Tests for G6PD deficiency, the most common underlying cause of drug-sensitive hemolytic anemia, are described earlier in this chapter.

Physical Agents

Heat

Extensive burns produce hemolytic anemia, probably because of direct damage to red cells. Gross hemoglobinuria may occur in patients with severe burns. The blood film may show remarkable morphologic abnormalities of the red cells, including budding fragmentation of the membrane and microspherocytosis. The most severe abnormalities are often found immediately after extensive burns before a reticulocyte response has had time to develop. Badly damaged cells are rapidly removed from the circulation.

Traumatic Hemolysis

Hemolytic anemia characterized by striking morphologic abnormalities of the red cells, which include fragments (schistocytes) and irregularly contracted cells (triangular cells, helmet cells), has been attributed to physical trauma to the red cells. The basis of the hemolytic process is probably damage to the red cells in their contact with loose fibrin meshworks (intravascular coagulation) or with pathologic vascular lesions. Fragmentation of the cells results with or without intravascular lysis. Two general categories are recognized in this group of disorders, aptly termed the “red cell fragmentation syndrome”: macroangiopathic and microangiopathic.

Macroangiopathic Hemolytic Anemia (Cardiac Valvular Disease and Prostheses).

Chronic intravascular hemolysis associated with low serum haptoglobin, hemosiderinuria, reticulocytosis, and red cell abnormalities (e.g., schistocytes, irregularly contracted cells) may occur after surgical replacement of a diseased heart valve with a prosthesis or after surgical repair of a septal defect with a plastic patch (Erslev, 2001d). This has been attributed to mechanical damage of red cells in the turbulent environment of a leaky valve or of a roughened surface uncovered by endothelial cells. Repair of the valve or coverage of the patch by endothelium has improved the hemolytic process. Other studies have shown that some patients with cardiac valvular disease have a hemolytic process that may be altered by surgery.

External mechanical trauma has been reported in **march hemoglobinuria**, a condition that is seen in soldiers after a long march and in joggers and other athletes following long practices, particularly on hard surfaces. In this condition, anemia and reticulocytosis are uncommon. The chronic intravascular hemolysis may lead to iron deficiency as a result of loss of Hb in the urine.

Thrombotic Microangiopathy (Microangiopathic Hemolytic Anemia).

Thrombotic microangiopathies (TMAs) are microvascular occlusive disorders characterized by systemic or intrarenal aggregation of platelets, thrombocytopenia, and mechanical injury to erythrocytes. Fragmented red cells (e.g., schistocytes, irregularly contracted cells) are probably produced when blood flows through turbulent areas in the microcirculation that are partially occluded by platelet aggregates (Moake, 2002). TMA may be idiopathic or precipitated by drugs such as mitomycin C, transplantation, malignancy, pregnancy, collagen vascular disease, or HIV (Ahmed, 2002).

The classification of TMA has been controversial for many years. In routine clinical practice, the term thrombotic thrombocytopenic purpura (TTP) is often used for adult cases with predominant neurologic symptoms, whereas the term hemolytic-uremic syndrome (HUS) has been used to describe childhood cases with thrombotic microangiopathy and predominant renal involvement (Moake, 2002). However, the distinction is not always possible, and overlapping symptoms may be observed. Authors suggested the inclusion of both entities under TTP/HUS, presuming a similar pathogenetic mechanism with variable organ tropism. Others group sporadic cases of HUS with TTP under idiopathic TMA and separate most cases of HUS under toxin-associated TMA (Ahmed, 2002).

Recent studies indicate a difference in pathogenetic mechanisms between HUS and TTP, as discussed later.

Hemolytic-Uremic Syndrome

HUS is classified into diarrhea-associated (D+) or typical form, and diarrhea-negative (D-) or atypical form. D+ HUS constitutes approximately 95% of cases in children and is less common in adults (Zheng, 2008). D+ HUS occurs most commonly in infants younger than 2 years of age, but it affects all ages. It is caused by one of several serotypes of *Escherichia coli* that produce a verotoxin (named for its toxicity against African green monkey kidney [vero] cells). The most common is *E. coli* O157:H7, which produces Shiga toxins 1 and 2. The annual incidence of infection with *E. coli* O157 is approximately 8 per 100,000 people in North America. The percentage of cases with bloody diarrhea that progress to HUS is 3%–7% for sporadic cases and 20%–30% for some outbreaks (Zheng, 2008). HUS usually occurs 4–6 days after the onset of diarrhea. Shiga toxins cause bloody diarrhea, then enter the circulation and travel in the plasma on the surface of platelets or monocytes (Moake, 2002). Recent studies suggest that these toxins become attached to glomerular capillary endothelium and other renal epithelial cells. Shiga toxins, together with locally secreted cytokines, cause the release of unusually large multimers of von Willebrand factor (vWF), which promote platelet aggregation in renal vasculature (Moake, 2002). Endothelial cell damage is the hallmark of D+ HUS in children, and endothelial swelling may be severe enough to occlude the capillary lumen. The thrombi of D+ HUS are composed predominantly of fibrin with few platelets and little vWF (Zheng, 2008). Hemolytic anemia with schistocytes (due to interaction of red cells with microvascular thrombotic lesions), variable thrombocytopenia, and uremia are the cardinal features. Death formerly occurred in almost half of cases; the renal pathology has included acute glomerulonephritis and thrombotic and necrotic vascular lesions associated with patchy, bilateral renal cortical necrosis. With supportive therapy, including transfusions and dialysis, some investigators have reported mortality reduced to 5%–15%. Nonetheless, minor to major renal impairment has been reported in approximately 50% of patients. Five to ten percent of patients with HUS have D- HUS, with no antecedent diarrhea of Shiga-toxin-producing organisms, and some of these patients have familial history of the disease (Zheng, 2008). Approximately 50% of patients with D- HUS have mutations in one of the complement regulatory proteins: factor H, factor I, membrane cofactor protein (MCP), or factor B. These patients have a much higher mortality rate (Moake, 2002). Approximately 5% of D- HUS patients have antibodies against factor H, raising the possibility of using plasma exchange or immunosuppressants for therapeutic strategy (Zheng, 2008).

Thrombotic Thrombocytopenic Purpura (TTP)

TTP may occur at any age but has a peak incidence in the third decade; it occurs more often in females than in males. The annual incidence is 3.7 cases per 100,000 (Ahmed, 2002). The triad of clinical manifestations present in most patients includes hemolytic anemia, thrombocytopenia, and neurologic symptoms; in addition, fever and renal diseases are often present. This constitutes the classic pentad. Pathologically, microvascular occlusive lesions with hyaline thrombi and endothelial proliferation are widespread throughout the body. Until 1997, the origin was unknown. Different theories included endothelial injury by oxidant stress, antiendothelial antibodies, anti-CD36 (glycoprotein IV located on microvasculature) antibodies, platelet aggregating factors, and release of large vWF multimers into the plasma. In 1996, a protease that cleaves vWF subunits was identified in normal plasma. In 1997 and the following years, several reports indicated deficient vWF-cleaving protease in patients with TTP due to low enzyme levels (in familial cases) or to the presence of IgG enzyme inhibitor (in nonfamilial cases). These observations were confirmed by additional studies, which showed normal levels of vWF-cleaving protease in HUS (Moake, 2004). The enzyme has been further characterized as number 13 in a family of 19 distinct ADAMTS-type enzymes identified to date (*a* disintegrin and metalloprotease with eight thrombospondin-1-like domains). Therefore, the vWF-cleaving metalloprotease is now referred to as ADAMTS13 (Moake, 2004). In the absence of vWF-cleaving protease, ultra-large vWF multimers secreted by endothelial cells would not be processed normally. These highly adhesive multimers may induce platelet clumping in the microcirculation under shear stress, resulting in the clinical manifestation of TTP. The disease is acute and until the 1980s was fatal in well over half of cases. With the therapy of plasma exchange by plasmapheresis and plasma transfusions (in addition to platelet inhibitors), the remission rate has improved, and long-term survival now approaches 90% (Moake, 2004). TTP can now be classified

into three main categories: familial, idiopathic, and secondary. The familial form (Upshaw-Schulman syndrome) results from a mutation in the *ADAMTS13* gene and is associated with a very low activity of the enzyme. More than 50 mutations have been described to date. Approximately 50% of patients with familial TTP experience their first episode during childhood, and exacerbations may occur in association with minor infections (Zheng, 2008). The idiopathic form is caused by antibodies to ADAMTS13. The secondary form may occur along the course of other conditions, such as malignancies, hematopoietic stem cell transplantation, chemotherapy, infection, and certain medications, such as cyclosporine, quinine, ticlopidine, and clopidogrel. The mechanism of TTP under these circumstances is unknown, although direct endothelial cytotoxicity and drug-induced autoimmunity are possible mechanisms (Zheng, 2008).

Preeclampsia/Eclampsia

Preeclampsia and eclampsia are microangiopathic disorders occurring with pregnancy and sharing some features of HUS or TTP. Approximately 4% to 39% of patients with severe preeclampsia develop HELLP syndrome: hemolysis, elevated liver enzymes and low platelet count. The syndrome becomes manifest usually during the third trimester, although some patients may develop it during the postpartum period. Most patients recover within a few days after delivery. In a small subset of patients, severe persistent multisystem disease requires plasma exchange (McMinn, 2001).

Infectious Agents

Destruction of erythrocytes by plasmodia is responsible for the anemia in malaria. This is supported by the observation that the osmotic and mechanical fragility of parasitized erythrocytes is increased. Inhibition of marrow activity may be an additional factor. Fulminant hemoglobinuria (blackwater fever) is a complication of *P. falciparum* malaria.

Oroya fever, a frequently fatal disease that occurs in Peru, is characterized by a hemolytic anemia and leukocytosis. *Bartonella bacilliformis* is the responsible agent.

Babesiosis, a protozoan infection transmitted by ticks from rodents or cattle, is associated with hemolysis; parasites may be seen in red cells in Romanowsky's-stained blood films.

Hemolytic anemia with cold agglutinins may complicate mycoplasmal pneumonia and infectious mononucleosis. This is due to the effect of antibody on the red cells.

Hemolytic anemia of varying severity is frequent in some bacterial infections. A notable example is *Clostridium perfringens* septicemia following septic abortion or biliary tract surgery, which may be accompanied by a dramatic and life-threatening hemolytic crisis.

Immune Hemolytic Anemias

Immune hemolytic anemias are disorders in which erythrocyte survival is reduced because of the deposition of immune globulin and/or complement on the red cell membrane. The immune hemolytic anemias can be grouped according to the presence of autoantibodies, alloantibodies, or drug-related antibodies (Table 32-11).

Autoimmune Hemolytic Anemia

The autoimmune hemolytic anemias (AIHAs) are due to an altered immune response, resulting in the production of antibody against the host's own erythrocytes, with subsequent hemolysis. The incidence of AIHA is estimated at 10–30 cases per 1 million population (Gehrs, 2002).

TABLE 32-11

Classification of Immune Hemolytic Anemias

Autoimmune hemolytic anemias
Associated with warm antibodies
Associated with cold antibodies
Combined warm and cold antibodies
Alloimmune hemolytic anemias
Transfusion-associated hemolytic anemia
Hemolytic disease of newborn
Rh incompatibility
ABO incompatibility
Drug-induced hemolytic anemia
Drug adsorption
Autoantibody induction
Neoantigen formation

CHAD, Cold hemagglutinin disease; PCH, paroxysmal cold hemoglobinuria.

*Numbers in parentheses are percentages.

The AIHAs can be classified according to serologic or clinical characteristics (Table 32-12). Some AIHAs are mediated by antibodies with maximum binding affinity at 37° C, and other AIHAs are mediated by antibodies with maximum binding affinity at 4° C. In addition, AIHAs could be viewed according to their association with other disorders. In a study of 1834 patients, approximately 40% of cases of AIHA have been associated with an underlying disease, while the remainder were idiopathic (Sokol, 1992). Lymphoproliferative disorders account for approximately half of cases of both warm and cold AIHA (Gehrs, 2002).

Etiology and Pathophysiology. The cause of the production of autoantibody in patients with AIHA is unknown. However, several mechanisms have been suggested. Autoimmune antibodies, particularly cold-reacting antibodies, are sometimes produced following an infection. This is typically seen with the elaboration of anti-I in patients with *Mycoplasma pneumoniae* infections and anti-i in patients with infectious mononucleosis. The cold agglutinins of anti-I and anti-i specificity are strikingly similar to one another in the structure of antigen binding sites. These antibodies react with antibodies that also identify the product of the *VH4-34* gene segment in B-cells. It has been hypothesized that infections can cause the production of antibodies of B cell, utilizing this gene segment. These antibodies will also have cold agglutinins activity against the I/i antigens (Rosse, 2004).

The amount of antibody, its avidity for the erythrocyte autoantigen, and its ability to fix complement are significant variables. Opsonization of red cells can destroy them in the circulation (intravascular hemolysis) or can cause their accelerated removal from the circulation by tissue macrophages (extravascular hemolysis). Major sites for these macrophages are the spleen and, to a lesser extent, the liver (Gehrs, 2002).

The development of AIHA in patients with lymphoproliferative disorders or with autoimmune disorders may relate to some abnormality with B cells, T cells, or macrophages, or the interaction among these cells. Perhaps loss of T cell suppressor function could result in unrestrained production of red cell antibody by B cells. This hypothesis is strengthened by the observation that methyl dopa, a drug known to cause the development of anti-red cell antibodies, inhibits the activation of suppressor T lymphocytes (Gehrs, 2002).

In AIHA associated with warm-type antibody, there is IgG coating of erythrocytes with or without complement fixation. Clearance of red cells

occurs mostly in the spleen. In the absence of complement fixation, it appears that the Fc portion of the red cell-bound IgG interacts with the Fc receptor present on the membrane of splenic macrophages located along the cords of Billroth. Thus, sensitized erythrocytes are retained, phagocytosed, or fragmented by splenic macrophages during their passage through the spleen.

In AIHA associated with the production of cold-type autoantibody, erythrocytes are usually coated with IgM. Under these circumstances, the fixation of complement frequently occurs. In paroxysmal cold hemoglobinuria, the offending antibody is an IgG that fixes complement. If the entire complement sequence is activated, there may be intravascular hemolysis. This phenomenon may occur in cases of cold hemagglutinin disease, as well as in paroxysmal cold hemoglobinuria. If complement activation fails to proceed to completion but is halted at an intermediate stage, intravascular lysis of the erythrocytes may not occur. However, extravascular hemolysis can still continue. In this situation, sensitized cells with C3b on the membrane are bound in the liver by the interaction of C3b and its receptors on Kupffer's cells. Erythrocytes may be phagocytosed entirely, or portions of the cells may be removed, resulting in fragmentation and spherocyte formation.

Approximately 7% of patients with AIHA satisfy diagnostic criteria for both warm and cold autoantibodies (Sokol, 1992). In these cases, IgG and C3d sensitize the erythrocytes. The serum contains IgM cold autohemagglutinins (optimally reactive at 4° C, but with a high thermal amplitude to 37° C) and IgG warm autoantibodies.

AIHA Associated With Warm Antibody. The warm antibody type of AIHA is slightly more frequent in females than in males and is most likely to occur in individuals 40 years or older; peak incidence occurs around the seventh decade. This age distribution may be related to the higher frequency of lymphoproliferative disorders with age (Packman, 2008). Idiopathic warm-antibody AIHA accounts for approximately 50% of cases. Chronic lymphocytic leukemia and lymphomas account for about half of secondary warm-antibody AIHA, and autoimmune disorders, such as SLE, account for most of the remaining cases (Packman, 2008). Clinical signs and symptoms frequently are those of an underlying disorder. However, the patient with idiopathic AIHA may have noted the presence of a mild upper respiratory tract infection just before the onset of hemolysis. As the disorder progresses, weakness, dizziness, and fever may be noted. Jaundice can be a presenting complaint. Pregnancy carries a fivefold risk of developing autoantibodies compared with the control population (Gehrs, 2002).

Laboratory findings include the presence of moderate to severe anemia. The neutrophil count may be increased. In a small proportion of cases, thrombocytopenia can exist. The peripheral film frequently shows spherocytosis, red cell fragmentation, polychromasia, and a few normoblasts. Reticulocyte percentage is high in approximately 50% of patients and is often associated with increased MCV. However, as many as one third of patients have transient reticulocytopenia, despite the presence of normal or hyperplastic erythroid precursors in the marrow (Packman, 2008). The lack of reticulocytosis should not keep one from making a diagnosis of AIHA. The bone marrow exhibits normoblastic erythroid hyperplasia, sometimes with mild megaloblastic changes.

There is usually a decrease in serum haptoglobin and an increase in unconjugated bilirubin and LD. The osmotic fragility and autohemolysis test can be normal or abnormal.

Direct and indirect antiglobulin tests indicate the presence of erythrocyte antibodies. The specificity of the autoantibodies is usually directed against antigens of the Rh system, membrane protein band 3 and band 4.1, and glycophorin A. However, activity against U, LW, Kell, jk^a, and Fy^a antigens may also occur. The warm antibody is most likely an IgG with subclass IgG1 and less frequently with IgG3. When IgG2 or IgG4 is present on the red cells alone, no hemolytic reaction is associated (Packman, 2001a). Occasionally, the antibody may be an IgA immune globulin, or rarely an IgM immune globulin. Complement may be detected on the erythrocyte membrane in slightly more than half of cases. Although many warm antibodies fix complement, intravascular complement-mediated hemolysis and hemoglobinuria are unusual, possibly because of the ability of complement regulatory proteins in plasma and on red cell surfaces to abort fixation of terminal complement components (Packman, 2008).

In some cases, sensitized red cells contain less immune globulin than can be detected using commercially prepared antiglobulins, which are normally sensitive to 250 to 500 molecules of IgG per red cell (Gilliland, 1976). Under these circumstances, the autoantibody at times can be detected with an antiglobulin consumption test.

The clinical course of AIHA associated with warm antibody is characterized by periods of remission and relapse. In secondary AIHA, the course and prognosis are related to the nature of the underlying disorder. In idiopathic AIHA, complications of the hemolytic disorder may be severe, leading to the demise of the patient. Pulmonary emboli, infection, and cardiovascular collapse are causes of death, and deep vein thrombosis and splenic infarcts are common complications during active hemolysis (Packman, 2008).

AIHA Associated With Cold Antibody. AIHA associated with cold antibody can be mediated by an IgM and less frequently by an IgG. The IgM autoantibody is associated with a syndrome known as cold agglutinin disease, whereas the IgG autoantibody is seen with paroxysmal cold hemoglobinuria.

Cold Agglutinin Disease

Cold agglutinin disease occurs in individuals usually over the age of 50 years and in females more often than in males. In some cases, cold agglutinin disease is associated with a lymphoproliferative disorder or infection (especially with *M. pneumoniae* or infectious mononucleosis). Cases unassociated with an underlying disorder are listed as idiopathic. Virtually all sera from healthy individuals contain low-titer cold agglutinins, regarded as benign or harmless, and are polyclonal. Postinfectious cold agglutinins are usually polyclonal. By contrast, monoclonal cold agglutinins are generally pathogenic and may arise from B cell lymphoma (Gehrs, 2002). Cold agglutinin disease represents approximately 20% of AIHA.

Symptoms and signs vary widely. Some individuals may complain of acrocyanosis or Raynaud's phenomenon. Others will have episodes of hemolysis, including hemoglobinuria, following exposure to cold. Temperatures of 30° C and lower are normally attained in the superficial skin vessels of those body parts exposed to cold. The thermal range of the antibody is clinically more important than the agglutination titer (Petz, 2008).

Laboratory findings usually indicate an anemia. Spherocytes and polychromatophilic erythrocytes are present to a variable degree in the blood film. There may be marked red cell agglutination, which should be differentiated from rouleaux formation (see Figs. 30-25 and 30-26). A mild leukocytosis can exist. Red cell agglutination may interfere with automated hematology counts, particularly MCHC, which tends to be high.

The cold antibody is usually an IgM with anti-I or, less frequently anti-i, specificity. Rarely do other specificities exist. In the chronic idiopathic form of cold agglutinin disease, the antibody tends to be monoclonal IgM, *k* with anti-I specificity (Gehrs, 2002). The autoantibody is also capable of fixing complement. When the titer of cold antibody is very high, the thermal range of antibody activity may extend up to 37° C. The direct antiglobulin test is positive only if the reagents contain anticomplement activity. Thus, one usually observes a positive antiglobulin reaction with broad-spectrum and non- γ -reagents, but no agglutination with only the γ -reagent. On cold exposure and antibody binding to red cells, the complement may be activated to the stage of C3b, which adheres to the red cells after entering the systemic circulation. In the hepatic circulation, macrophages carry specific receptors for C3b. However, cells usually escape hepatic destruction. Most patients experience chronic mild to moderate anemia, which they tolerate well, and patient outcome is significantly better than with warm-antibody AIHA (Petz, 2008). Some authors remain with the opinion that chronic cold agglutinin disease is a variant of Waldenström's macroglobulinemia in which the IgM M-component has cold agglutinin activity.

Paroxysmal Cold Hemoglobinuria

Paroxysmal cold hemoglobinuria is a very rare disorder that can occur in an individual of any age. However, more cases are now being reported in young children (Petz, 2008). Females are as frequently involved as males. Patients have symptoms of acute hemolysis following exposure to the cold. Chills, fever, pain in the back and legs, and hemoglobinuria are reported. The acute form may follow an acute upper respiratory illness or immunization by 1–2 weeks, but the chronic form is associated with congenital syphilis. Hemoglobinuria following exposure to cold is rare in the acute form.

Laboratory features consist of anemia, elevated reticulocyte count, increased concentration of indirect bilirubin, and the presence of Hb in the urine. Anemia is frequently severe and rapidly progressive.

The serum contains a cold hemolysin with biphasic activity. This antibody, first described by Donath and Landsteiner (1904), is an IgG that fixes the first components of complement (C1–C4) in the cold (4° C). As

the temperature rises to 25°–37° C, the antibody dissociates, but the remainder of the complement proteins are activated, and erythrocyte lysis results; this biphasic hemolysis is the basis for the Donath-Landsteiner autohemolysis test for the diagnosis of this condition. The direct antiglobulin test is positive with anti-C3 but is generally negative with anti-IgG unless performed at colder temperature. The specificity of the antibody is directed against the P antigen. In general, the prognosis is good.

AIHA Associated With Warm and Cold Antibodies

AIHA associated with both warm and cold autoantibodies is mediated by IgG warm antibodies and complement, as well as IgM cold hemagglutinins. Females are more likely involved than males. There appears to be an association between the combined warm and cold antibody AIHA and SLE in that 15%–42% of patients have SLE (Shulman, 1985; Sokol, 1985). In one study (Shulman, 1985), 6 of 12 patients (50%) had idiopathic AIHA, and 4 of these (33%) had concomitant thrombocytopenia (Evans' syndrome); all 12 patients had severe hemolysis that responded dramatically to corticosteroid therapy.

Alloimmune Hemolytic Disease of the Newborn

Alloimmune hemolytic disease of the newborn (HDN) usually occurs following the transplacental passage of maternal antifetal red cell antibodies. HDN most frequently results from incompatibility in Rh and ABO erythrocyte antigens between mother and fetus. In rare cases, some other red cell antigen may be responsible for this disorder.

In HDN due to **Rh incompatibility**, prior sensitization is necessary to initiate the disease process. This sensitization usually occurs during pregnancy when Rh(D)-positive fetal red cells cross the placenta and enter the circulation of a mother with Rh-negative cells. Most women have less than 1 mL of fetal blood in their circulation following delivery. However, intrapartum fetomaternal hemorrhage of more than 30 mL occurs in approximately 1% of pregnancies (Ramaseth, 2001). Maternal sensitization can also occur by a previous incompatible transfusion. Under either of these circumstances, maternal IgG antibodies are produced against the fetal cells. If a subsequent pregnancy occurs in a sensitized mother, fetal erythrocytes again reach the maternal circulation and restimulate an antibody response, resulting in transfer of anti-Rh(D) antibody across the placenta and reduced fetal red cell survival.

In the **ABO system**, anti-A or anti-B antibodies of the IgG class may arise spontaneously in the mother; their presence does not require prior transfusion or pregnancy. As a result, first-born children may suffer from HDN when ABO incompatibility exists. Although ABO incompatibility occurs in 15% of group O pregnancies, ABO hemolytic disease is estimated to occur in only 3% of all births (Ramaseth, 2001).

The clinical features of HDN due to Rh incompatibility vary greatly. Some newborns experience only mild jaundice. Others initially appear markedly pale and then develop jaundice. They can have prominent hepatosplenomegaly. The disease may be complicated by a bleeding diathesis, marked acid-base abnormalities, and kernicterus. In very severe cases, patients can present with hydrops fetalis.

Early examination of the blood usually reveals an increase in nucleated erythrocytes, which may include forms as immature as pronormoblasts. Although this finding gave the disease its name, **erythroblastosis fetalis**, erythroblastosis is not always present, especially if the examination is not performed immediately after birth.

Up to 2.0×10^9 nucleated red cells per liter in term infants and up to 5.0×10^9 /L in premature infants are commonly seen in this disorder. Normally, nucleated red cells average 0.5×10^9 /L in term infants and 1.0 – 1.5×10^9 /L in premature infants. Blood from the umbilical vein for early examination is more reliable than peripheral (capillary) blood because the erythrocyte count and the Hb may be significantly altered between birth and ligation of the cord.

Generally, there is macrocytic anemia of varying severity and an increase in reticulocytes. Occasionally, anemia may develop suddenly on the second or third day. The leukocyte count is frequently elevated, with immature leukocytes. Normoblastic hyperplasia of the marrow is pronounced.

In severely affected infants, thrombocytopenia, depression of prothrombin complex procoagulants, or diffuse intravascular coagulation may occur.

A direct antiglobulin test on fetal erythrocytes indicates the presence of an IgG antibody. When the maternal serum and an eluate from the fetal erythrocytes are incubated separately with a panel of O cells, one can usually demonstrate the presence of antibody with Rh(D) specificity. In

Rh-negative pregnant women known to be sensitized to Rh(D), the titer of anti-Rh(D) antibody is measured periodically during pregnancy to serve as a guide for performing amniocentesis.

HDN associated with **ABO incompatibility** is less severe than that observed with Rh incompatibility. Occasionally, the diagnosis is suggested by the presence of unexplained hyperbilirubinemia in a group A or B newborn infant from a group O mother.

Laboratory findings usually show a mild anemia and modest reticulocytosis. In contrast to Rh isoimmune disease, spherocytosis in ABO isoimmune disease may be prominent. However, there may be no anemia. Fetal cells are usually weakly positive with the antiglobulin reagents. Serum from the newborn and eluates from the cells should contain anti-A or anti-B antibody. In addition, maternal serum should contain high titers of anti-A or anti-B antibodies of the IgG subclass.

Drug-Induced Immune Hemolytic Anemia

Immune hemolytic anemia may occur following the administration of drugs. Most cases in the 1970s were associated with methyldopa or high-dose intravenous penicillin therapy. Recently, this picture has changed, with second- and third-generation cephalosporins being the most common causative agent and accounting for more than 80% of drug-induced immune hemolytic anemia (Garratty, 2007). Four mechanisms appear to mediate immune hemolysis (Packman, 2001b).

Formation of Ternary Complexes (Neoantigen Formation).

Numerous drugs are known to weakly bind to red cell membrane, even when given in small doses (Table 32-13). Antibodies recognize the combined drug and red cell membrane components as antigen and bind to them, forming a ternary complex. The drug-induced antibody is usually IgM and tends to fix complement, resulting in lysis of cells. In addition, red cells may be sequestered in the liver and spleen because of their coating with C3b.

Patients present with acute intravascular hemolysis, hemoglobinemia, and hemoglobinuria. The direct antiglobulin reaction is positive if the reagents contain anticomplement activity. The reaction usually is negative with the γ -reagent because it contains little anti-IgM or complement specificity.

The diagnosis can be determined by incubating the patient's serum with the offending drug in the presence of target erythrocytes, while observing agglutination, lysis, or sensitization of the erythrocytes.

Adsorption of Drug to Red Cell Membrane. Penicillin and cephalosporin, particularly in high doses, bind firmly to proteins, including red cell membrane. These drugs induce an antibody response to them, but the antibody specificity is not directed against a red cell membrane. Both IgM and IgG antibodies are made, but only the IgG antibodies are associated with immune hemolysis. Complement is not involved. The erythrocytes, coated with IgG antibody, are presumably removed via the Fc receptors on macrophages in the spleen.

The direct antiglobulin test is strongly positive. Antibody eluted from patients' erythrocytes will react only with red cells previously treated with penicillin or cephalosporins.

Induction of Autoantibody by Drugs. In approximately 15% of patients using the antihypertensive drug methyldopa, a positive direct antiglobulin reaction is present. The antibody is of the IgG class and in some studies appears to have Rh specificity (Packman, 2001b). The actual mechanism of autoantibody production is not known. However, it has been hypothesized that methyldopa causes activation of T cells and increased secretion of γ -IFN, which upregulates MHC class I and class II molecules on antigen-presenting cells and induces antibody production by B cells (Baier, 1994).

Development of the positive antiglobulin reaction occurs after a lag period of 3–6 months and is dose dependent. Thirty-six percent of patients have a positive antiglobulin reaction when consuming 2 g or more of methyldopa per day, and 11% have a positive reaction when taking only 1 g daily. An immune hemolytic anemia occurs in less than 1% of patients and is not dose dependent. Methyldopa also decreases mononuclear phagocytic activity, which may explain the rarity of hemolytic anemia despite the common presence of autoantibodies (Sokol, 1992). Levodopa, procainamide, fludarabine, and mefenamic acid are additional drugs that have been reported to cause an AHA in a fashion similar to methyldopa.

Nonimmunologic Adsorption of Immunoglobulins to Red Cell Membrane.

Drugs such as cephalosporins and cisplatin appear to alter the erythrocyte membrane, resulting in the nonspecific adsorption of plasma protein to its surface. As a result, IgG and IgM may be loosely bound to red cell membrane. This phenomenon can then cause a positive direct antiglobulin reaction. It is now believed that this mechanism can cause hemolytic anemia (Garratty, 2007).

LABORATORY DIAGNOSIS OF ANEMIA

The diagnosis and study of anemia require the proper use and interpretation of laboratory measurements. Prerequisites for the efficient use of the laboratory are a careful history and physical examination, both of which lead to initial laboratory measurements and provide important guidance in determining the nature of the anemia.

Whether the patient is anemic can be ascertained by determining whether the Hb, Hct, or erythrocyte count lies below (1) the reference intervals for age and sex, or (2) the patient's previous values, even though these are within the reference intervals. The task then is to define the underlying cause or mechanism for the anemia.

Usually, complete blood count (WBC, RBC, Hb, Hct, MCV, MCH, MCHC) and examination of a Wright's-stained film are parts of the routine examination of blood. It is possible that all these values could be normal in the presence of a mild macrocytic anemia, in which the RBC count does not fall below the normal range and the macrocytes present (and detectable on the blood film) do not elevate the MCV above the normal range.

Once anemia is discovered, the basic examination of the blood should include the following: (1) Hb, Hct, RBC count, and erythrocyte indices; (2) blood film examination; (3) leukocyte count; (4) platelet count; and (5) reticulocyte count.

With current multichannel instruments, all red cell values and their indices have comparable precision. Indices are **mean** values, however, and will not detect different populations of cells that balance each other. For example, combined deficiencies of folate and iron may give rise to populations of macrocytic and hypochromic microcytic cells, which could yield normal indices. Careful examination of the blood film is essential, and red cell volume RDW is very useful in defining this type of abnormality (see Chapter 30).

The size of the erythrocytes, determined by the MCV and by examination of the blood film, will determine the morphologic type of anemia. In addition, certain findings on the blood film will suggest mechanisms that are involved.

Increased numbers of **polychromatic** macrocytes, with or without normoblasts, suggest increased erythropoiesis, and in the untreated patient, this is usually due to hemorrhage or hemolysis. In this situation, the history (of blood loss) or physical examination (jaundice or splenomegaly) will help.

Findings suggestive of hemolysis are **poikilocytes** (abnormally shaped red cells), **sickle cells**, **irregularly contracted forms** (including red cell fragments or schistocytes), and **spherocytes**. Sometimes it is difficult to detect spherocytes in HS because of minimal anisocytosis. Morphologic findings in red cells that are helpful in this situation include the presence of a low MCD (mean cell diameter), between 6.0 and 6.5 μm (normal =

TABLE 32-13
Examples of Drugs Implicated in Causing Immune Hemolytic Anemia and Their Mechanism of Action

Drug Adsorption Mechanism	
Penicillins	Cephalosporins
Tetracyclines	Tolbutamide
Ternary Complex Mechanism	
Stibophen	Quinidine
Quinine	Cephalosporins
Rifampicin	Diethylstilbestrol
Chlorpropamide	Amphotericin B
Autoantibody Mechanism	
α -Methyldopa	L-Dopa
Procainamide	Cephalosporins
Mefenamic acid	Fludarabine

Modified from Packman CH. Drug related immune hemolytic anemia. In: Beutler E, Lichtman MA, Coller BS, Kipps TJ, Seligsohn U, editors. Williams hematology. 6th ed. New York: McGraw-Hill; 2001b, p. 657.

7.0–7.4 μm), red cells with small eccentric or no pallor, and red cells with slightly more intense staining due to Hb density.

Target cells may be found in hemoglobinopathies, especially in the presence of Hb C, Hb D, and Hb E, and in the thalassemias. They may be present in any **hypochromic** anemia, although usually in smaller numbers. Target cells without microcytosis are also found in liver disease and in the absence of the spleen or of splenic function.

Fine **basophilic stippling** (which is due to precipitation of RNA) may be found in polychromatic red cells associated with a significant increase in the generation of erythrocytes, as in response to hemorrhage or hemolysis. **Coarse basophilic stippling** suggests an abnormality in Hb synthesis. It is found in megaloblastic anemias, thalassemias, refractory anemias, some red cell enzyme deficiencies, unstable Hbs, and lead poisoning. In particular, hypochromasia or microcytosis with stippling is against the diagnosis of iron deficiency anemia and is more suggestive of thalassemia or lead poisoning. As mentioned earlier, some cases of iron deficiency may be associated with lead poisoning (see Iron Metabolism).

The combination of **oval macrocytes** (especially egg-shaped macrocytes) and **hypersegmented neutrophils** indicates the very likely existence of megaloblastic anemia.

Finally, examination of the blood film allows the evaluation of **qualitative abnormalities in leukocytes and platelets**, as well as an estimate of their numbers. Blood diseases that may be first suspected or detected in this manner are many and include compensated hemolytic anemia; early megaloblastic anemia; and anomalies of red cells, such as hereditary elliptocytosis, or of leukocytes, such as the Pelger-Hüet nuclear anomaly.

After the basic studies just mentioned, the choice of additional procedures depends on the morphologic type of the anemia, as determined by the indices and the blood film.

Macrocytic Anemia (Increased MCV)

The macrocytic anemias are normochromic, as determined by appearance on the film and by the MCHC. The first step is to ascertain whether the anemia is megaloblastic. Clues from the film have been mentioned. A **bone marrow aspiration** should be performed to confirm the presence of megaloblastosis.

Megaloblastic Marrow

If the marrow is **megaloblastic**, with characteristic changes in both red cell and white cell precursors, the anemia in all likelihood is due to folate or cobalamin deficiency.

See earlier sections on diagnosis of cobalamin deficiency and of folate deficiency. Once the **type** of deficiency is defined, the **cause** must be determined.

Nonmegaloblastic Marrow

If the marrow is **not megaloblastic**, conditions that can be associated with macrocytosis should be investigated. These include liver disease; hemolytic anemias; hypothyroidism; excessive alcohol intake; hypoplastic anemias; and refractory anemias with hyperplastic bone marrow, which include the myelodysplastic syndromes. Anemias associated with these disorders, although they *may* be macrocytic, are more usually normocytic, and thus are considered with the normocytic anemias as well.

Microcytic and Hypochromic Anemias (Decreased MCV and MCH)

If the counts are performed on a multichannel instrument, the MCHC is likely to be in the normal range, with slight to moderate degrees of

hypochromia. Consequently, the MCV has assumed the leading role in the detection of microcytic hypochromic anemias. These anemias reflect a quantitative defect in Hb synthesis. Major causes of microcytic anemia include the following:

1. **Iron deficiency anemias** are due to increased requirement or blood loss not balanced by intake.
2. **ACD** is associated with infection, neoplasia, or collagen disease. This anemia may be normochromic and normocytic, but in long-standing disease is often hypochromic and microcytic.
3. **Thalassemia** is a genetically determined impairment in the rate of globin synthesis.
4. **Sideroblastic anemia** is that group of refractory anemias with erythroid hyperplasia of the marrow in which a defect in Hb synthesis creates a population of hypochromic microcytic cells. The blood film is dimorphic and macrocytes may prevail, making the MCV normal or high, particularly in acquired forms of sideroblastic anemia.

Because **iron deficiency** is the most common anemia, the first step is to determine whether the body lacks iron.

When blood loss cannot be documented, serum ferritin, serum iron and iron-binding capacity, or bone marrow study for iron should be performed. These will usually discriminate between the two most common anemias in this category: iron deficiency and simple chronic anemia associated with some other disease, frequently chronic infection or cancer. In both, the serum iron concentration is low, but in iron deficiency, the TIBC is elevated, whereas in simple ACD it is normal or decreased. Storage iron in the marrow is depleted in iron deficiency but is normal or elevated in anemia of chronic disease. Iron deficiency anemia in an adult male almost always means chronic blood loss; the source must be found and corrected, if necessary.

Hypochromic anemias (or erythrocytoses) with basophilic stippling and normal or increased serum iron are most likely **thalassemias**, and the next examinations to perform are Hb electrophoresis and determination of Hb A₂ and Hb F. Family studies are often necessary.

Sideroblastic anemias include refractory anemia with ring sideroblasts, which are part of myelodysplastic syndromes (see Chapter 33), as well as anemias that occur after therapy with certain drugs (e.g., isoniazid) or in chronic lead poisoning. Coarse basophilic stippling is common in this group of anemias.

Table 32-14 summarizes some laboratory distinctions within the microcytic anemias.

Normocytic and Normochromic Anemias (Normal MCV)

This large group of anemias has many causes. A useful approach is evaluation of the erythrokinetics in a given patient (see Chapter 31). Often, the reticulocyte production index (RPI) and examination of the bone marrow will suffice. The RPI is the simplest measure of effective erythropoiesis.

Optimal Marrow Response: Reticulocyte Production Index Greater Than Two

If the output of reticulocytes has exceeded two times normal, as determined by the absolute reticulocyte count, or RPI, it can be assumed that the marrow has reached an optimal response. The cause for the anemia is then **acute blood loss** or **hemolysis**. If blood loss cannot be proved, evidence that hemolysis is in fact present must be sought.

TABLE 32-14
Laboratory Features in Microcytic Hypochromic Anemias

	Serum iron	Serum TIBC	% saturation	MARROW		Serum ferritin	ZPP	Hb A ₂	Hb F
				% sideroblasts	Iron stores				
Iron deficiency	↓	↑	↓	↓	↓	↓	↑	N↓	N
β-Thalassemia trait	N (↑)	N	N	N	N↑	N↑	N	↑	N↑
ACD	↓	N↓	↓	↓	N↑	N↑	↑	N	N
Sideroblastic anemia	↑	↓	↑	↑	↑	↑	↑ (↓)	N	N↑

ACD, Anemia of chronic disease; N, normal; TIBC, total iron-binding capacity; ZPP, zinc protoporphyrins; ↓, decreased; ↑, increased.

Erythroid hyperplasia of the marrow, serum bilirubin, and urine or fecal urobilinogen will indicate whether erythropoietic activity and destruction are increased. Red cell survival determination may be needed to prove hemolysis in some cases. Low serum haptoglobin and high LD point to hemolysis, but a normal level does not exclude it. None of these measurements will specify whether hemolysis is intravascular or extravascular, but elevated plasma Hb, hemoglobinuria, and hemosiderinuria indicate intravascular hemolysis.

Once it is determined that excessive hemolysis is occurring, the type of hemolytic mechanism must be ascertained.

Direct Antiglobulin (Coombs') Test. If the direct antiglobulin reaction is *positive* using broad-spectrum reagents, tests to determine the presence of IgG, IgM, or complement on the red cells should be undertaken. If immunoglobulin is present on the red cells, tests for antibody specificity, cold agglutinins, Donath-Landsteiner antibody, and serum protein electrophoresis may help to define the process.

If the direct antiglobulin reaction is *negative*, the examinations performed next will depend on the clinical findings and the results of measurements already made.

If HS is suspected, osmotic fragility before and after 24-hour incubation at 37° C and family studies will be necessary.

If a nonspherocytic congenital hemolytic anemia is suspected, screening for G6PD and PK deficiencies, Hb electrophoresis, and a sickle cell test will be helpful. If these are negative, the heat instability test, isopropanol solubility test, and autohemolysis test should be considered.

If thalassemia seems likely, determinations of Hb A₂ and Hb F and perhaps looking for Hb H inclusions are appropriate. Thalassemias are usually microcytic and hypochromic anemias; β -thalassemia major, β -thalassemia intermedia, and Hb H disease are hemolytic disorders and may have an increased RPI.

If drug-induced hemolysis is suspected, a test for Heinz bodies, a screening test for G6PD, and, if possible, tests for a drug-dependent autoantibody are indicated.

If the nature of the hemolytic anemia is obscure, a flow cytometry test for PNH should be performed.

Inadequate Marrow Response: Reticulocyte Production Index Less Than Two

The mechanism of the anemia may be ineffective erythropoiesis. Conditions with the greatest degree of ineffective erythropoiesis appear in other categories (e.g., megaloblastic anemia, thalassemia), but most of the myelodysplastic syndromes have a hyperplastic bone marrow and impaired delivery of cells to the blood. In some of these, morphologic changes in erythroid precursors may overlap with megaloblastic anemia, but granulocytic and megakaryocytic changes usually seen in megaloblastic anemia are lacking.

A low reticulocyte count may indicate decreased production caused by inadequate stimulation of the marrow. Chronic renal disease may result in impaired production of EPO. Certain endocrinopathies, such as hypopituitarism or hypothyroidism, may result in regulation of Hb production at a lower level as a result of decreased tissue need for O₂.

A large group of normochromic anemias associated with various chronic diseases form a heterogeneous group characterized by failure of the marrow to meet the need for slightly decreased red cell survival. Some of these are ACDs associated with infection, cancer, or rheumatoid arthritis; they have the defect in iron metabolism noted previously in the section on hypochromic microcytic anemias.

Inability of the marrow to respond to EPO may be due to damage to the marrow by drugs or toxic chemicals, to unknown causes, or to infiltration of the marrow by neoplastic cells or fibrous tissue.

In those conditions with low reticulocyte counts in which the marrow is not effectively producing erythrocytes, it is usually helpful to examine the bone marrow. Other studies conducted to determine the underlying disease process can then proceed according to the marrow picture, the assessment of erythrokinetics, and the clinical findings.

POLYCYTHEMIA

Polycythemia (erythrocytosis) is classically defined as an elevated Hct level above the normal range. In the clinical setting, polycythemia exists when Hb and red cell count are increased, reflecting an elevation of the total red cell volume (Maran, 2004). Yet, the recent World Health Organization (WHO) classification of hematologic malignancies has

TABLE 32-15

Pathophysiologic Classification of Polycythemia

Relative Polycythemia

1. Diminished plasma volume: dehydration; shock
2. Spurious polycythemia (stress polycythemia; Gaisböck's syndrome)

Absolute Polycythemia

1. Secondary polycythemia with appropriately increased EPO production
 - a. Decreased oxygen (O₂) loading: hypoxia; high altitude; pulmonary disease; cyanotic heart disease; carboxyhemoglobinemia; methemoglobinemia; Hb M
 - b. Decreased O₂ unloading: high O₂ affinity hemoglobinopathy; biphosphoglycerate deficiency
2. Secondary polycythemia with inappropriately increased EPO production
 - a. Neoplasms: Wilms' tumor; renal carcinoma; cerebellar hemangioma; hepatoma
 - b. Localized tissue hypoxia: polycystic kidney; renal artery stenosis
 - c. Postrenal transplant
 - d. Acute hepatitis
3. Genetic polycythemia
 - a. Primary familial congenital polycythemia (mutated EPO receptor)
 - b. Chuvash polycythemia (mutated *VHL* gene)
4. Primary marrow disorders
 - a. Polycythemia vera

Modified from Cazzola M. Serum erythropoietin concentration as a diagnostic tool for polycythemia vera. *Haematologica* 2004;89:1159–60. EPO, Erythropoietin; Hb M, methemoglobin.

defined polycythemia as Hgb >18.5 g/dL for men, >16.5 g/dL for women, Hct >99th percentile of the method-specific range, or lower values but with a documented unexplained Hgb increase of at least 2 g/dL (Swerdlow, 2008).

Absolute polycythemia refers to an increase in the total red cell mass in the body; in **relative polycythemia**, the total red cell mass is normal, but the Hct is elevated because the plasma volume is decreased. Polycythemia may be classified as in Table 32-15. Some classifications are based on EPO response (Cazzola, 2004), and others are based on the underlying mechanism (i.e., primary or secondary, and congenital or acquired) (Gordeuk, 2005).

RELATIVE POLYCYTHEMIA

Relative polycythemia refers to an increase in Hct or red cell count as a result of decreased plasma volume; total red cell mass is not increased. This occurs in acute dehydration (e.g., severe diarrhea, burns) and in patients on diuretic therapy.

In **spurious polycythemia** (apparent polycythemia, Gaisböck's syndrome), the red cell mass is often high normal and the plasma volume is low normal; these patients have been regarded as an extreme of the normal physiologic state. Almost all are men; they have a high incidence of tobacco smoking and tend to be obese and to have hypertension. Sleep apnea and diuretics may be contributory factors. Serum EPO level is normal (Cazzola, 2004).

ABSOLUTE POLYCYTHEMIA

Appropriately Increased Erythropoietin Production Due to Hypoxia

Cellular response to hypoxia is controlled by a family of α - β heterodimeric transcription factors, known as hypoxia-inducible factors (HIFs), which regulate the transcription of EPO. There are three HIF isoforms—HIF1 α , HIF2 α , and HIF3 α —with HIF2 α being the major isoform regulating EPO expression. In the presence of normoxia, HIF1 α is rapidly destroyed by the collaborative effect of O₂, prolyl hydroxylase domain-containing enzymes, and the von Hippel-Lindau tumor suppressor protein (VHL). Under hypoxic conditions, degradation of HIF α is slowed, resulting in increased transcription of its target genes, which include EPO. Binding of EPO to its receptor results in autophosphorylation of the receptor-associated Janus kinase 2 (JAK 2), which has tyrosine kinase activity (Patnaik, 2009).

Arterial Oxygen Unsaturation

Lack of O₂ reaching the blood for whatever reason results in arterial unsaturation, impaired O₂ delivery to the tissues, increased production of EPO, erythroid hyperplasia in the marrow, and resultant erythrocytosis. The red cell mass is increased. As a response to the hypoxia, the red cell 2,3-DPG and the p₅₀ are increased. In contrast to polycythemia vera, there is usually no leukocytosis or thrombocytosis, and the neutrophil alkaline phosphatase is normal. Arterial O₂ unsaturation may be the cause of polycythemia in persons living at high altitudes; in patients with chronic pulmonary disease and a block in diffusion of O₂ into the blood; in cyanotic heart disease in which there is right-to-left shunt; and in carboxyhemoglobinemia mostly related to cigarette smoking. In case of CO poisoning, hypoxia is caused by two mechanisms: direct reduction of O₂ saturation and interference with O₂ release from Hb (Landaw, 1990).

High Oxygen Affinity Hemoglobinopathy

Another cause of tissue hypoxia is the presence of structurally abnormal Hb that has a high affinity for O₂ (Prchal, 2003) (see earlier under Hemoglobins Associated With Altered Oxygen Affinity). As in other functional hemoglobinopathies, the disorder occurs in the heterozygote. More than 100 Hb mutations associated with increased O₂ affinity have been identified (Prchal, 2003). Abnormal Hb releases less O₂ to the tissues than does normal Hb at the same pO₂; the O₂ dissociation curve is shifted to the left, and the p₅₀ is decreased. The red cell 2,3-DPG is not increased. As in arterial O₂ unsaturation, EPO production and erythrocytosis are increased. It must be emphasized that routine Hb electrophoresis often does not detect these Hb variants because the amino acid substitution occurs at one of the αβ-contact sites, or near the heme pocket. A low p₅₀ therefore is presumptive evidence for a hemoglobinopathy. Some high-affinity Hbs associated with polycythemia are unstable; in these instances, the heat instability test is positive.

Other causes of altered O₂ affinity include Hb M and deficiency of red cell enzyme 2,3-DPG mutase, which is involved in the generation of 2,2-DPG (Gordeuk, 2005).

Inappropriate Erythropoietin Production

Neoplasms

Neoplasms, benign or malignant, have been associated with polycythemia. Renal neoplasms account for the majority. In almost all cases, erythrocytosis has disappeared after resection of the tumor. These neoplasms have been shown to express high levels of EPO mRNA. These tumors include cerebellar hemangiomas, renal cell carcinomas, Wilms' tumors, some hepatomas, uterine leiomyomas, pheochromocytoma, parathyroid adenomas, and meningiomas (Patnaik, 2009).

Renal Disorders

In other neoplasms or growths (e.g., renal cysts, hydronephrosis, ovarian carcinoma, some hepatomas), it appears that the mass impinging on the kidney induces increased renal production of EPO as a result of increased pressure or local hypoxia within the kidney. Renal artery stenosis is also associated with polycythemia. Posttransplant erythrocytosis occurs in 10%–20% of renal transplant recipients. The therapeutic effects of angiotensin-converting enzyme inhibitors in this condition suggest a role for angiotensin II in regulating erythropoiesis (Prchal, 2003).

Familial Polycythemia

The most common familial polycythemia is due to the presence of a **high oxygen affinity hemoglobin**, which is inherited as an autosomal dominant trait. Congenital polycythemia may be due to a defect in the hypoxia-sensing mechanism. Von Hippel–Lindau syndrome is an autosomal dominant disorder associated with mutations in the *VHL* gene. These mutations result in increased levels of HIF-1α and increased levels of EPO (Prchal, 2003; Gordeuk, 2005). Chuvash polycythemia is an autosomal recessive congenital polycythemia that is endemic in the Chuvash population of the Russian federation. It has been reported to be associated with a high mortality rate caused by thrombotic and hemorrhagic complications.

Congenital polycythemia may occur secondary to a defect in the EPO receptor in the presence of a normal hypoxia-sensing mechanism. Primary familial and congenital polycythemia (PFCP) is an autosomal dominant disorder that is present at birth. PFCP is associated with low serum EPO levels and in vitro hypersensitivity of erythroid progenitors to EPO. Sixteen germline mutations in the EPO receptor gene (*EPOR*) with resulting truncated receptors have been described in PFCP to date

(Patnaik, 2009). As mentioned earlier, marked decrease in red cell 2,3-DPG associated with **deficiency of 2,3-DPG mutase** activity results in polycythemia and appears to be inherited as an autosomal recessive condition.

Polycythemia Vera

Polycythemia vera is a panmyelosis, that is, a condition in which excessive proliferation occurs in megakaryocytes and granulocytes, as well as in erythrocytes. It is manifested by erythrocytosis, leukocytosis, and thrombocytosis of varying degrees. Mutation in the *JAK2* gene is now described as a constant finding. Polycythemia vera is discussed with the myeloproliferative neoplasms.

MEASUREMENT OF ERYTHROCYTE AND PLASMA VOLUME

The diagnosis of absolute polycythemia depends on reliable measurements of erythrocyte and plasma volumes. Erythrocyte and plasma volumes are measured with the use of radioactive isotopic tracers and the dilution principle. The most commonly employed tracers are ⁵¹Cr in the form of sodium chromate bound to erythrocytes for measurement of erythrocyte volume. ¹²⁵I or ¹³¹I iodine is bound to albumin and can be used to measure plasma volume.

For a detailed description of measurement of red cell and plasma volume, see the report of the International Committee for Standardization in Hematology (1980).

Erythrocyte Volume

In brief, blood is collected from the patient, and the erythrocytes are labeled with ⁵¹Cr. The chromated erythrocytes are washed in saline. An aliquot of the ⁵¹Cr erythrocytes diluted in saline is injected intravenously into the patient. After a period of equilibration, usually 10–20 minutes, a sample of blood is withdrawn from the opposite arm. In cases in which the equilibration time is likely to be prolonged (as in splenomegaly, heart failure, or shock), another sample should be withdrawn 60 minutes after injection.

Radioactivity of each sample is recorded by a scintillation counter. The erythrocyte volume (EV) is calculated using the following formula:

$$EV \text{ (mL)} = I \text{ (cpm)} / C \text{ (cpm/mL)}$$

where *I* is the total injected radioactivity (counts/minute) and *C* is the radioactivity in erythrocytes after mixing is complete (counts/minute/mL of erythrocytes).

Plasma Volume

Approximately 20 mL of blood is withdrawn from a patient. After centrifugation, the plasma is removed, and radioiodine-labeled albumin is added. After mixing, the labeled plasma is injected intravenously into the patient. At 10, 20, and 30 minutes following injection, 5 mL of blood is removed and radioactivity is counted in a well-type scintillation counter. The radioactivity at zero time (*P*₀) is determined by plotting the three points on semilogarithmic graph paper and extrapolating to zero time. A standard is prepared by diluting an aliquot of the radioiodine-labeled albumin with saline containing a small amount of detergent.

The plasma volume (PV) is calculated using the following formula:

$$PV \text{ (mL)} = S \text{ (cpm/mL)} \times D \times V \text{ (mL)} / P_0 \text{ (cpm/mL)}$$

where

S = counting rate of standard (counts/minute/mL)

D = dilution of diluted standard solution

V = volume of radioiodine-labeled albumin solution injected

*P*₀ = counting rate of plasma sample corrected to zero time (counts/minute/mL).

Interpretation

The normal erythrocyte volume for men is 20–36 mL/kg, and for women, it is 19–31 mL/kg. The plasma volume for men is 25–43 mL/kg; for women, 28–45 mL/kg. In newborns and premature infants, the red cell volume and plasma volume in milliliters per kilogram are higher than in adults.

Patients with polycythemia have red cell volumes exceeding 36 mL/kg for men and 32 mL/kg for women. Changes in erythrocyte volume and plasma volume in a variety of conditions are recorded in Table 32-16.

TABLE 32-16

Clinical Effect of Variable Relationship Between Red Cell Volume and Plasma Volume

Red cell volume	Plasma volume	Cause	Effect
Normal	High	Pregnancy Cirrhosis Nephritis Congestive cardiac failure	Pseudoanemia
Normal	Low	Stress Peripheral circulatory failure Dehydration Edema Prolonged bed rest	Pseudopolycythemia
Low	Normal	Anemia	Accurate reflection of degree of anemia
Low	High	Anemia	Anemia less severe than indicated by blood count
Low	Low	Hemorrhage Severe anemia (when hematocrit <0.2)	Anemia more severe than indicated by blood count
High	Normal to low	Polycythemia	Accurate reflection of polycythemia or polycythemia less severe than apparent
High	High	Polycythemia (when hematocrit >0.5)	Polycythemia more severe than apparent
Normal or even high	High	Marked splenomegaly	Pseudoanemia

KEY POINTS

- Leukocytes are regulated by complex homeostatic mechanisms which direct their responses to infection and inflammation.
- Leukocytosis often reflects an underlying abnormality; leukopenia, especially neutropenia, places a patient at risk for infection.
- Hematopoietic neoplasms have been categorized by a World Health Organization classification according to cell of origin, cytogenetic and molecular abnormalities, immunophenotype, and clinical features.
- Acute leukemias are rapidly progressing neoplasms of precursor myeloid or lymphoid cell origin. An understanding of biology is associated with improvements in therapy.
- Chronic myeloproliferative disorders and myelodysplastic syndromes are heterogeneous disorders of differentiated myeloid cells. They often are initially indolent but ultimately progress.
- Non-Hodgkin lymphomas most often arise from mature B cells. They are pathologically and clinically heterogeneous. T cell lymphomas are less common, also heterogeneous, and often difficult to treat successfully.
- Hodgkin lymphoma is now considered a neoplasm of defective B cells. Much of its pathology is due to an associated inflammatory milieu.

LEUKOCYTES

Leukocytes, or white blood cells, are found within the bone marrow (BM), the peripheral blood, and the tissues. Leukocytes are among the essential elements of the hematopoietic-lymphoreticular-immune system, which functions to protect the human body from nonself cells (infection) and altered-self cells (cancer). Normal leukocyte development is reviewed in Chapter 31.

Leukocyte function involves cell adhesion molecules (CAMs), proteases, and cytokines (Table 33-1). Molecular interactions with endothelial cells direct leukocytes to their ultimate destination. Tissue- or organ-specific molecules on endothelium, including selectins and integrins, influence specific leukocyte trafficking, as well as passage across the endothelium; chemokines also influence migration (Ruoslahti, 2000; Sallusto, 2000; Alon, 2002; Patel, 2002; Moser, 2004; Rot, 2004).

One very important leukocyte homeostatic mechanism is apoptosis, or programmed cell death. In B and T cell development, it eliminates those with nonfunctional or autoreactive antigen receptors and regulates activation of the inflammatory response (Marsden, 2003; Ivanovska, 2004). It also plays a critical role in granulocyte development by increasing their relatively short life span at sites of infection and downregulating inflammation at completion, and it prevents the release of enzymes and inflammatory mediators from senescent granulocytes into surrounding healthy tissue. Abnormalities of apoptosis are involved in numerous pathologic states (cancer, degenerative disease, persistent infection, autoimmune disease). Apoptosis occurs at the mitochondrial level through an intrinsic system that induces activation of a cascade of caspase enzymes, modulated by bcl-2 family proteins (Schultz, 2003; Martin, 2004; Petros, 2004; Saelens, 2004). An extrinsic pathway involves death receptors (DRs), including Fas/CD95 and tumor necrosis factor (TNF) receptor-1 (TNFR1). These transmit apoptotic signals via a transmembrane death domain to induce activation of caspases and other associated enzymes (Green, 2003; Ivanovska, 2004; Jiang, 2004). Fas can also activate nuclear factor (NF)- κ B that regulates a number of immune and inflammatory processes (Aggarwal, 2004; McDonald, 2004). This factor functions as a tumor promoter in a variety of tumors, including inflammation-associated cancer, myeloma, and Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL) (Pikarsky, 2004; Baud, 2009; Schmitz, 2009).

Although the underlying biology of leukocytes is complex, the task of the general pathologist is to interpret complete blood counts, peripheral blood smears, and occasionally BM samples; integrate clinical data; and

TABLE 33-1

Characteristics of Key Cell Signaling Biomolecules

Biomolecule	Target	Function
G-CSF	Myeloid bone marrow precursors	Increase proliferation and development of neutrophils
L-Selectins	Endothelial cell integrin receptors	Bind leukocytes to endothelial cells to facilitate adhesion and diapedesis
Chemokines	Leukocytes via chemokine receptors	Direct migration and activation of leukocytes via cytokine chemoattractant properties
Fas/CD95 ligand (membrane protein)	Fas/CD95 (membrane receptor)	Apoptosis via death-inducing complex
Caspases	Protein substrates	Apoptosis via enzymatic cascades
Bcl-2 antiapoptotic protein family (Bcl-2, Bcl-xL)	Mitochondrial outer membrane (MOM), nuclear membrane, endoplasmic reticulum	Decreases cell sensitivity to apoptosis
Bcl-2 proapoptotic protein family (Bax, Bok, Bak)	MOM, nuclear membrane, endoplasmic reticulum	Increases cell sensitivity to apoptosis

G-CSF, Granulocyte-colony stimulating factor.

render a diagnosis. Hematopathologists, in addition, perform more detailed analyses of hematologic specimens.

NONNEOPLASTIC DISORDERS

Currently, laboratory examination of leukocytes occurs as part of the automated complete blood count (CBC) for almost every patient. The total leukocyte or white blood cell (WBC) count, as well as the relative and absolute concentrations of neutrophils, lymphocytes, monocytes, eosinophils, and basophils, is determined and compared with normal values for the patient's age and sex. Absolute concentrations (i.e., the product of the WBC count and the percentage of the respective cell series, such as lymphocytes or neutrophils) are of greatest value in identifying abnormalities. Abnormal results from the automated count are "flagged" and are then reviewed by a skilled laboratory technologist.

These abnormalities include leukocytosis, which is an increase in the total WBC count, and leukopenia, which is a decrease in the total WBC count, each compared with normal values for age and sex. The differential count, usually first performed on an automated instrument, quantifies the relative and absolute concentrations of the various forms of white cells and the maturation state for neutrophils. Increases in the absolute concentration of cells in each series are termed neutrophilia (neutrophilic leukocytosis), lymphocytosis, monocytosis, eosinophilia (eosinophilic leukocytosis), and basophilia (basophilic leukocytosis). Decreases in the absolute concentration are termed neutropenia, lymphopenia (or lymphocytopenia), monocytopenia, eosinopenia, and basopenia. Increased numbers of band neutrophils and/or the presence of immature neutrophils (metamyelocytes and earlier) is noted and enumerated and often confirmed or modified by a manual differential count. Nucleated red blood cells (RBCs) are also enumerated, noted, and subtracted from the WBC count, by automated or manual methods. Abnormalities may occur in neoplastic conditions (e.g., leukemia, marrow infiltration by metastatic tumor) and in nonneoplastic conditions (e.g., infection, drug effect, nutritional deficiency). An increase in any cell type may be clinically important, but a decrease is usually significant only for neutrophils. Usually an isolated monocytopenia, eosinopenia, or basopenia identified in a CBC is not considered pathologic. Functional neutrophil abnormalities occasionally occur. One purpose of the examination of leukocytes is to help in establishing a diagnosis. Occasionally, this alone may furnish a specific diagnosis, for example, in leukemia. The leukocyte differential count and cytologic appearance are frequently helpful diagnostically when interpreted with other data, for example, in acute appendicitis, infectious mononucleosis, or another type of infection. Another purpose is to help in establishing a prognosis. For example, leukopenia in acute appendicitis or pneumonia is considered prognostically unfavorable.

Finally, study of the leukocytes is helpful in following the course of disease. For example, toxic effects of radiotherapy and chemotherapy may be recognized and recovery monitored by examination of leukocytes.

GRANULOCYTIC AND MONOCYTIC DISORDERS

The pathologist should grasp the mechanisms and determinants or causes, both quantitative and qualitative, of the following disorders and should be

TABLE 33-2

Key Causes of Neutrophilia

- Acute inflammatory—collagen vascular, vasculitis
- Acute infectious—bacterial, some viral, fungal, parasitic
- Drugs, toxins, metabolic—corticosteroids, growth factors, uremia, ketoacidosis
- Tissue necrosis—burns, trauma, MI, RBC hemolysis
- Physiologic—stress, exercise, smoking, pregnancy
- Neoplastic—carcinomas, sarcomas, myeloproliferative disorders

MI, Myocardial infarction; RBC, red blood cell.

able to consult with clinical colleagues as they consider their differential diagnosis.

Neutrophilia

Neutrophilic leukocytosis or neutrophilia refers to an absolute concentration of neutrophils in the blood above normal for age. The normal reference interval (established for each laboratory separately) is approximately $1.8\text{--}7.0 \times 10^3/\mu\text{L}$ for adults, with a slightly wider range ($1.0\text{--}8.5 \times 10^3/\mu\text{L}$) in young children. The neutrophilias are acquired disorders; none is inherited. Key causes of neutrophilia are listed in Table 33-2.

Mechanisms

The primary factors influencing the neutrophil count are (1) the rate of inflow of cells from the BM (mitosis/proliferation, maturation/storage, and release); (2) the proportion of neutrophils in the marginal (cells adhering to vessel walls) granulocyte pool (MGP) and the circulating (nonadherent cells) granulocyte pool (CGP) of the blood—MGP and CGP are approximately equal in size and in equilibrium in health; and (3) the rate of outflow of neutrophils from the blood (i.e., migration from and through vessels into tissue, both randomly and at sites of inflammation, infection, etc.).

Physiologic leukocytosis is produced by factors or situations that are not related to underlying tissue pathology. Severe exercise, hypoxia, stress, or injection of epinephrine will lead to a decrease in the MGP and a corresponding increase in the CGP, resulting in a **pseudoneutrophilia** (i.e., no change in total blood granulocyte pool, or TBGP). This simple redistribution of cells between the CGP and the MGP, also known as demargination, is the release and detachment of leukocytes from molecular receptors on vessel luminal walls. This may be due, in part, to epinephrine-induced activation of β -receptors on endothelial cells, releasing cyclic adenosine monophosphate (cAMP), which ultimately alters or modulates the properties and characteristics of cell surface adhesion molecules and increases the release of neutrophils (as well as other leukocytes) into the circulation (Gabriel, 1998; Heine, 2001; Shephard, 2003).

Stress of greater severity or injection of endotoxin or corticosteroids also results in increased inflow of cells to the blood from the marrow maturation/storage pool. Interleukin-6, an important regulator of the acute phase response, appears to play a significant role in both the demargination of circulating cells (initial wave of circulating neutrophils) and the release of neutrophils from the marrow (second wave of circulating neutrophilic granulocytes) (Suwa, 2000). As a result, the mitotic pool appears to be increased to replenish the maturation/storage pool from which more

mature cells exit into the TBGP, and both the MGP and the CGP are enlarged. A “greater” neutrophilia is possible in this situation because of the additional egress of cells from the maturation/storage pool (in addition to demargination); immature cells, such as band neutrophils and metamyelocytes, are likely to be present (Suwa, 2000).

As mentioned earlier, neutrophilia may be produced by corticosteroids, which increase the release of neutrophils from the marrow, decrease the egress of neutrophils from the blood, and increase demargination.

Pathologic leukocytosis is an increased WBC count that occurs as a result of disease, usually as a response to tissue damage. This leukocytosis is most often a neutrophilia.

In addition to the random loss of neutrophils from the circulation in various body secretions, neutrophils leave the blood by amoeboid movement when attracted to a focus of inflammation in tissues, presumably responding to a multitude of chemotactic molecules and gradients. It is from the MGP that the neutrophils leave the blood, pass between capillary endothelial cells, and reach the tissues.

In acute infection, increased margination of neutrophils and outflow from blood to tissues would lead to neutropenia were there not a flow of neutrophils from the marrow storage compartment into the blood. Because the latter overcompensates, the result is a neutrophilia. Usually, production and storage compartments then increase in the marrow and are able to sustain the increased CGP (neutrophilia) and MGP in the face of increased flow of neutrophils from the blood into the inflammatory site. In these instances, the marrow will show granulocytic hyperplasia (increased myeloid to erythroid [M:E] ratio and increased cellularity), with maturation intact. An increase in immature peripheral blood granulocytes is usually present, often termed “shift to the left.”

If the demand for neutrophils is extremely great, as in severe infection, there may be depletion of the marrow storage pool and decreased CGP (neutropenia) and MGP, because the supply of cells is insufficient for the demand. In these instances, the marrow will show increased numbers of early neutrophil precursors, through the myelocyte stage, but decreased numbers of metamyelocytes, bands, and neutrophils.

Determinants

Certain host factors modify the degree of neutrophilic response. Children respond more intensely than adults. The degree of neutrophilia may be impaired by the same factors that impair erythrocyte production (iron, folate, or cobalamin deficiency) or by marrow failure due to other causes. Imperfectly defined factors that enable the body to localize an infection may play a role: the more localized the process, the more pronounced is the neutrophilia.

Other factors modifying the neutrophilic response are due more to the microorganism than to the host. Pyogenic bacteria, especially, induce neutrophilia. Within limits, a more virulent agent results in a higher neutrophil count. When the infection is overwhelming, however, there is apt to be a neutropenia and a greater shift to the left.

Treatment of infections with antibiotics may modify the leukocytic response to infection. Steroid therapy, although causing neutrophilia, tends to impair the host response to infection, probably because of diminished movement of neutrophils into the tissues and increased lysosomal stability.

Neutrophilia, sometimes pronounced, is occasionally seen in patients with nonhematologic neoplasms and may be secondary to several factors, including response to tissue necrosis and underlying infection, as well as to the production of hematologic growth factors (Peterson, 1993; Granger, 2009). Neutrophilia can also be seen with gastrointestinal and hepatic tumors, HL, renal cell carcinoma, and metastatic BM disease (Blay, 1997; Hernandez, 2002). It is thought that cytokine production by tumor cells is, at least in some situations, responsible for hematologic changes such as neutrophilia, monocytosis, thrombocytosis, and lymphocytopenia in patients with malignancy (Ruka, 2001).

Neutropenia

Neutropenia is a reduction in the absolute neutrophil count (ANC) below $\approx 1.5\text{--}2 \times 10^9/\text{L}$ for white adults and below $\approx 1.2\text{--}1.3 \times 10^9/\text{L}$ for black adults. Remember that the ANC is the product of the WBC count and the percentage of neutrophils and bands that have been enumerated in the WBC differential count. The term *agranulocytosis* has been used for severe neutropenia, usually $<0.5 \times 10^9/\text{L}$; this can also be associated with depletion of eosinophils and basophils. The term severe chronic neutropenia (SCN) refers to patients with ANC $<0.5 \times 10^9/\text{L}$ for months or years, usually with diseases that primarily cause neutropenia in the absence of other cytopenias (Dale, 2002a). If the neutrophil count is less

TABLE 33-3

Key Causes of Neutropenia*

- Drugs—cancer chemotherapy, chloramphenicol, sulfas/other antibiotics, phenothiazines, benzodiazepine, antithyroids, anticonvulsants, quinine, quinidine, indomethacin, procainamide, thiazides
- Radiation
- Toxins—alcohol, benzene compounds
- Intrinsic defects—Fanconi’s, Kostmann’s, cyclic neutropenia, Chédiak-Higashi
- Immune-mediated—collagen vascular disorders, RA, AIDS
- Hematologic—megaloblastic anemia, myelodysplasia, marrow failure, marrow replacement
- Infectious—any overwhelming infection
- Others—starvation, hypersplenism

AIDS, Acquired immunodeficiency syndrome; RA, rheumatoid arthritis.

*Brief, partial list.

than $1 \times 10^9/\text{L}$, the risk of infection is considerably increased over normal, and if the neutrophil count is less than $0.5 \times 10^9/\text{L}$, the risk of infection is greater still.

The mechanisms by which neutropenia occurs include (1) decreased flow of neutrophils from marrow into blood as a result of lack of production or ineffective production (i.e., a proliferation or maturation defect); (2) increased removal of neutrophils from the blood (survival defect); (3) altered distribution between CGP and MGP; and (4) combinations of these mechanisms. Further, neutropenias may be inherited, acquired as part of an autoimmune disorder, or acquired secondary to a toxic or drug-associated insult. Neutropenias are not as neatly classified as anemias. It should be noted that drugs induce neutropenia through several mechanisms and are a very important consideration in any differential diagnosis of leukopenia. Partial lists of causes and conditions associated with neutropenia are shown in Table 33-3.

Intrinsic defects or constitutional disorders associated with neutropenia usually present at birth or in early infancy and are rare. Those due to myeloid hypoplasia or a proliferation defect include Fanconi’s anemia (FA), Kostmann’s syndrome, Schwachman-Diamond syndrome, and cyclic neutropenia. Those that are due to maturation defects include myelokathexis and Chédiak-Higashi syndrome.

FA is an inherited BM failure syndrome that usually occurs in childhood and rarely presents in adulthood. This condition is heterogeneous in its clinical manifestations but was classically defined by the presence of aplastic anemia and congenital physical malformations. The aplastic anemia of FA patients appears to be indistinguishable from acquired aplasia. FA patients are also susceptible to hematopoietic and certain solid organ malignancies. Diagnosis is made by cytogenetic analysis while looking for chromosome breakage after exposure to diepoxybutane or mitomycin C.

In keeping with variation in clinical presentations and manifestations of this syndrome, the underlying molecular pathology is complex. Currently, at least 11 FA genetic subtypes exist and 7 FA genes have been cloned. One gene, *FANCD1*, is actually *BRC42*, which, like *BRC41*, is a DNA repair gene that appears to be a putative breast and ovarian cancer susceptibility gene identified in certain families with an inherited predisposition to breast and ovarian cancer. These genes probably function as tumor suppressor genes and appear to be involved in the molecular pathway(s) responsible for the disruption of DNA repair in FA (Levitus, 2004; Tischkowitz, 2004). The mechanism of pathogenesis appears varied, but identification of DNA repair abnormality is useful for diagnosis (Auerbach, 2009).

Kostmann’s syndrome, originally termed **infantile genetic agranulocytosis**, is a rare severe (ANC usually $<200/\mu\text{L}$) congenital neutropenia appearing in early infancy. Initially identified as showing an autosomal recessive pattern of inheritance, autosomal dominant and sporadic cases also occur. The marrow usually shows the presence of early granulocytes (promyelocyte/myelocyte arrest), but few maturing forms are seen; neutrophil survival is normal. Although the underlying genetic defect in myeloid precursor cells is not entirely elucidated, mutations in the gene (*ELA2*) encoding neutrophil elastase appear to be present in most patients with autosomal dominant disease and with antiapoptotic gene *HAX-1* in recessive cases (Carlsson, 2007). These mutations may be responsible for the untimely initiation of apoptosis in myelocytes, producing their premature destruction and interrupting the normal cycle of maturation. In

addition, other underlying molecular/genetic changes may produce DNA mutations and genome instability, which contribute to initiation and progression of this disease (Zeidler, 2002; Christensen, 2004).

Patients with cyclic neutropenia typically present with recurrent episodes of symptomatic infection (fatigue, mouth ulcers, cervical lymphadenopathy, fever) due to cyclic episodes of severe neutropenia. The latter is due to the periodicity or cycling of neutrophil production. The disease usually presents in childhood but may present in adulthood. Typically, oscillations of neutrophil and monocyte levels (between near normal levels and very low levels) occur over an approximately 21-day period. Mutations in *ELA2*, the gene for neutrophil elastase, have been identified in many patients (Dale, 2002b). This appears to be responsible for selective apoptotic death of neutrophil progenitors, a mechanism similar to that seen in Kostmann's syndrome, as discussed earlier.

Chronic familial neutropenia or benign familial neutropenia refers to a lower than "normal" neutrophil count, as found in some ethnic populations. It is an incidental and clinically stable finding with no predisposition to infection and is considered a genetic variation.

It is important to note that the two most common causes of congenital neutropenia are neutropenia of pregnancy-induced hypertension (PIH—most common) and overwhelming bacterial infection. Typical signs of infection, including a granulocytic left shift, toxic granulation, and Döhle bodies, accompany the latter, but these changes are not seen in PIH. Neither usually continues beyond the first week of life, and other causes should be searched for in infants with persistent neutropenia (Christensen, 2004).

Patients with congenital or primary immunodeficiency diseases may exhibit some degree of neutropenia. Males with X-linked agammaglobulinemia (XLA) are often neutropenic, and XLA should be considered in the differential diagnosis of chronic neutropenia in an infant. An abnormal nonreceptor tyrosine kinase, associated with signal transduction and differentiation of hematopoietic cells, appears to be involved. This is due to various mutations in the gene *Btk* (Bruton's or *B* lymphocyte tyrosine kinase) on the long arm of the X chromosome (q22). Other congenital syndromes having a prominent association with neutropenia include selective immunoglobulin (Ig)A deficiency, common variable immunodeficiency, and hyper IgM syndrome (Cham, 2002).

Certain autoimmune diseases can also be associated with chronic neutropenia. Both rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE) show this association (Starkebaum, 2002). The combination of chronic neutropenia and RA is termed Felty's syndrome (FS), and patients develop symptoms owing to both RA (e.g., subcutaneous nodules, contractures, erythema, warmth, tenderness, symmetrical involvement of large and small joints, musculoskeletal pain) and chronic neutropenia (symptoms of recurrent bacterial and fungal infections). A portion of these cases are associated with large granular lymphocyte (LGL) leukemia (Shah, 2009). SLE may present with multisystem involvement, making presenting symptoms highly variable. Organ systems frequently affected include the skin, kidney, BM, and central nervous system (CNS); symmetrical involvement of the joints is also seen. Again, the pathophysiology is complex; alterations in neutrophil proliferation and survival with neutropenia due, at least in part, to immune-mediated destruction, occur in both SLE and FS, and increased neutrophil apoptosis may be noted in SLE (Starkebaum, 2002).

Primary autoimmune myelofibrosis (Bass, 2001; Pullarkat, 2003; Rizzi, 2004) is a relatively rare but recently described clinicopathologic entity in patients who do not have SLE or another well-defined autoimmune disease. Although this entity is still being defined, patients present with chronic peripheral blood cytopenias, BM fibrosis with variable marrow cellularity, and BM lymphoid aggregates in the absence of other disorders that typically cause myelofibrosis. These include primary marrow hematologic neoplasia, infection, metastatic cancer, or osteopathy such as Paget's disease or hyperparathyroidism. Prognosis for these patients appears to be very good with corticosteroid therapy.

Drugs (Andres, 2004; Bhatt, 2004) are an important cause of neutropenia, may act in different ways, and may affect progenitor or mature cell populations. Drugs are the most common cause of acute neutropenia (**agranulocytosis**) and typically show a lack of granulocytic cells in the marrow. In some patients, however, a pronounced progenitor hyperplasia may be present, sometimes termed **maturation arrest** or **promyelocytic hyperplasia**.

Drugs may initiate immune-mediated destruction via immune complex formation (quinidine) or complement-mediated cell lysis (propylthiouracil). Some drugs, including penicillin, aminopyrine, and gold, act as haptens. Inhibition of granulopoiesis or myeloid toxicity occurs with

chemotherapeutic agents, chlorpromazine, and others. These effects tend to be dose dependent and reversible. Important and limiting side effects of cancer chemotherapy are severe neutropenia with its risk of infection, as well as severe thrombocytopenia with risk of bleeding; anemia is more readily controlled with transfusion.

Radiation damages, alters, and destroys BM progenitor cells, as well as marrow stromal elements. Radiation type, dose, and duration are all factors that determine the extent of BM damage, such as aplasia or hypoplasia. Radiation affects a number of molecules and processes, including DNA structure, gene translation and transcription, apoptosis, and other signaling pathways. Lymphocytes are most sensitive and are directly killed by exposure. The lymphocyte count correlates with, and has been used to assess, dose and severity of exposure (Dainiak, 2002). In addition, hematopoietic precursors undergoing mitosis are very sensitive to injury and death.

Isolated neutropenia or agranulocytosis is fairly uncommon in adults. When a myelophthitic process, such as metastatic carcinoma, disseminated tuberculosis, or Gaucher's disease, infiltrates the BM, the damage is not limited to granulopoiesis but affects normoblasts and megakaryocytes as well. Because of the short life span of granulocytes, however, neutropenia is the earliest recognizable effect in the blood. It may take weeks before damage to the erythropoietic tissue becomes manifest because of the usually long life span of erythrocytes. Platelets have a rather short life span; on the other hand, megakaryocytes are more resistant to damage.

Neutropenia due to increased ineffective granulocytopoiesis occurs in megaloblastic anemias and with drugs that have an antifolate effect. In these conditions, anemia and thrombocytopenia are usually associated. The marrow is usually hyperplastic. In megaloblastic anemia due to nutritional deficiency, drug-induced suppression of DNA synthesis, or an inborn error of metabolism, asynchronous nuclear/cytoplasmic maturation (megaloblastic change or megaloblastosis) is identified in marrow progenitor cells. Ineffective granulocytopoiesis may also occur in myelodysplasia, discussed in the section on neoplastic disorders.

In starvation, cellularity tends to be decreased, and a morphologic marrow change termed serous fat atrophy or gelatinous transformation of the BM is present. This change shows a loss of hematopoietic cells within the marrow stroma replaced by small or shrunken fat cells expanded by an intercellular, homogeneous, eosinophilic material. BM hypocellularity is typically seen with advanced disease. Neutropenia with BM hypoplasia can be associated with a decrease in plasma or serum lysozyme (muramidase).

Transient neutropenia may occur early in some infections, followed by leukocytosis once marrow production catches up with the demand. As previously noted, in severe, extensive bacterial infection, neutropenia with a shift to the left may be due to inability of marrow production to keep up with peripheral utilization. Some bacterial infections, notably brucellosis and *Salmonella* infections, are prone to be associated with neutropenia; they may have some depressing effect on the marrow as well. Patients with viral infections such as measles and rubella have neutropenia for several days after appearance of the rash; this is probably due in part to increased utilization. Other acute viral infections, such as hepatitis, infectious mononucleosis, and influenza, may also cause acute neutropenia. Lymphocytosis is present and persists after the neutropenia subsides.

The neutropenia of hypersplenism has been attributed to selective removal of neutrophils by the spleen. It is associated with neutrophilic hyperplasia of the marrow and is corrected by splenectomy. Splenomegaly due to many causes may result in shortened neutrophil survival and neutropenia; these include congestive splenomegaly, Felty's syndrome, Gaucher's disease, and lymphoma. In some cases of Felty's syndrome (neutropenia and splenomegaly in rheumatoid arthritis), a neutrophil-specific antibody may be involved. Ramirez (2004) recently showed enhanced apoptosis in patients with cirrhosis and ascites, which appeared to be dependent upon elevated activity levels of caspase-3 in these patients. Patients are prone to neutropenia and infection; in the past, this was largely attributed to hypersplenism with increased splenic clearance of neutrophils. However, these recent findings suggest that other mechanisms, at least in part, may also be contributory.

Pseudoneutropenia may be caused by increased margination of neutrophils in some individuals, without a decrease in total granulocyte count. Rather than showing an equal distribution between MGP and CGP, an increased proportion of neutrophils appear to be present in the MGP. Small doses of endotoxin will cause a shift of neutrophils into the MGP from the CGP, giving an apparent neutropenia, before causing leukocytosis. In animals, anesthetic agents such as ether will cause the same type of pseudoneutropenia.

TABLE 33-4

Morphologic Alterations in Neutrophils

Toxic granulation—azurophilic cytoplasmic granules seen in severe infections, other toxic conditions, and reactive conditions
Cytoplasmic vacuoles—seen in infection, indicating phagocytosis
Döhle bodies—pale blue, oval cytoplasmic remnants of ribosomes seen in infection and other toxic conditions
May-Hegglin anomaly—rare autosomal dominant condition with pale blue cytoplasmic ribosomal inclusions resembling Döhle bodies
Alder-Reilly anomaly—prominent azurophilic granulation not related to infection
Pelger-Huët anomaly—bilobed or rounded nuclei with pince-nez shape
Chédiak-Higashi syndrome—autosomal recessive disorder with giant granules, likely representing giant fused lysosomes, and abnormal leukocyte function

Figure 33-1 A neutrophil with toxic granulation is pictured, along with two bands. Basophilic inclusions (Döhle bodies) are present as well ($\times 1000$).

Figure 33-2 Leukemoid toxic neutrophilia with left shift and toxic vacuolization ($\times 1000$).

Morphologic Alterations in Neutrophils

In addition to quantitative changes, qualitative morphologic alterations occur in neutrophils, and these too may be inherited or acquired. Some of these, such as toxic granules or cytoplasmic vacuoles, are acquired and disappear after the stimulus that provoked them is gone. Others are hereditary and persist through life, with or without functional impairment (Table 33-4). These are well illustrated and reviewed by Brunning (1970), and more recently by Kroft (2002).

It should be noted that disorders of leukocyte function may exist with no structural abnormality detectable with the usual modes of morphologic examination.

Toxic Granulation

Toxic granules are dark blue to purple cytoplasmic granules in the metamyelocyte, band, or neutrophil stage. They are peroxidase positive and may be numerous or few in number; less peroxidase activity may be seen in toxic than in normal neutrophils. Toxic granulation is noted in infections or other toxic conditions but may also be seen in noninfectious reactive conditions (Figs. 33-1 and 33-2).

Figure 33-3 May-Hegglin anomaly, showing Döhle-like inclusions ($\times 1000$).

Figure 33-4 The Alder-Reilly anomaly may be found in healthy individuals or in those with mucopolysaccharidoses, in which granules are metachromatic ($\times 1000$).

Döhle Inclusion Bodies

These small, oval inclusions in the peripheral cytoplasm of polymorphonuclear neutrophils stain pale blue with Wright's stain (see Fig. 33-1). They are remnants of free ribosomes or rough-surfaced endoplasmic reticulum, persisting from an earlier stage of development.

May-Hegglin Anomaly

This rare autosomal dominant condition involves the nonmuscle myosin heavy chain 9 gene (*MYH9*) linked to chromosome 22q12-13 (Kelley, 2000; Martignetti, 2000; Seri, 2000). The mutations appear to alter the assembly and stability of myosin and may be responsible for the underlying pathophysiology and changes seen in leukocyte and platelet structure and function. It appears that at the molecular level, various mutations in *MYH9* are, at least partially, responsible for a phenotypic spectrum of illness. This spectrum appears to include May-Hegglin anomaly and Sebastian, Fechtner, and Epstein platelet syndromes (Heath, 2001; Seri, 2003). This spectrum may be phenotypically modified by aberrant fibulin-1 gene expression, which also may be responsible for the clinical variability of disease (Toren, 2003). Fibulin-1 is a gene encoding for a secreted glycoprotein present in the basal membrane of many organs.

Although clinically variable, this anomaly is characterized by the presence of pale blue inclusions resembling Döhle bodies in neutrophils, by giant platelets, and, in some persons, by thrombocytopenia (Fig. 33-3). The inclusions are larger and more prominent than the Döhle bodies found in infections. They have been described in eosinophils, basophils, and monocytes, as well as in neutrophils (Brunner, 1970). The blue staining of the inclusions can be abolished by prior treatment of the cells with ribonuclease. With electron microscopy, the appearance of the inclusions differs from that of Döhle bodies (composed of parallel strands of rough endoplasmic reticulum), suggesting structural alterations in RNA and ribosomes (So, 2003). Granulocyte function is normal.

Alder-Reilly Anomaly

Dense, prominent, larger than normal azurophilic granulation in all white blood cells was described by Alder in 1939 (Fig. 33-4). In neutrophils, it may resemble toxic granulation, but it is unrelated to infection and is not transient. In 1941, Reilly described similar granulocytes in some but not all patients with gargoylism, Hurler's syndrome, or, more generally, the genetic mucopolysaccharidoses (Reilly, 1941). Other observations have

Figure 33-5 Genetic mucopolysaccharidoses often show abnormal lymphocyte granules with surrounding halos. In these cells from the same blood film, neutrophils showed similar changes ($\times 1000$).

Figure 33-6 Inherited Pelger-Huët anomaly ($\times 1000$).

shown that the heavy granulation in neutrophils can occur as a feature of the genetic mucopolysaccharidoses or independently in otherwise healthy persons (Brunner, 1970).

Occurring more often than the Alder-Reilly anomaly in the genetic mucopolysaccharidoses is a metachromatic inclusion in the lymphocytes surrounded by a clear space (Fig. 33-5). Macrophages in the marrow frequently contain similar granulation. This group of disorders is inherited and is characterized by deficiencies or derangement in various lysosomal enzymes required for degrading mucopolysaccharides. The result is abnormal deposition and storage of mucopolysaccharides in multiple organs. Skeletal abnormalities are prominent.

Pelger-Huët Anomaly

This hereditary, autosomal dominant condition involves failure of normal segmentation of granulocytic nuclei. Most nuclei are bilobed and rounded, with a characteristic spectacle or pince-nez shape (Fig. 33-6). The chromatin is quite coarse, and these are not normal young band forms. When a large number of band-like neutrophils appear in the differential count in a patient without infection or other cause, careful analysis of the blood films of the patient and of family members will occasionally establish the presence of the Pelger-Huët anomaly. The cells are functionally normal, and the underlying abnormality is mutation of the lamin B receptor gene (Speeckaert, 2009).

A similar appearing, acquired disorder of nuclear segmentation in granulocytes may be found in cases of granulocytic leukemia, myelodysplastic and some myeloproliferative disorders, and some infections, and after exposure to certain drugs (Brunner, 1970); this is called the pseudo-Pelger-Huët anomaly. In addition to band forms and neutrophils with only two segments, mature cells with round, nonsegmented nuclei and coarse chromatin are common. In contrast to the congenital Pelger-Huët anomaly, ring-shaped and other abnormal nuclei may be seen, and the cytoplasm is usually hypogranular.

Chédiak-Higashi Syndrome

Partial oculocutaneous albinism, photophobia, immune deficiency, abnormally large granules in leukocytes and other granule-containing cells, neurologic defects, and frequent pyogenic infections characterize this rare, autosomal recessive disorder (Introne, 1999). An accelerated lymphoma-like phase occurs, with lymphadenopathy, hepatosplenomegaly, and pancytopenia; lymphoid infiltrates are widespread, and death ensues at an early

Figure 33-7 Chédiak-Higashi neutrophils and lymphocytes with large granules ($\times 1000$).

age. Granulocytes, monocytes, and lymphocytes contain giant granules (Fig. 33-7), which appear to be abnormal lysosomes. The pathogenesis of this disorder is linked to an abnormality of granule maturation, causing enlargement and apparent fusion of granules and vesicles (such as lysosomes, melanosomes, and platelet dense granules) in all cell types. Leukocyte functional abnormalities exist. Although the mechanism is not fully elucidated, a mouse genetic model, *beige*, has revealed a mutation in the gene *CHS/beige*, coding for the CHS1 or Lyst protein. The *LYST* (lysosomal trafficking regulator) gene appears to be involved in regulation of vesicular size, trafficking, and intracellular movement, such that vesicular migration and release are abnormal (Ward, 2002).

Myelokathexis applies to peripheral neutropenia with the presence of BM neutrophils. WHIM (warts, hypogammaglobulinemia, infection, and myelokathexis) syndrome is a rare, autosomal dominant disease of leukocyte trafficking involving chromosome 2q21. The disease appears to be due to mutations in the chemokine receptor gene *CXCR4* and altered leukocyte response to its functional ligand CXCL12. Hematologic changes include severe peripheral neutropenia with lymphopenia also common, but with granulocytic hyperplasia of the BM (Gorlin, 2000; Hernandez, 2003; Gulino, 2003, 2004).

Functional Disorders of Neutrophils

Inherited and acquired disorders affecting neutrophils and other leukocytes may result in abnormal function and susceptibility to infections. Deficiencies of humoral factors (antibodies, components of complement) may result in defective chemotaxis or opsonization. As described previously, some inherited disorders, such as the May-Hegglin, Alder-Reilly, and Pelger-Huët anomalies, have altered morphologic appearances but apparently normal granulocytic function. Other inherited conditions, such as the Chédiak-Higashi syndrome and specific granule deficiency (SGD), display alterations in both morphology and function. Inherited conditions such as chronic granulomatous disease (CGD), myeloperoxidase deficiency (MYD), and leukocyte adhesion deficiency (LAD) exhibit functional disorders with essentially normal morphology on Wright's- and Giemsa-stained films.

Chronic granulomatous disease (Lakshman, 2001; Vignais, 2002; Heyworth, 2003; Jurkowska, 2004) is a rare, primary immunodeficiency affecting neutrophils, eosinophils, macrophages, and monocytes; it results from the inability of these phagocytic cells to kill intracellular microorganisms. Patients present with recurrent bacterial and fungal infections (skin, liver, mouth, lymph nodes). These lead to chronic granulomatous lesions (a hallmark of the disease) that may, in turn, obstruct vital organ systems and ultimately lead to death. Symptoms occur early in life, and both autosomal recessive ($\approx 66\%$) and X-linked ($\approx 33\%$) modes of inheritance are known.

The disease results from genetic defects in any of the membrane-bound or cytoplasmic components of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. This enzyme complex is not assembled and thus is inactive in the resting cell, but, with cell stimulation, the membrane and cytoplasmic components come together and are assembled into the active NADPH oxidase-protein complex, which can begin functioning. Once assembled, this enzyme is responsible for production of superoxide anion ($\text{NADPH} + 2\text{O}_2 \rightarrow 2\text{O}_2^- + \text{NADP}^+ + \text{H}^+$), as well as hydrogen peroxide and hypochlorous acid—molecular mediators of microbial cell death. The production of these highly reactive oxygen free-radical species is often referred to as the **respiratory burst**, indicating the increased oxygen consumption that occurs with NADPH oxidase activation. Thus, any

defect in this enzyme, which prohibits or significantly reduces its activity, will allow intracellular microorganisms to remain viable and ultimately spread (by cell mobility and seeding of adjacent tissue), producing recurrent infection and granulomatous disease. Global gene expression profiling studies (Kobayashi, 2004) suggest that both an increase in proinflammatory activity and defective neutrophil apoptosis may also be involved.

Myeloperoxidase (MPO) is present in neutrophils (in azurophil/primary granules) and monocytes (in lysosomes) but is not present in promonocytes and tissue macrophages. MPO catalyzes the cellular production of hypochlorite (ClO^-) or hypochlorous (HOCl) acid ($\text{H}_2\text{O}_2 + \text{Cl}^- \rightarrow \text{H}_2\text{O} + \text{ClO}^-$). HOCl is a strong oxidant normally involved in the destruction of intracellular microorganisms, as well as possibly tumor cells (Hoy, 2002). Although a single gene encodes MPO, the translation product undergoes a number of complex modification reactions, including insertion of heme, to produce the final active enzyme molecule (Nauseef, 2004).

Primary MYD is a congenital disorder that is not uncommon and that is easily identifiable with automated cell counters incorporating measurement of MPO activity in the differential count. Secondary MYD, which can be transient and corrected with treatment of the underlying disease, may occur secondary to conditions such as myeloid neoplasms, drugs, severe infectious diseases, diabetes mellitus, and pregnancy (Lanza, 1998). Primary MYD may be total or partial and does not show an increased frequency of infection in most individuals (Lanza, 1998; Lakshman, 2001; Suzuki, 2004), although an increase has been reported occasionally (Kutter, 2000).

Human eosinophil peroxidase is structurally related to MPO but is not identical and is encoded by a different gene. Deficiency is thought to be extremely rare, is unrelated to MYD, may show autosomal recessive inheritance, and appears to be without clinical symptoms (Nakagawa, 2001).

Patients with an extremely rare condition, SGD, present with multiple bacterial infections, atypical bilobed nuclei within neutrophils, and lack of secondary/specific cytoplasmic granules within neutrophils on Wright's-stained peripheral blood films. SGD also affects eosinophils. In addition to granule deficiencies and impaired bactericidal activity, neutrophils are defective in chemotaxis, receptor upregulation, and disaggregation. A mutation in a myeloid transcription factor gene (*CCAAT/enhancer binding protein-epsilon* or *C/EBPε*) appears to play a role in this disease (Rosenberg, 1993; Gombart, 2001; Khanna-Gupta, 2001).

Because proper neutrophil function is dependent upon cell-cell adhesion via the integrins, it is not surprising that LAD diseases exist. Integrins are essentially nonadhesive surface molecules in circulating leukocytes, which, upon proper stimulation, become adhesive or develop increased binding properties for their specific ligands. This appears to occur via conformational change in the integrin molecule structure and/or clustering of increased numbers of molecules on the cell surface. Ultimately, defective leukocyte adhesion and migration occur, resulting clinically in recurrent infection and leukocytosis.

Three types of leukocyte adhesion deficiencies have been described (Bunting, 2002; Gabius, 2002; McDowall, 2003; Etzioni, 2004). In LAD I, expression of integrin on the leukocyte cell surface is absent or abnormal because a mutation in the β_2 -subunit (of CD18) produces a lack of normal expression of the integrin, causing its absence or dysfunction at the cell surface. Recurrent severe infections, neutrophilia with severe infection, and delayed separation of the umbilical cord are seen. LAD II is due to a mutation affecting fucose transport, leading to the impaired expression of selectin ligands on leukocytes (CD15a or sialyl Lewis X), as well as other cells. Neutrophilia (with and without infection) and developmental abnormalities occur. In LAD III, CD18 and CD15a are normally expressed on leukocytes. Instead, there seems to be a defect in integrin activation (via endothelial chemokines) caused by a mutation in leukocyte-expressed G protein-coupled receptors (GPCRs). If binding between leukocyte GPCRs and endothelially expressed chemokines does not occur, integrin activation and leukocyte adhesion cannot occur. Recurrent severe infections, neutrophilia with infection, and bleeding tendencies have been noted. The latter is seen because platelet GPIIb/3 integrins are not activated. Some forms of LAD can be diagnosed by flow cytometry, by revealing the lack of expression of CD18 or CD15a on neutrophils (Roos, 2001).

Eosinophilia

Eosinophilia exists if blood eosinophils exceed $\approx 0.35 \times 10^9/\text{L}$ when large numbers of cells are counted, as with automated instruments or direct chamber counts; or $\approx 0.5 \times 10^9/\text{L}$ when the count is calculated from the 100- or 200-cell differential and the total leukocyte count. Increased eosinophils are chiefly acquired disorders and quantitative in nature, although Mathur has described impaired eosinophil function with aging, in the areas

TABLE 33-5

Key Causes of Eosinophilia

- Allergic—urticaria, hay fever, asthma
- Inflammatory—eosinophilic fasciitis, Churg-Strauss syndrome
- Parasitic—trichinosis, filariasis, schistosomiasis
- Nonparasitic infections—systemic fungal, scarlet fever, chlamydial pneumonia of infancy
- Respiratory—pulmonary eosinophilic syndromes (Löfller's, tropical pulmonary eosinophilia), Churg-Strauss syndrome
- Neoplastic—CML, Hodgkin lymphoma, T cell lymphomas
- Idiopathic hypereosinophilic syndromes—affecting heart, liver, spleen, CNS, other organs
- Others—certain drugs, hematologic and visceral malignancies, GI inflammatory diseases, sarcoidosis, Wiskott-Aldrich syndrome

CML, Chronic myelogenous leukemia; CNS, central nervous system; GI, gastrointestinal.

of degranulation, superoxide anion production, and adhesion (Mathurs, 2008). Eosinophilia is typically associated with allergic processes (the most common cause in ambulatory outpatients in North America) (Brigden, 1999) and parasitic infections; both are common secondary or reactive types of eosinophilia. Classically, the major function of eosinophils appeared to be the release of granule contents or reactive oxygen species generated by the cell membrane to damage the target organism or offending cell (Shurin, 1988). At present, eosinophil function appears more complex, in that additional functions with immunoregulatory and proinflammatory signaling roles also appear to exist. Thus, the eosinophil appears to be capable of acting as both an effector and/or a regulatory cell.

Similar factors influence the eosinophil count as described previously for the neutrophil count. These factors include (1) mitosis/proliferation, maturation/storage, and release in, and from, the BM; (2) the rate of outflow of eosinophils from the blood (rolling, tethering, adhesion, and migration); (3) trafficking of eosinophils to specific sites of accumulation; and (4) the survival and rate of eosinophil destruction in the tissues. Eosinophil production is stimulated by interleukin (IL)-5, migration is influenced by the chemokine eotaxin, and the two factors interact in producing eosinophilia (Palframan, 1998). Causes and conditions associated with eosinophilia are shown in Table 33-5.

Identification of a cause of secondary eosinophilia is often difficult, and extensive overlap between conditions has been noted. It may be more important to distinguish reactive eosinophilia from eosinophilia due to clonal hematopoietic neoplasms and from idiopathic hypereosinophilic syndrome.

The presence of an abnormal karyotype or other evidence of a myeloproliferative disorder suggests eosinophilia arising from a leukemic clone, although eosinophilia arising in lymphoid leukemias is likely reactive (Bain, 1996). Eosinophilia is usually present in chronic myeloid leukemia (CML), and some cases present with marked eosinophilia as the primary feature (Gotlib, 2003). Chronic eosinophilic leukemia is distinct from CML and shows different but varied cytogenetic abnormalities (Swerdlow, 2008).

A number of hematologic neoplasias may be accompanied by eosinophilia, including acute leukemias, systemic mast cell disease, plasma cell dyscrasias, and myelodysplastic and myeloproliferative diseases. It may also occur with a primary neoplasm originating in another organ, such as lung, soft tissue, or colon. Rare case reports in the literature describe associations of an eosinophilic leukemoid reaction with metastatic melanoma (Oakley, 1998), malignant fibrous histiocytoma (MFH) (Melhem, 1993), and lung carcinoma (Varindani, 1982). It appears that abnormalities in cytokine expression and regulation are responsible, at least in part, for this reaction. A granulocytic leukemoid reaction was reported in one patient with MFH (Melhem, 1993).

Eosinophilia is often a prominent component in tissue affected by HL, and extensive involvement has been reported to impart an adverse prognosis (von Wasielewski, 2003). Tissue and blood eosinophilia is also seen in T cell lymphomas and may similarly be a negative prognostic feature (Tancrede-Bohin, 2004). Eosinophilia is sometimes prominent in acute lymphoblastic leukemia, particularly those with $t(5,14)(q31;q32)$, in which the eosinophilia is considered to be reactive (Swerdlow, 2008).

Hypersensitivity and allergic reactions and atopic conditions such as bronchial asthma and seasonal rhinitis (hay fever) are characterized by eosinophilia. These immune reactions are mediated by IgE, which

results in mast cell and basophil degranulation with the release of a chemotactic factor for eosinophils. Eosinophils are found in the blood, marrow, and sputum (in bronchial asthma), and in nasal and conjunctival discharges (in hay fever). Blood eosinophilia usually is only mild or moderate ($0.4\text{--}1.0 \times 10^9/\text{L}$).

In asthma, absolute eosinophil counts have been useful in management because the level of eosinophils positively correlates with pulmonary performance, indicates the adequacy of steroid therapy, and may indicate the presence of complicating infections.

A variety of skin disorders exhibit cutaneous eosinophilic infiltrates. Some are commonly associated with peripheral eosinophilia, and others are not (Christophers, 2000). Atopic dermatitis and eczema are often accompanied by blood eosinophilia, especially in children. In pemphigus, eosinophilia is characteristic. Eosinophilia is frequently associated with acute urticarial reactions but is uncommon in chronic urticaria. In any case, it is important to recognize that the recruitment of eosinophils is dependent upon the proper interaction of chemokines (IL-5) and their receptor molecules, as well as their interaction with specific subset lymphocyte populations (T-helper type 2 [Th2] lymphocytes) in these cutaneous responses and conditions.

Moderate to severe peripheral blood eosinophilia is most commonly associated with infection by helminths (parasitic worms, including nematodes, trematodes, and cestodes), constituting the most common cause of eosinophilia in the world (Brigden, 1999). Eosinophilia is more pronounced if tissues are invaded (e.g., trichinosis) than when parasites inhabit the lumen of a viscus (e.g., tapeworm). Some parasites, such as *Taenia solium* (cysticercosis), produce little inflammatory response while alive but trigger an inflammatory response upon degeneration of the organism. Other parasites, such as *Trichinella spiralis* (trichinosis), incite peripheral eosinophilia upon larval invasion of the muscles and encystment. Note that the absence of eosinophilia does not exclude a parasitic infection (Schulte, 2002).

In trichinosis, eosinophil levels begin to rise in the blood within days after infection. The peak of the eosinophilia is seen during the third or fourth week. Eosinophilia may be absent, however, in severe infestation with trichinae.

Leukocytosis and eosinophilia extending over months are seen in toxocarasis or visceral larva migrans. Migrating larvae of the dog (*Toxocara canis*) or the cat (*T. cati*) nematode cause this infestation. In this condition, pulmonary lesions (Löfller's syndrome or simple eosinophilic pneumonia) may be present; an immune hypersensitivity reaction to the nematode *Ascaris lumbricoides* has been classically associated with Löfller's syndrome.

Another parasitic infestation with eosinophilia is creeping eruption (cutaneous larva migrans) caused by larvae of the dog (*Ancylostoma braziliense*) or cat (*A. caninum*) hookworm. Eosinophilia in these infections is T cell dependent (Basten, 1970) and, as indicated earlier, is dependent upon multiple chemokine and chemotactic molecules and receptors and intercellular interactions.

Eosinophilia of various degrees is seen in some infectious diseases. In scarlet fever, eosinophilia is commonly associated with the cutaneous rash, which is probably allergic in nature. Chorea may be associated with eosinophilia, but other forms of rheumatic fever are not.

Eosinophilic pneumonias with acute presentations typically include simple pulmonary eosinophilia or **Löffler's syndrome**, parasitic infections, drug-induced eosinophilic pneumonias, and idiopathic acute eosinophilic pneumonia. A number of pulmonary eosinophilic syndromes with more chronic presentations also exist. Other classification schemes divide eosinophilic pneumonia into idiopathic (of unknown cause) and secondary (infection, drug, immunologic and/or systemic disease) pneumonia.

Löffler's syndrome (simple eosinophilic pneumonia) affects all age groups and is characterized by repeated, transient pulmonary exudates accompanied by fever and clinical symptoms of bronchitis, often producing sputum that contains eosinophils. The syndrome resolves in a few weeks. It may be caused by a variety of exposures, including certain drugs, inhaled antigens, or helminth (see earlier) infestation. The latter occurs during periods of dissemination or migration when parasites pass from the blood into the alveoli of the lung. Löfller's syndrome may also be idiopathic.

Many drugs are associated with blood or pulmonary eosinophilia and pulmonary infiltrates. Symptoms may be mild, or more severe, leading to fulminant respiratory failure. However, the prognosis is favorable in most cases, with resolution of the disease occurring with elimination of the offending drug. Thus, a careful drug history is critical for diagnosis in these patients. Implicated drugs include pilocarpine, physostigmine, digitalis, *p*-aminosalicylic acid, sulfonamides, chlorpromazine, phenytoin, some

Figure 33-8 Marked eosinophilia of unknown cause, suggesting hypereosinophilic syndrome, peripheral blood ($\times 1000$).

antidiabetic drugs, some anticancer agents, and many others. A common mechanism for the production of eosinophilia has not been identified. Patients with kidney and/or liver disease have a higher incidence of drug reaction, including eosinophilia, than others.

Tropical pulmonary eosinophilia is a syndrome of paroxysmal cough and bronchospasm associated with marked eosinophilia. It is found mainly in India, Africa, Southeast Asia, and the South Pacific. However, it may be seen in any racial group living in an endemic area. *Wuchereria bancrofti* (a parasite of humans that inhabits the lymphatics) is the most common and widely distributed cause of this disease. Very high titers of serum IgG and IgE levels against microfilarial antigens are present. The disease is probably a hyperimmune reaction to microfilariae, which may be found occasionally in lung or lymph node biopsy specimens, but not usually in blood. Response to the antifilarial drug diethylcarbamazine is curative.

Persistent high levels of eosinophils for long periods of time, no evidence of known causes of eosinophilia, and signs and symptoms of organ damage and injury are criteria for inclusion of patients in idiopathic hypereosinophilic syndrome (HES) (Fig. 33-8). HES appears to be a heterogeneous syndrome composed of a number of different disorders of varying severity. Although the pathogenesis of HES is not entirely understood, dysregulation of intracellular or intercellular molecular communication(s) appears to be involved, at least in some forms of HES. This dysregulation leads to persistently activated eosinophils, which release eosinophil granule proteins and enzymes, lipid mediators, and cytokines, chemokines, and growth factors; this not only produces tissue damage and injury, but also sets up an **autocrine loop** that continually activates cells and continues to produce eosinophil degranulation, causing further cell and tissue damage. Some forms appear to be T cell mediated, involving a subset of Th2-type lymphocytes. At least two distinct forms or hematologic variants appear to exist: the myeloid variant and the lymphoid variant, differing in clinical presentation, long-term behavior, and risk for malignant transformation (Brito-Babapulle, 2003; Roufosse, 2003). Clonal populations of eosinophils have been found in some patients with HES (Chang, 1999). In other patients with HES, abnormal clonal populations of T cells have been identified; these clonal populations may be precursors of malignancy (Simon, 1999).

The organ most consistently affected in HES is the heart, with mural thrombi formation, myocarditis, endocardial and myocardial fibrosis, constrictive pericarditis, and fibroplastic endocarditis (Brito-Babapulle, 2003). Hepatosplenomegaly is common. Other organ systems may be involved and include the CNS, retina, lungs, skin, gastrointestinal (GI) tract, and kidney.

Occasional reports describe persistent eosinophilia occurring in families in the absence of any known cause. This condition is known as **familial** or **constitutional eosinophilia** and appears to be benign (Naiman, 1964). The exact prevalence of familial eosinophilia is unknown.

Basophilia

Basophilia is an increase in the absolute basophil count above $0.2 \times 10^9/\text{L}$. Causes of basophilia are listed in Table 33-6. Reactive basophilia is an uncommon finding overall. Basophilia is seen most frequently in hypersensitivity and allergic reactions, CML (Fig. 33-9), myeloid metaplasia (extramedullary myelopoiesis), and polycythemia vera. Relative basophilia may be transient following irradiation. Basophilia may be present in hypothyroidism and chronic hemolytic anemia and following splenectomy.

TABLE 33-6

Key Causes of Basophilia

- Myeloproliferative disease
- Allergic—food, drugs, foreign proteins
- Infectious—variola, varicella
- Chronic hemolytic anemia—especially post splenectomy
- Inflammatory—collagen vascular disease, ulcerative colitis

TABLE 33-7

Key Causes of Monocytosis

- Infectious—tuberculosis, subacute bacterial endocarditis, syphilis, protozoan, rickettsial
- Recovery from neutropenia
- Hematologic—leukemias, myeloproliferative disorders, lymphomas, multiple myeloma
- Inflammatory—collagen vascular disease, chronic ulcerative colitis, sprue, myositis, polyarteritis, temporal arteritis
- Others—solid tumor, immune thrombocytopenic purpura, sarcoidosis

Figure 33-9 Marked basophilia and an eosinophil in a patient with Philadelphia chromosome positivity ($\times 1000$). (Courtesy of Robin Abaya, MD.)

Monocytosis

Monocytosis is an increase in monocytes above the upper reference value, especially when greater than $1.0 \times 10^9/L$. The most common causes are recovery from neutropenia and indolent infections. Causes and associations of monocytosis are shown in Table 33-7.

Monocytosis is present during the recovery stage from acute infection and from agranulocytosis, in which it is considered a favorable sign. Monocytosis may be present in subacute bacterial endocarditis. In this condition, monocytes may show phagocytosis of other blood cells, red blood cells, and leukocytes. It may be present in mycotic, rickettsial, protozoal, and viral infections.

Infectious disease, however, is an uncommon cause of monocytosis. In a classic study of 160 successive cases of absolute monocytosis (Maldonado, 1965), more than half (85) were associated with **hematologic disease**. These included acute monocytic and granulocytic leukemias, lymphoma (HL most frequently), multiple myeloma, and myeloproliferative disorders.

Monocytopenia

Monocytopenia is a decrease in circulating monocytes below the lower reference value of $0.2 \times 10^9/L$. Few studies have dealt with monocytopenia because of (1) the large number of cells that must be counted in a differential to obtain reliable counts; (2) the distributional bias of wedge blood film for monocytes compared with the spinner-made blood film; and (3) the unavailability, until fairly recently, of automation allowing large numbers of cells to be counted routinely.

During therapy with prednisone, monocytes fall during the first few hours after the first dose but return to above original levels by 12 hours. Monocytopenia has also been observed in hairy cell leukemia (HCL). Monocytopenia is uncommon as an isolated finding.

TABLE 33-8

Key Causes of Lymphocytosis

- Infectious—many viral, pertussis, tuberculosis, toxoplasmosis, rickettsial
- Chronic inflammatory—ulcerative colitis, Crohn's
- Immune mediated—drug sensitivity, vasculitis, graft rejection, Graves', Sjögren's
- Hematologic—ALL, CLL, lymphoma
- Stress—acute, transient

ALL, Acute lymphoblastic leukemia; CLL, chronic lymphocytic leukemia.

LYMPHOCYTIC AND PLASMACYTIC DISORDERS

In these disorders, the pathologist should consider neoplastic conditions, which are covered in the later sections of this chapter, as well as the benign causes, discussed in the following sections.

Lymphocytes in Normal Individuals

In normal individuals, the absolute numbers of lymphocytes and T cells are highest in young children. The percentage of lymphocytes in the blood is normally up to about 50% for the first 5 years. During the first decade of life, the absolute lymphocyte count and the absolute number of T cells decrease but remain higher than observed in the adult. By the time of adolescence, the absolute lymphocyte count and the absolute number of T cells have leveled off to values observed throughout adulthood. The absolute number of B lymphocytes remains stable during all stages of life (Davey, 1977; Perkins, 2004). In adolescence and adulthood, lymphocytes constitute about 20%–40% of all leukocytes, or $1.5\text{--}4.0 \times 10^9/L$ cells/L.

Some disagreement is ongoing regarding the absolute numbers of lymphocytes and of T cells in aged individuals. Although some studies (Diaz-Jouanen, 1975) indicate that there is a decrease in total lymphocyte count and T cell numbers, other investigators have reported no significant change in total lymphocytes or T cells in aged individuals (Weksler, 1974; Davey, 1977). The normal CD4/CD8 ratio is between 1.0 and 3.4, but we have seen values as high as 12 in reactive conditions. In the neonate, the numbers of total T cells and CD8+ T cells may be similar or decreased compared with adults, whereas CD4+ T cells may be similar or increased (De Waele, 1988).

Lymphocytosis

Lymphocytosis is an increase in the number of lymphocytes in the peripheral blood; reference intervals are $\approx 1.5\text{--}4.0 \times 10^9/L$ in the adult and $\approx 1.5\text{--}8.8 \times 10^9/L$ in the child. Relative lymphocytosis (an increase in the percentage of lymphocytes) is present in various conditions and is especially prominent in disorders with neutropenia. Lymphocytosis is unusual in acute bacterial infections but is commonly associated with viral infection (Epstein-Barr virus [EBV], hepatitis) (Table 33-8).

Acute Infectious Lymphocytosis

Acute infectious lymphocytosis (AIL) is a contagious condition characterized by lymphocytosis and occurring mainly in children. The incubation period is 12–21 days. Antibody and viral studies have indicated a relationship between infectious lymphocytosis and coxsackievirus A, coxsackievirus B6, echoviruses, and adenovirus type 12. No association has been noted with EBV, cytomegalovirus, or herpesvirus. The disease has variable systemic manifestations, from mild and nonspecific to more marked symptoms such as vomiting, fever, abdominal discomfort, signs suggesting involvement of the nervous system, cutaneous rashes, upper respiratory infection, and diarrhea. Leukocytosis ($20\text{--}5 \times 10^9/L$, occasionally $>10 \times 10^9/L$) precedes the clinical manifestations.

In AIL, from 60%–95% of blood leukocytes are small mature lymphocytes and are probably of T cell origin (Cassuto, 1977). In contrast to infectious mononucleosis, atypical lymphocytes are uncommon. Eosinophilia is usually present. The lymphocytosis usually lasts 3–5 weeks, sometimes longer. Other blood changes are unusual. The marrow has no characteristic changes; an increased percentage of lymphocytes has been observed but is probably an artifact of an admixture of peripheral blood. Lymph node enlargement is rare and minimal when present. The spleen and the liver are rarely, if ever, enlarged. Lymph node biopsy may show reactive follicular hyperplasia but no characteristic changes. In some cases, white cells in the cerebrospinal fluid (CSF) are increased, with about 40% lymphocytes.

A chronic form of infectious lymphocytosis also occurs in children. The leukocyte count is $10\text{--}25 \times 10^9/\text{L}$, with 60%–80% lymphocytes of normal appearance. Slight eosinophilia, monocytosis, and plasmacytosis are also present. As a rule, children have enlargement of tonsils, lymph nodes, and spleen and a history of recurrent upper respiratory infection. The marrow shows no abnormalities.

Pertussis

Whooping cough (pertussis), although reduced by routine immunization, still occurs in unimmunized children and is most severe in infants. It also occurs in adults with immunity reduced since childhood vaccination. The etiologic agent is *Bordetella pertussis*, a highly infectious agent that produces an inflammatory reaction of the entire respiratory tract. The incubation period is approximately 6–20 days, and the first symptoms are those of a head cold. Later, the patient develops paroxysms of coughing productive of thick sputum. The paroxysms typically end with a “whooping” sound, due to deep inspiration, giving the disease its descriptive name. There is frequently pain over the trachea and bronchi. The disease typically lasts 6–12 weeks.

Patients frequently develop significant lymphocytosis with counts higher than $30 \times 10^9/\text{L}$ recorded. The lymphocytes are small, mature T cells with a normal CD4/CD8 ratio (Hudnall, 2000). The lymphocyte count is highest during the first 3 weeks of the illness, and then decreases during the fourth and subsequent weeks (Lagergren, 1963). The lymphocytosis is at least partially due to the release of lymphocytosis-promoting factor (LPF) or pertussis toxin from the organism. This factor may cause transient increased mobilization of lymphocytes from lymphoid organs, followed by inhibition of recirculation of lymphocytes from blood into the lymph flow. Thus, the lymphocytosis is due to redistribution of lymphocytes into the peripheral circulation without increased lymphopoiesis (Rai, 1971; Spangrude, 1985). At the molecular level, this absolute lymphocytosis appears to be due, at least in part, to the absence of L-selectin on many circulating lymphocytes (Hudnall, 2000). This seems reasonable in that L-selectin is an endothelial adhesion and lymph node homing receptor, and absence of this surface molecule would essentially prevent circulating lymphocytes from finding their “home” in most lymph nodes. They would remain in the circulation for longer time periods and cause an increase in number (lymphocytosis) in the blood. The exact mechanism of loss of L-selectin from the lymphocyte cell surface is not presently known.

Chronic Lymphocytosis/Persistent Polyclonal B Cell Lymphocytosis

Persistent reactive lymphocytosis is an uncommon event in adults, and significant lymphocytosis should raise suspicion of neoplastic disease, such as chronic lymphocyte leukemia. Coexistence of neutropenia or classic Feltz's syndrome suggests LGL leukemia. Often tissue biopsy and/or immunophenotyping of peripheral blood will point toward a specific disease or diagnosis. Mononucleosis or lymphocytosis due to other viruses occasionally presents in later life, however.

A rare condition, persistent polyclonal lymphocytosis, has been reported in adults, predominantly in female smokers, and in the postsplenectomy state (Himmelmann, 2001). Persistent polyclonal B cell lymphocytosis appears to be a benign polyclonal B cell proliferation, showing binucleated atypical lymphocytes in the peripheral blood. Polyclonal serum IgM is usually increased. A majority (65%–85% vs. 15%–20% in normal individuals) of the peripheral B cells appear to be IgM+/IgD+/CD27+ memory B cells (Loembe, 2002). Occasional *bcl-2/Ig* gene rearrangements (t[14;18]), commonly associated with follicular lymphoma, have been found (Delage, 1997). Although the cause is unknown, dysregulation of Fas-mediated apoptosis and the CD40 survival pathways appear to be involved (Loembe, 2001; Roussel, 2003).

Retrovirus-Associated Diseases and Conditions

Human T lymphotropic virus type 1 (HTLV-1), discovered in 1980 by Poiesz and Gallo, is a retrovirus associated with adult T cell leukemia/lymphoma (ATL) (Poiesz, 1980). It is endemic in areas of Japan, the Caribbean basin, and the southeastern United States. HTLV-2, a second human retrovirus, was found in a patient with HCL (Kalyanaraman, 1982). A third human retrovirus, human immunodeficiency virus type 1 (HIV-1), was recognized and confirmed as the cause of acquired immunodeficiency syndrome (AIDS [discussed further later]) over the next 2 years. Later, in 1985, a second but distinct type of HIV—HIV-2—was identified.

HIV-1 infects both monocyte/macrophages and T cells (both essential cells for normal immune system function), using cell surface chemokine

Figure 33-10 Infectious mononucleosis, showing a large activated lymphoid cell in the blood ($\times 1000$).

receptors (CCR5 on the former and CXCR4 on the latter); infection ultimately causes progressive loss of CD4+ lymphocytes, disrupts normal immune function, and produces immunodeficiency and disease. Disease encompasses not only many different types of infection, but also an increase in neoplastic disease, including lymphoma. At present, it appears that HIV-1 plays an indirect role (through immune dysregulation and not by direct induction) in the development of these lymphomas (Knowles, 2003). HTLV-1 and -2 also infect and transform T cells, primarily CD4+ cells with HTLV-1 and CD8+ cells with HTLV-2. HTLV-1 immortalizes CD4+ lymphoblasts in some patients, producing ATL. Although HTLV-2 was originally identified in a patient with HCL, a definitive link between HTLV-2 infection and human disease does not currently exist.

Several cases have now been reported of a transient T cell lymphocytosis in patients infected with HTLV-1 (Kinoshita, 1985; Ehrlich, 1988). In most patients, the disorder is characterized by few clinical symptoms consisting of fever, limited lymphadenopathy, and occasional skin rash. The peripheral blood lymphocyte count is usually less than $20 \times 10^9/\text{L}$; however, 10%–40% of these lymphocytes are immature forms. In most of these cases, the lymphocytosis is monoclonal and, therefore, leukemic. Although some patients with this infection progress to ATL, most (90%–95%) patients with antibodies against HTLV-1 are symptom free. Most individuals exhibit only a viral-like syndrome; however, others manifest a chronic progressive leukemia, and still others develop tropical spastic paraparesis (Davey, 1991). ATL typically develops decades after initial infection, and thus is usually seen in older patients.

Infectious Mononucleosis and Epstein-Barr Virus Infection

Infectious mononucleosis (IM) is usually a self-limited infectious disease characterized by sore throat, prolonged malaise, atypical lymphocytosis with the presence of large transformed lymphocytes (Fig. 33-10), lymphadenopathy (most often posterior cervical), and often splenomegaly. In immunocompromised patients, EBV is associated with benign B cell hyperplasia, malignant lymphoma, and posttransplantation lymphoproliferative disease (Hess, 2004; Thompson, 2004).

Etiology and Pathophysiology. IM is a disorder that occurs secondary to infection with EBV (human herpesvirus 4). When the primary infection occurs in healthy individuals during early childhood, the disease often goes unnoticed. However, when the infection involves healthy adolescent individuals or adults, the resultant disorder is the IM syndrome. In most cases, the virus gains entry into the body through the oropharyngeal epithelial and lymphoid tissues, and the virus appears to infect both tissues. The virus attaches to C3d complement receptors (CD21) on B lymphoid cells and enters into the cells. The EBV then stimulates DNA synthesis in these B cells and induces the formation of several new antigens, including the viral capsid antigen (VCA), the membrane antigen (MA), early antigen (EA)—both diffuse (EA-D) and restricted (EA-R) subtypes—Epstein-Barr nuclear antigens (EBNA), and the lymphocyte-detected membrane antigen (LYDMA) (Harrington, 1988). Thus, the earliest phase of this disease is characterized by an infection of B cells that proliferate, develop neo-antigens, circulate, stimulate an immune response, and synthesize immunoglobulin (Sixbey, 1984). VCA, EA, and EBNA are the viral proteins most important for serodiagnosis in immunocompetent patients (Hess, 2004). Clinical and laboratory features are summarized in Table 33-9.

Typically, the humoral immune response is characterized by the rise in titer of IgG and IgM viral capsid antibodies during the incubation and

TABLE 33-9

Summary of Features of Infectious Mononucleosis (IM) in Immunocompetent Patients

Epstein-Barr Virus (Human Herpesvirus-4)**Pathophysiology**

- Virus enters through oropharyngeal epithelial and lymphoid cells
- Virus attaches to CD21 on B cells
- Viral antigens—viral capsid antigen (VCA), early antigen (EA), Epstein-Barr nuclear antigen (EBNA)—are produced and elicit antibody production

Humoral Immune Response

- Immunoglobulin (Ig)M against VCA rises during incubation and prodrome, falls over few weeks to months
- IgG against VCA rises during incubation, decreases during convalescence, remains detectable for life
- Antibodies to EA rise 2–3 weeks after onset of illness, then fall
- Antibodies to EBNA rise during convalescence, detectable for life

Cellular Immune Response

- T cells activated during second week of illness
- CD8-positive cytotoxic T cells kill infected B cells
- Natural killer cells kill infected B cells
- Some resting memory B cells remain latently infected

Clinical Features

- 2- to 5-week incubation period
- Vague onset of symptoms
- Fever, sore throat, lymphadenopathy
- Adolescents, young adults more often symptomatic than younger children

Laboratory Features

- Leukocytosis with absolute lymphocytosis and atypical lymphocytes
- Transient monocytosis
- Relative and absolute neutropenia early on
- Mild thrombocytopenia in half of cases
- Hemolytic anemia in 1%–3% of cases, often with anti-I specificity
- Elevated transaminases in 85%–100% of cases, but clinical jaundice rare
- Spot test is simple, rapid, specific, based on agglutination of horse red blood cells (RBCs)
- Heterophil antibody (HA) test is based on differential absorption of IM-specific HA by beef RBC stroma and guinea pig kidney

early prodrome periods. The titer of IgM capsid antibody starts to fall during the second and third weeks of illness, and then diminishes to undetectable levels within the following several months. The IgG viral capsid antibody decreases during convalescence but remains detectable for life. Approximately 2–3 weeks after the onset of illness, Epstein-Barr virus antibodies against the early antigens appear and then decline over the succeeding 2 months. The titer of the Epstein-Barr virus nuclear antigen antibodies rises during the latter portion of convalescence and is apparently detectable throughout life.

The cellular immune response in IM is characterized by proliferation and activation of T cells, usually during the second week of illness, in response to EBV-induced B cell infection and activation. Because these activated T cells are derived mostly from the cytotoxic/suppressor cell subpopulation, marked suppression and destruction of EBV-infected B cells occur. Indeed, most of the atypical lymphocytes observed in the peripheral blood of patients with IM during the second week of illness possess the CD8 antigen. These cytotoxic/suppressor T cells kill infected B cells and diminish polyclonal antibody production induced by the Epstein-Barr virus. In addition to T-cytotoxic cells, the activity of natural killer (NK) cells has a profound effect on limiting the proliferation of EBV-infected B cells in patients with IM (Purtilo, 1981). It is also likely that EBV-infected B cells are destroyed, at least in part, through the mechanism of antibody-dependent cellular cytotoxicity—a process requiring the presence of both cytotoxic cells and antibody. This process of B cell proliferation followed by the inhibitory and destructive effects of EBV-directed antibody production, as well as T cell and NK cell cytotoxic effects, occurs within the patient's peripheral blood, BM, lymphoid tissues, and, perhaps to a limited degree, all tissues of the body.

Most (over 90%) immunocompetent adults have serologic evidence of past EBV infection. EBV has the capacity not only to infect cells (many of which are destroyed by an intact immune system) but to produce a latent infection in resting memory B cells and, in some cases, produce transformation of lymphocytes to malignant lymphoma (Kuppers, 2003; Thorley-Lawson, 2004). However, a majority of latently infected individuals show no disease manifestations throughout their lifetimes.

The resting memory B cells can act as a reservoir of EBV, because viral antigens (easily recognized by an intact immune system) are not expressed on the lymphocyte surface. In this model of EBV infection, mechanisms of viral persistence and transformation appear to be dependent on the interaction between the stage of maturation of the infected lymphocyte and the genetic expression of different groups (or “programs”) of viral proteins within the infected lymphocyte (Kuppers, 2003; Thorley-Lawson, 2004). In addition, different types of EBV-associated tumors (such as African Burkitt lymphoma [BL], nasopharyngeal carcinoma, B cell lymphoproliferative disease or posttransplant lymphoproliferative disease in immunocompromised individuals, and HL) appear to exhibit different groups of viral protein expression (Wong, 2002).

In IM, a spectrum of EBV expression patterns (programs) is found in different cells (Klein, 2007). In type III latency-growth program, cells express a full set of EBV-encoded proteins, including six nuclear proteins (EBNA1–6) and three latent membrane proteins (LMP1, -2 and -3).

LMP1 has strong immunogenic activity and is present only in acute infection, except in immunocompromised hosts. Type I latency program involves expression of only one nuclear protein, EBNA-1, and is found in some memory B cells. Type IIa latency involves expression of EBNA-1, LMP-1, and LMP-2. Type IIb latency expresses all EBNA (EBNA1–6) but not LMP-1. Tumor cells in posttransplant lymphoproliferative disorders (PTLDs) correspond to latency type III, BL cells to latency type I, and cells in EBV+ HL and EBV+ nasopharyngeal carcinoma (NPC) to latency type IIa, with LMP-1 expression. T/NK cells are not normally infected by EBV and in extranodal nasal T/NK cell lymphoma; infection is complex, involving inflammatory tissues, is of latency type II with abundant LMP-1, and is dependent on IL-2.

Given the diversity of EBV-related protein expressions, assay for more uniformly expressed molecules is warranted for diagnostic identification of EBV. EBV-encoded RNAs EBER-1 and EBER-2 are reliably expressed at high levels in virtually all latent EBV infections, and are detected with high sensitivity by in situ hybridization assays that are currently the standard for EBV identification (Gulley, 2008).

Clinical Features. IM has been observed in patients from 3 months–70 years of age but is most common in adolescents and young adults. A 2- to 5-week incubation period prior to onset of symptoms usually occurs. Onset is vague, indefinite, and similar to the onset of other infectious diseases. Patients usually have fever, sore throat with ulcerative pharyngitis, and lymphadenopathy.

Complications. Of the rare anemias associated with IM, hemolytic anemia is the most common, occurring in 1%–3% of cases. The cause now appears to be related to the anti-I antibody produced frequently in this disease.

Mild thrombocytopenia occurs in about half of cases, but the platelet count is not often less than $100 \times 10^9/L$. Thrombocytopenic purpura with hemorrhagic complications is exceedingly rare. Splenic rupture may also occur. Neutropenia, pancytopenia, and hemophagocytic syndrome may rarely occur and be fatal (Mroczek, 1987). Two rare conditions resulting from EBV infection in healthy individuals are chronic active EBV infection (CAEBV) and EBV hemophagocytic syndrome (EBVHS). Both conditions show high morbidity and mortality and appear to be related to ectopic EBV infection in T cells and natural killer cells, in contrast to the usual B cell infection that commonly occurs in IM (Kasahara, 2002).

Abnormal liver function tests indicative of hepatitis occur in 85%–100% of patients with IM. Clinical jaundice is rare, but cases have been reported in which jaundice and acute pharyngitis were the only clinical manifestations of IM, with positive hematologic and serologic findings. Although uncommon, complications may also involve the nervous system, heart, kidney, and lungs.

Approximately one third of patients with IM carry β -hemolytic streptococci in the pharynx. Thus, one should give attention to strict clinical, hematologic, and serologic criteria in distinguishing IM from streptococcal pharyngitis.

Hematologic Features. Leukocytes are increased, usually ranging from $12\text{--}25 \times 10^9/\text{L}$. Rarely, counts as high as $80 \times 10^9/\text{L}$ have been recorded. The leukocytosis is usually due to lymphocytosis (60%–90%) composed of a variety of atypical lymphocytes. The total leukocyte count, as a rule, returns to normal within 3 weeks. The atypical lymphocytes have nuclear alterations and an increase in the amount and basophilia of cytoplasm.

Lymphocytes include **monocytoid** lymphocytes, which likely correspond to immunoblasts in lymph nodes (see Fig. 33-10). Other atypical lymphocytes, which are more numerous, include plasmacytoid lymphocytes and those with small nuclei but abundant cytoplasm.

Often the number of monocytes rises transiently. The term **mononucleosis** refers to an increase in lymphocytes, not in monocytes.

Cytologic alterations are not pathognomonic of IM. Similar cells are found in a variety of disorders, including cytomegalovirus mononucleosis, toxoplasmosis, and infectious hepatitis, and usually to a lesser extent in viral pneumonia, varicella, mumps, and viral exanthemas of children.

Neutrophils are relatively and absolutely decreased in most cases during the first week of illness. During this time, a shift to the left may occur, with an increase in band cells and metamyelocytes. Toxic granules and Döhle bodies may be seen. The eosinophils are within normal limits.

The BM from patients with IM usually shows increased cellularity. Numbers of lymphocytes, macrophages, plasma cells, megakaryocytes, and erythroid cells are increased. The neutrophilic series appears decreased. About half of cases may have collections of mononuclear cells forming loose granulomas.

Serologic Findings in Immunocompetent Patients

Heterophil Antibody. Paul (1932) first described the presence of sheep cell agglutinins in the sera of patients with IM. Sheep cell agglutinins are not, however, specific for IM and can be present in other disorders.

Davidsohn (1937) demonstrated that the heterophil antibodies in patients with IM are absorbed by beef erythrocytes, in contrast to heterophil antibodies present in other disorders. The latter are absorbed by Forssman's antigen, such as that found in guinea pig kidney. The differential absorption test (Paul-Bunnell-Davidsohn test) is highly specific for IM (Davidsohn, 1969).

The spot test for IM (Lee, 1968) is based on the principle that horse erythrocytes are more sensitive than sheep erythrocytes in testing for IM. A positive test for IM shows agglutination of horse erythrocytes by serum absorbed with guinea pig kidney, but not by serum absorbed with beef erythrocyte stroma. The spot test has proved to be a simple, rapid, highly specific, and sensitive test for the heterophil antibodies of IM. False-positive tests occur but are very rare. The spot test is still in use, as are other similarly performing immunoassays and latex-based detection tests for heterophil antibody (Rogers, 1999). False-negative tests occur particularly in young children who produce heterophil antibodies (IgM) in limited amounts. In heterophil-negative IM, the diagnosis may be substantiated by assay for antibody to EBV.

As previously mentioned, several antibodies are produced by the host in response to a variety of Epstein-Barr virus antigens (see Table 33-9). Antibody to the viral capsid antigen arises within the first 2 weeks of onset. This antibody, measured by an immunofluorescent or other method, is used for determining exposure to EBV. Assaying for the presence of EBV antibody is usually limited to the few cases of heterophil-negative IM.

In addition to heterophil and EBV antibodies, patients with IM frequently produce antibodies to a wide variety of antigens. Antibodies against human erythrocytes, leukocytes, and platelets have been described. Patients with IM have an increased frequency of cold agglutinins. Positive tests for rheumatoid factor and antinuclear factor have been reported.

In immunocompromised patients, serologic tests are of limited value, and direct detection methods are considered more reliable. Determination of EBV viral load by polymerase chain reaction (PCR) appears to be one of the better tests for this patient population (Hess, 2004).

Differential Diagnosis. Clinical, hematologic, and serologic features of IM permit an accurate diagnosis to be made in more than 90% of cases. When the heterophil test is negative, one must consider several possibilities. The patient could still have EBV antibody-positive but heterophil-negative IM. Cytomegalovirus infection, however, is the most common cause of heterophil-negative mononucleosis. Other possibilities include toxoplasmosis, infectious hepatitis, human herpesvirus 6, human immunodeficiency virus types 1 and 2, and ingestion of drugs (*p*-aminosalicylic acid, phenytoin [Dilantin], and diaminodiphenylsulfone) (Tsaparas, 2000; Taylor, 2003).

Figure 33-11 Toxoplasmosis lymphadenitis shows follicular hyperplasia with monocytoid B cell hyperplasia (lower right-center) and scattered individual and aggregates of histiocytes, often impinging on the germinal center/mantle zone border (x200).

Course. Classic IM is a benign disorder, and complications occur in less than 5% of patients. The disorder usually resolves in 3–4 weeks. Fatalities are extremely rare but tend to occur in members of the same family (Purtilo, 1979). Additional studies indicate that affected individuals frequently suffer from X-linked lymphoproliferative disease (XLP). This group of immunosuppressed individuals possess a rare, familial, fatal form of combined immunodeficiency, apparently involving both B and T cells. All untreated patients die by approximately 40 years of age. EBV infection can produce any one of three severe complications in XLP: fulminant IM, life-threatening lymphoproliferative disease and B cell lymphoma, and dysgammaglobulinemia. Although classically associated with EBV infection, XLP can occur in patients seronegative for EBV. XLP has been mapped to human chromosome Xq24-25, which codes for a cell surface receptor present on T and NK cells, but not B cells. An uncontrolled cytotoxic T cell response is thought to be responsible for liver necrosis and BM failure, ultimately causing death (Thompson, 2004). In addition to XLP, EBV-associated lymphoproliferative disorders can occur in individuals with congenital and acquired immunodeficiencies.

Cytomegalovirus Infection

Some individuals infected with cytomegalovirus develop a syndrome similar to infectious mononucleosis. This disorder can occur following massive blood transfusion (posttransfusion mononucleosis) or spontaneously in previously healthy individuals (cytomegalovirus mononucleosis). The patient has fever, chills, profound malaise, and myalgia. Sore throat (but not exudative pharyngitis) and lymphadenopathy may be noted. Occasionally, splenomegaly is found, but hepatomegaly does not occur. Commonly involved systems in immunocompromised patients are the CNS, GI, and pulmonary systems, although disease may be found in almost any organ system.

Leukocytosis is characteristic with absolute lymphocytosis. Usually 20% or more of the leukocytes are atypical lymphocytes. BM aspirates have shown increased numbers of normal lymphocytes and atypical lymphocytes. Abnormal liver function test results are the most frequent abnormal laboratory finding (Wreghitt, 2003). In a small percentage of patients, titers of cold agglutinins, rheumatoid factor, or antinuclear antibodies may be increased. No rise in heterophil, Epstein-Barr virus, or *Toxoplasma gondii* antibodies occurs. The diagnosis is usually made by isolating the cytomegalovirus from urine, saliva, blood, or tissue biopsy, or by serology.

Toxoplasmosis

Toxoplasma gondii, a protozoan parasite, can produce in both young and old a disease (toxoplasmosis) similar to infectious mononucleosis. Diagnosis is critical in congenitally infected fetuses and newborns, women infected during pregnancy, immunocompromised patients, and patients with chorioretinitis (Remington, 2004).

Only a small proportion ($\approx 10\%$) of immunocompetent individuals are symptomatic. These patients typically present with lymphadenopathy, commonly cervical. Some patients may also show fever, headache, sore throat, hepatosplenomegaly, chorioretinitis, and an increased number of atypical lymphocytes in the peripheral blood. In immunocompromised patients, disease commonly involves the CNS and eyes but may also involve the lungs and heart.

The histopathology of lymph nodes is usually distinctive, with scattered epithelioid histiocytes which often blur the germinal center/mantle zone border, and with sinus monocytoid B cell hyperplasia (Fig. 33-11).

TABLE 33-10

Key Causes of Lymphopenia

- Destructive—radiation, chemotherapy, corticosteroids
- Debilitative—starvation, aplastic anemia, terminal cancer, collagen vascular disease, renal failure
- Infectious—viral hepatitis, influenza, typhoid fever, TB
- AIDS associated—HIV cytopathic effect, nutritional imbalance, drug effect
- Congenital immunodeficiency—Wiskott-Aldrich syndrome
- Abnormal lymphatic circulation—intestinal lymphangiectasia, obstruction, thoracic duct drainage/rupture, CHF

AIDS, Acquired immunodeficiency syndrome; CHF, congestive heart failure; HIV, human immunodeficiency virus; TB, tuberculosis.

Morphology correlates closely with elevated *Toxoplasma* antibody titers (Dorfman, 1973). BM biopsy specimens have no specific pathologic lesion.

The diagnosis is established by demonstrating an elevation of *Toxoplasma* antibodies in immunocompetent patients. In immunocompromised patients, serologic tests are not sensitive, and direct detection of the organism from blood, from body fluids, or in tissue is necessary for definitive diagnosis.

Autoimmune Lymphoproliferative Syndrome

Autoimmune lymphoproliferative syndrome (ALPS) is an uncommon cause of lymphadenopathy, splenomegaly, and autoimmune cytopenias with onset in childhood that is caused by an inheritable genetic defect, a mutation in one of the genes encoding Fas, or CD95, or occasionally a caspase gene. Fas is a key component of apoptosis. The disease has variable penetrance and is characterized by chronic lymphoid hyperplasia with presence of CD4/CD8 double negative T cells, and the above symptoms (Oliveira, 2010).

Other Nonneoplastic Causes of Lymphadenopathy

Other causes of benign or reactive lymphadenopathy include autoimmune disease and infection—in addition to the specific entities noted previously, Castleman's disease, Rosai-Dorfman disease (sinus histiocytosis with massive lymph node hyperplasia), Kikuchi histiocytic necrotizing lymphadenitis, Kawasaki disease, and others. Each has specific findings and is reviewed in detail elsewhere (Weiss, 2008).

Lymphocytopenia

Lymphocytopenia is present when the absolute lymphocyte count is below $\approx 1.0 \times 10^9/L$ in adults and below $\approx 2.0 \times 10^9/L$ in children. Normally, about 80% of circulating peripheral blood lymphocytes are CD3+ T cells, and a majority ($\approx 65\%$) of these cells are CD4+ helper T cells. A number of immunologic deficiency disorders that are genetically determined have lymphocytopenia, along with various other immunologic defects of humoral or cell-mediated immunity. Lymphocytopenia in these disorders is due to impaired lymphopoiesis. Increased levels of adrenocortical hormones, administration of chemotherapeutic drugs, or irradiation will result in lymphocytopenia. Impaired drainage of the intestinal lymphatics with loss of lymphocytes into the intestines due to a number of causes has been implicated as a mechanism for lymphocytopenia. In advanced cases of NHL and HL, as well as in terminal cases of carcinoma, lymphocytopenia is often observed. Causes and conditions associated with lymphocytopenia include those listed in Table 33-10.

Acquired Immunodeficiency Syndrome

Acquired immunodeficiency syndrome (AIDS), once a progressively fatal infectious disorder with characteristic clinical, hematologic, and serologic abnormalities, can now be controlled in most patients with highly active antiretroviral (HAART) therapy.

Etiology. AIDS is a disorder secondary to infection with HIV-1 and HIV-2—RNA retroviruses that are cytotoxic for CD4+ T cells and for other cells, including macrophages, monocytes, megakaryocytes, and CNS microglial cells. Viral entry into a cell results from interaction with the CD4 receptor and with chemokine coreceptors that determine target cell tropism (Starr-Spires, 2002). HIV is responsible for both direct killing of infected cells and indirect killing of neighboring cells, utilizing both apoptotic-dependent and apoptotic-independent mechanisms of cell destruction (Badley, 2003).

HIV infection is spread by contamination with secretions, excretions, blood, and tissues that contain the virus. Because of the cytotoxic effect of the AIDS viruses for CD4+ cells, there is a marked decrease in the number of T-helper cells and an imbalance in T-suppressor/cytotoxic cells in the blood and lymphoid tissues of the body. As a result, a profound cellular immune depression occurs, characterized by infection with a variety of opportunistic organisms. Initially, B cells are not involved and immunoglobulin levels are normal or increased. However, as the disease progresses, the frequency of malignancy in these patients is increased. AIDS-associated cancers include Kaposi's sarcoma, non-HL, and cervical cancer (all AIDS-defining cancers), as well as HL and anogenital cancers (Bellan, 2003; Mbulaiteye, 2003). Although the cause of these malignancies is undoubtedly multifactorial, recent studies suggest that HIV may possess oncogenic potential (Lazzi, 2002; De Falco, 2003). In addition, the functions of monocytes and NK cells are abnormal.

Hematologic Features. The most common hematologic abnormality in patients with AIDS is anemia of chronic disease and lymphopenia (80%–85% of cases), particularly of the T-helper/inducer (CD4) subset. Thrombocytopenia occurs in approximately 30% of cases and neutropenia in 40%, often with a left shift; the former is often immune mediated (Hoxie, 1995).

The peripheral blood film usually displays atypical lymphocytes that have a plasmacytoid appearance. Monocytes are often large with a fine nuclear chromatin and cytoplasmic vacuoles. Immune-mediated anemia, thrombocytopenia, and neutropenia in AIDS have also been described.

The BM is usually normocellular to hypercellular (Castella, 1985). Often increased numbers of immature myeloid precursor cells, macrophages laden with iron, and plasma cells occur. Defects occur in BM progenitor cells such as colony-forming unit-granulocyte, monocyte (CFU-GM); colony-forming unit-granulocyte, erythrocyte, monocyte, megakaryocyte, pluripotential stem cell (CFU-GEMM); colony-forming unit-megakaryocyte (CFU-MK); and burst-forming unit-erythrocyte (BFU-E). Many drugs used to treat AIDS and its infectious complications are also myelosuppressive. Suppression of the marrow is, in many patients, multifactorial, resulting from an interaction of direct HIV cytopathic effect, dysregulation of the immune system and of apoptosis, possible complicating infection and/or nutritional imbalance, and drug effect. The most clinically valuable information of BM biopsy is usually the identification of infection or malignancy in the marrow. The disease course has been converted to a relatively indolent chronic course in those who receive and adhere to HAART therapy, but remains a tragic illness in disadvantaged populations and in those not treated.

Functional Disorders of Lymphocytes

Functional disorders of lymphocytes can be inherited or acquired. The immune deficiency may be due to a disorder of maturation or function of monocytes and antigen-presenting cells, B cells, T cells, stem cells, suppressor cells, or a combination. These may cause antibody production defects or a combination of antibody production and T cell function defects. Acquired disorders may be due to malnutrition, infection, or malignancy, as well as any insult that may significantly perturb immune regulation and cellular communication. Acquired functional abnormalities of lymphocytes are frequently observed in lymphoid malignancies. For example, decreased B cell function is observed in chronic lymphocytic leukemia, in which two thirds of patients have hypogammaglobulinemia. In multiple myeloma, synthesis of normal immunoglobulin in the presence of high levels of paraprotein is diminished.

Diminished T cell activity has been described in patients with HL, sarcoidosis, and leprosy. In HL, diminished T cell activity may be the result of the suppressive effects of monocytes. In autoimmune disease, loss of suppressor T cells has been observed.

In severe malnutrition and in terminal malignancies, both humoral and cell-mediated immunity are diminished.

The diagnosis of functional disorders of lymphocytes requires the use of skin tests, enumeration of B and T cells and their subsets, measurement of serum immunoglobulin and antibodies, and a variety of in vitro lymphocyte assays that record their responses to mitogens and antigens. Molecular testing, including cytogenetic and fluorescent in situ hybridization (FISH) analysis, flow cytometry, and PCR, may be required for definitive diagnosis. A thorough history and physical examination should always precede any testing. It is probably best to begin a workup with less expensive and easily obtainable tests.

TABLE 33-11

Key Causes of Plasmacytosis

- Viral—infectious mononucleosis, measles, rubella, HIV
- Bacterial—tuberculosis, syphilis, streptococcus, staphylococcus
- Parasitic—malaria, trichinosis
- Inflammatory—SLE, RA, inflammatory bowel disease, alcoholic liver disease
- Neoplastic—plasma cell leukemia, myeloma
- Immune stimulation—immune complex disease (serum sickness), drug sensitivity, transfusion
- Trauma

HIV, Human immunodeficiency virus; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

This topic is covered more fully in Part 6, Immunology and Immunopathology.

Plasmacytosis

Plasma cells are not normally present in circulating blood. They are increased in a variety of chronic infections, in allergic states, in the presence of neoplasms, and in other conditions in which the serum γ -globulin concentration is elevated. Plasma cells have also been recorded in the blood of patients with viral disorders, including rubella, measles, chickenpox, and mumps. They are moderately increased in cutaneous exanthemas, infectious mononucleosis, syphilis, subacute bacterial endocarditis, sarcoidosis, and collagen disease. Rarely, bacterial sepsis may show a peripheral plasmacytosis mimicking plasma cell leukemia (Shtalrid, 2003). Their increase is usually linked with increases in lymphocytes, monocytes, and eosinophils. Causes and conditions associated with plasmacytosis include those illustrated (Table 33-11).

In the marrow, an average of 1%–2% of plasma cells are present in adults. An increase beyond 4% is significant; lower values are found in children. Increases of up to 20% of plasma cells may be found in a variety of conditions other than multiple myeloma, including metastatic carcinoma, chronic granulomatous infection, conditions linked with hypersensitivity, and following administration of cytotoxic drugs. They are often increased in aplastic anemia, but this is probably just a relative increase. On the other hand, they are decreased or absent in agammaglobulinemia.

LEUKEMOID REACTIONS

A leukemoid reaction is an excessive leukocytic response in the peripheral blood. It includes leukocytosis of $50 \times 10^9/L$ or higher with a shift to the left; lower counts, even below normal, with considerable numbers of immature granulocytes; and similar quantitative or qualitative changes in lymphocytes or monocytes. Depending on the predominant cell, leukemoid reactions may be neutrophilic, eosinophilic, lymphocytic, or monocytic. No clear explanation for these apparent temporary aberrations in normal regulatory control mechanisms is yet available, although in some instances they appear to be due to elevation of cytokines or granulocyte colony-stimulating factor by tumor (Melhem, 1993; Nara, 2003; Nimieri, 2003). The reactions are irregular in degree, even when associated with the same inciting agent.

Neutrophilic Leukemoid Reactions

Excessive neutrophilia may occur in many situations, including hemolysis, hemorrhage, malignancy with bone involvement, HL, myelofibrosis, infection (especially tuberculosis), severe burns, eclampsia, and certain intoxications.

Examination of the blood is usually more helpful than marrow examination. Leukemoid reactions lack the characteristic differential count that is seen in CML, including the myelocyte “peak,” eosinophilia, and basophilia (Fig. 33-12).

Eosinophilic Leukemoid Reactions

Cells as immature as eosinophilic myelocytes rarely appear in the blood in reactive eosinophilia, in which the leukocyte count may exceed $50 \times 10^9/L$ (see Fig. 33-8). Eosinophilic leukemoid reactions usually occur in children and usually are caused by parasitic infection. As with granulocytic leukemoid reactions, some eosinophilic leukemoid reactions have been associated with tumor (Melhem, 1993; Oakley, 1998).

Figure 33-12 Chronic myeloid leukemia with increased segmented neutrophils, myelocytes, and basophils and an occasional blast ($\times 500$).

Erythroblastosis and Leukoerythroblastosis

In patients with or without anemia, circulating normoblasts frequently are accompanied by a neutrophilic leukemoid reaction; this, then, is a **leukoerythroblastic reaction**. A moderate anemia with normoblasts in the peripheral blood is fairly common in metastatic carcinoma involving BM. Leukoerythroblastosis may also be associated with marrow infection and/or fibrosis, and may be seen in benign conditions such as GI bleeding and hemolytic anemia (Weick, 1974).

Lymphocytic Leukemoid Reactions

Extremely high counts of normal-appearing lymphocytes may occur in infectious lymphocytosis and in pertussis (see earlier). When atypical lymphocytes are strikingly increased or immature (which may occur in conditions such as infectious mononucleosis), the distinction from leukemia may be difficult.

Examination of the marrow may be useful because lymphocytes are minimally increased, if at all, in most leukemoid reactions in contrast to leukemia. Flow cytometric studies of peripheral blood and/or BM would reveal a nonclonal population of lymphocytes with a normal combination of cell surface markers in benign proliferations.

NEOPLASTIC DISORDERS PRIMARILY INVOLVING LEUKOCYTES

OVERVIEW OF HEMATOPOIETIC NEOPLASMS

Hematopoietic neoplasms consist of a diversity of disorders which have in common their derivation from hematopoietic stem cells of the BM or lymphoid organs, and which are known or assumed to be clonal processes arising as the result of genetic errors. Given the diversity and regulatory complexity of hematopoietic cells, it is not surprising that neoplasms involving these tissues are quite diverse, differing in predominant cells within a neoplasm, degree of differentiation, rates of proliferation and apoptosis, clinical features, and response to therapy. Diagnosis and classification of hematopoietic tumors have changed with our understanding of disease. In the 19th century, “leukemia” referred to the white or pale color of blood, which contained increased leukocytes compared with red corpuscles, neither of which could be microscopically seen in detail without differential staining. **Chlorosis** and **chloroma** referred to the grossly greenish tinge of granulocytic cells. **Lymphoma**, first used by Virchow, referred to tumors of the lymph glands.

After the development of Romanowsky’s stains (such as Wright-Giemsa), and later, hematoxylin and eosin (H&E), as well as improvements in microscopes, hematopoietic tumors could be classified by morphology, clinical features, and location of the abnormal proliferations. Hematopoietic tumors were referred to as leukemias when they primarily involved the blood and BM, and as lymphomas or sarcomas when they primarily involved the soft tissue. “Acute” referred to diseases with aggressive clinical courses, and “chronic” to those which progressed more slowly. Morphologic subtyping based on predominant cell types progressed into the 1950s and 1960s with the development of cytochemical stains to differentiate subtypes of myeloid cells and some lymphoid cells (such as HCL).

Since about 1970, an explosion of knowledge and new technology has occurred which provides many new tools for understanding these tumors. These include the discovery of B cells; T cells and other immunologic

compartments; monoclonal antibodies and leukocyte differentiation antigens; cytogenetic karyotyping; immunoglobulin and T cell gene rearrangements; PCR; nucleic acid arrays; and, most recently, proteomic assays. Many, although certainly not all, hematopoietic tumors can now be characterized at the level of the genetic abnormality and the resultant intracellular pathway perturbations. This offers tremendous opportunity to develop therapies targeted to specific abnormalities. Examples include (1) chronic myeloid leukemia, with a t(9;22)(q34;q11) *BCR/ABL* translocation and resultant abnormal tyrosine kinase, which has been targeted by the drug Gleevec (imatinib mesylate) (Druker, 2004), and (2) acute promyelocytic leukemia with t(15;17)(q22;q12) *PML/RAR α* and an abnormal receptor for retinoic acid, which responds to all-*trans* retinoic acid.

Classification of leukemias and, particularly, lymphomas became confusing in the 1970s and 1980s as knowledge progressed. The French-American-British (FAB) Cooperative Group developed consensus criteria for leukemias and myelodysplastic syndromes (Bennett, 1976, 1982), and lymphoma classification varied internationally. In North America, the standard lymphoma classification became the National Cancer Institute (NCI) Working Formulation for Clinical Usage (Non-Hodgkin Lymphoma Pathologic Classification Project, 1982), and in Europe, the updated Kiel Classification (Stansfeld, 1988). These were synthesized in the Revised European American Lymphoma Classification (Harris, 1995). Most recently, hematopathologists and oncologists began to recognize that uniform diagnostic criteria are essential for all hematopoietic neoplasms. The current global classification of hematopoietic tumors sponsored by the World Health Organization (WHO) (Swerdlow, 2008) recognizes the predominance of the abnormal biology of each tumor and utilizes a combination of diagnostic techniques, varying with each tumor, to arrive at the diagnosis. Morphology, immunophenotype, cytogenetics, and molecular genetics are all utilized, and cytochemical assays are used in some cases. Many tumors may present as leukemias or soft tissue tumors (lymphomas), and these terms remain descriptively useful. The WHO classification also utilizes a two-tiered approach for acute myeloid leukemias, which recognizes that in many areas of the world, molecular and cytogenetic testing is not available, and where it is available, it is not always productive. For such cases (acute myelogenous leukemia [AML], not otherwise specified), morphologic criteria are based on the earlier FAB classification.

CHRONIC MYELOPROLIFERATIVE DISORDERS

The chronic myeloproliferative disorders recognized by the WHO are chronic myeloid leukemia, BCR-ABL1-positive CML, chronic neutrophilic leukemia (CNL), polycythemia vera (PV), primary myelofibrosis (PMF), essential thrombocythemia (ET), chronic eosinophilic leukemia, not otherwise specified (NOS), mastocytosis, and myeloproliferative neoplasm, unclassifiable (Swerdlow, 2008). These are clonal proliferations of a pluripotential stem cell that can differentiate along granulocytic, erythroid, and megakaryocytic lines (Adamson, 1976; Fialkow, 1977). Each has a chronic course that may terminate as acute leukemia, myelofibrosis, or a coagulopathy. One, CML, has a characteristic genetic translocation (Nowell, 1960); another, PV, exhibits a mutation of *JAK2 V617F* that is shared with approximately 50% each of ET and PMF, while mastocytosis is characterized by *KIT* mutation. Key features of the major disorders and of myelodysplastic/myeloproliferative diseases are summarized in Table 33-12.

Chronic Myelogenous Leukemia

Clinical Features

CML occurs in young and middle-aged adults. The age-specific incidence, however, increases markedly after 50 years of age. Onset is insidious, and the disorder may be discovered accidentally on a routine blood test. The patient may have symptoms of anemia and weight loss or simply may complain of malaise. The spleen enlarges progressively, and the patient begins to lose weight and have fever and night sweats associated with increased metabolism as a result of granulocyte turnover. The discomfort associated with an enlarged spleen may bring the patient to the doctor. Infarcts in the spleen may produce left upper quadrant pain. Excessive bleeding or bruising may occur in the later stages of the disease. Lymphadenopathy, although often present, is rarely prominent (Cortes, 2004).

Laboratory Features

Blood. The leukocyte count is usually over $5 \times 10^9/L$ and may exceed $30 \times 10^9/L$. The differential count is characteristic. There is a complete spectrum of granulocytic cells, from a few myeloblasts to mature neutrophils,

with myelocytes and neutrophils exceeding the other cell types (Savage, 1997). This bimodal distribution helps to exclude other myeloproliferative disorders and reactive leukocytosis (see Fig. 33-12). Myeloblasts account for less than 10% of the cells. The relative percentage of neutrophil myelocytes increases as the total leukocyte count increases. Basophilia is consistently present and eosinophilia is almost always noted, along with the presence of eosinophil myelocytes. Monocytes are also absolutely increased in most patients.

Normocytic anemia is present in the majority of patients at diagnosis, and a few normoblasts can usually be found. Thrombocytosis is present in more than half, and less than 15% have thrombocytopenia.

Marrow. The marrow is markedly hypercellular, primarily as a result of granulocytic proliferation, with all stages represented. Eosinophil and basophil precursors are usually increased. Normoblasts tend to be relatively decreased. Frequently, the marrow cannot be aspirated because of the density of cellularity or (especially later in the disease) because of increased reticulin, which can be demonstrated on marrow biopsy. Macrophages laden with blue pigment (sea-blue histiocytes) or macrophages indistinguishable from Gaucher's cells are found in some patients.

It is good to remember that even a typical BM is not diagnostic of CML. On the other hand, the diagnosis can be made from the peripheral blood film in most cases.

Neutrophil Alkaline Phosphatase. The neutrophil alkaline phosphatase (NAP) is greatly reduced or absent in more than 90% of patients with CML. It is greatly elevated in polycythemia vera; elevated, normal, or low in idiopathic myelofibrosis; and normal or elevated in leukemoid reactions. During remission of CML with a normal-appearing blood picture, in most cases the NAP continues to be low; in about one third of patients, it returns to normal. The NAP increases in the accelerated and blastic phases of the disease. It may also increase in response to infection, as it does in normal individuals.

Cytogenetic Abnormalities. In more than 95% of patients with typical CML, cultured cells from the blood or bone marrow possess the cytogenetic abnormality t(9;22)(q34;q11), involving the *ABL1* gene on the long arm of chromosome 9 and the *BCR* gene on the long arm of chromosome 22. An abnormally small chromosome formed by this translocation is called the Philadelphia (Ph⁺) chromosome (Nowell, 1960). The *BCR-ABL1* gene fusion results in a novel RNA transcript and subsequently a protein growth factor with tyrosine kinase activity higher than that of the normal p145 protein coded for by *ABL1*. Variant translocations involving additional genes and cryptic translocations requiring molecular detection occur. Most translocations involve a *BCR* breakpoint at the major breakpoint region (M-BCR) with resultant p210 protein, and an occasional breakpoint at the μ region results in a p230 protein. Minor breakpoint region (m-BCR) translocations with resultant p190 protein are usually associated with acute lymphoblastic leukemia (ALL), but rare m-BCR translocations in CML are associated with increased monocytosis, and small amounts of p190 may be found in standard CML (Vardiman, 2008).

Other Findings. Serum cobalamin and transcobalamins are usually increased considerably as a result of increased transcobalamin I, and are thought to reflect the size of the total blood granulocyte pool. Serum muramidase (lysozyme) is also increased.

Course

Treatment with busulfan or hydroxycarbamide (hydroxyurea) in the past usually controlled the disease in the chronic phase, but without hematologic BM remission or clearing of the Ph⁺ chromosome. Improved results were obtained with recombinant interferon- α or allogeneic transplant (Silver, 1999). A synthetic protein kinase inhibitor, STI-571 (imatinib mesylate; Gleevec), specifically targets the BCR-ABL protein and, along with newer analogous inhibitors, provides remarkably improved results. This treatment usually results in clinical remission, although drug resistance and relapses occur (Kantarjian, 2010).

Except for those cases cured by transplantation, the disease changes after a variable period, depending in part on therapy, into a more aggressive or accelerated phase (Cortes, 2003). This is characterized by one or more features of progressive myeloproliferation: increased blood or marrow blasts of 10%–19%; peripheral blood basophilia >20%; persistent thrombocytopenia unrelated to therapy < $100 \times 10^9/L$; thrombocytosis > $1000 \times 10^9/L$; increasing leukocytosis and splenomegaly unresponsive to

TABLE 33-12

Key Features of Major Myeloproliferative and Myelodysplastic/Myeloproliferative Disease

Disorder	Demographics	Laboratory features, morphology	Cytogenetics	Prognosis
CML	Middle-aged	<i>BCR-ABL</i> present	t(9;22)(q34;q11) <i>BCR-ABL1</i>	Dependent on response to TKI
PV	Middle-aged, M > F	Major criteria: Hb >18.5 g/dL in M or >16.5 g/dL; <i>JAK2 V617F</i> Minor criteria: hypercellular marrow with panmyelosis; ↓EPO; endogenous erythroid colony formation in vitro; 2 major plus 1 minor, or first major plus 2 minor criteria	<i>JAK2 V617F</i> , negative t(9;22)	10–20 years
PMF	>50 years	Major criteria: megakaryocyte proliferation/atypia with marrow fibrosis; CML, PV, MDS ruled out; <i>JAK2 V617F</i> Minor criteria: leukoerythroblastosis, ↑LD, anemia, splenomegaly; all 3 major plus 2 minor criteria	+8, +9, del(20q), del(13q), del(1p), negative t(9;22)	Dependent on phase: ≈10 years in early prefibrotic phase; ≈5 years in fibrotic phase
ET	5th decade (M = F), second peak in 30s (F > M)	Platelet count >450 K; BM with proliferation of mature megakaryocytes; PV, PMF, CML, MDS ruled out; <i>JAK2 V617F</i> NOTE: All four criteria must be met.	<i>JAK2 V617F</i> in 50%; del(13q22), +8, +9 seen in 5%–10% of cases; negative t(9;22)	Stable for many years (most cases)
CMML	Median, 65–75 years, M > F	Monocytosis >1000, cytopenias, myeloid dysplasias, <20% blasts	+8, -7, 12p abn in 20%–40% of cases; negative t(9;22)	20–40 months with progression to AML in 15%–30%
JMML	Younger than 3 years, M > F	Monocytosis >1000, blasts <20%, plus 2 of ↑Hb F, immature grans, WBC >10K, clonal abn, GM-CSF hypersensitivity	Monosomy 7, negative t(9;22)	Poor; possible benefit from BMT
Myeloid/lymphoid neoplasms w/↑eos and <i>PDGFR/ FGFR1</i>	M 25–55 years	PB w/inc eos, BM eos with mast cells	<i>FIP1L1-PDGFRα, PDGFRβ, FGFR</i>	Variable response to TKI
Mastocytosis	All ages	Mononuclear w/central nuclei, variable basophilic granules (often not seen in fixed tissue); dense aggregates of spindle cells	<i>KIT D816V</i>	Cutaneous, indolent; systemic, variable; leukemia, aggressive
CEL NOS, idiopathic HES	Usually adult M; any age or sex	PB ≥1.5 K eos/μL, <20% blasts	+8, i(17q) 8p11 w/various partners	Indolent, 80% 5-year survival

Abn, Abnormalities; *AML*, acute myelogenous leukemia; *BM*, bone marrow; *BMT*, bone marrow transplant; *CEL*, chronic eosinophilic leukemia; *CIM*, chronic idiopathic myelofibrosis; *CML*, chronic myeloid leukemia; *CMML*, chronic myelomonocytic leukemia; *eos*, eosinophils; *EPO*, erythropoietin; *ET*, essential thrombocythemia; *F*, female; *GM-CSF*, granulocyte-macrophage colony stimulating factor; *grans*, granulocytes; *Hb*, hemoglobin; *HES*, hypereosinophilic syndrome; *inc*, increased; *JMML*, juvenile myelomonocytic leukemia; *LD*, lactate dehydrogenase; *M*, male; *MDS*, myelodysplastic syndrome; *NAP*, neutrophil alkaline phosphatase; *NOS*, not otherwise specified; *PB*, peripheral blood; *PMF*, primary myelofibrosis; *PV*, polycythemia vera; *TKI*, tyrosine kinase inhibitor; *WBC*, white blood cell.

therapy; or cytogenetic clonal evolution. Granulocytic dysplasia, increased small dysplastic megakaryocytes, and reticulin fibrosis are also suggestive.

Blast phase is essentially a progression to acute leukemia and is defined by >20% blasts in the blood or BM and large aggregates of blasts in the marrow or in extramedullary locations. Blast lineage is myeloid in 70% of cases and may include any myeloid cell types (neutrophilic, eosinophilic, basophilic, monocytic, erythroid, or megakaryocytic), although Auer rods are rarely found. In approximately one third of cases, however, the appearance is that of ALL (Rosenthal, 1977). Usually, these are of precursor B-lineage, with expression of terminal deoxynucleotidyl transferase (TdT), CD34, CD19, and CD10 but negative surface Ig. Occasional cases are precursor T-lineage with TdT, CD3, cytoplasmic CD3 (cCD3), and CD7. Myeloid antigens are often coexpressed, and bilineal myeloid/lymphoid cases also occur. Blast transformation appears because of secondary genetic changes involving *p53*, retinoblastoma (*Rb*), and other genes (Calabretta, 2004).

Chronic Neutrophilic Leukemia

Chronic neutrophilic leukemia is a rare myeloproliferative disorder characterized by persistent and unexplained neutrophilia of $>25 \times 10^9/L$ mature granulocytes resembling reactive neutrophilia (Elliott, 2001; Bain, 2008). It typically affects older adults and presents with splenomegaly and sometimes hepatomegaly, often with mucocutaneous bleeding, pruritus, or gout. There may be a left shift with bands present and toxic granulation.

BM findings include hypercellularity with granulocytic hyperplasia showing a myeloid/erythroid ratio of up to 20:1 and a predominance of mature neutrophils to myelocytes. Erythroid cellularity and megakaryocytes may be increased, but dysplasia is not present. Cytogenetics are usually (90%) normal, with some cases showing abnormalities including +8, +9, del(20q), and del(11q). Cases with variant Ph⁺-positive chromosome and neutrophilia are considered CML.

Because there is not a genetic marker for this disease, it is likely that many of these are reactive processes due to occult malignancy or other causes of inflammation. Multiple myeloma has most often been implicated, but other neoplasms may induce marked neutrophilia with or without marrow involvement.

Polycythemia Vera

Polycythemia vera is a clonal stem cell proliferation affecting primarily the erythroid series, characterized by excessive proliferation of erythroid and also usually granulocytic and megakaryocytic elements in the marrow (panmyelosis). It is genetically characterized by mutation of Janus 2 kinase, *JAK2 V617F*, or another functionally similar mutation such as *JAK2* exon 12 mutation (Levine, 2008). *JAK2* mutation occurs in essentially all patients with PV but is also present in approximately 50% of patients with thrombocythemia and primary myelofibrosis. The disease is manifested in the blood by an absolute increase in red cell mass, leukocytosis, and thrombocytosis. Serum and urine erythropoietin are decreased. The production of erythrocytes is autonomous with **endogenous erythroid colonies**

Figure 33-13 Bone marrow biopsy in polycythemia vera shows panmyelosis with normoblastic hyperplasia ($\times 500$).

(EECs) growing in vitro without erythropoietin, but it does respond to erythropoietin when the patient has become anemic through blood loss (Pierre, 2001). Pathology may be related to decreased expression of the thrombopoietin receptor c-Mpl (Kaushansky, 2003), and overexpression of the polycythemia rubra vera-1 messenger RNA (Pahl, 2004). There is initially a proliferative phase and eventually a spent phase with anemia, marrow fibrosis, increased splenomegaly, and extramedullary hematopoiesis.

Clinical Features

The disease is slightly more frequent in men than in women. It usually begins in middle age. Affected patients exhibit ruddy cyanosis, and splenomegaly is present in two thirds. Thrombotic or hemorrhagic phenomena occur in about half of patients, and thrombosis is most common (Chomienne, 2004). Myocardial infarction, cerebral thrombosis, splenic or pulmonary infarcts, and thrombophlebitis account for the most frequent thrombotic episodes; upper gastrointestinal bleeding, often from peptic ulcer, is the most common bleeding problem. Pruritus, especially after bathing, is common.

Laboratory Features

Blood. Erythrocytes exceed $6\text{--}12 \times 10^{12}/\text{L}$, and the hemoglobin is >18.5 g/dL (males) or >16.5 g/dL (females). Mean cell volume (MCV), mean cell hemoglobin (MCH), and mean cell hemoglobin concentration (MCHC) are normal or low. The erythrocytes become hypochromic and microcytic if chronic blood loss has occurred. Macrocytes, polychromatic cells, and normoblasts may be found but are not a prominent feature of the disease. Red cell production is increased. Red cell destruction is normal during the period of erythrocytosis; later in the disease, as splenomegaly develops, red cell survival diminishes. The total blood volume is increased, primarily because of increased red cell mass, and the plasma volume may also be elevated to a lesser degree. Blood viscosity is high, and it may be difficult to prepare good blood films. The erythrocyte sedimentation rate (ESR) is reduced.

The platelet count is increased in about two thirds of patients, often to levels exceeding $1000 \times 10^9/\text{L}$. In 80% of untreated patients, functional platelet abnormalities are present (Gilbert, 1975) with decreased aggregation in response to adenosine diphosphate (ADP) and epinephrine. Functional defects may be related to decreased expression of c-Mpl on platelets (Moliterno, 1998), although megakaryocytes are increased (Bock, 2004). No consistent abnormality of secondary hemostasis is present.

Moderate neutrophilic leukocytosis in the range of $10\text{--}30 \times 10^9/\text{L}$ is common. Immature granulocytes are seen in about one half of cases, and basophils are often absolutely increased. The NAP is markedly elevated in 80% of patients, and serum transcobalamins and serum muramidase are usually elevated.

The arterial oxygen saturation is normal. Hyperuricemia appears in many patients with PV as a result of increased nucleic acid metabolism; in some patients, secondary gout or renal uric acid stones occur.

Marrow. The marrow is moderately to markedly hypercellular, with prominent normoblastic erythroid hyperplasia in panmyelosis. Megakaryocytes show an increase in and clustering of variable small and large megakaryocytes associated with an increase in dilated sinuses (Michiels, 1997) and frequently cluster around sinusoids (Fig. 33-13). Increased reticulin is often present, and storage iron is decreased or absent in 95% of cases.

Figure 33-14 Bone marrow biopsy in chronic idiopathic myelofibrosis, with increased spacing between cells suggesting fibrosis and intrasinusoidal hematopoiesis ($\times 500$).

Diagnosis

Criteria of the WHO (Swerdlow, 2008) for the diagnosis of polycythemia vera are as follows:

1. Elevated Hb >18.5 (males) or 16.5 (females) g/dL, or other evidence of increased red cell volume.
2. Presence of *JAK2 B617F* or similar mutation such as *JAK2* exon 12 mutation.

Both of these major criteria must be present, along with any single minor criterion: BM biopsy showing panmyelosis with prominent erythroid and megakaryocytic proliferation, low serum erythropoietin, or endogenous colony formation in vitro. Alternatively, the diagnosis may be made by the first major and two minor criteria.

Polycythemia vera is a chronic disease; patients usually live 10–20 years under good control. Phlebotomy, chlorambucil, radioactive phosphorus (^{32}P), and hydroxycarbamide (hydroxyurea) have been used to control the manifestations of the disease.

In about 20%–40% of patients, the spent or postpolycythemic phase occurs with progressive anemia, gradual splenic enlargement, and further elevation of the leukocyte count, with more immature granulocytes and more circulating nucleated red cells. Many erythrocytes become oval, and teardrop cells (dacrocytes) become prominent. BM aspiration becomes impossible because of myelofibrosis, and splenomegaly increases, owing to extramedullary hematopoiesis. Manifestations at this stage of the disease are indistinguishable from those of myelofibrosis with myeloid metaplasia. Another late complication of polycythemia vera is acute leukemia or myelodysplastic syndrome (MDS) (Landaw, 1986). A slight increase, 2%–3%, is seen in patients treated with phlebotomy alone, and a greater increase (10%) is seen in those treated with cytotoxic agents.

Primary Myelofibrosis

This is a chronic, progressive clonal panmyelosis characterized by megakaryocytic and often granulocytic hyperplasia with varying degrees of reactive fibrosis of the marrow and extramedullary hematopoiesis (Swerdlow, 2008). Typically, leukoerythroblastic anemia occurs with marked red cell abnormalities, circulating normoblasts, immature granulocytes, and atypical platelets. Chronic idiopathic myelofibrosis (CIM) is an uncommon disease with an incidence one-third that of CML. It occurs typically in persons over the age of 50 and has an insidious onset, with weight loss, anemia, and abdominal discomfort due to the large spleen. Often the liver is enlarged as well, and the patient may be slightly jaundiced. Radiograph shows patchy osteosclerosis in up to half of patients, but osteoporosis may also be seen.

A prefibrotic stage in 20%–30% of cases is characterized by mild normocytic anemia with poikilocytosis, including dacrocytes, nucleated RBCs, thrombocytosis, and mild leukocytosis with some immature forms. The marrow is hypercellular and contains abnormal megakaryocytes, which cluster around sinuses and trabeculae. The histopathology of the BM is dominated by atypical, enlarged, and immature megakaryocytes with cloud-like immature nuclei (Michiels, 1999), and also small megakaryocytes. Fibrosis may be minimal initially. Intrasinusoidal hematopoiesis is often present (Fig. 33-14).

Characteristic findings of presentation in the fibrotic stage include moderate normochromic, normocytic anemia (often with some hypochromic cells and basophilic stippling), moderate anisocytosis, and marked poikilocytosis, including prominent teardrop forms (dacrocytes) and elliptocytes. Normoblasts are often increased out of proportion to the

degree of anemia with slight reticulocytosis. The anemia may have a complicated origin, with components of marrow failure, ineffective erythropoiesis, and hemolysis. Splenomegaly due to extramedullary hematopoiesis is typical.

The leukocyte count is moderately increased; immature neutrophils and occasionally myeloblasts are present. Basophils are often increased. Platelets are normal or decreased in number (rarely increased) and often atypical with distinct clear “zones.” Micromegakaryocytes the size of lymphocytes with both nucleus and cytoplasm or small megakaryoblasts may usually be found if searched for; on rare occasions, they are present in considerable numbers.

In vitro blood cell culture shows increased colonies (CFU-GM) similar to those in CML. Serum GM-CSF is high, serum uric acid is frequently increased, and cobalamin is normal or elevated.

It is usually impossible to aspirate marrow, and biopsy is necessary. The marrow is fibrotic, with residual islands of atypical megakaryocytes, erythroid, and granulocytic precursors. The fibrosis is of loose connective tissue with scanty collagen, but reticulin fibers are abundant. Foci of osteoid and/or new bone formation in endophytic plaques (Thiele, 2001b) may be found, and bony trabeculae may be irregularly thickened (myelofibrosis). The marrow may show a mixture of hyperplasia and fibrosis in one sample or may vary in different sites of the body. Megakaryocytes with abnormal nuclei cluster or form sheets which may be found in sinuses with other marrow precursors. Extramedullary hematopoiesis is found in the spleen and liver.

Biology

Although the proliferating megakaryocytes are neoplastic, the stromal proliferation is reactive because of inappropriate release of megakaryocyte/platelet-derived growth factors, including platelet-derived growth factor (PDGF), transforming growth factor (TGF)- β , basic fibroblast growth factor (bFGF) and calmodulin (Reilly, 1998).

Approximately 50% of patients show *JAK2 V617F* mutation. A small number, up to 5%, have an *MPL W515K/L* gene mutation. Chromosomal studies show absence of *BCR/ABL*, but variable cytogenetic changes: +8, +9, del(20q), del(13q)(q12-22), partial trisomy 1q, del(5q), and der(6)t(1;6)(q21-23;p21.3). Additional cytogenetic abnormalities may be associated with cytotoxic therapy and/or progression of disease.

Course

The natural course is increasing fibrosis with progressive anemia and enlargement of the spleen. Hemolysis frequently becomes an increasing element in the anemia, and infection may be a serious problem. Portal hypertension occurs in 10%–20% of cases and may result in bleeding esophageal varices. Hypertension may be due to portal vein thrombosis or intrahepatic obstruction as a result of myeloid metaplasia coupled with increased portal blood flow.

Androgen preparations, corticosteroids, and erythropoietin are helpful in control of anemia (Tefferi, 2003). Median survival has been about 5 years—considerably less than that of polycythemia vera; however, some patients live longer, and in those patients, the terminal event is frequently an acute leukemia. Recent therapeutic advances with durable remission of cytopenias have been reported with thalidomide and prednisone (Mesa, 2004). Hydroxyurea is used in patients who require control of excess myeloproliferation.

Occasionally, patients exhibit cytopenias and marrow fibrosis due to other causes, some of which may show favorable response to specific therapies. These include metastatic tumors, primary hematopoietic tumors such as HCL or plasma cell dyscrasia (Meerkin, 1994), damage from radiation, and rarely autoimmune myelofibrosis (Hasselbalch, 1987; Pullarkat, 2003). Malnourished children with vitamin D deficiency (rickets) sometimes show myelofibrosis. A role of solvents in myelofibrosis has been postulated (Brandt, 1987) but is not clear or well documented; neither is it known whether solvent-associated cases are neoplastic or secondary myelofibrosis. Benzene has been most often suspected and is a known inducer of AML at threshold levels of exposure. General environmental exposure appears much lower than that likely to be associated with hematologic malignancies (Duarte-Davidson, 2001). Peritrabecular marrow fibrosis occurs in primary hyperparathyroidism or secondary hyperparathyroidism of chronic renal failure.

Essential Thrombocythemia

Thrombocythemia is a clonal myeloproliferative disorder primarily affecting the megakaryocytic lineage with the principal manifestation of sustained thrombocytosis. Forty percent to 50% carry a *JAK2 V617F*

Figure 33-15 Bone marrow biopsy in essential thrombocythemia, with increased and clustered megakaryocytes (x500). Nuclei in this case are unusual, resembling primary myelofibrosis.

mutation (Levine, 2008). It most often occurs in the fifth decade, with equal sex distribution and a second peak of incidence in females in their 30s (Thiele, 2008a).

Clinical Features

Patients often (50%) present with asymptomatic thrombocytosis, but up to half of patients present with hemorrhage or thrombosis. The latter occurs as arterial or venous thrombosis or as microvascular occlusion resulting in transient ischemic attacks (TIAs) or digital ischemia. Characteristic recurrent, spontaneous mucosal hemorrhages are most common in the GI tract or the upper airway. Hemorrhages are occasionally preceded or accompanied by thrombosis. Mild splenomegaly occurs in 50% of cases.

Laboratory Features

Blood. The most striking feature is the marked increase in platelets ($\geq 450 \times 10^9/L$; usually $>1000 \times 10^9/L$), often with abnormal and giant forms, and usually accompanied by fragments of megakaryocytes. Neutrophilic leukocytosis is sometimes present. Hypochromic microcytic anemia due to chronic blood loss is present in many cases. Platelet function defects in thrombocythemia are frequently demonstrable. The most typical finding is decreased aggregation in response to epinephrine.

Marrow. The marrow shows increased and enlarged megakaryocytes with mature cytoplasm and multilobulated nuclei and a tendency to cluster in a normal or only slightly hypercellular BM (Michiels, 1999) (Fig. 33-15). Megakaryocyte nuclei are not described as atypical but often are distinctive and resemble other myeloproliferative disorders (MPDs). Erythroid proliferation may be present secondary to blood loss. Biopsy features may be indistinguishable from those of PV, but usually with less erythroid prominence. Splenic extramedullary hematopoiesis may be present.

Cultured marrow typically shows in vitro spontaneous colony formation of megakaryocytes and also erythroid colonies (Niittyuopio, 2004). Abnormal (decreased) labeling of BM for the thrombopoietin (TPO) receptor c-Mpl may aid in separating ET from reactive thrombocytosis (Gale, 2003).

Diagnosis

Criteria of the WHO for the diagnosis of thrombocythemia are as follows (Swerdlow, 2008):

1. Sustained platelet count $\geq 450 \times 10^9/L$.
2. BM biopsy showing proliferation of mainly megakaryocytes with enlarged mature nuclei, no increase or left shift of granulopoiesis or erythropoiesis.
3. Not meeting WHO criteria for polycythemia vera, PMF, BCR-ABL1-positive CML, MDS, or other myeloid neoplasm.
4. Demonstration of *JAK2 V617F* mutation or, in its absence, no evidence of reactive thrombocytosis.

Genetics

Forty percent to 50% of cases carry a *JAK2 V617F* mutation. BCR/ABL translocations must be ruled out to exclude CML. Ph⁺-positive thrombocytosis is likely an early form of CML and differs morphologically by lack of the characteristic large clustered megakaryocytes (Michiels, 2004). Some cases show +8 abnormalities of 9q or del(20q) (Swerdlow, 2008). Other abnormalities such as del(5q) or abnormalities of 3q21q26.2 suggest MDS with thrombocytosis.

Most cases are stable for many years, but a small proportion may merge into other chronic myeloproliferative disorders or, rarely, may develop into acute leukemia. Historically, alkylating agents and radiophosphorus have been used to treat essential thrombocythemia, but these were complicated by secondary leukemias. Hydroxycarbamide (hydroxyurea) has been used more recently, but it too has leukemogenic potential. Anagrelide is currently in use and is considered more safe and reliable (Silverstein, 1999). Development of erythrocytosis with increased red cell mass raises the possibility of polycythemia vera, and there is some crossover between the two entities. Endogenous erythroid colony formation may allow early identification of cases at risk for PV (Griesshammer, 2004). Fibrosis rarely occurs.

Chronic Myeloproliferative Disease, Unclassifiable

Chronic myeloproliferative disease, unclassifiable (CMPD, U) includes disorders with features of MPD but which do not meet criteria for a specific entity or have intermediate features (Swerdlow, 2008). Examples of CMPD, U include prefibrotic CIM, prepolycythemic PV, and postpolycythemic PV (without prior diagnosis), as well as cases with features of MPD but presenting with some dysplasia or increased blasts. BCR/ABL and other specific cytogenetic abnormalities are absent. This category overlaps with myelodysplastic/myeloproliferative disease, unclassifiable. Often, with follow-up, characteristic findings develop which allow definite diagnosis (Swerdlow, 2008).

Chronic Eosinophilic Leukemia, Not Otherwise Specified, and Idiopathic Hypereosinophilic Syndrome

Chronic eosinophilic leukemia (CEL) is a clonal proliferation of eosinophils with a chronic increase in the blood and often organ damage due to tissue infiltration. The blood contains $\geq 1.5 \times 10^9/L$ mostly mature eosinophils and often increased but less than 20% blasts in the blood or marrow. If blasts are not increased, if there is no evidence of underlying cause or monoclonality, or if organ involvement or dysfunction occurs and eosinophilia has persisted at least 6 months, the term idiopathic hypereosinophilic syndrome may be used. HES is, however, a diagnosis of exclusion (see Fig. 33-8), and causes of reactive eosinophilia must be ruled out. The differential diagnosis of reactive processes includes parasitic infection, Löffler's syndrome, cyclic eosinophilia, cutaneous angiolymphoid hyperplasia, Kimura's disease, autoimmune disease including vasculitides, and granulomatous disease. Neoplasms, including T cell lymphoma, HL, systemic mastocytosis, acute leukemias, and myeloproliferative diseases, are often causes of secondary eosinophilia due to cytokine production (IL-2, IL-3, IL-5, GM-CSF) or, in some cases, clonal involvement of the eosinophil series. When associated with a defined CMD, the eosinophilia is considered a component of that disease and is not termed CEL. Myeloproliferative diseases with eosinophilia and *PDGFRA*, *PDGFRB*, or *FGFR1* gene abnormalities are classified separately.

Some cases of CEL have clonal cytogenetic abnormalities, such as +8, i(17q), or 8p11 translocations, including t(8;13)(p11;q12), t(8;9)(p11;q32-34), and t(6;8)(q27;p11). The 8p11 translocation may also occur in AML, precursor acute lymphoblastic leukemia of B-lineage (B-ALL), or precursor ALL of T-lineage (T-ALL). Other abnormalities, including *JAK2 V617F* mutation and trisomy 10, may occur (Swerdlow, 2008). The clinical outcome of CEL and HES is usually indolent with 5-year survival of about 80%.

Mastocytosis

Mastocytosis is a clonal neoplastic proliferation of mast cells involving skin, BM, lymph nodes, and/or spleen (Swerdlow, 2008), with variable degrees of malignancy. Subtypes are described based on distribution of disease and clinical manifestations. Symptoms are complex and arise from secretion of vasoactive amines, including histamine and serotonin, as well as from mass effects.

Mastocytosis is associated with mutations of the *KIT* proto-oncogene that encodes the tyrosine kinase receptor for stem cell factor (SCF), most frequently, *KIT D816V* with CD117 expression. Morphologically, increased mast cells are found in involved organs, often with associated fibrosis. Mast cells normally are mononuclear cells with central nuclei, clumped chromatin, and dense basophilic granules. They are frequently difficult to identify, however, as mast cell granules are not well preserved in fixed tissue, and cells may appear like bland clear cells, histiocytes, fibroblasts,

Figure 33-16 Mastocytosis in the bone marrow, presenting after treatment for acute myeloid leukemia ($\times 500$).

or others. Mast cells may be identified in tissue using Giemsa or toluidine blue stain and immunohistochemistry. Mast cell tryptase is the most specific marker, but cells also express CD117, as well as CD45, CD33, CD68, CD2, and CD25. Mast cells lack myeloperoxidase but often express chloroacetate esterase. Diagnostic testing should include immunologic assays (immunohistochemistry and/or flow cytometry) for CD117, CD2, CD25, and tryptase, as well as assays for *KIT D816V* mutation in marrow, blood, or other extracutaneous organs for systemic disease.

Urticaria with melanin pigmentation is common with skin involvement and is referred to as **urticaria pigmentosa (UP)** or **maculopapular cutaneous mastocytosis (MPCM)**. This form occurs in both children and adults. In children, lesions are often large and papular, or are associated with blistering in children younger than 3 years old. It is often self-limited or may spontaneously regress. Histology shows aggregates of spindle-shaped mast cells filling the papillary dermis and extending into reticular dermis (Swerdlow, 2008). A diffuse cutaneous variant is referred to as **diffuse cutaneous mastocytosis**, and a localized variant as **mastocytoma of skin**.

Systemic mastocytosis is defined by involvement of at least one extracutaneous organ with or without skin involvement. It presents with variable cutaneous and constitutional symptoms, including urticaria, pruritus and dermatographism, symptoms of systemic histamine release, bone pain, arthralgia and fractures, splenomegaly, hepatomegaly, or lymphadenopathy.

BM involvement is sometimes difficult to identify, with paratrabecular and perivascular aggregates of increased lymphocytes, eosinophils, neutrophils, mast cells, and fibroblasts. Marrow biopsy of most cases shows multifocal, sharply demarcated compact aggregates of mast cells. These may be spindle shaped and lacking in apparent granules on H&E stain, or may consist of mixed infiltrates of mast cells, lymphocytes, eosinophils, histiocytes, and fibroblasts, with a peripheral rim or central core of lymphocytes. Compact infiltrates of hypergranular mast cells also occur and are referred to as **tryptase-positive round cell infiltrates**, or **TROCI**. The latter may also be seen in basophilic leukemia or acute myeloid leukemia. Mast cells are frequently increased in hematologic neoplasms such as HCL, lymphoplasmacytic lymphoma, and myeloid neoplasm and are most apparent around BM particles on aspirate smears. Reactive mast cells do not typically show compact aggregates.

In addition, systemic mastocytosis (SM) not infrequently presents simultaneously with or in close temporal relationship with other hematopoietic neoplasms, including acute leukemia, myeloproliferative and/or myelodysplastic neoplasms, and occasionally other hematopoietic neoplasia. SM is sometimes detected only after treatment for an acute process (Figs. 33-16 and 33-17). These cases are referred to as systemic mastocytosis with associated clonal non-mast cell lineage disease (SM-AHNMD). The non-mast cell (MC) disease is categorized by criteria for the same disorder without SM.

Mast cell leukemia also occurs and is defined by the presence of atypical mast cells constituting more than 20% of a marrow aspirate. More than 10% of the circulating cells are usually mast cells (Swerdlow, 2008).

Mast cell sarcoma refers to localized, destructive extramedullary tumors of highly atypical mast cells, occurring in larynx, bowel, meninges, bone, and skin. Extracutaneous mastocytoma of mature granulated mast cells occurs rarely in the lung.

The outcome is highly variable, with cutaneous disease usually indolent. In children, it usually regresses. Systemic disease without skin

Figure 33-17 Acute leukemia with early mast cell disease before therapy (earlier specimen from case shown in Fig. 33-16) ($\times 1000$).

Figure 33-18 Drug-induced dyserythropoiesis, with irregular nuclear lobation in the cells above right, compared with two relatively normal normoblasts ($\times 1000$).

involvement is more aggressive than with skin disease, and mast cell leukemia and sarcoma are highly aggressive.

Myeloproliferative Neoplasm, Unclassifiable

These are disorders with features of myeloproliferative neoplasm (MPN) but which do not meet criteria for a specific entity or have intermediate features (Swerdlow, 2008). Examples of CMPD, U include prefibrotic CIM, prepolycythemic PV, and postpolycythemic PV (without prior diagnosis) cases with features of MPN but presenting with some dysplasia or increased blasts, and those with convincing evidence of MPN that is, however, obscured by a concurrent inflammatory or neoplastic condition. *BCR/ABL* and other specific cytogenetic abnormalities are absent. This category overlaps with myelodysplastic/myeloproliferative disease, unclassifiable. Often, with follow-up, characteristic findings develop which allow definitive diagnosis.

Myeloid and Lymphoid Neoplasms with Eosinophilia and Abnormalities of *PDGFRA*, *PDGFRB*, or *FGFR1*

This disease category was established in the 2008 WHO Classification for a group of myeloid neoplasms associated with eosinophilia that have genetic abnormalities resulting in abnormal tyrosine kinases that may be successfully treated with tyrosine kinase inhibitors, of which the prototype is imatinib. It and related drugs have been used successfully in the first two conditions listed in this group.

PDGFRA rearrangement is most often associated with a *FIP1L1-PDGFRA* fusion protein resulting from a cryptic deletion at 4q12. The disease usually presents as chronic eosinophilic leukemia with peripheral eosinophil counts $>1.5 \times 10^9/L$, with multisystem involvement and organ damage. BM eosinophilia is often accompanied by increased mast cells that are considered part of the disease. It usually occurs in men between 25 and 55 years, but also may occur in others. Presentation also occurs as AML and as T-lymphoblastic lymphoma/leukemia (T-LBL). Diagnosis and appropriate therapy depend on identification of the genetic abnormality by reverse transcriptase polymerase chain reaction (RT-PCR) or by cytogenetic FISH assay for deletion of the *CHIC2* gene, or use of a break-apart probe encompassing *FIP1L1* and *PDGFRA*. Other genetic variants have been described and are generally imatinib sensitive (Swerdlow, 2008).

Rearrangement of *PDGFRB* at 5q31-33, usually due to t(5;12) (q31-33;p12) with production of *ETV6-PDGFRB*, resembles CMML with eosinophilia. Variant translocations involving *PDGFRB* may be associated with other morphologies, including CEL, MPN, and others. This disease occurs most often in middle age, but with a wide age range and a 2:1 M/F ratio. The morphology is similar to CMML with increased eosinophils and sometimes increased mast cells but is now classified by the genetic abnormality. The disease is sensitive to imatinib. Diagnostic testing is completed by cytogenetics to detect t(5;12) and/or by RT-PCR. Secondary trisomy 21 is frequent.

Hematologic neoplasms involving *FGFR1* at chromosome region 8p11 are heterogeneous and may present as MPN, AML, T or less often B lymphoblastic leukemia/lymphoma, or mixed phenotype acute leukemia. Eosinophilia is present in 90% of cases overall. Although an abnormal tyrosine kinase is produced, it is not imatinib sensitive, and no specific inhibitor is yet described. The genetic abnormalities are most often translocations and karyotyping may be diagnostic. Prognosis is poor.

Figure 33-19 A ring sideroblast is present in the center of the field ($\times 1000$).

Myelodysplastic and Myelodysplastic/Myeloproliferative Neoplasms

Myeloproliferative diseases, in general, are disorders in which proliferation of hematopoietic cells outpaces apoptosis, and cellular elements in the blood are increased while the morphology of hematopoiesis is near normal. Myelodysplastic diseases or syndromes are disorders in which apoptosis predominates, hematopoiesis is ineffective, and cytopenias occur. The myelodysplastic/myeloproliferative disorders show features of both, with variable increases in cells, as well as cytopenias and morphologic dysplasia. These include chronic myelomonocytic leukemia, atypical chronic myeloid leukemia, *BCR-ABL1*-negative, juvenile chronic myelomonocytic leukemia, and myelodysplastic/myeloproliferative neoplasm, unclassifiable.

MDS occurs primarily in persons over age 50 and usually present as an anemia refractory to hematinics, with or without neutropenia and thrombocytopenia. Liver, spleen, or lymph nodes are not usually enlarged. The marrow is hypercellular with abnormal maturation in one or more of the three hematopoietic cell lines, and blast cells are often increased. This group of disorders has also been called dysmyelopoietic syndromes or **preleukemias** because of the high proportion of cases that ultimately progress to overt acute leukemia. The FAB Cooperative Group (Bennett 1976, 1982) described and classified these disorders, and their nomenclature remains useful with certain modification, per the WHO classification (Swerdlow, 2008). A scoring system for predicting survival and risk of acute leukemic transformation has been developed based on percentage of blasts, cytogenetics, and extent of cytopenias. In general, blast count $>5\%$ elevates risk and $>10\%$ increases risk further; complex chromosomal abnormalities or chromosome 7 abnormalities are high risk; del(5q), isolated del(2q), -Y, and normal cytogenetics are low risk; other cytogenetic findings are intermediate risk; and more than one cytopenia increases risk.

Types of Abnormal Cellular Maturation

Dyserythropoiesis resembles megaloblastic change and includes nuclear fragmentation or karyorrhexis, multinuclearity, nuclear budding or bridging, basophilic stippling, and ring sideroblasts (Bennett, 1986). These features may also be seen in toxicity due to drugs, chemotherapy, heavy metals, alcohol, and other toxins (Swerdlow, 2008) (Figs. 33-18 and 33-19). Erythroid cells may be decreased or increased in number. Erythrocytic abnormalities in the blood film include presence of oval macrocytes, anisochromia, basophilic stippling, dacryocytes, and reticulocytopenia.

Dysgranulopoiesis includes nuclear/cytoplasmic asynchrony, hypogranulation, nuclear hyposegmentation with increased chromatin condensation, occasionally abnormal large azurophilic granules, inappropriately prominent nucleoli, or other abnormalities. Neutrophil precursors and monocytes often resemble one another. Neutrophils with mature chromatin but with decreased granulation and bilobed or unilobed nuclei resemble the cells of Pelger-Huët anomaly and are termed **pseudo Pelger-Huët** cells (Figs. 33-20 and 33-21).

Dysmegakaryocytopoiesis includes large megakaryocytes with unsegmented nuclei, micromegakaryocytes, and megakaryocytes with two or more small, unconnected nuclei (Fig. 33-22). Megakaryocytes may be decreased in number. In the blood film, giant hypogranular platelets are frequent, and micromegakaryocytes are seen rarely.

Myelodysplastic/Myeloproliferative Neoplasms

Chronic Myelomonocytic Leukemia

CMML is a clonal stem cell disorder in which the predominant feature is persistent monocytosis ($>1 \times 10^9/L$ for longer than 3 months) for which other causes have been excluded (Swerdlow, 2008). Typically, cytopenias are present in the blood (anemia, thrombocytopenia, and/or neutropenia), but neutrophilia with morphologic abnormalities also occurs. There is absence of a Philadelphia chromosome or *BCR/ABL*, dysplasia of one or more myeloid lineages, and less than 20% blasts plus promonocytes in the marrow (Fig. 33-23). The marrow also shows monocytosis and often has increased promonocytes, which may be distinguished from abnormal myelocytes by nonspecific esterase (α -naphthyl acetate, or α -naphthyl

butyrate esterase) staining or strong labeling with antilysozyme or CD68. Eosinophilia or basophilia may be present, and plasmacytoid-appearing monocytes are seen frequently. When eosinophils exceed $1.5 \times 10^9/L$, the WHO recommends the subcategory of CMML with eosinophilia.

In CMML and also in the acute myeloid leukemias with monocytic differentiation, promonocytes are considered equivalent to blasts and are included with them for determining the blast percentage. Promonocytes are monocytic precursors which have recognizable monocyte morphology but immature chromatin and finely convoluted or cerebriform nuclei (Fig. 33-24). Blast percentages typically are $<5\%$ in the blood and $<10\%$ in the marrow, and such cases are referred to as CMML-1. The subcategory CMML-2 refers to cases with 5% – 19% blasts in the blood, with 10% – 19% in the marrow, or with the presence of Auer rods. This indicates aggressive disease with likely impending transformation to acute leukemia.

The immunophenotype is CD13/CD33+, with variable CD14/CD68/CD64/CD4-positive. Plasmacytoid monocytes may be seen and may express CD14, CD43, CD56, CD68, and CD4, with variable CD2/CD5. Cytogenetic abnormalities in 20%–40% of cases include +8, -7/del, and abnormalities of 12p.

CMML occurs most often at older age (median, 65–75 years) with a male predominance. Symptoms are usually those related to cytopenias (fatigue, infection, bleeding) or hypermetabolic state (fever, weight loss, night sweats). Hepatosplenomegaly may be present, particularly in patients with elevated WBCs. Lymphadenopathy may be associated with granulocytic sarcoma and evolution to acute leukemia. Median survival is 20–30 months, with progression to AML in 15%–30%.

Atypical Chronic Myeloid Leukemia, *BCR-ABL1* Negative

This disease shows myelodysplastic and myeloproliferative features, a predominant component of increased neutrophils and precursors with dysplastic features, and dysplasia of other cell lines (Swerdlow, 2008). Ph' chromosome or *BCR/ABL* is absent. These cases were previously considered along with CML or CMML, but they are Ph' chromosome and *BCR/ABL* negative, and, although monocytosis is often present, it is less prominent than neutrophilia. Clinical features may include anemia, thrombocytopenia, or splenomegaly. The marrow is hypercellular with variable features of each lineage. A variant, "syndrome of abnormal chromatin clumping," shows exaggerated chromatin condensation, as well as other dysplastic features.

Cytogenetics show +8, +13, del(20q), i(17q), or del(12p) in up to 80% of cases. There is no *BCR-ABL1* fusion gene, and cases with *PDGFRA* or *PDGFRB* rearrangements are excluded. This disease usually occurs in later

Figure 33-20 Pseudo-Pelger-Huët neutrophil ($\times 1000$).

Figure 33-21 Other forms of neutrophil dysplasia. **A**, Ring neutrophil along with dysplastic erythroid and megakaryocytic cells in the marrow ($\times 1000$). **B**, Pelger-Huët neutrophil resembling a monocyte ($\times 1000$). **C**, Mononuclear Pelger-Huët cell ($\times 1000$). **D**, Large, irregularly bilobed and granulated neutrophil precursors ($\times 1000$).

Figure 33-22 A dysplastic megakaryocyte showing unconnected nuclear lobes. Mononuclear forms are also frequent in myelodysplasia (x500).

Figure 33-23 This case of chronic myelomonocytic leukemia shows moderate trilineage dysplasia and monocytosis (x500).

Figure 33-24 Promonocyte (center) shows immature chromatin and finely convoluted nuclear folds in comparison with monoblasts.

years, although with a wide reported age distribution down to the teen years. It has a generally poor outcome with median survival of 20 months, and a 25%–40% transformation to acute leukemia.

Criteria for diagnosis of aCML include the following (Swerdlow, 2008):

- Leukocytosis (WBC $\leq 13 \times 10^9/L$) due to increased neutrophils and precursors with prominent dysgranulopoiesis
- Prominent dysgranulopoiesis
- No Ph' chromosome or *BCR/ABL-1* fusion gene
- No rearrangement of *PDGFRA* or *PDGFRB*
- Neutrophil precursors (promyelocytes, myelocytes, metamyelocytes) $\geq 10\%$ of WBCs
- Minimal absolute basophilia; basophils usually $<2\%$ of leukocytes
- No or minimal absolute monocytosis; monocytes $<10\%$ of WBCs
- Hypercellular marrow with granulocytic proliferation and granulocytic dysplasia, with or without dysplasia of erythroid and megakaryocytic lineages
- Less than 20% blasts in blood or marrow

Juvenile Myelomonocytic Leukemia

Juvenile myelomonocytic leukemia (JMML) is a clonal disorder of predominantly granulocytic and monocytic lineages, with dysplasia in these and frequently other lineages, occurring in children or young adolescents

(Luna-Fineman, 1999; Swerdlow, 2008). *BCR/ABL-1* is absent, and *RAS/MAPK* pathway mutations are characteristic. The occurrence is 1.3 cases per million children younger than 14 years, and most affected children are younger than 3 years of age, with a 2:1 male predominance. JMML is frequent in children with neurofibromatosis type 1.

In all, 25% of patients show monosomy 7, 35% exhibit mutations of *PTPN11* (encoding *SHP2*), and 20% each have mutations in *NRAS*, *KRAS2*, and *NF1*. Some infants with Noonan syndrome and *PTPN11* mutation may have spontaneous recovery or accelerated disease. Patients with normal karyotype often have markedly increased hemoglobin F. Immune phenomena of hypergammaglobulinemia and autoantibodies are frequent.

Blood shows leukocytosis, thrombocytopenia, and often anemia. The WBC is relatively high, usually $25\text{--}30 \times 10^9/L$, and mature neutrophils predominate, while monocytosis is also present. Circulating nucleated red blood cells (NRBCs) are frequent. The marrow is hyperplastic with granulocytic hyperplasia, variable erythroid cellularity, and often decreased megakaryocytes. Cutaneous leukemic infiltrates are common.

The prognosis is poor, and death is usually due to organ failure from leukemic infiltrates, although some patients benefit from BM transplant.

Criteria for diagnosis of JMML follow here (Swerdlow, 2008):

- Peripheral blood monocytosis $>1 \times 10^9/L$
- Absence of Ph' chromosome or *BCR/ABL-1*
- Blasts and promonocytes less than 20% of blood and marrow
- Plus two of the following:
 - Hemoglobin F increased for age
 - Immature granulocytes in the blood
 - WBCs $>10 \times 10^9/L$
 - Clonal chromosomal abnormality (may be monosomy 7)
 - GM-CSF hypersensitivity of myeloid progenitors in vitro

Myelodysplastic/Myeloproliferative Disease, Unclassifiable

This category of the WHO classification is used for those cases with features of myelodysplastic disease, but with the addition of prominent myeloproliferative features, including thrombocytosis $\geq 450 \times 10^9/L$ with megakaryocytic hyperplasia or WBC $>13 \times 10^9/L$, with or without splenomegaly, no previous CMPD or MDS, and absence of a chromosomal abnormality specific to another disease (no *BCR/ABL* or rearrangement of *PDGFRA*, *PDGFRB*, or *FGFR1*; no *del[5q]*, *t[3;3][q21;q26]* or *inv[3][q21;q26]*) (Swerdlow, 2008).

Refractory Anemia with Ring Sideroblasts Associated With Marked Thrombocytosis

This disorder is included in the WHO classification under the category of MDS/MPD, unclassified, because of not-yet-resolved questions regarding whether it is truly a distinct entity or an overlap syndrome of coexisting disorders. It is characterized by features of myelodysplastic neoplasm and refractory anemia with ring sideroblasts (RARS; see description later), along with features similar to essential thrombocythemia, with peripheral thrombocytosis $\geq 450 \times 10^9/L$, and increased, large atypical BM megakaryocytes. A majority of cases (60%) carry a *JAK2 V617F* mutation identical to that in MPN; occasional cases show a *MPL W515K/L* mutation.

Myelodysplastic Syndromes

These are clonal hematopoietic neoplasms characterized by cytopenias due to ineffective hematopoiesis and increased apoptosis. They show morphologic dysplasia of at least one and usually more lineages and have varied cytogenetic findings (but not typically those associated with myeloproliferative neoplasms), and many have a propensity to progress to acute leukemia (Table 33-13).

Refractory Cytopenia with Unilineage Dysplasia

This category consists of neoplasms, with dysplasia affecting $>10\%$ of one myeloid cell lineage, and cytopenia of the affected cell line, with $<10\%$ dysplasia of other lineages.

Refractory Anemia

This clonal disorder involves primarily the erythroid lineage with ineffective erythropoiesis but without increased blasts. Anemia (Hb <10 g/dL) with reticulocytopenia and abnormal erythrocytes are the presenting

TABLE 33-13

Key Features of the Major Myelodysplastic Syndromes

Disorder	Demographics	Laboratory features, morphology	Cytogenetics	Risk group
Refractory cytopenia with unilineage dysplasia, anemia (RA), thrombocytopenia, or neutropenia	Median age, 65–70 years	Peripheral blood (PB) with unicytopenia or bicytopenia, blasts <1%; bone marrow (BM) with >10% unilineage dysplasia and <5% blasts	Del (20q), +8, abnormalities of chromosome 5 or 7	Low
Refractory anemia with ringed sideroblasts	Median age, 60–73 years	Similar to RA with >15% ringed sideroblasts in BM	Rare abnormalities of single chromosome	Low
Refractory cytopenia with multilineage dysplasia	Median age, 70 years	PB with cytopenias of ≥ 2 cell lines, <1% blasts, <1 $\times 10^9$ /L monocytes; BM with dysplasia of $\geq 10\%$ of precursors of ≥ 2 cell lines, <5% blasts	+8, -5, -7, del(7q), del(20q), complex in up to 50%	Intermediate
Refractory anemia with excess blasts (RAEB)	Over age 50	RAEB-1: PB with <5% blasts, <1 $\times 10^9$ /L monocytes; BM with hypercellularity, dyspoiesis, 5%–9% blasts without Auer rods; RAEB-2: PB with 5%–9% blasts, or 10%–19% BM blasts, or Auer rods	+8, -5, del(5q), -7, del(7q), del(20q)	RAEB-1, intermediate; RAEB-2, high
5q- syndrome	Middle-aged to older females	PB with thrombocytosis, <5% blasts; BM with increased, hypolobulated megakaryocytes, <5% blasts	5q- is sole abnormality	Low

findings. Abnormal granulocytes are rare, and blasts are less than 1% in the blood. The marrow is normocellular to hypercellular with erythroid hyperplasia and/or dyserythropoiesis and less than 5% blasts. Survival is relatively good (>5 years), and progression to acute leukemia (AL) low (6%).

Refractory Neutropenia

The absolute neutrophil count is $<1.8 \times 10^9$ /L. Dysplasia usually consists of nuclear hypolobation and hypogranulation. Toxic/secondary neutropenia is excluded.

Refractory Thrombocytopenia

Platelets are $<100 \times 10^9$ /L. More than 10% of at least 30 megakaryocytes evaluated in smears and sections show dysplastic features of hypolobation, binucleation or multinucleation, and/or micromegakaryocytes.

Refractory Anemia with Ring Sideroblasts

In RARS, in addition to the findings of RA, ring sideroblasts are present and constitute 15% or more of marrow erythroid precursors. These are nucleated RBC precursors in which stainable iron particles (iron-encrusted mitochondria) form a ring of 10 or more closely associated with and encircling at least one third of the nucleus (see Fig. 33-19). Defective cytoplasmic maturation and anisochromic erythrocytes are associated abnormalities. Survival is similar to RA, with a lower progression to AL ($\leq 2\%$).

Refractory Cytopenia with Multilineage Dysplasia

Refractory cytopenia with multilineage dysplasia (RCMD) is a clonal disorder with bicytopenias or pancytopenia and dysplasia of 10% or more of the precursors of two or more lineages. Blasts are not increased, with <1% in the blood and <5% in the marrow. Ring sideroblasts may be present; when numerous (>15%), the case is still classified as RCMD and is not categorized separately, as in prior classifications.

This disease usually occurs in older individuals (median age, ≈ 70 years). In contrast to RA and RARS, which infrequently show cytogenetic abnormalities (<10%), RCMD and RCMD with ring sideroblasts (RCMD-RS) show them in up to 50%. These include trisomy 8, monosomy 7, del(7q), monosomy 5, del(5q), del(20q), and complex karyotypes. Survival is ≈ 33 months, and AL conversion is 11%.

Refractory Anemia with Excess Blasts

In refractory anemia with excess blasts (RAEB), the blood shows cytopenia in two or three of the cell lines, and less than 5% circulating blasts. The marrow is hypercellular, with variable erythroid or granulocytic hyperplasia. Dyspoietic changes are present in all three cell lines, and 5%–9% of marrow cells are blasts. Less than 5% blasts are present in the blood, and no Auer rods are found. Clusters of 5–8 blasts and promyelocytes in the

marrow interstitium are frequently seen on sections and have been referred to as abnormal localization of immature precursors (ALIP). Hypocellular marrow is seen in a minority of cases (10%–15%). These may be difficult to interpret, as the patients are often older, with decreased cellularity to begin with, and because marrow stress in hypoplastic anemia often causes some dysplasia. A diagnosis of MDS should be made cautiously when the marrow is hypoplastic.

Cases of RAEB with concurrent myelofibrosis are referred to as **RAEB with fibrosis (RAEB-F)**. Megakaryocytes are increased and dysplastic, and reticulin fibrosis is significant, often resulting in a dry tap.

RAEB-2 has findings similar to RAEB, but with any of the following: (1) greater than 5% blasts in the blood, (2) 10%–19% blasts in the marrow, or (3) the presence of Auer rods. Cytogenetic abnormalities include +8, -5, del(5q), -7, del(7q), and del(20q). Survival is usually less than 2 years in RAEB-1 or -2, with progressive marrow failure and cytopenias or progression to AL in 25% for RAEB and in 33% for RAEB-2.

Myelodysplastic Syndrome with Isolated del(5q)

This disorder is characterized by anemia and/or thrombocytosis with increased megakaryocytes and isolated deletion of chromosome region 5q. Some cases also exhibit a *JAK2 V617F* mutation. Blasts are less than 5% in the marrow and blood; lymphoid aggregates are often present. Megakaryocytes are usually small and hypolobulated. Anemia may be severe and macrocytic, and an otherwise normocellular to hypercellular marrow may have erythroid hypoplasia. Outcome is relatively favorable.

Myelodysplastic Syndrome, Unclassified

The myelodysplastic syndrome, unclassified category is used when clinical and hematologic findings of myelodysplasia exist, but without specific features to allow placement in one of the other categories. Patients usually have neutropenia or thrombocytopenia with a hypercellular BM and dysplasia of granulocytic or megakaryocytic lineage. Less than 5% blasts are found in the BM, and they are not increased in the blood.

Childhood Myelodysplastic Syndrome; Refractory Cytopenia of Childhood

In the WHO classification, it is recognized that MDS, although rare in children, does occur but tends to show different features than in adults. Refractory cytopenia of childhood (RCC) is defined as MDS with persistent cytopenia with <5% blasts in the BM and <2% in the blood and dysplasia, at least unilineage but usually multilineage, in the marrow. The marrow is also frequently hypocellular. Pancytopenia is frequent, with macrocytic anemia showing anisopoikilocytosis. The cytogenetic abnormality of monosomy 7 is the most common genetic abnormality and is associated with progressive disease. Cases with trisomy 8 may show a long

stable period. This disorder may be morphologically indistinguishable from results of infection, vitamin deficiency (B_{12} , folate, vitamin E), metabolic or autoimmune disease, paroxysmal nocturnal hemoglobinuria (PNH), or acquired aplastic anemia.

ACUTE MYELOID LEUKEMIA

AML is the most common form of acute leukemia during the first few months of life, but during childhood and adolescence it accounts for approximately one third of AL. In the middle and later years of life, it becomes the most frequent AL, with a median age of 60, and an occurrence of 10/100,000 per year in those older than 60 years. Viruses, radiation, cytotoxic chemotherapy, benzene, and smoking have been linked to increased incidence, but most cases are not known to be associated with such factors.

The onset often resembles acute infection and includes signs of granulocytic insufficiency, with ulcerations of mucous membranes (especially of the mouth and throat) and fever. Enlargement of lymph nodes, spleen, and liver is not pronounced. Marked prostration and general malaise may be present. In untreated cases, the course is rapidly progressive (Table 33-14).

AML classification currently utilizes a multilayered approach which recognizes recurrent acquired cytogenetic abnormalities associated with specific types, history of predisposing factors (prior cytotoxic therapy),

association with MDS or related abnormalities, and morphologic stratification for those for which none of these can be appreciated. This approach requires, or at least encourages, attempts to define the morphology, cytogenetics, and immunophenotype of each case. With advances in molecular cytogenetics and FISH, and with widespread adoption of these and other methods, it is likely that most cases will eventually be categorized by their genetic abnormalities. Knowledge of these changes is particularly important because therapies may be targeted to the biochemical pathways or even to the nucleic acid perturbations involved (Gilliland, 2004). See Tables 33-15 and 33-16.

The French-American-British Cooperative Group published proposals in 1976 for the classification of acute leukemias (Bennett, 1976) and subsequently revised criteria for the classification of ALL (Bennett, 1981) and AML (Bennett, 1985a, 1985b) based on morphology of cells in Romanowsky's-stained blood and marrow films and certain supplemental cytochemical reactions or serum lysozyme levels. These criteria have been superseded by the current WHO classification (Swerdlow, 2008), but basic morphologic tenets remain, and FAB criteria serve as the basis for subtyping AML, not otherwise specified.

The diagnosis of AML requires the presence of 20% blasts in the marrow or blood. Myeloblasts generally have central nuclei with fine, uncondensed chromatin and often prominent nucleoli (usually three to five) but have variable cytoplasm and may have some cytoplasmic granules. Primitive myeloblasts are identified by monoclonal antibodies against myeloid-associated antigens (MPO, CD13, CD33, CD117). More mature myeloblasts can also be identified by cytochemical reactions with granulocyte-associated enzymes using MPO, Sudan black B (SBB), and chloroacetate esterase (CAE) assays, although flow cytometric assays are utilized more often in current practice. Monoblasts are frequently large with abundant cytoplasm, diffuse chromatin, and often prominent nucleoli. Monoblasts are characterized by strong reaction with α -naphthyl acetate esterase (ANA), which is inhibited in monocytes by sodium fluoride, or with α -naphthyl butyrate esterase (ANB), or antibodies including anti-lysozyme, CD68, CD64, and CD36. For cases with monocytic differentiation, promonocytes are considered equivalent to blasts (Fig. 33-24). Promonocytes are immature recognizable monocytes with some chromatin condensation but with fine nuclear convolutions. Abnormal

TABLE 33-14

Clinical and Laboratory Features of Acute Myeloid Leukemia

- Affects all ages, but increases with older age (>60 years)
- May resemble acute infection at presentation
- Requires 20% blasts in blood or marrow for diagnosis
- Key myeloid antigens: myeloperoxidase, CD13, CD33, CD117, and CD14/CD64
- Recurrent cytogenetic abnormalities that characterize defined subtypes
- Classification made by morphology, cytogenetics, flow cytometry, cytochemistry

TABLE 33-15

Key Features of the Major Acute Myeloid Leukemias

Category	Cell morphology	Cell surface markers	Cytogenetics	Prognosis
AML with t(8;21)	≥20% blasts, ≥10% maturing granulocytes, Auer rods, dysplasia, abnormal granules	CD13, CD33, CD117, CD19, CD34	t(8;21)(q22;q22) AML1/ETO	More favorable
AML with inv(16)	Blasts with both monocytic and neutrophilic differentiation, increased eosinophils/immature eosinophils	CD13, CD33, CD14, CD4, 64	inv(16)(p13;q22) or t(16;16)(p13;q22)	More favorable
APL with t(15;17)	Promyelocytes with azurophilic granules, Auer rods	CD13, CD33 CD2, ± CD117	t(15;17)(q22;q12) PML/RAR α ; Variants all involve 17q12	More favorable if responsive to ATRA
AML with t(9;11)	Monoblasts and promonocytes predominate	CD33, CD65, CD4, HLA-DR	t(9;11)(p22;q23) MLLT3-MLL	Intermediate
AML, therapy related	Multilineage dysplasia, RS, increased basophils	CD13, CD33, CD34, ± CD56, CD57	11q23 abnormality seen with topoisomerase II inhibitor-associated AML	Less favorable
AML with t(6;9)	Any morphology may be seen but myelomonocytic is most common	CD13, CD33, CD38, HLA-DR, CD117	DEK-NUP214; t(6;9)(p23;q35)	Less favorable
AML with inv(3) or t(3;3)	Any morphology may be seen except APL	CD13, CD33, HLA-DR, CD34, CD38	Inv(3)(q21;q26.2) or t(3;3)(q21;q26.2) RPN1-EVI1	Less favorable
AML with t(1;22)	Megakaryoblastic morphology with small and large megakaryocytes	CD41, CD61, ± CD13, CD33	t(1;22)(p13;q13) RBM15-MKL1	Less favorable
AML with <i>FLT3</i> mutation/duplication	Any	Any	t(6;9)(p23;q34), t(15;17)(q22;q12) or normal	Less favorable
AML with <i>NPM1</i> mutation	Myelomonocytic and monocytic features	CD13, CD33, CD34 is negative	<i>NPM1</i> mutation, cytoplasmic expression	More favorable in absence of <i>FLT3</i>
AML with <i>CEBPA</i> mutation	Variable, generally similar to less differentiated AMLs in FAB scheme (M1, 2)	CD13, CD33, CD65, CD11b, CD15	<i>CEBPA</i> mutation	More favorable

AML, Acute myeloid leukemia; APL, acute promyelocytic leukemia; ATRA, all-trans retinoic acid; PML, promyelocytic leukemia; PB, peripheral blood; RAR α , retinoid acid receptor gene- α .

TABLE 33-16

Key Features of the Acute Myeloid Leukemias, Not Otherwise Specified

Category	Cell morphology	Cell surface markers
All categories	≥20% blasts in BM and/or blood	Myeloid differentiation, any lineage
AML, minimally differentiated	Myeloblasts, <3% positive for SBB, MPO, or ANA	CD13, CD33, CD117
AML without maturation	Myeloblasts ≥90% of nonerythroids in BM, ≥3% positive for MPO	CD13, CD33, CD117
AML with maturation	Same as for AML with t(8;21)	CD13, CD33, CD117
Acute myelomonocytic leukemia	Monocytic and granulocytic cells, each 20%–80%,	Variable CD13, CD33, CD14, CD4, CD11b, CD11c, CD64, CD36, CD68
Acute monoblastic/ monocytic	≥80% of nonerythroid monoblasts (M5a) or differentiating monos (M5b)	CD13, CD33, CD117, CD14, CD4, CD11b, CD11c, CD64, CD68, CD36
Erythroleukemia	≥50% erythroid precursors and ≥20% of nonerythroids are myeloblasts; pure erythroleukemia without myeloid blasts is rare	Glycophorin A in erythroids; CD13, CD33, CD117 in myeloblasts
Acute megakaryoblastic leukemia	Blasts with cytoplasmic blebs, often clusters; PB may show megakaryocytic fragments; MPO negative	CD41, CD61, CD36, often CD13, CD33

AML, Acute myeloid leukemia; ANA, antinuclear antibody; BM, bone marrow; MPO, myeloperoxidase; PB, peripheral blood; SBB, Sudan black B.

Figure 33-25 Auer rods vary from prominent, as in this cell, to thin and delicate.

Figure 33-26 This case of acute myelogenous leukemia with t(8;21) shows granulocyte maturation with abnormal granulation and bilobed precursors ($\times 500$).

promyelocytes are also considered blast equivalents for the diagnosis of acute promyelocytic leukemia. Megakaryoblasts are identified by antibodies against platelet-associated antigens or electron microscopy for platelet peroxidase.

Initial assessment for suspected AML is based on a differential WBC count of the blood and a 500-cell count of the marrow aspirate. Acute leukemia is diagnosed when blasts exceed 20% of the marrow or blood. Otherwise, it is necessary to calculate the percentage of erythroid precursor cells. The diagnosis of AML-erythroleukemia is established when more than 50% of BM cells are erythroid precursors, and when myeloblasts represent more than 20% of the remaining nonerythroid (NE) cells (i.e., nucleated cells not including erythroid precursors, lymphocytes, or plasma cells). MDS is suggested when less than 20% of the nucleated marrow cells, or less than 20% of nonerythroid cells (when RBC precursors exceed 50%), are myeloblasts. Once the diagnosis of AML has been made, only nonerythroid cells should be considered in the differential count for the further assignment of morphologic subtypes.

A helpful finding in the diagnosis of AML is the presence of Auer rods, eosinophilic rod-like cytoplasmic inclusions derived from myeloperoxidase-positive primary granules. Phi bodies, which appear as strings of eosinophilic bead-like granules, are derived from catalase-positive microperoxisomes and are seen in larger numbers in AML and also in MDS (Cardullo, 1981). They are not, however, generally given the same diagnostic import as Auer rods. With Romanowsky's stains, Auer rods are linear or spindle-shaped, red-purple inclusions in myeloblasts or promyelocytes (Fig. 33-25). Less commonly, they may be seen in more mature neutrophils (in AML with t(8;21)). Auer rods, derivatives of azurophilic granules, stain positively for SBB, MPO, CAE, and acid phosphatase. Auer rods can be found in any of the subtypes of AML, but they are especially associated with those with granulocytic differentiation.

The main categories of AML in the WHO classification are (1) AML with recurrent cytogenetic abnormalities; (2) AML with multilineage dysplasia; (3) AML, therapy related; and (4) AML, not otherwise specified (subclassified by morphology and immunophenotype).

Acute Leukemia with Recurrent Genetic Abnormalities

(Swerdlow, 2008).

AML with Balanced Translocations/Inversions

AML with t(8;21)(q22;q22), RUNX1-RUNX1T1. The morphology usually corresponds to acute myeloid leukemia with neutrophilic maturation, and these represent 5%–12% of AML, with predominance in young patients. Blasts are 20% or greater in the marrow (or blood), and maturing neutrophilic precursors constitute more than 10% of marrow nucleated cells (not including NRBCs, lymphocytes, and plasma cells). Morphologic findings are characteristic but variable: large blasts with abundant basophilic cytoplasm; maturing neutrophil precursors with peripheral cytoplasmic basophilia; frequent Auer rods, often long, sharp, and tapered, and sometimes present in myelocytes and mature forms up to segmented neutrophils; abnormal granulation, including giant Chédiak-Higashi-like or secondary granules or homogenous waxy-appearing secondary granulation; and nuclear dysplasia with bilobed nuclei which may be widely separated (Fig. 33-26). Monocytosis is not prominent, and monocytes are less than 20% of the marrow. Eosinophilia is common, and basophils or mast cells may be increased. The immunophenotype is distinctive with high-intensity CD34 along with myeloid markers MPO and CD13, but relatively weak CD33 and sometimes CD56. One or more B cell markers—CD19, PAX5, and cytoplasmic CD79a—are often coexpressed.

The presence of t(8;21) is diagnostic of AML, even when blasts appear to be less than 20%. This disease is referred to as a **core binding factor leukemia** because RUNX1, also known as AML1 or core binding factor α (CBFA), encodes a transcription factor required for hematopoieses. The outcome of AML with t(8;21) is generally more favorable than AML without recurrent genetic abnormalities, or with MDS-associated abnormalities. Additional genetic abnormalities also occur, including *KIT* mutations associated with less favorable outcome.

Figure 33-27 Acute myelogenous leukemia with *inv16* shows myelomonocytic differentiation with eosinophilia. (Two eosinophils are present in this view.)

Figure 33-29 Acute myelogenous leukemia with monocytic differentiation and 11q23 abnormality ($\times 1000$).

Figure 33-28 Acute promyelocytic leukemia with *t(15;17)* shows predominantly abnormal promyelocytes ($\times 500$). Inset (top right): Abnormal promyelocytes with bundles of Auer rods are known as **faggot cells** from their resemblance to bundles of firewood, or faggots ($\times 1000$).

AML with *inv(16)(p13q22)* or *t(16;16)(p13.1;q22)*, *CBFβ/MYH11*. These correspond to acute myelomonocytic leukemia with abnormal eosinophils (Bitter, 1984). Occurrence and outcome are similar to AML with *t(8;21)*. These cases show $>20\%$ blasts in marrow and/or blood with differentiation to monocytic and neutrophilic lineages ($\geq 20\%$ each). Eosinophils are characteristically increased (Fig. 33-27), including those with large basophilic granules (as in eosinophil promyelocytes), and cytoplasmic positivity is often weak for chloroacetate esterase. This type is associated with the chromosomal abnormality *inv(16)(p13q22)* or its variant *t(16;16)(p13.1;q22)* with fusion of the *CBFβ* gene on 16q and *MYH11* on 16p and variable resultant chimeric mRNAs (due to differing breakpoints) and a BCGB-MYH11 fusion protein. This additional core binding factor leukemia generally has relatively favorable outcomes compared with other AMLs. In addition to karyotyping, RT-PCR or FISH is useful for timely diagnosis. Secondary genetic abnormalities are common, including trisomy 22, which is relatively specific for this disease, and *KIT* mutations.

The immunophenotype typically shows both granulocytic (CD13, CD15, CD33, CD65, MPO) and monocytic (CD4, CD14, CD64, CD36, CD11b, CD11c, and lysozyme) markers, sometimes with CD2 coexpression.

Acute Promyelocytic Leukemia with *t(15;17)(q22;q12)*, *PML/RARα*, and Variants. Promyelocytes instead of myeloblasts predominate in the marrow in hypergranular promyelocytic leukemia (PML) (M3) (McKenna, 1982) (Fig. 33-28). Azurophilic granules are abundant and intensely stained. Auer rods are found in most cases and frequently are multiple (10 or more) in a given cell (see Fig. 33-28). Hemorrhagic complications are frequent as the result of disseminated intravascular coagulation (DIC), apparently initiated by procoagulant material from leukemic cell granules.

The characteristic chromosomal abnormality *t(15;17)(q22;q21)* shows fusion of the retinoid acid receptor gene- α (*RARα*) on chromosome 17 with the *PML* gene on chromosome 15. The *RARα-PML* fusion gene is transcribed as a chimeric mRNA. Leukemia usually responds to therapy with all-*trans* retinoic acid (ATRA), which is usually given in addition to chemotherapy, and the prognosis is relatively favorable. The molecular genetic abnormality may be detected in the laboratory by cytogenetics, RT-PCR, or FISH. Achievement of remission often occurs as a slow

“maturation” process, rather than therapy-induced aplasia followed by remission as seen in treatment of other acute leukemias.

Variant translocations include *t(11;17)(q23;q21)*, *t(5;17)(q32;q12)*, and *t(11;17)(q13;q21)*. Some variants, such as *t(11;17)(q23;q21)*, do not respond to ATRA. *FLT3* mutations are present in $\approx 40\%$ and are associated with higher WBC count, microgranular morphology, and a *bcr* breakpoint of PML.

Hypogranular or microgranular variants of M3 (M3V) occur in which cytoplasmic granules appear sparse by light microscopy, and numerous but smaller by electron microscopy (Bennett, 1980; Golomb, 1980). Nuclei of most leukemic cells are bilobed or reniform, and confusion with an atypical monocytic leukemia is frequent. Cytochemical staining reactions are somewhat less positive than in the hypergranular M3. Auer rods, single or multiple, and typical hypergranular promyelocytes are found in variable numbers, and there appears to be a spectrum between typical and hypogranular types. The WBC may be high.

In acute promyelocytic leukemia, a majority of leukemic cells stain for MPO, SBB, and CAE, along with ANA in 25%. The immunophenotype is typically bright CD33; heterogeneous CD13, CD64, and CD117; and dim to absent HLA-DR, CD34, CD11a, CD11b, CD15, CD18, and CD64.

AML with *t(9;11)(p22;q23)*; *MLL3-MLL*. The 11q23 abnormalities are present in a more diverse group of leukemias than other recurrent genetic abnormalities. Chromosome band 11q23 abnormalities, which involve the *MLL* gene, are not specific for AML, but are also found in ALL, mixed lineage leukemias, and occasionally in lymphomas. The most common translocation in AML involving this region is *t(9;11)(p22;q23)*. Others include *t(6;11)(q27;q23)*, *t(10;11)(p12;q23)*, *t(11;17)(q23;q21)*, and *t(11;19)(q23;p13)* (Caligiuri, 1997). Most cases of *t(9;11)* show monocytic differentiation (monoblastic or myelomonocytic) (Fig. 33-29). In general, the prognosis of AML with 11q23 abnormalities is less favorable than that of other AML with standard chemotherapy, but evidence suggests that children with *t(9;11)* respond similarly to patients without 11q23 abnormalities (Martinez-Climent, 1999).

AML with *t(6;9)(p23;q34)*; *DEK-NUP214*. This disease shows variable morphology and granulocytic and/or monocytic differentiation but is usually associated with multilineage dysplasia and basophilia of marrow and blood ($>2\%$). Immunophenotype includes usual MPO, CD13, CD33, CD38, and HLA-DR, with variably positive CD117, CD34, CD64, and Tdt, but not lymphoid lineage-associated antigens. A *DEK-NUP214* fusion protein acts as an abnormal transcription and nuclear transport factor. *FLT3-ITD* mutations are present in most cases. Prognosis is generally poor.

AML with *inv(3)(q21q26.2)* or *t(3;3)(q21;q26.2)*; *RPN1-EVI1*. This disease shows multilineage dysplasia, increased atypical megakaryocytes with monolobed or bilobed nuclei, and normal to increased platelet counts. Pseudo-Pelger-Huët cells are common, and differentiation may be granulocytic and/or monocytic. Marrow eosinophils, basophils, and/or mast cells are often increased. *EVI1* is a transcription factor which, likely promoted by *RPN1*, induces proliferation and transformation while impairing differentiation. This is an aggressive disease with short survival.

AML (Megakaryoblastic) with *t(1;22)(p13;q13)*; *RBM15-MKL1*. This is an acute leukemia of infants and young children, more often reported in girls, presenting as acute megakaryoblastic leukemia

with hepatosplenomegaly. This form is not associated with Down syndrome. Blasts are usually medium-sized to large with fine reticular chromatin, one to three nucleoli, and basophilic cytoplasm with blebs or pseudopods. Cytochemistry/immunophenotype shows absence of MPO and SBB and expression of platelet markers CD41 and CD61 (best demonstrated by cytoplasmic labeling techniques), CD36, and variable CD13, CD33, and CD34. Micromegakaryocytes are often found, and biopsy sections show reticulin fibrosis. Patients may respond well to chemotherapy.

AML with Gene Mutations

Although many cases of AML have been associated with recurring translocations or inversions, many have shown normal karyotype. Most if not all of these carry genetic mutations not detectable by Giemsa banding morphology; mutations are also found in cases with karyotypic abnormalities. Several carry prognostic implications. As these continue to be investigated, new, specific categories of AML are certain to be described. Biological and clinical associations are available for some common AML-associated mutations, and two of these are recognized by provisional categories in the WHO classification.

Mutations of *fms*-related tyrosine kinase 3 (*FLT3*), encoding a tyrosine kinase receptor involved in hematopoietic proliferation and differentiation, occur in about one third of cases of AML. Two types of *FLT3* mutations have been noted: one change of length type involving internal tandem duplications (*FLT3*-ITD), and another affecting the tyrosine kinase domain (*FLT3*-TK) at codon 835 or 836. *FLT3* mutations are seen in any AML, but primarily those with t(6;9), t(15;17), and normal karyotype. *FLT3*-ITD mutations are associated with less favorable prognosis, particularly in cases with normal karyotype.

AML with *NPM1* Mutation. This constitutes a provisional entity in the WHO classification. Most cases have monocytic or myelomonocytic differentiation, but cases with multilineage dysplasia and erythroid differentiation are also found. Mutations of *NPM1*, encoding the nuclear shuttle protein nucleophosmin, are found in similar frequency as *FLT3*, or one half of cases with normal karyotype, but are associated with better prognosis. This favorable association is especially noted in cases with normal karyotype and without *FLT3* mutation. *NPM1* mutation may be detected by immunohistochemical assay of sections, in which affected cells show abnormal cytoplasmic localization of NPM protein, or it may be detected by PCR assays.

AML with *CEBPA*. *CEBPA* encodes the CCAAT/enhancer binding protein- α , another hematopoietic proliferation- and differentiation-inducing transcription factor. Similar to *NPM1* mutation, it is associated with improved prognosis in AML with normal karyotype and without *FLT3* mutation. It is found in less than 20% of cases of AML. The morphology is most often AML without differentiation or AML with differentiation, although monocytic differentiation may also occur. Immunophenotype includes usually CD34, frequently CD7, with myeloid markers HLA-DR, CD11b, CD13, CD15, CD33, and CD65.

KIT mutations are also seen in cases of AML, as well as in GI stromal tumors and mast cell disease. In AML with t(8;21) and t(15;17), *KIT* mutation is associated with diminished prognosis. Other AML-associated mutations include those involving *WT1*, *MLL*, *NRAS*, and *KRAS*.

Acute Myeloid Leukemia with Myelodysplasia-Related Changes

(Swerdlow, 2008).

These leukemias show morphologic features of myelodysplasia or history of prior MDS or MDS/MPN, or they have MDS-related cytogenetic abnormalities. Patients with a history of cytotoxic chemotherapy or radiation for another malignancy are not included. These cases are characterized by 20% or more blasts in blood and/or marrow, as well as dysplasia in $\geq 50\%$ of cells of at least two lineages. Dysplastic features are similar to those of MDS of various types (Fig. 33-30).

Cytogenetic abnormalities qualifying for this disorder include -5/del(5q), i(17q)/t(17p), -13/del(13q), del(11q), del(12p)/t(12p), del(9q), idic(X)(q13), t(11;16)(q23;p13.3), t(3;21)(q26.2;q22.1), t(1;3)(p36.3;q21.1), t(2;11)(p21;q23), t(5;12)(q33;p12), t(5;7)(q33;q11.2), t(5;17)(q33;p13), t(5;10)(q33;q21), and t(3;5)(q25;q34). The immunophenotype often includes primitive blasts with myeloid phenotype and CD34 expression, CD56, and/or CD7. Prognosis is generally poor.

Figure 33-30 Acute myelogenous leukemia with multilineage dysplasia showing dysgranulopoiesis and dyserythropoiesis ($\times 1000$).

Figure 33-31 Acute myelogenous leukemia, minimally differentiated, resembles acute lymphoblastic leukemia and requires immunophenotyping for diagnosis ($\times 500$).

Therapy-Related Myeloid Neoplasms

These disorders are related to prior radiation or cytotoxic chemotherapy utilizing alkylating agents or topoisomerase inhibitors. They include cases of AML, MDS, and MDS/MPN. Most patients have been treated for prior malignancies, but some have been treated for nonneoplastic conditions.

Most commonly, disease is related to mutagenic effects of alkylating agents (including chlorambucil, cyclophosphamide, thiopeta, and busulfan) or radiation. These effects usually occur 5–10 years post exposure and most often present as MDS. Cytogenetic features are similar to those of MDS and AML with multilineage dysplasia. Loss of portions of chromosome 5 or 7 is common. Response to therapy and outcomes are poor.

Cases secondary to prior chemotherapy with topoisomerase II inhibitors (including epipodophyllotoxins etoposide and teniposide, and doxorubicin) occur after a shorter latency period of 1–5 years and most often are associated with overt AML with balanced chromosomal translocations involving 11q23 (*MLL*) or 21q22 (*RUNX1*). These most often show AML with maturation, monocytic or myelomonocytic morphology. Response to therapy is possibly similar to de novo AML.

Acute Myeloid Leukemia, Not Otherwise Specified

These cases do not fulfill criteria for the previous categories, or cytogenetic studies were unsuccessful or could not be performed. Categorization is similar to French-American-British Cooperative Group criteria.

Acute Myeloblastic Leukemia, Minimally Differentiated

In acute myeloblastic leukemia, minimally differentiated, myeloblasts display less than 3% positivity with SBB, MPO, or ANA (Bennett, 1991). When examined for myeloid and lymphoid markers using flow cytometry or immunocytochemistry, however, at least 20% of the blasts exhibit myeloid-associated antigens (CD13, CD33, CD117, and/or MPO). Stem cell antigens CD34, CD38, HLA-DR, and TdT are often expressed, while lineage-specific lymphoid markers cCD3, cCD20, and cCD79a are absent. Some primitive markers often associated with lymphoid lineage, including CD2, CD7, and CD19, are not lineage specific and are sometimes expressed (Fig. 33-31).

Figure 33-32 Acute myelogenous leukemia without maturation shows blasts with less than 10% maturing neutrophils. Auer rods are present in the cell at upper left.

Figure 33-33 Acute myelogenous leukemia with maturation shows maturing granulocytic cells on this biopsy ($\times 200$).

Acute Myeloblastic Leukemia without Maturation (M1)

In this category, myeloblasts represent at least 90% of nonerythroid cells in the BM (Bennett, 1985a, 1985b) and at least 3% of blasts labeled with MPO or SBB. Positive staining for CAE is sometimes also present but is less sensitive. CD13, CD33, CD117, and/or MPO antigens are usually detectable, as are other, less specific markers. CD3, CD20, and CD79a are usually absent (Fig. 33-32).

Acute Myeloblastic Leukemia with Maturation

Myeloblasts represent 20% (per WHO) to 89% of total marrow cells, granulocytes from promyelocytes to neutrophils are greater than 10% of nonerythroid cells, and monocytes and their precursor cells are less than 20% (Fig. 33-33). Most blasts stain with MPO, SBB, and CAE.

Cases with t(8;21)(q22;q22) are categorized as AML with recurrent cytogenetic abnormality t(8;21).

Acute Myelomonocytic Leukemia

In acute myelomonocytic leukemia, myeloblasts constitute more than 20% of total marrow cells. The sum of the monoblasts, promonocytes, and monocytes is greater than 20% but is less than 80% of nonerythroid cells. Cells of the granulocytic series (myeloblasts, promyelocytes, myelocytes, and other more mature forms) also represent 20%–80% of nonerythroid cells (Fig. 33-34). Peripheral blood monocytois ($\geq 5 \times 10^9/L$) is usually present.

In myelomonocytic leukemia, variable staining of leukemic cells with MPO, SBB, CAE, and periodic acid–Schiff (PAS) has been noted. In most cases, leukemic cells exhibit diffuse and intense staining with ANA and ANB. In some cases, these nonspecific esterases cannot be demonstrated, and the diagnosis may be made on the basis of Romanowsky's stains and/or immunophenotyping.

Immunologic markers are variable but usually show myeloid antigens CD13 and/or CD33, as well as variable expression of monocytic markers CD14, CD4, CD11b, CD11c, CD64, CD36, CD68, and lysozyme. Some pure myeloblasts may be present, including those with CD34 and CD117 expression, and a second population of variably mature monocytes. Cases with recurrent cytogenetic abnormalities are categorized separately.

Acute Monoblastic and Acute Monocytic Leukemia

In this disorder, 80% or more of marrow nonerythroid cells are monoblasts, promonocytes, or monocytes (see Figs. 33-24 and 33-35). Two

Figure 33-34 Acute myelomonocytic leukemia shows blasts and dual differentiation to granulocytes and monocytes ($\times 1000$). Acute monocytic leukemia shows monoblasts and maturing monocytes. Promonocytes are counted as blasts and show finely convoluted nuclei ($\times 1000$).

Figure 33-35 Acute monoblastic leukemia shows predominantly monoblasts ($\times 1000$).

Figure 33-36 Erythroleukemia, erythroid/myeloid, shows predominance of erythroid precursors with myeloblasts constituting 20% or more of nonerythroid cells. An Auer rod is seen in the blast at upper center ($\times 1000$).

subtypes are recognized. The monoblastic subtype is characterized by large blasts accounting for 80% or more of marrow monocytic cells. The monocytic subtype has fewer monoblasts (<80% of marrow monocytic cells) and greater numbers of promonocytes and monocytes (Bennett, 1985b). In both, ANA and ANB label the leukemic cells diffusely and intensely (80% or more of leukemic cells). Occasional cases fail to show nonspecific esterases, and the diagnosis is made from Romanowsky's stains and/or immunophenotypic techniques. Antilysozyme and CD68 are particularly useful on slides. Both myeloid and monocytic markers are frequently expressed, as in acute myelomonocytic leukemia. The translocation t(8;16)(p11;p13) has been associated with AML-M5 (or M4) with erythrophagocytosis.

Erythroleukemia

The diagnosis of erythroleukemia is made when more than 50% of nucleated cells of the BM are erythroblasts, and 20% or more of nonerythroid cells are myeloblasts. In most cases, termed erythroleukemia (erythroid/myeloid), a mixture of variable proportions of erythroid precursors and myeloblasts (sometimes abnormal monocytic and megakaryocytic elements are present as well) is seen (Fig. 33-36).

Figure 33-37 Coarse periodic acid-Schiff-positive granules are often seen in erythroid precursors in erythroleukemia ($\times 1000$).

Figure 33-38 Blasts sometimes cluster in acute megakaryocytic leukemia ($\times 1000$).

Very rarely, there is virtually no granulocytic involvement in the neoplastic process, and primitive erythroblasts predominate. This has been known as **erythremic myelosis** and is now known as **pure erythroid leukemia**. Morphologic abnormalities of erythroblasts are often pronounced, with atypical megaloblastic features, bizarre nuclear shapes, and multinucleated giant forms. The cytoplasm may contain pseudopods and/or vacuoles, particularly in the probasophilic and basophilic erythroblasts.

In some cases, erythroid cells may show strong cytoplasmic PAS positivity (Fig. 33-37). This is granular in early erythroid precursors and diffuse in later stages. Erythroid precursors are PAS negative in normal individuals and in most diseases, including nutritional megaloblastic anemia. They are sometimes positive, however, in iron deficiency anemia, thalassemia, and RARS. In erythroleukemia, myeloblasts usually stain with SBB, MPO, and CAE. A nonspecific esterase-positive monocytic component may also be present. Neoplastic erythroid precursors are sometimes positive for ANA and ANB (Hayhoe, 1984).

Acute Megakaryoblastic Leukemia

The diagnosis of acute megakaryoblastic leukemia, like other forms of acute myeloid leukemia, requires $\geq 20\%$ blasts in the marrow. Megakaryoblasts are highly polymorphic; some blasts simulate lymphoblasts, while others are larger and have pseudopods or stringy cytoplasmic projections. The cytoplasm is usually light blue and may or may not possess granules (Fig. 33-38). The nuclei often have one to three nucleoli. Micromegakaryocytes may be present and are not counted as blasts.

The blasts are cytochemically undifferentiated. They do not stain with SBB, MPO, CAE, or ANB. However, ANA is usually positive in a focal cytoplasmic pattern (Fig. 33-39). The PAS reaction shows diffuse and peripheral granular (often in large blocks) staining.

Megakaryocytic lineage is most often (Bennett, 1985a) demonstrated by immunophenotyping using monoclonal antibodies against platelet glycoprotein Ib (CD41) or IIb/IIIa (CD61) (Erber, 1987). Blasts are often also positive for myeloid antigens CD13 and CD33, and characteristically for CD36. Care must be taken to differentiate this disease from AML with minimal differentiation by flow cytometry, which may show artifactual positivity for platelet markers due to adherence of platelets to blasts; this can be done by immunochemical examination of cytopsins. Truly positive cells show membrane and/or cytoplasmic labeling rather than adherent platelets.

Figure 33-39 Alpha naphthyl acetate esterase-positive granules in megakaryoblasts.

Figure 33-40 Acute panmyelosis with myelofibrosis shows involvement of all three myeloid lineages, with fibrosis ($\times 200$).

In the peripheral blood, there is usually pancytopenia with marked leukopenia and anemia. Megakaryocytic fragments are sometimes present in the blood. The BM shows variable and sometimes pronounced myelofibrosis, often resulting in futile attempts at obtaining marrow aspirate films.

Clumping of blasts may simulate metastatic tumor such as neuroblastoma or small cell carcinoma. Infants with $t(1;22)(p13;q13)$ often show marrow infiltration mimicking neuroblastoma.

Young children (1–4 years of age) with Down syndrome (trisomy 21) have an increased incidence of megakaryoblastic leukemia, which may be transient and spontaneously remit in 1–3 months. Subsequent transient or persistent relapses may occur. Blasts also tend to show erythroid features, indicating derivation from a multipotential erythroid/megakaryocytic precursor (Zipursky, 1992). Patients often respond well to therapy but tolerate intensive therapy less well than others (Gamis, 2005).

Acute Basophilic Leukemia

Acute basophilic leukemia is a rare form of AML in which the blastic cells differentiate along the basophil lineage. The peripheral blood usually demonstrates anemia and thrombocytopenia with leukocytosis. The BM is infiltrated by blastic cells simulating lymphoblasts or myeloblasts. Blasts are generally negative for Sudan black B and myeloperoxidase. An increase in mature basophils or in blasts staining with toluidine blue may occur. Diagnosis historically rests on the identification of blasts with basophilic granules by ultrastructural methods (Brunner, 1994).

Acute Panmyelosis with Myelofibrosis

This is a rare form of acute leukemia with panmyeloid proliferation and marrow fibrosis. Pancytopenia is typically seen. Red blood cells show minimal poikilocytosis, but dysplastic features in myeloid cells are often seen, as are atypical platelets.

The BM sample frequently shows a dry tap; on biopsy, clusters of blasts, late erythroid precursors, and dysplastic megakaryocytes are seen in a variably fibrotic background (Fig. 33-40). This is differentiated from acute megakaryoblastic leukemia by involvement of all three myeloid lineages, rather than only the megakaryocytic.

Myeloid Sarcoma

This neoplasm has been called myeloblastic sarcoma, granulocytic sarcoma, extramedullary myeloid cell tumor, and chloroma. It represents a localized

Figure 33-41 Granulocytic sarcoma, in this case presenting in the skin, resembles lymphoma but with large blastic or monocytoid cells. Eosinophils or precursors are frequently present (×500).

tumor of myeloblasts or monoblasts infiltrating extramedullary sites (Fig. 33-41). These tumors have been reported to occur in the skin, lymph nodes, nasopharyngeal and upper respiratory tract tissues, breast, ovary, bone, perineural and epidural structures, and the eye and other orbital structures, as well as in a variety of soft tissues (Neiman, 1981). Myeloid sarcomas have been reported in 3%–8% of autopsied cases of chronic myelogenous leukemia and may precede the occurrence of acute myeloid leukemia in <1% of cases (Muss, 1973).

Myeloid sarcomas may occur at any age. Three clinical settings are found: (1) no known disease, (2) a known myeloproliferative disorder, and (3) acute myeloid leukemia (Neiman, 1981). The diagnosis depends on recognizing the nature of the primitive cells that can often be mistaken for solid tumors, including non-HLs, amelanotic melanomas, or undifferentiated carcinoma (Hutchison, 1990). The diagnosis is facilitated by making touch imprint preparations of cut sections of the tumor and staining them with Romanowsky's stains, by cytochemical reactions, and by immunophenotyping. Anti-MPO and CD68 are particularly useful for granulocytic or monocytic lineage in paraffin sections.

Myeloid Proliferations Related to Down Syndrome

Children and adults with Down syndrome have a much higher frequency of leukemia than those without the syndrome. This includes ALL and AML, and diagnostic considerations for most are similar to leukemia occurring outside the syndrome. In addition, two specific and likely related disorders are unique to this group of patients.

Transient Abnormal Myelopoiesis

Transient abnormal myelopoiesis (TAM) occurs in 10% of neonates with Down syndrome and in a small number who are phenotypically normal but have trisomy 21 mosaicism. It presents as acute megakaryoblastic leukemia, frequently with thrombocytopenia and leukocytosis, often with higher blast proportions in blood than in marrow, and hepatosplenomegaly. Blasts are of megakaryocytic/myeloid lineage and express CD41 and CD61, as well as CD34, CD117, CD13, CD33, CD7, CD4, CD36, and CD71. Genetics show trisomy 21 and *GATA1* mutations.

Uniquely, this disorder resolves spontaneously in the vast majority of cases. However, 20%–30% subsequently develop nonremitting AML, as described later.

Myeloid Leukemia Associated with Down Syndrome

AML of Down syndrome occurs most often in the first 3–5 years at an incidence greater than 50 times that of others. It is usually of megakaryocytic lineage and may be preceded by a preleukemic phase similar to RCC, or by TAM. Compared with TAM, blasts are similar but lack CD34 and often CD56 and/or CD41. Trisomy 8 is frequent, as is trisomy 21. *GATA1* mutations are usually absent.

Blastic Plasmacytoid Dendritic Cell Neoplasm

This tumor used to be included in the WHO classification with the lymphomas and was called blastic NK-cell lymphoma or CD4+ CD56+ hematodermic neoplasm. It is now known to be derived from plasmacytoid dendritic cell precursors and presents in skin with frequent involvement of blood and marrow, and often lymph nodes. Skin lesions may be nodules, plaques, or patches. Tumors resemble lymphoblastic lymphomas with

Lineage Requirements in Mixed Phenotype Acute Leukemia

Myeloid lineage
Myeloperoxidase or monocyte differentiation markers (NSE, lysozyme, CD14, CD64, CD11c)
T lineage
Cytoplasmic or surface CD3
B lineage
Strong CD19 + strong CD79a, cytoplasmic CD22, or CD10
or
Weak CD19 + at least two: strong CD79a, cytoplasmic CD22, or CD10

From Swerdlow (2008).

NSE, Neuron-specific enolase.

monomorphic dermal infiltrates of blasts with fine chromatin and irregular nuclei, along with agranular cytoplasm. Cytochemical stains for myeloid precursors are absent, and immunohistochemistry shows characteristic findings of CD4, CD56, CD43, and CD45RA. Plasmacytoid dendritic cell markers CD123, TCL1, CLA, MxA, and BDCA-2/CD303 are positive. CD99 is reported positive (Shapiro, 2003). CD7, CD68, and CD33 are often expressed, and CD3, CD5, CD13, CD34, CD117, CD20, and CD79a are negative. Cytotoxic T cell markers are also negative in tissue sections. Immunoglobulin and usually T cell receptor genes are germline. The disease is aggressive, usually relapsing after initial therapy, but occasionally responding well to aggressive therapy.

Acute Leukemias of Ambiguous Lineage

(Swerdlow, 2008).

Some cases of acute leukemia have features that are indeterminate between lymphoid and myeloid lineage, or have features of more than one lineage. This is a controversial area of difficult-to-classify leukemia. Many leukemias that appear to be of defined lineage have one or more immunologic markers which are aberrant, or show lineage infidelity. A single such marker is usually insignificant. ALL with myeloid markers responds similarly to other types of ALL, and lymphoid markers in AML are clinically important, mostly if they help suggest a subtype, such as CD19 expression in AML with t(8;21). CD117 has been proposed as a good indicator of myeloid lineage (Bene, 1998), but CD117, CD13, and CD33 are not considered adequate to assign myeloid lineage in an otherwise lymphoid blast proliferation (Swerdlow, 2008).

Ambiguous acute leukemias fall into two main categories per the WHO classification: acute undifferentiated leukemia (AUL) and mixed phenotype acute leukemia (MPAL). MPAL is divided into several entities. In the past, the term **bilineal acute leukemia** has been applied to rare disorders in which there are distinct blast populations of more than one lineage. Biphenotypic leukemia has referred to those with one population of leukemic cells with multiple lineage expression (mixed lineage). These concepts remain, and criteria are established to assign more than one lineage to a blast population (Table 33-17). Subcategories of MPAL are listed in the following sections.

Undifferentiated Acute Leukemia

These are rare acute leukemias in which the predominant cells are blast forms that cannot be classified using morphologic, cytochemical, ultrastructural, immunologic, or DNA analytic methods (Raghavachar, 1986; Sobol, 1988). CD34, CD38, and HLA-DR are frequently expressed, and CD7 and TdT may be expressed as well.

Mixed Phenotype Acute Leukemia with t(9;22) (q34;q11.2); *BCR-ABL1*

These are cases of MPAL with t(9;22) translocation and associated *BCR-ABL1*. They are rare disorders, more common in adults than in children. Cases with prior CML are excluded.

Mixed Phenotype Acute Leukemia with t(v;11q23); *MLL* Rearranged

This disease is more common in children than in adults. Dimorphic blast populations are frequent and consist of monoblasts and lymphoblasts. Prognosis is generally poor.

Mixed Phenotype Acute Leukemia, B/Myeloid, NOS

Myeloperoxidase or monocytic differentiation and CD19 with CD79a, cCD22, and/or CD10; neither t(9;11) or 11q23 translocation occurs.

Mixed Phenotype Acute Leukemia, T/Myeloid, NOS

Myeloperoxidase or monocytic differentiation and cytoplasmic or surface CD3; neither t(9;11) or 11q23 translocation occurs.

Mixed Phenotype Acute Leukemia, NOS—Other Rare Types

This category includes T- and B-lineage disease and cases with trilineage differentiation.

Natural Killer Cell Lymphoblastic Leukemia/Lymphoma

This category considers the possibility of bilineage NK and T-lineage lymphoblastic leukemia/lymphoma, but such an entity remains ambiguous.

PRECURSOR LYMPHOID NEOPLASMS

Historically, lymphoid leukemias and lymphomas have been classified separately. Leukemias are hematopoietic malignancies primarily involving BM and blood and have been most extensively categorized by the FAB group. Lymphomas are those primarily involving lymphoid organs or other soft tissues and have been subject to numerous classification schemes that evolved rapidly because of advances in immunology, oncology, and genetics. Since publication of the Revised European–American Lymphoma (REAL) classification (Harris, 1994), lymphoid leukemias and lymphomas have been classified by biological features of the disease, rather than by the anatomic distribution, and an international consensus in classification has generally been attained (Berard, 1997). The WHO classification focuses on cytogenetic and molecular findings whenever possible (Swerdlow, 2008).

B Lymphoblastic Leukemia/Lymphoma**Clinical Features**

This category of malignancy most often presents as leukemia and is the prototype of ALL. The other major type of ALL is T lymphoblastic, which is less common and tends to present as lymphoma or concurrently as both leukemia and lymphoma. ALL is generally thought of as a clinical entity which is pathologically subtyped and warrants some general discussion.

Acute lymphoblastic leukemia is the most common malignancy of children and adolescents. In the United States, 3000–4000 new cases are reported per year, two thirds of which affect children. The evolution of treatment with combination chemotherapy, CNS treatment, and intensified therapy for high-risk categories has led to cure rates of nearly 80% in children. Favorable factors are age 5–10 years, hyperdiploidy (best, 54–62 with trisomy 4, 10, and/or 17), t(12;21), and normal or low WBC. Poor risk factors include age younger than 1 year, t(9;22), and t(4;11). Among adults, only 30%–40% are cured, in part because of the higher frequency of adverse genetic abnormalities (Pui, 2004). Adult ALL incidence increases in middle to older age, similarly to genetically high-risk AML. Individuals with this disorder often present with symptoms of fatigue, fever, and bleeding. Generalized lymphadenopathy, splenomegaly, and hepatomegaly are common findings. Because leukemic cells infiltrate many tissues of the body, other symptoms may occur. Leg pain can be associated with periosteal infiltrates, as well as headache, nausea, and vomiting with meningeal leukemia. Rapid onset of unconsciousness may indicate subarachnoid hemorrhage.

Presentation occurs occasionally in skin, bone, and/or lymph node without BM involvement (<25% blasts in the marrow). These cases are referred to as lymphoma. They most often occur in young people (<18 years) and show overlapping features with precursor B-ALL, TdT, and B-lineage markers, and frequently additional 21q chromosome material (Maitra, 2001). Morphology in tissue sections shows diffuse infiltrations of small cells (nuclei smaller than histiocyte nuclei) with diffuse chromatin, inconspicuous nucleoli, scant cytoplasm, high mitotic rate, and frequently a “starry-sky” pattern of admixed histiocytes (indicating high apoptotic rate).

Anemia is present in precursor B-ALL if clinical manifestations are fully developed. It is usually normocytic. Frequently, nucleated red cells are present. Thrombocytopenia of moderate to marked degree is the rule. The leukocyte count occasionally is very high ($>100 \times 10^9/L$) and often is

Figure 33-42 Precursor acute lymphoblastic leukemia of B-lineage, with small to medium-sized blasts and lack of conspicuous nucleoli ($\times 1000$).

slightly elevated, but it is perhaps most frequently normal or decreased. The predominant cell is the lymphoblast.

Marrow

By the time the patient is symptomatic, hematopoietic cells and fat are usually replaced by a diffuse infiltration of lymphoblasts. Blast percentage is usually greater than 50%. Predominance of small blasts with high nuclear/cytoplasmic (N/C) ratios and inconspicuous nucleoli (L1 type in the FAB classification) is most common in childhood ALL (Fig. 33-42). Chromatin is diffuse in some cells but may show variable condensation, and blasts may be difficult to distinguish from the normal lymphocytes of young children. Larger blasts with more abundant cytoplasm, prominent nucleoli, and often irregular nuclei (FAB L2) also occur and tend to predominate in adult ALL.

The blasts are negative for SBB, peroxidase, and naphthol ASD CAE. Azurophilic granules may be present, but they are SBB and peroxidase negative. In other cases, ALL blasts may exhibit some SBB reactivity, but peroxidase is negative.

Blasts characteristically express TdT, cytoplasmic CD22 and CD79a, CD19, and HLA-DR. CD10 (common ALL antigen) is expressed in many, and expression of CD34 is variable. Cytoplasmic μ immunoglobulin heavy chain (cyt- μ) indicates a slightly more mature state, but surface immunoglobulin is negative. Myeloid-associated antigens CD13, CD33, and CD15 may be expressed.

Cytogenetics

Cytogenetic findings are increasingly important in diagnosis and prognostication in ALL and have been previously reviewed (Mrozek, 2004). The current WHO classification divides B-ALL into groups based on frequently found (recurrent) cytogenetic findings.

B Lymphoblastic Leukemia/Lymphoma with t(9;22)(q34;q11.2); BCR-ABL1

The Ph' chromosome t(9;22) with production of a fusion BCR-ABL occurs in about 30% of cases of adult (20% detected at karyotyping) and 6% of cases of childhood ALL. The t(9;22) is the most frequent adult ALL translocation and is associated with poor prognosis. Two types are found: that identical to CML, involving the bcr region of BCR with resultant p210 kD fusion protein, occurring in half of adult cases of Ph'-positive ALL; and another with breakpoint upstream of bcr, producing a smaller chimeric message and p190 kD protein. The latter occurs in most childhood Ph'-positive cases. Ph'-positive ALL is most often of precursor B cell lineage but also may present with biphenotypic myeloid differentiation.

B Lymphoblastic Leukemia/Lymphoma with t(v;11q23); MLL Rearranged

Abnormalities of the *MLL* gene at chromosome region 11q23 are seen in 5%–7% of cases of ALL (Le Beau, 2000), as well as in AML, and are often associated with *FLT3* overexpression. ALL with t(4;11)(q21;q23) is associated with poor prognosis, high WBC count, and immature B-lineage phenotype with lack of CD10 or CD24 but with CD15 expression. It involves *MLL* and the partner gene *AF4*. It is most common in infants, and many cases of ALL with this abnormality are biphenotypic. Translocation t(11;19)(q23;p13.3) is the next most frequent *MLL* abnormality in ALL but also occurs in AML (monocytic). Overall, 11q23 (*MLL*) abnormalities, with the possible exception of t(9;11) in AML, confer poor prognosis.

B Lymphoblastic Leukemia/Lymphoma with $t(12;21)(p12;q22)$; TEL-AML1 (ETV6-RUNX1)

This constitutes approximately 25% of B-ALL, correlates with high-density CD10 and HLA-DR expression with negative CD9 and CD20, and is associated with good prognosis. The *TEL* gene at 12p12 is fused with the *AML1* gene at 21q22 with a resultant fusion protein. *AML1* (*RUNX1*) is a transcription factor involved in hematopoietic differentiation/proliferation. The abnormality is difficult to detect by karyotyping but can be detected by RT-PCR analysis for the chimeric mRNA or by FISH.

B Lymphoblastic Leukemia/Lymphoma with $t(1;19)(q23;p13.3)$; E2A-PBX1 (TCF3-PBX1)

Another translocation, $t(1;19)(q23;p13)$, and variants are associated with pre-B cell ALL (with cytoplasmic μ Ig). It involves the *E2A* gene at 19p13, which encodes transcription factors, and *PBX1* at 1q23. This has also been associated with decreased response to therapy.

B Lymphoblastic Leukemia/Lymphoma with $t(5;14)(q31;q32)$; IL3-IGH

This rare variant of B-ALL is associated with eosinophilia. The rearrangement results in constitutive expression of *IL3* and interleukin effects. Immunophenotype is CD19+, CD10+.

B Lymphoblastic Leukemia/Lymphoma with Hyperdiploidy

B-ALL with multiple trisomies and between 50 and 66 chromosomes (normal = 46) is referred to as hyperdiploid. This usually occurs in children and implies favorable prognosis. Trisomies of chromosome 4, 10, and 17 are considered markers for low-risk disease in pediatric leukemia protocols. Blasts usually express CD19, CD10, and CD34 but often are CD45 negative.

B Lymphoblastic Leukemia/Lymphoma with Hypodiploidy

Hypodiploid B-ALL shows fewer than the normal 46 chromosomes. Prognosis is unfavorable, especially when chromosomes are fewer than 45, and even more so when fewer than 44.

B Lymphoblastic Leukemia/Lymphoma, Not Otherwise Specified (Refers to All Other B-ALL)

Precursor T Lymphoblastic Leukemia/Lymphoblastic Lymphoma

Precursor T lymphoblastic leukemia (T-LBL), which accounts for 10%–20% of cases of ALL, occurs predominantly in boys who tend to be slightly older than children with precursor B lymphoblastic ALL. Patients with T-lineage ALL often have a high leukocyte count and mediastinal involvement. Blast morphology is heterogeneous, similar to B-ALL, and immunophenotyping is required for diagnosis. The immunophenotype reflects thymic T cells which have a distinct maturation pattern (Reinherz, 1980), and the blasts show varying maturity. Most cases exhibit TdT, CD7, and cytoplasmic CD3 with variable CD1a, CD2, and CD5. Some cases, of early thymic phenotype, lack CD4 or CD8, but most (midcortical thymic phenotype, particularly in lymphoma presentation) coexpress CD4 and CD8. In late cortical thymic phenotype, CD4 or CD8 alone may be present, and in these, TdT and/or CD1a is particularly helpful for diagnosis. Myeloid markers such as CD13, CD33, and/or CD117 may be present, and CD79a may be present occasionally.

Presentation as lymphoma often shows a more mature thymic phenotype than leukemic presentation (Crist, 1988). These are relatively common lymphomas of adolescents and young adults (one third of pediatric NHLs) and also occur later in life. They typically present in the mediastinum and/or peripheral lymph nodes, and pleural effusions are common. Airway compromise or superior vena cava syndrome is frequently present, resulting in emergent need for therapy and limiting diagnostic procedures.

Morphology. T-LBL usually shows diffuse tissue involvement by blasts with nuclei smaller than those of histiocytes or reactive endothelial cells (Fig. 33-43), although some show nuclei similar in size to Burkitt lymphoma. Chromatin is usually finely dispersed to slightly clumped, but

Figure 33-43 Precursor T lymphoblastic lymphoma (x500).

rarely as much as Burkitt lymphoma. Mitotic rates are high, and there is often a “starry sky” pattern similar to Burkitt. Neoplastic cells sometimes show selective T-zone involvement of lymph nodes and/or a leukemia-like infiltration pattern in soft tissue.

The differential diagnosis of T-LBL in young patients primarily involves it, BL, and occasionally large B cell lymphoma (LBCL). Mediastinal location favors T-LBL over BL, but not LBCL. In adults, the differential diagnosis includes blastoid and blastic variants of mantle cell lymphoma. Granulocytic sarcoma is also in the differential in any age group. Expression of TdT and lineage-specific T cell markers without B or myeloid markers is usually diagnostic.

Genetics. T cell receptor genes are frequently rearranged, but Ig heavy chain genes may also be rearranged (Racke, 2011). Patients with T cell ALL frequently show translocations of α and δ T cell receptor loci at 14q11.2, the β locus at 7q35, or the γ locus at 7p14–15, usually with genes encoding transcription factors. Partner genes include *MYC* (8q24.1), *TAL1* (1p32), *RBTN1* (11p15), *RBTN2* (11p13), *HOX11* (10q24), *HOX11L2* (5q35), and *LCK* (1p34.3–35). *TAL1* regulatory gene deletions occur in 25% of cases, and *del(9p)* involving *CDKN2* is also frequent (Mrozek, 2004).

MATURE B CELL NEOPLASMS

These constitute the most numerous and possibly the most diverse group of hematopoietic neoplasms. Overall rates vary from 1.2/100,000 population/year in China to 15/100,000 in the United States. Geographic variation is seen in mature lymphoma/leukemia, with follicular and diffuse large B cells predominating in Western developed countries, constituting 50% of NHLs; myeloma is also common (Catovsky, 2008). The cells affected in mature B cell malignancies are those making up the humoral immune system, which itself is very complex and includes innumerable clones of B lymphocytes with genetically distinct immunoglobulin gene rearrangements. They exist at many states of maturation and are influenced by and affect many regulatory pathways. Normal cells and tumors are influenced by immune status and perturbations, viruses, other microorganisms, and antigenic stimuli. Tremendous variation in growth rates and in aggressiveness of tumors is seen in this large group, corresponding to high proliferative rates of some cells and quiescence of others. A correspondingly variable tendency toward apoptosis influences response to antineoplastic therapies. Clinical behaviors relate to clonal escape from regulation, the balance of proliferation and apoptosis, and modulation by therapy. Features of major categories are shown in Table 33-18.

Monoclonal B Cell Lymphocytosis

Diagnosis of chronic lymphocytic leukemia requires the presence of leukocytosis of $\geq 5 \times 10^9/L$ monoclonal lymphocytes with **chronic lymphocytic leukemia (CLL)** phenotype (see later) for at least 3 months, or lower counts with the presence of cytopenias and/or disease-related symptoms. Otherwise, a diagnosis of **monoclonal B cell lymphocytosis** is made, analogous to the concept of monoclonal gammopathy of unknown significance (MGUS).

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

This is a clonal proliferation of small B lymphocytes involving BM, blood, and lymph nodes. It is common, usually indolent, at least initially, but

TABLE 33-18

Key Features of Major Mature B Cell Neoplasms

Lymphoma	Demographics, clinical and laboratory presentations	Morphology	CELL SURFACE MARKERS		
			Positive	Negative	Cytogenetics
CLL/SLL	M > F, over 60 years; insidious onset of fatigue, lymphadenopathy; WBC >5 K/ μ L, anemia, thrombocytopenia, occasionally AIHA	Small lymphocytes with condensed chromatin	CD19, CD20, CD5, CD22, CD23, CD79a, dim slg	CD10, bcl-6, FMC-7	+12, del(13q14.3), del(11q22-23), del(17q)(TP53)
B cell PLL	M > F, mean age 65 years; massive splenomegaly, minimal lymphadenopathy, WBC >100 K	Prolymphocytes \geq 55%	CD19, CD20, FMC-7, bright slg	CD5, CD23, often negative	Occ del(17p), del(13q14)
Hairy cell leukemia	M > F, median age 50 years; insidious onset with splenomegaly, leukopenia with monocytopenia	Medium-sized cells with round to oval indented nuclei, reticular chromatin, frayed cytoplasmic borders	CD20, CD22, CD79a, CD103, CD25, CD11c	CD5, CD10, CD23	
Lymphoplasmacytic lymphoma	M > F, mean age 63 years; BM, nodal and splenic involvement, symptomatic IgM paraprotein	Plasmacytoid lymphocytes and plasma cells with PAS-positive inclusions (Dutcher bodies)	CD19, CD20, CD22, CD25, CD38, CD79a, bright slgM, clgM	CD5, CD10, CD23, CD103, bcl-6	del(6q), +3, +4, +18, none specific
Heavy chain disease (α -HCD, immunoproliferative small intestinal disease, prototype)	Younger adults in poorer Mediterranean communities with malabsorption, diarrhea	Lymphoplasmacytic infiltrate of intestinal mucosa, variant of MALT	NA	NA	
Marginal zone lymphomas: splenic, nodal, MALT	F > M, median age 61 years; indolent course involving stomach, other mucosal sites, spleen, or nodes	Lymphocytes with condensed chromatin and moderate cytoplasm; lymphoepithelial lesions in MALT type	CD20, CD79a, slgM, bcl-2	CD5, CD10, CD23, bcl-6	+3, t(11;18)(q21;q21) in MALT type, 7q abnormalities
Follicular lymphoma	F > M, median age 59 years; lymphadenopathy, BM and splenic involvement frequent	Follicle-like structures with centrocytes and varying numbers of centroblasts	CD19, CD20, CD22, CD23, CD79a, CD10, bcl-2, bcl-6, slgM	CD5, CD43	t(14;18)(q32;q21)
Mantle cell lymphoma	M > F, median age 60 years; lymphadenopathy, splenomegaly, BM involvement; typically refractory	Atrophic germinal centers, prominent mantle zones, small lymphs with irregular nuclei; blastoid/pleomorphic variants	CD5, CD43, FMC-7, bcl-2, cyclin D1, slgM	CD10, CD23, bcl-6	t(11;14)(q13;q32)
Diffuse large B cell lymphoma	M > F, all ages, moderately aggressive but responds to chemo and anti-CD20	Diffuse infiltrate of large B cells, variable morphology	CD19, CD20, CD22, CD79a, slg, bcl-2 \pm , bcl-6 \pm , CD30 \pm , MUM1 in post-GC types	CD5 (usually)	t(14;18) in 20%, 3q27 (bcl-6) abnormalities in 30%, occ secondary myc translocations
Mediastinal large B cell lymphoma	F > M, young to middle-aged adults; airway compression, superior vena cava syndrome	Sclerotic lesions with clear, multilobulated, or RS-like cells	CD19, CD20, CD22, CD79a, CD30	CD5, CD10	Amplifications of 9p24, 2p15, others
Primary effusion lymphoma	Rare, associated with HHV-8 in immunosuppressed younger male homosexuals; pleural effusion	Immunoblastic or anaplastic cells	CD45, CD30, CD38, CD138	CD19, CD20, CD79a, slg, bcl-6	
Plasmablastic lymphoma	Rare, associated with EBV in immunosuppressed	Plasmacytoid	CD45, CD38, CD138, CD79a	CD45, CD20, PAX-5 negative or weak	
EBV associated; chronic inflammation, of the elderly, lymphomatoid granulomatosis, post transplant	Immunosuppressed, elderly, others	Variable	CD20, EBV-EBER		

TABLE 33-18

Key Features of Major Mature B Cell Neoplasms—Cont'd

Lymphoma	Demographics, clinical and laboratory presentations	Morphology	CELL SURFACE MARKERS		
			Positive	Negative	Cytogenetics
Burkitt lymphoma	1. Endemic: children in Africa, jaw mass M > F 2. Sporadic: children to young adults, worldwide, M > F 3. Immunodeficiency-associated: HIV patients	Uniform cells with round to oval nuclei, multiple nucleoli, high mitotic rate	CD19, CD20, CD10, bcl-6, slg	TdT, bcl-2	t(8;14)(q24;q32), t(2;8)(p12;q24), t(8;22)(q24;q11)
Intermediate BL/DLBCL lymphoma	Children w/ rapidly growing mass, adults	Intermediate between BL and DLBCL	CD19, CD20, CD10, bcl-6, slg		t(8;14)(q24;q32), 8q24/MYC, variable, others

AIHA, Autoimmune hemolytic anemia; BL, Burkitt lymphoma; BM, bone marrow; clg, cytoplasmic immunoglobulin; CLL, chronic lymphocytic leukemia; EBV, EBV-encoded RNA; DLBCL, diffuse large B cell lymphoma; EBV, Epstein-Barr virus; F, female; GC, germinal center; HHV, human herpesvirus; HIV, human immunodeficiency virus; Ig, immunoglobulin; M, male; MALT, mucosa-associated lymphoid tissue; MYC, c-Myc gene; NA, not applicable; PAS, periodic acid-Schiff; PLL, prolymphocytic leukemia; RS, Reed-Sternberg; slg, surface immunoglobulin; SLL, small lymphocytic lymphoma; TdT, deoxyribonucleotidyl transferase; WBC, white blood cell.

Figure 33-44 B cell chronic lymphocytic leukemia (×1000).

difficult if not impossible to cure (Muller-Hermelink, 2008). Cases with predominant involvement in the marrow and blood are traditionally called CLL, and lymphomas are called small lymphocytic lymphoma (SLL), but these are considered manifestations of a single entity. A majority of cases are leukemic and constitute 90% of chronic lymphoid leukemias in the United States and Europe. It is rare in those younger than age 40; most cases occur over the age of 60, and the condition is more than twice as common in men as in women. Onset is insidious, and the disease is commonly discovered by chance during the investigation of another problem. Most patients are >50 years of age.

The tumors show diffuse infiltrates of small mature lymphocytes with clumped chromatin and scant to moderate cytoplasm (Fig. 33-44). Admixed prolymphocytes and proliferation centers (containing increased prolymphocytes and lymphocytes with increased cytoplasm) are characteristic. Mitotic rates are very low.

CLL/SLL shows a characteristic phenotype of monoclonal B cells (CD19/CD20/CD79a) with dim surface Ig (single light chain with IgM or IgM and IgD), coexpression of usual T cell marker CD5, and expression of CD23. CD22, CD10, and cyclin D1 are negative. This pattern is very useful in distinguishing CLL/SLL from mantle cell, follicular, and marginal zone lymphomas. Bcl-6 is negative, and bcl-2 variable.

Ig heavy and (monotypic) light chain genes are rearranged, and Ig heavy chain (IGH) genes have undergone somatic hypermutation in 50%–60%. Mutation is associated with adverse prognosis and is associated with expression of the tyrosine kinase ZAP-70, normally expressed in T cells. ZAP-70 can be detected by flow cytometry, but the protein undergoes degradation in vitro and is imperfectly associated with gene expression.

Cytogenetic studies show del 13q14.3 in 50%, trisomy 12 in 20%, del(11q22-23) and/or mutations in this region in 20%, del(17p13) at the p53 locus in 10%, and del(6q21) in 5%. The first of these is associated with favorable outcome, and the latter three with adverse outcome. Cytogenetic abnormalities vary with mutation status. These abnormalities often

cannot be detected by karyotype because CLL cells do not grow well in culture, but they are detectable by FISH probes. Other adverse features include expression of CD38, doubling of lymphocyte count in <12 months, and elevated β_2 -microglobulin.

The leukocyte count is usually between 30 and 20 × 10⁹/L. In the typical type of CLL, 90% or more of the cells are small lymphocytes that are monotonously similar in appearance and usually look normal. Nuclear chromatin may be coarsely condensed and more sharply separated by parachromatin than in normal lymphocytes, or, in some cases, the chromatin is less condensed than normal. Nucleoli are evident in many of the lymphocytes. Size variation is minimal, and the amount of cytoplasm is slight to moderate. Less than 10% of lymphocytes are prolymphocytes or reticular lymphocytes (transformed lymphocytes).

Often there is neither anemia nor thrombocytopenia at the time of diagnosis. Anemia due to impaired production does develop as the marrow is replaced by leukemic cells. In addition, erythrocyte life span in some patients with CLL may be reduced. This is especially true when there is marked splenomegaly. Autoimmune hemolytic anemia develops in about 10% of patients. Thrombocytopenia is often slight and occasionally becomes severe as the disease progresses, so that hemorrhagic manifestations appear. Thrombocytopenia is usually due to hypoproliferation but may also be secondary to an immune process or splenic sequestration. Patchy, nodular, or interstitial involvement of the BM by neoplastic lymphocytes is associated with a relatively good outcome. A diffuse infiltrate of the BM, however, usually correlates with a poor prognosis and/or advanced disease (Bartl, 1982b; Montserrat, 1987). An increased proportion of prolymphocytes (between 10% and 55%) has been referred to as mixed CLL/prolymphocytic leukemia (PLL) and may correlate with aggressive disease (Melo, 1987; Bennett, 1989). Expression of markers CD38 and ZAP-70 and p53 abnormalities have been investigated for possible prognostic value, but results are inconclusive (Kim, 2004; Mainou-Fowler, 2004). Anemia, B symptoms, and International Prognostic Index (IPI) may provide the best prognostic information (Nola, 2004). The median survival for patients with CLL is about 7 years, but recent therapy such as fludarabine shows promise for better survival.

B Cell Prolymphocytic Leukemia

Prolymphocytic leukemia was originally described as a variant of CLL (Galton, 1974). The male/female ratio is 6.5:1, and mean age is 65 years. PLL is characterized by a very marked lymphocytosis (usually greater than 100 × 10³/μL), massive splenomegaly, moderate hepatomegaly, and inconspicuous lymphadenopathy. The malignant lymphoid cells have a large vesicular nucleolus, condensed nuclear chromatin, and a moderate amount of cytoplasm (Fig. 33-45). More than 55% of blood leukemic cells are prolymphocytes. Immunophenotype varies from SLL/CLL by bright surface Ig (monoclonal IgM with or without IgD), lack of CD5 in two thirds of cases, and usually lack of CD23 and presence of FMC-7. Abnormalities of p53 are frequent, and deletions at 11q23 and 13q14 occur. Prolymphocytic leukemia is usually less responsive to treatment than CLL in general, and it has a poorer prognosis.

Figure 33-45 B cell prolymphocytic leukemia typically shows high white blood cell count, large lymphocytes with moderately abundant cytoplasm, and prominent nucleoli, although variability is noted ($\times 1000$).

Figure 33-48 Hairy cell leukemia shows lymphoid cells with foamy cytoplasm and cytoplasmic projections, and oval or indented nuclei with reticular chromatin ($\times 1000$).

Figure 33-46 Splenic marginal zone lymphoma showing mild white pulp expansion and patchy red pulp involvement ($\times 100$).

Figure 33-49 Hairy cell leukemia in a bone marrow biopsy shows small nuclei with moderate cytoplasm and distinct cytoplasmic boundaries ($\times 500$).

Figure 33-47 Higher-power view of splenic red pulp involvement by monocytoid splenic marginal zone cells in splenic marginal zone lymphoma ($\times 200$).

Splenic Marginal Zone Lymphoma

Splenic marginal zone lymphoma (SMZL) has many clinical, laboratory, and morphologic features similar to HCL and features similar to SLL/CLL (Swerdlow, 2008). The disease is more common in men than in women. Patients are often in their seventh decade of life when they present with splenomegaly.

In the spleen, the neoplastic infiltrate expands from the white pulp into the red pulp. Some patients ($\approx 1/3$) show a small monoclonal gammopathy, usually IgM. The BM may demonstrate patchy infiltrates or massive involvement. The tumor arises from splenic marginal zones, which in reactive processes are seen as an outer zone of pale lymphocytes with moderately abundant cytoplasm surrounding the white pulp and imparting a target-like appearance. In some cases, reactive follicles with germinal centers are present, and an expanded marginal zone surrounds the white pulp and involves the red pulp. Marginal zone hyperplasia may mimic this disorder. Other cases show predominantly red pulp involvement (Figs. 33-46 and 33-47). Red cell lakes are not present, and lymph nodes are not characteristically involved. The tartrate-resistant acid phosphatase (TRAP) stain is usually negative, although positive reactions have been recorded.

The immunophenotype is mature B cell with surface IgM/IgD (similar to SLL/CLL), positive CD20, CD79, and other pan-B cell markers. CD5, CD10, CD23, cyclin D1, CD103, annexin A1, and CD43 are characteristically negative.

Immunoglobulin genes are clonally rearranged, and half of cases show somatic mutations. Translocation/loss of 7q21-32 is noted in 40% of cases, and trisomy 3q in some (Dogan, 2003). Bcl-2 is variable and is typically expressed according to some studies (Pawade, 1995) but not others (Menendez, 2004). Hepatitis C may play a role in the pathogenesis in some cases (Weng, 2003; Iannitto, 2004; Kelaidi, 2004).

SMZL is indolent but has shown poor response to therapy. New approaches utilizing chemotherapy combined with anti-CD20 therapy appear promising (Arcaini, 2004).

Hairy Cell Leukemia

Bouroncle (1958) initially described this disorder, which is clinically variable in its manifestations. HCL occurs more frequently in males than in females. The mean age of afflicted patients is 50 years. It has an insidious onset and is characterized by proliferation of abnormal cells in the reticuloendothelial organs and blood. Splenomegaly is the predominant physical finding (Foucar, 2008). Pancytopenia or depression of only two cell lines is the usual finding, with variable numbers of hairy cells. Monocytopenia is characteristic and hairy cells are usually infrequent in the blood, although they may result in leukocytosis. In most cases, BM aspiration is difficult. Marrow biopsy shows a marrow that varies in cellularity, often having both hypocellular and hypercellular areas and reticulin fibrosis. Hypocellular cases of HCL occur and mimic aplastic anemia. Morphologically, the cells are medium sized (10–20 μm in diameter) with round to oval nuclei, although many are notched or dumbbell or bean shaped. The chromatin pattern is usually uniformly reticular, and nucleoli are small and inconspicuous. In some cells, chromatin is more condensed, resembling that of a lymphocyte. The cytoplasm is moderate in amount, is light blue-gray, and exhibits numerous hair-like projections and frayed borders, most prominent on electron micrographs (Fig. 33-48).

In marrow sections, cells with small central nuclei, abundant cytoplasm, and reticulin fibrosis produce a characteristic fried-egg appearance, which may resemble erythroid islands when involvement is not extensive (Fig. 33-49). Chromatin is usually more delicate and nuclei more irregular than

Figure 33-50 Villous lymphocytes (×1000).

Figure 33-51 Hairy cell leukemia (HCL) variant shows morphology intermediate between usual HCL and prolymphocytic leukemia.

Figure 33-52 Lymphoplasmacytic lymphoma involving the marrow, with associated Waldenström's macroglobulinemia. Lymphocytes, plasma cells, plasmacytoid lymphocytes, and a rare Dutcher body (upper right) can be seen (×1000).

in erythroid precursors. In small or poorly preserved biopsies, HCL may be mistaken for large B cell lymphoma.

Splenectomy specimens are usually diagnostic, with red pulp infiltrates of cells similar to those in the marrow. In addition, the cells tend to line splenic sinuses, obliterating the endothelium and producing red cell "lakes," which lack visible endothelium. Lymph nodes may show paracortical infiltrates, and the liver may show sinus infiltration.

Cytochemically, these cells contain acid phosphatase, which is resistant to inhibition by tartrate-resistant acid phosphatase; this is in contrast to the isoenzymes of acid phosphatase present in other hemic cells (Yam, 1971).

Immunophenotype is mature B cell (CD19, CD20, CD22, CD79a, DBA.44, FMC-7, and surface membrane immunoglobulin [SMIg]) with expression of hairy cell-associated markers CD103, CD25, CD11c, annexin A1 (ANXA1), and (dim) cyclin D1 (Falini, 2004). Cells are negative for CD5, CD10, and CD23. Immunoglobulin heavy and light chain genes are rearranged, with somatic mutation of V gene regions. No specific genetic abnormalities are yet described.

The clinical course is usually chronic but may be acute or subacute. Median survival is between 5 and 6 years. Traditionally, splenectomy has offered significant benefit to many patients. Treatment with α -interferon provided the first chemotherapy remissions, but 2'-deoxycoformycin and 2-chlordeoxyadenosine now produce more durable remissions.

Splenic B Cell Lymphoma/Leukemia, Unclassifiable

Splenic Diffuse Red Pulp Small B Cell Lymphoma

This is a lymphoma of small B cells with diffuse splenic red pulp involvement and involvement of BM sinusoids and blood. At least some cases were previously referred to as splenic lymphoma with circulating villous lymphocytes due to circulating neoplastic cells with short cytoplasmic villi, often with a polar distribution (Fig. 33-50). Neoplastic lymphocytes show clumped chromatin and moderate basophilic cytoplasm. Patients have massive splenomegaly but often low levels of lymphocytosis. Neoplastic cells may circulate in the blood, even in the absence of marrow involvement. The phenotype is B cell with expression of DBA.44 and surface IgG, but usually absent CD103 and absent Annexin A1.

Hairy Cell Leukemia Variant

Most cases of **hairy cell variant** are described as lymphoproliferative disorders resembling HCL but with high WBCs and the presence of prominent nucleoli (Sainati, 1990), and not closely related biologically. These cases have morphology and clinical features intermediate between HCL and PLL (Fig. 33-51). Response to chemotherapy is poor, but the clinical course is chronic, and remission may be attained with splenectomy. TRAP and CD103 are variable, and CD25 and Annexin A1 are usually negative. A very rare form of variant HCL has been described, mostly in Japanese patients, and is referred to as **Japanese variant** (Machii, 1993). This disorder shows slightly more prominent nucleoli than typical HCL, but less so than prolymphocytoid variants, also variable CD103 and TRAP, negative CD25, and usually lack of surface Ig (Yamaguchi, 1996; Wu, 2000). It shows clonal rearrangement of Ig genes and must be distinguished from polyclonal B cell lymphocytosis with similar morphology (Machii, 1997).

Lymphoplasmacytic Lymphoma

Lymphoplasmacytic lymphomas (LPL), a term derived from the Kiel Classification (Stansfeld, 1988), refers to tumors of small lymphocytes with

plasmacytoid differentiation and plasma cells, secretion of a monoclonal IgM paraprotein, and lack of CD5 expression. They usually involve BM, lymph nodes, and spleen (Fig. 33-52).

Lymph nodes show diffuse infiltrates of lymphocytes, plasmacytoid lymphocytes, and plasma cells. Proliferation centers are not present, and monocytoid B cells are not seen. The infiltrate may be paracortical with sparing of sinuses. PAS-positive inclusions are often seen in the cytoplasm, and Golgi-centered inclusions frequently invaginate into the nucleus of the lymphoid cells, forming **Dutcher bodies**. Tissue mast cells are frequently increased.

The BM usually shows nodular and/or diffuse interstitial infiltrates of similar cells. Blood involvement may be present, but with lower WBCs than CLL.

The immunophenotype shows B cell markers CD19, CD20, CD22, and CD79a with bright surface and cytoplasmic IgM (occasionally IgG or IgA) but not IgD, and a monoclonal κ or λ light chain. It differs from CLL by absence of CD5 and bright immunoglobulin expression. CD10 and CD23 are also negative; CD38 is positive, and CD43 is variable.

Ig heavy and light chain genes are clonally rearranged, and there is somatic mutation of variable regions, consistent with a postantigen selection (post germinal center) state of maturation and differing from CLL (Swerdlow, 2008).

Del6q21 and trisomy 4 are frequent in LPL, and trisomies 3 and 18 and other abnormalities are sporadically reported.

The term **Waldenström's macroglobulinemia** refers to LPL with BM involvement and a monoclonal IgM paraprotein. It has a peak incidence between the ages of 60 and 70. Symptoms of increased viscosity include visual disturbances, neurologic symptoms, impaired kidney function, and congestive heart failure. Hemorrhagic phenomena may occur as the result of interference of complexes with platelets and clotting factors. Cryoglobulinemia occurs somewhat more frequently than with myeloma and often results in Raynaud's phenomenon.

Normochromic, normocytic anemia is sometimes associated with thrombocytopenia or pancytopenia. Relative or slight absolute lymphocytosis is usually found. Marked rouleaux formation is evident on the blood film, and the sedimentation rate is usually extremely rapid, although it may be low if macrocryoglobulins are present and the test is carried out at a lower temperature. Anemia is occasionally hemolytic with a positive Coombs' test.

Serum globulin is usually markedly increased. The relative serum viscosity may be simply measured using an Ostwald viscometer. The average time for descent of the serum at room temperature is expressed as a ratio to that of distilled water. The normal range is 1.4–1.8. It is considerably elevated in most patients with macroglobulinemia. Symptoms of hyperviscosity appear in most patients when the relative serum viscosity is between 6 and 8, although the threshold varies among patients. The paraprotein is identified by immunoelectrophoresis. Light chain proteinuria occurs in about 10% of patients.

Many cases previously placed in this category are now believed to represent low-grade lymphoma of mucosa-associated lymphoid tissue (MALT) lymphoma with plasmacytoid expression. No definite biological marker can be used to separate the two, but MALT lymphomas typically involve epithelial organs, and macroglobulinemia is not the presenting feature. Many cases of cryoglobulinemia due to LPL and MALT lymphoma are associated with hepatitis C virus (Sansonno, 1996).

Heavy Chain Diseases

A small number of patients produce and excrete heavy chain fragments without associated light chains. Some of these proteins show structural mutations. The classification of associated lymphoproliferative disorders is somewhat ambiguous. Lymphoproliferative disorders associated with γ heavy chain disease often resemble LPL or plasmacytoma; μ heavy chain disease may resemble CLL, and α heavy chain disease is associated with MALT lymphoma.

γ Heavy Chain Disease

γ heavy chain disease (HCD) is a lymphoproliferative disorder characterized by secretion of a truncated γ -chain without light chain binding sites. It presents with lymphadenopathy, hepatosplenomegaly, fever, and propensity to infection. Anemia is constantly present, often with leukopenia and thrombocytopenia. Atypical lymphocytes or plasma cells are frequently present in the blood, and a few cases have terminated in plasma cell leukemia. The marrow is usually abnormal, with increased plasma cells, lymphocytes, and eosinophils. A rather broad serum protein “spike” has been found in the $\beta\gamma$ -region in most patients, accompanied by hypogammaglobulinemia. The diagnosis is made by showing that the protein reacts on immunoelectrophoresis with antisera to γ -chains but not to light chains. The protein is also found in the urine in varying amounts, although concentration techniques may be necessary to demonstrate it.

α Heavy Chain Disease

α heavy chain disease appears to be more common than γ -HCD and involves a younger age group. The uniform clinical pattern in most patients is malabsorption and diarrhea accompanying a massive lymphoplasmacytic infiltration of intestinal mucosa, sometimes evolving to large B cell lymphoma. It has also been referred to as Mediterranean abdominal lymphoma and immunoproliferative small intestinal disease (IPSID). In a few patients, the respiratory tract has been involved instead. BM and other lymphoid organs have not been involved. Usually, routine protein electrophoresis is negative, but small amounts of α -chain may be detected in the serum and sometimes in the urine with immunoelectrophoresis. The abnormal protein does not contain light chains. It is most common in Mediterranean areas and is associated with poor living conditions in low socioeconomic groups. Similar to MALT lymphoma, many cases may initiate an infectious antigen-driven proliferation.

μ Heavy Chain Disease

The few patients who have been described with μ heavy chain disease have had chronic lymphocytic leukemia with vacuolated plasma cells in the marrow. Routine serum electrophoresis showed only hypogammaglobulinemia. The μ heavy chain was detected by serum immunoelectrophoresis; it was not found in the urine. In most patients, however, the urine contained κ light chain in large amounts (Franklin, 1975).

Plasma Cell Neoplasms

Clonal neoplasms of mature plasma cells are common neoplasms that have been difficult to treat and are greatly feared. They are now known, however, to consist of a spectrum of disease varying from indolent and nonprogressive to highly aggressive and refractory to therapy. The best measures of disease course are the clinical findings themselves, and treatments using new agents are rapidly evolving to increase efficacy and improve outcome. Major categories now are monoclonal gammopathy of undetermined significance, that is, usually indolent (but may be associated with amyloidosis), asymptomatic myeloma and symptomatic myeloma (Table 33-19).

TABLE 33-19

Diagnostic Criteria for Monoclonal Gammopathy of Undetermined Significance, Indolent and Smoldering Myeloma, and Plasma Cell Myeloma

Monoclonal Gammopathy of Undetermined Significance

M-protein in serum <30 g/L
Marrow plasmacytosis <10%
No lytic bone lesions
No myeloma-related symptoms (no CRAB)

Asymptomatic (Smoldering) Myeloma

Serum M-component >30 g/L
Marrow plasmacytosis >10%
No organ or tissue impairment (no CRAB)

Plasma Cell Myeloma

M-protein in serum or urine (no specific level need be met)
Bone marrow clonal plasma cells
Organ or tissue impairment (hypercalcemia, renal insufficiency, anemia, bone lesions; CRAB)

CRAB, Hypercalcemia, renal insufficiency, anemia, or bone lesions.

Monoclonal Gammopathy of Undetermined Significance

Monoclonal gammopathy of undetermined significance is the term utilized when a monoclonal serum immunoglobulin is present but no myeloma is detectable. Most cases (75%) are IgG, with smaller proportions of IgM (15%) and IgA (10%). It is a preneoplastic condition with progression to myeloma in about 1% of affected patients per year. The condition consists of a monoclonal Ig (M-component) of <30 g/L IgG, <10% clonal plasma cells in the marrow, absence of lytic bone lesions, no melanoma-related organ or tissue impairment (CRAB: hypercalcemia, renal insufficiency, anemia, or bone lesions), and no evidence of other B cell lymphoproliferative disorder. Cytogenetic and immunophenotypic abnormalities are similar to those in myeloma, and none is known to be predictive of progression.

Plasma Cell Myeloma

Plasma cell myeloma is a neoplastic proliferation of plasma cells, occurring primarily in the BM. Although plasma cells also proliferate in lymph nodes and spleen, these organs are rarely enlarged (Swerdlow, 2008). Symptomatic myeloma is defined by the WHO 2008 classification simply as the presence of M-protein in serum or urine, BM clonal plasma cells or plasmacytoma, and the presence of related organ or tissue impairment (CRAB, see previously).

Multiple myeloma is rare in those younger than 40 years of age. The mean age at the time of diagnosis is 62 years with an equal sex distribution. Bone pain is the most common symptom, and pathologic fractures are frequent. Neurologic symptoms may be prominent from encroachment of tumor that has broken through the bony cortex on spinal nerves or spinal cord. Bone destruction leads to calcium mobilization, with increased calcium in the serum and metastatic calcification. Growth of myeloma cells in the marrow produces multiple tumors, which appear on a radiograph as multiple punched-out osteoporotic lesions; occasionally, the growth is diffuse and appears as diffuse osteoporosis. A propensity to infection is common because of impaired production of antibodies. Plasma cell disorders may be associated with human herpesvirus type 8 (HHV-8).

A normochromic, normocytic anemia usually occurs, and normoblasts may be present in the blood. The leukocyte count is slightly decreased, normal, or slightly increased. Occasional myeloid left shift to the myeloblast may be noted. The platelet count is usually normal but may be decreased. The most striking feature of the blood film is the marked degree of rouleaux formation.

The BM shows the presence of plasma cells or myeloma cells, ranging from less than 1% to over 90%, depending on the degree of involvement at the site of the aspirated marrow. Diagnosis of myeloma and its variants is based on both pathology and clinical findings, including serum monoclonal immunoglobulin and radiologic evidence of lytic bone lesions (Durie, 2003; Swerdlow, 2008). Lytic bone lesions are associated with increased osteoclastic activity, hypercalcemia, and neurologic changes. This may be related to activity of the receptor activator for NF κ B (RANK)

Figure 33-53 Myeloma in the bone marrow showing large plasma cells with nucleoli ($\times 1000$).

Figure 33-54 Plasma cell leukemia with cells resembling immunoblasts ($\times 1000$).

ligand (Sezer, 2003) and has stimulated interest in its receptor, osteoprotegerin (OPG).

Cytologically, the cells may be indistinguishable from normal plasma cells, but they usually show abnormal chromatin, such as less clumping of nuclear chromatin, large nucleoli, lack of perinuclear clear zone, lighter blue cytoplasm, or varying degrees of anaplasia (Fig. 33-53). Immature, plasmablastic, and anaplastic variants are described.

The immunophenotype is variable, most typically with expression of CD38 and CD138, loss of CD19 expression (normally present on plasma cells), and absence of CD20, but with abnormal acquisition of CD56 and often CD117. Immunohistochemical labeling or mRNA in situ hybridization of BM sections for κ and λ usually identifies monoclonal plasma cells. Cyclin D1 expression is associated with t(11;14).

Cytogenetic analysis divides myeloma into two main groups: hyperdiploid with multiple trisomies involving odd-numbered chromosomes and associated with good prognosis; and hypodiploid associated with adverse prognosis. Karyotype and FISH studies show frequent del13q14 (50% of cases), translocations t(4;14), t(14;16) or t(14;20), or deletion of TP53 (del 17p13) that, along with aneuploidy, are unfavorable when detected by karyotype, or t(11;14) or t(6;14) that is favorable when detected only by FISH. The translocation t(11;14)(q13;q32) involves the same gene as that in mantle cell lymphoma, but the breakpoints are different. Losses of 8, 13, 14, and X are common. Elevated serum β_2 -microglobulin is also an adverse feature. A high-risk molecular signature has been described (Zhou, 2009).

Serum globulin is usually increased, often strikingly so. This increase is responsible for the tendency toward rouleaux formation and an elevated ESR. Serum protein electrophoresis usually shows an M-spot, a homogeneous band in the γ - or β -region; less commonly, there is hypogammaglobulinemia (when only light chains are produced by the neoplastic plasma cells). Immunoelectrophoresis indicates that the monoclonal protein is IgG in over 50% of cases, IgA in about 20%, IgD in less than 1%, and IgE very rarely. Roughly 5% of myeloma proteins are cryoglobulins, that is, proteins that precipitate from cooled serum and redissolve on warming. Some tumors secrete free monoclonal light chains (Bence Jones protein), in addition to the whole immunoglobulin molecule, and in about 25%, only light chains are produced. Hypogammaglobulinemia is found in the latter group because light chains are filtered through the renal glomerulus, leaving little or none in the serum, in addition to the fact that immunoglobulin production by nonmalignant plasma cells is greatly reduced. If renal damage has occurred, albumin and whole immunoglobulin molecules are also found in the urine. Excretion of light chains sometimes results in obstruction and loss of nephrons and so-called myeloma kidney. Renal insufficiency is common and is the presenting feature of multiple myeloma in some cases. Amyloidosis, which is present in about 10%–15% of cases of multiple myeloma, may be a factor in renal failure.

Median survival after diagnosis of multiple myeloma has been approximately 3–4 years, but new drugs are likely altering this.

Clinical Variants

Asymptomatic (Smoldering) Myeloma. Smoldering myeloma shows M-protein at myeloma levels (>30 g/L) and/or 10% or more clonal plasma cells in the marrow with no related organ/tissue impairment (CRAB). Patients with solitary plasmacytoma and bone lesions detected only by magnetic resonance imaging (MRI) are included. These asymptomatic patients differ from those with MGUS primarily by a higher rate of progression: 10% per year for the first 5 years, 3% for the next 5 years, and then 1% per year.

Nonsecretory Myeloma. These patients are similar to others with myeloma, except that tumor cells do not produce (15%) or secrete (85%) immunoglobulin. The incidences of renal insufficiency, hypercalcemia, and depression of normal Ig are less.

Plasma Cell Leukemia. Often in multiple myeloma, a few plasma cells are found in the peripheral blood. Only in the rare instances of myeloma in which large numbers of plasma cells circulate (either $>20\%$ of blood leukocytes, or $>2 \times 10^9/L$) is the term plasma cell leukemia used (Fig. 33-54). Patients with plasma cell leukemia tend to have tissue infiltration, advanced-stage disease, and poor survival (Woodruff, 1978).

The immunophenotype varies from usual myeloma in that CD56 is often absent.

Solitary Plasmacytoma of Bone. These patients show no clinical features of myeloma but may have a monoclonal immunoglobulin without suppression of normal immunoglobulin. Tumors are controlled by radiation, but two thirds of cases eventually progress to myeloma.

Extrasosseous Plasmacytoma. Extramedullary solitary plasmacytomas occur in GI tract, bladder, CNS, breast, thyroid, testis, parotid gland, lymph nodes, or skin and are irradiated. They recur in one quarter of patients but progress to myeloma in only about 15%.

Monoclonal Immunoglobulin Deposition Diseases

Primary Amyloidosis

Primary amyloidosis, an uncommon presentation of plasma cell neoplasms of various types, results from abnormal polymerization of immunoglobulin into β -pleated sheets in connective tissue. A variety of amyloid types occur, including hereditary, secondary associated with chronic inflammation, the type associated with Alzheimer's disease, and others. All amyloid is biochemically composed of an A protein component and a P component. In plasma cell dyscrasia, the A component is derived from immunoglobulin light (L) chains and is referred to as AL amyloid. It may be detected by homogeneous pink staining of thickened blood vessels in abdominal fat, BM, rectum, or other tissues. Congo Red stain shows characteristic apple-green birefringence under polarized light. It may also be detected by thioflavin T, antibodies against amyloid P, and antibodies against immunoglobulin light chains. It may involve the heart with subsequent congestive failure, liver with hepatomegaly, kidney with nephrotic syndrome or renal failure, nerves with sensory/motor loss, and other organs. It may occur in overt myeloma (20%), but most often it is seen in patients with disease otherwise fulfilling criteria for MGUS.

Monoclonal Light and Heavy Chain Deposition Diseases

Nonamyloid immunoglobulin deposition may result in organ dysfunction in rare disorders known as light chain deposition disease (LCDD) or heavy chain deposition disease (HCDD) (Swerdlow, 2008).

Osteosclerotic Myeloma

This is a syndrome of polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes (POEMS) associated with osteosclerotic multiple myeloma showing marrow fibrosis and sclerosis, and with lymph node changes resembling plasma cell Castleman's disease.

Figure 33-55 Mucosa-associated lymphoid tissue lymphoma with nests in lymphocytes in gastric epithelium (×500).

The plasma cells usually express λ light chain, and heavy chain is IgG or IgA.

Extranodal Marginal Zone B Cell Lymphoma of Mucosa-Associated Lymphoid Tissue

Extranodal marginal zone B cell lymphoma of mucosa-associated lymphoid tissue is an indolent lymphoma of mucosal tissue, including stomach, other GI tract, bronchi, salivary glands, thyroid, skin, and other areas. MALT lymphoma of the stomach is in many cases an antigen-driven clonal B cell proliferation related to infection by *Helicobacter pylori*, which is also associated with gastric ulcer; early cases may respond to antibacterial therapy. Other patients have autoimmune disorders such as Sjögren's syndrome or Hashimoto's thyroiditis. The terminology of MALT lymphomas refers only to those of predominantly small cells, although large cell and other aggressive lymphomas may arise in the same tissues. α heavy chain disease, or IPSID, is considered a special subtype of this disease (see earlier).

Gastric or other mucosa is infiltrated by small lymphocytes that form clusters within the epithelium, referred to as lymphoepithelial lesions (Fig. 33-55). Submucosa contains diffuse infiltrates of small lymphocytes, centrocytes, monocytoid lymphocytes, and plasma cells. Germinal centers, apparently reactive to the entire process, are usually present. Plasma cells often are abundant at the periphery of the lesions and generally are monoclonal.

The immunophenotype is B cell (CD19, CD20, CD22, CD79a) with surface Ig. CD5, CD10, bcl-6, and usually CD23 are negative. Bcl-2 is frequently positive, and CD43 is variable (Isaacson, 2008). Follicular dendritic cell-associated markers CD21 and CD35 often reveal expanded follicular meshworks and colonized germinal centers.

Immunoglobulin genes are clonally rearranged with somatic mutations of V regions. Trisomies 3 and 18 are frequent. t(11;18)(q21;q21), involving the apoptosis-inhibiting gene *API2* with *MLT* at 18q21, is common in pulmonary and gastric tumors. t(1;14)(p22;q32) is associated with ocular adnexae, orbit, and salivary gland lesions; t(14;18)(q32;q21), with activation of NF- κ B-mediated antiapoptotic pathways, is common in thyroid, ocular adnexae, and skin lesions (Gascoyne, 2003). These tumors are typically indolent with good response to radiation therapy.

Nodal Marginal Zone Lymphoma

These tumors are derived from post-germinal center marginal zone B cells and show small lymphocytes surrounding reactive follicles and expanding in the interfollicular zones. They may resemble nodal involvement by MALT lymphoma or splenic marginal zone lymphoma (Fig. 33-56). Germinal center colonization is frequent, as are plasma cell differentiation and occasional eosinophilia. Increased large cells may be present and do not apparently affect prognosis, although transformation to diffuse large B cell lymphoma may occur.

The immunophenotype is similar to MALT or SMZL, with surface Ig (IgM/IgD, IgM, less often IgA or IgG), B cell markers (CD19, CD20, CD22, CD79a), expression of CD23, variable CD43, and absence of CD5 or CD10. Bcl-2 is expressed in a majority of cases, and survivin is overexpressed in about 50%, suggesting activation of antiapoptotic pathways. Nodal MZL is heterogeneous at the molecular and immunohistochemical levels (Camacho, 2003). Ig heavy and (monotypic) light chain genes are rearranged. Trisomies 3, 7, and 18 may occur, and 5-year survival is greater than 50%.

Figure 33-56 Nodal marginal zone lymphoma showing a nodule of monocytoid B cells (×200).

Figure 33-57 Low-power view of follicular lymphoma, recapitulating lymph node germinal centers (×200).

Pediatric Nodal Marginal Zone Lymphoma

A clinical subtype of nodal marginal zone lymphoma occurs in the pediatric age group, usually in boys, with localized lymphadenopathy of the head and neck. Tumors contain progressively transformed germinal center and resemble reactive lymphadenopathy, but show clonal immunoglobulin gene rearrangement. Children have excellent outcomes with conservative treatment.

Follicular Lymphoma

Follicular lymphoma (FL) is a group of related lymphomas of germinal center-derived B cells. Morphologic distinction between the subgroups is based on the numbers of centroblasts in the neoplastic follicles (Harris, 2011).

The overall morphologic pattern (Fig. 33-57) shows recapitulation of lymph node follicles, but with limited diversity of cell type and lack of proliferation of other lymph node structures. The tumors generally show crowded follicles of more than usual uniformity, lacking distinct mantles and with little intervening paracortex, and lacking normal germinal center **tingible body** macrophages and polarization. Most often, small irregular cells (small cleaved cells or centrocytes) predominate with variable numbers of admixed large cells (large cleaved and noncleaved cells or centroblasts). There may be diffuse infiltrates as well. The term **follicular** indicates a greater than 75% follicular pattern; **follicular and diffuse** refers to cases that are 25%–75% follicular; **focally follicular** refers to cases with less than 25% follicular pattern; and **diffuse** indicates that no follicular component is present (Table 33-20). BM involvement is frequent and usually first involves the paratrabecular regions, often in a spotty fashion.

Cytologic grading is based on the average number of centroblasts (CBs) per high-power field (hpf) within neoplastic follicles (Figs. 33-58 and 33-59). It is now recommended that grades 1 and 2 be combined into grade 1-2. An hpf is defined as that with a 40 \times lens and a 10 \times ocular with an 18-mm field of view. A 50 \times lens with a 22-mm 10 \times ocular, often used in wet hematology, provides a nearly equivalent field of view.

Marginal zone or monocytoid B cell differentiation occurs in up to 10% of cases. It usually appears around follicles and in interfollicular areas and resembles a composite lymphoma. FL shows an immunophenotype of mature B cells with bright monoclonal surface Ig, CD19, CD20, CD22, CD23, CD79a, and CD10 expression. Bcl-2 (cytoplasmic) and bcl-6 (nuclear) are both usually expressed, which helps to separate FL from

TABLE 33-20

Follicular Lymphoma: Grading and Variants

Grading	Definition
Grade 1	0–5 centroblasts per hpf*
Grade 2	6–15 centroblasts per hpf*
Grade 3	>15 centroblasts per hpf*
3a	Centrocytes present
3b	Solid sheets of centroblasts
Reporting of pattern	Proportion follicular
Follicular	>75%
Follicular and diffuse	25%–75%†
Focally follicular	<25%†
FOLLICULAR LYMPHOMA: VARIANTS	
Diffuse large B cell lymphoma with follicular lymphoma	Presence of diffuse areas with >15 centroblasts/hpf

From Swerdlow (2008).

*hpf = high-power field of 40× lens with 10× 18-mm eyepiece or 50× lens with 10× 22-mm eyepiece (average of 10 fields within follicles).

†Give approximate percentage in report.

Figure 33-58 Follicular lymphoma, grade 2, showing centrocytes with 5–15 centroblasts per high-power field (hpf). Grade 1 shows <5 centroblasts per hpf.

Figure 33-59 Follicular lymphoma, grade 3a, shows centrocytes with >15 centroblasts per high-power field (hpf) (×500).

reactive hyperplasia (bcl-2-negative/bcl-6-positive) and other lymphomas not of germinal center cell (GCC) derivation (bcl-6-negative). CD5 and CD43 are typically absent.

IgH is clonally rearranged along with a light chain Ig gene, and there is t(14;18)(q32;q21) with juxtaposition of IgH and *BCL-2*. Bcl-2 protein is inappropriately expressed, and subsequent inhibition of apoptosis is considered a primary pathogenic mechanism of FL. Standard PCR assays are relatively insensitive for IgH and t(14;18) because only 75% of IgH breakpoints are in the major breakpoint region (MBR) or minor cluster region (mcr) targeted by standard primers. Quantitative real-time PCR and FISH assays provide improved sensitivity (Jenner, 2002; Jiang, 2002). Other abnormalities may be seen, including a variant Bcl-2 rearrangement, t(2;18)(p12;q21), 6q23–36 abnormalities, and deletions/abnormalities of 9p or 17p13 involving TP53 (both associated with large cell transformation), rearrangements or mutations of BCL-6 at 3q27, and abnormalities of X, 1, 2, 4, 5, 7, 12, 13, and 18 (Nathwani, 2001).

Figure 33-60 Mantle cell lymphoma, showing an expanded mantle around residual germinal center.

Prognosis is variable, with grade 1 and 2 disease generally showing an indolent course but lack of cure. Grade 3 is more aggressive but likely more curable. Attempts to identify patients requiring aggressive therapy have led to a follicular lymphoma international prognostic index (FLIPI) (Solal-Celigny, 2004) based on age, stage, hemoglobin, number of nodal areas involved, and lactate dehydrogenase, which appears to be valid at least for FL in first relapse (Montoto, 2004). Diffuse large B cell lymphoma (DLBCL) is considered by WHO authors to be a different entity even when it arises in FL (Swerdlow, 2008). In these situations, two diagnoses are recommended, such as “follicular lymphoma, grade 3/3 (75%), with diffuse large B cell lymphoma (25%),” when the DLBCL occupies 25% of the sampled tumor. Leukemic involvement by FL may also occur and is sometimes known as **lymphosarcoma cell leukemia**. Flow cytometry is helpful to distinguish between that, CLL, and leukemic mantle cell or marginal zone lymphomas.

Diffuse follicular lymphoma is essentially a diffuse transformation of grade 1 or 2 FL. Diagnosis requires phenotyping and/or cytogenetic studies to rule out mantle cell or marginal zone lymphoma, and includes previous categories of diffuse small cleaved cell, centrocytic diffuse, diffuse mixed small cleaved, and large cell and centrocytic/centroblastic diffuse.

Follicular lymphoma occurring in the pediatric age group (pediatric follicular lymphoma) is a distinct entity that usually lacks t(14;18) or bcl-2 expression and behaves in an indolent fashion. Most cases are grade 3. Primary intestinal follicular lymphoma may occur in duodenal polyps and is usually indolent, as are many other extranodal follicular lymphomas. Intrafollicular in situ follicular lymphoma of bcl-2-positive follicle cells has been described.

Primary Cutaneous Follicle Center Lymphoma

This is the most common primary cutaneous B cell lymphoma and consists of variably distinct follicular to diffuse lesions in the dermis composed of bcl-6/CD20/CD79a-positive centrocytes and admixed centroblasts, with a background of CD21/CD35 positive follicular dendritic cells. Bcl-2 is usually negative, and CD10 is associated with more distinct follicular patterns. A bcl-2-positive follicular lymphoma in the skin suggests extension of disease from another location. Prognosis is excellent with typical response to radiation.

Mantle Cell Lymphoma

Since the REAL classification was published, it has become recognized that mantle cell lymphoma (MCL) is a dangerous form of lymphoma that combines refractoriness to therapy with an aggressive clinical course and poor survival (ILSG, 1997). Refractoriness is likely due in part to strong expression of Bcl-2, also seen in normal mantle cells, follicular lymphomas, and some other leukemias, lymphomas, and solid tumors (Korsmeyer, 1999). Bcl-2 inhibits apoptotic pathways.

The tumor usually shows a diffuse or sometimes mantle zone pattern (Swerdlow, 2008). In the mantle zone pattern, atrophic germinal centers are often seen in the center of nodules, and these may be seen as occasional small naked follicles within a diffuse infiltrate. Nuclei are small to medium sized with clumped to moderately dispersed chromatin and a moderately increased mitotic rate. Nuclear membranes are typically slightly irregular with occasional small round and cleaved nuclei also present. Scattered histiocytes with lightly eosinophilic cytoplasm are often present. A blastic or “blastoid” variant shows slightly larger nuclei with blast-like chromatin and a higher mitotic rate, simulating lymphoblastic lymphoma (Fig. 33-60).

Figure 33-61 Diffuse large B cell lymphoma with centroblasts and admixed centrocytes (x500).

Figure 33-63 T cell and histiocyte-rich large B cell lymphoma resembles lymphocyte predominant Hodgkin lymphoma, but most small cells are T cells (x500).

Figure 33-62 Diffuse large B cell lymphoma, with polymorphism and Reed-Sternberg-like cells (x1000).

These are monoclonal (monotypic surface IgM and IgD) B cells (CD19, CD20, CD22) with characteristic coexpression of CD5 (and CD43) and absence of CD23. Bcl-2 and cyclin-D1 are expressed while bcl-6 and CD10 are negative. Rare cases occur without CD5 expression (Liu, 2002).

Immunoglobulin heavy and (monotypic) light chain genes are rearranged. A majority of cases have t(11;14)(q13;q32) involving the Ig heavy chain gene and bcl-1 with overexpression of PRAD-1, which encodes cyclin-D1. In diagnostic laboratories, many cases do not show demonstrable bcl-1 translocation by PCR, and cyclin-D1 expression may not be detected for technical reasons. FISH assay, which may be performed from fresh cell suspensions, nuclei extracted from paraffin, or, in some cases, thin sections from paraffin blocks, is usually confirmatory. Complex karyotype is often seen in advanced, blastoid, or pleomorphic variants, and secondary 8q24 abnormalities are associated with blastic/blastoid morphology and leukemic presentation (Viswanatha, 2000; Au, 2002; Hao, 2002). BCL-2 rearrangements are absent.

Diffuse Large B Cell Lymphoma, NOS

DLBCL includes a variety of morphologies, all of which share a diffuse pattern, large cells, and mature B cell phenotype (Swerdlow, 2008). It occurs in both nodal and extranodal sites and at all ages. It is frequent in immunosuppressed patients (often in association with EBV in these) and is the most common lymphoma of the CNS. Various morphologies are mimicked by peripheral T cell lymphomas, and phenotyping is required for diagnosis.

DLBCL presents with diffuse infiltration by large B cells (nuclei larger than histiocytes or endothelial cell nuclei) with variable morphology. They may be centroblasts and/or centrocytes with scant cytoplasm and multiple nucleoli (centroblastic morphologic variant) (Fig. 33-61). Some cases show plasmacytoid immunoblasts with large nuclei, one or more prominent nucleoli, and abundant amphophilic cytoplasm that may be eccentric (immunoblastic variant). Other cases of DLBCL show polymorphic cell morphology with large and small cells and Reed-Sternberg-like giant cells (anaplastic variant) (Fig. 33-62). Still others occasionally show large cells with clear cytoplasm.

Neoplastic cells show surface Ig, sometimes cytoplasmic Ig, and B cell markers (CD19, CD20, CD22, CD79a). CD30 is occasionally present in variable numbers of cells. CD20 expression by immunohistochemistry

(IHC) is usually very helpful in paraffin-section diagnosis. CD10 and/or BCL6 suggests germinal center differentiation, and IRF4/MUM1 suggests post-germinal center differentiation.

In DLBCL, Ig heavy and (monotypic) light chain genes are rearranged. Bcl-2 and/or bcl-6 abnormalities and protein expression are frequent (Skinnider, 1999; Capello, 2000).

Gene array studies have separated DLBCL into at least four major expression groups: GCC-like, activated B cell (ABC)-like, type 3, and mediastinal large B cell lymphoma (Rosenwald, 2002, 2003; Savage, 2003). Of the first three, GCC-like shows better response to therapy than ABC or type 3. BCL-2 and BCL-6 are in the gene cluster of GCC-like tumors and may be surrogates for this category. In the GCC category, cases with t(14;18) show lower proliferation but do not differ in outcome by treatment (Iqbal, 2004). Bcl-2 protein is associated with resistance to apoptosis and chemotherapy, but this may be overcome with humanized monoclonal anti-CD20 (Mounier, 2003).

Subgrouping by immunophenotyping roughly follows expression grouping. Cases with CD10 expression (>30% of cells) or CD10-, BCL-6+, and IRF4/MUM1 are considered germinal center types. All others are non-germinal center types. A variety of other specific types of DLBCL are also described by the WHO classification, as follows (Swerdlow, 2008).

T Cell/Histiocyte-Rich Large B Cell Lymphoma

T cell/histiocyte-rich large B cell lymphoma (TCHRLBCL) variant is very difficult to distinguish from nodular lymphocyte predominant HL (NLPHL), but the distinction is important, as this is a usually aggressive tumor which presents with advanced stage, while lymphocyte predominant HL (LPHL) is often localized and indolent and requires less therapy. TCHRLBCL exhibits a diffuse infiltrate of large B cells, which may appear as centroblasts or immunoblasts or resemble lymphocyte and histiocytic (L&H) cells of LPHL and include Reed-Sternberg-like cells (Fig. 33-63). Large B cells constitute 10% or less of total cells, and T cells constitute the majority. The phenotype is similar to LPHL, with CD20, CD79a, and epithelial membrane antigen (EMA) positivity. J-chain, Oct-2, and Bob-1 are also expressed. Surface/cytoplasmic Ig, if monoclonal, is somewhat helpful, but LPHL is also now considered a clonal B cell disease. Helpful distinctions are the diffuse infiltrate, T cell background, lack of CD3/CD57 rosettes around neoplastic cells in a nodular B cell background as seen in nodular LPHL, lack of residual IgD-positive mantle cells, and lack of a follicular dendritic meshwork by CD21/CD23/D35 staining. Advanced-stage presentation also suggests TCHRLBCL, but rare cases of NLPHL may present with disseminated disease.

Primary DLBCL of the CNS

CNS DLBCL usually presents in middle age as supratentorial tumors with various neurologic symptoms. Homogeneous to focally necrotic on MRI, they frequently show characteristic perivascular tumor cell accumulations on biopsy. These express pan-B cell markers with BCL-6 and strong IRF4/MUM1 positivity in most and variable BCL-2 expression, and they are typically EBV negative. Tumors typically respond to modern chemotherapy.

Primary Cutaneous DLBCL, Leg Type

These are aggressive B cell lymphomas that typically arise in older adults, women more often than men, and often on the lower legs, although they may occur anywhere in the skin. They are composed of monotonous sheets of large B cells with expression of pan-B cell markers, with monotypic Ig,

Figure 33-64 Lymphomatoid granulomatosis, showing a polymorphous angiodestructive pulmonary infiltrate (×200). (Courtesy Dr. Anna-Luise Katzenstein.)

Figure 33-65 Mediastinal large B cell lymphoma with sclerosis (×500).

strong BCL2, IRF4/MUM1, and FOX-P1. BCL-6 is usually positive, and CD10 negative.

EBV-Positive DLBCL of the Elderly

These are DLBCLs arising in patients older than 50 years of age and associated with EBV. Histology varies from mostly large cells to a more polymorphic distribution of cell sizes, often geographic necrosis, with EBV demonstrable by antibody staining for EBV LMP-1 and by ISH for EBV-encoded ribonucleotides. CD10 and BCL6 are negative, IRF4/MUM1 is usually positive, and CD30 is frequently expressed. These aggressive tumors are similar to DLBCL arising in immunosuppressed patients, and a form of age-related immunosuppression is surmised.

DLBCL Associated with Inflammation

This is another EBV-associated tumor that arises in situations with protracted chronic inflammation, the prototype being pyothorax-associated lymphoma (PAL). Features are similar to EBV+ DLBCL of the elderly.

Lymphomatoid Granulomatosis

This is an angiocentric lymphoproliferative disorder involving the lung and/or other sites, including brain, kidney, liver, skin, upper respiratory tract, and GI tract (Katzenstein, 1979). It is considered to be an EBV-driven B cell neoplasm with a prominent reactive T cell component, sometimes in a setting of immunosuppression (Katzenstein, 1990; Wilson, 1996). It has histologic features similar to NK/T cell lymphoma of nasal type (Pittaluga, 2008).

Presentation is usually cough, dyspnea, and chest pain with constitutional symptoms, including fever, malaise, weight loss, GI symptoms, myalgias, and neurologic symptoms. Bilateral mid to lower lung nodules are most commonly seen, often with nodules in the brain, kidney, skin, and subcutaneous tissue.

Histology shows an angiocentric and angiodestructive infiltrate of polymorphic lymphocytes, plasma cells, immunoblasts, and histiocytes, with inconspicuous neutrophils and eosinophils and without well-formed granulomas. Fibrinoid necrosis of vessels is often seen (Fig. 33-64), as is tissue infarction.

Immunophenotyping shows variable numbers of CD79a, usually CD20-positive B cells with EBV LMP-1 expression, variable CD30 expression, and lack of CD15. EBER is generally positive in some studies (Myers, 1995). A majority of background cells are reactive T cells with CD4 predominance. Higher-grade lesions (with more B cells) show clonal rearrangement of the IgH receptor genes. T cell receptor genes are not clonally rearranged.

Grading is related to the number of clonal EBV-positive lymphocytes. Grade I lesions are polymorphic with only occasional large cells. Grade II is mixed with large pleomorphic cells in a mixed inflammatory background. Grade III is essentially diffuse large B cell lymphoma.

Outcome is variable, with waxing and waning, sometimes spontaneous remissions, and often progression to pulmonary failure in a median of 2 years. Appropriate therapy is related to determination of grade. Grade III lesions are treated with systemic chemotherapy, and grades I and II may be treated with α -interferon.

Primary Mediastinal (Thymic) Large B Cell Lymphoma

Primary mediastinal (thymic) large B cell lymphoma (PMBL) often appears in young adulthood to middle age and is more frequent in

women. Histology is variable, but diffuse or compartmentalizing sclerosis is frequent, and clear cells, multilobulated cells, or Reed-Sternberg-like cells may be present (Fig. 33-65). Symptoms are often related to location, with airway compression or superior vena cava syndrome and often local invasion and local recurrence after therapy. CD45, CD19, and CD20 are expressed, but not CD5 or CD10 (Swerdlow, 2008). CD30 is expressed in some cases, but not with the phenotype of classical HL. Ig genes are clonally rearranged; *IgV* and *Bcl-6* gene hypermutations are consistent with GCC cell derivation but occur similarly to normal thymic B cells (Csernus, 2004). Gene expression array analysis shows MLBCL to be similar to classical HL (Savage, 2003). A majority of patients respond to standard CHOP (cyclophosphamide, hydroxydaunorubicin, Oncovin, and prednisone/prednisolone) chemotherapy, but long-term survival may be better with more aggressive approaches (Zinzani, 2001; Andreopoulou, 2004).

Intravascular Large B Cell Lymphoma

Intravascular large B cell lymphoma is a rare tumor which is largely restricted to the intravascular lumina of small vessels (Swerdlow, 2008). It is very aggressive, widely disseminated at diagnosis, and often undiagnosed until autopsy. Findings often include hemorrhage, thrombosis, and/or necrosis of tissues throughout the body, with tumor only inconspicuously present in the small vessels. B cell markers are expressed (CD19, CD20, CD22, D79a) and CD5 in some. Clonal Ig gene rearrangements are present with somatic hypermutation consistent with post-GCC derivation (Kanda, 2001). Rare T cell cases are described (Merchant, 2003). Vascular adhesion molecules CD29 (β 1 integrin) and CD54 (CAM-1) have been reported absent (Ponzoni, 2000).

ALK-Positive Large B Cell Lymphoma

Diffuse large B cell lymphomas with expression of full-length anaplastic lymphoma kinase (ALK) protein resemble T cell anaplastic large cell lymphoma (ALCL) in morphology and expression of ALK, but lack t(2;5) and NPM-ALK fusion protein. Most described cases show t(2;17)(p23;q23) with clathrin gene involvement (CLTL-ALK); other rare abnormalities include t(2;5)(p23;q23), as in typical ALCL. These are of B cell derivation with expression of CD79a but absent CD20 and frequently lack CD30 expression (Laurent, 2010).

Plasmablastic Lymphoma

Plasmablastic lymphoma expresses plasma cell antigens CD38 and CD138 and is associated with EBV. CD20, CD45, and PAX5 are weak to absent, but CD79a and IRF4/MUM1 are positive. There is cytoplasmic IgG. It has an aggressive behavior and has been reported primarily in the oral cavity of HIV patients, but is now known to occur in other patients and other locations as well.

Large B Cell Lymphoma Arising in HHV8-Associated Multicentric Castleman's Disease

This tumor, arising in multicentric Castleman's disease and frequently in patients with HIV, resembles an IgM-producing plasmablastic lymphoma. CD20 and CD38 are variably expressed, CD79a and CD138 are negative, and EBER is negative. HHV-8 is detectable by IHC. The disease is aggressive.

Primary Effusion Lymphoma

This is another rare tumor presenting in serous effusions but without tumors. Cytology is usually immunoblastic or anaplastic. It is associated

Figure 33-66 Burkitt lymphoma (×500).

Figure 33-67 Burkitt lymphoma cytology (×1000).

with the Kaposi's sarcoma virus human herpesvirus-8 (HHV-8) in immunodeficient patients. Tumor cells label as B cells and have Ig rearrangements, although T cell varieties have been reported. EBV can usually be detected using in situ hybridization (ISH) for EBER, but EBV-latent membrane protein-1 is absent by immunohistochemistry (Said, 2011). The pathogenesis may be related to viral activation of the alternative NF- κ B pathway (Matta, 2004).

Burkitt Lymphoma

BL was first described in the jaws of African children by Dennis Burkitt in 1958 (Burkitt, 1958). It was first defined as a distinct tumor entity by the WHO in 1968 (Berard, 1985) and remains so in the current WHO classification (Leoncini, 2008). It represents approximately one third of pediatric NHL, but also occurs in adults. Several epidemiologic types of BL exist. The prototype is **endemic BL**, which occurs predominantly in children in Africa and other equatorial regions and is associated with EBV. **Sporadic BL** occurs worldwide in children and adults and is not usually associated with EBV. Patients with HIV or other immune suppression often have EBV-related BL, which is, however, different from the endemic form at the molecular level. BL is a highly proliferative tumor that grows very rapidly.

The tumor shows a diffuse infiltrate with pushing borders of medium-sized relatively uniform cells with round to oval nuclei containing three to five moderately prominent nucleoli in relatively clear parachromatin (Fig. 33-66). Cytoplasm is moderate and basophilic, and tends to square off between adjacent cells. Lipid-laden cytoplasmic vacuoles are seen in imprints (Fig. 33-67). Both high mitotic and high apoptotic rates are noted, along with a prominent pattern of "starry sky" macrophages. In most cases, the histology is distinctive, but some overlap is seen with both DLBCL and occasionally lymphoblastic lymphoma.

Burkitt leukemia/lymphoma exhibits leukemic cells with moderately clumped chromatin and basophilic vacuolated cytoplasm (see Fig. 33-66) with surface immunoglobulin restricted to one light chain. Typically, they show lack of TdT, presence of B cell antigens CD19, CD22, CD20, CD79a, and often CD10, and expression of monoclonal surface Ig. Rare cases show lack of surface membrane immunoglobulin or expression of TdT, and these require cytogenetic confirmation. Burkitt leukemia/lymphoma shows very high proliferative rates and rapid disease progression. Although the condition is rapidly fatal if untreated, recent results of therapy in pediatric patients have shown long-term survival of better

Figure 33-68 Atypical Burkitt or Burkitt-like lymphoma, with moderate pleomorphism and increased numbers of prominent nucleoli (×500).

than 90% (Patte, 2001). Outcome in adults has also improved, but long-term survival is less than in children (50%–70%) (Blum, 2004; Kasamon, 2004).

Burkitt leukemia/lymphoma shows characteristic cytogenetic abnormalities consisting of translocation of c-myc on chromosome region 8q24 to one of the immunoglobulin genes (heavy chain-14q32, κ -2q11, or λ -22q11) to give t(8;14), t(2;8), or t(8;22). Most cases show t(8;14)(q24;q32). C-myc promotes both proliferation and apoptosis (Le Beau, 2000) and presumably causes uncontrolled proliferation of immunoglobulin-bearing B cells. These cells are sensitive to chemotherapy, however.

B Cell Lymphoma, Unclassifiable, with Features Intermediate Between DLBCL and Burkitt Lymphoma

Cases of lymphoma occur with histologic and clinical features intermediate between Burkitt and large B cell lymphoma. The histology is similar to BL, except that generally more pleomorphism is seen with the presence of large cells (up to 25%) and medium-sized cells, and with greater irregularity of nuclei and more prominent nucleoli than in typical Burkitt (Fig. 33-68). Cytoplasm is usually less distinct than in BL.

Previously called Burkitt-like, non-Burkitt, or atypical Burkitt lymphoma, some cases were found to have bcl-2 and not c-myc abnormalities (Yano, 1992). The REAL classification placed most cases with this histology in the category of diffuse large B cell lymphoma.

In children, the clinical presentation is similar to Burkitt (Hutchison, 1989), although cytogenetic studies in one report did not show c-myc translocations (Lones, 2004). In other studies in adults, 8q24/MYC translocations have been reported in nearly half of patients (McClure, 2005) REF Bcl-2 along with c-myc translocations have been identified in some patients and are adverse features (MacPherson, 1999).

In a child with a rapidly growing tumor and presentation similar to Burkitt (such as ileocecal or other abdominal site, extranodal site with effusions, endocrine or gonadal sites, etc.), these are treated as BL (Cairo, 2003). Fixation and other technical artifacts blur the morphologic distinction, and classification shows greater interobserver variation than other pediatric lymphomas (Lones, 2000).

In adults, children with slower growing tumors, children with tumors with 90%–95% proliferation rates, and those with complex karyotypes, the classification becomes murky. The trend in treatment of large B cell lymphoma in young people is to use therapies designed for BL (Patte, 2001). In adults, the condition is often treated as DLBCL. There may be a role for more aggressive therapy, but this generally means increased morbidity, so it is controversial. However, aggressive pediatric regimens have been successfully tested in adults with BL (Nicola, 2004).

B Cell Lymphoma, Unclassifiable, with Features Intermediate Between DLBCL and Classical Hodgkin Lymphoma

These are essentially **gray zone tumors** with overlap features that prevent precise diagnosis. Mediastinum is often involved, and the differential diagnosis is usually between PMBL and classical HL. These disorders have shown overlap by gene expression studies, so it is not surprising that morphologic overlap occurs.

MATURE T CELL AND NATURAL KILLER CELL NEOPLASMS

T cell and NK cell lymphomas and leukemias are a diverse group of neoplasms which are uncommon to rare compared with B cell lymphomas. Although they account for only about 12% of lymphomas overall, an approximately equal number of categories is recognized by the WHO. Most of these are typified by clonal rearrangement of genes encoding CD3, the T cell receptor complex which is an antigen receptor of the immunoglobulin supergene family, although true NK cell neoplasms do not show clonal rearrangement by clinical tests (Cheuk, 2011). Features of major T/NK neoplasms are summarized in Table 33-21.

A majority of postthymic (peripheral) T cells express $\alpha\beta$ -chains of the T cell receptor (TCR); a small minority do not, but rather express $\gamma\delta$ -chains. NK cells express only ϵ -chains with cytoplasmic CD3. T cell clonality studies in the laboratory usually focus on $\gamma\delta$ -receptor rearrangement, which is present in all or most T cells. This is because in early T cell development, the γ - and β -chain genes rearrange simultaneously, with TCR commitment dependent on expression of surrogate α -chain and development of a pre-TCR (Haks, 1998; Kang, 2001). The repertoire of significant γ -gene "families" is much smaller (four to six) than β -families, and TCR- γ PCR assay is far more efficient for routine use than is TCR- β PCR, which requires approximately 25 different primer sets (Shadrach, 2004). TCR- γ PCR is also effective with DNA extracted from formalin and has largely replaced Southern blot analysis of TCR- β . Flow cytometry assays using antibodies for each TCR V β -family is also useful and rapid but requires a large number of antibodies, and RT-PCR for V β -family transcripts may be utilized (Langerak, 2001; Morice, 2004).

Mature $\alpha\beta$ T cells express CD2, CD3, CD5, CD7, and either CD4 or CD8. They are negative for TdT and CD1. Normal resting lymphoid tissue usually shows a CD4/CD8 ratio of 2:1. Differentiation to one or the other in the thymus involves activation or silencing of CD4 or CD8 from CD4+CD8+ cells, but is poorly understood (Yasutomo, 2000). Primarily mature CD4 cells proliferate in the postthymic environment (Foa, 1980). The CD4/CD8 ratio drops in acute inflammation and rises to often high levels in recovery and chronic inflammation, so that these are not good markers of clonality. Peripheral T cell neoplasms often lose expression of a normal pan-T cell antigen such as CD7 and show predominance of CD4 or CD8 (Knowles, 1989). Care must be taken to distinguish abnormal $\alpha\beta$ T cells from normal NK cells.

$\gamma\delta$ T cells typically are doubly negative for CD4 and CD8 and are also often CD5 negative with CD2 expression and show a maturation sequence of CD7. Because they usually account for only 1%–2% of normal T cells, an increase in these cells is a suspicious finding in itself. NK cells are highly variable in expression of pan-T cell antigens CD2 and CD7, are often CD5 negative, and typically express CD16 (a low-affinity Fc receptor also found on monocytes and granulocytes), with variable CD56 and CD57. CD3 is detectable in the cytoplasm with polyclonal antibodies but is also present on the surface in some NK neoplasms. Cytotoxic granule constituents TIA-1, granzyme-B, and perforin are usually present in NK cells and cytotoxic T cells.

T-Prolymphocytic Leukemia

T-prolymphocytic leukemia is an uncommon disorder with a median age of 69 years, and the disease is slightly more frequent in males than in females. Patients present with a marked lymphocytosis ($>100 \times 10^9/L$), anemia, and thrombocytopenia. In most cases, the neoplastic cell is a prolymphocyte with a prominent **punched-out** nucleolus showing distinct perinucleolar chromatin and moderately abundant cytoplasm. In approximately 20% of patients, however, the lymphocytes lack distinctive features and do not possess a prominent nucleolus. Hepatosplenomegaly, lymphadenopathy, and skin involvement are common (Campo, 2008).

The immunophenotype is most often CD4+ peripheral T cell (60%), with CD4/CD8 coexpression in 25%, and CD8+ in 15%. CD7 is strong, and surface CD3 weak.

There is clonal TCR $\alpha\beta$ (and $\gamma\delta$) rearrangement. In all, 80% show $inv(14)(q11;q32)$ and 10% $t(14;14)(q11;q32)$ involving TCR $\alpha\beta$ locus and oncogenes TCL1 and TCL1b. Chromosome 8 abnormalities $t(8;8)(p11-12;q12)$ or trisomy 8q is seen in 70%; other abnormalities include $t(X;14)(q28;q11)$ and deletions at 11q23.

T-prolymphocytic leukemia is a rapidly progressive malignancy with survival usually less than 1 year. Recent progress has been made with new therapies, including alemtuzumab (Campath-1H) (Dearden, 2001; Cao, 2003).

Figure 33-69 Large granular lymphocyte leukemia ($\times 1000$).

Large Granular Lymphocyte Leukemia

The median age of these patients is 63 years. Sixty percent to 70% of patients are symptomatic with recurrent infections due to neutropenia. Anemia or rheumatoid arthritis is also common (Lamy, 2003). Lymphocytosis is usually mild (up to $20 \times 10^9/L$), and lymphocyte number may be normal. Large granular lymphocyte (LGL) cells are usually at least $2 \times 10^9/L$ (Chan WC, 2008). Chronic neutropenia is frequent, splenomegaly may be present, and there may be anemia and/or thrombocytopenia. LGLs are at least relatively increased and show moderate size with abundant light blue cytoplasm and condensed chromatin. Azurophilic cytoplasmic granules vary in number and size (Fig. 33-69). The BM exhibits a moderate interstitial infiltrate of granulated lymphocytes. Erythroid and myeloid elements may be normal or hypoplastic in occasional cases. The spleen typically shows red pulp infiltrates.

The common variant is CD3/CD8/CD57/TCR $\alpha\beta$ +, CD4 negative. Uncommon variants express CD4 (Lima, 2003), dually express CD4 and CD8, show doubly negative CD4/CD8, and/or have variable expression of CD57 and CD56. Cases reactive with CD3 and CD56 tend to behave aggressively (Gentile, 1994). Cases of LGL leukemia following renal transplant have been seen (Gentile, 1998), along with those of donor origin following BM transplant (Au, 2003). Benign LGL lymphocytosis following BM transplant is likely related to the early emergence of LGL cells (Niederwieser, 1987).

TCR γ -gene rearrangement is usually clonal by PCR, and TCR- β is usually rearranged. Although a single clonal band usually confirms a suspicious diagnosis, PCR assays may show a dominant clone emerging from an oligoclonal population of autoimmune disorders. This, along with a typically indolent course, makes cases with low WBCs very difficult to diagnose. Low-dose methotrexate, cyclosporine, or cyclophosphamide often induces long-lasting remission (Lamy, 2003).

Chronic Lymphoproliferative Disorders of NK Cells

Chronic lymphocytosis of LCLs of NK phenotype occurs rarely. These are generally indolent asymptomatic processes that come to light as incidental findings or may be associated with neutropenia and/or anemia. They resemble LGL leukemia but are CD3 negative, with expression of CD16, dim CD56, cytotoxic granule markers TIA-1 and granzyme B and M, and variable CD2, CD7, and CD57. CD5 and CD8 are often expressed. KIR NK-receptors (NKR) are abnormally expressed in restricted or negative fashion, but are not frequently assayed in clinical laboratories. T cell receptors are not clonally rearranged, and no characteristic cytogenetic abnormalities of EBV are associated.

Aggressive NK Cell Leukemia

This is a rare aggressive leukemia of NK cells associated with EBV and usually occurring in Asian teens and young adults. It usually presents with constitutional symptoms. The WBC is variable and hepatosplenomegaly is common; it sometimes shows lymphadenopathy, hepatosplenomegaly, coagulopathy, hemophagocytic syndrome, and/or multiorgan failure (Cheuk, 2011).

Morphology of leukemic cells is variable, sometimes resembling LGL leukemia, sometimes showing larger lymphoid cells with condensed chromatin and basophilic cytoplasm, and sometimes showing blastic or transformed cells.

TABLE 33-21

Key Features of the Major Mature T and NK Cell Neoplasms

Lymphoma	Demographics; clinical and laboratory presentations	Morphology	CELL SURFACE MARKERS (TYPICAL PROFILE)		Gene rearranged, involved
			Positive	Negative	
T cell PLL	M > F; median age, 65 years; lymphocytosis $>100 \times 10^3/\mu\text{L}$, anemia, thrombocytopenia, HSM, skin lesions	Prolymphocyte	CD7; CD4 (60%), CD4/8 (25%), CD8 (15%)		TCR- $\gamma\delta$ TCR- $\alpha\beta$ inv(14) (q11;q32)
LGL leukemia	Median age, 63 years; neutropenia causing infection, anemia, mild lymphocytosis ($>2 \times 10^3/\mu\text{L}$)	Moderately sized cell with condensed chromatin, abundant pale blue cytoplasm, azurophilic granules	CD3, CD8, CD57, TCR- $\gamma\delta$; some variants are CD4+ or CD4/8+ or CD4/8-	CD4	TCR- $\gamma\delta$ TCR- $\alpha\beta$
Aggressive NK cell leukemia	Asian teens to young adults; constitutional symptoms, HSM, variable WBC count	Variable, may resemble LGL cells or appear blastic	cCD3 ϵ , CD2, CD56	sCD3, 57	TCR- $\gamma\delta$ TCR- $\alpha\beta$ Clonal EBV, del(6) (q21;q25)
Adult T cell leukemia/lymphoma	Associated with HTLV-1, frequent in Japan, Caribbean, Central Africa; acute variant with skin, lymph node involvement, hypercalcemia	Moderately large blastic cells with convoluted nuclei (floret cells), agranular, basophilic cytoplasm	CD2, CD3, CD4, CD5, CD25, often CD30	CD 7, 8	TCR- $\gamma\delta$ TCR- $\alpha\beta$
Extranodal NK/T cell lymphoma, nasal type	Most prevalent in Asia, Native Americans of Mexico and Central and South America	Angiocentric and destructive, involving upper aerodigestive tract	CD2, CD56, cytotoxic granules, cyto CD3 ϵ	Surface CD3	Germline receptor genes
Enteropathy-associated T cell lymphoma	All ages and regions; increased in celiac disease (may present concurrently), jejunum and ileum	Large cells with inflammatory background, occasionally monomorphic (type II) medium-sized cells	CD3, CD7, CD103; CD3, CD8, CD56 (type II)	CD4, CD5	TCR- $\gamma\delta$ TCR- $\alpha\beta$
Hepatosplenic T cell lymphoma	Rare, increased in adolescents and young adults and with chronic immunosuppressive therapy; involves liver/spleen/marrow	Medium-sized cells involving splenic red pulp and sinuses of liver and marrow	CD3, CD8 \pm , CD56 \pm	CD4, CD5, often CD4/CD8 double negative	TCR- $\gamma\delta$
Subcutaneous panniculitis-like T cell lymphoma	Rare, F > M; subcutaneous panniculitis with neoplastic cells	Involves fat lobules, spares septa, variable-sized monomorphic cells, rimming of fat cells, histiocytes	CD3, βF1 , CD8, cytotoxic granules	CD4, CD56	TCR- $\gamma\delta$ TCR- $\alpha\beta$
PTCL, NOS	Peripheral nodes, disseminated disease, sometimes cutaneous	Varies in cell size and from polymorphic to monomorphous	Variable with CD3, CD4, other pan-T cell markers	CD7, CD5, others often lost	TCR- $\gamma\delta$ TCR- $\alpha\beta$
Angioimmunoblastic T cell lymphoma	Middle-aged and elderly; generalized disease, systemic symptoms, hypergammaglobulinemia	Partial nodal effacement involving paracortex, increased venules, clear cell clusters, EBV+ B cells	CD3, CD2, CD5, CD4, (reactive CD8), CD10, CXCL13	CD8	TCR- $\gamma\delta$ TCR- $\alpha\beta$ +3, +5, +X
Mycosis fungoides/Sézary syndrome (SS)	M > F, middle-aged to older; dermatitis progressing to ulcerated lesions; PB involvement in SS	Dermal band-like infiltrates of lymphocytes with cerebriform nuclei, microabscesses	CD2, CD3, CD4	CD7, CD8	TCR- $\gamma\delta$ TCR- $\alpha\beta$
Primary cutaneous CD30-positive	M > F, adults to elderly; limited to skin lesions	Polymorphic lymphoid cells, some anaplastic	CD4, CD30	Often CD2, CD3, CD5, ALK	TCR- $\gamma\delta$ TCR- $\alpha\beta$
Anaplastic large cell lymphoma	M > F, teens, young adults; peripheral, abdominal adenopathy, extranodal and BM involvement, frequent B symptoms	Pleomorphic large cells, wreath-like nuclei, multiple nucleoli, abundant cytoplasm	CD30 (cytoplasmic and Golgi), CD2, CD4, CD5	CD3, CD7, EBV	TCR- $\gamma\delta$ TCR- $\alpha\beta$ t(2;5)(p23;q35) Other variants involve 2p23

BM, Bone marrow; EBV, Epstein-Barr virus; HSM, hepatosplenomegaly; HTLV, human T lymphotropic virus type 1; LGL, large granular lymphocyte; NK, natural killer; NOS, not otherwise specified; PB, peripheral blood; PLL, prolymphocytic leukemia; PTCL, peripheral T cell lymphoma; TCR, T cell receptor; WBC, white blood cell.

Figure 33-70 Natural killer cell leukemia in an adult, with floret cells resembling adult T cell leukemia.

The immunophenotype is surface CD3 negative and cytoplasmic CD3 ϵ /CD2/CD56 positive, and it expresses cytotoxic molecules (TIA-1, granzyme-B, and/or perforin). CD16 is variable, and CD57 negative.

TCR genes are not rearranged. Clonality may be established by detecting clonal episomal EBV (analyzing tandem repeats by Southern blot) or finding clonal cytogenetic abnormalities such as del(6)(q21;q25).

Indolent NK cell proliferation also occurs and is characterized by adult onset, lack of constitutional symptoms, lack of EBV, and a CD57+ phenotype (along with CD2, CD16, and CD56, with negative surface CD3) (Fig. 33-70).

EBV-Positive T Cell Lymphoproliferative Disorders of Childhood

These are rare lymphomas occurring most often in Asian or Native Americans from Central or South America that are associated with EBV. **Systemic EBV-positive T cell lymphoproliferative disease of childhood** is an aggressive, often fulminant disease following acute or chronic EBV infection and characterized by indistinct monoclonal infiltrates of small T cells, occasionally with some pleomorphism, associated with hepatosplenomegaly and hemophagocytic syndrome involving these organs and BM. Cells are mature T cells with CD2, CD3, and TIA-1 expression, variable CD4 (chronic EBV) or CD8 (acute EBV), and negative CD56. **Hydroa vacciniforme-like lymphoma** is an EBV-positive cutaneous T cell lymphoma of sun-exposed skin. The infiltrate is that of CD56+ cytotoxic T or NK cells predominantly involving the dermis. The disease course is variable and tends to be initially indolent, but more aggressive following dissemination.

Adult T Cell Leukemia-Lymphoma

Adult T cell leukemia-lymphoma (ATLL) is a highly variable but often clinically aggressive T cell leukemia/lymphoma associated with HTLV-1 retrovirus infection (Poiesz, 1980). It is most endemic in southwestern Japan but also in the Caribbean basin, the southeastern United States, and central Africa. Transmission of HTLV-1 may occur vertically (from mother to child), or through sexual contact, intravenous drug abuse, or blood transfusion. Only a minority of individuals infected with HTLV-1 (2.5%) develop ATLL, typically after a latent period of many years. Acute infection results in a flu-like syndrome.

The acute variant typically shows leukemia, skin involvement, generalized lymphadenopathy, lytic bone lesions, and hypercalcemia. The blood film demonstrates anemia and thrombocytopenia with the presence in blood and marrow of moderately large blastic cells with convoluted or clover-leafed nuclei and condensed chromatin (**floret cells**). Nucleoli are small or absent, and the cytoplasm is agranular and basophilic. Admixed blast-like cells are present. Marrow involvement is often patchy with increased osteoclastic activity. Skin lesions resemble mycosis fungoides, including the presence of Pautrier's microabscesses, but often with more pleomorphic cells.

Lymph nodes in acute or lymphomatous variants show highly variable morphology, often with features and diversity reminiscent of anaplastic large cell lymphoma (Jaffe, 2011). Histology may resemble common ALCL, small cell variant, HL, or typical large cell lymphoma (Fig. 33-71).

The chronic variant often resembles mycosis fungoides, and the smoldering variant shows low-level leukemic involvement with <5% circulating neoplastic cells. Clonal integration of HTLV-1 is an invariable finding and

Figure 33-71 Adult T cell leukemia/lymphoma, with anaplastic features ($\times 500$).

Figure 33-72 Nasal/nasal-like T/natural killer cell lymphoma, showing angioinvasion and destruction ($\times 200$).

is essentially diagnostic (Yamaguchi, 2002), but it should be noted that HTLV-1 infection is chronic, and these patients may have other hematologic diseases, just as other people do.

The immunophenotype of ATLL is CD2/CD3/CD5/CD25 positive, usually CD4+ and CD7 negative. CD30 is often positive, but ALK is negative. Cytotoxic markers are negative. TCR genes are clonally rearranged. Occasional patients with smoldering disease show a Hodgkin-like lymphoproliferative disorder of EBV-infected B cells with CD30 and CD15 expression, likely related to chronic immunosuppression. It may be noted that both HTLV-1 and EBV are potent inducers of CD30.

Extranodal NK/T Cell Lymphoma, Nasal Type

These lymphomas have been referred to as lethal midline granulomas, polymorphic reticulosis, and angiocentric T cell lymphoma. They are extranodal lymphomas usually of NK cell derivation which are associated with EBV and are most common in Asia and Latin America. They typically involve nasopharynx, palate, skin, GI tract, testes, or other sites. The hemophagocytic syndrome is sometimes associated (Cheuk, 2011).

The histology shows diffuse infiltrates of lymphoid cells of varying, often polymorphic, cytology, from small lymphocytes to large cells, immunoblasts, and/or anaplastic cells. Typically, mucosal ulcerations are present and some areas show an angiocentric and angioinvasive pattern (Fig. 33-72) with fibrinoid necrosis of vessels and associated infarction-like necrosis.

Immunophenotype is usually CD2/CD56 positive, with cCD3- ϵ and expression of cytotoxic molecules. CD43, CD45Ro, HLA-DR, CD25, CD95, and FAS ligand are also expressed, but CD4, CD8, CD5, CD16, and CD57 are negative.

TCR $\alpha\beta$ and $\gamma\delta$ and IgH genes are germline, but clonal episomal EBV is present. EBER ISH is positive. Del(6)(q21;q25) is occasionally described. Prognosis is variable.

Enteropathy-Associated T Cell Lymphoma

This is a clonal T cell malignancy of intraepithelial T cells. It is associated with celiac disease, but patients often present simultaneously with malabsorption and lymphoma (Swerdlow, 2008). It usually occurs in the jejunum or ileum, with other locations in or outside of the GI tract reported.

Morphology shows variable small, medium-sized to large neoplastic cells, often with pale to eosinophilic cytoplasm and eccentric angulated nuclei. In some cases, the cytology is similar to anaplastic large cell

Figure 33-73 Enteropathy-associated T cell lymphoma infiltrating the muscularis of the small bowel (x500).

Figure 33-75 Subcutaneous panniculitis-like T cell lymphoma (x500).

Figure 33-74 Hepatosplenic T cell lymphoma showing intrasinusoidal involvement of the bone marrow (x500).

Figure 33-76 Cutaneous T cell lymphoma, showing a large Pautrier's microabscess (x20).

lymphoma with wreath-like multinucleation and horseshoe nuclei (Fig. 33-73). Other cases have bland-appearing small lymphocytes. Histiocytes and eosinophils are often abundant.

The phenotype is CD3, CD7, CD103 positive, CD8 variable, CD4 negative, often with double-negative CD4/CD8. Small cell variants are CD8/CD56 positive. Cytotoxic molecules are expressed. TCR genes are clonally rearranged, and patients with celiac disease typically have HLA DQA1*0501 and DQB1*0201. This is usually an aggressive disease.

Hepatosplenic T Cell Lymphoma

This is a rare neoplasm, usually of $\gamma\delta$ T cells, which shows sinusoidal infiltration of spleen, liver, and BM. It is most common in adolescent or young adult males. Patients present with massive splenomegaly, hepatomegaly, pronounced thrombocytopenia, and sometimes leukocytosis and anemia (Swerdlow, 2008).

Histology shows diffuse splenic red pulp involvement by small to medium-sized lymphoid cells with slightly dispersed chromatin and moderate cytoplasm. Liver shows similar cells in sinuses. Diagnosis is best made in the BM with presence of a characteristic infiltration of sinuses but otherwise intact architecture and hematopoiesis (Fig. 33-74). Immunophenotyping of sections is extremely helpful because of inconspicuous morphology on H&E.

The immunophenotype is CD3 and TIA-1 positive, with double-negative CD4 and CD8, negative CD5, granzyme B, and perforin (Belhadj, 2003). TCR $\delta 1$ antibodies are positive and TCR $\alpha\beta$ negative, although some cases of $\alpha\beta$ type occur.

TCR γ PCR is positive, and TCR β occasionally positive. Most cases are EBV negative, but EBV-positive cases may occur (Taguchi, 2004). Isochromosome 7q is usually described, with occasional trisomy 8. The disease is aggressive, with early responses to therapy but usual relapse and progression. No data have been obtained from clinical trials.

Subcutaneous Panniculitis-like T Cell Lymphoma

Subcutaneous panniculitis-like T cell lymphoma (SPLTCL) is a neoplasm of cytotoxic T cells that usually occurs as multiple nodules in the subcutaneous fat of the trunk or extremities and mimics benign panniculitis. The overlying epidermis and dermis are not involved, but the septa of subcutaneous adipose are infiltrated. The lymphoid infiltrate is polymorphic and may be deceptively bland, although some large cells are usually present

(Fig. 33-75). There is rimming of fat cells by lymphocytes and usually vascular involvement with areas of necrosis and histiocytic infiltrates. Acute inflammatory cells are not typically present as they are in benign panniculitis, and multinucleated giant cells usually are not seen.

The immunophenotype is usually mature CD8+ T cell with expression of granzyme B, perforin, and TIA-1, with a genotype of clonal $\alpha\beta$ T cell type (Go, 2004). Twenty-five percent are $\gamma\delta$ T cell with double-negative CD4/CD8 and expression of CD56 (Swerdlow, 2008).

The disease is typically aggressive, and hemophagocytic syndrome is seen in about 37%. Median survival is approximately 27 months, but long-term remissions may be obtained with anthracycline-based therapy (Go, 2004).

Mycosis Fungoides and Sézary Syndrome

Mycosis fungoides (MF) occurs twice as frequently in men as in women. It usually affects individuals in their middle to late years.

The disorder first appears as an eczematoid, psoriasiform, or non-specific exfoliative dermatitis. The lesions tend to form plaques and then tumors that often ulcerate. Some patients develop generalized erythroderma.

Biopsies of the skin reveal band-like lymphocytic infiltrates in the dermis (see Fig. 33-71), often with admixed histiocytes and occasional eosinophils (LeBoit, 2011). T cells with irregular nuclei (Fig. 33-76) show single-cell infiltration of the epidermis and often form clusters known as Pautrier's abscesses (Fig. 33-77). These are usually accompanied by parakeratosis and acanthosis, typically with minimal or no spongiosis, and elongation of rete pegs. The nuclei of at least a portion of neoplastic cells typically have a cerebriform appearance. The extent of the cutaneous infiltrate is not always directly correlated with severity of disease. Communication with the dermatologist or other treating physician is important, and even subtle changes in a clinically suspicious patient should be taken seriously.

Phenotype is usually mature T cell with CD8 expression and lack of CD7, but this is not usually conclusive. TCR genes are clonally rearranged, and PCR analysis of formalin-fixed biopsy tissue should be attempted in suspicious cases.

In advanced stages of the disease, neoplastic cells infiltrate the lymph nodes, liver, spleen, and other organs. Early nodal involvement (category I) shows dermatopathic changes with scattered atypical cerebriform

Figure 33-77 Neoplastic lymphocytes with convoluted nuclei in mycosis fungoides (×1000).

Figure 33-79 Cutaneous anaplastic large cell lymphoma (×1000).

Figure 33-78 Sézary cell in the blood, along with a neutrophil (×1000).

Figure 33-80 Angioimmunoblastic lymphoma showing arborizing vessels and lymphoid infiltrate infiltrating fat. In other areas of this case, plasma cells and immunoblasts are present. Clear cells are also frequently present (×200).

lymphocytes. Category II shows partial nodal effacement, and category III shows diffuse involvement.

Rare atypical mononuclear cells with cerebriform nuclei (Sézary cells) may be present in the peripheral blood (Fig. 33-78). Lymphocytosis with these cells (especially in the erythemic patient) is called Sézary syndrome.

The disorder may follow a prolonged chronic course. However, following lymph node infiltration, the disease becomes more progressive, and death, usually due to infection, occurs within 2 years.

Therapy is topical in early cases. More advanced disease has been treated with PUVA, retinoids, α -interferon, and, more recently, alemtuzumab (Campath) (Pichardo, 2004) or vorinostat (Duvic, 2009).

Primary Cutaneous CD30-Positive T Cell Lymphoproliferative Disorder

This category in the WHO classification includes primary cutaneous ALK negative, lymphomatoid papulosis, and borderline lesions (Kadin, 2011). These disorders share the features of dermal infiltrates of polymorphic lymphoid cells, including variable proportions of anaplastic or Reed-Sternberg-like cells with expression of CD30, and a typically relapsing/remitting clinical course.

Cutaneous ALCL resembles systemic ALCL (Fig. 33-79), except that it is indolent and does not exhibit detectable ALK expression or genetic translocations. Lymphomatoid papulosis has been considered a variant of pityriasis lichenoides et varioliformis acuta (PLEVA), with an inverted vase-like lymphoid infiltrate containing variable numbers of CD30-positive large cells. It has been associated with HL in a number of instances.

Both disorders share the phenotype of CD4-positive mature T cells with variable loss of pan-T cell antigens, expression of cytotoxic molecules, and strong CD30 expression. ALK is negative, and *TCR* genes are clonally rearranged. Atypical regressing histiocytosis is an older term used for both disorders.

Primary Cutaneous $\gamma\delta$ T Cell Lymphoma

Primary cutaneous $\gamma\delta$ T cell lymphoma is a rare lymphoma of adults consisting of a heterogeneous pattern of presentation (dermal, epidermal, and/or subcutaneous) in the skin of adults comprising $\gamma\delta$ T cells. These express CD3, CD2, and CD56, often dually negative for CD4 and CD8 or CD8 positive, with lack of CD5 and β F1. They express TCR γ receptor,

and TCR- γ is clonally rearranged. Histologically, they may mimic SPLTCL or MF.

Primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T cell lymphoma is another rare cutaneous T cell lymphoma of cytotoxic T cells. Cells are small-medium or medium-large and often pleomorphic or blast-like. They express CD3, β F1, CD8, and granzymes B and TIA-1, with variable CD2 and CD7, but negative CD4 and CD5. These often resemble MF in their epidermotropism. The disease is aggressive.

Primary cutaneous CD4-positive small-medium T cell lymphoma is characterized by pleomorphic CD-positive T cells, without clinical patches or plaques (as seen in MF). They are CD3 and CD4 positive without CD30. Lesions are often localized. *TCR* genes are clonally rearranged, but the disease is indolent and is often treatable by excision.

Angioimmunoblastic T Cell Lymphoma

This disorder has been termed angioimmunoblastic lymphadenopathy with dysproteinemia (AILD) and abnormal immune response. It is a clonal T cell lymphoma that presents with constitutional symptoms and polyclonal hypergammaglobulinemia. Although once thought to be initially a reactive process with a spectrum of progression to lymphoma, it is now believed to be neoplastic from the onset.

Histology shows paracortical lymph node hyperplasia with depletion of lymphocytes, increased plasma cells, and prominent high endothelial postcapillary venules with PAS-positive hyalinization and “burned-out” residual follicles (Fig. 33-80). Clusters of lymphocytes with small nuclei but moderately abundant clear cytoplasm are usually present and increase in prominence with progression. The tumor is derived from follicular T-helper cells (THCs). The immunophenotype is mature T cell with CD4 predominance but often abundant reactive CD8 cells, coexpression of CD10, CXCL13, and PD-1, polyclonal plasma cells and B-immunoblasts, and prominent dendritic cells near vessels detected by CD21/CD23. CD20 is occasionally expressed, and secondary clonal B cell proliferations occur (Warnke, 2007).

TCR genes are usually rearranged and *IgH* genes are also rearranged in a minority of cases, at least some of which are associated with EBV and/or immunosuppression. Trisomy 3 or 5 or an additional X chromosome has been described. The disease is aggressive, and infectious complications are common (Swerdlow, 2008).

Figure 33-81 Peripheral T/natural killer cell lymphoma, unspecified; CD3 expression is seen in inset ($\times 1000$).

Peripheral T/NK Cell Lymphoma, Unspecified

Peripheral T/NK cell lymphoma (PTCL), unspecified, are characteristically diverse and may consist of sheets of large cells (Fig. 33-81), paracortical lymph node expansion by mixed small and large cells, clear cells, predominantly small cells, and cases with striking pleomorphism resembling ALCL or HL. Abnormal patterns of T-antigen expression are helpful for diagnosis. Pan-T cell antigens (CD3, CD2, CD5, CD7) are usually present in some combination, but one or more are often aberrantly not expressed. CD4+ cases are more frequent than CD8+, but both double-positive and double-negative cases may occur (Swerdlow, 2008). In paraffin sections, CD3, CD45Ro, and CD43 are helpful if positive, but the latter two are also present in myeloid tumors and some B cell lymphomas. CD68 is rarely expressed.

T-zone variant of PTCL, unspecified, shows paracortical expansion with preserved GCC. The cytomorphology is variable with small and medium-sized cells, lymphocytes, plasma cells, endothelial hyperplasia, and sometimes clusters of clear cells and/or cells resembling those in HL.

The lymphoepithelioid variant, formerly known as Lennert's lymphoma, exhibits clusters of epithelioid histiocytes.

These tumors are typically aggressive and often belie their sometimes bland or reactive appearance. Clonal rearrangement of *TCR* genes is essential for confident diagnosis.

Anaplastic Large Cell Lymphoma

ALCL was first recognized relatively recently as NHL reactive with the Hodgkin-associated antibody Ki-1 (anti-CD30) (Stein, 1985). Primary ALCL is most common in adolescents and young adults and accounts for about 10%–15% of pediatric lymphomas. Cases in young people were likely overlooked previous to routine immunophenotyping, and retrospective review shows that about half of pediatric large cell lymphomas have been of T cell phenotype with **polymorphic immunoblastic** morphology, which is now associated with ALCL (Hutchison, 1991). In addition, the morphology is variable and is not of itself diagnostic, and a variety of secondary ALCLs (including progressions of other lymphomas, post-transplant tumors, and EBV- and HTLV-1-associated lymphomas) also express CD30.

Primary ALCL appears associated with chromosomal abnormalities involving chromosome region 2p23 such as t(2;5)(p23;q35), in which the gene for a tyrosine kinase anaplastic lymphoma kinase is fused to that of the nucleolar shuttle protein nucleophosmin, with a resultant NPM-ALK fusion protein that is highly expressed (Morris, 1994). The terms ALKoma and ALK lymphoma have been proposed (Benharroch, 1998). Variant genetic abnormalities involving ALK also occur, usually with ALK overexpression (Falini, 1999). Secondary ALCL and primary cutaneous ALCL are usually ALK negative. The clinical implications of primary or secondary ALCL have not yet been fully elucidated.

ALCL usually shows diffuse infiltrates or aggregates of large, sometimes pleomorphic cells with abundant cytoplasm and indented or horseshoe-shaped nuclei and sometimes wreath-like multilobulated nuclei (Fig. 33-82). Lymph node sinus and superficial paracortical involvement are common, cohesive sheets of tumor cells often simulate carcinoma, and some cases show a polymorphic Hodgkin-like pattern. True Reed-Sternberg cells are not seen. Histologic variants include small cell and lymphohistiocytic types, but these also express ALK and show similar phenotype otherwise.

Essentially all exhibit CD30. Most primary cases in young people express ALK, which is usually both nuclear and cytoplasmic, but is only

Figure 33-82 Anaplastic large cell lymphoma in an adolescent ($\times 500$).

Figure 33-83 A Reed-Sternberg cell in a case of mixed cellularity Hodgkin lymphoma ($\times 1000$).

cytoplasmic in some genetic variants. Slightly more than half show peripheral T cell phenotype by IHC, but with variable expression of CD3, CD43, and CD45Ro. Variable expression of CD45, CD25, and EMA has also been noted. CD68 or CD15 is only occasionally expressed. T cell surface marker-negative cases have been referred to as **null**, but recent evidence suggests that even though up to 90% show *TCR* rearrangements, expression of *TCR* is typically defective (Bonzheim, 2004).

CD56 expression occurs and is related to adverse prognosis (Suzuki, 2000). Cytotoxic granules with labeling by marker TIA-1 are also described (Felgar, 1999). Signal transducer and activator of transcription 3 (STAT3) is often overexpressed, with activation of antiapoptotic pathways and increased expression of bcl-2, bcl-xl, surviving, and others, and decreased caspase-mediated apoptosis (Amin, 2004). Survivin expression in about half of cases is possibly associated with adverse outcome (Schlette, 2004). ALCL differs from HL in that ALK expression abrogates CD30 induction of NF- κ B, whereas CD30 activates NF- κ B in HL (Horie, 2004).

A majority exhibit t(2;5)(p23;q35), but variants are also seen, including t(1;2)(q25;p23) involving *TPM3*, which encodes a tropomyosin; inv(2)(p23;q35) involving *AT1C*; and t(2;3)(p23;q35) involving *TFG* (TRAFK-fused gene). These all show cytoplasmic without nuclear ALK. Other partner genes include *TPM4*, *CLTC*, *MSN*, *ALO17*, and *MYH9* (Lamant, 2003). Those with translocations involving the clathrin gene (*CLTC*-ALK) have been identified as large B cell lymphoma (CD20-negative, CD79a+), each with *IgH* rearrangement and *TCR* rearrangement combined. They show granular cytoplasmic staining with ALK. Cytogenetics showed t(2;17)(p23;q23) (De Paepe, 2003). Rare cases of B cell ALCL, with or without ALK, are classified by the WHO with LBCL.

HODGKIN LYMPHOMA

The nomenclature of HL, formerly called Hodgkin's disease, is little changed from that of the Rye Conference (Lukes, 1966). The hallmark of HL is the Hodgkin Reed-Sternberg (HRS vs. RS) cell, which is a large binucleated, multinucleated, or mononuclear (Hodgkin) cell with each nucleus bearing a very large inclusion-like nucleolus (Fig. 33-83). These neoplastic cells appear in an immunoproliferative background containing variable numbers of lymphocytes, histiocytes, eosinophils, and plasma cells. Degenerating "mummified" neoplastic cells are also often present.

TABLE 33-22

Key Features of Hodgkin Lymphomas

Lymphoma	Demographics, clinical presentation	Morphology	Cell surface markers	Prognosis
Nodular, lymphocyte predominant (NLPHL)	M > F, 30–50 years, with peripheral lymphadenopathy	Mononuclear cells with convoluted nuclei (popcorn or L&H cells) loosely aggregated in nodules of small B cells	CD45, CD20, bcl-6, J-chain, Oct-2, BOB.1, EBV absent in LP cells	Excellent for stages I, II
Nodular sclerosis	M = F, <30 years with mediastinal mass, occasional spleen or lung involvement; 40% have B symptoms; most patients present with stage II disease	Broad bands of collagen, nodules of lymphoid tissue with aggregates of HRS cells and lacunar cells, multinucleated variants	CD15, CD30, CD45-EBV in 1%–40%	Good with systemic therapy
Mixed cellularity	M > F; median age, 38 years; peripheral lymphadenopathy common, spleen, BM; B symptoms common; patients often stage III or IV	Classic HRS cells in mixture of lymphocytes, plasma cells, eosinophils, histiocytes	CD15, CD30, CD45-EBV in 75%	Good with systemic therapy
Lymphocyte depletion	M > F; median age, 30–37 years; B symptoms, advanced stage common; associated with HIV	Classic HRS cells common with paucity of background lymphocytes; pleomorphic HRS cells mimic sarcoma	CD15, CD30, CD45-EBV pos in HIV-affected patients	Associated with advanced stage
Lymphocyte-rich classical	M > F, older age; peripheral lymphadenopathy; B symptoms rare; most patients with stage I or II disease	Scattered classic HRS cells among numerous small lymphocytes; nodular growth pattern	CD15, CD30; Oct2 and BOB.1 vary; J-chain absent; EBV in 40%–75%	Good, similar to NLPHL

BM, Bone marrow; CHL, classical Hodgkin lymphoma; EBV, Epstein-Barr virus; F, female; HIV, human immunodeficiency virus; HRS, Hodgkin Reed-Sternberg; L&H, lymphocytic and histiocytic; LP, lymphoplasmacytic; M, male.

Figure 33-84 Dense fibrosis in a case of nodular sclerosis Hodgkin lymphoma (×200).

Figure 33-85 A cluster of Hodgkin Reed-Sternberg cells in a nodule of nodular sclerosis Hodgkin lymphoma (×500).

Classical Hodgkin Lymphoma

Mixed cellularity, nodular sclerosis, lymphocyte-depleted, and lymphocyte-rich classical subtypes have similar biology and are all referred to as “classical” HL (Stein, 2008). NLPHL appears to be a different entity (Fig. 33-84).

The most common phenotype of HRS cells in classical HL is expression of CD30, CD15, and fascin with absence of CD45 and T cell markers. B cell–associated markers CD20 and/or CD79 are expressed in a minority of cases (<30%) and are usually focal and weak. Occasional cases show strong CD20 expression. B cell transcription factors Oct2 and Bob.1 are absent, as is immunoglobulin J chain. Light chain immunoglobulin antibodies may show generalized cytoplasmic labeling. Standard Ig and TCR gene rearrangement studies are negative in classical HL, but sequencing of amplified single-cell *IgH* genes suggests that most cases of HL are derived from clonal B lymphocytes (Stein, 1999). EBV is associated with a substantial portion of cases of classical HL (Herbst, 1992).

HL may occur from early childhood to old age. Increased frequency is noted between 15 and 35 years and after age 50. Males predominate, especially in childhood; disease in females younger than age 30 is usually nodular sclerosis in type (Table 33-22).

Nodular Sclerosis

Nodular sclerosis (NS) is characterized by broad bands of collagen separating nodules of lymphoid tissue and the presence of **lacunar variants** of

Figure 33-86 Scattered Hodgkin Reed-Sternberg cells in mixed cellularity Hodgkin lymphoma (×500).

HRS cells with pale cytoplasm and variable nucleoli (Figs. 33-85 and 33-86). Classic HRS cells are variable in number. Fibrosis may be inconspicuous in early lesions, but neoplastic cell clustering is usually present.

NS HL is graded on the basis of the number of neoplastic cells. When sheets of neoplastic cells are present in 25% or more of nodules, the tumor is designated grade 2. This is frequently associated with necrosis and has

Figure 33-87 Lymphocyte-depleted Hodgkin lymphoma shows predominance of neoplastic cells with few lymphocytes (×500).

Figure 33-88 Lymphocyte predominant Hodgkin lymphoma, with lymphocyte and histiocytic cells showing round rather than popcorn nuclei (×500).

been termed syncytial variant. The NS variety of HL is common, often presenting as a mediastinal mass in a young woman.

Mixed Cellularity

Mixed cellularity shows a diffuse polymorphic infiltrate of lymphocytes, plasma cells, eosinophils, histiocytes, and Reed-Sternberg cells, which sometimes are numerous (Fig. 33-87). Necrosis and disorderly fibrosis may be present. This subtype is less common in young people than is NS, and it is the most frequent subtype with EBV involvement.

Lymphocyte Depletion

This type is uncommon, often presents at older age, and may be associated with diffuse fibrosis. Neoplastic cells predominate and lymphocytes are relatively diminished compared with other forms of HL (Fig. 33-88). It is sometimes associated with an acute febrile illness accompanied by pancytopenia and lymphocytopenia. BM involvement is common, but lymphocytosis and thrombocytosis, often seen in other types of HL, are usually absent (Neiman, 1973).

Normocytic anemia is seen in about 50% of HL cases. Leukocyte and platelet counts are variable, and eosinophilia may be present. Blood and marrow findings and many of the histologic features appear to be manifestations of host responses to the disease. Immunologic studies in HL have shown that cell-mediated immunity is defective when extensive disease is present.

Clinical staging defines Stage I disease as limited to lymph nodes in one anatomic region or two contiguous regions on one side of the diaphragm. Stage II disease involves more than two contiguous regions or two noncontiguous regions on one side of the diaphragm. Stage III disease is present on both sides of the diaphragm but is confined to lymphoid tissue. Stage IV disease involves BM or any other organ, in addition to lymphoid tissue. The incidence of BM involvement in untreated cases of HL is approximately 10% (Bartl, 1982a). All stages are additionally classified as “A” if systemic symptoms are absent and “B” if they are present. An aggressive approach to the management of HL has resulted in improved survival with many cures, especially in young patients.

Nodular Lymphocyte Predominant HL

The histology of NLPHL consists of effacement of lymph node architecture by a nodular infiltrate of small B cells with an associated follicular dendritic network and clustered or scattered large cells referred to as L&H cells, after the original Lukes and Butler terminology of lymphocytic and

histiocytic HL. Nodularity may be vague. L&H cells are variable in cytology from case to case, although they are usually more uniform within a case. The appearance most often described exhibits large nuclei with vesicular chromatin, moderately prominent nucleoli, and convoluted nuclei resembling popcorn (“popcorn cells”). Cytoplasm is moderate in amount and clear, retracted, or slightly eosinophilic. Probably more often, the neoplastic cells show round to oval nuclei with distinct eosinophilic or basophilic nucleoli, but less prominent than in HRS cells (see Fig. 33-84). With experience, these cells become distinctive. Occasional HRS cells may be seen but are not always present and rarely predominate. Their phenotype, however, is different from that of classic HRS cells. L&H cells are usually loosely aggregated in the centers of nodules but are scattered elsewhere.

The phenotype of L&H cells is mature B cell, expressing CD45, CD20, CD22, CD79a, bcl-6, BOB.1, Oct-2, CD75, and usually J-chain. CD30 is absent or weak, and EMA is frequently expressed. The nodules are composed mostly of B cells but with abundant admixed CD3 and CD3/CD57-positive T cells, which tend to form rosettes around L&H cells. These are not always present, but are diagnostically helpful when they are. Nodules contain a follicular dendritic network which may be illuminated by CD21, CD35, or CD23 antibodies (Pileri, 2002). Cytoplasmic Ig is present but does not appear clonal, even though B cells have been proven to be monoclonal by single-cell PCR (Atayar, 2011).

IgH is clonally rearranged by sensitive assays in the research setting, but this usually is not detectable in routine clinical laboratory settings. L&H cells are of germinal center or post-germinal center derivation with somatic mutations of *Ig* genes which are ongoing in about half of studied cases (Braeuninger, 1997; Pileri, 2002).

Progressive transformation of lymph node germinal centers (PTGC) has been described as a precursor lesion to NLPHL, but no relationship has been proven. Most cases of PTGC do not lead to lymphoma.

Nodular Lymphocyte-Rich Classical HL

Nodular lymphocyte-rich classical Hodgkin lymphoma (NLRCHL) is a type of HL that morphologically and clinically resembles NLPHL but shows immunophenotypic characteristics of classical Hodgkin lymphoma (CHL). Typically, germinal centers are preserved and HRS cells are found in the mantle zones. It usually presents in peripheral lymph nodes with early-stage disease. The HRS cells in this type express CD30 and uniformly lack immunoglobulin J-chain that is present in NLPHL (Agnagnostopoulos, 2000). Recent studies show overlap between NLRCHL and NLPHL in expression of B cell factors bcl-6, Oct-2, and Bob.1, which are variable in NLRCHL but nearly constant in NLPHL, with less frequent CD20 and EBV. (However, EBV-EBER positivity is rarely seen in LPHL.) CD15 and MUM-1 are more frequent in NLRCHL, and Pax-5 is expressed in most cases of both types (Nam-Cha, 2009). A large clinical study has shown that patients with NLRCHL are older than those with other CHL, and that response and outcome are excellent, resembling NLPHL (Shimabukuro-Vornhagen, 2005).

IMMUNODEFICIENCY-ASSOCIATED LYMPHOPROLIFERATIVE DISORDERS

Lymphomas and uncontrolled polyclonal lymphoid proliferations occur with increased frequency in patients with immune dysfunction. These dysfunctional states fall into three main categories: primary (congenital) immune deficiency states, HIV infection, and iatrogenic immunodeficiency, particularly due to posttransplant immunosuppression but also due to prolonged immunosuppressive therapy for other reasons.

Most of these are B cell lymphoproliferative disorders associated with infection or reactivation of EBV or other virus and include large B cell lymphoma and variants, BL, and polymorphic B cell hyperplasia. Hodgkin and peripheral T cell lymphomas occur rarely. See Table 33-23 for a summary of lymphoid diseases associated with EBV.

Primary immune deficiencies are rare disorders and include Wiskott-Aldrich syndrome (WAS), ataxia-telangiectasia (AT), common variable immunodeficiency syndrome (CVID), severe combined immunodeficiency (SCID), X-linked immunoproliferative disorder (XLP), Nijmegen breakage syndrome (NBS), and hyper-IgM syndrome (Lim, 2011).

ALPS is an autoimmune disorder that also causes lymphadenopathy and involves inherited mutations of the *FAS* gene, which blocks apoptosis. This involves different mutations of varying effect; it may be more common than was previously thought and may show adult onset in some cases (Oren, 2002). Hyper-IgM syndrome results from mutations in CD40

TABLE 33-23

EBV Associations

Mononucleosis-type illness
 Hodgkin lymphoma: MC > LR > NS; LD seen in HIV patients
 Immunodeficiency-associated lymphoproliferative disorders
 Posttransplant lymphoproliferative disorders
 Some DLBCL cases (associated w/inflammations, in elderly)
 Lymphomatoid granulosis
 Primary effusion lymphoma
 EBV+ lymphoproliferative disorders of childhood
 Burkitt lymphoma (endemic and HIV associated)
 Nasal NK-T cell lymphoma
 Angioimmunoblastic lymphoma
 Plasmablastic lymphoma

DLBCL, Diffuse large B cell lymphoma; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; LD, lymphocyte depletion; LR, lymphocyte rich classical; MC, mixed cellularity; NS, nodular sclerosis.

ligand with inhibition of T/B cell interaction and B cell maturation. AT and NBS are abnormalities of DNA repair. WAS is a syndrome of thrombocytopenia, skin rash, and recurrent infections which is fatal but curable by allogeneic BM transplantation.

Fatal EBV infectious mononucleosis is a common occurrence in XLP and SCID. Large B cell lymphomas are the most common tumors in most primary immunodeficiencies, and lymphomatoid granulomatosis is increased in WAS.

HIV-Associated Lymphomas

Inadequately treated HIV shows a markedly increased incidence of high-grade B cell lymphomas associated with EBV (Knowles, 1988; Said, 2011). These are primarily Burkitt, atypical Burkitt, and large B cell lymphoma. HIV-associated BL is similar to endemic Burkitt with EBV association and c-myc translocation but with different breakpoints (Haluska, 1989). BL with plasmacytoid differentiation is unique to HIV. MALT lymphomas occur even in children with HIV; HL and NK lymphomas occur rarely. Primary effusion lymphomas in HIV are due to KHSV/HHV-8 infection and are associated with Kaposi's sarcoma and multicentric Castleman's disease. The incidence of HIV-associated lymphoma has dropped substantially in developed nations since the introduction of HAART.

Posttransplant Lymphoproliferative Disorders

These are also EBV associated and result from chronic infection and/or reactivation (Collins, 2002). PTLDs are composed of a unique spectrum of lymphoproliferative disorders, which have been divided into morphologic categories (Swerdlow, 2011). In many cases, these tumors regress when immunosuppressive therapy is reduced, but this is unpredictable.

Plasmacytic hyperplasia (PH) is composed of numerous plasma cells and scattered immunoblasts. Infectious mononucleosis-like PTLTD shows paracortical expansion of lymph nodes with increased immunoblasts. Both are early or low-grade lesions with a slow progression.

Polymorphic PTLTD shows increased immunoblasts and plasma cells in a lymphoid background. Monomorphic PTLTD is essentially diffuse lymphoma, usually large B cell. A Hodgkin-like PTLTD is likely to be a large B cell lymphoma with Hodgkin-like features, previously called polymorphic immunoblastic in the Working Formulation (Fig. 33-89). Monomorphic T cell lymphomas also occur rarely.

A disorder similar to PTLTD also may occur with chronic immunosuppression for other reasons, such as the use of methotrexate in the treatment of rheumatoid arthritis. (See also previous descriptions of large B cell lymphomas of the elderly and those occurring in chronic inflammation, which are also EBV related.)

HISTIOCYTIC AND DENDRITIC CELL NEOPLASMS

These are rare disorders that affect lymph nodes and soft tissues, and occasionally the BM (Jaffe, 2008a).

Histiocytic sarcoma, also known as true histiocytic lymphoma, is a malignant tumor of noncirculating cells of monocyte macrophage lineage (Chang, 2011). The differential diagnosis includes monocytic leukemia

Figure 33-89 Large B cell lymphoma (anaplastic subtype) arising in polymorphic posttransplant lymphoproliferative disorder, in the gastrointestinal tract (x500).

Figure 33-90 Histiocytic sarcoma in a child. This case showed expression of monocytic markers and enzymes, lack of lymphoid markers, and lack of lymphoid gene rearrangements (x500).

and large B or peripheral T cell lymphoma. It resembles a large cell lymphoma or histiocytic sarcoma of monocytic lineage (Fig. 33-90). Tumor cells show nuclear features of malignancy. These label with CD68, lysozyme, α_1 -antitrypsin, and antichymotrypsin; others label with other monocyte macrophage markers (e.g., CD64, CD14). Some hemophagocytosis may be seen.

Hemophagocytic Syndromes

These are often mistaken for histiocytic malignancy. They present with hepatosplenomegaly, fever and other constitutional symptoms, cytopenias, and infiltrates of macrophages in involved organs, including BM with hemophagocytosis primarily of red blood cells (Fig. 33-91). Hemophagocytosis may be difficult to identify in occasional otherwise usual cases. These are usually associated with recent viral infection, EBV, or cytomegalovirus (CMV), but familial hemophagocytic syndromes may also occur.

The cause of the disorder is often cryptic, but frequently an aggressive course is followed. Approximately 60% of patients succumb within 2 months (Chen, 2004; Karras, 2004), but some patients respond to immune therapy.

Langerhans Histiocytosis

Langerhans cell histiocytosis (LCH) is a neoplastic proliferation of Langerhans cells, which are dendritic cells normally found primarily in the skin (Jaffe, 2008b). It presents in a variety of ways, including unifocal disease, usually in the bone, and occasionally in the lymph node, skin, or lung, of an adolescent or young adult. These have been termed eosinophilic granuloma. Multifocal unisystem disease usually involves bone of children with frequent spread to adjacent soft tissues, also known as Hand-Schüller-Christian disease. Skull involvement may lead to diabetes insipidus, tooth loss, or exophthalmos. Multiple lung lesions may be seen in adults. Multifocal multisystem disease, that is, Letterer-Siwe disease, occurs in infants. It is an aggressive disease with fever, skin rash, hepatosplenomegaly, lymphadenopathy, bone involvement, and pancytopenia.

Histologically, the disease consists of infiltrates of Langerhans cells. They resemble benign histiocytes but have a coffee bean-shaped nucleus with a linear central groove (Fig. 33-92). Variable numbers of eosinophils and lymphocytes are usually present. The infiltrates form nodules in bone, involve the upper dermis of the skin, and may involve lymph node sinuses and splenic red pulp. Giant cells are sometimes present but differ from

Figure 33-91 **A**, Histiocytic hyperplasia occurring in infection-associated hemophagocytic syndrome; this macrophage contains platelets as well as erythrocytes ($\times 1000$). Compare with **B**, a histiocyte containing cell debris in a patient with human immunodeficiency virus ($\times 1000$); **C**, an abnormal macrophage in Gaucher's disease ($\times 1000$); and **D**, one in Niemann-Pick disease ($\times 1000$).

Figure 33-92 Langerhans cell histiocytosis, showing typical nuclear folding and grooves ($\times 500$).

multinucleated histiocytes (as in juvenile xanthogranuloma) by the presence of characteristic nuclei.

Immunophenotyping shows reactivity for CD1a and S-100 protein and may be weakly reactive with CD45 and CD68, but is negative for T and B cell-specific antibodies and follicular dendritic markers CD21 and CD35. Electron microscopy remains useful in some cases because of characteristic Birbeck granules, which are pentalaminar racket-shaped structures pathognomonic of Langerhans cells.

Outcome is largely dependent on extent of organ involvement, with localized disease showing a high rate of event-free survival and extensive disease showing only a variable response to chemotherapy. Pulmonary disease in adults may remit spontaneously on cessation of smoking.

A cytologically malignant form of LCH has been termed Langerhans cell sarcoma (Swerdlow, 2008). Patients usually present with multiorgan disease, a high mitotic rate, and aggressive behavior.

Interdigitating Dendritic Cell Sarcoma/Tumor

Interdigitating dendritic cell sarcoma/tumor (IDCS) is a rare tumor of lymph node paracortical interdigitating dendritic cells (Weiss, 2008b). It has the gross and microscopic appearance of a sarcoma and is tan in color, with a firm lobulated appearance, sometimes with hemorrhage or necrosis and microscopic fascicles, whorls, and/or a storiform pattern. Lymphocytes are scattered throughout, and plump epithelioid cells may be present. Atypia is variable.

Immunophenotyping is essential to diagnosis. The tumor cells are positive for S-100, with variable weak positivity for CD45 and monocyte markers CD68 and lysozyme. CD1a, CD21, and CD35 are negative. Other myeloid B and T cell markers, EMA, and CD30 are also negative. Background lymphocytes are reactive T cells. Prognosis is variable.

Follicular Dendritic Cell Sarcoma/Tumor

This is another rare dendritic cell tumor derived from follicular dendritic cells, which are phenotypically different from IDCS (Chan JKC, 2008). Involvement is usually with cervical lymph nodes, with axillary, mediastinal, mesenteric, and retroperitoneal node involvement also described. Microscopically, nodes show fascicles, a storiform pattern, and/or complete whorls.

The immunophenotype shows positivity for CD21, CD23, and CD35, with variable S-100 and CD68, negative CD1a, and occasional CD45 and CD20. Other myeloid T and B cell markers, cytokeratins, and HMB-45 are negative. CD117 is also negative (Hornick, 2002).

These tumors are indolent, with frequent good response to simple resection.

Dendritic Cell Sarcoma, Not Otherwise Specified

Dendritic cell sarcomas which do not fall into the previous specific categories may be termed DCS, not otherwise specified (Weiss, 2008a). They include indeterminate cell sarcomas that express CD1a and S-100 without Birbeck granules, and fibroblastic reticular cell tumor.

- Flow cytometry is a powerful, rapid, and cost-effective technique for the identification and monitoring of hematopoietic neoplasms.
- Successful implementation of flow cytometry requires careful attention to details of instrument and reagent performance.
- Normal hematopoietic cells are characterized by a reproducible gain and loss of antigen expression with maturation.
- Hematopoietic neoplasms show deviation from the normal patterns of antigen expression, allowing for their diagnosis and classification.
- The flow cytometric detection of residual disease following therapy allows for the monitoring of therapeutic response.

The diagnosis, classification, and post-therapeutic monitoring of hematopoietic neoplasms have greatly benefited from the widespread application of immunophenotypic studies over the past two decades. The subdivision of hematopoietic neoplasms by their correspondence to normal hematopoietic lineages and stages of differentiation is a basic tenet of current classification systems (e.g., the World Health Organization [WHO] classification) (Swerdlow, 2008). This information is largely provided by immunophenotyping and has resulted in the incorporation of immunophenotypic data into the definition of many hematopoietic neoplasms to the extent that certain diagnoses cannot be confidently made without immunophenotypic studies.

Flow cytometry is a rapid and convenient technique for generating immunophenotypic data. The ability to perform multiparametric analysis on an individual cellular basis is a unique feature of the technique and offers distinct advantages over competing immunophenotypic methods such as immunohistochemistry. Guidelines on the use of flow cytometry for the immunophenotyping of leukemic cells in the clinical laboratory have been published (Clinical and Laboratory Standards Institute, 2007), and National Institutes of Health-sponsored consensus conferences on the flow cytometric analysis of leukemia and lymphoma were convened in 1995 (U.S.-Canadian Conference, 1997) and 2006 (Davis, 2007; Wood 2007) to attempt standardization of clinical practice. Despite these efforts, considerable heterogeneity exists in the clinical application of this technique to the evaluation of leukemia and lymphoma, and this lack of standardization represents a significant challenge to the ability to consistently provide high-quality results.

Medical indications for performing flow cytometry in a clinical setting currently can be divided into four basic areas:

1. The diagnosis and classification of hematopoietic neoplasms. The ability to accurately identify abnormal subpopulations of cells, assign lineage, and determine maturational stage adds improved reproducibility to the diagnosis of hematopoietic neoplasms, particularly for chronic lymphoproliferative disorders and acute leukemias. Flow cytometry is widely used for this purpose.
2. Assessment of biological parameters associated with prognosis. The expression of specific molecules at the time of diagnosis has been associated with long-term clinical outcome and can be easily assessed by flow cytometry. An example is the expression of CD38 or Zap-70 in chronic lymphocytic leukemia (CLL), where increased expression of either has been associated with poor long-term survival (Damle, 1999; Crespo, 2003).
3. Detection of antigens used as therapeutic targets. A variety of immunologic reagents are now available for therapeutic use that specifically target antigens expressed by hematopoietic neoplasms (e.g., CD20, CD52, CD33). Confirmation of expression of the antigen of interest by the tumor is a necessary prerequisite for use of these expensive therapies.
4. Detection of residual neoplastic cells following therapy. The ability of flow cytometry to routinely identify and quantitate the presence of abnormal hematopoietic cells with a sensitivity of 0.01% is increasingly being used as a surrogate measure of response to therapy and impending relapse (Campana, 2003).

**TECHNICAL CONSIDERATIONS
INSTRUMENTATION**

The basic principle of flow cytometry relies on the injection of a mono-disperse suspension of particles (cells) into the center of a flowing stream of fluid (sheath) that then passes through a small quartz capillary tube at a constant velocity (Shapiro, 2003). The sheath fluid serves to maintain the particles in the center of the flowing stream, where they may be illuminated by one or more focused light sources, typically lasers. The light scattered by the particles is collected by detectors positioned at a variety of angles around the capillary to obtain information about the cross-sectional area, and hence size (low angle or forward scatter) or complexity/granularity (high angle or side scatter), of each individual particle as it transits the capillary. In addition, if fluorescent molecules or fluorochromes are attached to the particles, they may be excited by the incident light, giving rise to fluorescent emission that can be collected with the use of additional detectors and optical filters (Fig. 34-1). The net result is a

Figure 34-1 Schematic of a flow cytometer. A flowing stream of particles (center) is illuminated by a laser (left) and the resulting low angle (forward scatter) or right angle (side scatter) light scatter collected by appropriately positioned detectors. In addition, fluorescent molecules attached to the particles may be excited by the laser light and the resulting emission routed through a series of optical mirrors and filters to the appropriate detectors (fluorescence 1 and fluorescence 2).

multiparametric analysis of each individual particle with the number of parameters evaluated dependent on the number of fluorescent molecules used and the complexity of instrument design. Modern clinical instrumentation is capable of assessing up to 10 simultaneous fluorochromes (Wood, 2006).

Optimization and standardization of instrument performance are critical for the success of any flow cytometric study, but are of particular importance in the analysis of hematopoietic neoplasms because of the wide range of signal intensities that must be detected. The preferred approach is to define a set of instrument conditions that allow for optimal instrument performance and perform daily quality control of the instrument to consistently achieve that level of performance. Adherence to a consistent and fixed level of instrument performance greatly simplifies quality control and provides reproducible data for subsequent interpretation. Daily assessment of the fluorescence intensity and coefficient of variation, using particles that have stable, moderately bright fluorescence and assessment of instrument noise using nonfluorescent particles, is the cornerstone of instrument quality control.

The operator has control over relatively few instrument variables on a flow cytometer, principally detection threshold, detector gain, rate of sample flow and, for some multilaser instruments, laser delay time. The detection threshold or discriminator is associated with a single parameter and is the value that must be achieved for the system to recognize that a particle has passed through the capillary to initiate signal processing. Typically, forward scatter is used to identify particles that have a size greater than some desired value (e.g., cells equal to or larger than lymphocytes). Of particular importance is the gain or voltage supplied to each detector, commonly a photomultiplier tube, as this has a direct impact on the ability to separate signals of interest from background instrument noise (signal-to-noise ratio). The voltage applied to each detector should be adjusted to optimize the signal-to-noise ratio and allow detection of the weakest required signals for each detector. This often results in positioning of negative cellular populations in such a way that they completely occupy the lowest decade of a logarithmic scale. Finally, for instruments having multiple lasers that intersect the capillary stream at different points (spatially separated lasers), a parameter must be supplied to allow synchronization of signal processing to account for the different times at which a single particle encounters each laser as it transits through the capillary. This laser delay time should be adjusted to maximize signal intensity for each laser. It should be noted that the laser delay time is highly dependent on the transit time of the particle through the capillary, and so requires a stable fluidic system to remain constant—a problem historically on certain instruments.

The rate at which the sample is introduced or aspirated through the system can be controlled by the operator but is limited by two factors: the rate at which the instrument electronics can process signals that are generated, and sample concentration. If particles pass through the instrument more rapidly than they can be processed by the electronics, the data for a subset of the particles will be lost, and another subset will show unusual and undesirable artifacts, typically variable loss of signal intensity over a

wide range. It is critically important to select a sample aspiration rate and concentration appropriate to the instrument to be used. One additional phenomenon related to sample concentration is termed **coincidence**, the simultaneous presence of more than one particle in the laser, resulting in a single recorded event that has composite characteristics of the particles involved. Coincidence can represent a significant problem for rare event detection and can be minimized using methods for doublet discrimination during analysis—techniques beyond the scope of this chapter (Wood, 2006).

REAGENTS

The identification of cellular characteristics beyond those provided by light scatter measurements commonly utilizes fluorochromes that directly interact with cellular structures such as DNA or that indirectly interact through conjugation to antibodies. Each fluorochrome has a unique excitation and emission spectrum that partly determines the performance characteristics of the reagent and dictates which fluorochromes may be used simultaneously (Fig. 34-2). In an effort to increase the number of usable simultaneous fluorochromes possible from a single excitation source, tandem fluorochromes have been devised (e.g., PE-Cy5) that rely on excitation of a primary fluorochrome that transfers its energy to a secondary fluorochrome (Cy5), providing the predominant fluorochrome emission at a longer wavelength. Tandem fluorochromes are required for high-level multicolor flow cytometry, but they have more complex emission spectra, as well as decreased fluorochrome stability under some circumstances. The other important fluorochrome characteristic, the intensity of emission, is related to the relative efficiency of excitation by the light sources utilized and the quantum efficiency of the fluorochrome itself (Fig. 34-3). Differences in emission intensity directly correlate with differences in detection sensitivity and are a key consideration in the design of reagent panels, as discussed later.

The use of multiple simultaneous fluorochromes (i.e., multicolor flow cytometry) is required for the analysis of leukemia and lymphoma, with three being the minimum number recommended under current consensus guidelines (U.S.-Canadian Consensus, 1997). Because most fluorochromes have overlapping emission spectra, determination of the fluorescence due to a specific fluorochrome in a single detector requires subtraction of the portion of the signals contributed by each of the other fluorochromes in the sample, a process termed **compensation**. The appropriate amount of each signal to subtract (i.e., compensation coefficient) may be represented by an n -by- n matrix, where n is the number of fluorochromes. Consequently, as the number of fluorochromes used increases, the number of compensation coefficients that must be determined increases geometrically, and software rapidly becomes required to do this process correctly. To determine the compensation coefficients, a series of samples singly labeled with each fluorochrome are evaluated, with the positive population as bright as the brightest signal one plans to evaluate. Because the spectral characteristics of the tandem fluorochromes can vary significantly between lots and manufacturers, separate compensation controls are often required for each lot and conjugate of these reagents. Software, either on the instrument or on offline computers, is used to analyze the resulting data and to calculate compensation coefficients.

Although the process of determining and correctly applying compensation is now made simple through software, the use of multiple fluorochromes can result in significant display artifacts that reflect compromised low-level detection sensitivity (Roederer, 2001). This is a particular problem when one attempts to detect low-level signals in the presence of brightly overlapping fluorochrome emissions. Understanding the impact of compensation-related effects is the single most difficult aspect of multicolor flow cytometry and the least understood by most users. The implications of overlapping fluorochrome emission have direct consequences for panel design and data interpretation (Fig. 34-4). When compensation settings are not appropriate for the reagents used, artifacts arise that can lead to both the misattribution of low-level positivity and an inability to recognize the presence of subpopulations (Fig. 34-5). The use of software compensation provides a nondestructive method for data collection and allows the adjustment of compensation settings following acquisition, thereby supplying a way to correct for inadvertent compensation errors.

Antibodies are an integral part of the immunophenotypic evaluation of leukemia and lymphoma. It is important to determine the correct amount of each antibody to use by evaluating a series of samples labeled with different concentrations of antibodies (i.e., titrating) (Stewart, 2000). The object of titrating is to maximize the signal-to-noise ratio by providing as bright a signal as possible on positive populations, while maintaining a low

Figure 34-2 Fluorochrome emission spectra. Each fluorescent molecule possesses a characteristic absorption (dotted line) and emission spectrum (solid line) whose wavelength maxima are spectrally separated; the degree of separation is termed the **Stokes shift**. Although a small amount of fluorescein emission occurs at the same wavelength as phycoerythrin, the fluorescence emission of fluorescein (green) can be separated from that of phycoerythrin (orange) using appropriate optical filters (shaded areas). The 488-nm laser commonly used to excite each of these fluorochromes is indicated by a black, vertical line.

Figure 34-3 Comparison of fluorochrome emission intensity. Fluorochromes are characterized by differences in relative intensity of emission that are important to take into account to achieve optimal sensitivity. The relative fluorescence intensity for CD4 expression on lymphocytes is pictured for fluorescein (FITC) (blue), phycoerythrin (PE) (green), PE-Texas-Red (orange), PE-Cy5 (yellow), PerCP-Cy5.5 (red), PE-Cy7 (light blue), allophycocyanin (APC) (magenta), and APC-Cy7 (purple). The actual intensities observed are dependent on the clone of antibody used, the ratio of fluorochrome to protein in the antibody conjugate, the method of specimen preparation used, the instrument performance characteristics, and the method of instrument setup.

level of background nonspecific binding. For high-specificity antibodies used for cell surface labeling, one should be able to achieve saturation, a consistent intensity on positive populations at higher antibody concentrations, without significant increases in background on negative populations. The inability to do so indicates a poor-quality antibody. For intracellular labeling, saturation typically is not achieved because of relatively high levels of nonspecific antibody binding by intracellular constituents, generally a linear function of antibody concentration, and optimization of signal-to-noise by titrating becomes critical for adequate reagent performance.

PANEL DESIGN

The pairing of reagents with appropriate fluorochromes is a key factor in ensuring appropriate signal intensity and detection sensitivity. The following four steps can aid in the construction of appropriate reagent panels:

1. Determine the purpose for each potential combination of reagents. Each reagent combination should have a clearly defined objective or should not be further pursued.

2. Select a group of cellular targets. The selected group of targets or antigens should be able to successfully address the purpose of the reagent combination and should be relatively independent of fluorochrome or availability of commercial conjugates. The reagent combination should be the minimum needed to answer the question being asked. Antibodies are commonly combined in a variety of ways for use in the identification of abnormal hematopoietic populations, but these generally fall into one of the categories outlined in Table 34-1.
3. Assign a fluorochrome to each target. The basic principle is that highly expressed antigens should be coupled with dim fluorochromes, and dimly expressed antigens should be coupled with bright fluorochromes. This principle provides reasonable signal intensities and avoids compensation problems due to excessively bright fluorescence. Commercial availability often limits the choice of fluorochromes, although most companies offer custom conjugation services that can provide reagents that might be better suited to a particular purpose than those more generally available.

Figure 34-4 Compensation. The fluorescence emission of lymphocytes labeled with CD8-PE appears in both PE and PE-Texas Red detectors as the result of emission of PE in both regions of the spectrum examined by these detectors. Note that no PE-Texas Red conjugated antibody is used in this experiment. Without compensation applied (*left*), cells expressing abundant CD8 show bright signals for both PE and PE-Texas Red with a width to the population (*arrows*) due to measurement errors inherent in the method. Once compensation is correctly applied (*right*), the centers of the positive and negative populations have the same low level of PE-Texas Red emission (*dotted line*), with many events lying on the horizontal axis. However, the PE-positive population shows a much broader degree of apparent PE-Texas Red background fluorescence than the PE-negative population (*solid line and arrow*). If a PE-Texas Red conjugated antibody had been used, CD8-positive cells might have been erroneously interpreted as doubly positive, but this apparent “positivity” is a direct result of measurement errors and logarithmic data display. The practical result is that the sensitivity for the detection of low-level PE-Texas Red is compromised in the presence of bright PE fluorescence.

Figure 34-5 Inappropriate compensation. The fluorescence emission of lymphocytes singly labeled with CD8-FITC shows minimal apparent PE fluorescence when 8% of the FITC signal is subtracted from the PE signal (i.e., appropriate compensation) (*left*). If the degree of compensation is decreased to 7.2% (*center*), the CD8-positive population appears to express low PE and could be misinterpreted as immunophenotypic aberrancy, depending on the PE antibody included. Note the lack of symmetry and the pointed end of the positive population as a clue to the inaccurate compensation. If the compensation is increased to 8.8%, the positive population is compressed on the x-axis and appears not to exist.

4. Test reagent combinations. The reagent combination must be empirically tested to ensure that signal intensities are as expected, that low-level sensitivity is appropriate where important, and that unexpected interactions between reagents do not occur. A sample prepared with all reagents of interest should be compared with the same sample prepared with a series of preparations, each lacking one of the component reagents (fluorescence-minus-one controls), as well as with a second series containing each single reagent independently (single-stained controls). Unexpected changes in intensity of one or more reagents indicate potential problems with the reagent combination.

SPECIMEN HANDLING AND SAMPLE PREPARATION

Any specimen from which a single cell suspension can be generated is suitable for flow cytometric immunophenotyping, including peripheral blood, bone marrow, and lymph node, to name a few. Blood and bone marrow may be anticoagulated with ethylenediaminetetraacetic acid, heparin, or acid citrate dextrose, with heparin generally preferred because of improved stability with specimen age. Tissue specimens are best transported and stored in tissue culture media, such as RPMI 1640, and a single cell suspension is generated by mechanical dissociation using scalpel and

TABLE 34-1
Reagent Panel Design Strategies for the Detection of Hematopoietic Neoplasms

Principle	Example implementation
At least one reagent for population identification	CD45 for general cell type Lineage-associated antigen for specific cell lineage (e.g., CD19 for B cells)
Multiple antigens of same lineage and maturational stage to identify inappropriate expression levels	Use of CD2, CD3, CD4, CD5, CD7, or CD8 simultaneously to evaluate mature T cells
Multiple antigens of same lineage but different maturational stages to identify normal maturation and asynchronous expression	Use of CD13 and CD16 simultaneously to demonstrate neutrophilic maturation
Separation of different cell lineages	Use of CD11b and CD15 simultaneously to separate monocytic and neutrophilic maturation
Demonstration of clonality	Use of κ and λ in combination with a B cell lineage reagent (e.g., CD19)
Identification of frankly aberrant antigen expression	Use of T or NK cell-associated antigens such as CD7 or CD56 in combination with CD34

NK, Natural killer.

forceps, needle and syringe, or wire screen mesh (Braylan, 1989), followed by filtration through fine-gauge wire mesh to remove aggregates. Specimens of all types are commonly stored at room temperature before preparation, although refrigeration will retard degradation when preparation must be delayed.

Analysis of white blood cells in peripheral blood or bone marrow requires erythrocyte removal for efficient evaluation. Density-gradient centrifugation (e.g., ficoll-hypaque) was historically used for this purpose, but it leads to selective loss of cellular subpopulations and gives relatively poor recovery on bone marrow specimens. Erythrocyte lysis using ammonium chloride or a variety of commercial preparations has become the standard technique for sample preparation in clinical laboratories (Carter, 1992). Currently recommended methods involve the addition of antibodies to an aliquot of blood or marrow, followed by erythrocyte lysis and washing with a buffered salt solution such as phosphate buffered saline to remove cell debris, the lysing reagent, and unbound antibody. Inclusion of a small amount of formaldehyde (0.25%–0.5%) with the lysing reagent or following washing is a convenient way to stabilize both antibody binding and specimen stability. When analysis of light chain expression on B cells is required, plasma immunoglobulin (Ig) must be removed by repeated washing before antibody addition. Once prepared, samples should be acquired on the instrument as soon as reasonably possible to avoid sample and fluorochrome degradation, although fixation and refrigerated storage will delay degradation.

DATA ACQUISITION

As the prepared sample is evaluated on the flow cytometer, it is important to collect enough events to allow detection of the population of interest. For populations that represent a large percentage of the total, relatively few events need to be acquired, but infrequent populations require the acquisition of larger numbers of events. Because in the evaluation of hematopoietic neoplasms, one rarely knows what the likely population frequency will be for a given sample, it is most convenient to acquire a fixed number of total events that ensures the desired minimum level of sensitivity. For example, if a sensitivity of 0.1% is desired and 50 events are determined to be adequate for confident population identification, then 50,000 total white blood cell events will need to be acquired. The acquisition of fewer events will compromise the ability to detect low-frequency populations—an important consideration when evaluating for residual disease following therapy and in situations where the acquisition of a larger number of events is often desirable.

Instrument carryover between samples becomes a significant concern when evaluating for the presence of small abnormal populations. Most commercial instruments have a manufacturer's specification for carryover

of roughly 1%—a relatively high level when one is looking for infrequent populations. To minimize carryover, a small amount of water should be run between each aliquot of sample acquired until background returns to an acceptably low level. Failure to do so will result in the sporadic appearance of populations having unexpected immunophenotypes that can be mistaken for neoplastic disease.

INTERPRETIVE CONSIDERATIONS

The identification of hematopoietic neoplasia by immunophenotyping relies on the principle that neoplastic cells express patterns of antigen expression that are distinctly different from those of their normal counterparts. Antigen expression in normal cells is a tightly regulated process, resulting in a characteristic pattern of antigen acquisition and loss with maturation that is cell lineage specific. Neoplastic cells commonly show nonrandom alterations in antigen expression that include the following:

1. Gain of antigens not normally expressed by cell type or lineage.
2. Abnormally increased or decreased levels of expression (intensities) of antigens normally expressed by cell type or lineage, including the complete loss of normal antigens in some instances.
3. Asynchronous antigen expression (i.e., expression of antigens normally expressed by cell type or lineage), but at an inappropriate time during maturation.
4. Abnormally homogeneous expression of one or more antigens by a population that normally exhibits more heterogeneous expression.

The consequence is that the immunophenotypic identification of hematopoietic neoplasia rests on a thorough knowledge of the normal patterns of antigens expressed by hematopoietic cells.

NORMAL PATTERNS OF ANTIGEN EXPRESSION

All hematopoietic cells arise from the hematopoietic stem cell, a quiescent cell population that possesses long-term regenerative potential and is present at a low frequency in the bone marrow. The stem cell population in humans can be identified if a sufficient number of cells are evaluated and show expression of bright CD34 and CD133, intermediate CD45, dim to absent CD38, variable CD90, and dim CD123, CD117, HLA-DR, CD13, and CD33. Maturation toward lineage-committed progenitors is accompanied by a slight decrease in CD34 and CD45, loss of CD133 and CD90, and an increase in CD38 and HLA-DR. Further maturation along each lineage occurs in the bone marrow until mature, functional, albeit naive progeny are released into the peripheral blood. The one exception is T cells, whose earliest precursors migrate to the thymus, where maturation to functional forms occurs. The patterns of antigenic change with maturation for B cell, T cell, neutrophilic, monocytic, and erythroid lineages have been elucidated by multiple investigators (Loken, 1987, 1988; Inghirami, 1990; Terstappen, 1990a; Terstappen, 1990b; Terstappen, 1990c; Terstappen, 1992b; Harada, 1993; Hoffkes, 1996; Ginaldi, 1996b; Almasri, 1998; Lucio, 1999; McClanahan, 1999; Wood, 2004), and a summary of each lineage is presented in Figures 34-6 through 34-10, respectively.

ABNORMAL PATTERNS OF ANTIGENIC EXPRESSION IN HEMATOPOIETIC NEOPLASIA

Most hematopoietic neoplasms have abnormal immunophenotypes that are characteristic enough to allow their detection, even at relatively low levels of involvement. In some cases, the immunophenotype is characteristic enough to allow classification using immunophenotypic data alone. However, each group has sufficient variability that correct diagnosis relies on recognition of the overall immunophenotypic pattern, and not on the expression of individual antigens or the rigid application of immunophenotypic profiles. The following discussion emphasizes general immunophenotypic principles useful for the diagnosis and classification of hematopoietic neoplasia, as a complete discussion of the antigenic abnormalities seen in each subtype of disease is beyond the scope of this chapter (Craig, 2008).

Acute Leukemia

Diagnosis and Classification

The diagnosis of acute leukemia relies on enumeration of the percentage of blasts in the peripheral blood or bone marrow; the current criterion in

Figure 34-6 B cell differentiation. The intensity of antigen expression throughout B cell maturation is depicted for antigens commonly used in the clinical laboratory. Normal mature B cells express κ or λ light chains, never both. Darker colors represent higher levels of antigen expression.

Figure 34-7 T cell differentiation. The intensity of antigen expression throughout T cell maturation is depicted for antigens commonly used in the clinical laboratory. T cell maturation occurs largely in the thymus, and most maturational stages will not be seen outside of that organ. At the common thymocyte stage, immature T cells express both CD4 and CD8, with subsequent stages showing expression of one or the other, but not both. Darker colors represent higher levels of antigen expression.

Figure 34-8 Neutrophil differentiation. The intensity of antigen expression throughout neutrophil maturation is depicted for antigens commonly used in the clinical laboratory. Darker colors represent higher levels of antigen expression.

the WHO classification for the diagnosis of acute leukemia is greater than 20% blasts (Swerdlow, 2008). In flow cytometry, identification of blasts relies on the demonstration of expression of immature antigens by a population having appropriate CD45 expression and light scatter characteristics. Although it is the overall immunophenotype that allows identification

of blasts, antigens commonly used for blast identification include CD34, CD117, CD133, and terminal deoxynucleotidyl transferase (TdT). White blood cells express CD45 at distinct levels of intensity characteristic of both lineage and stage of differentiation that when used in conjunction with orthogonal light scatter (side scatter) allow delineation of the basic

white blood cell populations (Borowitz, 1993; Stelzer, 1993) (Fig. 34-11). This technique is particularly useful for the identification of blasts, given their expression of intermediate CD45 and low side scatter; CD45 versus side scatter analysis has become standard practice in the clinical laboratory for this purpose.

Figure 34-9 Monocyte differentiation. The intensity of antigen expression throughout monocyte maturation is depicted for antigens commonly used in the clinical laboratory. Darker colors represent higher levels of antigen expression.

Although flow cytometry is excellent at identifying and enumerating blasts, two issues suggest caution in utilizing flow cytometric blast percentages for making an initial diagnosis of acute leukemia. First, the blast percentage obtained from bone marrow specimens is often inaccurate because of a combination of peripheral blood dilution (artifactual decrease) and compromise of nucleated erythroid precursors during specimen processing using lysing reagents (artifactual increase). Second, blasts identified by immunophenotyping do not always directly correspond to blasts as identified by morphology. This is true because leukemic populations, similar to normal populations, consist of a maturational continuum, and there is not perfect concordance between specific antigenic changes and the arbitrary morphologic changes that distinguish blasts from more differentiated cells. Moreover, in some types of leukemia, early neutrophilic (promyelocytes) and monocytic (promonocytes) precursors are intentionally included in morphologic blast counts. Nevertheless, if one pays attention to these limitations, the diagnosis of acute leukemia can generally be correctly suggested.

Although in most cases of acute leukemia the diagnosis (i.e., recognition of the presence of 20% blasts) is made by morphology, flow cytometry can be extremely useful in excluding a diagnosis of acute leukemia when the marrow is populated by cells that may mimic acute leukemia. A common situation in which this can occur is the presence of increased normal B cell precursors that may resemble primitive lymphoblasts morphologically, especially in suboptimal specimens. Although these cells superficially resemble leukemic precursor-B lymphoblasts immunophenotypically, multiparameter flow cytometry can readily distinguish these normal immature precursors (hematogones) from acute leukemia (Lucio,

Figure 34-10 Erythroid differentiation. The intensity of antigen expression throughout erythrocyte maturation is depicted for antigens commonly used in the clinical laboratory. Darker colors represent higher levels of antigen expression.

Figure 34-11 CD45 versus side scatter. The display of CD45 versus side scatter is increasingly used in the clinical laboratory as a starting point for the identification of white blood cell populations. Data are commonly displayed with side scatter on a logarithmic (left) or linear (right) scale. Major white cell populations colored are lymphocytes (blue), B cells (light blue), monocytes (purple), maturing neutrophils (green), blasts (red), basophils (dark purple), and maturing erythrocytes (orange).

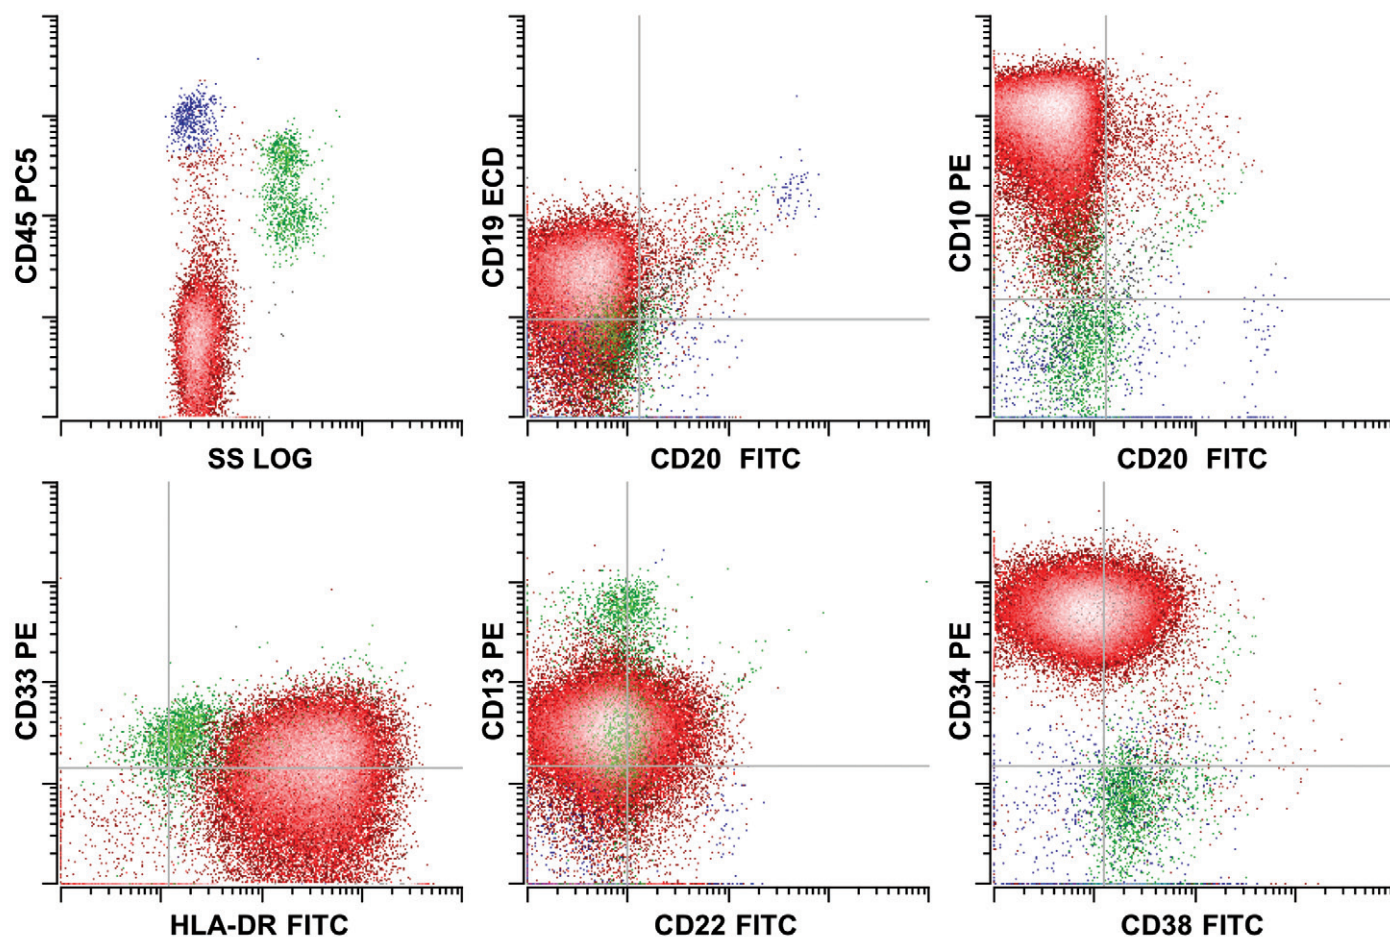

Figure 34-12 Precursor B cell lymphoblastic leukemia/lymphoma (acute lymphoblastic leukemia). The neoplastic cell population (*red*) in comparison with normal immature B cells shows abnormal expression of B cell-associated antigens CD19 (dim), CD22 (very dim), and CD10 (bright), along with aberrant expression of CD45 (absent), CD34 (bright), and CD38 (dim). In addition, the low-level expression of myeloid-associated antigens CD13 and CD33 is seen—a feature frequently seen in this disorder and not suggesting myeloid differentiation by itself. The cells have low side scatter, as is typical of lymphoid blasts.

1999; Weir, 1999; McKenna, 2001). Additionally, some nonhematolymphoid tumors such as small cell carcinoma or pediatric small round cell tumors can resemble leukemic blasts on smears but are readily distinguished from leukemic blasts by flow cytometry, where they appear as CD45-negative cells lacking specific markers of B cell, T cell, or myeloid lineage, often with higher side scatter than might be expected for a cell with so little cytoplasm (Chang, 2003).

The major role for flow cytometry in acute leukemia is classification. Classification is largely a matter of lineage assignment and correlation with normal maturational stage. The determination of lineage in particular is a decision of major therapeutic importance, with the primary distinction being whether the leukemia is of myeloid or lymphoid lineage. The immunophenotypic characteristics of acute myeloid leukemia (Terstappen, 1992a; Reading, 1993; Bradstock, 1994; Macedo, 1995a, 1995b; Weir, 2001; Orfao, 2004) and acute lymphoblastic leukemia (Farahat, 1995; Khalidi, 1998; Weir, 1999) and their similarities to normal populations have been well described in numerous publications. In general, it is the overall pattern of antigen expression rather than expression of any single antigen that allows determination of lineage. This is due in part to the lack of lineage specificity of many antigens commonly used for immunophenotyping. As a rule, the more closely an antigen is expressed at the level commonly seen in cells of that lineage, the more likely it accurately reflects lineage differentiation, for example, dim expression of the B cell antigen CD19 has relatively poor lineage specificity, as it may be seen in acute myeloid leukemia, but brighter and more uniform CD19 expression at the level seen on normal B cells is more typical of precursor B cell lymphoblastic leukemia. A subset of cytoplasmic antigens are the most lineage-restricted antigens currently known and are used to arbitrate lineage assignment in cases where the surface immunophenotype is unclear. Table

TABLE 34-2

Antigens Used for Lineage Assignment in Acute Leukemia

	AML	ALL-B cell	ALL-T cell
Definitive	Cytoplasmic MPO	None	Cytoplasmic CD3 Surface CD3 T cell receptor
Strongly associated	CD117	Cytoplasmic CD79a Cytoplasmic CD22 CD19 CD10—bright	CD7—bright
Moderately associated	CD13 CD33	TdT—moderate to bright	CD5 CD2

ALL, Acute lymphoblastic leukemia; AML, acute myeloid leukemia. MPO, myeloperoxidase.

34-2 lists antigens commonly used for lineage assignment. In rare cases, the leukemic cells may show differentiation along more than one lineage (Hanson, 1993; Bene, 1995; Matutes, 1997), most commonly either myeloid and B cell or myeloid and T cell, as evidence of the stem cell nature of these forms of acute leukemia. If a single blast population shows such differentiation, it is commonly termed **biphenotypic acute leukemia**; if two abnormal blast populations are present, each having a distinct and different lineage, this is termed **bilineal acute leukemia**. Examples of immunophenotypic patterns seen in acute leukemia are provided in Figures 34-12 through 34-15.

Figure 34-13 Acute myeloid leukemia with differentiation. The neoplastic cell population consists of blasts (red) showing abnormal expression of the myeloid-associated antigens CD33 (dim), CD13 (bright), and CD15 (dim partial) in association with immature antigens CD34 and CD117. The blasts do not express the more mature neutrophilic antigens CD11b and CD16, and are typical of the relatively immature forms seen in many cases of acute myeloid leukemia. Background maturing granulocytes are present (green) that are normal and are not part of the leukemic population.

Prognostic Factors

Although several reports have discussed the prognostic significance of particular surface markers in both acute lymphoid and myeloid leukemia (Schabath, 2003), for the most part, these have not stood the test of time, and they currently do not have a significant impact on therapy. One reason for this is that the presence of recurrent cytogenetic or molecular abnormalities in acute leukemia is now recognized as an important prognostic feature that has therapeutic implications; these are now an integral part of the WHO classification of acute leukemia. In many cases, the underlying cytogenetic abnormality is associated with characteristic immunophenotypic features that aid in suggesting an appropriate classification (Orfao, 1999; Hrusak, 2002); with few exceptions, once cytogenetic abnormalities are accounted for, immunophenotype is no longer prognostic. However, some markers, such as CD56 expression in acute myeloid leukemia (AML) with t(8;21) (Baer, 1997), have been associated with an adverse prognosis within that cytogenetically defined leukemia. A summary of phenotypic features associated with cytogenetic or molecular abnormalities is provided in Table 34-3.

Therapeutic Targets

In AML, the most commonly used therapeutic target is anti-CD33 (gemtuzumab ozogamicin). CD33 is expressed in the great majority of cases of AML, although its level of expression correlates with response to anti-CD33 therapy (Walter, 2007). Relatively little is known about the role of monitoring changes in CD33 expression. In acute lymphoblastic leukemia (ALL), to date few studies have used targeted monoclonal antibodies, although anti-CD22 (epratuzumab) and CD52 (alemtuzumab) are now used in some clinical trials (Raetz, 2008). The near ubiquitous expression of CD22 in B precursor ALL limits the role of flow cytometry in determining eligibility for such trials.

TABLE 34-3 Association of Immunophenotype with Cytogenetic Abnormalities in Acute Leukemia	
Immunophenotype	
Acute Myeloid Leukemia	
t(15;17)	HLA-DR negative, CD15 low to absent, CD33 bright, CD34 low to absent
t(8;21)	CD34 bright, CD56 positive, CD19 dim, TdT positive, CD15 positive
Acute Lymphoblastic Leukemia	
t(12;21) (by FISH)	CD10 positive, CD20 low to negative, CD9 low to negative
MLL (e.g., t[4;11])	CD10 negative, CD15 positive

MLL, Mixed lineage leukemia.

Residual Disease Monitoring in Acute Leukemia

Many of the large number of antibodies that can be used to help classify acute leukemia are not, in and of themselves, essential for determination of lineage. However, a larger panel of antibodies, properly selected, can be very useful in identifying specific differences between the leukemic population and background normal elements, thereby enhancing the ability to use flow cytometry to detect small abnormal populations. Thus, the purpose of flow cytometric immunophenotyping in acute leukemia at diagnosis goes beyond simple assignment of lineage and extends to the description of a “leukemia-associated immunophenotype” characteristic of

Figure 34-14 Acute promyelocytic leukemia. The neoplastic cell population consists of promyelocytes (red) showing abnormal expression of the myeloid-associated antigens CD33 (bright) and CD13 (intermediate), with high side scatter indicating abundant cytoplasmic granularity. The population lacks expression of CD34 and HLA-DR, antigens commonly present on true myeloid blasts, and retains expression of CD117, as is seen on a subset of normal promyelocytes. However, in contrast to normal promyelocytes, abnormal cells lack significant expression of CD15, a characteristic and common abnormality in this disorder.

that leukemia, knowledge of which is useful in assessing follow-up samples (Campana, 2003). An important caveat is that immunophenotypic changes between diagnostic samples and persistent or recurrent disease are frequently observed in both ALL (Borowitz, 2005; Galpa 2008) and AML (Baer, 2001; Voskova, 2004). Accordingly, it is necessary that one monitor more than one antigenic pattern and not expect exactly the same immunophenotype seen at diagnosis to persist after therapy. Examples of particularly informative combinations useful for detecting aberrant expression of antigens in minimal residual disease are shown in Table 34-4. The detection of minimal residual disease in acute leukemia has been demonstrated to be correlated with risk of relapse and overall survival for both AML (San Miguel, 2001; Feller, 2004; Maurillo, 2008) and ALL (Coustan-Smith, 2000; Dworzak, 2002; Borowitz, 2008), and is increasingly used to guide therapeutic decision-making. An example of minimal residual disease detection in ALL is shown in Figure 34-16.

Lymphoma

Diagnosis and Classification

As with leukemia, flow cytometry can contribute both to the diagnosis and to the classification of lymphoma. The immunophenotypic diagnosis of lymphoma relies on the identification of an expanded population of abnormal mature lymphocytes. By far and away, the most common way in which such an expansion is assessed by flow cytometry is through the demonstration of light chain restriction in B cell proliferations. As with all neoplastic cells, neoplastic lymphocytes arise from a single precursor that undergoes clonal expansion. However, unlike most cells, each lymphocyte normally expresses one of a series of polymorphic molecules on its surface that provides a unique identity; in the case of B cells, this identifying molecule is Ig. Because individual Ig molecules contain one of two

TABLE 34-4

Four-Color Antibody Combinations Useful for Minimal Residual Disease Detection

forms of light chain— κ or λ —reagents directed against light chains can be used as markers of clonality for B cells (Braylan, 1993; Geary, 1993; Fukushima, 1996).

In the case of T cell proliferations, the T cell receptor genetic locus is more complex, but a larger series of reagents directed against the β -chain families of the T cell receptor can be used to demonstrate clonality for T cells (Lima, 2001; Morice, 2004). The use of reagents directed against killer-inhibitory receptors (KIR antigens) has even been suggested to allow demonstration of natural killer cell clonality (Morice, 2003). The assumption behind all of these assays is that clonality equates with malignancy.

Figure 34-15 Acute myelomonocytic leukemia. The neoplastic cells consist of a relatively small population of blasts (*red*) with a larger population of cells showing monocytic differentiation (*violet*). The blasts show abnormal expression of CD33 (bright), CD13 (intermediate), HLA-DR (intermediate), and CD117 (intermediate) without CD34. The monocytic differentiation is reflected in the acquisition of early monocyte antigens CD64 (bright) and CD36 (intermediate to bright), along with other more mature myelomonocytic antigens CD15 (intermediate) and CD11b (low to intermediate), without significant acquisition of the mature monocyte antigen CD14 (absent) or marked gain in the expression of CD45, as is seen in mature monocytes. This finding suggests differentiation to the promonocyte stage, a population usually included in morphologic blast counts. In addition, a lesser degree of neutrophilic differentiation (*green*) is present.

Although clonality is a necessary consequence of neoplasia, clonal expansion is also a normal and necessary component of the immune response following antigenic stimulation, so the demonstration of clonality by itself is not entirely sufficient for the diagnosis of lymphoma.

It is increasingly recognized that a subset of otherwise normal individuals may contain small clonal populations of lymphocytes, best documented in the case of B cells (Rawstron, 2002; Chen, 2004; Kussick, 2004). It is not clear whether these clonal populations represent an early subclinical stage of disease, a precursor population without the full complement of genetic abnormalities required for neoplasia, or an incidental finding of no clinical consequence. Nevertheless, the term **monoclonal B cell lymphocytosis** has been adopted to describe such small populations in the peripheral blood, and numeric criteria have been suggested to allow their distinction from true neoplasia (Shanafelt, 2009). Consequently, it is necessary that flow cytometric findings suggesting lymphoma be put in a morphologic and clinical context before a definitive diagnosis of lymphoma is made.

In addition to light chain restriction, or restricted T-cell receptor β -chain usage, lymphomas, like leukemias, show alterations in antigen expression that deviate from normal maturation. In many cases, these alterations also provide evidence of neoplasia. Moreover, specific alterations are seen in specific types of lymphoma, thereby permitting classification as well as diagnosis in many cases, for example, increased expression of the T cell-associated antigen CD5 in CLL or mantle cell lymphoma (Matutes, 1994b; Tworek, 1998). Alteration in the intensity of Ig expression is also a common abnormality in B cell lymphoma and can be useful even when Ig expression is entirely absent (Li, 2002). Similarly, T cell lymphoma often shows alterations in the expression of one or more T cell

antigens (Picker, 1987; Ginaldi, 1996a). However, special care must be taken in interpreting small populations of phenotypically abnormal T cells, especially in unusual sites, because a large number of reactive conditions can be associated with expansions of populations that are not commonly seen in normal blood or lymph nodes (McClanahan, 1999).

An even more powerful method to diagnose lymphoma is to combine the detection of clonality with the ability to identify alterations in antigen intensity through multicolor flow cytometry. For instance, coupling the identification of follicle center B cells using CD19 and CD10 with the detection of κ and λ light chains in a four-color analysis allows one to identify the presence of light chain restriction specifically within the follicle center B cell population, greatly increasing both the specificity and the sensitivity of the analysis. Examples of immunophenotypic patterns seen in lymphoma are provided in Figures 34-17 through 34-21. One important limitation of this type of analysis is that neoplasms containing relatively rare, large abnormal cells (e.g., Hodgkin lymphoma) may be difficult to recognize unless an appropriate antibody combination is used and a sufficiently large number of events are acquired (Fromm, 2009). In this regard, the approach is essentially similar to minimal residual disease detection. An example of the flow cytometric detection of classical Hodgkin lymphoma is shown in Figure 34-22.

The classification of lymphoma relies on the recognition of specific patterns of antigenic expression that are similar to some normal maturational stage, yet deviate sufficiently to allow identification of the abnormal population. Among B cell lymphoma, there are two entities that can be both diagnosed and classified with a high degree of confidence based on immunophenotypic data alone: chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) and hairy cell leukemia. CLL/SLL is

Figure 34-16 Minimal residual disease detection. An abnormal population of immature B cells is identified (*red*) that have abnormally increased expression of CD10 and CD58, abnormally decreased expression of CD45, and normal expression of CD20 and CD38. This composite immunophenotype is different from normal immature B cells (*cyan*) or mature B cells (*dark blue*), allowing its discrete identification at a level of 0.1% of white cells.

characterized by the coexpression of CD5 by abnormal B cells, decreased intensity of clonal light chain expression, decreased expression of a variety of mature B cell antigens, including CD20, CD22, and CD79b, and presence of the activation antigen CD23 without significant FMC7, an activation epitope of CD20 (Serke, 2001) (see Fig. 34-17). This constellation of immunophenotypic findings is diagnostic for CLL/SLL (Matutes, 1994b; Tworek, 1998). The only other B cell neoplasm that consistently expresses CD5 is mantle cell lymphoma, a more aggressive lymphoma that is important to distinguish from CLL/SLL. In contrast to CLL/SLL, mantle cell lymphoma shows relatively bright expression of mature B cell antigens such as CD20 and CD79b, expresses clonal Ig at a relatively normal to high level, and expresses FMC7 without significant CD23 (see Fig. 34-18). Although mantle cell lymphoma generally can be readily distinguished from CLL/SLL, because some other low-grade lymphoproliferative disorders can occasionally express CD5 and mimic the mantle cell phenotype, a definitive diagnosis requires either fluorescent in situ hybridization (FISH) demonstrating t(11;14) or overexpression of cyclin D1 by immunohistochemistry. These other rare CD5-positive B cell neoplasms cannot be distinguished by their immunophenotypic criteria, and a combination of clinical history, morphology, and cytogenetic abnormalities is often required to reach a correct classification.

Hairy cell leukemia is characterized by increased expression of a variety of B cell antigens, including CD19, CD20, and CD22, clonal surface light chain restriction, markedly increased expression of the cell adhesion molecules CD11c and CD103, and expression of the α -chain of the

interleukin-2 receptor CD25 (see Fig. 34-19) (Robbins, 1994; Matutes, 1994a). In addition, the cells exhibit a variable degree of increased side scatter caused by the abundant cytoplasm they possess, often giving the cells light scatter characteristics similar to those of monocytes. This finding, in combination with the monocytopenia that is common in this disorder, is a frequent cause of false-negative results, particularly when one relies on relatively tight gates to identify the lymphocyte population by light scatter parameters alone or with CD45 versus side scatter.

Another immunophenotypic finding which aids in the classification of B cell lymphoma is expression of CD10, an antigen present on immature B cells and on normal mature B cells as they transit through the follicle center. Among B cell lymphomas, CD10 is expressed in most cases of follicular lymphoma (Almasri, 1998) (see Fig. 34-20), in a significant subset of large B cell lymphomas, and in Burkitt's lymphoma, in each of these cases indicating origin from the follicle center. In follicular lymphoma, the expression of CD10 is often coupled with decreases in CD19, CD20, and CD38 intensity (Yang, 2005; Mantei, 2009) that differ from the normal somewhat higher levels seen in normal germinal center B cells. Demonstration of bcl-2 overexpression by the CD10-positive B cell population can be useful in confirming neoplasia (Cook, 2003), particularly in cases lacking surface light chain expression, and reflects the presence of an underlying t(14;18) characteristic of follicular lymphoma. Although CD10 positivity alone does not allow definitive classification, its presence significantly reduces the possible entities that must be considered, with morphology generally being required to allow definitive classification.

Figure 34-17 Chronic lymphocytic leukemia/small lymphocytic lymphoma. The neoplastic B cell population (*gold*) shows abnormal expression of the B cell antigens CD19 (intermediate) and CD20 (low) with surface λ light chain expression (low) and coexpression of CD5 and CD23 (intermediate). The combination of CD5 coexpression, low-level light chain restriction, and low-level CD20 and CD23 without FMC7 is diagnostic for this particular disorder. The important differential is seen with mantle cell lymphoma (see Fig. 34-18).

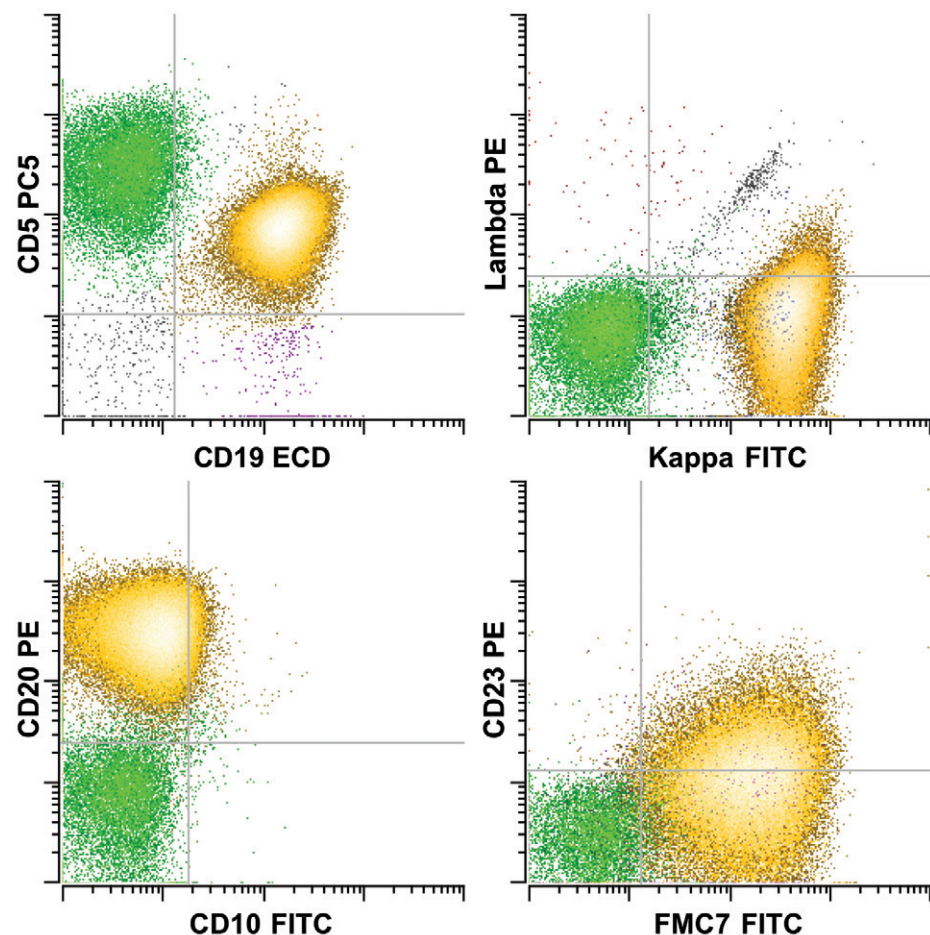

Figure 34-18 Mantle cell lymphoma. The neoplastic B cell population (*gold*) shows expression of B cell antigens CD19 (intermediate) and CD20 (intermediate) and κ light chain restriction (bright), along with coexpression of CD5 (intermediate) and FMC7 (intermediate) with only low CD23. The overall pattern of antigen expression differs from that seen in CLL/SLL (see Fig. 34-17) and suggests mantle cell lymphoma. Definitive diagnosis would require demonstration of t(11;14) by FISH or cyclin D1 overexpression by immunohistochemistry.

Figure 34-19 Hairy cell leukemia. The neoplastic B cell population (red) shows expression of B cell antigens CD19 (intermediate), CD20 (bright), CD22 (bright) and surface λ light chain restriction (intermediate) with aberrant expression of the adhesion molecules CD11c (variably bright), CD103 (intermediate), and CD25 (intermediate). This immunophenotype is diagnostic for hairy cell leukemia. Note the absence of monocytes by CD45 versus side scatter, a characteristic finding in hairy cell leukemia.

The role of immunophenotyping in the classification of T cell lymphoma is less well described, although certain associations have been noted that require larger studies for validation. As a general rule, a majority of T cell lymphomas are composed of CD4-positive T cells and exhibit abnormal patterns of antigenic expression. In angioimmunoblastic T cell lymphoma, abnormal T cells are CD4-positive and commonly show loss or decreased expression of surface CD3 (Serke, 2000) with abnormal coexpression of CD10 (Attygalle, 2002) (see Fig. 34-21). In mycosis fungoides/Sézary syndrome, abnormal T cells are also typically CD4-positive and can show a variety of immunophenotypic abnormalities, commonly including alterations in the intensity of CD3 and CD4 and decreased expression or loss of CD7 (Bogen, 1996; Lima, 2003). However, CD7 is normally variably expressed on CD4-positive T cells, decreased expression is associated with a normal memory immunophenotype, and expanded subpopulations with this immunophenotype may be seen in a variety of reactive conditions, including inflammatory skin lesions (Murphy, 2002). Consequently, demonstration of the loss of CD7 by itself does not allow definitive classification nor a definitive diagnosis of lymphoma and generally requires the presence of additional antigenic abnormalities to be informative. Expression of CD30 in combination with an aberrant pattern of T cell antigen expression can be useful in the identification of anaplastic large cell lymphoma (Jucó, 2003). Finally, a large granular lymphoproliferative disorder (large granular lymphocytic leukemia) is generally characterized by clonal expansion of CD8-positive T cells having variably decreased expression of CD5 or CD7 and expression of NK cell-associated antigens such as CD57 or CD16 (Richards, 1995). However, similar clonal expansions may be seen in a wide variety of nonneoplastic conditions, and knowledge of the clinical context is required for an understanding of the clinical significance.

Prognostic Factors

As noted earlier, flow cytometry is widely used to assess markers of prognostic significance in CLL, including CD38 (Damle, 1999) and ZAP-70

(Crespo, 2003). Although these assays are widely available, problems with interpretation and standardization have been reported. The distribution of CD38 on CLL cells is often continuous, not discrete, and arbitrary criteria have been used to distinguish positive from negative cases. This problem is even greater in the case of ZAP-70 assessment, where expression is often very dim, and where questions have been raised about the best method to determine positivity. Nonetheless, most cases are either clearly positive or clearly negative for each of these markers, and many papers, using varying techniques, have demonstrated their prognostic significance (Rassenti, 2008). However, a certain number of cases with borderline positivity are best considered as indeterminate for expression. To date, there are no prognostic markers in other types of lymphoma that are as well established as those in CLL/SLL.

Therapeutic Targets

The most widely used therapeutic antibody is anti-CD20 (rituximab). Determination of CD20 expression is essential to establish the suitability of this therapy, although it is expressed by the great majority of B cell lymphomas. Following therapy, B cells may persist but show loss of CD20 expression. Assessment of samples with more than one B cell marker, such as the combination of CD19 and CD20, is helpful in demonstrating the presence of residual B cells lacking CD20. Anti-CD52 (alemtuzumab) is occasionally used to treat cases of refractory lymphoma; because of the profound immunosuppression associated with this therapy, documentation of expression is important, although the great majority of lymphomas will express CD52.

Minimal Residual Disease Detection

Detecting low levels of involvement can be important in accurately staging patients with lymphoma (Douglas, 1999). This is particularly applicable to studies of bone marrow, where detection of small populations of light chain-restricted B cells can be seen in cases in which morphology is either negative or equivocal (Duggan, 2000; Palacio, 2001; Sanchez, 2002;

Figure 34-20 Follicular lymphoma. The neoplastic B cell population (*gold*) shows abnormal expression of the B cell antigens CD19 (dim), CD20 (intermediate), and surface κ light chain restriction (intermediate) with coexpression of the follicle center-associated antigen CD10 (intermediate). In addition, the neoplasm shows overexpression of cytoplasmic Bcl-2 due to the presence of the t(14;18) characteristic of follicular lymphoma. Overexpression of Bcl-2 by itself is not diagnostic of follicular lymphoma, but its combined expression with CD10 is much more specific, as normal CD10-positive follicular B cells would be expected to be negative.

Figure 34-21 Angioimmunoblastic T cell lymphoma. The neoplastic T cell population (*blue*) shows expression of the T cell-associated antigens CD2 (intermediate) and CD5 (intermediate), along with the helper T cell antigen CD4, but without surface CD3. In addition, the neoplastic cells coexpress CD10. The composite immunophenotype is characteristic of that seen in angioimmunoblastic T cell lymphoma.

Figure 34-22 Classic Hodgkin lymphoma. A discrete population of cells is identified that differs from normal lymphocytes and macrophages, having expression of CD15, CD30, high CD40, high CD71, and high CD95. This immunophenotype is typical for classical Hodgkin lymphoma. Note that these cells commonly show increased autofluorescence that appears as apparent low positivity for FITC-labeled reagents (CD64 in the current example). Also note that Hodgkin cells commonly are rosetted by T cells, giving apparent positivity for CD5 and CD45 (*top left panel*).

Stacchini, 2003), although the cost-effectiveness of this approach has been questioned (Hanson, 1999). Similarly, the peripheral blood may be evaluated for lymphoma to aid in the timing or advisability of stem cell collection, and the resulting harvested stem cell product may be tested for the presence of residual lymphoma to minimize the amount of tumor reinfused in patients undergoing bone marrow transplantation. In addition, as in acute leukemia, minimal residual disease studies have been used in patients with CLL and have demonstrated an association between the presence of residual disease following therapy and both event-free and overall survival (Rawstron, 2001; Moreton, 2005). In these cases, methods to demonstrate clonal populations of light chain-restricted B cells are not as sensitive as methods that rely on the presence of small phenotypically aberrant populations using principles similar to those used in acute leukemia.

Plasma Cell Neoplasms

Plasma cell neoplasms generally are not difficult to identify by flow cytometry (Ruiz-Arguelles, 1994; Ocqueteau, 1998), and their immunophenotype at diagnosis (Paiva, 2009) and detection following therapy are associated with outcome (Paiva, 2008). The expression of bright CD38 and/or CD138 is used to identify the plasma cell population, with common abnormalities being decreased CD45, decreased CD19, and abnormal coexpression of CD56 or CD117 in combination with the identification of cytoplasmic light chain restriction. An example of immunophenotypic abnormalities seen in plasma cell neoplasms is presented in Figure 34-23.

It is important to recognize that flow cytometric analysis typically underestimates the percentage of plasma cells present in a specimen, sometimes dramatically, possibly because of plasma cell aggregation, apoptosis, and peripheral blood dilution.

Myelodysplastic Syndromes and Myeloproliferative Disorders

The same principles used to identify other hematopoietic neoplasms can be used to identify myelodysplastic syndromes and myeloproliferative disorders (Elghetany, 1998; Wells, 2003; Kussick, 2003a, 2003b; Wood, 2007; Matarraz, 2008). Abnormalities in antigen expression can be identified on myeloid blasts, maturing neutrophils, and maturing monocytes; common abnormalities include (1) alterations in the intensity of expression of CD34, CD117, and HLA-DR, and aberrant expression of antigens such as CD7 or CD56 on myeloid blasts (Wells, 2003; Kussick, 2003b; Matarraz, 2008), (2) abnormal patterns of CD13 and CD16 expression and decreased side scatter on maturing neutrophils, and (3) aberrant CD56 expression on maturing monocytes (Wells, 2003; Kussick, 2003b). Abnormalities in erythroid maturation have also been described (Della Porta, 2006). Similar abnormalities in addition to basophilia may be identified in myeloproliferative disorders (Kussick, 2003a), although this has been less well studied. Although abnormalities can be demonstrated in essentially all cases having cytogenetic abnormalities, low-grade myelodysplasia

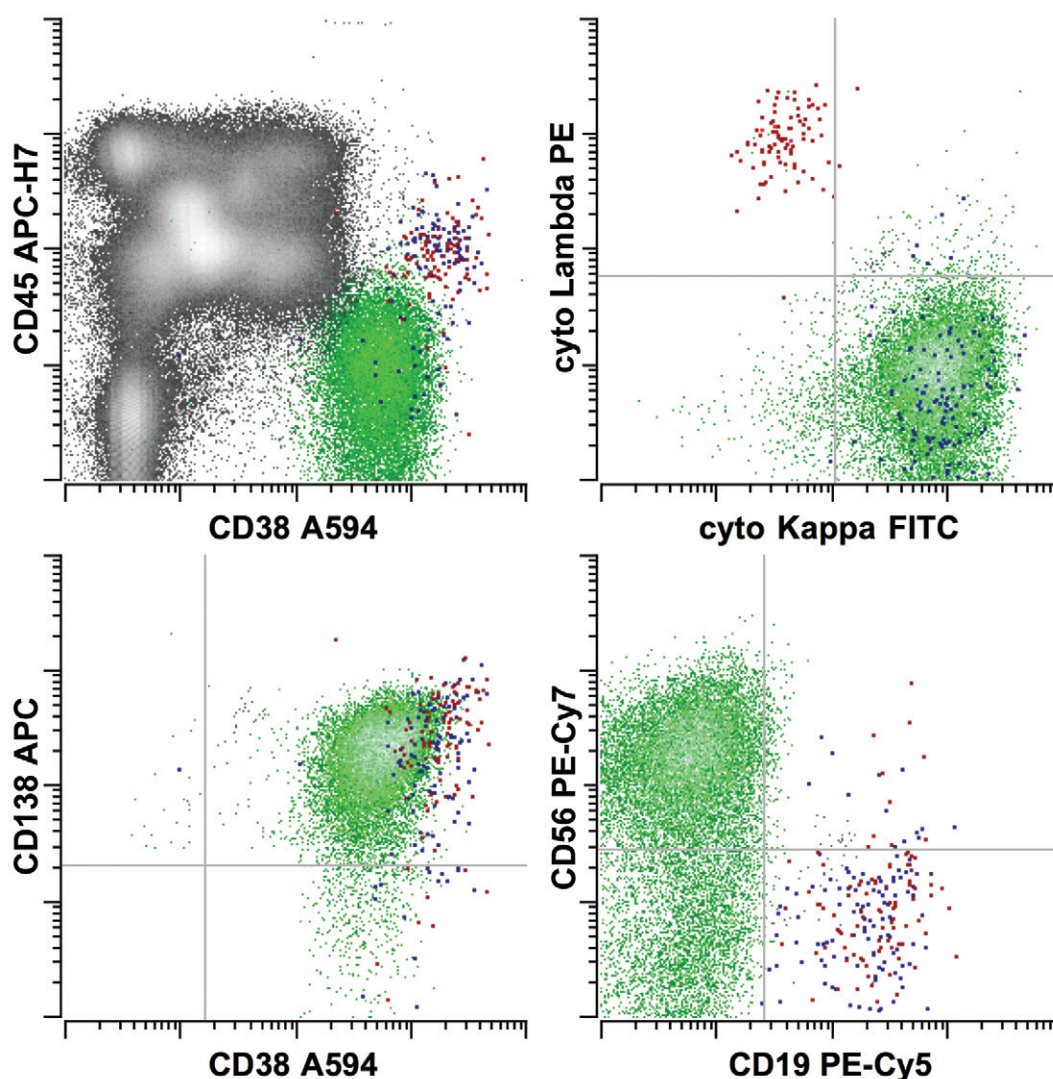

Figure 34-23 Plasma cell neoplasm. The neoplastic plasma cell population (*green*) is identified by the bright expression of CD38 and CD138, but both are slightly decreased in comparison with the few normal polyclonal plasma cells (*emphasized in blue and red*). Abnormal plasma cells show abnormal expression of CD45 (low to absent) and CD19 (absent) and cytoplasmic κ light chain restriction, with aberrant expression of CD56. This immunophenotype is characteristic of that seen in a variety of plasma cell neoplasms, including multiple myeloma, plasmacytoma, and monoclonal gammopathy of uncertain significance (MGUS). Definitive classification requires clinical and laboratory correlation.

predominantly affecting the erythroid lineage, as well as polycythemia vera and essential thrombocythemia, is not consistently identified currently, and new methods are needed. An example of immunophenotypic abnormalities seen in myelodysplasia is presented in Figure 34-24.

Paroxysmal Nocturnal Hemoglobinuria

Certain nonneoplastic hematopoietic disorders can be diagnosed using the same principles used to identify hematopoietic neoplasms. Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired clonal stem cell disorder characterized by the loss of a variety of cell surface proteins on all progeny of the hematopoietic stem cell, including erythrocytes, neutrophils, monocytes, lymphocytes, and platelets. The loss of these proteins is the result of mutation of a key enzyme required for synthesis of the glycosylphosphatidylinositol (GPI) linkage used to attach these proteins to the cell surface. Detection of the loss of GPI-linked proteins is readily accomplished by flow cytometry (Richards, 2000) and serves as the principal diagnostic method for this disorder. For clinical testing, it is recommended

that at least two GPI-linked antigens be evaluated on at least two different cell lineages, with commonly evaluated antigens being CD55 and CD59 on both erythrocytes and white blood cells, CD14 on monocytes, and CD66b on granulocytes. Platelets and lymphocytes generally are not evaluated. Another reagent increasingly used for the diagnosis of PNH is the fluorescent derivative of a mutant form of the bacterial toxin aerolysin, which binds specifically to the GPI linkage and can identify GPI-deficient cells with a high degree of sensitivity and specificity (Brodsky, 2000). An example of PNH is shown in Figure 34-25.

SUMMARY

Flow cytometry is a powerful, rapid, and cost effective technique for the identification and monitoring of hematopoietic neoplasms. Successful implementation requires careful attention to instrument and reagent performance, as well as a strong working knowledge of normal patterns of antigenic expression on hematopoietic cells.

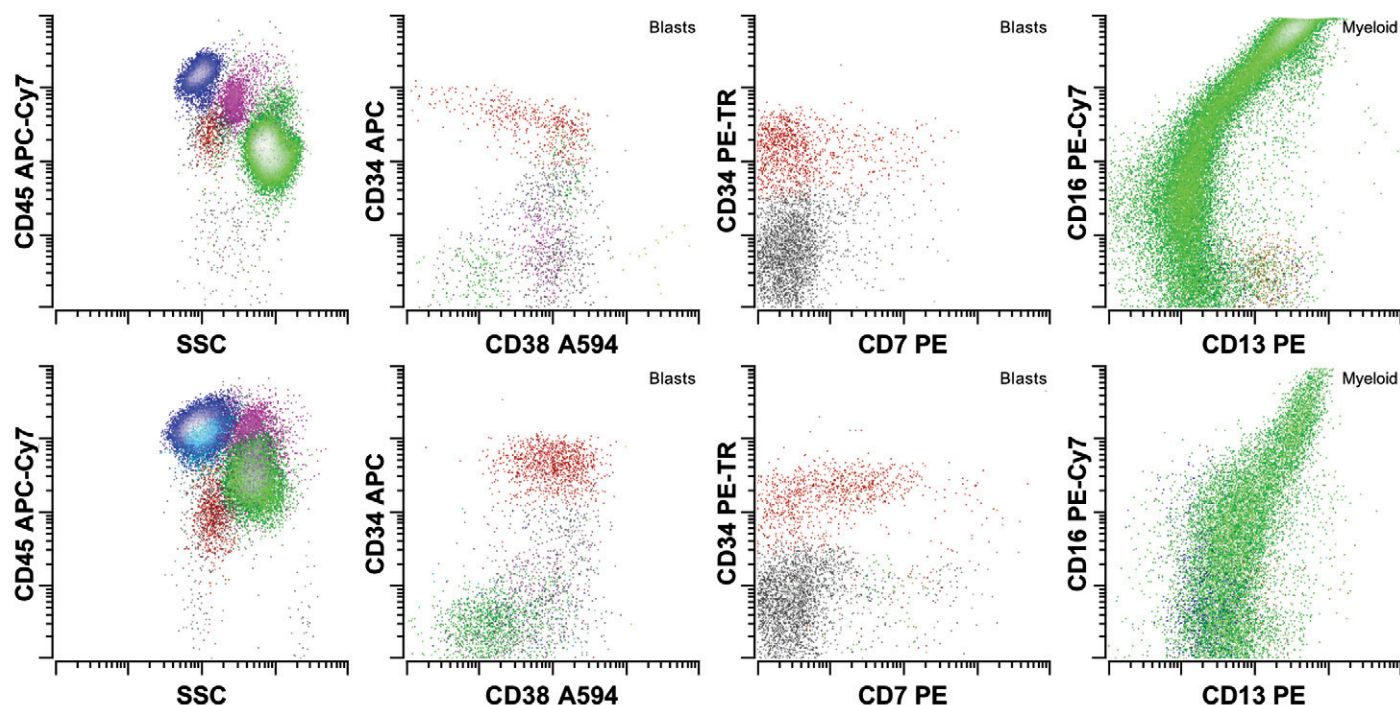

Figure 34-24 Myelodysplasia. A sample from a patient with low-grade myelodysplasia (lower row) is compared with normal bone marrow (upper row). Abnormalities commonly seen in myelodysplasia include neutrophil hypogranularity as indicated by decreased side scatter (left), decreased CD45 expression by the blasts (red, left), homogeneity of the myeloid blasts (red, left center), acquisition of lymphoid-associated antigens (CD2, CD5, CD7, and CD56) by myeloid blasts (right center), and abnormal patterns of myelomonocytic maturation, such as abnormal CD13 and CD16 on maturing neutrophilic forms (right). Decreased side scatter is best noted by comparing the relative positions of neutrophils (green) and monocytes (magenta). It is the combined presence of these abnormalities that suggests the presence of a myeloid stem cell disorder, such as myelodysplasia.

Figure 34-25 Paroxysmal nocturnal hemoglobinuria. Erythrocytes (left panel) identified by light scatter properties show differing levels of CD59 expression, corresponding to normal (Type I, 36%), partially deficient (Type II, 9%), and completely deficient (Type III, 54%) forms. Monocytes (center panel) identified by a combination of CD45, CD15 (low), CD33 (high), and side scatter (intermediate) show a mixture of normal (positive for CD14 and fluorescent aerolysin [FLAER]) and GPI-deficient forms (gated, 81%). Granulocytes (right panel) identified by a combination of CD45, CD15 (high), CD33 (low), and side scatter (high) show a mixture of normal (positive for CD24 and FLAER) and GPI-deficient forms (gated, 85%). Note the greater percentage of GPI-deficient monocytes and granulocytes compared with GPI-deficient erythrocytes, a common finding in PNH.

KEY POINTS

- Blood group antigens play a variety of physiologic roles as membrane structures involved in maintaining erythrocyte cytoskeleton integrity, as well as in membrane transport, cell signaling, and immune complement regulation, and as receptors/modulators of disease.
- The ABO histo-blood group antigens are widely expressed throughout the body and are the single most important blood group for selection and transfusion of blood products, as well as a major consideration in solid organ and bone marrow transplantation.
- The recipient immune response to exposure to foreign red cell antigens through transfusion or pregnancy may include antibody production and complement activation resulting in hemolysis (e.g., transfusion reaction, hemolytic disease of the fetus and newborn).
- Pretransfusion and perinatal blood testing is performed to prevent transfusion reactions and hemolytic disease of the fetus and newborn, and must include the key serologic evaluations of ABO and Rh antigen typing, antibody detection/identification, and crossmatching.
- Antihuman globulin reagents as used in direct or indirect testing are integral to virtually all red cell antibody detection and identification techniques.
- Patients with complex serologic problems such as antibodies to high-frequency antigens and autoantibodies may require utilization of a variety of special immunohematologic studies (enzymes, adsorption, elution) to identify compatible blood for transfusion.

BASIC IMMUNOHEMATOLOGIC CONCEPTS

The term immunohematology refers to the serologic, genetic, biochemical, and molecular study of antigens associated with membrane structures on the cellular constituents of blood, as well as the immunologic properties and reactions of blood components and constituents. Fundamental discoveries in the area of immunohematology have played an integral role in the development of transfusion medicine, which includes the transfusion of blood, its components, and its derivatives (see Chapter 36). In this

integrated relationship, immunohematologists perform and interpret a wide variety of serologic and molecular assays to aid in the diagnosis, prevention, and management of immunization associated with transfusion, pregnancy, and organ transplantation. Over the years, research in the field of immunohematology has contributed significantly to the fundamental understanding of human genetics and immunology, with broad applications to membrane physiology and function, epidemiology, anthropology, and forensic science.

BLOOD GROUP ANTIGENS

The term blood group refers not only to genetically encoded erythrocyte antigens but also to the immunologic diversity expressed by other blood constituents, including leukocytes, platelets, and plasma. Most blood group genes, with few exceptions, are located on the autosomal chromosomes and are inherited following Mendelian rules of inheritance. A majority of blood group alleles demonstrate codominance as well, meaning that genetic heterozygotes at a particular locus will express both gene products.

Many membrane-associated structures on blood cells may be defined as antigens because they have the capability of reacting with a complementary antibody or cell receptor. A majority of these antigens are also immunogens, in that they are able to elicit an antibody-mediated immunologic response in a responsive host. Each antigen may have a variety of different epitopes or specific antigenic determinants. Epitopes are discrete, immunologically active regions of the antigen, whose molecular configuration can interact with specific lymphocyte membrane receptors or secreted complementary antibody. Clinically, about a dozen antigen systems are significant and are commonly encountered on the transfusion service. In general, these antigens demonstrate polymorphic epitopes with varied distribution, often along racial or ethnic lines, in the population. Patients who lack certain antigens may form antibodies when exposed to them, and these antibodies may be detected on routine testing in the blood bank.

Immunogenicity

The ability of an antigen to elicit an immune response is known as its immunogenicity. The immunogenicity of an antigen is determined not only by certain innate characteristics of the antigen itself but also by the host's genetically determined immune responsiveness. Characteristics of

antigens that determine their immunogenicity include degree of foreignness; molecular size and configuration, which may change with temperature, pH, and ionic environment; and antigenic complexity, as measured by the number of available epitopes or antigenic determinants.

Blood group antigens vary greatly in their ability to elicit an immune response. The A, B, and RhD antigens are certainly the most immunogenic; thus all blood transfused must be matched for these antigens between the blood donor and the recipient. Approximately 50%–75% of D-negative individuals would produce anti-D if transfused with only one unit of D-positive blood. After the D antigen, K is the next most immunogenic, followed by Fy^a and common Rh antigens, based on the frequency with which their corresponding antibodies are encountered. Using the same criteria, other common blood group antigens such as Fy^b, Jk^a, Jk^b, and s are much less immunogenic. The relative immunogenicities of some clinically important red cell antigens are listed in Table 35-1.

Chemical Characteristics

The chemical composition, complexity, and molecular size of an antigen determine most of its physical and biological properties, including immunogenicity. As a general rule, pure polysaccharides are not immunogenic except in certain species such as humans and mice (Virella, 2001). Pure lipid and nucleic acids are not immunogenic but can be antigenic because they can serve as haptens. Haptens are well-defined chemical groupings that are too small to be immunogenic by themselves but can induce an antibody response when attached to a carrier protein.

Although pure protein may be immunogenic, the most potent immunogens are usually complex macromolecular glycoproteins and lipoproteins. Thus, it is not surprising that red blood cell (RBC) antigens are glycoproteins, lipoproteins, and glycolipids. Experiments with peptide chain polymers have shown that aromatic amino acids, such as tyrosine and phenylalanine, can contribute significantly to overall immunogenicity (Virella, 2001). In glycoproteins, immunogenicity may also be influenced by the extent of branching in the polysaccharide side chains. Whereas the

immunogenicity of an antigen relates to the total complex molecular structure, the areas where antigen combines with specific antibody (i.e., the epitopes) are usually limited to one or a few simple structures (terminal sugars, amino acids) exposed on the exterior, mobile surface of the molecule (Delves, 2006). These are often referred to as immunodominant structures because they determine the specificity and optimal binding energy of antigen–antibody interactions.

Antigen Density

The number of antigenic sites on a foreign substance, whether a complex molecule or a cell, will contribute to the strength of an immunologic response. Studies of blood group antigens have demonstrated that antigen density contributes to the efficiency of antibody binding and the extent of complement activation, thus determining the likelihood of RBC hemolysis.

Various techniques have been used over the years to determine the number of copies of specific blood group antigens on the RBC membrane. Historically, radioimmunoassay, enzyme-linked immunosorbent assay, electron microscopy using ferritin-labeled antiimmunoglobulin, and flow cytometry have been used to indirectly calculate the number of antigen sites on RBC membranes. Table 35-2 lists the estimated densities of common RBC antigens.

BLOOD GROUP ANTIBODIES

Immunoglobulins and Antigen Binding

Immunoglobulin (Ig) is a protein molecule that is produced in response to antigenic stimulation and that demonstrates specific antibody activity. To understand antibodies, one first must be familiar with Ig structure and function. Information on Igs that is relevant to blood banking is summarized in Tables 35-3 and 35-4.

The specificity of an antibody is determined by the hypervariable or complementarity-determining regions of an Ig molecule. Three hypervariable regions are included in each of the light and heavy chains that make up the Ig molecule (Delves, 2006). Amino acid sequence heterogeneity in the hypervariable regions, which allows for variation in the configuration of the peptide chains in the variable loops, determines the combining specificity for each antibody. The combining site of an antibody, where it is in physical contact with an antigenic determinant or epitope, is called the paratope. For simple, linear antigens (sequential epitopes), the combining site may be in contact with five or six amino acids or hexose units. In the case of a globular protein antigen, as many as 16 amino acids of what is generally a discontinuous or conformational epitope may be in contact with the antibody-combining site (Delves, 2006).

Binding involves formation of multiple noncovalent bonds between the antigen and amino acids of the paratope. The attractive forces between antigen and antibody, which include electrostatic and van der Waals forces, hydrogen bonds, and hydrophobic interactions, become significant when the distance between the interacting groups is small. As a result, the better the physical fit between epitope and paratope, the higher is the overall binding energy and the greater is the affinity of the resulting reaction between antibody and antigen (Delves, 2006).

TABLE 35-1

Relative Immunogenicity of Selected Clinically Important Blood Group Antigens*

Antigen	Relative potency	Antigen	Relative potency
D	0.70	K	0.10
C	0.041	E	0.0338
k	0.030	e	0.0112
Fy ^a	0.0046	C	0.0022
Jk ^a	0.0014	S	0.0008
Jk ^b	0.0006	s	0.0006

*These figures represent the approximate percentage of persons negative for a specific antigen who, if transfused with one unit of corresponding antigen-positive blood, would develop antibodies to that specific antigen. When the relative potency of K antigen is 0.1, as estimated by Kornstad (1958), the relative potency of other blood groups can be estimated as shown by Klein (2006).

Blood Group Alloantibodies and Autoantibodies

A majority of clinically significant blood group antibodies are IgG or IgM, although occasionally an IgA antibody is encountered. Blood group antibodies are usually classified as (1) an **alloantibody**, which reacts with a foreign antigen not present on the patient's own erythrocytes, or (2) an **autoantibody**, which reacts with an antigen on the patient's own cells. RBC autoantibodies are discussed later in this chapter.

Some alloantibodies to erythrocyte antigens are called **naturally occurring**, that is, the antigenic stimulus is unknown. Naturally occurring antibodies may appear regularly in the serum of persons who lack the corresponding antigen, such as in the ABO blood group system. Other naturally occurring antibodies are produced only in a small subset of individuals.

Most blood group alloantibodies are produced as the result of immunization to foreign erythrocyte antigens by exposure through transfusion of blood components or through pregnancy. Alloantibodies to RBCs frequently require the selection of specific antigen-negative components for transfusion. Identification of alloantibodies and selection of compatible blood components remain the most important functions of a transfusion medicine service.

THE COMPLEMENT SYSTEM AND BLOOD BANKING

Complement plays a key role in the pathophysiology of hemolysis through its involvement in the sensitization and destruction of transfused RBCs by alloantibody, or the destruction of autologous RBCs by autoantibody. Complement is also important in immunohematologic testing.

Role of Complement in Erythrocyte Destruction

Antibody binding to RBC antigens is the most common reason for complement activation on the RBC membrane in vivo. Complement may also be activated on RBCs via a carrier–haptan antibody complex such as penicillin-coated RBCs and antipenicillin antibodies. Complement components may also be attached to the membrane via a nonspecific mechanism induced by certain drugs, or when erythrocytes are **innocent bystanders** in another immune reaction.

RBC–antibody complexes usually activate complement by the classical pathway. However, the mode of destruction and the extent of RBC hemolysis depend primarily on the class of Ig involved and the activity of an individual's reticuloendothelial (RE) system.

Intravascular Hemolysis

Intravascular RBC hemolysis is usually caused by antibodies directed against the ABO antigens. Rarely, other IgM blood group antibodies, as well as some complement-fixing IgG antibodies (e.g., anti-Kidd antibodies), can induce intravascular hemolysis. Intravascular lysis occurs when large amounts of complement are rapidly activated, resulting in complete activation of the complement cascade with assembly of the terminal membrane attack complex (C5b6789). This complex polymerizes to form pores in the RBC membrane, so that extracellular fluid enters the cell, causing it to swell and burst by osmotic lysis.

Extravascular Hemolysis

IgG antibodies cause the majority of extravascular hemolysis via the RE system, which removes complement-coated RBCs. When IgG antibodies bind RBCs and activate complement, complement regulatory proteins generally stop the activation process at the C3/C4 level. RBC-bound C3b

Figure 35-1 Action of factor I in the release of C3b-coated erythrocytes from reticuloendothelial system sequestration.

TABLE 35-5

Complement Receptors on Human Cells

CR1 (CD35)	C3b, C4b	Erythrocytes, neutrophils, monocytes, macrophages, B lymphocytes, follicular dendritic cells
CR2 (CD21)	C3d, C3dg, iC3b	B cells
CR3 (CD11b/CD18)*	iC3b	Monocytes, macrophages, neutrophils, natural killer cells
CR4 (CD11c/CD18)*	iC3b	

*Members of the integrin receptor family.

is degraded to iC3b, which is enzymatically inactive, by factor I and factor H. iC3b is further degraded to C3c and C3dg by factor I and CR1, a cofactor and C3b/C4b receptor (Freedman, 1994) (Fig. 35-1). Decay accelerating factor (DAF) participates by inhibiting C3 convertase (C4b2b) formation and by promoting C3 convertase degradation. On RBCs, CR1 and DAF carry the Knops and Cromer blood group antigens, respectively.

Initially, C3b/iC3b-coated RBCs are rapidly sequestered in the liver by monocytes and macrophages, which have receptors for C3b (Table 35-5). Although phagocytic cells also have receptors for C4b, the role, if any, of C4b in immune hemolysis of erythrocytes is not defined (Freedman, 1994). A portion of the RBCs sequestered in the liver are immobilized and destroyed by phagocytosis with a half-life of about 2 minutes (Klein, 2006). Within 15–20 minutes, however, destruction slows, and many of the cells escape extravascular destruction through the action of the complement regulatory protein, factor I, as previously described. C3dg, the iC3b fragment produced by factor I cleavage, remains attached to RBCs but has no enzymatic or opsonic properties. As a result, sequestered C3dg-coated RBCs are released back into the circulation and survive normally (see Fig. 35-1). In the circulation, C3dg is cleaved, leaving C3d attached to the RBC membrane.

In the absence of complement activation, IgG-coated RBCs are removed by phagocytic cells via Fcγ receptors. Although phagocytosis is not complement dependent, Mollison (1989) demonstrated that RBCs coated with both IgG and complement tend to show accelerated removal by the liver, whereas RBCs coated only with IgG tend to be destroyed more slowly in the spleen, displaying a linear pattern of removal with a minimum half-life of 20 minutes. Theoretically, RBCs coated only with IgG antibody could also be the targets of antibody-dependent cellular cytotoxicity mechanisms (Klein, 2006), because natural killer cells possess Fcγ receptors.

ERYTHROCYTE ANTIGENS AND ANTIBODIES

More than 700 erythrocyte antigens have been reported in the literature and have been organized into 30 blood group systems by the International Society of Blood Transfusion (ISBT) (Table 35-6). Many described erythrocyte antigens are high-frequency or public antigens expressed by most donors (>90%–99%), whereas others are extremely rare (private antigens). In the following section, we review the more common RBC antigens and antibodies encountered on the transfusion service. Table 35-7 summarizes several commonly encountered RBC alloantibodies according to their Ig class, serologic phase of detection, clinical significance, and statistics on finding compatible blood.

ABO AND H BLOOD GROUP SYSTEMS (ISBT NO. 001 AND 018)

Originally discovered in 1900, the ABO blood group system is the single most important blood group for the selection and transfusion of blood. As histo-blood group antigens, ABO epitopes are found on many tissues and body fluids, including RBCs, platelets, and endothelial cells (Issitt, 1998). Because they are so widely expressed, ABO antigens are a major consideration in solid organ and bone marrow transplantation (Wu, 2003).

The ABO blood group system consists of two antigens—A and B—and four phenotypes—groups A, B, AB, and O. A and B are autosomal codominant antigens (ISBT No. 001) and are expressed on group A, B, and AB

TABLE 35-6

red cells, respectively. In contrast, the group O phenotype is an autosomal recessive phenotype, reflecting the absence of a functional ABO gene. Group O individuals express the H antigen (ISBT No. 018), the biosynthetic precursor of both A and B antigens (Fig. 35-2). Group O is the most frequent ABO phenotype in most populations tested, particularly among Native Americans. Expression of ABO antigens on RBCs is usually accompanied by the presence of naturally occurring antibodies against the missing antithetical antigen(s). Table 35-8 shows the serologic reactions and frequencies of the four major ABO phenotypes.

Null and Weak Phenotypes

The ABO system also contains several phenotypes associated with weakened, anomalous, or complete absence of ABO antigen expression. The most common ABO subtypes encountered in the blood bank are A₁ and A₂ (Table 35-9). A₁ red cells are distinguished from A₂ (and other weak A subtypes) by agglutination with the lectin *Dolichos biflorus*. Comparison of A₁, A₂, and other weak A subtypes indicates both quantitative and qualitative differences in A antigen expression (Issit, 1998; Swensson, 2005). The ABO system contains additional weak A and weak B phenotypes. The serologic characteristics of some weak group A, B, and O subtypes are shown in Table 35-10.

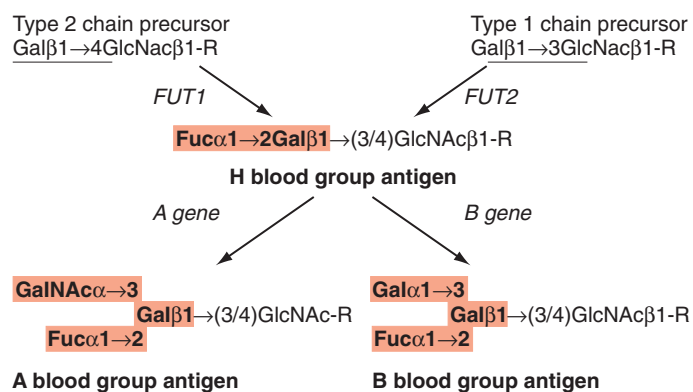

Figure 35-2 Synthesis of type 1 and type 2 chain H and AB antigens. Type 1 chain and type 2 chain precursors (underlined) are fucosylated by FUT1 and FUT2 fucosyltransferases to form H antigen. H antigen then serves as a substrate for A and B glycosyltransferases. The terminal carbohydrate epitopes denoting blood group H, A, and B antigens are highlighted in amber. *Fuc*, Fucose; *Gal*, galactose; *GalNAc*, *N*-acetylglactosamine; *R*, other oligosaccharide.

–	+	+	–	B	11	20	4	27
+	+	–	–	AB	4	4	<1	5

Composite figures calculated from Mourant (1976).

Anomalous ABO expression can be inherited (*cis*-AB, B[A]) or acquired (acquired B). In the *cis*-AB phenotype, A and B antigens are synthesized by the same enzyme and are inherited as a single, autosomal dominant allele. Likewise, the B(A) phenotype, an autosomal dominant phenotype characterized by trace A antigen expression on group B RBCs, is due to synthesis of A antigen by the *B*-gene enzyme. The acquired B phenotype, on the other hand, is an acquired enzymatic modification of group A₁ red cells in vivo. The acquired B phenotype usually occurs in the setting of bacterial infection or cancer and reflects enzymatic deacetylation of group A antigen to form a B-like antigen on RBCs. The *cis*-AB, B(A), and acquired B phenotypes are usually detected because of discrepancies in ABO typing (Issitt, 1998; Roback, 2008).

Bombay and para-Bombay are two rare null phenotypes characterized by an absence of all ABH antigens on RBCs. In the classic Bombay phenotype (O_B), neither AB nor H antigens are present on RBCs or in secretions. Para-Bombay also shows few or no ABH antigens on RBCs, sometimes accompanied by normal expression of ABH antigens in secretions and body fluids.

Biochemistry

The ABO antigens are carbohydrate antigens and, therefore, represent a posttranslational modification of glycoproteins and glycolipids. On RBC glycoproteins and polylectosaminylceramides, ABO antigens are usually expressed on type 2 chain oligosaccharides, characterized by repeating

[§]Bombay secretors (para-Bombay) have been reported.

lactosaminyl (Galβ1–4GlcNAcβ1–3)_n motifs (see Fig. 35-2). On glycosphingolipids, ABO antigens can be expressed on multiple (type 1, 2, 3, and 4 chain) oligosaccharide precursors. ABH antigens expressed on RBC glycoproteins and most glycosphingolipids (type 2, 3, and 4 chain) are of RBC origin. In contrast, type 1 chain ABO antigens are synthesized by gastrointestinal mucosa, secreted into plasma, and passively adsorbed onto red cell membranes. Synthesis of type 1 chain ABO antigens is linked to the Lewis blood group system.

The first step in the synthesis of ABH antigens is the synthesis of the H or group O antigen, the immediate biosynthetic precursor of both A and B antigens. The H antigen is formed by the addition of fucose (Fuc), in an α1–2 linkage, to a terminal galactose. This reaction is catalyzed by two different enzymes, depending on whether the fucose is being added to a type 1 or type 2 chain oligosaccharide acceptor. Fucosyltransferase type 1 (*FUT1*), the product of the H or *FUT1* gene, catalyzes the formation of type 2 chain H antigen. In contrast, fucosyltransferase type 2 (*FUT2*), the product of the *Secretor* gene, catalyzes the transfer of fucose to type 1 chain precursors to form type 1 chain H or Le^x antigen (Lowe, 1994). Inactivating mutations in *FUT1* are responsible for the Bombay and para-Bombay phenotypes (Kelly, 1994). Bombay and para-Bombay nonsecretors also have inactivating mutations in *FUT2* (Lowe, 1994; Daniels, 2002).

Once H antigen is formed, it can serve as a substrate for A gene and B gene glycosyltransferases. The A antigen is formed by A gene glycosyltransferase, which adds an N-acetylgalactosamine (GalNAc), in an α1–3 linkage, to the subterminal galactose of H antigen. Likewise, the B antigen is formed by the addition of an α1–3 galactose (Gal) to the same galactose by the B gene glycosyltransferase. Biochemically, the A and B antigens are very similar, differing only by the presence of an N-acetyl group. It is fascinating that such a minor chemical modification should have such profound immunologic consequences. Removal of the N-acetyl group on A antigen by circulating deacetylase enzymes is responsible for the acquired B phenotype (Issitt, 1998).

Molecular Biology

FUT1 (H gene) and *FUT2* (Se gene) are located together on chromosome 19q13.3 and reflect a gene duplication (Lowe, 1994). *FUT1* is a 365 amino acid, type II transmembrane glycoprotein, composed of a large, 240 amino acid, carboxy-terminal catalytic domain, which is anchored within the Golgi lumen by a short transmembrane and a cytosolic domain. More than 20 mutant *FUT1* alleles have been described (Issitt, 1998; Reid, 2004).

The ABO gene locus is located on chromosome 9q34 and encodes the A and B glycosyltransferases (Yamamoto, 1995). The gene is large,

TABLE 35-11

Key Amino Acids in Distinguishing A, B, and Hybrid Glycosyltransferases*

RBC, Red blood cell.

*Modified from Reid (2004) and Daniels (2002). Amino acids that differ from the A101 (A₁ type) consensus allele are highlighted in bold.

†Gene type refers to amino acid positions 176, 235, 266, and 268. These four positions differ between A (AAAA) and B alleles. Amino acids at 235, 266, and 268 strongly influence substrate specificity. Hybrid glycosyltransferases have amino acids matching both A and B consensus alleles at these positions.

‡O03 allele (historically O²), associated with a group O phenotype, possesses an inactivating missense mutation at amino acid 268.

spanning 18kb, and contains seven exons, although exons 6 and 7 encode the majority of the active enzyme. The product of the *ABO* gene is a 41-kD, 353 amino acid type II transmembrane glycoprotein. Comparison of A and B enzymes shows nearly 98% identity, differing by four key amino acids at residues 176, 235, 266, and 268 (Table 35-11). Amino acid 268 is absolutely critical in determining the activity and substrate specificity (UDP-GalNAc vs. UDP-Gal) of the enzyme. Substrate specificity is also influenced by amino acid residues 235 and 266. The polymorphism at residue 176 is not biologically significant. To date, more than 200 ABO alleles have been identified.

The cloning and sequencing of the *ABO* gene locus have also uncovered the molecular basis of group O and ABO subtypes. Two deletion mutants (O¹, O^{1var}) are the most common and the ancestral genes for most other group O alleles (Roubinet, 2004). It is interesting to note that the O² allele (O03), found in many Europeans, contains a single missense mutation at amino acid residue 268 (see Table 35-11) (Yamamoto, 1995). O03 and a related allele (*Aw*08) have been linked to ABO typing discrepancies by an absence of anti-A and/or anti-B in these individuals (Wagner, 2005). It has been suggested that the absence of anti-A or -B is the result of weak residual enzyme activity (Seltsam, 2005); however, this has not been confirmed (Yazer, 2008).

Several ABO subtypes are also the result of mutations at the *ABO* gene locus, including single-nucleotide polymorphisms (SNPs) and nonsense, frameshift, and translation-initiator mutations (Yamamoto, 1995; Reid, 2004; Seltsam, 2006). For example, the A₂ and A₃ phenotypes are associated with a single nucleotide deletion (nucleotide 1060) and frameshift, resulting in the loss of a stop codon and synthesis of a longer A enzyme with decreased enzyme activity. Single point mutations appear to be responsible for the decreased enzyme activity of A₃, A_x, A_{finn}, A_{end}, B₃, B_x, and B_y alleles (Yamamoto, 1995; Reid, 2004). In contrast, the *cis*-AB and B(A) alleles, which can synthesize both A and B antigens, are molecular chimeras with characteristics of both A₁ and B gene consensus alleles (see Table 35-11) (Yamamoto, 1995).

ABO Antibodies

Antibodies against ABO antigens are the most important antibodies in transfusion medicine. The practicing pathologist should note that the routine antibody screen does not test for ABO antibodies. All reagent cells in the antibody screen are group O. Patients demonstrate anti-A or anti-B on reverse typing (vide infra).

In general, ABO antibodies are naturally occurring. It is believed that the immune stimulus for the formation of ABO antibodies may be exposure to ABH-like substances found in nature, particularly on the bacterial polysaccharides. It is interesting that ABO titers have progressively decreased over the past two decades with increasing consumption of pasteurized, commercially packaged foods that are relatively sterile (Mazda, 2007). This trend may be reversed with increasing use of probiotic

nutritional supplements that contain live bacteria. The latter have been shown to stimulate ABO antibodies, with marked increases in ABO titers within several months (Daniel-Johnson, 2009).

ABO antibodies are weak or absent in the sera of newborns until 3–6 months of age. Adult levels of ABO antibodies are reached by 5–10 years of age and decrease only slightly with advancing age (Auf der Maur, 1993). Anti-A,B is found exclusively in group O individuals and appears to recognize an epitope common to both A and B antigens. Before the development of anti-A and anti-B monoclonal antibody typing reagents, anti-A,B was useful in identifying A_x and weak B subgroups. Anti-A,B is still used for typing donor units and cord samples (see ABO Grouping section).

In general, ABO antibodies are detected as room temperature, saline agglutinins with optimal reactivity at 4° C (see Table 35-7). Most naturally occurring ABO antibodies are of IgM isotype, although IgA and IgG antibodies with ABO specificity are also present (Rieben, 1991). ABO IgG antibodies, reactive at 37° C, can also occur following immune stimulation by transfusion or pregnancy. These antibodies generally are of higher titer and are less readily neutralized by soluble blood group substances. ABO antibodies can fix complement and can cause hemolysis in vivo and in vitro.

Clinically, ABO antibodies are a cause of hemolytic transfusion reactions and hemolytic disease of the fetus and newborn (HDFN). ABO antibodies are also a cause of acute rejection in solid organ transplantation. As a result, solid organ transplants should be ABO compatible with the recipient's sera. Rare exceptions to the latter are heart transplantation in children younger than 6–8 months of age, who have not yet developed ABO antibodies (West, 2001), and transplantation of A₂ organs, which have very weak ABO expression on epithelium and vascular endothelium (Wu, 2003). In ABO-incompatible bone marrow transplantation, ABO antibodies can result in hemolysis and a delay in erythroid and megakaryocyte engraftment (Cooling, 2007). For additional information on ABO-incompatible marrow and organ transplants, see section on Antibody Titers.

Less Common ABO Antibodies

Anti-A₁. Anti-A₁ is a naturally occurring antibody found in the sera of some A₂, A₂B, and other weak A subtypes. Anti-A₁ hemagglutinates A₁ RBCs, but not A₂ and other weak A phenotypes. Although uncommon, anti-A₁ has been implicated in transfusion reactions and solid organ rejection.

Anti-H. Anti-H is usually a benign, naturally occurring antibody in the sera of A₁ and A₁B nonsecretors. Anti-H reacts most strongly with group O erythrocytes, followed by A₂, B, A₂B, A₁, and A₁B (refer to Table 35-48 later in this chapter). Because H antigen is present to some degree on all RBCs, anti-H is an autoantibody in most individuals. In contrast, alloanti-H is a clinically significant alloantibody in Bombay (O_h) and para-Bombay individuals. Because all RBCs express some H antigen, finding compatible RBCs can be extremely difficult in these patients.

Biological Role

The biological role of ABH antigens is still not known. Multiple studies have linked specific ABO types with a higher incidence of many diseases, including autoimmune, neoplastic, and infectious disorders. Depression of A and B antigen expression can occur in malignancy and is often associated with increased metastatic potential. Malaria has been shown to bind A and B antigens with rosette formation, a possible risk factor in cerebral malaria (Cserti, 2007). Genotyping studies suggest a “parent of origin effect” between severe malaria and inheritance of a functional maternal ABO allele (Fry, 2008). A and B antigen expression may also stabilize the clustering and spatial organization of sialoglycoproteins, which also serve as malaria receptors (Cohen, 2009). For a complete review of ABH and human disease, the reader is referred to Issitt (1998) and Garratty (1994).

MNS BLOOD GROUP SYSTEM (ISBT NO. 002)

Discovered in 1927, the MNSs blood group was the second blood group system identified after ABO. Today, the MNSs blood group system consists of more than 46 antigens, of which only four (M/N and S/s) are commonly encountered in the clinical setting (Reid, 2009). As shown in Table 35-12, the M and N antigens are fairly evenly distributed in both blacks and

TABLE 35-12

Figure 35-3 Glycophorin A (GYPA) and B (GYPB). GYPA and GYPB possess 11–15 O-linked glycans (—●—), consisting predominantly of a disialotetrasaccharide (78%), along the amino-terminal half of the extracellular domain. GYPA also possesses a single, biantennary N-glycan, indicated by a branched structure. The single transmembrane domain for both molecules is indicated by a solid amber cylinder. The allelic antigens, M and N, reside at the extreme amino-terminus of GYPA and differ by only two amino acids at residues 1 and 5. The N antigen is also present at the amino-terminus of GYPB and is designated “N” antigen. The S/s antigens are located at amino acid 29 of GYPB. The locations of high- and low-incidence antigens are shown. The En (a) and U antigens involve large stretches of protein near the lipid bilayer and are missing in deletion and recombinant glycoproteins.

Caucasians, with approximately 25% of donors homozygous for M or N antigen. In contrast, the S antigen is nearly twice as frequent in Caucasians (57%) as in black people (30%). In a minority (<1%) of blacks, an S-s- or null phenotype can be observed. As with Rh antigens, the MNSs blood group antigens are expressed only on RBCs. Approximately one million M/N and 170–250 thousand S/s epitopes are present per RBC.

Null Phenotypes

Three major null phenotypes are present in the MNSs system: U-, M^k, and En (a-). The U- phenotype is the most common and is observed exclusively in blacks. In S-s-U- individuals, complete loss or a recombination of glycophorin B occurs, leading to altered expression of S/s and U antigens. Recombinant glycophorin B, such as the Henshaw phenotype, can react weakly with some examples of human anti-U and are known as U variants (S-s-U^{var}). The En (a-) phenotype is the result of recombination between glycophorin A and B genes to form a Lepore-type A-B hybrid

(exons A1-B2-B5) lacking most of glycophorin A (GYPA). The M^kM^k phenotype lacks all MNSs antigens, including En(a), as the result of recombination and deletion of glycophorins A and B (GYPA and GYPB). Loss of GYPA can coincide with loss of Wr^b expression, an antigen on Band 3. It is believed that Wr^b requires an electrostatic interaction between a glutamic acid (Glu658) on Band 3 and the ENEP antigen on glycophorin A (Poole, 1999).

Biochemistry

The M/N antigens reside on GYPA (CD235A), a major RBC membrane glycoprotein. In the membrane, GYPA is present as a dimer, usually in association with Band 3, the erythrocyte anion exchanger. Structurally, GYPA is a 31-kD, 131 amino acid, type 1 glycoprotein composed of a large, 72 amino acid extracellular domain, a transmembrane domain, and a short cytoplasmic tail (Fig. 35-3). The molecule is heavily glycosylated, possessing 15 O-linked and one N-linked carbohydrate side chain. The

O-linked glycans consist predominantly of a disialotetrasaccharide linked to a serine or threonine residue. Because of the large number of sialylated O-linked glycans on GYPA, nearly 60% and 50% of the total molecular weight is carbohydrate and sialic acid, respectively. Not surprisingly, GYPA is the major sialomucin on RBCs and contributes significantly to the overall negative charge or ζ potential (Huang, 1995). The M and N antigens reside on the extreme amino-terminus of GYPA.

The S/s and U antigens reside on GYPB, a related RBC glycoprotein (see Fig. 35-3). GYPB (CD235B) is a 20-kD, 72 amino acid glycoprotein composed of a large, extracellular N-terminal domain containing 11 O-linked glycans. Although GYPB shares considerable homology with GYPA at the amino-terminus, GYPB is smaller, lacking both an N-glycan and a cytoplasmic tail. In the membrane, GYPB appears to be closely associated with the Rh immune complex. The S/s epitope is located at amino acid 29 (Daniels, 2002).

Molecular Biology

The genes for GYPA and GYPB reside on chromosome 4q28-q31 as part of a 330-kb gene cluster encoding GYPA, GYPB, and glycophorin E (GYPE) (5'-A-B-E-3'). Studies indicate that GYPB and GYPE arose from GYPA by gene duplication and nonhomologous recombination. Similar to many erythroid-specific genes, the promoter region contains consensus sequences for Sp1 and GATA-1, an erythroid transcription regulatory binding factor (Rahuel, 1994). The greater stability of GYPA mRNA (>24 hours) over GYPB mRNA (<17 hours) may explain the greater numbers of GYPA on RBCs (Rahuel, 1994).

The biochemical nature of the MNSs antigens has long been known. The M and N antigens lie at the extreme amino-terminus of GYPA (amino acids 1-5) and include both protein and carbohydrate as part of the immune epitope. It is amino acid differences at positions 1 and 5, however, that define the M/N antigens (Table 35-13). It is not surprising that several low-incidence M and N antigen variants are the result of different amino acid substitutions (M^E , M^C) and/or altered expression of O-linked glycans (M_I , T_m , Can). In addition to GYPA, the N antigen is expressed on the extreme amino-terminus of GYPB. The latter is referred to as the 'N' antigen to distinguish it from N antigen on GYPA (Issitt, 1998). GYPA also possesses several high-incidence antigens (see Table 35-13).

Unlike the complexity of the M/N antigens, the S/s antigen is a single amino acid polymorphism on GYPB (Met29Thr). The U antigen is a high-incidence antigen involving amino acids 33-39 on GYPB. Loss of S-s-U antigens can be observed with M^k and other recombinant GYPB alleles such as Henshaw. It is estimated that 90% Henshaw+ RBCs are U- or U^{var} and account for 23% of all S-s-U- patients.

Recombination resulting in recombinant glycophorin proteins is associated with the loss of high-frequency antigens and the generation of new, low-frequency antigens (see Table 35-13). Historically, these were classified as the Miltenberger subsystem. Misalignments with single crossovers leading to A-B Lepore-type (e.g., Hil) and B-A anti-Lepore (Dantu) variants are known, as are gene conversion or double crossover events, in which segments of one glycophorin are inserted into the other to form B-A-B and A-B-A hybrids (Reid, 2004, 2009). Mutant GYP molecules can express MNSs antigens more strongly or weakly than normal and display unusual resistance or sensitivity to enzyme treatment (Reid, 2009). Some mutant GYPs are associated with increased Band 3 (Diego) expression (Hsu, 2009).

MNSs Antibodies

Anti-M and -N

Antibodies against M and N antigens are naturally occurring antibodies of IgM isotype, usually detected as room temperature saline agglutinins (see Table 35-7). Anti-M and anti-N may show dosage, reacting more weakly with heterozygous (M/N) cells than with homozygous (M/M or N/N) cells. Because the M and N antigens reside on GYPA, the reactivity of anti-M and anti-N is destroyed by pretreatment of RBCs with proteolytic enzymes or neuraminidase. Some examples of anti-M and anti-N can be enhanced by acidification of serum to pH 6.5, use of an albumin diluent, or preincubation of RBCs in a glucose-containing solution.

Clinically, anti-M is a commonly encountered antibody in the blood bank. In contrast, anti-N is distinctly uncommon, despite the fact that 25% of patients are negative for N antigen (M homozygous). The rarity of anti-N is due to the presence of 'N' antigen on GYPB. When observed, anti-N is usually an autoantibody, reacting with both N and 'N' antigens. An autoanti-N (anti-N₂) was reported in hemodialysis patients in the past,

caused by the use of formaldehyde to sterilize membranes. Formaldehyde reacted with the terminal leucine on N and 'N' antigens, creating a neo-antigen (Issitt, 1998). In general, anti-M and anti-N are clinically insignificant antibodies and only rarely cause hemolytic transfusion reactions or HDFN. In contrast, potent hemolytic alloanti-N is observed in patients lacking GYPB (M+N-S-s- phenotype). In these patients, severe hemolytic transfusion reactions and HDFN can occur after transfusion of N+ RBCs.

Anti-S, -s, and -U

Unlike anti-M and anti-N, antibodies against S, s, and U antigens are always clinically significant (see Table 35-7). All are antibodies of IgG isotype, reactive at 37° C, arising from immune stimulation. Some examples of anti-S and anti-s show dosage. Enzymatic modification of RBCs with proteases, but not neuraminidase, can decrease the reactivity of some anti-S and anti-s. The reactivity of anti-U is resistant to proteolytic digestion. Anti-S, -s, and -U are causes of hemolytic transfusion reactions and HDFN.

Biological Role

Despite the prevalence of GYPA and GYPB on RBCs, their biological role is still unknown: Their absence is not associated with any known hematologic or pathologic sequelae. Because they are rich in O-glycans and sialic acid, GYPA and GYPB contribute significantly to the ζ potential of red cells, decreasing homotypic and heterotypic red cell adhesion. GYPA also facilitates transport and expression of Band 3 (AE1/Diego), a critical protein in gas exchange. Increased Band 3 expression and osmotic resistance can be observed with Miltenberger type III red cells, a GYP B-A-B hybrid (Hsu, 2009). Finally, GYPA and GYPB may play a role in *Plasmodium falciparum* infections. *P. falciparum* can adhere to RBCs via sialic acid, which is highly expressed on glycophorins. Glycophorin-deficient phenotypes, such as En (a-), are relatively resistant to *P. falciparum* in vitro. Similar results can be obtained after neuraminidase treatment of RBCs (Garratty, 1994).

P BLOOD GROUP SYSTEM (ISBT NO. 003 AND 028)

The P blood group system historically consists of one antigen (P₁, ISBT 003) and two members of the GLOB collection, P^k and P (ISBT 028). Similar to the Lewis system (see later), the P blood group antigens are glycosphingolipids, consisting of an antigenically active carbohydrate moiety covalently linked to a ceramide lipid tail. P^k and P antigens are high-frequency antigens on most donor RBCs (>99.9%). RBCs are particularly rich in P antigen, which makes up nearly 6% of the total RBC lipid (van Deenen, 1974). P^k and P antigens are also expressed on nonerythroid cells, including lymphocytes, platelets, plasma, kidney, lung, heart, endothelium, placenta, uroepithelium, fibroblasts, and synovium (Cooling, 1995, 1998; Spitalnik, 1995). In contrast, the P₁ antigen is uniquely expressed on RBCs (Cooling, 1998). Approximately 79% of Caucasian and 94% of black donors express P₁ on their RBCs (Table 35-14). P₁ expression is variable between individuals and can be lost with in vitro storage.

Null/Weak Phenotypes

Several P blood group phenotypes have been described (see Table 35-14). The P₁ and P₂ phenotypes account for >99% of donors. Both possess P^k and P antigens and differ only in expression of the P₁ antigen. Three autosomal recessive null phenotypes have been identified, as well as weak variants (Issitt, 1998; Kundu, 1978, 1980). The molecular basis for the null phenotypes has been elucidated (Steffensen, 2000; Hellberg, 2002). An association between the P^k variant and Luke (LKE)-negative phenotype has been noted in some donors (Cooling, 2001, 2003a). Because they lack P antigen, p and P^k individuals are resistant to parvovirus B19 (Brown, 1994).

Biochemistry

Synthesis of the P^k, P, and P₁ antigens proceeds from the stepwise addition of sugars to lactosylceramide, a ceramide dihexose (CDH) (Fig. 35-4). The first step is the synthesis of the P^k antigen, the ultimate precursor of all globo-type glycosphingolipids. To make P^k antigen, Gb₃ synthase (α 4GalT1) adds a galactose, in an α 1-4 linkage, to CDH. The P^k antigen can then serve as a substrate for Gb₄ synthase (β 3GalNAcT1). In some cells, including RBCs, the P antigen is further elongated to form

*Glycophorin A (GYP A), glycophorin B (GYP B) or hybrid, recombinant glycophorins containing elements of GYP A and GYP B. ψB refers to GYP B pseudoexons.

additional, globo-family antigens such as Luke (LKE), Forssman, NOR, and type 4 chain ABH antigens (globo-ABH) (Roback, 2008).

Unlike P^k and P antigens, the P1 antigen is not a globo-glycosphingolipid but is a member of the neolacto-family (type 2 chain glycosphingolipids). In P₁ individuals, a terminal α1,4 galactose is added to paragloboside to form P1. The P1 antigen is not expressed on RBC glycoproteins despite the presence of multiple type 2 chain precursors (polylactosamine) on N-linked glycans (Yang, 1994).

Molecular Biology

The genes responsible for P^k, P1, and P have been cloned. It is believed that both P^k and P1 antigens are synthesized by α4GalT1, an α1,4 galactosyltransferase (Steffensen, 2000; Iwamura, 2003). The α4GalT1 gene resides on chromosome 22q13 and is organized into two exons, of which only one (exon 2) encodes the enzyme. The α4GalT1 enzyme is a 353

amino acid type II glycoprotein containing two N-glycosylation sites and five cysteine residues. Similar to many galactosyltransferases, it possesses a DXD motif or a UDP-Gal binding site. Several missense and frameshift mutations (insertions and deletions) in the enzyme catalytic domain have been identified among p individuals (Steffensen, 2000; Koda, 2002). The absence of P1 antigen in P₂ individuals was originally reported as the result of decreased transcription arising from mutations in the α4GalT1 promoter (–551C–500; Iwamura, 2003); however, subsequent studies questioned these findings (Tilley, 2006). A more recent study indicates that P1 synthesis arises from an alternate start codon and α4GalT1 transcript (Thursson, 2009). As a result, the P1 system has been renamed P1PK by the ISBT.

Globoside or P antigen, a β1,3 N-acetylgalactosaminyltransferase, is the product of β3GalNAcT1 (β3GalT3 in original literature; Okajima, 2000). The gene resides on chromosome 3q25 and contains six exons,

TABLE 35-14

RBC, Red blood cell.

*Recent study suggests that P₁ is transcribed by an alternate α4GalT1 transcript (Thursson, 2009).

[†]Multiple inactivating mutations have been identified in β3GalNAcT1 open reading frame associated with the P^k phenotype (Hellberg, 2002).

[‡]Multiple inactivating mutations have been identified in α4GalT1 open reading frame associated with the p phenotype (Steffensen, 2000; Koda, 2002).

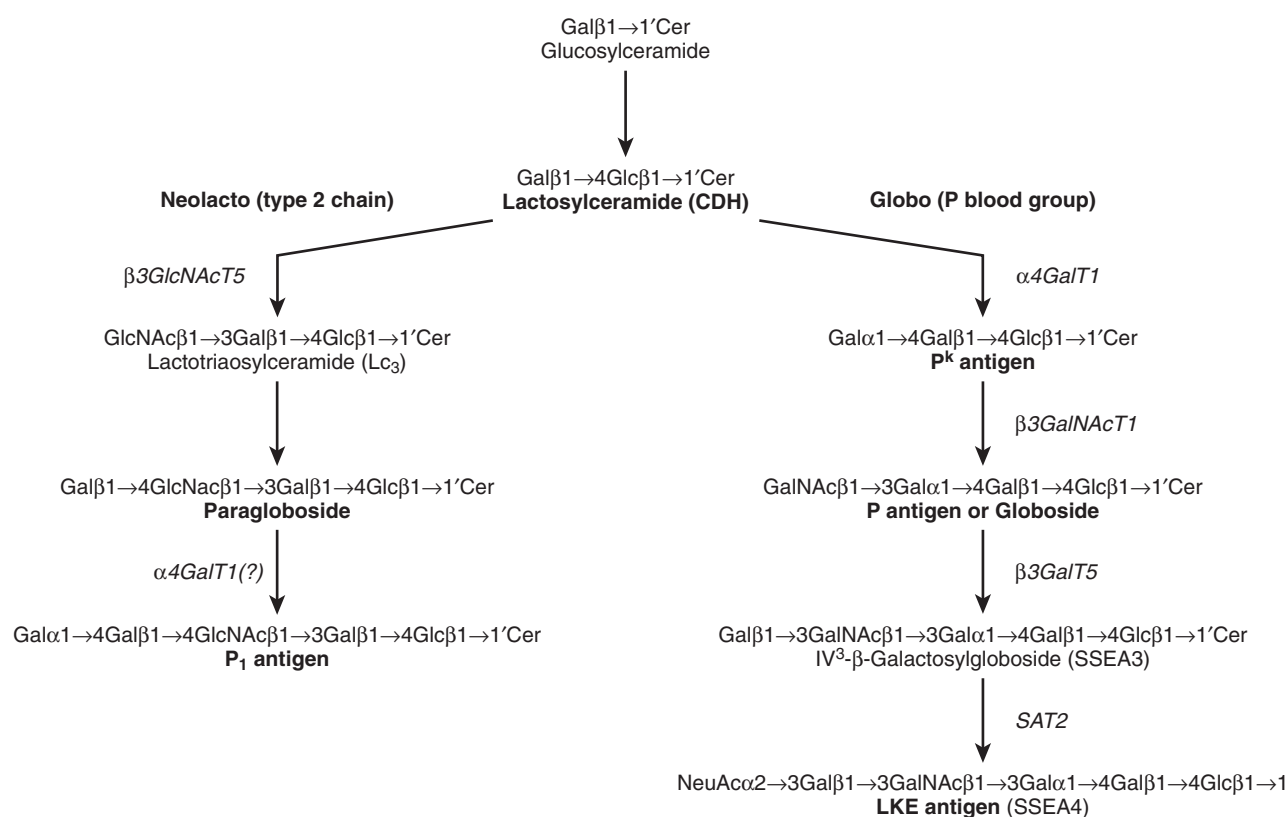

Figure 35-4 Synthesis of P blood group antigens. Cer, Ceramide; Gal, galactose; GalNAc, N-acetylgalactosamine; Glc, glucose; GlcNAc, N-acetylglucosamine; SSEA, stage-specific embryonic antigen; NeuAc, acetylneuraminic acid.

although only exon 6 encodes the enzyme. A member of the β1,3 galactosyltransferase family, β3GalNAcT1 possesses seven conserved domains common to most β1,3 galactosyltransferases, as well as a DXD motif. A variety of mutations have been identified in P^k individuals (Hellberg, 2002). In mice, the absence of β3GalNAcT1 is lethal (Vollrath, 2001).

P Blood Group Antibodies

Anti-P₁

Clinically, the most common antibody observed is anti-P₁, which is detected in one quarter to two thirds of P₂ donors (Issitt, 1998). Anti-P₁ is a naturally occurring antibody of IgM isotype and is often detected as a weak, room temperature agglutinin. Rare examples of anti-P₁ are reactive at 37° C or show in vitro hemolysis. Because P₁ expression varies in

strength between individuals, anti-P₁ may not react with all P₁-positive cells tested. Anti-P₁ can bind complement and may be detected in the indirect antiglobulin test (IAT) if polyspecific antihuman globulin (AHG) is used. Antibody reactivity can be eliminated by prewarming sera or by adding soluble P₁ substance from hydatid cyst fluid, earthworms, and bird eggs. Anti-P₁ titers are often elevated in patients with hydatid cyst disease or fascioliasis (liver fluke), and in bird fanciers (Issitt, 1998). Some examples of anti-P₁ have I blood group specificity (anti-IP₁).

In general, anti-P₁ is not clinically significant, and its presence rarely requires transfusion of antigen-negative blood. The exception is seen in patients with an anti-P₁ showing in vitro hemolysis. Because of the risk of immediate and delayed hemolytic transfusion reactions, these patients should receive P₁-negative (P₂), crossmatch compatible units. Anti-P₁ is not a cause of HDFN.

Alloanti-PP₁P^k

Anti-PP₁P^k (historically known as anti-Tj^a) is a separable mixture of anti-P₁, anti-P₂, and anti-P^k in the sera of p individuals. These antibodies are naturally occurring and may be IgM only or IgM plus IgG (IgG3). Because anti-PP₁P^k antibodies are potent hemolysins, patients can be transfused only with p RBCs. In women, alloanti-PP₁P^k and alloanti-P are associated with HDFN and spontaneous abortion. Early and frequent plasmapheresis has been used with therapeutic success in alloimmunized pregnant women of the p and P^k phenotypes (Spitalnik, 1995).

Alloanti-P

Anti-P is also a naturally occurring IgM alloantibody in the serum of P^k (and p) individuals. It is a potent hemolysin and can cause in vivo hemolysis following transfusion of P-positive (P₁ and P₂) RBCs. Alloanti-P is a cause of HDFN and is associated with spontaneous abortions.

Auto-Anti-P (Donath-Landsteiner)

An autoantibody with anti-P specificity is seen in patients with paroxysmal cold hemoglobinuria (PCH), a clinical syndrome that may occur in children following viral infection. In PCH, autoanti-P is an IgG, biphasic hemolysin capable of binding RBCs at colder temperatures, followed by intravascular hemolysis at body temperature. This characteristic can be demonstrated in vitro in the Donath-Landsteiner test. See full description in later sections on immunohematologic methods.

Biological Role

Unlike many antigens, the physiologic role of the P blood group antigens is not known. Evidence suggests that the P^k antigen may be associated with the α -interferon and major histocompatibility class II receptors (Ghislain, 1994; George, 2001) and may modulate cell signaling via lipid rafts (Kovbasnjuk, 2001). The P blood group antigens may also play a role in cellular differentiation and neoplasia. The P^k and P antigens are differentially expressed during embryogenesis, hematopoiesis, and intestinal mucosal differentiation (Jacewicz, 1995; Cooling, 2003b). The P^k antigen is a marker of apoptosis in germinal center B cells, Burkitt lymphoma, and lymphoblastic leukemia (Mangency, 1991). LKE is a marker of embryonic and mesenchymal stem cells (Gang, 2007) and is implicated in adhesion, cell signaling, and metastasis in renal cell and breast carcinoma (Satoh, 1996; Steelant, 2002).

Several P blood group antigens are receptors for microbial pathogens. The P blood group antigen is the receptor for parvovirus B19, a single-stranded DNA virus associated with multiple clinical sequelae, including aplastic crises (Brown, 1994; Cooling, 1995). P^k can bind human immunodeficiency virus (HIV) and may confer resistance to HIV infection (Lund, 2009). The P₁ and P^k antigens are receptors for shiga toxins, produced by *Shigella dysenteriae* and enterohemorrhagic *Escherichia coli* (EHEC) strains. In addition to gastroenteritis, EHEC infection is the most common cause of community-acquired hemolytic-uremic syndrome, probably reflecting toxin binding to P^k antigen on glomerular vascular endothelium and platelets (Boyce, 1995; Cooling, 1998; Karpman, 2001). P, P^k, and LKE blood group antigens on uroepithelium are cell receptors for P-fimbriae, a bacterial adhesin and colonization factor expressed on uropathogenic *E. coli* strains. The P^k antigen also serves as a receptor for *Streptococcus suis* and *Pseudomonas aeruginosa* (Spitalnik, 1995).

RH AND RHAG BLOOD GROUP SYSTEMS (ISBT NO. 004 AND 030)

The first and most clinically important characterization of the Rh system antigens came when Landsteiner and Wiener (1940) published studies of animal experiments involving the immunization of guinea pigs and rabbits with rhesus monkey RBCs. The resulting antiserum agglutinated 85% of human RBCs, and the antigen defined was called the Rh (rhesus) factor. This anti-Rh was later reported to have the same specificity as antibodies studied earlier by Levine and Stetson (1939) that were responsible for HDFN. It is interesting to note that the anti-Rh developed by Landsteiner and Wiener was later shown to recognize a different blood group antigen, named LW for its discoverers.

Today, the Rh system is probably the most complex red cell antigen system in humans, encompassing some 50 antigens, many phenotypic variants, and complex serologic relationships. Hence, the following review is basic and highlights the most current information. For a detailed, historical review of the Rh system, readers should consult Issitt (1998) and Daniels (2002).

†In historical Fisher-Race nomenclature, RhD-negative was designated as "d." At this time, RhD-negative phenotypes using Fisher-Race denote only the RHCE antigens present on red cells.

Theories of Rh Inheritance and Classification System

Using five basic antisera—anti-D, anti-C, anti-E, anti-c, and anti-e—Wiener identified five different factors or antigens (Table 35-15) that, from population and family studies, appeared to be inherited as two complexes of up to three factors each. Eight possible combinations of three-factor complexes were identified if one included "d" as designating the lack of D, because no anti-d had ever been demonstrated. Wiener proposed a single-locus inheritance system with eight alternative common alleles coding for two Rh agglutinogens, capable of expressing up to three different antigenic determinants. Wiener's nomenclature for the eight different genes and allelic frequencies is provided in Tables 35-16 and 35-17.

Fisher and Race later proposed a different inheritance theory and nomenclature system based on genetic evidence of the antithetical or allelic nature of the C/c and E/e antigens (Race, 1948). These investigators proposed a system of three closely linked loci or subloci on each chromosome, which were inherited as a block of genes (haplotype). They also introduced the DCE nomenclature to name the alleles, including the use of "d" to designate the lack of D locus (see Table 35-15). Rosenfield proposed a numeric system of naming the antigens in 1962, because the increasing number of Rh antigens rendered an alphabetic notation impractical (Table 35-18). It was also appreciated that this nomenclature contained no inferences as to the genetic inheritance of the antigens.

Biochemistry

Tremendous progress has been made in deciphering the biochemistry and molecular biology of the Rh blood group system. It is now clear that Rh complex consists of three integral membrane proteins: RhD, RhCE, and Rh-associated glycoprotein (RhAg). RhD and RhCE are highly homologous proteins, differing by approximately 30 amino acids. Both are 30-kD, 416 amino acid multipass proteins containing 12 transmembrane domains, six extracellular loops, and a cytoplasmic amino- and carboxy-terminus (Fig. 35-5). Both proteins possess two to three molecules of palmitate (C16 fatty acid) covalently linked to transmembrane cysteine residues. Palmitoylation of Rh proteins may help maintain the phospholipid asymmetry of the RBC membrane (Avent, 1999).

Figure 35-5 RH proteins. Both RHD and RHCE proteins are multipass proteins with 12 transmembrane domains, indicated by solid amber cylinders. The location of Rh antigens denoted by single-amino acid polymorphisms is denoted (•). The RhD epitope is a complex antigen involving structures on the third, fourth, and sixth extracellular loops. Missense mutations in RHD, leading to weak D expression, are indicated by open circles (○).

RhAg is a 45–70-kD multipass glycoprotein, evolutionarily related to RhD and RhCcEe glycoproteins. RhAg is a 409 amino acid glycoprotein with 12 transmembrane domains and a single, large *N*-linked carbohydrate side chain on the first extracellular loop. Overall, approximately 170,000 molecules each of Rh and RhAg proteins are present per RBC. RhD, RhCE, and RhAg are erythroid-specific proteins (Avent, 1999).

In the RBC membrane, RhD, RhCE, and RhAg proteins exist as part of an Rh immune complex, composed of two molecules of Rh (RhD and RhCE) and two molecules of RhAg (Eyers, 1994). The importance of RhAg for the expression and correct assembly of Rh proteins cannot be understated. In the absence of functional RhAg protein, neither RhD nor RhCE proteins will be expressed (Rh_{null} and Rh_{mod} phenotypes). In addition to RhAg, Rh proteins may be topologically associated with CD47 (Lutheran), ICAM4 (LW), DARC (Duffy), Band 3 (Diego), and GYPB. At least two non-Rh antigens, Fy5 and U, may require noncovalent interactions between Rh, DARC glycoprotein (Fy5), and GYPB (U), respectively (Ridgwell, 1994).

Molecular Biology

The genes for RhD (*RHD*) and RhCE (*RHCE*) proteins span 65kb on chromosome 1p34–36.1 and share nearly 92% sequence identity. The two genes are separated by only 30kb and have opposite orientations, facing each other at their 3' ends (Fig. 35-6). The *RHD* gene is also flanked by two homologous sequences known as rhesus boxes. The *RHAG* gene (*RHAG*) resides on chromosome 6p11.1 and shares 36% homology with the *RHD* and *RHCE* genes. All three genes possess 10 exons and at least one GATA-1 consensus sequence in the promoter region (Cherif-Zahar, 1994; Iwamoto, 1998). It is believed that *RHAG* and *RH* genes arose by gene duplication 250–350 million years ago. A second gene duplication 8–11 million years ago resulted in the ce and D alleles (cDe or R₀ haplotype). The remaining RHCE alleles are believed to be the product of point mutations, recombination, and gene conversion of the *RHD* and *RHCE* genes (Avent, 1999).

D Antigen

The cloning of *RHD* and *RHCE* genes opened the door to understanding the complex immunology of many Rh antigens and phenotypes. The D antigen, the most immunogenic of all the Rh antigens, resides on the RHD protein. Current evidence suggests that D is a highly complex antigen, depending on both specific amino acids and the tertiary structure of the RHD protein itself. At least nine “D-specific” amino acids (Met169,

TABLE 35-18

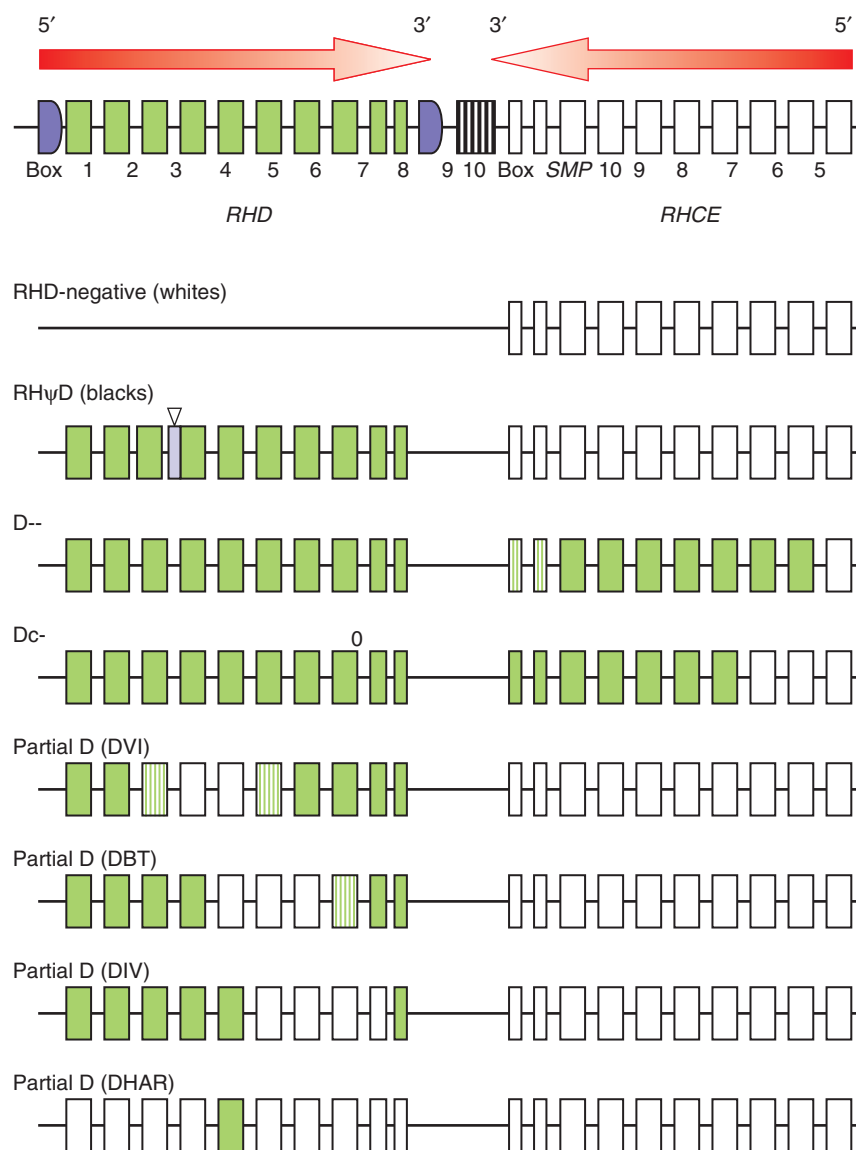

Figure 35-6 The *Rh* gene cluster. *RHD* and *RHCE* genes are closely situated and face each other at their 3' ends. The *RHD* gene is also flanked by Rh boxes. *SMP* is an unrelated gene. RHD-negative phenotype can result from deletion of the *RHD* gene or, in black people, a 37-base pair (bp) insertion leading to a frameshift (pseudogene). Also shown are examples of partial D and CE phenotypes that are the result of recombination between *RHD* and *RHCE* genes.

Met170, Ile172, Phe223, Ala226, Glu233, Asp350, Ala353, and Gly354) have been identified as functional D epitopes. The nine amino acids lie along the third, fourth, and sixth external loops of the RHD protein, creating six distinct D-epitope clusters or footprints (see Fig. 35-5). How the immune system recognizes these clusters is a matter of intense investigation (Avent, 1999).

Weak D Antigen

Approximately 1% of D-positive individuals type as weak D (historically known as D^w), characterized by weak or absent RBC agglutination by anti-D during routine serologic testing. In weak D individuals, the D antigen usually requires enhancement with AHG owing to a quantitative decrease in RhD protein. In these individuals, the number of RhD molecules is decreased 40–100-fold, ranging from 66–5200 molecules per red cell (Reid, 2004).

A weak D phenotype can occur with many partial D phenotypes, Ce *in trans* with suppression of RHD, in the Rh_{mod} phenotype, and via autosomal recessive inheritance of two weak RHD alleles. The latter accounts for the majority of weak D phenotypes present in the general population. To date, more than 40 different weak RhD alleles have been identified. Nearly all possess missense mutations, leading to amino acid substitutions, along the transmembrane and cytoplasmic domains (see Fig. 35-5). Because of their location, it is hypothesized that these mutations may interfere with the assembly or efficient insertion of the RhD protein. Furthermore, because all the mutations are intramembranous or intracellular, it is

assumed they do not significantly alter the presentation of D epitopes on the extracellular loops (Wagner, 1999). This may explain why most weak D individuals do not make alloanti-D when transfused with D-positive blood (see later).

Partial D Antigen

Partial D antigens are RHD proteins with missing D epitopes. Although they type as D-positive, persons with partial D antigens can make alloanti-D antibodies reactive with allogeneic, but not autologous, RBCs. The alloanti-D produced by these individuals recognizes D-specific epitopes missing on their own RBCs (see Fig. 35-6). Partial D can result from missense mutations or from genetic recombination of *RHD* and *RHCE* genes (Avent, 1999). Partial D phenotypes arising from genetic recombination are frequently associated with the generation of new, low-incidence antigens (see Table 35-18).

Rh-Negative Phenotype

Rh-negative (D⁻) occurs in approximately 15% of white donors, almost always in association with a ce/ce or rr phenotype. In most Caucasian people, D⁻ reflects a deletion of the entire *RHD* gene (see Fig. 35-6). In blacks, D⁻ can result from gene deletion or from inheritance of an *RHD* pseudogene. Nearly 60% of D-negative black people inherit a mutant *RHD* allele (RHψD) containing a 37-base pair (bp) internal duplication, frameshift, and premature stop codon (Avent, 1999). *RHD* genes containing nonsense mutations and nucleotide deletions have also been reported

in some D-negative Japanese and Caucasian donors (Daniels, 2002; Reid, 2004).

C/c, E/e, and Compound Rh Antigens

In contrast to the complexity of the D antigen epitope, the C/c and E/e antigens are single-amino acid polymorphisms on the RhCE protein (see Fig. 35-5). Three additional amino acid polymorphisms (Cys16Trp, Ile-60Leu, and Ser68Asn) may help stabilize the C and c antigens. Arg229 appears critical to e and f expression (Chen, 2004). Because C/c and E/e epitopes are present on the same protein, alloantibodies dependent on the expression of both C/c and E/e antigens can occur. Four alloantibodies with “compound” Rh specificity have been described: anti-ce (f or RH6), anti-Ce (RH7), anti-cE (RH27), and anti-CE (RH22). These antibodies react only with RBCs carrying the appropriately paired antigens, in *cis*, on the same RhCE protein (see Table 35-18). The RHCE protein is home to several additional high- and low-incidence antigens.

G Antigen

The G antigen (RH12) is a high-frequency antigen present on virtually all D-positive and C-positive RBCs. G has been identified as Ser103, a C-type antigen, on RHD and RHCE proteins (see Fig. 35-5). It is not surprising that anti-G alloantibodies have both anti-C and anti-D specificity (anti-C + D) and are frequently accompanied by anti-C (anti-G + anti-C) (Shirey, 1997).

Weak and Deletion C/c and E/e Phenotypes

Similar to D, phenotypes with weakened or absent C/c and E/e are known. *RHCE* alleles with point mutations, deletions, and recombinations can lead to weakened CcEe expression. African ethnic groups, in particular, show significant molecular diversity in *RHCE* alleles. A recent study reported partial C [(C)ce^s] phenotype in nearly 25% of sickle cell patients (Noizat-Pirenne, 2009). Although these patients serologically type as C+c+, rare patients can produce an alloanti-c (Ong, 2009; Pham, 2009). Likewise, point mutations and rearrangements resulting in weakened e expression and alloantibody formation (anti-e, hr^s) are well known (Reid, 2004; Vege, 2009).

The deletion phenotypes D••, D— (↑D+, C—c—E—c—), DC— and Dc— are the result of genetic recombination between *RHCE* and *RHD* genes to yield RHCE-D-CE hybrids (see Fig. 35-6). As a consequence, total ablation of Ee and/or Cc epitopes occurs, with many recombinants expressing new low-frequency Rh antigens (see Table 35-18). Furthermore, many recombinants (e.g., D••, D—) demonstrate exalted D antigen expression on serologic testing owing to a double dose of some D epitopes on both RHD and mutant RHCE-D-CE proteins. For a detailed summary, the reader is referred to Reid (2004).

RHAG Alloantigens

RHAG is a new blood group system with three antigens; Ol^a, Duclos, and DSLK (Tilley, 2010). All three are the result of an amino acid polymorphism in the RhAg protein. Both Duclos and DSLK are associated with weak U expression, suggesting an interaction between RhAg and GYPB.

Rh_{null} Phenotype

Rh_{null} erythrocytes lack all Rh antigens as a result of an apparent absence of RhD and RhCE proteins. In addition, Rh_{null} erythrocytes lack the high-frequency antigens Fy5 and LW and may have markedly decreased expression of S/s and U antigens. The absence of these non-Rh antigens reflects the complex topologic association of Duffy, LW, and GYPB proteins with Rh proteins on RBC membranes.

Extremely rare (<1 in 6 million), Rh_{null} cells have abnormalities in RBC morphology (spherocytes, stomatocytes), water content, cell volume, cation fluxes, carbon dioxide (CO₂) permeability, and phospholipid asymmetry (Issitt, 1998; Endeward, 2006). Rh_{null} cells show increased osmotic fragility and a shortened circulating half-life, often accompanied by a mild hemolytic anemia (Rh deficiency syndrome). Because Rh_{null} individuals can become sensitized to multiple Rh antigens, including high-frequency antigens, transfusion support can be quite difficult. Some alloimmunized Rh_{null} individuals can produce anti-RH29, which reacts with all RBCs except Rh_{null}.

The Rh_{null} phenotype can arise from two distinct genetic backgrounds—regulator and amorph. The Rh_{null}-amorph type is the result of nonsense mutations in the *RHCE* gene in D-negative people. Because of the absence of RhD and RhCE proteins, Rh_{null}-amorph RBCs have reduced (but not absent) expression of RhAg protein (Daniels, 2002). The Rh_{null} regulator type arises from mutations in *RHAG* (Reid, 2004).

Rh_{mod} Phenotype

Mutations in *RHAG* are also observed in the Rh_{mod} phenotype. Rh_{mod} RBCs have markedly decreased Rh and RhAg expression, detectable only by careful adsorption and elution studies. Similar to Rh_{null} individuals, persons with Rh_{mod} may have laboratory evidence of Rh deficiency syndrome with a mild hemolytic anemia. Three Rh_{mod} samples have been studied, each containing a single, different missense mutation in the *RHAG* gene (Reid, 2004).

Rh Antibodies

Antibodies against Rh antigens are routinely encountered in the blood bank (see Table 35-7). D is the most immunogenic Rh antigen, followed by c, E, C, and e (Harmening, 2005). In general, antibodies against Rh antigens are the result of immune stimulation by transfusion or pregnancy. Exceptions include some examples of anti-C^w and anti-E, which can be naturally occurring. Most antibodies against Rh antigens are of IgG isotype (IgG₁ and IgG₃), although rare examples of IgM and IgA are known. Anti-Rh antibodies are reactive at 37° C and are usually detected in the AHG phase of testing. The reactivity of anti-Rh antibodies can be enhanced with enzyme-treated RBCs. The gel method is extremely sensitive for the detection of Rh antibodies (Weisbach, 2006).

Clinically, antibodies against Rh are associated with hemolytic transfusion reactions. However, because Rh antibodies do not fix complement, incompatible RBCs are almost always cleared through extravascular destruction. To prevent sensitization to the D antigen, Rh-negative patients should be transfused with Rh-negative RBCs. This is particularly true for young girls and women of childbearing age. For transfusion in alloimmunized patients, RBC units should be negative for the Rh antigen of interest and crossmatch compatible with the recipient's serum through the AHG phase of testing. One possible exception may be R₁R₁ (DCE/DCe) patients who have developed anti-E alloantibodies. Because these patients are at increased risk of delayed hemolytic transfusion reactions because of the subsequent development of anti-c, many blood bankers advocate transfusing only R₁R₁ units to R₁R₁ patients (Shirey, 1994).

Antibodies against Rh antigens are also a major cause of HDFN. All Rh-negative women should receive Rh immune globulin (IgG anti-D) prophylactically in midpregnancy, following an invasive procedure (i.e., amniocentesis), and immediately after delivery to prevent alloimmunization. Rh immune globulin prophylaxis is also recommended in women with partial D phenotypes because these women can be at risk for D alloimmunization (Ansart-Pirenne, 2004). Rh immune globulin may also be given following transfusion of RhD+ platelet concentrates or after accidental transfusion of RhD+ RBCs. In the latter, Rh immune globulin is given after two-volume RBC exchange with RhD-negative RBCs (Nester, 2004). Administration of one vial of Rh immune globulin is recommended for every 30 mL whole blood or 15 mL packed RBCs transfused (Roback, 2008). Rh immune globulin should be given within 72 hours of exposure to prevent active immunization. Rh immune globulin is not given to Rh-negative women who are already immunized to D antigen (i.e., have anti-D).

It is also recommended to give Rh immune globulin to Rh-negative women with anti-G alloantibodies. As stated earlier, anti-G behaves as an anti-C + anti-D because of recognition of a Ser103 or C-type antigen on both RhD and RhCE proteins. In general, HDFN secondary to anti-G or anti-C + anti-G is mild when compared with HDFN due to anti-D. However, because these women may still become immunized to D-specific epitopes on the RhD protein, many blood bankers advocate giving Rh immune globulin to Rh-negative women with anti-G antibodies (Shirey, 1997). Separation of anti-G from a true anti-C + anti-D is very laborious, requiring sequential adsorption and elution (Jesus, 1985). One clue suggesting the presence of anti-G is an anti-C titer at least fourfold higher than anti-D (Shirey, 1997). It is not necessary, however, to separate anti-G from anti-C + anti-D for routine transfusion. With very rare exceptions, RBCs negative for D and C antigens are also negative for G antigen.

Biological Role

The specific physiologic function of the Rh proteins is still unclear; however, there is a strong belief that Rh proteins may constitute a membrane transporter. The Rh proteins are homologous with ammonium transporters of the Mep/Amt family. In addition, Rh-like homologs have been discovered in invertebrate life forms such as the nematode worm *Caenorhabditis elegans* and a marine sponge, *Geodia cydonium* (Avent, 1999). Evidence suggests that RhAg is capable of facilitating NH₄ transport. It is speculated that the Band 3/Rh complex may serve as an O₂/CO₂ gas exchange metabolon (Daniels, 2007).

LUTHERAN BLOOD GROUP SYSTEM (ISBT NO. 005)

The Lutheran (Lu) blood group system contains 19 antigens including four pairs of allelic antigens and 11 high-incidence antigens. Lutheran is a minor constituent of RBC membranes, averaging only 2000–5000 molecules per cell, and can vary in strength between donors (Issitt, 1998). Even within a single individual, considerable heterogeneity in Lutheran expression is seen, with only 40%–50% of red cells positive for Lutheran antigens by flow cytometry (El Nemer, 1998). Lutheran appears on red cells at the orthochromatic erythroblast stage, concurrent with binding of red cells to laminin (Daniels, 2009). Lutheran antigens are ubiquitously expressed on human tissues. In addition to RBCs, Lutheran glycoprotein is expressed by colon, small intestine, ovary, testis, prostate, thymus, spleen, pancreas, kidney, skeletal muscle, liver, lung, placenta, brain, heart, and bone marrow (Rahuel, 1996).

Null/Weak Phenotypes

A Lu(a-b-) phenotype can occur in three settings with distinct patterns of inheritance: autosomal recessive, autosomal dominant (*In(Lu)*), and X-linked recessive (Table 35-19). The autosomal recessive phenotype is a true null phenotype, characterized by complete absence of all Lutheran antigens on RBCs. As a consequence, these individuals can make an allo-antibody to Lutheran glycoprotein (anti-Lu3) which reacts with all Lu-positive RBCs. The Lu_{null} phenotype is extremely rare and is not associated with altered expression of other red cell antigens.

The autosomal dominant and X-linked recessive forms are characterized by very weak Lutheran expression, often detected only after adsorption and elution. *In(Lu)* is an autosomal dominant Lu_{mod} phenotype with an incidence of 0.02%–0.12% (Daniels, 2009). In addition to Lutheran antigens, *In(Lu)* red cells can show weakened expression of P₁, i, Indian/CD44, and Knops/CD35 antigens and enhanced expression of CDw75 (Daniels, 2002, 2009). The X-linked Lu_{mod} phenotype has weakened Lutheran, enhanced i and CDw75, and normal P₁, i, and CD44 expression. Because both *In(Lu)* and X-linked recessive Lu_{mod} phenotypes express some Lutheran antigen on RBCs and other tissues, neither is associated with the development of anti-Lu3. *In(Lu)* RBCs can display subtle abnormalities, including increased poikilocytosis and increased hemolysis, during in vitro storage (Ballas, 1992).

Biochemistry

The Lutheran antigens reside on two isomeric, type 1 glycoproteins: Lu-glycoprotein (85kD) and epithelial cancer antigen (B-CAM, 78kD) (Daniels, 2009). The 85-kD glycoprotein is the predominant isoform found on RBCs and normal tissues. Members of the Ig superfamily, the 78- and 85-kD glycoproteins share a common, large (518 amino acid) extracellular domain with five Ig regions and five potential N-glycosylation sites (Fig. 35-7). Three Ig domains are of the constant-region-2 (C2) type, whereas the remaining two are variable-region (V) domains. A laminin binding site resides in a flexible hinge region between C2 and V domains.

Figure 35-7 Lutheran glycoprotein. The Lutheran antigens reside on one of five immunoglobulin domains (V, C2-like). The transmembrane domain is indicated by a solid amber cylinder. The length of the cytoplasmic domain can vary from 19 amino acids (78-kD form) to 59 amino acids (85-kD isoform). The latter also possesses a consensus-binding motif for Src protein (SH3 domain).

ISBT, International Society of Blood Transfusion.

The 7-kD difference between the 78-kD and 85-kD isoforms reflects the length of the COOH-terminal cytoplasmic tail. In addition to its longer length, the cytoplasmic domain of the 85-kD isoform possesses an SH3 motif, a potential binding site for Src protein. The cytoplasmic domain also interacts with spectrin, a cytoskeletal protein (Kroviarski, 2004). Because it is a highly folded protein, stabilized by disulfide bonds, Lutheran is destroyed by sulfhydryl-reducing agents and many proteases.

Molecular Biology

The gene for Lutheran (LU) resides on chromosome 19q13.2-13.3. It is a 12.5-kb gene containing 15 exons: Alternate splicing of exon 13 is responsible for the 78-kD minor isoform (Rahuel, 1996; El Nemer, 1997). Although no TATA or CAAT boxes are present in the 5' flanking or promoter region of the gene, it does possess consensus sequences for several *cis*-regulatory elements, including the ubiquitous Sp1, AP2, EGR-1, EKLF, Ets, and GATA-1, an erythroid transcription binding protein (El Nemer, 1997; Singleton, 2008).

The molecular basis for most Lutheran antigens is now known (Table 35-20). Most are the result of SNPs (Daniels, 2002, 2009). The autosomal recessive, true Lu_{null} phenotype arises from inheritance of two silent amorph LU alleles due to nonsense mutations and deletions (Daniels, 2009). The molecular basis for the autosomal dominant *In*(Lu) phenotype was finally identified in 2008. Most *In*(Lu) individuals are heterozygous for a mutant *EKLF* gene, an erythroid transcription factor active in late erythroid differentiation (Singleton, 2008). The *In*(Lu) phenotype, therefore, is the result of reduced transcriptional activation and expression of LU glycoprotein. Reduced EKLF activity likely accounts for decreased expression of other blood group antigens. The basis for the X-linked recessive (XS2) has been identified as mutations in the transcription factor GATA1, which resides on the X chromosome.

Lutheran Antibodies

In general, Lutheran antibodies are not clinically significant and are only rarely associated with HDFN and hemolytic transfusion reactions. Anti-Lu^a is the most common Lutheran alloantibody encountered in the blood bank and is often an IgM, room temperature agglutinin. Because not all RBCs express detectable Lu antigens (El Nemer, 1998), anti-Lu^a can display mixed field agglutination. Antibodies against Lu^b and other Lutheran antigens are most often of IgG isotype, reacting best in the IAT. Reactivity of anti-Lu^a, Lu^b, and other Lutheran antibodies can be inhibited by pretreatment of RBCs with chymotrypsin, trypsin, 2-aminoethylisothiuronium bromide (AET), and dithiothreitol (DTT).

Biological Role

Biologically, Lutheran is a high-affinity receptor for laminin, a basement membrane protein involved in cell differentiation, adhesion, migration, and proliferation. Overexpression of LU glycoprotein in ovarian carcinoma and other cancers is hypothesized to facilitate tumor cell adhesion and metastasis (Rahuel, 1996). In sickle cell patients, increased Lutheran expression on reticulocytes and sickle cells may contribute to the pathophysiology of vaso-occlusive crises. Patients with sickle cell disease have indirect evidence of chronic vascular injury with shedding of microvascular endothelial cells and exposure of vascular basement membrane (Solovey, 1997). In these patients, increased exposure of laminin on the thrombotic subendothelium, coupled with increased expression of laminin receptor on reticulocytes and sickle cells, may promote red cell adhesion and circulatory stasis (El Nemer, 1998; Parsons, 2001). Likewise, LU glycoprotein may contribute to thrombosis in polycythemia vera. The *JAK2* mutation was shown to increase phosphorylation of LU glycoprotein and red cell adhesion (Daniels, 2009). In normal erythropoiesis, LU may play a role in migration of maturing erythroid cells out of the marrow (Daniels, 2009).

KELL AND KX BLOOD GROUP SYSTEMS (ISBT NO. 006 AND 019)

First identified in 1945, the Kell blood group system currently consists of 46 high- and low-frequency antigens (Table 35-21). Eleven Kell antigens belong to five sets of allelic antigens, whereas the remainder are predominantly high-incidence antigens (>99% of the population). Many low-incidence Kell antigens (K, Js^a, U^k, Kp^a, Kp^b) show distinct racial differences. The Kell antigen is found on RBCs, erythroid and megakaryocyte progenitors, skeletal muscle, and testis. RBCs express approximately 2000–6000 copies of Kell protein per cell (Issitt, 1998).

Null and Weak Phenotypes

K₀K₀ is an autosomal recessive, null phenotype that completely lacks all Kell antigens (Table 35-22). As a consequence, these individuals can make an alloantibody to the Kell glycoprotein (anti-Ku). Unlike McLeod RBCs (see later), K₀K₀ RBCs have enhanced expression of Kx antigen, present on the XK protein. Unlike Rh_{null} red cells, K₀K₀ red cells have no decrease in CO₂ permeability (Endeward, 2006). A K₀K₀ RBC can be produced in the laboratory by treating Kell-positive RBCs with sulfhydryl-reducing agents.

Kell antigens are significantly depressed/absent on McLeod RBCs, an X-linked recessive phenotype characterized by the absence of XK protein on RBCs (Kx antigen, XK1; ISBT 019), acanthocytes, and neuromuscular disorders. Because McLeod individuals lack XK and Kell proteins, these individuals can make alloantibodies directed against both proteins. As a consequence, McLeod individuals are incompatible with both Kell-positive and K_0K_0 RBCs. Depressed Kell expression is also observed on K_{mod} and Gerbich-negative RBCs, two autosomal recessive phenotypes. As with the K_0K_0 phenotype, some K_{mod} individuals have increased Kx (KEL15) expression and can develop an anti-KEL5 (anti-Ku) following RBC transfusion. Transient depression and masking of Kell antigens have been reported in septic patients and in autoimmune hemolytic anemia due to anti-Kell autoantibodies (Judd, 1981; Issitt, 1998; Bosco, 2009). Kell antigens are also depressed (up to 80%) in alleles bearing KEL3 in *cis* (e.g., KKp^a , $KEL^*1,3$; kKp^a , $KEL^*2,3$) (Poole, 2006; Kormoczi, 2009).

Biochemistry

The Kell antigens (ISBT No. 006) reside on a 93-kD, 732 amino acid glycoprotein (CD238), possessing a short 47 amino acid amino-terminal cytosolic domain; a single transmembrane domain; and a large, 665 amino acid extracellular domain that includes the carboxy-terminus and 4-5 *N*-linked glycans (Fig. 35-8). In the KEL1 phenotype, a Thr183>Met substitution voids a glycosylation site, resulting in only four *N*-linked glycans (Lee, 1997).

Overall, the molecule has a complex, folded tertiary structure due to the formation of multiple disulfide bonds by the 15 cysteine residues present in the extracellular domain of the molecule (Lee, 1997). Because of its highly folded nature, the Kell glycoprotein is fairly resistant to proteolytic digestion but is exquisitely sensitive to sulfhydryl-reducing agents such as DTT, AET, 2-mercaptoethanol (2-ME), and ZZAP, a combination of DTT and cysteine-activated papain.

Figure 35-8 Diagram of KELL and XK protein. KELL is covalently linked to the XK protein by a disulfide bond (---) through Cys72 of Kell and Cys347 of XK. The sites of different Kell antigens are indicated by solid lines. The highlighted area at the carboxy-terminus of KELL represents the domain sharing the most homology to other NECK family proteins (NEP-24.11, ECE-1, PEX). The zinc-binding motif (HELLH) is a consensus sequence shared by zinc-dependent metalloproteinases. The transmembrane domains of KELL and XK protein are indicated by solid amber cylinders. The *N*-glycosylation sites are indicated by branched structures. The *N*-glycosylation site marked by an asterisk is not present in individuals of the KEL1-positive phenotype.

In the RBC membrane, the Kell glycoprotein is covalently linked to the XK protein (ISBT No. 019), a 444 amino acid, nonglycosylated, multipass protein containing 10 transmembrane domains. Encoded by a gene on chromosome Xp21, the XK protein is hypothesized to be a membrane transport protein. On RBCs, the XK protein is covalently linked to the Kell protein through a disulfide bond at C347 on the fifth extracellular loop of XK protein and C72 of Kell. In the absence of XK protein (McLeod phenotype), Kell expression is decreased on RBCs, suggesting that XK protein may help transport Kell. Transfection studies in COS cells, however, show normal transport and folding of the Kell protein in the absence of XK protein (Russo, 1998). Nor is expression of XK dependent on Kell expression. The XK protein is expressed on several nonerythroid tissues, including liver, skeletal muscle, heart, brain, and pancreas (Ho, 1994).

Molecular Biology

Cloned in 1991, the Kell gene (*KEL*) contains 19 exons spanning 21.5kb on chromosome 7q34 near the cystic fibrosis gene. The promoter region and exon 1 contain several consensus-binding sequences for GATA-1, an erythroid transcription regulatory binding factor. Kell is a member of the M13 neprilysin family of zinc neutral endopeptidases and shares homology with common acute lymphocytic leukemia antigen (CALLA, CD10), endothelin-converting enzyme-1 (ECE-1), neutral endopeptidase 24.11 (NEP-24.11), and PEX. The region of greatest homology lies in the carboxy-terminal half of the molecule (amino acids 550–652) and is sometimes referred to as the NECK domain (N-24.11, EC-1, K family). This relatively conserved region shares 34%–36% homology with the carboxy-terminal catalytic domains of NEP-24.11 and ECE-1, as well as a pentameric zinc-binding motif (HELLH), a common feature of zinc-dependent metalloproteinases (Lee, 1997).

With cloning of the Kell gene, the molecular and biochemical basis of several Kell antigens became possible. As shown in Table 35-21, all the Kell alloantigens identified and sequenced are single-amino acid polymorphisms in the translated Kell protein. Furthermore, nearly every amino acid polymorphism occurs in the amino half of the molecule (Lee, 1997).

Several individuals with absent or depressed Kell expression have also been studied. K_0K_0 phenotype arises from homozygosity for a silent *KEL* morph gene. Multiple inactivating mutations of the *KEL* gene have been identified, including splice-site mutations and premature stop codons (Reid, 2004). Missense mutations, sometimes leading to premature stop codons, are responsible for the K_{mod} phenotype (Reid, 2004). Several mutations have been identified in the XK protein on Xp21, responsible for the McLeod phenotype (Russo, 2002). The molecular basis for decreased Kell antigen expression with Gerbich-negative phenotypes is unknown. It is speculated that Kell and glycophorin C (Gerbich) may be near neighbors on the RBC membrane.

Kell Antibodies

Alloantibodies against antigens in the Kell blood group system are clinically significant (see Table 35-7). They can be associated with both immediate and delayed hemolytic transfusion reactions. Anti-Kell antibodies are also associated with HDFN. HDFN secondary to maternal anti-Kell antibodies is often characterized by reticulocytopenia, with little or no bilirubinemia. It is now known that maternal anti-Kell (anti-KEL1 or K1) directly suppresses erythroid progenitors, leading to a severe reticulocytopenic anemia in the fetus (Vaughan, 1998) with up to 30% of affected infants presenting with fetal hydrops (van den Akker, 2008). Anti-K1 is present in approximately 1% of pregnancies, with HDFN affecting 40% of K1-positive infants (Finning, 2007). Several centers now routinely screen and refer prenatal patients with Kell antibodies, with improved perinatal outcomes (Kamphuis, 2008). Reports have also described neonatal thrombocytopenia due to suppression of marrow megakaryocytes (Wagner, 2000). In general, thrombocytopenia is mild, with only 2% of infants having platelet counts of $<100 \times 10^9/L$ (van den Akker, 2008). Similar to RHID, fetal genotyping can be performed on maternal plasma (Finning, 2007).

The most commonly encountered antibody against the Kell blood group system is anti-K1, which is second only to Rh D in immunogenicity. Antibodies against Kell antigens are of IgG isotype, arising from immune stimulation via transfusion or pregnancy, although examples of naturally occurring anti-Kell alloantibodies are known (Judd, 1981). Because Kell antigens are sensitive to sulfhydryl-reducing agents, the activity of anti-Kell antibodies can be eliminated by pretreatment of RBCs with AET, DTT, 2-ME, or ZZAP.

Biological Role

Kell cleaves endothelin-3, a vasoactive peptide that functions in endothelial cell migration, neovascularization, axonal growth, and neural crest development. In a murine Kell_{null} model, absence of Kell led to only subtle effects, including decreased blood pressure, blunting endothelin-3 activation of Ca⁺⁺-dependent K⁺ channels, decreased microvascular formation, and mild changes in motor function (Zhu, 2009). Because endothelin-3 is also cleaved by ECE-1, a related endothelin converting enzyme, Kell may have only a minor physiologic role in endothelin-3 homeostasis. The ability of anti-Kell to suppress fetal erythropoiesis also suggests a possible role for Kell during erythroid differentiation and maturation (Vaughan, 1998); however, only minor differences in mean corpuscular volume, mean corpuscular hemoglobin, hemoglobin (Hg), and reticulocyte counts were observed in Kell_{null} mice (Zhu, 2009).

In contrast to Kell, the absence of XK protein is strongly associated with several abnormal clinical and laboratory findings. McLeod RBCs have shortened survival, decreased permeability to water, and abnormal morphology (acanthocytes). The McLeod syndrome, characterized by both hematologic and neuromuscular abnormalities, typically presents with areflexia, dystonia, and choreiform movements late in life. Late-onset muscular dystrophy and cardiomyopathy can also be seen. Both hematologic and neuromuscular defects in McLeod patients are believed to result from the absence of XK protein on red cells, brain, heart, and skeletal muscle (Ho, 1994). It is interesting that the Huntington's disease gene, another neurodegenerative disorder, is located near the XK gene on the X chromosome (Issitt, 1998).

The McLeod phenotype can also be associated with chronic granulomatous disease (CGD), a functional neutrophil defect resulting in severe, recurrent, life-threatening bacterial infections. In two thirds of patients, CGD results from a deletion or mutation of the cytochrome *b* gene (*CYBB*) on the X chromosome. Because of the proximity of the *CYBB* and *XK* genes on the X chromosome, approximately 7% of patients with X-linked CGD also express a McLeod phenotype (Curnutte, 1995).

LEWIS BLOOD GROUP SYSTEM (ISBT NO. 007)

The Lewis blood group system is unusual in that the Lewis antigens are not of erythroid origin. It primarily consists of two antigens: Lewis^a (Le^a) and Lewis^b (Le^b). Four additional antigens (Le^{ab}, Le^{bH}, ALe^b, BLe^b) reflect the influence of ABO on Lewis synthesis and antigenicity. On RBCs, the Lewis antigens reside on glycosphingolipids, composed of a Lewis-active carbohydrate head group linked to a ceramide (*N*-acyl sphingosine) lipid tail. Lewis antigens are synthesized in the gastrointestinal tract and passively adsorbed onto RBCs from a soluble pool of secreted Lewis substance in plasma (Hauser, 1995). Tissues and fluids expressing Lewis include plasma, saliva, RBCs, platelets, lymphocytes, endothelium, uroepithelium, and bowel mucosa. In some tissues, Lewis antigens are expressed on glycosphingolipids, glycoproteins, and mucins (Issitt, 1998).

Three Lewis phenotypes are observed in adults: Le (a+b-), Le (a-b+) and Le (a-b-). The Le (a+b+) is only rarely observed, usually on RBCs of very young children and some individuals of Polynesian, Japanese, or Taiwanese ancestry (Issitt, 1998). As shown in Table 35-23, the Le (a-b-) phenotype is five times more common in blacks than in Caucasians. The Le (a-b-) phenotype is also increased in neonates owing to developmentally delayed expression of the *Lewis* and *Secretor* genes. By 5 years of age, most children will express adult levels of Lewis antigens on their RBCs. The amount of Lewis antigen on RBCs is also influenced by ABO type.

Le (a-b+) RBCs from group O donors appear to have more Le^b than A₁ and B cells. As will be discussed later, group A₁ and B donors can convert Le^b to ALe^b and BLe^b, respectively (Issitt, 1998).

Biochemistry

Although biosynthetically related to each other, the Le^a and Le^b antigens are not allelic antigens. They represent the complex interaction of two distinct glycosyltransferases: fucosyltransferase type II (FUT2) and fucosyltransferase type III (FUT3). FUT3 is the product of the *Lewis* gene (*Le/FUT3*) and is an α1-3/4 fucosyltransferase. FUT2, the product of the *Secretor* gene (*Se*), is an α1-2 fucosyltransferase related to the *H* gene, FUT1. How *Le*, *Se*, and *ABO* genes interact to yield the different combinations of RBC and plasma phenotypes is shown in Table 35-23 and Figure 35-9.

The precursor molecule for Lewis and related antigens is a type 1 chain precursor, historically known as the Le^c antigen. In Le (a+b-) donors, FUT3 or *Lewis* adds an α1-4 linked fucose to Le^c to form the Le^a antigen. Because these donors lack the *Se/FUT2* gene (*se/se*), no type 1 chain H (Le^b) is made. As a result, only Le^a antigen is present in plasma, saliva, and RBCs. The Le (a-b+) red cell phenotype results from the inheritance of both *Le* and *Se* genes. FUT3 still converts a small amount of type 1 chain precursor to Le^a antigen. However, most Le^c substance is converted to type 1 chain H or Le^d by FUT2 (see Fig. 35-9). FUT3 subsequently adds a second fucose to form Le^b antigen (Lowe, 1994). In group A and B persons, type 1 chain H is further modified by the A/B glycosyltransferase to form type 1 chain A and B antigens. Similar to type 1 chain H and Le^c antigens, these molecules can serve as substrates for FUT3 to form ALe^b and BLe^b (see Fig. 35-9). In group A₁ donors, ALe^b is the major Le^b antigen found in plasma (Lindstrom, 1992).

The Le (a-b-) red cell phenotype occurs in individuals who lack the *Le/FUT3* gene. Individuals who are negative for both *Le* and *Se* alleles (*le/le*, *se/se*) are unable to synthesize Le^a antigen or type 1 chain H antigens. As a result, only type 1 chain precursor or Le^c antigen is present in secretions and plasma. In contrast, individuals who inherit at least one *Se* allele can express type 1 chain glycolipids with ABH activity.

Molecular Biology

The *FUT3* or *Lewis* gene resides on chromosome 19p13.3 near two other α1-3 fucosyltransferase genes, *FUT5* and *FUT6*. All three α1-3 fucosyltransferases are highly homologous, consistent with gene duplication (Weston, 1992). The gene encodes a 361 amino acid type II glycoprotein with both α1→4 (Le^a) and α1→3 (Le^x) fucosyltransferase activity. FUT3 is highly expressed in colon, stomach, small intestine, lung, and kidney, with weaker expression in salivary gland, bladder, uterus, and liver. FUT6 is coexpressed with FUT3 in most tissues (Cameron, 1995).

The Le (a-b-) or null phenotype arises from inactivating mutations in *FUT3*. More than 10 missense mutations in the *FUT3* gene have been identified, with most *FUT3* null alleles possessing at least two mutations (Daniels, 2002; Reid, 2004). The Lewis weak (Le^w) phenotype, characterized by a Le (a-b-) RBC phenotype and the presence of Lewis-active substance in saliva, is due to a single missense mutation in the transmembrane domain (T59>G). The latter has normal enzyme activity but decreased Golgi retention (Mollicone, 1994).

The *FUT2* (*Se*) gene resides on chromosome 19q13.3 as part of a 100-kb gene cluster that includes the *H* gene (*FUT1*) and *Sec1*, an inactive *FUT2*-like pseudogene (Kelly, 1995). Multiple null alleles have been reported, with distinct geographic and ethnic distributions. Most null alleles are the result of nonsense mutations (Daniels, 2002). There are also examples of recombination between *FUT1*, *FUT2*, and *Sec1* (Koda, 1996;

Soejima, 2008). The partial secretor phenotype has been linked to an Ile129>Phe mutation (Yu, 1995).

Lewis Antibodies

Similar to ABO, antibodies against Le^a and Le^b antigens are naturally occurring IgM antibodies (see Table 35-7), but unlike ABO antibodies, Anti-Lewis antibodies are seldom clinically significant. Most examples are detected as room temperature agglutinins; however, some examples are reactive in the IAT. Although uncommon, some examples demonstrate in vitro hemolysis. Because Le^a and Le^b are glycosphingolipids, antibody reactivity can be enhanced by pretreatment of RBCs with enzymes. Antibody reactivity is neutralized by the addition of commercially available soluble Lewis substance or plasma containing the soluble Lewis antigen of interest. Anti- Le^b can be observed in individuals of Le (a+b-) or Le (a-b-) phenotype, whereas anti- Le^a is observed only in Le (a-b-) individuals. Anti- Le^a is not observed in the Le (a-b+) phenotype because these individuals synthesize a small amount of Le^a . It is interesting to note that some Le (a-b+) women can transiently become phenotypically Le (b-), with the development of anti- Le^b , during pregnancy. Some examples of anti- Le^b can demonstrate ABH specificity (anti- Le^bH , anti- ALe^b , anti- BLe^b), reacting more strongly with Le^b -positive RBCs of specific ABO types.

They are not associated with HDFN and are only rarely associated with hemolytic transfusion reactions. It is speculated that they could play a role in renal graft rejection in black, Le (a-b-) individuals (Spitalnik, 1984). For transfusion, patients with anti-Lewis antibodies reactive only at room temperature may be safely transfused with crossmatch-compatible RBCs. In contrast, rare examples of anti- Le^a or anti- Le^b that are hemolytic in vitro should receive antigen-negative, crossmatch-compatible RBCs. If antigen-negative blood is not available, infusion of plasma containing the soluble Lewis antigen of interest may be helpful in neutralizing or inhibiting circulating antibody before RBC transfusion (Klein, 2006).

Biological Role

The Lewis blood group antigens play an important role in disease. *Helicobacter pylori*, a causative agent of gastritis and ulcers, binds H, Le^b , and Le^x antigens via BabA recognition of a terminal $Fuc\alpha1-2Gal$ epitope (Boren, 1993). The latter appears to explain the increased incidence of ulcers and stomach cancer among blood group O secretors (Yamaoka, 2008). A Lewis null and/or nonsecretor phenotype has also been linked with a higher incidence of recurrent *Candida* vaginitis and urinary tract infection (Sheinfeld, 1989; Hilton, 1995). A Le (a-b-) phenotype is associated with an increased incidence of heart disease (Ellison, 1999). Conversely, a nonsecretor phenotype protects against Norovirus infection, a

highly contagious RNA virus responsible for 23 million gastrointestinal infections a year (Lindesmith, 2003). Aberrant expression of sialyl- Le^a occurs in many gastrointestinal and uroepithelial cell cancers and may contribute to tumor metastasis. Sialyl- Le^a is a ligand for the endothelial adhesion molecule E-selectin and may mediate tumor cell-endothelium interactions (Takada, 1993). Sialyl- Le^a is also the epitope for the tumor marker CA 19-9, a useful serologic marker for monitoring patients with gastrointestinal and other malignancies.

DUFFY BLOOD GROUP SYSTEM (ISBT NO. 008)

The Duffy (FY) blood group system is best understood in terms of its interaction with *Plasmodium vivax* and its racial heterogeneity. Discovered in 1951, it contains five antigens: Fy^a , Fy^b , $Fy3$, $Fy5$, and $Fy6$. Fy^a and Fy^b are autosomal codominant antigens, whereas $Fy3$, $Fy5$, and $Fy6$ are high-incidence antigens present on all RBCs except the Duffy null phenotype. The $Fy4$ antigen, originally described on Fy (a-b-) RBCs, is now thought to be a distinct, unrelated antigen and is no longer included in the FY system. Fy^a and Fy^b antigens are common in Caucasians, whereas the Duffy null or Fy (a-b-) phenotype is the predominant phenotype in blacks (Table 35-24). Fy^x , characterized by extremely weak Fy^b expression, is somewhat rare. In addition to RBCs, the Duffy antigens are expressed on cerebellar Purkinje cells and postcapillary venule endothelial cells. Duffy antigens have also been reported on endothelial cells of renal glomeruli, vasa recta, thyroid, and pulmonary capillaries, as well as on alveolar type 1 squamous cells and epithelial cells of renal collecting tubules (Chaudhuri, 1997; Hadley, 1997). RBCs possess approximately 12,000–14,000 copies of DARC glycoprotein (DARC) per cell (Daniels, 2002).

Biochemistry

The Duffy antigens reside on DARC or Duffy antigen receptor for chemokines (Fig. 35-10). The latter is a 338 amino acid, integral membrane glycoprotein, containing a 62 amino acid extracellular amino-terminus, seven transmembrane domains, and an intracellular carboxy-terminus rich in serine and threonine residues. The amino-terminal domain possesses three N-glycans (Czerwinski, 2007) and is linked to the third extracellular loop by a disulfide bond to form a hepatohelical structure. A second disulfide bond exists between the first and second extracellular loops. DARC exists as a homodimer or as a hetero-oligomer with CCR5, a β -chemokine receptor that plays a role in HIV internalization (Chakera, 2008).

See accompanying text.

Figure 35-10 Duffy glycoprotein or Duffy antigen receptor for chemokine molecule (DARC). DARC contains a 62 amino acid, extracellular amino-terminal domain and seven transmembrane domains, indicated by solid amber cylinders. A disulfide bond exists between the amino-terminal domain and the third extracellular loop. A second disulfide bond exists between the first and second extracellular loops. Three N-glycosylation sites are indicated by branched structures. The sites of the Fy³, Fy⁶, and Fy^a/Fy^b antigens are indicated by arrows. The binding site for *Plasmodium vivax* exists between amino acids 8 and 44 and includes the Fy⁶ and Fy^a/Fy^b antigens. The chemokine-binding site lies in a cleft between the amino-terminal domain and the third extracellular loop. The mutation leading to the Fy^x phenotype, characterized by weak Fy^b expression, is present in the first cytoplasmic loop.

The Fy^a, Fy^b, and Fy⁶ antigens reside on the amino-terminal domain of DARC and are sensitive to proteolytic cleavage. The amino-terminal domain is also the binding site for *P. vivax* and plays a role in chemokine binding. Site-directed mutagenesis has confirmed that amino acids 19–26 are critical for *P. vivax* binding (Tournamille, 2005). The high-incidence antigen Fy³ is believed to reside on the third extracellular loop (Hadley, 1997; Wasniowska, 2004).

Molecular Biology

Located on chromosome 1q22–23, the Duffy gene (*FY*) is a 1014-bp gene containing two exons, a small upstream exon encoding the first seven amino acids, and a second exon encoding the rest of the molecule (Hadley,

1997). The promoter region contains consensus sequences for multiple *cis*-regulatory elements, including AP-1, Sp1, and GATA-1, an erythroid transcription activator binding protein that controls transcription of DARC in erythroid cells (Iwamoto, 1996). Phylogenetic studies indicate that FY^{*B} is the ancestral gene of human and nonhuman primates (Li, 1997). Genetic studies have identified four Duffy alleles—FY^{*A}, FY^{*B}, FY^{*Fy}, and FY^{*X}—responsible for the Fy^a, Fy^b, Fy^{null}, and Fy^x phenotypes, respectively (see Table 35-24). The codominant alleles, FY^{*A} and FY^{*B}, differ by a single amino acid (Asp42Gly). The Fy^x phenotype (FY^{*X}), characterized by extremely weak Fy^b expression, arises from an R89C substitution in the first cytoplasmic loop, leading to protein instability (Yazdandakhsh, 2000; Reid, 2004).

Three distinct mechanisms are responsible for the Fy^{null} or Fy (a–b–) serologic phenotype. In Caucasians, the *FY* gene is disrupted (FY^{*amorph}), leading to complete absence of DARC on all tissues (Daniels, 2002; Reid, 2004). As a result, these individuals can make alloantibodies to all Duffy antigens, including high-incidence antigens (Fy³, Fy⁵). In contrast, black Fy (a–b–) individuals are homozygous for FY^{*Fy} (FY^{*B}³³), a FY^{*B} variant allele that possess a point mutation in the *FY* gene promoter (–33T>C) that abrogates the consensus binding site for GATA-1. The latter is an erythroid transcription binding factor that regulates the expression of *FY* and other genes in RBCs (Iwamoto, 1996). As a result, *FY* transcription is absent in RBCs but is present in endothelial and epithelial cells, which utilize other promoter enhancer elements. Because Fy^b is expressed on nonerythroid cells, black Fy (a–b–) individuals do not make anti-Fy^b and only rarely make anti-Fy³. Finally, there is increasing recognition that some individuals, particularly donors, who historically typed as Fy (a–b–) by serology, are actually Fy (a–b^x) on genotyping.

Duffy Antibodies

Antibodies against Fy^a, Fy^b, and other Duffy antigens are clinically significant. They are associated with HDFN and both immediate and delayed hemolytic transfusion reactions. They are usually of IgG isotype, reactive at 37° C, and are detected only in the IAT. Antibodies against Fy^a, Fy^b, and Fy⁶ antigens, which reside on the long amino-terminal domain of DARC, can be inhibited by prior protease digestion of RBCs. In contrast, Fy⁵ and Fy³ antigens are relatively resistant to protease digestion. Antibodies against Duffy antigens can demonstrate dosage.

Clinically, anti-Fy^a is the most common alloantibody encountered and can be observed in Fy (a–) individuals of all races. Anti-Fy^b is relatively uncommon and is observed primarily in nonblacks. Alloantibodies against the high-incidence antigens Fy³ and Fy⁵ are relatively rare, occurring predominantly in white, Fy^{null} individuals. Anti-Fy³ behaves like an anti-Fy^{a+b}, reacting with all Duffy-positive RBCs. Occasionally, potent anti-Fy³ can be produced by sickle cell, Fy (a–b–) patients despite the expression of Fy^b on nonerythroid tissues (Castilho, 2009). Anti-Fy⁵ also reacts like an anti-Fy^{a+b} but requires the presence of Rh antigens for reactivity. Anti-Fy⁶ has not been observed clinically but is the epitope for an anti-Duffy monoclonal antibody that blocks *P. vivax* binding (Tournamille, 2005).

Biological Role

DARC is a chemokine-binding protein, capable of binding several inflammatory chemokines from the C-X-C and C-C families (Gardner, 2004), including interleukin-8, RANTES (regulated upon activation, normal T

*Weak Jk antigens detected only by adsorption and elution techniques.

cell expressed, and presumably secreted), and monocyte chemotactic protein-1 (see Fig. 35-10). Because DARC lacks a DRY motif, DARC does not transmit an intracellular signal upon binding chemokines. DARC can form heterodimers with the β -chemokine and HIV receptor CCR5, suppressing CCR5 signaling (Chakera, 2008). DARC may facilitate leukocyte recruitment to sites of inflammation by establishing a chemokine gradient and transporting chemokines across activated endothelium (Horne, 2009). In murine models, DARC functions in chemokine homeostasis and neutrophil recruitment, particularly during inflammatory insults. It is interesting to note that the absence of DARC in mice was protective against acute lung injury (Zarbock, 2010).

In humans, no distinct clinical syndrome is associated with a Fy_{null} phenotype; however, the Fy_{null} phenotype has been linked to lower neutrophil counts, susceptibility to infection, renal disease, and reduced graft survival following renal transplantation. A recent study linked low neutrophil counts in people of African ancestry to the FY^*FY (-33C) allele (Reich, 2009), leading to speculation regarding the impact of the Fy_{null} phenotype and recovery from chemotherapy and other marrow insults. The role of DARC and Fy phenotype in renal transplantation is mixed, with some studies showing an increase in rejection and chronic lesions (Lerut, 2007; Horne, 2009). In patients with sickle cell disease, the Fy_{null} phenotype is associated with increased chronic organ damage and proteinuria (Afenyi-Annan, 2008).

DARC is also the receptor for *P. vivax*, which binds DARC at the $Fy6$ epitope. Fy_{null} individuals are resistant to most *P. vivax* strains, providing a selective advantage to populations living in malaria endemic areas (Storti-Melo, 2009). The latter likely explains the prevalence of the Fy_{null} phenotype among blacks. Likewise, the Fy_{null} phenotype (-33C/C) may provide a survival advantage in HIV infection, particularly in patients with baseline neutropenia (Kulkarni, 2009). Vigorous controversy is ongoing regarding reports linking Fy_{null} with increased susceptibility to HIV infection (Winkler, 2009).

KIDD BLOOD GROUP SYSTEM (ISBT NO. 009)

The Kidd blood group system is strongly associated with delayed hemolytic transfusion reactions and with intravascular hemolysis (recall that most hemolysis with non-ABO antibodies is extravascular). It consists primarily of two allelic antigens: Jk^a and Jk^b. Inheritance is autosomal codominant with three predominant phenotypes (Table 35-25). A fourth phenotype, Jk^{null} or Jk (a-b-), is very rare, except among Polynesians ($\leq 1\%$) and Finns. Weak or altered Jk expression due to novel JK alleles is also known (Whorley, 2009). In addition to RBCs, Kidd antigens are expressed along descending vasa recta endothelial cells of the renal medulla. Evidence suggests low-level, constitutive expression of Kidd on heart, skeletal muscle, colon, small intestine, thymus, brain, pancreas, spleen, prostate, bladder, and liver (Olives, 1996). More than 14,000 Kidd epitopes are present per human RBC (Lucien, 2002).

Null Phenotypes

Jk^{null} is autosomal recessive, reflecting homozygosity for a Jk^{null} or amorph allele (see Table 35-25). *In (Jk)* is a second Jk (a-b-) phenotype that is

Figure 35-11 The Kidd/urea transporter glycoprotein. The site of Jk^a/Jk^b polymorphism at residue 280 is indicated by a solid line. The N-glycosylation site is indicated by a branched structure on the third extracellular loop. The 10 transmembrane domains are represented by amber cylinders.

characterized by very weak Kidd expression. Similar to *In (Lu)*, the *In (Jk)* phenotype is autosomal dominant owing to a suppressor gene at a distant, unrelated locus. It is interesting to note that Jk^{null} RBCs are resistant to lysis by 2M urea, a lytic agent used by some automated hematology analyzers. *In (Jk)* RBCs have intermediate resistance to urea (Issitt, 1998). No change in gas permeability is seen with Jk^{null} cells (Endeward, 2006).

Biochemistry

Apparent resistance to urea by Jk^{null} RBCs became clear with cloning and isolation of the human erythroid urea transporter (UT-B). The latter is a 43–45-kD multipass glycoprotein, which shares 60% homology with the vasopressin-sensitive urea transporter of rabbits (UT2) and humans (HUT2, UT-A) (Lucien, 1998). The molecule is a 391 amino acid protein with 10 transmembrane domains and a cytosolic amino- and carboxy-terminus (Fig. 35-11). A single N-glycan is present on the third extracellular loop (Asn222) and expresses ABO antigens (Lucien, 2002). The Jk^a/Jk^b antigens reside on the fourth extracellular loop at amino acid 280. The third extracellular loop may play a key role in urea transport.

Molecular Biology

The Kidd glycoprotein is encoded by a 30-kb gene (*JK*, *SLC14A1*, *UT-B*) on chromosome 18q12-21. This is the same location as the human HUT2/UT-A urea transporter (61% homology), suggesting that the two genes arose by gene duplication. The *JK* gene is organized over 11 exons, although only exons 4–11 encode the mature protein (Lucien, 1998). Similar to many blood group genes, the promoter region contains a GATA-1 consensus sequence, as well as other *cis*-regulatory elements (AP-2, AP-3, NF-ATp, Sp1, Ets-1). A single-bp transition (G823A) is the molecular basis of the Jk^a/Jk^b polymorphism, resulting in an Asp280 (Jk^a) or Asn280 (Jk^b) (Lucien, 2002). Three novel missense mutations associated with JK*A (W171R, E44K) and JK*B (A183V) alleles have been reported, resulting in weak and/or discrepant phenotyping with different commercial typing reagents (Whorley, 2009). In the autosomal recessive Jk^{null} phenotype, more than 10 distinct inactivating mutations have been identified, including splice-site, nonsense, and missense mutations (Reid, 2004; Wester, 2008; Liu, 2009). The etiology of the *In (Jk)* phenotype is unknown.

Kidd Antibodies

Clinically, anti-Jk or Kidd antibodies are a common cause of hemolytic transfusion reactions, accounting for nearly one quarter of all delayed hemolytic transfusion reactions and 75% of those with true hemolytic sequelae (Ness, 1990). They are usually of IgG1 or IgG3 isotype and are capable of activating complement (see Table 35-7). Antibody reactivity can be enhanced with enzyme-treated RBCs and by the presence of complement. Anti-Jk is not enhanced by polybrene (Liu, 2009). An anti-Jk3, which reacts with all RBCs except Jk_{null}, is observed in Jk_{null} individuals (see Table 35-25). Anti-Jk3 was also reported in one individual carrying the Jk*A^{44K} allele (Whorley, 2009).

Anti-Jk antibodies can be difficult to detect or identify in the blood bank. Anti-Jk antibodies are often of low titer with weak avidity and can display dosage in vitro. Furthermore, anti-Jk antibodies are frequently transient, disappearing rapidly after immune stimulation. As a consequence, patients previously sensitized to Kidd antigens may be negative for anti-Jk antibodies in later blood samples. Following transfusion of crossmatch-compatible, Jk-positive RBCs, sensitized patients can mount a brisk anamnestic antibody response with rapid and extensive in vivo hemolysis as RBCs are cleared by extravascular and intravascular hemolysis. Although uncommon, anti-Jk can cause a mild HDFN.

Biological Role

Biologically, JK/UT-B functions in the facilitated transport of urea. In kidney, transport of urea by JK/UT-B on vasa recta endothelial cells is thought to help stabilize osmotic gradients in the renal medulla during the concentration of urine. On RBCs, JK/UT-B may help preserve the osmotic stability of RBCs as they pass through the kidney. Although Jk_{null} individuals exhibit a slightly decreased capacity to concentrate urine, the absence of JK/UT-B is not associated with a clinical syndrome. It is likely that other mechanisms exist to compensate or reduplicate the function of JK/UT-B on tissues (Lucien, 1998).

DIEGO BLOOD GROUP SYSTEM (ISBT NO. 010)

The Diego blood group system consists of 21 antigens, including four sets of allelic antigens (Table 35-26). Nineteen antigens are rare, low-incidence antigens present on less than 1% of donors. In general, there are no apparent racial differences in the expression of most Diego antigens except Di^a. Initially described in 1955, Di^a antigen is rare in all populations except those of Mongolian ancestry, Asian people, and native South American Indians. In some South American Indian populations, the frequency of Di^a

can reach 50% (Issitt, 1998). In addition to RBCs, Diego antigens are expressed by human kidney along the collecting ducts (Tanner, 1993). One million copies of Diego glycoprotein (AE1) are present per RBC.

Biochemistry

The Diego blood group system resides on Band 3, also known as AE1. AE1 is a 100-kD, 991 amino acid glycoprotein containing two functionally distinct domains: a large 40-kD amino-terminal cytoplasmic domain and a transmembrane domain comprising the carboxy-terminal half of the molecule (Fig. 35-12). On RBCs, AE1 is an oligomer, usually existing as a dimer or tetramer through the formation of intramolecular disulfide bonds. The amino-terminal cytoplasmic domain binds several key cytoskeletal proteins (band 4.1, band 4.2, and ankyrin) and three glycolytic enzymes: glutaraldehyde-3-phosphate dehydrogenase, aldolase, and phosphofructokinase. Binding of hemochromes or denatured Hg to the extreme amino-terminus of AE1 is believed to play a role in Heinz body formation. There is also an apparent, noncovalent association of AE1 with GYPA on RBC membranes (Low, 1986). Miltenberger type III cells (Gp.Mur), a glycophorin B-A-B hybrid, have increased AE1 on red cells (Hsu, 2009).

The remainder of AE1 is membrane associated, containing 12–14 transmembrane domains, which constitute the carboxy-terminal half of the molecule. Whereas the amino-terminal domain is involved in membrane stability, the carboxy-terminal domain functions as an anion transporter, facilitating transfusion of Cl⁻ and HCO₃⁻ anions across the cell membrane (Tanner, 1993). The carboxy-terminal, transmembrane domain is also the site of all the Diego antigens described to date. There is a single N-glycosylation site, which displays a massive, highly branched, polylactosaminoglycan with both ABO and I blood group activity (Fukuda, 1984). It is estimated that nearly half of all ABO epitopes on RBCs are associated with AE1.

Molecular Biology

AE1 is the product of a 20-exon, 17-kb gene (*SLC4A1*) on chromosome 17q21-q22. The cloning of the *AE1* gene was invaluable in assigning several orphan antigens to the Diego system. Like so many blood group antigens, every Diego antigen identified to date is the result of a point mutation, leading to an amino acid polymorphism in the translated protein (see Table 35-26 and Fig. 35-12). Most of these amino acid polymorphisms occur among nonconserved amino acid residues, based on a comparison of AE1 with the sequences of other anion transporters (Reid, 2004). The Diego system also contains two examples of allelic, low-incidence antigens: Mo^a/Hg^a and Jn^a/KREP. In each case, two distinct amino acid substitutions at the same amino acid residue lead to different

*Referenced in Daniels (2004) and Reid (2004b).

[†]Di^a antigen has a much higher incidence among North and South American Indians, Asian people, and people of Mongolian ancestry (e.g., Eastern Poland).

Figure 35-12 Structure of anion exchange protein AE1 (Band 3). AE1 is a multipass glycoprotein with 14 transmembrane domains, indicated by solid amber cylinders. The Diego blood group antigens reside along the extracellular loops and are indicated by solid lines. The AE1 senescent autoantigen is on the third extracellular loop between Rb^a and Vg^a antigens. The massive N-glycan is shown by a branched structure on the fourth extracellular loop. The large cytoplasmic domain has binding sites for cytoskeletal proteins 4.2, 4.1, and ankyrin, as well as the glycolytic enzymes phosphofructokinase (PFK) and glutaraldehyde-3-phosphate dehydrogenase (G3PD). In the red cell membrane, AE1 exists as oligomers (dimers, tetramers) linked by interchain disulfide bonds along the amino-terminal cytoplasmic domain (solid rectangles). An 8 amino acid deletion at the boundary of the amino-terminal cytoplasmic domain and the first transmembrane domain is responsible for Southeast Asia ovalocytosis (SAO).

alloantigens. A similar example exists in the Kell system (Kp^a, Kp^b, and Kp^c).

The most interesting Diego antigen, however, is Wr^b. As stated earlier, AE1 is typically associated with GYPA in the RBC membrane. RBCs lacking GYPA (En [a-] phenotype) are phenotypically Wr (a-b-), implying that Wr^b is on GYPA. Available evidence now suggests that Wr^b is formed by an electrostatic interaction between GYPA and a glutamic acid (Glu658) on AE1 (Poole, 1999). Which specific amino acid on GYPA is critical to Wr^b formation is still a matter of debate, but clearly part of the Wr^b epitope involves amino acids on GYPA (see Fig. 34-3).

Diego Antibodies

Antibodies against Diego blood group antigens can be immune stimulated or naturally occurring. Antibodies against Di^a, Di^b, Wr^b, and ELO are usually immune stimulated. These antibodies are of IgG isotype and are detected in the AHG phase of testing. Anti-Di^a, Di^b, and Wr^b can be associated with decreased red cell survival, hemolytic transfusion reactions, and HDFN. Anti-Wr^b is also associated with autoimmune hemolytic anemia (Issitt, 1998).

In contrast, antibodies against the majority of other Diego antigens are usually naturally occurring, room temperature, saline agglutinins. Anti-Wr^a is particularly common, occurring in 1 in 100 donors. Antibodies against Wd^a and WARR are also fairly common, with anti-WARR reported in 13%–18% of donors (Issitt, 1998).

Biological Role

Functionally, AE1 plays a critical role in gas transport and acid-base equilibrium. To facilitate the removal of CO₂, RBCs hydrate CO₂ via carbonic anhydrase to form bicarbonate ion (HCO₃⁻), which is readily soluble in plasma. As the level of intracellular HCO₃⁻ rises, RBCs exchange HCO₃⁻ ions for Cl⁻ in plasma (the Cl⁻ shift, or Hamburger shift). This process is mediated by AE1 as RBCs pass through capillaries and small capillary venules. Because of the high copy number of AE1 on the RBC membrane,

anion exchange is 90% complete within 0.4–0.5 second. An increase in HCO₃⁻ capacity and osmotic resistance is observed with Miltenberger III red cells owing to significantly higher AE1 expression (Hsu, 2009). In the kidney, AE1 is expressed along the basolateral membrane of type A intercalated cells of renal collecting ducts, where it functions in acid secretion and bicarbonate reabsorption (Tanner, 1993). Given the physiologic importance of AE1, it is not surprising that no Diego null phenotype has been described to date.

AE1 also plays a role in the RBC cytoskeleton (see Fig. 35-12). The long, amino-terminal half of the molecule binds several peripheral proteins involved in the stability of the RBC membrane. AE1 tetramers bind ankyrin, protein 4.2, and protein 4.1, which help to anchor and stabilize the RBC membrane to the underlying cytoskeleton (Tanner, 1993). AE1 protein may contribute to red cell senescence. Cold storage is rapidly associated with the formation and clustering of large, AE1 oligomers, which could promote red cell clearance (Karon, 2009). In addition, at least one senescent autoantigen on RBCs is located on AE1, between amino acids 538 and 554 (between Rb^a and Vg^a antigens; see Fig. 35-12) (Kay, 1994).

CARTWRIGHT BLOOD GROUP SYSTEM (ISBT NO. 011)

Discovered in 1956, the Cartwright (Yt) blood group system consists of two autosomal codominant antigens: Yt^a and Yt^b. Yt^a is a high-incidence antigen expressed by 99.8% of Caucasian donors. The incidence of Yt^b varies by race, ranging from 0% in Japanese to 24%–26% in the Mideast (Issitt, 1998). Yt antigens are missing on PNH III RBCs, which are devoid of all glycoposphoinositol (GPI)-linked glycoproteins. In addition to RBCs, Cartwright antigens are expressed on neural synapses and neuromuscular junctions (Masson, 1994). A total of 7000–10,000 molecules of Yt glycoprotein are present per RBC.

Figure 35-13 Blood group antigens on glycosphosphoinositol-linked glycoproteins.

Biochemistry

The Cartwright antigens are located on acetylcholinesterase (AChE), a β -carboxyesterase responsible for degradation of the neurotransmitter acetylcholine. Several different molecular forms of AChE have been isolated, including large heteromeric forms composed of several catalytic subunits covalently linked to collagen. On RBCs, AChE is expressed as a palmitoylated, GPI-linked glycoprotein (Fig. 35-13) (Li, 1991). Human erythrocyte AChE is unique in the palmitoylation or covalent linkage of a palmitic fatty acid to the inositol ring, which renders the molecule resistant to phospholipase C. In RBC membranes, AChE usually exists as a 160-kD dimer and possesses both *N*- and *O*-linked glycans.

Molecular Biology

The gene for AChE possesses four exons, spanning 4.5–4.7kb, on chromosome 7q22. Alternate splicing of exon 3 is responsible for the GPI-linked form of AChE observed in RBCs (Li, 1991). The Yt^a and Yt^b antigens represent a single-amino acid polymorphism at residue 322, where His322 is Yt^a and Asn322 is Yt^b (Bartels, 1993). The Yt^a/Yt^b polymorphism is not located near the catalytic site of the enzyme and has no effect on enzyme activity (Masson, 1994).

Cartwright Antibodies

In general, anti- Yt^a and Yt^b are usually clinically benign, although shortened red cell survival and even delayed hemolytic transfusion reactions have been reported. Neither antibody is associated with HDFN (Issitt, 1998). Anti- Yt^a and anti- Yt^b are of IgG isotype, arising from immune stimulation, and are usually detected in the IAT. Despite the high incidence of Yt^a in the general population, anti- Yt^a is more common than anti- Yt^b , suggesting that Yt^a is the more immunogenic antigen. Anti- Yt^a is also more likely to cause a positive monocyte-monolayer assay with decreased red cell survival (Arndt, 2004).

Biological Role

AChE is a critical enzyme required for the rapid degradation of acetylcholine on postsynaptic membranes of nerves and muscles. The role of AChE in RBCs is unknown.

XG BLOOD GROUP SYSTEM (ISBT NO. 012)

The Xg blood group system contains a single antigen, Xg^a . As a result, only two phenotypes are known: Xg^a -positive and Xg^a -negative. Because the Xg^a antigen is encoded by a gene on the X chromosome, the incidence of the Xg^a -positive phenotype is higher among women. Among Caucasians, approximately 89% of women and 66% of men are Xg^a -positive. Similar results have been found in other ethnic populations (Byrne, 2004). Xg appears to be specific for RBCs. Approximately 9000 molecules of Xg^a are present per RBC (Reid, 2004).

Biochemistry and Molecular Biology

The Xg^a antigen is located on a 24–29-kD, 180 amino acid glycoprotein named XG protein. A type 1 glycoprotein, XG protein possesses a large, 117 amino acid, amino-terminal extracellular domain, a single transmembrane domain, and a short, carboxy-terminal cytoplasmic tail. Of 11 potential *O*-glycosylation sites, only three appear to be glycosylated. The protein is encoded by a 2.4-kb gene (*XG*) located on the X chromosome at the pseudoautosomal boundary/X-specific boundary (pAB1X).

In the RBC membrane, the XG protein may be topologically associated with a second protein, MIC2 or CD99. The latter is a 32.5-kD glycoprotein biochemically similar to XG protein. Evidence suggesting a near-neighbor relationship of the XG and MIC2 proteins includes MIC2 inhibition of anti- Xg^a antibodies and coimmunoprecipitation of MIC2 by anti- Xg^a . And finally, high MIC2 expression is observed on Xg^a -positive, but not Xg^a -negative, erythrocytes (Daniels, 2002).

Xg^a Antibodies

Anti- Xg^a is not associated with hemolytic transfusion reactions or HDFN (Byrne, 2004). Anti- Xg^a may be immune stimulated or naturally occurring. Most examples are of IgG isotype, including some capable of activating complement. Because of differences in Xg^a -positive phenotype between men and women, most examples (>85%) of anti- Xg^a are observed in men.

SCIANNA BLOOD GROUP SYSTEM (ISBT NO. 013)

The Scianna (Sc) blood group system contains seven antigens. Sc1 and Sc2 are antithetical antigens, with most individuals typing as Sc:1,-2. Sc2 and Sc4/Rd are low-incidence antigens, whereas Sc3, Sc5, Sc6, and Sc7 are high-incidence antigens (Table 35-27) (Wagner, 2003; Flegel, 2005; Hue-Roye, 2005). Sc3 is a high-incidence antigen present on all RBCs except Sc_{null} (Sc: -1, -2, -3). Scianna appears to be specific for RBCs and erythropoietic tissues.

Biochemistry

Scianna antigens reside on erythrocyte membrane-associated protein (ERMAP), a 60–68-kD, 446 amino acid glycoprotein. Similar to Lutheran, Ok, and LW proteins, ERMAP is a member of the Ig superfamily. The molecule is a type 1 single-pass transmembrane protein possessing a single IgV domain and a large cytoplasmic domain that is likely involved in signal transduction. The latter possess both SH3 and B30.2 domains, as well as multiple phosphorylation sequences for protein kinase C, tyrosine kinase, and casein kinase II (Su, 2001). The molecule possesses 11 cysteine residues and is sensitive to sulfhydryl-reducing agents.

Molecular Biology

The *ERMAP* gene resides on chromosome 1p34 and consists of 11 exons spanning 19kb. Most Sc antigens are the result of an SNP and amino acid

polymorphism (see Table 35-27). Of three Sc_{null} studied to date, one was the result of a deletion and frameshift mutation (307del2) and two were the result of an SNP leading to a stop codon (Wagner, 2003; Flegel, 2005). An additional amino acid polymorphism (His26>Tyr) has been identified in the leader sequence, which is not expressed on the mature red cell protein (Flegel, 2005; Fuchisawa, 2009). Approximately 25% of Caucasians are positive for the His26>Tyr polymorphism (Fuchisawa, 2009).

Scianna Antibodies

Anti-Scianna antibodies are rare and generally benign. They are usually of IgG isotype with some examples binding complement. Most examples are immune stimulated; however, naturally occurring anti-Sc2 antibodies are known. The antigens are relatively resistant to enzymes but can be weakened with DTT and AET. They are not a cause of transfusion reactions. Anti-Sc4 and anti-Sc2 have been associated with HDFN. Autoantibodies against Sc1 and Sc3 antigens have been associated with warm autoimmune hemolytic anemia (Issitt, 1998). Anti-Scianna antibodies can be neutralized with soluble recombinant ERMAP protein (Seltsam, 2009).

Biological Role

The biological role of ERMAP is unknown, although its structure suggests that it may play a role in RBC adhesion and signaling. The IgV domain possesses a C1q recognition sequence that may mediate adhesion between marrow macrophages and erythroblasts in erythroid islands. Because ERMAP shares homology with the B7 family of proteins (CD80, CD86) and neural autoantigens, it is speculated that ERMAP could be involved in immune recognition and autoimmune anemia (Su, 2001).

DOMBROCK BLOOD GROUP SYSTEM (ISBT NO. 014)

The Dombrock blood group system contains seven antigens. Do^a (DO1) and Do^b (DO2) are autosomal codominant antigens expressed by 67% and

82% of white donors, respectively (Table 35-28). Gy^a , Hy , Jo^a , DOYA, and DOMR are high-incidence antigens found on virtually all donors. In addition to RBCs, Dombrock mRNA has been identified in fetal liver and spleen (Gubin, 2000).

Null/Weak Phenotypes

The Do_{null} or $Gy(a-)$ phenotype is a rare, autosomal recessive phenotype (see Table 35-28). An acquired Do_{null} phenotype can be observed in paroxysmal nocturnal hemoglobinuria type III (PNH-III). A hematopoietic stem cell disorder, PNH III is characterized by chronic hemolysis due to an absence of all GPI-linked glycoproteins, including Cromer, Dombrock and Cartwright antigens.

Loss of one high-incidence Dombrock antigen is often accompanied by weakened expression of other Dombrock antigens (see Table 35-28). This is due to the heterogeneity of Dombrock alleles, which carry different combinations of Dombrock antigens (Reid, 2005; Baleotti, 2006). $Hy(-)$ and $DOMR(-)$ individuals typically have weakened Do^b and Gy^a and weak/absent Jo^a expression, whereas $Jo(a-)$ is often associated with weak Do^a , Hy , and Gy expression (Reid, 2005; Costa, 2009). The one example of DOYA(-) types as $Co(a-b-)$ with weakened expression of Gy , Hy , and Jo^a (Daniels, 2009).

Biochemistry

Dombrock antigens reside on an adenosine diphosphate (ADP)-ribosyl-transferase (CD297), which catalyzes the transfer of ADP-ribose from nicotinamide adenine dinucleotide (NAD) to a protein acceptor. The cloned molecule is a 47–58-kD, 314 amino acid glycoprotein that is anchored into the RBC membrane via a GPI glycolipid tail (GPI-linked; see Fig. 35-13). The molecule has five potential *N*-glycosylation sites, two myristoylation sites, and five cysteine residues (Gubin, 2000; Daniels, 2002). As a consequence, Dombrock can be destroyed by disulfide-reducing agents and phosphatidylinositol phospholipase C, which cleaves GPI-linked proteins (Gubin, 2000).

Molecular Biology

The gene for Dombrock (*ART4*) spans 14 kb on chromosome 12p13.2-12.1. The gene consists of three exons, although exon 2 encodes more than 70% of the translated protein and includes all seven Dombrock antigens. Do^a , Do^b , Jo^a , Hy , DOYA, and DOMR are the result of a single-amino acid polymorphism (see Table 35-28). The Do_{null} or $Gy(a-)$ phenotype is the result of mutations that abolish exon 2 (Reid, 2005).

Dombrock Antibodies

Anti-Dombrock antibodies can be clinically significant, although many examples are benign. They are commonly found in mixtures of alloantibodies and can be difficult to identify. Anti-Dombrock antibodies are capable of causing shortened RBC survival and acute and delayed hemolytic transfusion reactions. Transfusion reactions and accelerated clearance due to anti-Dombrock antibodies can be missed in routine testing, with implicated units often testing as **crossmatch-compatible**, even in a full IAT crossmatch. Moreover, a posttransfusion direct antiglobulin test and eluate can be negative with no observable rise in antibody titer with

ISBT, International Society of Blood Transfusion.

*Loss of exon 2 has been associated with splice-site, frameshift, and nonsense mutations (Reid, 2003a; 2004b).

[†]Also associated with PNH III red blood cells (RBCs), which lack all glycoposphoinositol (GPI)-linked glycoproteins, including Dombrock, Cartwright, and Cromer antigens.

time (Reid, 2005; Baumgarten, 2006). Anti-Dombrock is not associated with HDFN.

Antibodies against Dombrock antigens are usually of IgG isotype, arising from immune stimulation by transfusion or pregnancy. Antibody reactivity can be enhanced by the use of papain- or ficin-treated RBCs. Conversely, antibody reactivity is reduced or abolished by the treatment of red cells with sulfhydryl-reducing agents (DTT, AET), trypsin, chymotrypsin, and pronase. Anti-Dombrock can deteriorate with *in vitro* storage, complicating pretransfusion testing (Baumgartner, 2006). In addition, Dombrock titers may decrease over time *in vivo*, falling below the level of detection (Reid, 2005).

Biological Role

Although Dombrock is an ADP-ribosyltransferase, no enzyme activity has been reported on RBC membranes (Reid, 2005). No known clinical syndrome is associated with a Do_{null} phenotype. It has been hypothesized that Dombrock may play a role in clearing circulating NAD^+ and/or post-translational modification of proteins (Reid, 2005). Dombrock may also contribute to integrin-mediated cell adhesion via an RGD motif at the Do^b antigen; the RGD motif is abolished in the Do^a phenotype.

COLTON BLOOD GROUP SYSTEM (ISBT NO. 015)

The Colton blood group system was initially identified in 1967 and consists of two autosomal codominant antigens, Co^a and Co^b , and a third high-incidence antigen ("TOR") (Arnaud, 2008). Co^a is a high-incidence antigen present on 99.7% of donors. Co^b is expressed by less than 11% of donors, with only 0.3% being $Co(a-b+)$. Although very rare, a $Co(a-b-)$ or null phenotype is reported. Colton antigens are expressed on RBCs, renal proximal tubules, thin descending limb of Henle, renal vasa recta endothelium, choroid plexus, ciliary body, microvessels, gallbladder, placenta, and some epithelial cells. More than 120,000–160,000 molecules of Colton glycoprotein are present per RBC.

Biochemistry

The Colton blood group antigens reside on aquaporin 1 (AQP-1) or channel-forming integral protein, a water-selective membrane channel (Fig. 35-14). Cloned in 1991, AQP-1 is a 269 amino acid multipass integral membrane protein containing six transmembrane domains. Crystallographic studies suggest that the first intracellular and third extracellular loops fold back into the plasma membrane, overlapping at two Asp-Pro-Ala (NPA) sequences to form a water channel. A single *N*-glycosylation site (Asn42), capable of expressing ABH antigens, is found in the first extracellular loop near the Co^a/Co^b and TOR epitopes (residues 45 and 47). The latter is variably glycosylated *in vivo*, leading to a spectrum of

Figure 35-14 Structure of aquaporin-1 (AQP-1, channel-forming integral protein [CHIP]). AQP-1 is a multipass protein containing six transmembrane domains, indicated by solid amber cylinders. The first cytoplasmic and third extracellular loops fold back into the lipid bilayer, overlapping at two Asp-Pro-Ala (NPA) motifs, to form a water channel. The *N*-glycosylation site is indicated by a branched structure on the first extracellular loop. The Co^a/Co^b polymorphism at amino acid 45 is indicated by a solid line. TOR is a rare antigen adjacent to the Co^a/Co^b polymorphism at amino acid 47. The sites of two mutations leading to a Colton null phenotype are also shown.

AQP-1 glycoforms, ranging from 40–60kD (Agre, 1994). In RBC membranes, AQP-1 exists as a homotetramer, a square array of AQP-1 monomers, which may help stabilize the structure and functional integrity of individual monomers (Knepper, 1994).

Molecular Biology

AQP-1 is a 17-kb gene on chromosome 7p14. The gene has four exons and both TATA and Sp1 consensus sequences in the promoter region (Moon, 1993). The Co^a and Co^b antigens are the result of an A314T polymorphism, leading to Ala45 (Co^a) or Val45 (Co^b) (Smith, 1994). A third polymorphism (Gln47>Arg) just distal to the Co^a/Co^b polymorphism was recently identified in an alloimmunized Turkish patient (TOR) with an apparent anti- $Co3$ (Arnaud, 2008). Several different inactivating mutations of the AQP-1 gene are associated with the Co_{null} phenotype, including deletion of exon 1 and frameshift and missense mutations. An acquired Co_{null} phenotype is also reported in rare patients with monosomy 7 and congenital dyserythropoietic anemia (Agre, 1994).

Colton Antibodies

Anti-Colton antibodies can be clinically significant: They can be associated with shortened RBC survival, hemolytic transfusion reactions, and HDFN (see Table 35-7). Antibodies to Co^a and Co^b are usually of the IgG isotype, resulting from immune stimulation by transfusion or pregnancy. Some examples of anti- Co^a and anti- Co^b are reported to bind complement. Anti-Colton antibodies are detectable in the AHG phase of testing and are enhanced with protease-treated RBCs. Rare Co_{null} and "TOR-negative" individuals can make an anti- $Co3$ (anti- Co^{a+b}), an alloantibody that reacts with both $Co(a-b-)$ and $Co(a-b+)$ RBCs (Reid, 2004; Arnaud, 2008).

Biological Role

Biologically, AQP-1 is a major molecular water channel on RBCs that facilitates the concentration of urine in kidney (Verkman, 2009). Co_{null} red cells also have decreased CO_2 permeability (Endeward, 2006). Despite its importance in water regulation, Colton-null individuals show few or no adverse clinical effects. Co_{null} RBCs appear morphologically normal in appearance and number, although mild decreases in RBC life span are reported (Mathai, 1996). The absence of any clinically significant hematologic sequelae in Co_{null} individuals is most likely due to the presence of a second aquaporin, AQP-3. A glycerol and, perhaps, urea transporter, AQP-3 (GIL blood group) is moderately permeable to water and appears to account for the residual water permeability on Co_{null} RBCs (Roudier, 1998; Verkman, 2009).

LW BLOOD GROUP SYSTEM (ISBT NO. 016)

Named in honor of its discoverers, the LW, or Landsteiner-Wiener, blood group system is most important for its role in the history of the Rh blood group system. Landsteiner and Wiener originally developed antibodies against the LW antigens by immunizing rabbits with rhesus monkey red cells. The resulting "anti-Rh" antibodies were initially believed to recognize the RhD antigen; however, later investigators proved that the antibodies developed by Landsteiner and Wiener recognized a non-Rh (LW) antigen.

The LW blood group system consists of two allelic antigens: LW^a and LW^b . LW^a is a high-frequency antigen (99% of white donors). Expression of LW antigen is dependent on RhD protein expression, with the highest expression observed on RhD-positive red cells and weaker expression on RhD-negative cells. LW antigens are absent from Rh_{null} erythrocytes. An LW ($a-b-$) or null phenotype can also be seen in very rare individuals who are homozygous for a silent LW allele. The LW antigen is expressed on RBCs and placenta. Approximately 3600–5000 molecules of LW glycoprotein are present per RBC (Issitt, 1998).

Biochemistry

The LW antigens reside on intracellular adhesion molecule type 4 (ICAM-4, CD242), a 40–47-kD type 1 glycoprotein. A member of the Ig superfamily, ICAM consists of two extracellular C2-like domains: a single transmembrane domain and a short cytoplasmic tail. Four *N*-glycosylation sites are present, along with evidence of *O*-glycosylation, which may influence adhesion (Toivanen, 2008). Although several amino acids are critical for ICAM-4/integrin binding, the first C2 or Ig domain is most critical (Toivanen, 2008). The molecule has three disulfide bonds and is sensitive to reducing agents such as DTT (Reid, 2004).

		Ch5	94%	Gly1054>Asp			

*Calculated from Giles (1987) and Issitt (1998).

[†]Conformational epitopes require the presence of two Ch/Rg antigenic determinants.

Molecular Biology

The *ICAM4* gene resides on chromosome 19p13. The LW^a and LW^b antigens arise from an SNP (A308G), leading to Gln70 (LW^a) or Arg70 (LW^b). Of two LW_{null} individuals studied, one possessed a 10-bp deletion in the coding sequence (Hermand, 1995).

LW Antibodies

Clinically benign, anti-LW antibodies are rarely a cause of hemolytic transfusion reactions or HDFN. They usually are of IgG isotype and are detected in the IAT. Antibody activity can be reduced by ethylenediaminetetraacetic acid (EDTA) and pretreatment of RBCs with sulfhydryl-reducing agents (DTT, AET). In addition to anti-LW^a and -LW^b, LW_{null} individuals can make an anti-LW^{ab}, which reacts with both LW (a+b-) and LW (a-b+) erythrocytes.

Biological Role

LW glycoprotein is a potential counterreceptor for the β2-integrin protein Mac1 (CD11b/CD18), LFA-1 (CD11a/CD18), and platelet GPIIb/IIIa. It is hypothesized that the LW glycoprotein may participate in adhesive interactions during early erythroid development. Mice lacking ICAM-4 have a decrease in erythroblastic islands in their marrow, although peripheral red cell mass is normal (Toivanen, 2008). LW expression is elevated in sickle cell patients and may be involved in microvascular occlusion (Reid, 2004). LW glycoprotein may also be involved in red cell senescence by binding to CD11/CD18 integrin on splenic macrophages (Issitt, 1998; Toivanen, 2008).

CHIDO/RODGERS BLOOD GROUP SYSTEM (ISBT NO. 017)

The Chido/Rodgers (Ch/Rg) blood group system contains 10 antigens, including two pairs of antithetical antigens and three conformational antigens. The latter require coexpression of two spatially distinct Ch/Rg antigens that together generate a third, conformational antigen (Table 35-29). Most Ch/Rg antigens are high-incidence antigens (>90%). Similar to Lewis blood group antigens, Ch/Rg antigens are of plasma origin and are passively adsorbed onto RBC membranes. Ch/Rg antigens are weakly expressed on cord RBCs and some GYPA-deficient RBCs (Issitt, 1998).

Biochemistry/Molecular Biology

Ch/Rg antigens are antigenic determinants on the C4d fragment of the C4 complement molecule. C4 is the product of two highly homologous genes (99% identity), *C4A* and *C4B*, on chromosome 6p21.3 near the HLA locus. At present, more than 50 C4 alleles have been identified, including null alleles, making the genetics of this system difficult. Each gene spans approximately 22kb and is organized into 41 exons. Four amino acids in exon 26 are responsible for distinguishing C4A from C4B. Most Ch/Rg antigens are determined by amino acid polymorphisms encoded in exons 25 and 28 (Giles, 1988). In general, Chido antigens are on C4B and Rodgers antigens are on C4A, although examples of C4B-expressing

Rodgers antigens (and vice versa) are known (Giles 1987, 1988). On protein electrophoresis, C4A migrates faster than C4B.

Chido/Rodgers Antibodies

Antibodies against Ch/Rg antigens do not cause hemolytic transfusion reactions or HDFN. Rare reports have described anaphylaxis following transfusion of plasma and platelets (Westhoff, 1992). Anti-Ch/Rg antibodies are of IgG isotype and are usually detected with AHG. Antibody reactivity can be enhanced by incubating RBCs in a low-ionic sucrose solution. Antibody reactivity can be inhibited by plasma or by treatment of RBCs with proteases (Reid, 2004).

Biological Role

C4 deficiency is associated with autoimmune disorders and susceptibility to bacterial meningitis. Specific C4 allotypes have been linked to several autoimmune disorders, including rheumatoid arthritis and Graves' disease.

GERBICH BLOOD GROUP SYSTEM (ISBT NO. 020)

The Gerbich (Ge) blood group system contains seven antigens: three high-frequency (>99%; Table 35-30) and four low-frequency antigens. The Gerbich glycoproteins (GPC/D; Fig. 35-15) are on fetal and adult RBCs, platelets, and kidney and fetal liver. Between 180,000 and 250,000 molecules of Gerbich are present per RBC (Reid, 2004).

Null/Weak Phenotypes

Three autosomal recessive phenotypes are associated with the loss of high-incidence Gerbich antigens: Yus (Ge-2,3,4), Gerbich (Ge-2,-3,4), and Leach (Ge-2,-3,-4). Gerbich antigens are decreased in patients with hereditary elliptocytosis due to protein 4.1 deficiency (Daniels, 2002).

Biochemistry

Gerbich antigens are expressed on two biosynthetically related type 1 glycoproteins: glycophorin C (GYPC; see Fig. 35-15) and glycophorin D (GYPD). GYPC is a 40-kD, 128 amino acid glycoprotein bearing one N-linked and 12 O-linked glycans. GYPD is a 107 amino acid variant, lacking 21 amino acids at the amino-terminus (Reid, 2004b). The cytoplasmic domain interacts with several cytoskeletal proteins, including spectrin, protein 4.1, and p55.

Molecular Biology

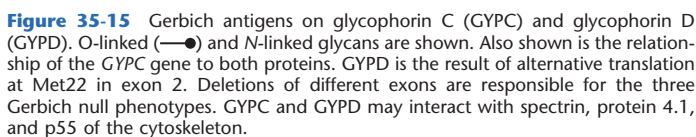

GYPC and GYPD are the products of a single gene, *GYPC*, on chromosome 2q14-121. The gene spans 13.5kb and is organized into four exons. Exons 1-3 encode the extracellular domain; exon 4 is responsible for the transmembrane domain and the cytoplasmic tail. The promoter region contains classical CCAC and TATA sequences, as well as transcription factor binding sites for Sp1, GATA-1, and NF-E6. GYPD is the product of leaky translation at a downstream, alternative AUG residue (Met22).

Gerbich Blood Group Antigens

*Glycophorin C (GYPC) or glycophorin D (GYPD).

*Glycophorin C (GYPC) or glycophorin D (GYPD).

[†]Yus and Gerbich phenotypes are the result of mutant GPC alleles. No GPD is found in Yus, Gerbich, or Leach phenotypes.

As shown in Table 35-30, the high-frequency antigens Ge2 and Ge4 are the NH₂-termini of GYPD and GYPC, respectively. Ge3 is encoded by exon 3 and is shared by both molecules. With the exception of Ls^a, low-frequency Ge antigens are the result of single-amino acid polymorphisms. The Leach phenotype results from deletion of exons 3 and 4. As a result, no GYPC nor GYPD protein is expressed (see Fig. 35-15). The Yus and Gerbich phenotypes are deletion mutants characterized by variant GYPC synthesis and complete loss of GYPD synthesis. As a result, Yus and Gerbich can express high-incidence antigens present on GYPC (Ge3, Ge4) but not on GYPD (Ge2).

Anti-Gerbich antibodies are usually, but not always, clinically significant. Reports have described shortened RBC survival and delayed hemolysis following transfusion of Gerbich-incompatible RBCs. One report described severe HDFN. Autoantibodies against Gerbich antigens have been associated with severe autoimmune hemolytic anemia (Reid, 2004).

Anti-Gerbich antibodies can be of IgM or IgG isotype. Most are immune stimulated, although naturally occurring anti-Ge are known. They may be detected at room temperature and are enhanced by AHG. Gerbich antigens are resistant to chymotrypsin but are sensitive to other proteases (trypsin, pronase).

Similar to Diego/Band 3, GYPC and GYPD help anchor the membrane to the underlying cytoskeleton. In patients with protein 4.1 deficiency and hereditary elliptocytosis, GYPC and GYPD are decreased (75% normal). Likewise, the Ge null (Leach) phenotype is associated with marked elliptocytosis due to reduced membrane stability and deformability (Daniels, 2002). Because they are rich in sialic acid, GYPC and GYPD can bind influenza virus. GYPC may also bind specific *P. falciparum* strains owing, in part, to its *N*-glycan (Mayer, 2006). Evolutionary studies have presented the odd finding that GYPD is the ancestral protein and is shared among all primates. The formation of an upstream start codon with synthesis of GYPC is relatively new and is limited to humans (Wilder, 2009).

The Cromer system (Cr/CROM) contains 15 antigens, including five antithetical antigens and 10 high-incidence antigens (Table 35-31). Cromer antigens are present on DAF (CD55), which is widely expressed on tissues and in secretions. DAF has been identified on all hematopoietic cells, vascular endothelium, gastrointestinal and genitourinary epithelium, brain, and body fluids (Storry, 2002). Cromer is expressed on cord RBCs and placental trophoblasts.

Inab or Cromer null phenotype is a rare autosomal recessive phenotype, characterized by complete absence of all Cromer antigens but normal expression of CD59 and other GPI-linked glycoproteins. Many individuals with the Inab phenotype suffer from chronic gastrointestinal disorders, particularly a chronic protein-losing gastroenteropathy. CD55/Cromer is also missing on PNH III RBCs, which lack all GPI-linked glycoproteins. Weak Cromer expression (40% normal) is observed in the Dr(a-) phenotype.

ISBT, International Society of Blood Transfusion.

*Because of their proximity, Wes^a weakens Es^a expression.

Biochemistry

CD55/DAF is a highly glycosylated, 381 amino acid, 70-kD GPI-linked glycoprotein (see Fig. 35-13). The extracellular domain consists of four short consensus repeat (SCR) domains, capable of binding complement components (C3b/C4b), followed by a 70 amino acid stretch rich in *O*-linked glycans (50% serine/threonine) that may protect the molecule from proteolysis. X-ray crystallography indicates that the molecule is rod-like, held by a rigid stalk composed of the serine/threonine-rich regions (Lublin, 2005). Each SCR domain contains four highly conserved cysteine residues, resulting in two intrachain disulfide bonds per SCR. As a consequence, DAF is sensitive to sulfhydryl-reducing agents. The molecule contains a single *N*-glycosylation site near SCR1 (Medof, 1987). SCR2 and SCR3 are the binding sites for the C3 convertase complexes C3bBb or C4b2a (Lublin, 2005).

Molecular Biology

The *DAF* gene spans 40kb on chromosome 1q32 and is organized into 11 exons. Most Cromer antigens reflect single-amino acid polymorphisms (see Table 35-31) (Hue-Roye, 2007). The Inab phenotype is the result of nonsense or splice-site mutations. The origin of the Dr(a-) phenotype is interesting. A single-amino acid polymorphism (596C>T) leads to both an Ser199>Leu polymorphism and an alternative splice site. In Dr(a-) individuals, two mRNA species are observed, encoding a truncated mutated protein arising from alternate splicing (major transcript) and the full DAF bearing the Leu165 polymorphism (minor transcript). Dr(a-) RBCs have weakened expression of DAF and all Cromer antigens (Storry, 2002).

Cromer Antibodies

The clinical significance of anti-Cromer antibodies is variable. In some individuals, anti-Cromer antibodies are associated with decreased RBC survival and hemolytic transfusion reactions. Cromer antibodies do not cause HDFN owing to adsorption of antibodies by DAF on trophoblast epithelium (Storry, 2002; Lublin, 2005). In several cases, a transient loss of anti-Cromer antibodies was noted in the second and third trimesters with reappearance of the antibody following delivery (Hue-Roye, 2007).

Anti-Cromer antibodies are usually of IgG isotype, arising from immune stimulation. They are detected in the IAT and can give weak, variable results (historically, high-titer, low-avidity [HTLA] antibodies). Anti-Cromer can be inhibited by plasma, urine, and platelet concentrates. Antibody reactivity is highly sensitive to pretreatment of RBCs with chymotrypsin and pronase, but not with other proteases. Cromer antigens are weakened, but not destroyed, by AET and DTT.

Biological Role

CD55/DAF protects cells from complement by promoting the decay of two C3 convertases: C4b2a and C3bBb. In murine models of induced autoimmune disease, CD55 knockout mice demonstrate increased disease

severity (Lublin, 2005). CD55 is also a receptor for uropathogenic and intestinal *E. coli* strains bearing Afa/Dr and X adhesins, echovirus, and coxsackie B virus.

KNOPS BLOOD GROUP SYSTEM (ISBT NO. 022)

The Knops blood group contains 10–12 antigens, including six antithetical antigens (Table 35-32). Several Knops antigens (Kn^b, Mc^b, Sl^a, KCAM) are racially segregated. Knops antigens are present on adult and cord RBCs, neutrophils, B lymphocytes, and dendritic cells (Reid, 2004). Knops can vary in strength between individuals, with approximately 1% of donors showing extremely weak Knops expression (10% normal, Helgeson phenotype).

Biochemistry

Knops resides on complement receptor 1 (CR1, CD35), a 220-kD glycoprotein (Daniels, 2002; Reid 2004). The extracellular domain consists of 30 SCRs, arranged into four long homologous regions (LHRs) that are capable of binding C4b and C3b. The molecule also possesses six to eight *N*-glycosylation sites.

Molecular Biology

The *CR1* gene resides on chromosome 1q32. Four CR1 alleles (CR*1–4) are present, of which CR1*1 is the most common (Daniels, 2002). Variation in CR1 strength and copy number appears to be genetically determined. To date, all Knops antigens arise from amino acid polymorphisms (see Table 35-31; Moulds, 2002; Covas, 2007). KN4/7 (Sl/Vil) antigens may be expanded to include five antigens, reflecting the influence of a second amino acid polymorphism (Ser1610>Ser) and a conformational antigen (Sl3) that requires Sl1 and Sl4 coexpression (Moulds, 2002).

Knops Antibodies

Knops antibodies are clinically insignificant. Knops-incompatible RBCs have normal survival following transfusion. Knops antibodies are of IgG isotype, arising from immune stimulation, and are usually detected only with AHG. Historically classified as an HTLA antibody, Knops antibodies are notoriously difficult to work with because of their low avidity, biological variation in Knops expression, antigen degradation, and the common presence of additional alloantibody specificities. Knops antigens are resistant to proteases but are weakened by sulfhydryl-reducing agents (AET, DTT).

Biological Role

A complement regulatory protein, CR1 can bind C3b/C4b immune complexes, promoting their degradation by factor 1. CR1 also enhances

TABLE 35-32

Knops Blood Group Antigens

HIGH FREQUENCY				LOW FREQUENCY

ISBT, International Society of Blood Transfusion.

*SI4 and SI5 are theoretical antigens not formally added to the Knops family at this time.

[†]SI3 is a conformational antigen that requires the presence of both SI1 (Arg1601) and 'SI4' (Ser1610).

phagocytosis of C3b/C4b-coated particles and could play a role in *Leishmania*, *Legionella*, and *Mycobacterium* infections (Daniels, 2002). CR1 also binds *P. falciparum* with rosette formation—a clinical finding associated with severe malaria. Because SI(a–) RBCs show reduced *P. falciparum* binding and rosetting, it was hypothesized that the SI 1/SI 2 phenotype, which is present in 70% of African black people, may provide protection against severe malaria. A later study, however, found no correlation among SI1/SI2 phenotype, malaria infection, or disease severity (Zimmerman, 2003). Despite the latter, the extremely high incidence of the SI(a–) or SI 2 phenotype in Africa suggests a past selective advantage for the SI(a–) phenotype in this population.

INDIAN BLOOD GROUP SYSTEM (ISBT NO. 023)

The Indian (IN) blood group contains two autosomal codominant antigens: In^a (IN1) and In^b (IN2). In^b is a high-frequency allele (99% white people), whereas In^a is relatively rare except among Indian (4%) and Arab populations (11%–12%). Three additional high-incidence antigens are known: IN3, IN4, and AnWj. Rare IN3– and IN4– have been identified only in Moroccans and Pakistanis, respectively (Poole, 2007). Indian antigens are carried by the CD44 glycoprotein and are widely expressed on all hematopoietic cells, epithelial cells, and neural tissue. Approximately 6000–10,000 CD44 molecules are present per RBC (Byrne, 2004; Reid, 2004).

Null/Weak Phenotypes

Indian antigens, including AnWj, are depressed on *In(Lu)* RBCs. They are transiently depressed on cord RBCs during pregnancy and autoimmune hemolytic anemia as a result of autoanti-AnWj (Daniels, 2002).

Biochemistry

Indian antigens are present on CD44, a ubiquitous glycoprotein on many cell membranes. CD44 is heterogeneous between tissues owing to tissue-specific differences in mRNA processing and glycosylation. In RBCs, CD44 is an 80–85-kD, 341 amino acid type 1 glycoprotein bearing a large, heavily glycosylated extracellular domain containing six cysteine residues, six N-glycans, three chondroitin sulfate glycans, and several O-linked glycans. Similar to Diego/Band 3, CD44 can bind the cytoskeletal proteins, protein 4.1, and ankyrin (Daniels, 2002).

Molecular Biology

CD44 resides on chromosome 11p13. The gene spans 50kb and contains 20 exons, which are able to generate an array of splice-form variants. In RBCs, CD44 is encoded by exons 1–5, 16, 17, 18, and 20. A single-amino acid polymorphism is responsible for the In^a (IN1, Pro46) and In^b (IN2, Arg46) antigens. Missense mutations are responsible for the loss of high-incidence antigens IN3 (H85Q) and IN4 (T163R) (Poole, 2007). The basis of the AnWj antigen is unknown.

Indian Antibodies

Antibodies against both Indian and AnWj antigens can be clinically significant, with shortened RBC survival and transfusion reactions. They are not associated with HDFN. Autoimmune anemia due to autoanti-AnWj has been reported. Anti-Indian antibodies are usually of IgG isotype, arising from immune stimulation. They can present as saline agglutinins and are enhanced by AHG. With the exception of AnWj, Indian antigens are destroyed by proteases and AET. Anti-Indian antibodies are also inhibited by plasma, which contains soluble CD44.

Biological Role

CD44 is a major adhesion molecule on leukocytes. CD44 binds a spectrum of extracellular matrix proteins, including collagen, fibronectin, laminin, and hyaluron. In bone marrow, CD44 may participate in the adhesion of erythroid progenitors to stromal fibroblasts. In leukocytes, CD44 may facilitate white blood cell (WBC)–endothelial adhesion, helping to localize WBC to sites of inflammation. CD44 has been implicated in tumor metastasis, wound remodeling, and embryonic differentiation. AnWj/CD44 is also a receptor for *Haemophilus influenzae*.

OK BLOOD GROUP SYSTEM (ISBT NO. 024)

The OK system contains a single high-frequency antigen, Ok^a (>99% donors), residing on CD147. CD147 is present on RBCs, WBCs, hematopoietic progenitors, endothelial cells, brain, and many tumor cell lines.

Biochemistry and Molecular Biology

Ok^a resides on CD147, a 35–68-kD, 251 amino acid N-linked glycoprotein. A member of the Ig superfamily, CD147 possesses IgC2 and IgV domains. The gene for CD147 resides on chromosome 19p13.2-pter. The Ok(a–) phenotype arises from a E92K polymorphism (Daniels, 2002).

CD147 Antibodies

Anti-Ok^a is rare and has been described only in Japan. Anti-Ok^a is of IgG isotype, arising from immune stimulation, and is associated with shortened RBC survival following transfusion of Ok^a-incompatible RBCs. It is not associated with HDFN. The Ok^a antigen is resistant to enzymes, sialidases, and sulfhydryl-reducing agents. Three monoclonal antibodies against Ok^a were recently developed by the New York Blood Center (Tian, 2009).

Biological Role

On WBCs, CD147 is a leukocyte activation-associated protein and may participate in cell adhesion, tumorigenesis, and wound healing via stimulation of enzymes required for remodeling of the extracellular matrix (Daniels, 2002). CD147 may also play a role in the trafficking of red cells out of the spleen. In a murine model, CD147 blockade was associated with anemia, splenomegaly, and de novo erythropoiesis (Coste, 2001). It is interesting to note that red cell aging is accompanied by progressive loss

of CD147, suggesting a possible role for CD147 in splenic removal of senescent red cells (Khandelwal, 2006).

RAPH BLOOD GROUP SYSTEM (ISBT NO. 025)

The RAPH blood group system contains a single antigen, RAPH or MER2, located on CD151 or tetraspanin (TM4). CD151 is widely expressed on epithelium, fibroblasts, endothelium, muscle, renal glomeruli and tubules, CD34 cells, early erythroid precursors, megakaryocytes, and platelets. CD151 is strongly expressed in early erythroblasts but is progressively lost with increasing maturation. As a result, MER2 expression is variable among adult donors, with 92% typing MER2-positive and 8% typing MER2-negative. MER2-negative donors strongly express CD151 on other cell lines such as platelets and lymphocytes.

Null Phenotypes

A MER2-negative, autosomal recessive phenotype was identified in three individuals of Indian ancestry (Crew, 2004). All three individuals had nephrotic syndrome with end-stage renal disease and neurosensory deafness. In addition, two individuals had severe pretibial epidermolysis bullosa, bilateral lacrimal duct stenosis, and nail dystrophy. Renal biopsies revealed splitting and fragmentation of the tubular and glomerular basement membranes, respectively. Likewise, skin biopsies showed classic separation of the epidermis with focal edema.

Biochemistry

CD151 or tetraspanin is a 253 amino acid, 28–32-kD multipass protein with four transmembrane domains, four cysteine residues, two extracellular loops, and a single *N*-glycosylation site. The second, large extracellular loop contains a QRD motif for integrin binding (aa 194) and is the site of polymorphisms associated with alloantibody formation (Crew, 2008). In the cell membrane, tetraspanins are associated with integrins ($\alpha 3 \beta 1$, $\alpha 6 \beta 1$, $\alpha 7 \beta 1$) and are implicated in cell adhesion, tumor metastasis, and signaling.

Molecular Biology

CD151 (TSPAN24) is located on chromosome 11p15 and consists of eight exons: exons 2–8 encode the translated protein. The MER2 null phenotype with renal disease has been linked to a nucleotide insertion (exon 5, G383) and a frameshift mutation, leading to a 140 amino acid, nonfunctional protein (Crew, 2004). In addition, two SNPs (R171C, R178H) have been identified in three individuals with MER2 alloantibodies (Crew, 2004, 2008).

MER2 Antibodies

Six examples of anti-MER2 are known in patients of Indian, Turkish, and Pakistani origin (Crew 2004, 2008). All were of IgG isotype, arising from transfusion and pregnancy. Three examples fixed complement. Reactivity is sensitive to disulfide-reducing agents and most proteases except papain (Crew, 2004). No reports have described HDFN due to anti-MER2. MER2 can cause hemolytic transfusion reactions in some patients. A monocyte-monolayer assay may be helpful in determining the clinical significance of anti-MER2 antibodies (Crew, 2008).

Biological Role

The occurrence of renal disease and neurosensory deafness in all three patients with frameshift mutations suggests that CD151 is critical for basement membrane assembly in kidney and inner ear. The clustering of tetraspanin (CD151) and $\beta 1$ integrins, which are important in laminin adhesin, also supports a role for CD151 in basement membrane function and assembly (Crew, 2004).

JMH BLOOD GROUP SYSTEM (ISBT NO. 026)

The JMH (John Milton Hagen) system contains six high-incidence antigens and can vary in strength between individuals. In addition to RBCs, JMH is found on lymphocytes, activated macrophages, thymus, brain, respiratory epithelium, placenta, testes, and spleen (Reid, 2004).

Variant and Null Phenotypes

JMH weak, JMH variant, and JMH negative have been described (Seltsam, 2007). An acquired, JMH weak to negative phenotype can occur in the elderly, accompanied by the occurrence of JMH autoantibodies. Five

distinct, autosomal recessive JMH variants have been described as the result of single missense mutations. At least one example of an autosomal dominant, JMH-negative phenotype has been described.

Biochemistry

JMH is carried on CD108 (SEMA-L), a semaphorin family glycoprotein (see Fig. 35-13). The protein is a 666 amino acid protein composed of a large 500 amino acid SEMA domain, a C2-type Ig domain, and five *N*-glycosylation and six myristoylation sites. The molecule contains an RGD sequence essential for promoting axonal growth (Seltsam, 2007). The molecule is anchored into the cell membrane by a GPI tail (GPI-linked) and is absent on PNH III RBCs. The molecule contains 19 cysteine residues and is sensitive to sulfhydryl-reducing agents.

Molecular Biology

SEMA7A resides on chromosome 15q24.1 and consists of 14 exons ranging from 42–362 bp in size (Seltsam, 2007). JMH variants are the result of missense mutations at two mutational hotspots in propellar 3 (R207W, R207H) and propellar 7 domains (R460H, R461C). All four mutations may lead to conformational changes based on molecular modeling. An additional missense mutation has been identified among four Native Americans (R347L; St Louis, 2009).

No mutations were identified among JMH-weak and JMH-negative samples. It is interesting to note that SEMA7A mRNA can be identified in reticulocytes from JMH-negative individuals, suggesting that the absence of JMH on red cells is posttranscriptional. The absence of JMH on red cells was not due to PNH or related defects in GPI biosynthesis: CD55 and CD59 expression on JMH-negative red cells was normal (Seltsam, 2007).

JMH Antibodies

Anti-JMH antibodies do not cause hemolytic transfusion reactions or HDFN, although shortened RBC survival has been documented in some patients. The latter may reflect true alloantibodies in JMH-variant individuals. The antibodies are of IgG isotype and can be naturally occurring. The JMH antigen is sensitive to proteases and DTT. An assay for detection of anti-JMH antibodies was recently developed for gel using immobilized recombinant SEMA7A on polystyrene beads (Seltsam, 2008).

Biological Role

Semaphorin proteins are implicated in cell signaling. In hematopoietic cells, SEMA7A can modulate cellular immunity via effects on T cells, monocytes, and natural killer (NK) cells. SEMA7A inhibits NK cell proliferation (Figueiredo, 2009) and is a negative regulator of T cell activation. Conversely, SEMA7A stimulates chemotaxis, secretion of inflammatory cytokines, and dendritic cell maturation in monocytes (Ji, 2009).

I BLOOD GROUP SYSTEM (ISBT NO. 027)

The I blood group system contains two biosynthetically related antigens: I and i. The system was named I for “individuality” after an extensive search of 22,000 individuals identified only five I- adult donors (Cooling, 2010). The biosynthetic precursor to I antigen, the i antigen, is strongly expressed on cord cells because of developmental delays in the enzyme responsible for I antigen synthesis. By 3 months of age, there is a perceptible decrease in i antigen, accompanied by increased I antigen, with an adult I+/- phenotype by 18–24 months of age (Marsh, 1961). Increases in I antigen are accompanied by parallel increases in A and B antigens (Cooling, 2010). Both I and i antigens are ubiquitously expressed on glycolipids and glycoproteins on red cells and other tissues.

Null Phenotype

The i_{adult} phenotype is a rare, autosomal recessive phenotype found in <1/10,000 donors. In Asia, the i_{adult} phenotype can be associated with congenital cataracts (Inaba, 2003; Yu, 2003). Elevated i antigen is also observed on cord RBCs and reticulocytes and in megaloblastic anemia, leukemia, and chronic hemolytic states as a sign of stressed erythropoiesis (Cooling, 2010). Elevated i antigen is also observed in HEMPAS (hereditary erythroblastic multinuclearity with positive acidified-serum test), a congenital dyserythropoietic anemia associated with chronic hemolysis, binucleated erythroblasts, and altered red cell glycosylation (Denek, 2009). The molecular basis of HEMPAS was recently identified as altered Golgi trafficking due to mutations in SEC23B, a COPII protein (Schwarz, 2009).

Figure 35-16 Structure of the I and i antigens. The I antigen is composed of two successive lactosaminyl subunits. I antigen requires the action of GCNT2, a 1-6-N-acetylglucosaminyltransferase. (Gal, Galactose; GlcNAc, N-acetylgalactosamine; R, other oligosaccharide.)

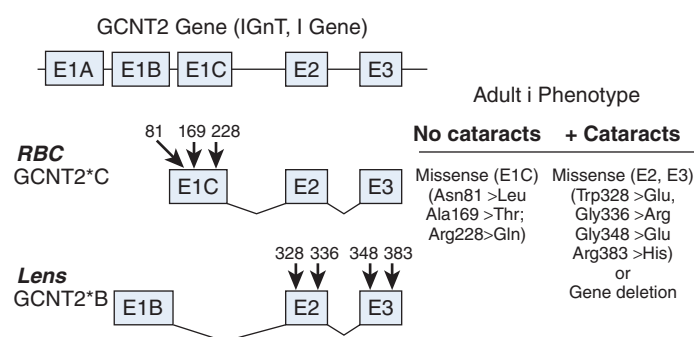

Figure 35-17 The I gene, showing three different exons 1. In human red blood cells (RBCs) and lens, a different GCNT2 mRNA is translated, based on which exon 1 is utilized. Mutations in GCNT2 gene can result in an *i*_{adult} phenotype and cataracts. In Europeans, mutations usually are seen only in exon 1C and affect I antigen synthesis in RBCs. In Asia, *i*_{adult} phenotype involves gene deletion or mutations in exons 2 and 3. As a result, loss of GCNT2 activity is seen in all tissues.

Biochemistry

Type 2 chain oligosaccharides, both *i* and I antigens, terminate in a Galβ1→4GlcNAc or lactosaminyl epitope and differ only in complexity and multivalency. As shown in Figure 35-16, the *i* antigen is a linear oligosaccharide containing at least two successive lactosamine epitopes. The I antigen is derived from *i* antigen by the action of a β1-6 N-acetylglucosaminyltransferase, a first step in the synthesis of large, branched multivalent complex polylectosamines (see Fig. 35-16). Both *i* and I can be further modified by other glycosyltransferases to yield ABH, LeX, and related antigens (Cooling, 2010).

Molecular Biology

The I antigen, a β1-6 glucosaminyltransferase, is the product of the GCNT2 or IGnT gene. The gene spans approximately 100 kb on chromosome 6p24. The gene contains five exons, including three tissue-specific exon 1 (Fig. 35-17). As a consequence, three different GCNT2 splice-forms are possible, depending on which exon 1 is utilized (Inaba, 2003). GCNT2*A is ubiquitously expressed, whereas GCNT2*B is primarily expressed in human lens epithelia, fetal brain, and cerebellum (Yu, 2003). GCNT2*C, composed of exons E1C, E2, and E3, is the predominant transcript in erythroblasts and reticulocytes. In hematopoietic stem cells, erythroid differentiation is accompanied by transcriptional upregulation of GCNT2*C (Tiw, 2007). The promoter for GCNT2*C contains transcription factor binding sites for Sp1, Oct-2, and C/EBPα. C/EBPα phosphorylation and binding is critical for transcriptional activation (Tiw, 2007).

The translated GCNT2 protein consists of 402 amino acids with five N-glycosylation sites and 9 conserved cysteine residues. Unlike most galactosyl- and glucosaminyltransferases, GCNT2 does not contain a DXD motif. The enzyme is likely highly folded, based on crystallography

data from C2GnT, a closely related β1,6 glucosaminyltransferase (Pak, 2006; Cooling, 2010). Sequence differences in exon 1, which encodes 77% of the translated enzyme, may account for the enhanced enzyme activity observed with the GCNT2*C isoform (Yu, 2003). Oligosaccharide analysis and enzyme studies indicate that the minimum acceptor for enzyme activity is a tetrasaccharide composed of two lactosamine motifs (Cooling, 2010).

Both the *i*_{adult} phenotype and congenital cataracts have been linked to mutations in GCNT2. In *i*_{adult} individuals without cataracts, missense mutations have been found in exon E1C, leading to an isolated loss of GCNT2*C activity in RBCs (Inaba, 2003; Cooling, 2010). In contrast, *i*_{adult} with cataracts is the result of mutations in exon E2 or E3 or a major deletion of the IGnT gene. As a result, GCNT2 activity is lost in all tissues, including RBC and lens (Yu, 2003; Cooling, 2010). Loss of GCNT2*B activity in the lens is believed to underlie the formation of cataracts in humans; however, a direct causal link has yet to be established. No increase in cataracts was observed in a GCNT2 knockout mouse model (Chen, 2005).

Anti-I and -i Antibodies

Anti-I and anti-i are antibodies of IgM isotype, reactive at room temperature (see Table 35-7). Autoantibodies to I are relatively common and are usually low-titered cold agglutinins. Some anti-I can have IH specificity, reacting stronger with group O and A₂ RBC (refer to Table 35-48). Although generally benign, hemolysis secondary to high-titered anti-I is observed in cold autoimmune hemolytic anemia (CAIHA). CAIHA can occur in the setting of malignancy and occasionally infection (e.g., *Mycoplasma pneumoniae*). These antibodies display high thermal amplitude, often agglutinating RBCs at temperatures of 30°–34° C. In contrast, alloanti-I is relatively rare and is found as a naturally occurring antibody in *i*_{adult} individuals. Anti-i is also uncommon but has been reported in CAIHA, infectious mononucleosis, choriocarcinomatosis, and alcoholic cirrhosis.

Biological Role

Despite the common occurrence of major maternal-fetal ABO incompatibility, severe HDFN due to ABO incompatibility is rare (0.04%). It is hypothesized that the developmental delay in I antigen synthesis may play a protective role against HDFN-ABO by minimizing the number of ABH antigens expressed on fetal red cells (Cooling, 2010). This is supported by parallel increases in I and ABH during the first 2 years of life. Additional evidence comes from extended studies of the N-glycan on Band 3, which accounts for 50% of the ABH antigen on red cells. Adult red cells had a fourfold increase in ABH expression on Band 3 owing to chain extension and branching (Fukuda, 1984; Cooling, 2010).

GIL BLOOD GROUP SYSTEM (ISBT NO. 029)

The GIL blood group system contains one high-incidence antigen, GIL (100% donors). The GIL protein is highly expressed on RBCs, kidney, small intestine, stomach, colon, spleen, eye, and respiratory tract (Reid, 2004).

Biochemistry

GIL is carried by aquaglyceroporin (AQP-3), a member of the major intrinsic protein family of water channels. Similar to Colton (AQP1), AQP3 is a 46-kD, 292 amino acid multipass protein containing six transmembrane domains and a single N-glycosylation site. The molecule is present in the cell membrane as dimers, trimers, and tetramers (Daniels, 2002).

Molecular Biology

The AQP3 gene spans 6kb on chromosome 9p13 and is organized into six exons. The one example of a GIL-negative phenotype is the result of splice site and frameshift mutations, resulting in a truncated 218 amino acid protein. In general, AQP3 is highly conserved; no missense mutations in the translated protein were identified in a recent study of European and African individuals. Two SNPs were identified in the promoter region (A-14G, C-46A); however, neither polymorphism had an impact on AQP3 mRNA levels (Bahamontes-Rosa, 2008).

GIL Antibodies

Anti-GIL is associated with hemolytic transfusion reactions. No reports have described clinical HDFN due to anti-GIL despite a positive DAT.

Anti-GIL is usually of IgG isotype, reactive at 37° C and enhanced with AHG. The antigen is resistant to proteases, sialidases, and DTT.

Biological Role

AQP3/Gil is a membrane channel capable of transporting urea and glycerol. On red cells, AQP3 may play a role in malaria infection. AQP3 was shown to be internalized during *P. falciparum* infection as part of the parasitophorous vacuole (Bietz, 2009). Because AQP3 protects against hydroxyl radicals and osmotic stress, internalization and loss of AQP3 from the red cell extracellular membrane may contribute to the pathology and severity of malarial infections (Bahamontes-Rosa, 2008).

AQP3 is highly expressed in epidermis, where it plays a significant role in skin differentiation and hydration through regulation of glycerol content and metabolism (Boury-Jamot, 2009). A decrease in AQP3 is associated with decreased skin elasticity, poor wound healing, and eczema. Conversely, increased AQP3 is observed in basal cell carcinoma. Dermal AQP3 expression can be modulated by inflammatory mediators, ultraviolet radiation, and topical glycerol (Boury-Jamot, 2009; Horie, 2009). It is not surprising that cosmetic and pharmacologic companies are actively pursuing topical agents capable of modulating AQP3 expression in the skin.

IMMUNOHEMATOLOGY TESTS AND PROCEDURES

BASIC PRINCIPLES—HEMAGGLUTINATION

Specific hemagglutination is the single most important in vitro immunologic reaction in blood banking because it is the endpoint of almost all test systems designed to detect RBC antigens and antibodies. The hemagglutination process actually occurs in two stages. The first stage, often referred to as RBC sensitization, is simply the combination of paratope and epitope in a reversible reaction that follows the law of mass action and has an associated equilibrium constant. Antigen and antibody are held together by noncovalent attractions. In stage two, multiple RBCs with bound antibody form a stable latticework through antigen-antibody bridges formed between adjacent cells. This latticework is the basis of all visible agglutination reactions.

Formation of the latticework during the second stage of hemagglutination is naturally impeded by the fact that RBCs in solution normally repel each other. This is due to the net negative charge of the RBC membrane created by sialic acid. If RBCs are suspended in an ionic medium such as normal saline, cations arrange themselves around each cell to form an ionic cloud. Cations closest to the cell membrane are firmly bound and move with the RBC, while the outer cations move freely. The difference in charge at the surface between the inner and outer cation layers, called the surface of shear, creates an electrical potential named the ζ potential (Fig. 35-18). The ζ potential keeps RBCs in solution about 25 nm apart (Harmening, 2005). Another factor that may be important in keeping RBCs apart is the water of hydration. Proponents of this theory suggest that the hydrophilic polar heads of lipid molecules making up the outer cell membrane bilayer attract water molecules. The water thus creates a surface tension that helps to keep the cells apart.

One situation whereby the natural influence of the ζ potential to keep RBCs apart is circumvented is the phenomenon of rouleaux formation or “pseudoagglutination.” Patients with multiple myeloma, Waldenström’s macroglobulinemia, and hyperviscosity syndromes have high concentrations of abnormal serum proteins that change the net surface charge on the RBC membrane. The cells thus cluster together in clumps that resemble macroscopic hemagglutination. Plasma expanders, such as dextran and hydroxyethyl starch, as well as some intravenous X-ray contrast materials can also cause rouleaux formation. Rouleaux can be differentiated from true agglutination by direct microscopy (1) by the classical “stacked-coin” formation in rouleaux, and (2) by the loss of rouleaux after washing and resuspension in saline. Nonspecific agglutination can also be seen in cord blood samples contaminated with Wharton’s jelly. The presence of hyaluronic acid and albumin in cord blood is responsible for this problem.

Factors Affecting Specific Hemagglutination

The extent of RBC sensitization and the facilitation of second-stage latticework formation are influenced first by inherent characteristics of the specific antigens and antibodies involved. In most immunohematology procedures, IgM antibodies can facilitate the second stage of hemagglutination because of their large diameter (35 nm) and multivalency, which allows them to span the distance between two adjacent RBCs in solution

Figure 35-18 Erythrocytes are kept apart in an ionic medium by the ζ potential, which in turn influences the agglutinating capacity of immunoglobulin (Ig)G and IgM.

(see Fig. 35-18). Because of their innate agglutinating ability, IgM antibodies are frequently referred to as direct agglutinins. Most IgG antibodies, on the other hand, are considerably smaller (14 nm) and are unable to induce visible agglutination without the assistance of secondary enhancing reagents. Thus, IgG antibodies are commonly referred to as indirect agglutinins.

The density and accessibility of specific antigens on the RBC membrane are also critical in second-stage latticework formation. This can be illustrated by comparing the ABO and Rh antigens. Approximately 1 million ABO antigens are present per RBC, displayed on large N-glycans of extramembranous glycoproteins. Because of their high density and easy accessibility, ABO antibodies can readily bind exposed ABO antigens and agglutinate RBCs. In contrast, only 10,000–30,000 Rh antigens are readily accessible per RBC and, as multipass integral membrane proteins, are considered intramembranous. As a consequence, Rh antigens are less easily agglutinated by Rh antisera. In another example of the influence of antigen density, RBCs that are homozygous for a particular blood group gene will often give stronger reactions than heterozygous cells. This is because homozygotes express twice as many copies, or a double dose, of antigen per cell. In immunohematologic testing, this phenomenon is frequently referred to as dosage.

Secondarily to inherent antigen and antibody characteristics, the first and second stages of the hemagglutination reaction may also be influenced by manipulating various physical and/or chemical parameters of the reaction environment. An outline of how these various parameters may be controlled is shown in Table 35-33.

Grading of Hemagglutination Reactions

Hemagglutination in blood bank testing is observed and graded according to the strength of the reaction. Currently, three methods are available for evaluating visual hemagglutination reactions: Tube testing, column agglutination (gel technology), and solid-phase technology. In test tube reactions, reagents and patient sample are added to a test tube and centrifuged, creating a cell button at the bottom of the test tube. The cell button is gently dislodged while observing for macroscopic agglutination. Column agglutination or gel technology utilizes a dextran acrylamide gel microtube prepared by the manufacturer. The gel traps agglutinates at the top of the chamber if hemagglutination has occurred, while unagglutinated cells pass through the gel layer and form a pellet at the bottom of the microtube. In solid-phase technology, a microplate is the vessel for the reaction. Reagent or reagent cells (as a monolayer of cells or cell stroma) coat the well to which patient sample is added. Following incubation and washing, indicator cells are added. When hemagglutination occurs, there is a diffuse adherence of RBC to the well. If no reaction occurs, the RBCs settle to the bottom of the well.

TABLE 35-33

Factors Affecting the Hemagglutination Reaction

Reaction parameter	Effect	Manipulation
Temperature	Influences the equilibrium constant and/or reaction rate depending on the class of antibody involved	Decreasing the temperature to 24° C or even to 4° C enhances the reaction of IgM antibodies Prewarming or maintaining a reaction temperature of 37° C provides the optimum temperature for detection of IgG antibodies, while preventing most IgM antibodies from reacting
Incubation time	Different Ag/Ab reactions reach equilibrium over different time periods	Increasing the time of incubation in a given test system may enhance the detection of a weakly reactive antibody
pH	At a pH range of 6.5–7.5, chemical groups on Ag and Ab are oppositely charged, providing optimal ionic forces of attraction for most blood group antibodies	Changing the pH affects the equilibrium constant for selected antibodies that may react preferentially in a more acidic environment (e.g., anti-M, anti-Pr)
Ionic strength	In an isotonic saline medium, sodium cations and chloride anions cluster around erythrocyte Ag and blood group Ab, respectively, acting to neutralize Ag/Ab attractive forces	Addition of LISS reduces the shielding effect on oppositely charged Ab and Ag, thus increasing the rate of reaction and the equilibrium constant for red cell sensitization
Antibody concentration	Can affect first- and second-stage agglutination by influencing the number of antibody molecules attached to each erythrocyte	Increasing the serum-to-cell concentration increases the rate and/or affects the equilibrium constant of red cell sensitization by IgG antibodies May help to induce second-stage agglutination by IgM antibodies Addition of PEG, a large space-occupying molecule, effectively increases the relative concentrations of ag and ab relative to the volume of the reaction, greatly increasing the rate of reaction; is used only in AHG testing to detect IgG antibodies
ζ Potential	Causes red cells to repel each other in solution; if the ζ potential can be reduced or the red cells brought together by physical means, second-stage agglutination of sensitized red cells can be facilitated	Centrifugation—forcing cells closer together facilitates latticework formation Enzymes—cleave sialic acid residues to lower the ζ potential and improve accessibility of certain blood group antigens Albumin—reduces ζ potential and/or water of hydration to allow red cells to approach each other more closely Polybrene/protamine—provides an excess of cations that neutralize the repulsive force between red cells, producing both nonspecific aggregation and antibody-mediated latticework formation; the final addition of sodium citrate disperses nonspecific aggregates, while specific ag/ab agglutinates remain

ab, Antibody; ag, antigen; AHG, antihuman globulin; LISS, low-ionic strength saline; PEG, polyethylene glycol.

Tube Reactions

Hemolysis is considered the strongest positive reaction that can occur and indicates the presence of a potent, complement-fixing antibody. After recipient serum and reagent RBCs are incubated and centrifuged at 37° C, the serum should first be examined for hemolysis before the cell button is resuspended. When reading for agglutination, the tube should be shaken, using a gentle wrist action, until all cells are dislodged. This is most easily accomplished by gently holding the test tube at the top of the tube in a vertical fashion and using the wrist to gently dislodge the cell button, while watching closely for agglutinates. As the cell button begins to resuspend, tip the tube gently to observe for agglutinates. Proper illumination with a concave mirror is an invaluable aid for macroscopic reading. By placing the tube about 2.5 inches above a 3-inch concave mirror, aggregates can be differentiated easily from the free cells by looking at the mirror, not at the tube.

Table 35-34 lists two protocols for evaluating the strength of agglutination using numeric grading and/or scoring. Figure 35-19 shows the appearance of different agglutination grades. Although the agglutination grade gives an approximate idea regarding the potency or strength of a particular antibody, the scoring method is much more useful in semiquantitative procedures, particularly when used in conjunction with titration to compare the relative antibody strengths of two different sera.

Unlike tube testing, microcolumn gel technology and solid-phase red cell adherence reactions are fixed after the centrifugation phase. The card or well is ready to read without the need to dislodge the cell button. (See Figures 35-22 and 35-23 for examples of reactions in gel and solid phase).

THE ANTIHUMAN GLOBULIN TEST

Many IgG antibodies are not able to directly produce detectable hemagglutination, even after centrifugation and the use of enhancement media and techniques such as polyethylene glycol, low-ionic strength saline (LISS), albumin, or enzymes. To visualize reactions by these antibodies, AHG reagents, which contain specific antibodies to human Igs or

TABLE 35-34

Grading and Scoring of Hemagglutination

Grade	Appearance	Score
H	Hemolysis—presence of free hemoglobin in the serum	10
4+	One solid aggregate	10
3+	Several medium to large aggregates	8
2+	Many small to medium aggregates with a clear background	5
1+	Many small aggregates with a turbid background	3
+ or w	Few small aggregates with many unagglutinated cells	2
± ^m or + ^m	Aggregates visible only under microscopic magnification	1
0	Negative—absence of aggregates; all cells unagglutinated	0
mf	Mixed-field agglutination—presence of minor population of agglutinated cells superimposed on a negative background	NA
R	Rouleaux—nonspecific aggregation appearing like a stack of coins; disappears with addition of saline	NA

NA, Not applicable.

complement components, must be utilized. The antibodies in AHG sera act as bridges between RBCs already sensitized with antibody or complement to produce the characteristic latticework of second-stage hemagglutination (Fig. 35-20). This is the basis of the AHG test.

The AHG test is also called the Coombs' test, in honor of one of the investigators who first developed the test for laboratory use (Coombs, 1945), although the principle was actually described much earlier (in 1908) by Moreschi (Harmening, 2005). When the test is used to detect

Figure 35-19 Agglutination grading system showing macroscopic hemagglutination reactions.

Figure 35-20 Antihuman globulin antibodies form a bridge between adjacent erythrocytes sensitized with human immunoglobulin (Ig)G or complement components.

antibodies or complement bound to RBCs in vivo, it is called the direct antiglobulin test (DAT). When the test is used to detect the reaction of antibody and RBCs in vitro after an appropriate incubation phase, it is called the indirect antiglobulin test (IAT). The red cell antibody screen is an example of an IAT.

Antihuman Globulin Reagents and Procedures

Various preparations of AHG sera are available for blood bank testing, depending on the application (direct or indirect) and whether one wishes to detect RBC sensitization by IgG, complement, or both.

Polyspecific Reagents

Polyclonal, polyspecific AHG reagents are produced by hyperimmunizing animals, usually rabbits, with purified Ig or complement to produce

high-titered, high-avidity IgG antibodies. For a given batch of reagent, animal sera are harvested, pooled, adsorbed to remove heterophil agglutinins, and then titrated to ascertain the dilution necessary for optimal reactivity in routine use. Conventional polyspecific (also called broad-spectrum) AHG contains polyclonal IgG antibodies to the spectrum of human IgG subclasses and the C3 complement cleavage products C3b and C3d. Some anti-C4b and anti-C4d activity may also be present. However, most manufacturers adsorb out anti-C4 activity from their polyspecific AHG reagents because it has been shown that in vitro complement activation by clinically insignificant cold agglutinins results in much more C4d than C3d binding (Klein, 2006). Excluding anti-C4 activity thus reduces the number of false-positives in both DAT and IAT testing using polyspecific reagents. Because immunization against IgG will also produce anti-light chain antibodies in a polyclonal response, one should remember that

TABLE 35-35

Applications for Direct and Indirect Antiglobulin Techniques

	Applications	Purpose	What is detected
Direct antiglobulin test (DAT)	Investigation of HTR	To detect circulating donor red cells that are sensitized with recipient antibody. A positive DAT is the first immunohematologic evidence of a hemolytic reaction after transfusion	DAT positive owing to IgG and/or C3d depending on the antibodies responsible
	Diagnosis of HDFN	To detect maternal antibodies that have crossed the placenta to sensitize fetal red cells	DAT almost always positive as a result of IgG; occasionally C3d if ABO antibodies involved
	Diagnosis of AIHA	To detect autoantibody sensitizing a patient's own red cells	Warm autoantibodies: DAT almost always positive owing to IgG Cold autoantibodies: DAT may be due to C3d only
	Investigation of drug-induced hemolysis	To detect anti-drug/red cell antibodies and/or subsequent activation of the complement system	DAT may be positive owing to IgG, C3d, or both, depending on the mechanism involved (see under Investigation of Autoimmune Hemolytic Anemia section)
Indirect antiglobulin test	Antibody detection (or antibody screen)	To detect clinically significant IgG alloantibodies in the recipient	Recipient IgG antibodies bound to reagent screening cells*
	Antibody identification	To specifically identify those antibodies detected by reagent screening cells or by donor red cells	Recipient IgG antibodies bound to reagent cells from a panel of 10–12 donors*
	Crossmatching	To detect antibodies that may have been missed by the antibody screen because of absence of the corresponding antigen or presence of a dosing antibody	Recipient IgG antibodies bound to donor red cells*
	Red cell antigen typing	To type patient or donor red cells for antigens that can be detected by IgG antisera reactive only by the AGT. A common example of this would be the weak D test	Specific binding of reagent IgG antibodies to red cells positive for the corresponding antigen

AGT, Antihuman globulin test; AIHA, autoimmune hemolytic anemia; HDFN, hemolytic disease of the fetus and newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin.

*If complement is fixed in vitro, it may be detected if polyspecific antiglobulin is used.

polyclonal antiglobulin sera may cross-react with IgA or IgM light chains unless the manufacturer specifies that the anti-IgG component is heavy chain specific.

At present, the most commonly used polyspecific AHG reagents consist of rabbit polyclonal anti-IgG blended with murine monoclonal antibodies to C3b and C3d complement components. Also available is a polyspecific reagent derived exclusively from murine monoclonal antibodies to IgG, C3b, and C3d. The activity of anti-IgG and anti-complement in polyspecific antisera, whether polyclonal or monoclonal, will vary somewhat among different manufacturers and between lots produced by the same manufacturer. However, all AHG sera must contain levels of anti-IgG and anti-C3d activity that meet or exceed the reference standards of the FDA (21CFR660.52; Code of Federal Regulations, 2001b).

Monospecific Reagents

Commercially available FDA-licensed monospecific reagents include anti-IgG, anti-C3b+C3d, and anti-C3d. Monospecific anti-IgG or anticomplement may also be polyclonal or monoclonal in origin. For monoclonal anti-IgG, manufacturers must blend monoclonals against a variety of IgG epitopes or select a clone with specificity for an epitope common to all variants of IgG to ensure that the spectrum of human IgG subclasses will react with their reagent. With polyclonal monospecific anti-IgG, again one should keep in mind that it may contain anti-light chain activity unless the manufacturer labels it as heavy chain specific. Production of murine monoclonal blends of monospecific anticomplement has allowed manufacturers to develop reagents containing quantities of purified anti-C3b and -C3d of known potency that are less likely to give false-positive results by other anticomplement activities found in polyclonal reagents (Harmening, 2005).

Choosing Which AHG Reagent to Use

The DAT is an important diagnostic serologic technique used for the detection of antibody binding to RBC membranes in vivo. Polyspecific AHG reagents containing both anti-IgG and anticomplement activity are typically used for initial DAT evaluation. This is especially important when the DAT is being performed to aid in the diagnosis of CAHA and some forms of drug-induced hemolytic anemia in which complement may be the only evidence of immune-mediated hemolysis. Circulating red cells

that have been involved in complement activation will have mostly C3d on their surface as the result of complement regulatory protein degradation of C3b (see Fig. 35-1). Therefore, polyspecific AHG sera used in DAT testing must contain anti-C3d reactivity and usually contain some anti-C3b reactivity as well. One notable exception to the use of polyspecific AHG for DAT testing is cord blood. Because *only* IgG can cross the placenta, the DAT may be performed with an anti-IgG reagent only (see Prenatal and Postnatal Testing section).

A positive DAT with all reagents tested (polyspecific, IgG, C3) may indicate spontaneous agglutination or autoagglutination. Cells already heavily coated with IgG can agglutinate upon centrifugation in the absence of AHG reagent. IgM cold autoagglutinins that were not dissociated during the washing procedure can also cause autoagglutination. All positive DAT tests should be tested with an inert control such as saline or 6% albumin before positive test reactions are concluded.

The IAT is used for detection of in vitro antibody binding to RBCs, regardless of the antibody's ability to fix complement. It is unclear whether polyspecific AHG, which contains anticomplement reactivity, improves serum antibody detection by the IAT. Rare reports have described antibodies that were detected only by their ability to bind complement in vitro and would have been missed with the use of monospecific anti-IgG reagents (Roback, 2008). In addition, polyspecific AHG can yield stronger reactions in the IAT than monospecific anti-IgG alone (Wright, 1979). A major disadvantage of polyspecific AHG is unwanted detection of complement activation by clinically insignificant cold-reactive autoagglutinins or alloantibodies. As a result, many laboratories choose to use monospecific anti-IgG in antibody detection and identification tests and in crossmatch procedures.

Table 35-35 compares various applications for DAT and IAT techniques. Antiglobulin testing may be performed using test tubes, capillary tubes, microtiter plates, or gel microtube techniques (see later section on Compatibility Testing). These procedures may be semiautomated or fully automated, particularly in facilities that perform large-volume testing, such as blood collection centers. Unless otherwise specified, procedures referred to in this chapter employ tube testing. *The American Association of Blood Banks Technical Manual* (Roback, 2008), *Judd's Methods in Immunohematology* (Judd, 2008), and *Immunohematology Methods* (Mallory, 1993) are excellent general references for most common procedures, as well as more specialized techniques.

TABLE 35-36

Basic Procedures for Direct and Indirect Antiglobulin Testing by Tube Method

Procedure		REASONS FOR INVALID REACTIONS IN ANTIGLOBULIN TESTING	
		False-positive	False-negative
Direct antiglobulin test (DAT)	<ol style="list-style-type: none"> 1. Prepare a 3%–5% suspension in normal saline of the red cells to be tested. 2. Add 1 drop of red cell suspension to a tube and wash three to four times with saline. 3. Blot the tube after the last wash. 4. Add 2 drops of polyspecific AHG (anti-IgG + anticomplement). 5. Centrifuge and examine for agglutination.* 6. Add check cells to all negative tubes (see Quality Control of the Antihuman Globulin Test section). <p>Note: For DAT, blood samples should be collected in EDTA to prevent fixation of complement in vitro by clinically insignificant cold autoagglutinins.</p>	<ul style="list-style-type: none"> • Overcentrifugation • Direct agglutination by strong cold agglutinins • Overincubation with enzyme-treated cells • Improper use of PEG or poly-cation enhancement reagents • Inadequate resuspension of cell button • Rouleaux formation† • Dirty glassware • Small fibrin clots may trap cells and mimic agglutination • Cells with a positive DAT will yield false-positive results in any indirect antiglobulin test 	<ul style="list-style-type: none"> • AHG reagent failure† • Failure to add AHG reagents† • Improper or inadequate washing† • Delayed washing (elution of weakly attached antibody) • Serum/cell ratio too low • Failure to add test serum or enhancement reagents • Undercentrifugation • Resuspension of cell button too vigorous
Indirect antiglobulin test (IAT)	<ol style="list-style-type: none"> 1. Add 2–3 drops of patient serum or the recommended number of drops of commercially prepared antisera to each tube. 2. Place 1 drop of the 3%–5% red cell suspension to be tested in a tube (e.g., donor cells, reagent screening cells). 3. Add recommended number of drops of enhancement media (e.g., LISS, PEG) if indicated. 4. Incubate at 37° C for the time period indicated for the assay being performed (from 15–60 minutes). 5. If indicated in the procedure, centrifuge and examine the serum for hemolysis and the cells for agglutination. 6. Whether step 5 is performed or not, continue by washing the tube(s) three to four times with normal saline. 7. Blot tubes dry after the last wash. 8. Add 2 drops of antiglobulin sera (polyspecific or monospecific anti-IgG) to all tubes. 9. Centrifuge and examine for agglutination.* 10. Add check cells to all negative tubes, 		

AHG, Antihuman globulin; EDTA, ethylenediaminetetraacetic acid; Ig, immunoglobulin; LISS, low-ionic strength saline; PEG, polyethylene glycol.

*Protocol may include optional microscopic examination to confirm macroscopically negative tests.

†Will be detected by the use of Coombs' control cells.

‡Rouleaux will cause false-positive results in indirect tests read after 37° C incubation.

Quality Control of the Antihuman Globulin Test

To standardize antiglobulin sera and to confirm true-negative antiglobulin reactions, two types of quality control RBCs are normally used: those coated with IgG and those coated with C3b and/or C3d. To sensitize RBCs with IgG, Rh antibodies are usually used. RBCs coated with C3b are prepared by incubation of whole blood in low ionic strength saline (LISS) or with human anti-Le^a or anti-I. C3d-coated RBCs are prepared by incubating C3b-coated cells with fresh serum or trypsin to split C3b→C3d. IgG or complement-coated control cells should give a 1+ to 2+ reaction (see Fig. 35-19) when tested with anti-IgG or anti-C3b+C3d.

Quality control cells for the antiglobulin test are referred to as check cells, Coombs' control cells, and sensitized cells. In a true-negative test, free active antiglobulin reagent should remain. Control cells, sensitized with IgG and/or C3, are added to all negative tests and centrifuged. Hemagglutination of check cells confirms both the presence and the reactivity of the AHG reagent, thus validating a negative test result. If the control cells fail to agglutinate in any tube, the tests must be repeated because they are invalid and may have yielded false-negative results. False-negative tests can occur for a variety of reasons and are listed in Table 35-36.

Sensitivity of the Antihuman Globulin Test

Although the antiglobulin test is extremely sensitive, a negative test does not exclude the possible presence of antibodies on RBCs. It is estimated that 200–500 IgG or C3 molecules bound per cell are required for detection by antiglobulin antibodies (Issitt, 1998). A negative reaction can occur with small quantities of bound IgG and C3. In addition, AHG sera may possess greater activity against some subclasses of IgG than against others. Consequently, certain AHG sera may produce negative results with RBCs coated by a particular IgG subclass.

COMPATIBILITY TESTING

The term compatibility testing has historically been used synonymously with the serologic crossmatch test. In its broader context, however, compatibility testing is an entire quality process composed of many procedures designed to provide the safest blood product possible for the recipient of a transfusion. These procedures include proper record keeping, accurate donor and recipient identification, and actual serologic testing of the recipient specimen before transfusion. Outlined in the following sections and in Table 35-37 are the steps in compatibility testing required by the American Association of Blood Banks (AABB) Standards for Blood Banks and Transfusion Services (Price, 2009), referred to henceforth as the AABB Standards.

Specimen Requirements

Recipient Sample Identification

A physician order is required before blood is drawn for a type and screen. The order may be verbal (followed by a written order) or may be given on paper or electronically. Proper identification of patient blood samples and donor units is absolutely essential in blood banking. Recipient blood specimens must be labeled by the phlebotomist at the bedside directly from information on the patient's wristband. If the patient's wristband is not attached for any reason, signed confirmation of the patient's identity by nursing staff should be obtained before the blood is drawn. The recipient's blood specimen label should be legible and should include at least the patient's full name, hospital identification number, and specimen collection date, and it should be securely attached to the specimen tube when it is accepted by blood bank personnel. Unlabeled or improperly labeled blood

Donor testing	<p>Confirm ABO and Rh types on donor red cell units as required</p> <ul style="list-style-type: none"> • Confirmation testing for ABO group required on all units (serum testing not required) • Confirmation of Rh type required only on those units labeled as Rh-negative (weak D testing is not required)
Crossmatch	<p>Select ABO- and Rh-compatible red cell components for transfusion</p> <p>Perform serologic or electronic crossmatch of red cell components</p> <ul style="list-style-type: none"> • Full antiglobulin crossmatch required if current antibody screen is positive or the patient has a known history of clinically significant antibodies
Labeling	<p>Label all red cell products or other components with the recipient's identifying information</p> <ul style="list-style-type: none"> • Label must contain at least two independent patient identifiers, donor unit number, and compatibility test results, if performed

*Requirements paraphrased from Roback (2008). See American Association of Blood Banks (AABB) Standards (Price, 2009) for specific wording.

specimens are unacceptable under any circumstances. During testing, all test tubes or other types of aliquot or reaction containers must be accurately identified directly from the label on the recipient sample.

Each pretransfusion blood sample should be accompanied by an appropriate order or requisition, containing at least the patient's full name and hospital identification number. The signature or initials of the phlebotomist should be on the requisition, as the test requisition is a permanent record of that particular specimen collection. With increasing use of electronic order entry, a computer-based system may record the physician order and capture the person performing the phlebotomy. The phlebotomist, however, should still sign the specimen for verification and matching against the electronic record. Upon specimen receipt, the label on the tube is compared with the information on the requisition for any discrepancies. If there is any doubt as to the proper identity of the sample, another sample must be obtained.

Type of Sample

Although serum has traditionally been the preferred specimen for compatibility testing, plasma is increasingly used owing to newer testing technologies (e.g., gel test). If serum is used, blood samples should be collected in siliconized plain tubes without serum separator gel. Other test methods, such as gel column agglutination, microtiter plates, and automated testing systems, may require a specific type of sample per manufacturer instructions.

Problems with plasma in conventional antiglobulin techniques are primarily technical. Plasma can be associated with small fibrin clots which can trap RBCs and resemble agglutination. Fibrin may also trap serum and cause neutralization of AHG reagent if not removed before washing. Finally, plasma can enhance rouleaux formation if fibrinogen levels are particularly high.

Appearance

Most blood bank laboratories have policies in place to reject grossly hemolyzed recipient blood samples as unacceptable for pretransfusion testing unless there is no other choice. Using serum that is already hemolyzed may mask antibody-induced hemolysis that would ordinarily be detectable in antibody screening tests. Lipemia may rarely cause difficulty in

evaluating agglutination results, although lipemia is not usually a cause for rejection of a pretransfusion sample. Automated instruments may have additional specifications regarding sample appearance. For example, a grossly hemolyzed or lipemic sample can give false-positive readings with an automated gel technology instrument.

Age of Sample

According to AABB Standards, a pretransfusion specimen for testing and red cell transfusion is valid for 72 hours. After 72 hours, a new sample must be drawn. Requiring a new pretransfusion sample every 72 hours on previously transfused or pregnant individuals ensures that the sample being tested is fairly representative of the patient's current immune status.

In elective surgery patients, some facilities will extend the age of a preoperative sample up to 1 month provided that the patient (1) has a negative antibody screen, (2) has no history of clinically significant antibodies, (3) is not pregnant, and (4) has not been transfused within the preceding 3 months. Patients failing to meet these criteria are required to have a sample drawn within 72 hours of planned surgery (King, 2008).

Sample Storage

AABB Standards require that all pretransfusion samples be stored at 1°–6° C for at least 7 days after testing is completed, along with at least one representative segment from each of the donor units crossmatched on the recipient. The purpose of this is to ensure that repeat or additional testing of the donor or patient may be performed later if the patient experiences a delayed hemolytic reaction or other adverse effect of transfusion.

Documentation and Record Keeping

General Considerations

All blood banks must have a manual or computerized system of record keeping that contains the results or outcomes of all tests and activities carried out in the blood bank. Records must be complete and retrievable within a reasonable time frame. Transfer or dissemination of information from any patient records must conform to requirements of the institution's confidentiality policies in accordance with federal and state laws and

TABLE 35-38

Some Causes of ABO Grouping Discrepancies

	Problems with red cell testing	Problems with serum testing
Unexpected positive reactions	Acquired B antigen associated with colon and gastric cancers, intestinal obstructions Cord cells contaminated with Wharton's jelly Autoagglutination caused by cold autoantibodies Cells heavily coated with warm autoantibody Polyagglutination Acriflavine antibody (against dye used in anti-B) Genetic chimerism* Bone marrow transplants* Administration of red cells outside ABO group* B(A) phenomenon Fetomaternal hemorrhage*	Rouleaux-forming proteins present (e.g., plasma expanders, monoclonal gamma globulins) Room temperature alloantibody present (e.g., anti-M, N, P1) Room temperature alloantibody in immunoglobulin (Ig)M phase (e.g., anti-c) Cold autoagglutinin present (e.g., anti-I, IH) Passively acquired ABO antibodies, (e.g., incompatible plasma transfusion) Passenger lymphocyte-derived antibody associated with minor incompatible bone marrow or solid organ transplant Subgroup of A with anti-A1 in serum Cis-AB with weak anti-B in serum
Unexpected negative reactions	A or B subgroups Antigen depression due to leukemia or other disease state High levels of soluble blood group substances Massive transfusion with compatible red cells outside of ABO group Bone marrow transplants	Age of patient (elderly, newborn) Hypogammaglobulinemia Immunosuppression Bone marrow transplants ABO subgroups Long-term parenteral nutrition Snake venom

*Look for mixed-field appearance of reactions with reagent antisera.

regulations. Records must be preserved for different periods of time, depending on federal, state, and accrediting agency requirements.

Documentation of the entire compatibility testing process must include records of patient identification, order entry, individual special transfusion needs, date and time of testing, results of patient testing, identity of the technologist who performed the testing, and blood component issues. A computerized system is ideal for capturing this information and enables rapid and easy retrieval of these data for a given patient, including records of ABO and Rh type, antibody problems, transfusion history, and requirements for special types of blood products. From a more global perspective, computerized retrieval of data for groups of patients also greatly enhances the monitoring of blood product utilization within the facility, including blood ordering and transfusion practices of physicians.

Results and interpretations of all patient testing should be documented on appropriate manual worksheets or entered into the computer immediately upon observation of the results. In a manual record-keeping system, all forms should be filled out with ink, not pencil. If results must be changed on manual worksheets, original results must not be obliterated; a single line should be placed through them, and the new results dated and initialed by the technologist making the change. A continuously updated list of initials used by all personnel working in the blood bank on all shifts must be part of the permanent blood bank records. Changes to computerized results must also be completely documented as part of the computerized result record with ability to track both original and corrected data (Roback, 2008).

Check of Previous Records

Manual or computerized records must be checked for previous results on a given patient when a new sample is received. ABO and Rh tests on the current specimen should be checked against previous results, if available, to help verify that the specimen was collected from the correct individual. Information on any unexpected antibodies identified previously is also extremely important because the titer of an antibody may fall to levels that cannot be detected by antibody screening procedures. If a clinically significant antibody was previously identified, the patient must receive RBCs negative for the corresponding antigen (antigen-negative) even if current antibody screening tests are negative. Previous significant adverse events to transfusions and special requirements should also be reviewed before crossmatching is done.

ABO Grouping

Antisera and reagent RBCs for ABO grouping are standardized and readily available commercially. Most blood bank laboratories use monoclonal reagent antisera derived from antibodies produced by hybridoma cell lines. ABO grouping consists of two parts, commonly referred to as red cell

grouping (forward type) and serum grouping (back type). In forward grouping, a 3%–5% RBC suspension is tested with commercially prepared anti-A and anti-B to test for antigens on the RBC membrane. In reverse grouping, patient or donor serum is tested against reagent cells of known A₁ and B phenotype to test for the expected ABO antibodies in the patient's serum (see Table 35-8). ABO grouping is carried out at room temperature, with only an immediate-spin centrifugation step required to promote a macroscopic agglutination reaction. The manufacturer's directions must be followed for all commercial reagents.

ABO Grouping of Donors

The collecting facility is required to perform a forward and reverse ABO type on all donors. The transfusion service or other laboratory responsible for compatibility testing must confirm the ABO group of all units of RBCs or whole blood received. RBC forward grouping is performed from an integral segment attached to each donor unit. For units labeled as group O, anti-A,B alone may be used for donor confirmatory testing because only group O RBCs will fail to hemagglutinate with anti-A,B.

ABO Grouping of Recipients

Every pretransfusion patient blood specimen must also be tested for ABO group. Both cell and serum groupings are required for initial ABO testing of all patient samples, and the results of RBC and serum testing should agree with each other (see Table 35-8) before any results are reported and blood is transfused.

Some blood banks routinely include the use of anti-A,B in the RBC grouping procedure, although this reagent does not usually yield any additional useful information except for the detection of A_x or B_x subgroups. Anti-A,B is used as a convenient reagent in repeat testing to confirm initial typing of a group O patient. Anti-A,B can also be used for confirmatory typing with neonate and infant samples, especially when the infant has been transfused with Group O RBCs. Infant red cells can give weaker reactions on forward typing owing to the decreased number of ABO antigens on infant red cells (see ABO and I Blood Group sections).

ABO Grouping Discrepancies

Interpretation of ABO blood grouping results is generally straightforward. In the event that the results of RBC and serum grouping do not agree, testing is repeated to rule out any clerical or technical error. If results still disagree, an ABO discrepancy is present owing to problems with the patient's serum or cells that must be resolved before an ABO type can be confirmed. Table 35-38 lists some of the many reasons for ABO discrepancies. Several references are available that provide a complete description of these problems and the protocols for resolution (Harmening, 2005; Roback, 2008).

If a blood transfusion is needed emergently and an ABO discrepancy occurs that cannot be resolved in a timely manner, group O packed RBCs, AB plasma components, or both may be given. However, it is important to be certain that a sufficient pretransfusion blood specimen is obtained from the patient so that the workup may be continued. In some cases, it may be necessary to send a pretransfusion specimen to a reference laboratory for further evaluation.

Rh Typing

Several types of antisera are available for detection of the RhD antigen. Today, the most commonly utilized anti-D typing reagents in tube testing are (1) a saline-reactive, low-protein, monoclonal/polyclonal blend containing murine monoclonal IgM anti-D for immediate direct agglutination of D-positive red cells, and (2) a human polyclonal IgG anti-D necessary for weak D (formerly called D^u) testing. Also available is a reagent blend of monoclonal IgM and monoclonal IgG anti-D from human/murine heterohybridoma lines suitable for both direct and subsequent weak D testing of RBCs.

Before monoclonal blended reagents became available, most routine D typing was performed using rapid tube anti-D made from pooled human sera and containing high molecular weight protein additives that enhanced the direct agglutinating capability of human IgG anti-D. However, because of the high protein concentration in these rapid tube reagents, spontaneous, false-positive aggregation can be observed in patients with abnormal serum proteins, or whose RBCs are heavily sensitized with autoantibody. As a control, manufacturers of high-protein Rh typing sera recommend running a parallel diluent control containing no antibody to detect false-positive reactions. For saline-reactive Rh typing reagents in use today, a concurrent negative reaction with anti-A or anti-B is a sufficient negative control. However, patients who appear to be AB, RhD-positive should be retyped for D with anti-D and an inert control reagent such as 6%–8% bovine albumin.

Direct typing for the D antigen is carried out at room temperature by the immediate spin technique, after mixing one drop of saline-suspended 3%–5% RBCs and one drop of commercial anti-D. If weak D testing is necessary, RBCs are tested by IAT with an IgG anti-D. A parallel test with a negative diluent control is always included for the weak D test.

Rh Typing of Donors

As required by the AABB Standards, all whole blood donor units are tested by the collecting facility for the D antigen by direct agglutination methods. All donor units testing as Rh-negative by direct agglutination are tested for a weak D phenotype by the IAT. If routine D testing or weak D testing is positive, the unit is labeled Rh-positive. The transfusion service must reconfirm the D type of all RBC units labeled Rh-negative by testing red cells from an integral attached segment by a direct anti-D agglutination method. Repeat testing of donor units by the transfusion service for weak D is not required by the AABB Standards.

Rh Typing of Recipients

Every pretransfusion recipient blood specimen must be tested for the D antigen by direct typing. Indirect testing for weak D in recipients is not necessary: Patients who fail to agglutinate after direct agglutination are typed as Rh-negative. Some blood banks do perform weak D testing for prenatal specimens; however, more recent data show that many individuals typing as weak D possess a partial D phenotype and are at risk for RhD alloimmunization. Erythrocyte typing for the C, c, E, and e antigens of the Rh system is not performed routinely but may be done to determine the most probable Rh genotype in the evaluation of antibody problems, in parentage studies, and in patients with long-term transfusion requirements.

ANTIBODY DETECTION

All specimens submitted for pretransfusion testing must be screened for clinically significant antibodies in the recipient serum (antibody screen). Because clinically significant antibodies typically react at body temperature, most laboratories omit room temperature incubation entirely. AABB Standards require that the method used incorporate incubation at physiologic or body temperature (37° C) followed by conversion to the IAT. If a method other than the IAT is used, it must have documented and validated equivalent sensitivity in its ability to detect clinically significant antibodies (Roback, 2008). A variety of different antibody screening protocols, utilizing different technologies, are in use today. Currently, none of the available technologies is capable of detecting all RBC antibodies.

Reagent Red Blood Cells

Reagent RBCs or screening cells used for the detection and identification of antibodies in a patient's serum are usually obtained from commercial manufacturers. AABB Standards require that antibody detection in recipients be performed using reagent cells that are not pooled. Typically, antibody screening cells consist of two to three group O reagent cells selected from different donors of known phenotype. Sets of cells are prepared so that all antigens to the most commonly encountered blood group antibodies are represented and must include C, c, D, E, e, Fy^a, Fy^b, Jk^a, Jk^b, K, k, Le^a, Le^b, P₁, M, N, S, and s antigens. An **antigram** that lists the blood group antigenic makeup of each cell (Fig. 35-21) accompanies each lot of screening RBCs. When possible, cells that are homozygous for selected antigens are used, which increases the likelihood of detecting weak or dose-dependent antibodies. A three-cell screening panel ensures homozygosity for more antigens such as Jk^a, Jk^b, Fy^a, Fy^b, S, and s, against which the corresponding antibodies are likely to exhibit dosage, but the additional cell adds expense to pretransfusion testing. Several studies (Cordle, 1990; Judd, 1997) have shown that use of three red blood samples for antibody detection rarely reveals a clinically significant antibody not detected by a two-cell screening procedure.

Antibody Detection Protocols

Tube Tests

In conventional test tube methods, one volume 3%–5% screening reagent cells and two volumes patient serum (giving an average volume/volume ratio of serum to cells of approximately 50:1) are incubated at 37° C with an enhancement medium for the time specified by the manufacturer, and are centrifuged and examined for hemolysis or agglutination. The screening cells are then washed three to four times with saline, and AHG reagent is added for final detection of IgG alloantibodies.

Because different blood group antibodies commonly show characteristic reaction patterns by IAT technique (see Table 35-7), close examination at different phases of testing in this conventional protocol may yield helpful information in evaluating cases in which the screen is positive:

- Direct agglutination of the cells in albumin or LISS after 37° C incubation frequently indicates the presence of an Rh antibody.
- IgM antibodies possessing a wide thermal range, such as anti-I, anti-P₁, and Lewis antibodies, may show reactions in albumin or LISS. However, these reactions generally become much weaker after conversion to the IAT.
- With rare exceptions, in vitro hemolysis of reagent cells after 37° C indicates the presence of Lewis, Kidd, Ii, P, PP₁^{pk}, or Vel antibodies.
- The vast majority of IgG antibodies, with the exception of Rh, will not be detected until after washing and conversion to the IAT.

Screening Cell Master List

Vial	Donor	Rh								Kell				Duffy		Kidd		Sex linked	Lewis		MNSs				P	Lutheran

- Reactions of different screening cells in multiple phases or with varying strengths usually indicate that more than one antibody is present.

Column Agglutination Technologies

Column agglutination is an alternative method for alloantibody detection used by many transfusion services. This technology utilizes the differential migration of RBC agglutinates through a small microtube containing a dextran acrylamide size exclusion gel column (Lapierre, 1990). The ID-Microtyping System gel agglutination test (ID-MTS, Ortho-Clinical Diagnostics, Raritan, NJ) commercially available in the United States is a 5 × 7-cm plastic card holding six microtubes containing gel matrix infused with anti-IgG. With six microtubes per card, a two-cell screen for three different patients can be performed with one gel card. In addition to antibody detection, anti-IgG gel cards can be used for antibody identification, red cell crossmatching, and DAT testing. Gel cards for ABO/Rh typing are also available.

For testing, precisely measured volumes of screening reagent RBCs (0.8% suspension in LISS) and plasma are incubated at 37° C in the reaction chamber above the column matrix. Following incubation, the plastic cards are centrifuged under carefully controlled conditions. IgG-coated RBCs agglutinate as they come into contact with the AHG reagent in the matrix and are trapped. Reaction strength and size determine the migration of the agglutinates, ranging from the largest (4+) agglutinates at the top to migration of weaker, smaller agglutinates farther into the gel column (Fig. 35-22). Unagglutinated RBCs pass easily through the column and are found as a pellet at the bottom. Because the plasma or serum remains in the reaction chamber above the matrix, repeated washing steps and addition of control cells to check the activity of the AHG reagent are unnecessary. The endpoint hemagglutination reactions are very stable, allowing the cards to be kept for supervisory review of questionable reactions. The cards can be photocopied or digitally photographed and downloaded as permanent laboratory data.

Column agglutination or gel technology has equivalent sensitivity to standard LISS tube testing for antibody detection and is particularly sensitive for detection of anti-Rh antibodies (Weisbach, 2006). Gel testing can offer several advantages over conventional tube procedures. It is more standardized than conventional tube testing with a reliable, stable agglutination endpoint, making it an attractive method for small facilities with cross-trained generalists. It is also less sensitive to clinically insignificant cold antibodies, eliminating unnecessary antibody workups. Additional time savings are achieved through the elimination of repetitive washing steps and manual macroscopic and/or microscopic readings. Finally, testing can be automated (ProVue, Ortho-Clinical Diagnostics, Rochester, NY), permitting high-throughput testing, electronic interpretation and validation, and digital documentation of results.

Solid-Phase Adherence Tests

Another alternative to tube tests for alloantibody detection is indirect solid-phase adherence test systems. In this application, reagent RBCs are bound to the bottom of microplate wells. Serum and an enhancement reagent are added and incubated at 37° C, allowing the alloantibody to bind to the solid phase. After washing to remove unbound serum globulins, indicator RBCs coated with antihuman IgG are added, and the plates are centrifuged. If a reaction has occurred between the reagent cells and the

serum alloantibody, the antiglobulin-coated indicator cells will bind and cover the bottom surface of the well, whereas a discrete button in the bottom of the well indicates a negative reaction (Fig. 35-23). Wells may be read manually or with an automated reading device. As with column agglutination, positive reactions are very stable, so the plate may be covered, stored at 2°–8° C, and read up to 2 days later.

Direct solid-phase test systems are also available for applications such as ABO and Rh typing of red cells. For these tests, microplate wells are coated with the appropriate antibodies. Test cells are added and incubated, and the plates are then centrifuged. For positive reactions, the RBCs adhere to the entire bottom surface of the antibody-coated well; negative reactions result in a tightly packed cell button in the bottom of the well. Instrumentation is available for automated and semiautomated testing using solid-phase technology (Galileo, Immucor, Inc., Norcross, GA).

Antibody Identification

When red cell alloantibodies are detected in the serum of a prospective blood recipient, as indicated by a positive antibody screen, the antibody must be identified so that antigen-negative blood can be provided for transfusion, if required. Antibody identification is accomplished by first testing an extended panel of reagent RBCs of known phenotype against the recipient's serum by the IAT technique. An autocontrol is always included as part of the testing to help differentiate whether autoantibody, alloantibody, or both are present. The immunohematologist then compares the pattern of positive and negative serum reactions against the antigen phenotype pattern on the printed worksheet that accompanies each panel to find a match.

Interpreting the Results of Antibody Identification

Table 35-39 is a simple example of an antibody panel. Serum Y reacts with cells No. 1 through 3, which are positive for the D antigen, but does not react with cells No. 4 through 6, which are negative for the D antigen. The pattern of positive and negative serum reactions matches the phenotype pattern for the D antigen; therefore serum Y appears to contain anti-D. Similarly, the pattern of reactivity for serum Z matches the phenotype pattern for the E antigen; thus serum Z appears to contain anti-E.

Figure 35-22 Appearance of reaction patterns and grading for gel or column agglutination technology.

Figure 35-23 Principle of solid-phase adherence technology with appearance of positive and negative reactions.

Before such identification can be conclusively stated, one must be sure that enough cells of differing antigenic composition are tested to definitively identify a single antibody or combination of antibodies in a given serum.

Fisher's exact method has traditionally been used to statistically calculate the probability that a single antibody has been correctly identified within a confidence interval of 95% (i.e., the probability that the same results would be obtained by random chance because of a different antibody is 1 in 20). This method compares the numbers of positive and negative results against the number of cells tested that express or lack the corresponding antigen and against the total number of cells tested (Race, 1975).

Table 35-40 lists the probability values calculated by Fisher's exact method that are achieved with differing combinations of positive and negative cells in the total number tested. It can be seen that a p value of 0.05 can be achieved with a minimum of six cells, with three cells being positive for an antigen reacting with the antibody, and three cells negative for the antigen failing to react with the antibody. Most manufacturers supply reagent cell panels with 10–11 cells, with at least one of the combinations of positive and negative cells from Table 35-40, for most of the antigens to which unexpected antibodies are commonly encountered. Consequently, most simple antibody identifications are valid at a p value considerably less than 0.05, except in cases where there are antibodies to low- or high-frequency antigens, or where multiple antibodies are present in the same serum. In these situations, additional cells from other panels may have to be tested to achieve identification within the 95% confidence interval.

Figure 35-24 shows the results of a panel tested against patient serum with a conventional tube antiglobulin testing method and examined for agglutination after the 37° C incubation phase, and finally after the

addition of AHG. In a quick overview of the panel results, an immunohematologist will at once notice that there is agglutination with different cells after centrifugation in both phases of the test, indicating the probable presence of multiple antibodies.

Following is an outline of the strategy used in evaluating antibody identification results:

1. The autocontrol is negative, indicating that the serum reactivity is most probably due to alloantibodies. However, if the autocontrol is positive, it is important that DAT testing be performed to confirm or rule out prior *in vivo* sensitization of the patient's cells. The DAT should be examined closely for the appearance of mixed field agglutination. In recently transfused patients, attachment of alloantibody to a minor population of transfused donor RBCs causes classic mixed field agglutination and is frequently the first sign of a developing immune response that may result in a delayed hemolytic transfusion reaction. In a massively transfused patient, only a small percentage of cells may be DAT-positive.
2. The first step that is performed by many immunohematologists in evaluating antibody identification results is to rule out those antibodies where the serum has failed to react with a cell known to carry

Figure 35-24 A typical panel worksheet showing an example of antibody identification results. AHG, Antihuman globulin; CC, Coombs' control cells. *Unless otherwise specified, it is understood that all cells are positive for the high frequency antigens Kp^b and Js^b.

the corresponding antigen. Although not required, whenever possible it is best to rule out antibodies based on lack of reactivity with cells demonstrating the homozygous form of an antigen, so as not to erroneously rule out weakly reactive antibodies that show dosage. Using the homozygous “rule of thumb” for ruling out antibodies, cells No. 3, 5, 6, and 7 are not reactive with the serum and may be used to rule out anti-D, anti-C, anti-c, anti-e, anti-M, anti-N, anti-s, anti-P₁, anti-Lu^b, anti-k, anti-Fy^b, anti-Jk^a, and anti-Jk^b. Expression of the antigens f, V, Le^a, Le^b, and Xg^a cannot be characterized as homozygous owing to the mechanisms of their inheritance, but because at least one of the four cells above is positive for these antigens and the serum did not react with them, the corresponding antibodies may be eliminated from consideration.

3. Because of reactions seen in different phases and demonstrating different agglutination strengths, at least two antibodies are likely present in the serum:
 - Cells No. 4 and 10 show direct agglutination in the 37° C phase, followed by stronger agglutination in the AHG phase, which is very typical of Rh system antibodies. These are the only two cells on the panel positive for the E antigen, which has not been ruled out. Thus, it is likely that anti-E is one of the antibodies involved.
 - Cells No. 2 and 8 show very strong agglutination in the AHG phase only. Upon examining the antigens across the top of the panel that have not been ruled out, one sees that the phenotype of the panel cells for the K antigen fits the serum reactivity of these two cells. Thus, it is likely that anti-K is a second antibody involved.
 - The remaining serum reactions with cells No. 1, 9, and 11 cannot be explained by anti-E or anti-K but may be explained by anti-Fy^a, because all three of these cells are positive for the Fy^a antigen, and Fy^a has not been ruled out.
4. Anti-S should be ruled out by testing another cell positive in the homozygous state for S antigen that at the same time is negative for Fy^a, K, and E antigens.
5. Antibodies to low-frequency antigens such as C^w, Lu^a, Kp^a, and Js^a may be ruled out by testing appropriate cells if available. When antibodies to low-frequency antigens are not ruled out, an antiglobulin crossmatch is used to detect any potential incompatibility between donor cells and the theoretical presence of one or more of these antibodies in the patient's serum.
6. Ruling out of additional antibodies may sometimes be accomplished by typing the patient's cells for selected antigens. This is particularly helpful when a patient's serum contains multiple antibodies and the reagent cell resources available to the blood bank are limited. If one of the antibodies that must be ruled out in a mixture of antibodies is anti-Jk^b, for example, the patient's cells may be typed for the Jk^b antigen with specific antisera. If the patient expresses the Jk^b antigen, then the presence of an alloantibody to Jk^b can be conclusively eliminated.
7. On the panel in [Figure 35-24](#), there are at least three cells negative for all three antigens—Fy^a, K, and E—that do not react with the serum. However, to conclusively identify all three antibodies within the 95% confidence interval, three separate cells must be positive only for Fy^a antigen, three positive only for K antigen, and three positive only for E antigen that do react with the serum. Thus, anti-Fy^a can be identified with confidence; however, two more cells positive for K antigen and one more cell positive for E antigen must be tested with the serum to conclusively identify the presence of anti-K and anti-E.
8. If antibody identification is being performed for the first time on a particular patient, it is common practice to type patient RBCs for the antigens to which he or she has developed antibodies, as a confirmation of the antibody identification. The patient's RBCs should lack the antigens corresponding to the antibodies present.

Crossmatching

For many years, a major serologic crossmatch was required before the transfusion of whole blood or packed RBCs. This protocol required a 37° C incubation followed by conversion to the IAT. In 1984, this requirement was eliminated by the AABB Standards as long as (1) the current antibody screen on the patient is completely negative, and (2) there is no past history of clinically significant antibodies. For patients who meet these criteria, an abbreviated procedure designed to detect ABO incompatibility may be used. This may consist of an immediate spin crossmatch or an electronic crossmatch.

Immediate Spin Serologic Crossmatch

The serologic test to detect ABO incompatibility commonly consists of an immediate spin protocol employing a 3%–5% saline suspension of donor RBCs prepared from an integral segment taken from the selected donor unit. Cells usually are washed once to remove any anticoagulant or plasma protein that could interfere with the testing. A drop of donor cell suspension is mixed with recipient serum, centrifuged immediately, and examined for hemolysis and/or agglutination. This procedure has come to be known as the abbreviated or immediate-spin crossmatch.

Use of the immediate-spin crossmatch procedure in clinical settings has shown it to be a safe and cost-effective alternative to the antiglobulin crossmatch (Judd, 1988; Cordle, 1990; Shulman, 1990), although reports indicate that this technique may fail to detect ABO incompatibility when recipient ABO antibodies are of low titer, or when donor cells belong to a weak ABO subgroup (Berry-Dortch, 1985; Shulman, 1987). Rare false-negative results can occur as the result of a prozone effect in Group O/Group A major incompatibility, particularly if a delay in centrifugation occurs (Judd, 1988). The prozone/delay apparently allows for the fixation of C1 complement on RBC membranes, which sterically hinders hemagglutination. Suspension of donor cells in EDTA-saline eliminates this problem by chelating calcium necessary for formation of the C1 complement complex. In addition to false-negatives, the immediate-spin crossmatch can cause false-positive results due to rouleaux, cold-reactive antibodies, and fibrin—all of which may cause delays in issuing the blood for transfusion. In a recent College of American Pathologists (CAP) challenge, approximately 70% of participating hospitals reported using the immediate-spin crossmatch for patients with no clinically significant antibodies (Downes, 2009). In a multicenter study involving 1.3 million immediate-spin crossmatches, the observed risk of acute hemolytic reaction using the immediate-spin crossmatch technique was 0.0004% (Shulman, 1990).

Electronic Crossmatch

In 1994, Butch et al. first reported on a proposed standard operating procedure that would replace the immediate-spin serologic crossmatch with a computer **electronic crossmatch**, or EXM. Similar to the immediate-spin crossmatch, the electronic crossmatch may be used only for patients who have no currently detected clinically significant antibodies or any history of alloantibodies. The EXM reduces human error by assigning final verification of ABO compatibility between donor and recipient by the laboratory computer system (Judd, 1991). In addition, it eliminates time-consuming investigation of false-positive serologic reactions. In a recent CAP survey, nearly 20% of 3216 responding hospitals currently performed or were in the process of implementing the EXM (Downes, 2009).

The EXM is permissible provided that specific testing criteria are met and extensive validation of the blood bank information system has been performed to meet current AABB Standards and FDA requirements as outlined in a 1997 FDA internal document (Judd, 2002). Critical elements required in computer validation for the EXM (Judd, 1998) include updated hardware, instrumentation interfaces, historical records checks, reaction interpretation algorithms, prevention functions and warnings for ABO assignment/release, and personnel competency assessment. Because the safety of this procedure will be only as good as the electronic information that is entered and stored in the system, maximal use of bar codes to identify both donors and patients should be implemented. After extensive experience with electronic crossmatching at the University of Michigan, Judd (1998) recommends that bar-coded patient identification be mandatory, both at the time of sample collection and prior to transfusion, and that pretransfusion specimen labels be generated at the bedside from the bar code on the patient identification wristband. The FDA requirement that facilities wishing to implement the EXM must submit a request for variance to the Code of Federal Regulations for Compatibility Testing (21CFR606.151; 2001a) has been eliminated. Table 35-41 summarizes the AABB Standards requirements.

Antiglobulin Crossmatch

If the pretransfusion antibody screen detects a clinically significant antibody, or a check of patient records indicates that such antibodies have been detected previously, a major or long crossmatch must be performed. In the antiglobulin crossmatch, compatibility between recipient serum and donor red cells is tested by the antiglobulin method that is routinely used by the laboratory. Red cell units chosen for transfusion should lack the antigen of interest (antigen-negative) by phenotyping units with commercially available antisera. In the future, units may be chosen on the basis of donor genotyping by the blood center.

TABLE 35-41

Requirements for Implementation of the Electronic Crossmatch*

- Computer system has been validated onsite to ensure that only ABO-compatible red cell components are selected for transfusion.
- There have been at least two determinations of the recipient's ABO group, one of which is from the current sample.
- The donor unit blood type has been confirmed serologically from an integrally attached segment.
- The system contains the following data items:
 - Donation identification number
 - Component name
 - ABO/Rh type of component
 - Confirmed unit ABO group
 - Two unique identifiers for recipient
 - Recipient's ABO group/Rh type
 - Recipient's current antibody screen results†
 - Interpretation of compatibility
- A method exists to verify the correct entry of data prior to the release of components.
- The software contains logic to warn user of discrepancies between donor unit labeling and confirmatory test results, or of ABO incompatibilities between the recipient and the donor unit.

*Requirements paraphrased from Roback (2008). See Price (2009) for specific wording.

†The electronic crossmatch can be used only if current antibody detection tests on the recipient are negative and there is no known history of clinically significant blood group antibodies.

Some blood bank laboratories still choose to perform a full antiglobulin crossmatch for all transfusions, regardless of history and pretransfusion testing results. For patients with a negative antibody screen, the full crossmatch may *rarely* detect alloantibodies to low-frequency antigens not present on the screening cells (e.g., Kp^a, Wt^a). In addition, antibody detection tests could theoretically fail because of the presence of an antibody displaying dosage, deterioration of antigen from the reagent cells during storage, or technical error. Despite these concerns, the actual incidence of missing a clinically significant antibody with an abbreviated crossmatch is very low—less than 0.05% (Mintz, 1982; Cordle, 1990).

Compatibility Testing in Emergencies

In urgent situations, blood may have to be released for transfusion before the completion of compatibility tests, or even before a patient blood specimen is available. If the ABO and Rh types of the patient are not known, group O packed RBCs are released. Practice varies when selecting the Rh of emergency blood components. Some facilities use Rh-negative only for females <50 years of age, whereas others may start with Rh-negative and switch to Rh-positive after 4 (or more) units. If a blood specimen is available and there is time to perform ABO and Rh typing, type-specific blood may be released. All units must be conspicuously labeled to indicate that they are uncrossmatched, and that the patient's serum has not been screened for unexpected antibodies. In these situations, the patient's physician must sign a release form stating that the clinical situation warrants the release of uncrossmatched blood. In such cases, the antibody screen is promptly completed, and crossmatches are performed according to the laboratory's protocol. In the event of a positive screen or incompatible crossmatch, the physician should be notified immediately of any antibodies or incompatibility detected.

Massive transfusion occurs when the number of emergently transfused RBCs equals or exceeds the patient's blood volume in a relatively short time frame (<24 hours). Under these circumstances, many blood banks initiate a massive transfusion policy that permits switching to an immediate-spin or electronic crossmatch, even in a patient with known RBC alloantibodies. In these instances, serum antibody is typically diluted and undetectable *in vitro* owing to the large volume of donor blood and fluids transfused. Most protocols for massive transfusion return to use of the routine crossmatch procedure within 24 hours of the time the patient is stabilized. Transfusion of antigen-positive units could result in an increase in antibody titer and lead to a delayed hemolytic transfusion reaction in patients with alloantibodies. Communication with the patient's physician is critical in such cases to monitor the patient for hemolysis.

Preoperative Crossmatch Protocols

Most transfusion services have adopted a type and screen-only protocol for elective surgical procedures that do not routinely require transfusion. Blood orders for elective surgical procedures requiring transfusion are set at a level that reflects actual usage patterns for a given operative procedure at a particular institution. The type and screen-only protocol, when used in conjunction with preoperative blood ordering guidelines (maximum surgical blood order schedule; Friedman, 1976; Henry, 1977), allows for much more efficient blood inventory management and reduction in the crossmatch/transfusion (C/T) ratio. For blood ordering guidelines to be successful, they should come under periodic review and revision as new surgical procedures are adopted and techniques are refined.

The preoperative type and screen protocol requires no further serologic work as long as the patient's antibody screen is negative and there is no known history of clinically significant antibodies. If a patient unexpectedly requires transfusion during surgery, ABO- and Rh-compatible units are selected, and an immediate-spin crossmatch or EXM may be performed. If no ABO incompatibility is detected, the blood can be safely released to the operating room with a minimal turnaround time. If the preoperative antibody screen is positive, or if previous records indicate a known clinically significant antibody, standard operating procedures should specify a minimum number of antigen-negative units that would be held by the blood bank for use by the patient during surgery. These units must be crossmatched with the patient's serum using a full antiglobulin crossmatch procedure prior to transfusion.

Prenatal, Postnatal, and Infant Testing

All women should be screened as soon as possible for red cell alloantibodies and the potential for HDFN. The initial test is generally a blood type and antibody screen. If clinically significant antibodies are detected, the pregnancy is monitored with titration studies and other clinical diagnostic tests at specific intervals. Note that RhD-negative women who have received Rh immune globulin prophylaxis can have a weak anti-D on testing. In addition, Rh immune globulin can cross the placenta and cause a positive antibody screen in fetal and cord samples.

At birth, all cord samples are typed for ABO, RhD, and DAT, if indicated: A type and screen is not routinely performed because cord samples are frequently contaminated with maternal blood. Because only IgG antibodies cross the placenta, the DAT can be tested with anti-IgG only. A comparison should be made between mother and infant blood type to evaluate the potential for ABO HDFN. If the mother has clinically significant antibodies, the cord should have a DAT and be phenotyped for the corresponding antigens of interest. An antibody identification should be performed using maternal or cord sample, although maternal blood is often used owing to insufficient serum/plasma in cord samples. If the cord DAT is positive, and the mother does not have clinically significant antibodies, the laboratory should decide whether an eluate procedure should be routinely performed. The cord sample may be used for antibody identification and for eluates if needed.

In RhD-negative women, special precautions and testing are taken both prepartum and postpartum in an effort to prevent RhD alloimmunization (see Rh System). Prepartum, the father may be typed for RhD to determine the risk for HDFN. Alternatively, the fetus may be genotyped to determine RhD status (Finning, 2007). Unless the fetus or the father is confirmed as RhD-negative, the mother must receive prophylactic Rh immune globulin at 28 weeks and after invasive procedures. Once delivery has occurred, a fetal RhD type is performed on cord blood to determine the need for additional Rh immune prophylaxis. If the infant is RhD-negative or if the mother has become sensitized, Rh immune globulin is not given. However, if the infant is RhD-positive and the mother is not sensitized, the mother should receive additional Rh immune globulin. To determine how much Rh immune globulin should be administered postpartum, the mother should be screened for a possible maternal fetal bleed.

The most common screening test for a possible fetal bleed in an RhD-negative mother is the rosette test, which can detect approximately 10 mL of fetal cells in the mother's circulation (Bayliss, 1991). To perform the test, maternal blood is incubated with anti-D, which will bind circulating RhD-positive fetal red cells but not maternal RhD-negative red cells. After incubation and washing, indicator red cells are added and the sample is centrifuged and then examined under a microscope. If fetal red cells are present, indicator red cells will bind to anti-D on fetal red cells, forming a rosette. If no fetal red cells are present, the mixture will be smooth without rosettes.

If the fetal bleed screen is positive, additional studies are necessary to quantitate the extent of the bleed. The Kleihauer-Betke test and flow

TABLE 35-42

Special Techniques in Antibody Identification: Serum Procedures*

	Procedure	Application/effect
Hemagglutination inhibition	Inhibit antibody reactivity by mixing serum with a specific soluble antigen source in parallel with a dilution control; retest against known antigen-positive cells	Confirm specificity by neutralizing the following antibodies: anti-P1, anti-Le ^a and Le ^b , anti-Sd ^a , anti-ABH, anti-I, anti-Ch/Rg. May also allow for easier identification of other antibodies in a mixture
Serum adsorption	Adsorb serum antibodies with autologous cells, selected allogeneic cells, or rabbit erythrocyte stroma (REST) at appropriate temperature for reactivity of antibody	Physically removes broadly reactive autoantibodies or alloantibodies from serum by reacting with absorbing cells to allow for detection of underlying IgG antibodies—particularly useful in cases of WAIHA. May be combined with elution in complicated cases involving identification of multiple antibodies
Sulfhydryl reagents	Pretreat serum with sulfhydryl reagents such as 2-mercaptoethanol (2-ME) or dithiothreitol (DTT)	Destroys pentameric structure of agglutinating IgM antibodies, effectively bypassing cold reactive autoantibodies and alloantibodies to allow for detection of underlying IgG alloantibodies
Titration	Prepare serial twofold dilutions of serum and test against antigen-positive indicator cell	Aids in identification of HTLA antibodies (titer of 1:64 or greater) Used to measure increase in production of IgG antibodies during pregnancy ABO-incompatible organ transplantation May rarely be useful in identifying alloantibodies of a higher titer present with a warm autoantibody
Prewarming	Keep all test components (test tubes, cells, serum, saline) at 37° C prior to testing; use monospecific anti-IgG AHG reagents	Bypasses reactivity of cold autoagglutinins or alloagglutinins of limited titer and thermal amplitude—prevents direct agglutination of test cells and/or in vitro complement activation in antibody detection and identification tests
Saline replacement	For tests in which patient or test red cells are suspended in serum and are suspected to have formed rouleaux, the serum is removed and replaced with equal volume of saline	Useful in obtaining valid results in ABO serum grouping or evaluating the presence of apparent agglutination when examining screening cells after 37° C incubation and centrifugation. Pseudoagglutination due to rouleaux will be dispersed by removal of the offending proteins and addition of a high-ionic strength medium.

AHG, Antihuman globulin; HTLA, high-titer, low-avidity; Ig, immunoglobulin; WAIHA, warm autoimmune hemolytic anemia.

*See also Table 35-33 for effects of antibody concentration, pH, incubation time, etc.

cytometry are two methods used to calculate the quantity of fetal red cells in maternal circulation. The Kleihauer-Betke test is based on the resistance of fetal Hg to acid, which looks bright pink in a sea of adult red cell ghosts on a peripheral blood smear. The percentage of fetal red cells present is manually determined and then multiplied by 50 to determine the volume (mL) of fetal blood present (Roback, 2008). Flow cytometric methods are less labor intensive and are used to calculate the percentage of RhD-positive fetal cells by immunofluorescence (Radel, 2008). Once the size of the bleed is determined, the mother should receive sufficient Rh immune globulin to neutralize all circulating fetal red cells. Calculations to determine the size of the fetal bleed and the number of Rh vials required are available in the *AABB Technical Manual* (Roback, 2008). In general, one vial of Rh immune globulin will suppress immunization of 15 mL of RhD-positive red cells.

SPECIAL ANTIBODY IDENTIFICATION TECHNIQUES

Patients who have undergone repeated transfusions may respond by forming multiple unexpected blood group antibodies. Autoantibodies and alloantibodies to high-frequency antigens will react with all cells tested, including all RBCs used for antibody identification, making it extremely difficult to detect other underlying alloantibodies. When complicated problems such as these are encountered, special techniques are required to resolve the problem and find compatible units for transfusion. Special techniques used in antibody identification frequently involve (1) an attempt to eliminate selected antibody reactivity that is interfering with identification of other specificities in the same serum, or (2) an effort to enhance or more clearly characterize the reactivity of an antibody that thus far has escaped definitive identification. Some of these techniques are outlined later in this chapter, as well as in Tables 35-42 and 35-43. The reader is also referred to the American Association of Blood Banks *Technical Manual* (Roback, 2008), *Applied Blood Group Serology* (Issitt, 1998), *Judd's Methods in Immunohematology* (Judd, 2008), and *Immunohematology Methods* (Mallory, 1993) as excellent references for most common procedures, in addition to more specialized techniques.

Serum Procedures to Eliminate Antibody Reactivity

Hemagglutination Inhibition

Hemagglutination inhibition is used to neutralize selected blood group antibodies with their corresponding antigen found in soluble form in human saliva, serum, or other body fluids, as well as in substances in nature (Table 35-44). Recently, reagents for antibody neutralization have been synthesized using modern molecular techniques (Seltsam, 2009). The identity of a suspected antibody is confirmed if it no longer agglutinates antigen-positive reagent cells after addition of soluble antigen. Hemagglutination inhibition may be particularly useful when working with a serum specimen containing multiple specificities. The principle of hemagglutination inhibition is also used to determine the secretor status of individuals with weak ABO subgroups (see Table 35-10). Care must be taken in interpreting results because weak reactions may be diluted by the inhibition substance. A control set of tubes containing an inert substance (typically saline) should be used in parallel to verify that a negative reaction was the result of inhibition and not of sample dilution.

Antibody Adsorption

Adsorption is a process used to physically remove antibodies from sera. The adsorption procedure may be performed using washed and/or enzyme-treated autologous RBCs, phenotypically matched allogeneic cells, cells selected to be positive for a specific combination of blood group antigens, or RBC stroma. The incubation temperature and times used in the adsorption process depend on the Ig class and the thermal range of the antibodies being adsorbed. In general, using a low antibody/cell ratio will increase adsorption efficiency.

Adsorption using allogeneic cells is helpful in separating multiple alloantibodies in a complex mixture (differential adsorption) or in eliminating the reactivity of an alloantibody to a high-frequency antigen. In patients with autoantibodies, adsorption with autologous RBCs, phenotypically matched cells, and rabbit erythrocyte stroma (REST) is often used to selectively remove warm and cold-reactive autoantibodies, respectively. Removal of autoantibodies is necessary to identify any potential underlying alloantibodies that the patient may have (see later in Investigation of Autoimmune Hemolytic Anemia section; Fig. 35-25).

TABLE 35-43

Special Antibody Identification Techniques: Red Cell Procedures

	Procedure	Application/effect
Enzyme treatment	Two-stage procedure (preferred): <ul style="list-style-type: none"> • Incubate test red cells with enzyme solution at 37° C. • Wash cells thoroughly to remove enzyme completely and retest cells with serum being investigated 	<ul style="list-style-type: none"> • Eliminates some antibody reactivity by destroying corresponding antigen structures—MNS, Duffy, Ch/Rg; may be easier to pick out different specificities in a serum containing multiple antibodies • Enhances sensitization, agglutination, and/or hemolysis by other antibodies—Rh, Kidd, many IgM blood group antibodies; may allow for easier identification of weakly reactive antibodies
AET/DTT	Pretreat test red cells with AET or DTT; wash away reagent and retest cells with serum being investigated	Effectively creates Kell “null” cells for use in identifying alloantibodies in a mixture containing antibody to a high-frequency antigen in the Kell system
Elution	Remove and recover antibody from red cells by techniques such as glycine acid, organic solvents	Concentrates antibody that was coating red cells into a solution suitable for further identification procedures. Used in investigating positive DAT in cases of HDFN, HTR, autoimmune hemolytic anemia
Chloroquine diphosphate	<ul style="list-style-type: none"> • Washed packed red cells are incubated in a 1:4 ratio with chloroquine at room temperature. • Reagent is removed by multiple saline washes 	Dissociates IgG from patient red cells with a positive DAT so that they may be typed with blood grouping reagents that require an indirect antiglobulin technique. Only anti-IgG should be used as the AHG reagent, as complement proteins are not dissociated with chloroquine
ZZAP	For adsorption purposes, aliquots of washed, packed red cells are incubated with ZZAP at 37° C. Cells are then washed with large volumes of saline to remove ZZAP. The combination of DTT and enzymes destroys coating of IgG autoantibodies	<ul style="list-style-type: none"> • Removal of autoantibodies from patient cells provides free antigen sites for adsorption of autoantibody from the serum • ZZAP also can be used to destroy Kell, Cartwright, Gerbich, and Dombrock system antigens
Dispersal of IgM-mediated autoagglutination	Incubate cell suspension with sulfhydryl reagents or wash cells multiple times with 37° C saline	Dissociation of cold autoagglutination permits valid ABO red cell typing and may aid in evaluating DAT results
Lectin typing	Reagents commonly derived from plant seeds are used to test for the presence or absence of a specific blood group antigen on the red cell membrane—used in place of an antibody reagent	Useful in typing for specific antigens such as A ₁ , H, and N and in classifying different polyagglutinable red cell conditions
Cell separation techniques	<ul style="list-style-type: none"> • Washed cells from the patient are centrifuged in microhematocrit tubes, and the top 5 mm containing the lightest cells is harvested • Differential agglutination may be performed based on known differences in antigen phenotype between donor and recipient 	Useful in the following: <ul style="list-style-type: none"> • Phenotyping of autologous cells in recently transfused individuals • Evaluating whether a DHTR may be evolving in a patient with autoimmune hemolytic anemia • Estimating survival of transfused cells

AET, 2-Aminoethylisothiuronium bromide; AHG, antihuman globulin; DAT, direct antiglobulin test; DHTR, delayed hemolytic transfusion reaction; DTT, dithiothreitol; HDFN, hemolytic disease of the fetus and newborn; HTR, hemolytic transfusion reaction; Ig, immunoglobulin; ZZAP, combination of DTT and cysteine-activated papain.

Principle of Autoadsorption Procedure

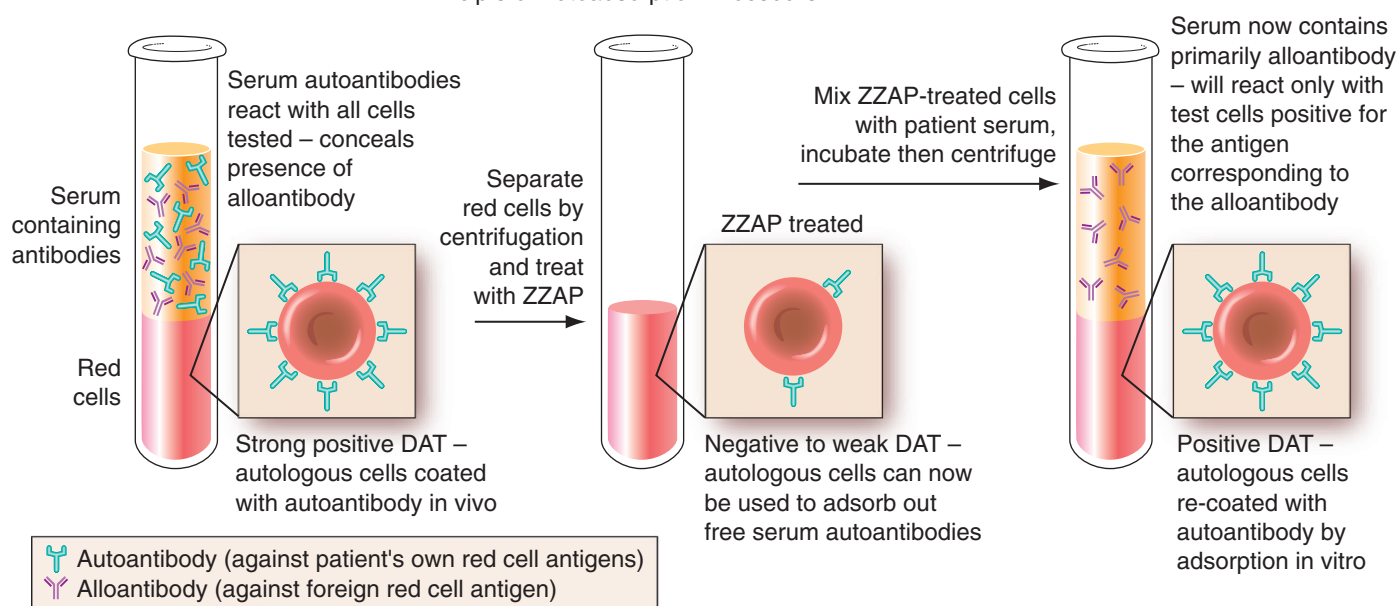

Figure 35-25 Autoadsorption procedure used to evaluate whether underlying alloantibodies are present in a patient with autoimmune hemolytic anemia.

TABLE 35-44

Sources of Soluble Antigens for Hemagglutination Inhibition

Soluble substance	Source
ABH	Secretor saliva
Le ^a , Le ^b	Secretor saliva
P1	Hydatid cyst fluid or pigeon eggs
Sd ^a	Human or guinea pig urine
Ch, Rg	Plasma from Ch/Rg (+) individuals
I	Human milk

It is crucial to verify transfusion information before performing an adsorption because recently transfused individuals will have multiple red cell populations. In these patients, circulating donor cells could adsorb an alloantibody of interest. If the patient's phenotype is available, testing can be performed with allogeneic phenotype-matched red cells. If the phenotype is not known, three separate adsorptions with R₁R₁, R₂R₂, and rr cells can be performed and tested, and the results compared.

Thiol Reagents

Sulfhydryl compounds such as 2-ME or DTT cleave disulfide bonds and are frequently used to inactivate the agglutinating capacity of IgM antibodies by cleaving intersubunit disulfide bonds, as well as bonds linking IgM subunits to the J-chain (Klein, 2006), thus destroying the pentameric structure of the IgM molecule. These reagents are useful in investigating the presence of clinically significant IgG alloantibodies in a serum that contains broadly agglutinating IgM cold autoantibodies. They can also be used to dissociate autoagglutination caused by cold antibodies that may interfere with ABO/Rh typing and DAT testing. In prenatal studies, sulfhydryl reagents are frequently utilized to evaluate a serum containing an antibody such as anti-M that commonly has both IgM and IgG components. By destroying the agglutinating anti-M, the serum can be tested for IgG anti-M that is capable of crossing the placenta to cause a mild HDFN.

Serum Antibody Titration

Serum titration is a method used to semiquantitatively determine the amount of antibody present in a given serum/plasma. Serial twofold dilutions of serum are prepared and then tested with RBCs possessing the corresponding antigen. Each dilution is read for macroscopic agglutination, and the titer of the antibody is expressed as the reciprocal of the highest serum dilution that gives macroscopic agglutination. Titers are performed in obstetric patients, ABO-incompatible solid organ and bone marrow transplantation, and, occasionally, antibody identification studies.

In prenatal studies, clinically significant IgG alloantibodies capable of causing HDFN are titrated periodically in the maternal serum during pregnancy (Judd, 2005). An increasing titer usually indicates that fetal cells possess the corresponding antigen and are stimulating the mother to produce more antibody, thus providing valuable information to the physician regarding how the pregnancy should be managed. Because of the clinical importance of consistency in prenatal titer reporting, some laboratories require that the initial titer be performed by two technologists for agreement. If a discrepancy exists, a third technologist should perform the titration. The initial sample should be frozen for future studies. When the next titer request is submitted, the initial sample should be tested in parallel with the new sample.

Titers are also performed in the rare setting of major ABO-incompatible solid organ transplantation, which has risen in popularity with improvements in immunosuppressive therapy. ABO-incompatible heart transplants can be performed in children younger than 6–8 months owing to low-titer ABO antibodies in early infancy (West, 2001). ABO incompatible living donor kidney transplants, once unthinkable because of the risk of hyperacute rejection, have also been performed in adult patients. To prevent hyperacute rejection, intended recipients undergo an aggressive course of immunosuppression and therapeutic apheresis before and after transplant to reduce ABO titers below a critical threshold (Tobian, 2009). Similar to obstetric patients, these patients require a series of ABO titers to monitor treatment efficacy and screen against humoral rejection. Finally, ABO titers may be necessary in ABO-incompatible allogeneic bone marrow transplants. In contrast to peripheral blood stem cells, bone marrow contains significant quantities of red cells and can place the recipient at risk for a severe acute hemolytic transfusion reaction. ABO titers are performed

before transplant to assess the risk of hemolysis and the need for pretransplant therapeutic apheresis (Cooling, 2007).

Antibody titration can also be used in the presumptive identification of HTLA antibodies. Most antibodies (excluding HTLA) that initially give weak (+/- or +/-^m) reactions in IAT tests will seldom react at dilutions greater than 1:2. In contrast, HTLA antibodies characteristically give the same weak reactions at multiple serum dilutions, often reacting at dilutions equal to or greater than 1:64. If such an antibody is suspected, a titration is performed to demonstrate that the weakly reactive antibody is still reactive at a high dilution, thus allowing its classification as an HTLA. These antibodies are often directed against Ch/Rg, JMH, and Knops antigens.

It is important to note that both serologic technique and cell selection can affect titer results. For example, if the initial titer was tested against a cell with homozygous antigen expression, all subsequent titers should also be tested with a homozygous cell. Likewise, some laboratories use a tube technique without additives (saline), and others may use a LISS, tube, or gel method—all of which can yield significantly different end titers in parallel testing. Each laboratory should have a policy regarding appropriate cell selection and should perform titers using a technique approved by the laboratory director with proper validation. Titer results and their meaning should be communicated clearly to the physician. Any change in procedure or method *must* be communicated because this can affect titer results and have a direct impact on patient care.

Special Red Cell Procedures for Antibody Identification

Reagent or patient RBCs can be modified in various ways by the immunohematologist to abolish or enhance the reactivity of corresponding antibodies. Patient cells are also subjected to procedures designed to remove antibody that has bound *in vivo*, so that the antibody may be recovered and identified (eluate) and/or may provide RBCs for further testing.

Destruction of Red Cell Antigens

Available reagents for treating RBCs for the purpose of destroying certain blood group antigens include various proteolytic enzymes (e.g., papain, ficin), neuraminidase (removes sialic acid), ZZAP, AET, and DTT. In a serum containing multiple alloantibodies, selective pretreatment of RBCs with enzymes can destroy specific antigens, eliminating specific alloantibody reactivity. Enzymes are also thought to remove the water of hydration and decrease the ζ potential, allowing RBCs to more closely approach each other. As a result, they can enhance the reactivity of a weak, potentially significant antibody and facilitate its identification. Table 35-45 lists antibodies whose reactivity will be enhanced or eliminated by enzyme treatment of test RBCs. Note: AET and DTT can be used to create RBCs negative for all antigens of the Kell blood group system (except Kx); these reagents may also destroy certain antigens reacting with HTLA antibodies.

Antibody Elution

Elution is the process used to remove antibodies bound to RBCs, as indicated by a positive DAT. Elution is commonly used to concentrate and solubilize antibodies from RBCs for subsequent identification studies. The elution of an antibody with known blood group and/or drug specificity can be diagnostic in the evaluation of acute and delayed hemolytic transfusion reactions, HDFN, autoimmune hemolytic anemia, and immune hemolytic anemia induced by medication.

Elution may be accomplished by a variety of methods that alter or reverse the forces of attraction that hold the antigen and antibody together. Various methods involve adding heat, disrupting antigen structure by exposing the RBC membrane to freezing and thawing, using organic solvents, and altering the pH to dissociate RBC-antibody complexes. Freeze-thaw and heat elution techniques work well for removal of cold-reactive antibodies, whereas organic solvents and pH alteration are used to remove warm reactive IgG antibodies. Because organic solvents are carcinogenic, many laboratories have a commercially available acid elution kit.

All methods require numerous washes before elution to remove any serum containing unbound antibody. To ensure the complete removal of serum antibody, the saline from the last wash must be tested against appropriate cells to detect any residual unbound antibody. The last wash control should show an absence of antibody reactivity before the elution procedure is performed. Optimally, eluates should be tested on the same day they are prepared but may be stored at -20° C or lower if there is a delay in testing. Table 35-46 lists some of the common elution methods and their applications. For a more comprehensive listing and specific descriptions of elution procedures, see Mallory (1993) and Judd (2008).

Removal of Antibody From Red Cells to Facilitate Antigen Typing

Many antisera used for RBC antigen typing require the IAT technique. As a result, RBC samples with a positive DAT cannot be used for antigen typing because these cells are already coated with IgG antibody and will yield a false-positive result. Most elution methods that remove blood group antibodies from the surface of erythrocytes destroy the cells or the antigens. However, treatment of antibody-coated RBCs with chloroquine diphosphate dissociates antibody while leaving the antigens relatively intact (Edwards, 1982). Glycine/EDTA can also be used under carefully controlled conditions to dissociate IgG from RBCs, but overtreatment with this reagent can cause irreversible damage to the RBC membrane. After chloroquine or glycine treatment, RBCs can be antigen typed with AHG-reactive antisera. Note that glycine/EDTA-treatment destroys Kell protein. As a result, glycine/EDTA cells cannot be phenotyped for Kell system antigens.

Care should be exercised when interpreting antigen typing results with chloroquine-treated cells. Reports indicate that Rh antigens, and possibly other blood group antigens, can be weakened, resulting in false-negative reactions. Saline-reactive antisera, including monoclonal grouping

reagents, should not be used with chloroquine-treated cells (Gamma Biologicals Inc., 2001). For chloroquine or glycine/EDTA, it is prudent to treat known antigen-positive cells in parallel as a control. Only monospecific anti-IgG should be used in the IAT because complement components are not dissociated by chloroquine from DAT-positive RBCs.

Red Blood Cell Typing With Lectin Reagents

Lectin typing reagents contain proteins that will recognize specific carbohydrates on the RBC membrane, causing direct hemagglutination. Lectin reagents are usually derived from plant seeds, but these receptor proteins are also found in some invertebrate animals and lower vertebrates. Because the potency of lectin reagents may vary with the preparation, each lot should be standardized before use. Although many lectins have been described, only a few have been found useful in blood banking (Bird, 1988). Sources for selected lectin reagents and their applications are listed in Table 35-47. Procedures for preparation of purified lectins may be found in *Judd's Methods in Hematology* (2008).

Separation of Autologous From Transfused Red Cells

In transfused patients, it may be necessary to separate autologous from transfused cells. Autologous RBCs for antigen typing may be necessary (1) in a transfused patient with multiple alloantibodies, (2) with a warm auto-antibody and possible alloantibodies, or (3) with an antibody to a high-incidence antigen. Performing a DAT, and possibly even elution, on separated autologous and/or transfused cells can help determine whether a recently transfused individual with a warm autoimmune hemolytic anemia (WAIHA) is developing a delayed hemolytic transfusion reaction (DHTR) due to new alloantibodies. In rare cases, DAT testing on separated autologous RBCs may be required to differentiate a WAIHA from a DHTR involving a high-incidence antigen. In a final application, one could roughly estimate the proportion of surviving, transfused RBCs when a DHTR is suspected.

Two basic techniques for separating autologous from transfused RBCs are differential agglutination and density separation using centrifugation. In the first technique, antibodies are used to agglutinate only one population of cells, based on known antigenic differences between recipient and donor. Unagglutinated cells are physically removed from the agglutinates and are sequentially reacted with more antisera until no more agglutinates are formed. In the second technique, washed packed RBCs are centrifuged in multiple sealed microhematocrit tubes. Transfused cells are older, smaller, and denser than newly formed autologous cells (reticulocytes) and will spin toward the bottom of the tube. After centrifugation, the top 5 mm of each tube is cut away, and the cells are harvested from these small segments. These sections will contain the larger and lighter autologous cells. This method will be effective only if the patient is producing normal or high numbers of reticulocytes. When testing separated red cells, nonseparated cells should be tested in parallel as a control. The separated red cells should show clear positives and negatives, and the nonseparated cells should show mixed field agglutination.

*Formerly known as *Bandeiraea simplicifolia* I and II.

Hypotonic cell lysis is a third method that is available for harvesting autologous red cells in patients with sickle cell disease. The method is based on the resistance of Hg S red cells to hypotonic saline. The patient sample is repeatedly washed with 0.3% hypotonic saline to lyse normal donor red cells until gross hemolysis is no longer present. The cells are then washed and resuspended in 0.9% saline for antigen typing. Because sickle cell patients are regularly transfused, this technique is useful for facilities that provide antigen-matched red cells for their sickle cell patients.

Molecular Typing

Because most common blood group antigens are the consequence of SNPs, several commercial and home-brew assays have been developed to genotype donors and patients. The ability to genotype individuals for blood group antigens is extremely useful for multitransfused patients in whom standard serologic typing cannot be performed as a result of circulating donor red cells. Several transfusion services routinely genotype all hemoglobinopathy patients (e.g., sickle cell anemia, β -thalassemia) who have long-term transfusion needs and require antigen-negative units. Genotyping is also useful in patients with multiple alloantibodies or autoantibodies, in whom it can be difficult to exclude an antibody to a high-incidence antigen because of the lack of commercial reagents (e.g., Dombrock). Likewise, serologic phenotyping often cannot be performed in patients with a positive DAT because many reagents require the addition of anti-IgG for typing. Genotyping is commonly used in prenatal testing to identify a fetus at risk for HDFN. Fetal genotyping can often be performed with a maternal blood sample, offering a significant safety advantage over serologic testing, which requires fetal blood sampling (Finning, 2007). Finally, large-scale genotyping of donors has the potential to increase the availability of antigen-negative units for patients with clinically significant alloantibodies (Montpetit, 2006).

Several methods have been developed for red cell and platelet genotyping, including restriction fragment length polymorphism, allele-specific PCR, real-time PCR, direct sequencing, and microarray technology (see Chapters 65, 66, and 67). High-throughput screening methods, such as microarray, are amenable to semiautomated processes and permit extended typing for high- and low-incidence antigens. It is important to stress that genotype does not always reflect red cell phenotype because most genotyping methods focus on known common polymorphisms. Unknown polymorphisms may alter protein or gene expression not detected by the primers used. A well-known example is Fy(a-b-) phenotype in blacks, who genotype as FY*B but lack Fy expression on red cells because of a promoter mutation. Likewise, many partial RhD and RhCE phenotypes can lead to discrepancies between phenotype and genotype (see Rh section).

INVESTIGATION OF AUTOIMMUNE HEMOLYTIC ANEMIA

Autoantibodies, in general, are produced by an individual's own immune system against self or an antigen that is present in that same individual. Although produced against self-antigens, these antibodies typically react with the same antigen found in other normal individuals. If the antibodies produced are against blood cell constituents, the pathologic result could be hemolytic anemia, thrombocytopenia, or leukopenia. In many cases, these autoantibodies cause no demonstrable clinical symptoms.

The DAT is integral to the diagnosis of autoimmune hemolytic anemia (AIHA) because it can confirm the presence of antibody that has attached to the patient's own red cells in vivo. The DAT can help differentiate AIHA from congenital anemias caused by abnormalities in RBC cytoskeleton, enzymes, or Hg. The DAT may be positive owing to IgG and/or complement components, depending on the class or subclass of autoantibody involved. A positive DAT by itself, however, does not mean that an individual has AIHA. Approximately 8% of hospitalized patients have a positive DAT without any signs of hemolysis (Petz, 1993). In patients with suspected AIHA, the antibody screen may also be positive because of free autoantibody in the serum.

Autoantibodies are categorized as cold (usually IgM) or warm (usually IgG), based on the temperature of in vitro reactivity in the IAT. In some cases, patients may have mixed-type AIHA with both cold and warm reactive autoantibodies. The causative antibodies of these categories of anemias will be described here; additional information regarding the origin and pathophysiology of AIHA is provided in Chapter 32.

Warm Autoimmune Hemolytic Anemia

Individuals with warm reactive autoantibodies account for approximately 70%–80% of cases of AIHA, having an overall incidence of about 1 in 50,000 to 1 in 80,000 (Issitt, 1998). WAIHA may be classified as primary or idiopathic (of unknown origin), or as secondary. Secondary WAIHA is often observed in autoimmune diseases (frequently systemic lupus erythematosus), in lymphoproliferative disorders, and following viral infections. With the advent of improved diagnostic procedures, the percentage of WAIHA classified as idiopathic has dropped to about 30% of cases (Issitt, 1998). Patients with warm autoantibodies and a positive DAT will not all present with symptomatic anemia but may exist in a chronic compensated state for some time before progressing to overt clinical anemia.

Serologic Characteristics

Autoantibodies in WAIHA are usually IgG and polyclonal in nature, showing optimal in vitro reactivity at 37° C. A vast majority of warm

autoantibodies present in serum and/or recovered in eluates from patients' RBCs can be demonstrated only by the IAT technique. The DAT will be positive in approximately 80% of cases. The DAT profiles in several large studies show that 40%–50% are due to IgG only, 45%–60% are caused by IgG and complement, and 0–15% are the result of complement only (Issitt, 1998). In those instances where the DAT is negative, the use of more sensitive techniques, such as radioisotope or enzyme-labeled DAT, can demonstrate low levels of IgG or, less frequently, IgM and IgA on red cells (Englefriet, 1992).

Ig subclass studies in WAIHA indicate that causative antibodies are predominantly IgG1 and/or IgG3. Despite the ability of these subclasses to activate complement, immune destruction of the patient's autologous cells occurs largely through the spleen and liver via extravascular pathways. Patients whose RBCs are coated with IgG3 antibodies are more likely to show overt anemia, apparently because of the greater capacity of IgG3 for binding to Fc receptors on macrophages (Englefriet, 1992). A more recent study shows that the presence of multiple IgG subclasses, rather than a single subclass, has a synergistic effect on the severity of hemolysis (Fabjanska-Mitek, 1997).

In general, warm autoantibodies display a broad specificity, reacting with all normal RBCs. Many broadly reactive antibodies can show Rh specificity, as evidenced by weak or absent reactivity to Rh_{null} red cells. On occasion, autoantibodies will demonstrate Rh pseudospecificity such as anti-e (most frequently), anti-c, and anti-E. Studies with recombinant cell lines show that in most instances, these antibodies are broadly reacting with the RhCE, RhD, and Band 3 proteins, regardless of Rh phenotype (Iwamoto, 2001). Notable exceptions to the latter are African Americans with partial RhCE proteins, who serologically type as c- and/or e-positive, but can produce true alloanti-c and alloanti-e after immune stimulation (see Rh section). Autoantibodies with apparent specificity for Kell, Kidd, MNSs, ABO, Vel, and LW antigens have also been reported. Relatively few individuals with WAIHA will show a single simple specificity (Issitt, 1998).

Serologic Testing Beyond the DAT

Transfusion is usually avoided for as long as possible in patients with WAIHA. If transfusion is necessary, it is important to characterize the autoantibody and exclude the presence of RBC alloantibodies (Eder, 2005). Typical investigation strategies should always include adsorption of the serum, followed by antibody detection and identification on the adsorbed serum. Subsequent testing can also be performed on eluted antibody, although it seldom yields further useful information *unless* the serum is nonreactive.

Autoadsorption. Because a strong, broadly reactive serum autoantibody can mask the presence of significant alloantibodies, adsorption studies should be performed in these patients. Autoadsorption using autologous cells can be performed on patients who have not been recently transfused (within the last 3 months). For patients who have a strong positive DAT, autologous cells should be treated with ZZAP (Branch, 1982) before adsorption. ZZAP contains DTT, which reduces disulfide bonds in the IgG autoantibodies coating the RBCs. This destabilizes the Ig structure, rendering the autoantibodies susceptible to digestion by cysteine-activated papain, the second component of ZZAP. By stripping bound autoantibody from cells, ZZAP treatment increases the adsorptive capacity of autologous RBCs (see Fig. 35-25). If the serum contains a high concentration of autoantibody, multiple, sequential autoadsorptions may be necessary to remove all autoantibody activity. If available in sufficient quantity, autoadsorbed serum may be used to perform crossmatching, particularly if antibody detection studies reveal the presence of underlying alloantibodies.

If the patient has had recent RBC transfusions, and the patient's red cell phenotype is known, adsorption may be performed using allogeneic cells of the same phenotype as the patient. Alternatively, if the patient's RBC phenotype is unknown, differential adsorptions may be performed on three separate aliquots of the patient's serum with different red cell samples of R₁, R₂, and rr phenotypes. One of the red cell samples should lack Jk^a and one should lack Jk^b (Roback, 2008). ZZAP treatment of the adsorbing cells will effectively destroy Fy^a, Fy^b, all Kell system antigens, and the M, N, S, and s antigens, thereby conferring on the adsorbing cell samples the capacity to remove autoantibody activity while preserving potential alloantibodies in the serum. The different aliquots of serum are then tested against cells of known phenotype to detect and/or identify alloantibody specificity.

Elution. In most cases of WAIHA, an eluate of the patient's cells will demonstrate the same broadly reactive antibody seen in serum. In the rare instances where the serum is only weakly reactive or negative, an eluate may concentrate the warm autoantibody to facilitate identification and evaluation of its spectrum of reactivity. If the eluate is nonreactive with normal reagent RBCs, the presence of drug-induced autoantibodies should be investigated (see later).

Cold Autoimmune Hemolytic Anemia

Cold autoantibodies may be detected in the serum of many normal individuals if tested under the right conditions. However, most of these antibodies are benign cold agglutinins that show optimal reactivity at 4° C and little or no reactivity at 37° C. Cold agglutinins are often a nuisance that can interfere with ABO/Rh typing, antibody detection, and crossmatching when polyspecific AHG is used. Although usually ignored as clinically insignificant, cold agglutinins may become pathologic by virtue of expanded thermal amplitude and a significant increase in titer, frequently in association with certain disease states. DAT, serum titration, and characterization of thermal amplitude are the most important serologic tests in evaluating a possible diagnosis of CAIHA. Table 35-48 outlines some of the serologic differentiating characteristics of various cold agglutinating autoantibodies, both pathologic and benign.

Cold Agglutinin Disease

Cold agglutinin disease (CAD) accounts for about 20% of total cases of AIHA (Issitt, 1998). As with WAIHA, CAD may be idiopathic or secondary following infection or malignancy. Anti-I is the most frequent autoantibody in idiopathic CAD and *M. pneumoniae* infections. In contrast to the anti-I cold agglutinins found in normal sera (usually less than 1:64 when tested at 4° C), anti-I in CAD is often of very high titer, with ranges of 1:10,000 to 1:1,000,000 (Cooling, 2010). The antibody also has expanded thermal amplitude, reacting with RBCs at temperatures in the range of 30°–34° C in vitro, especially in tests with albumin-suspended RBCs (Issitt, 1998). The DAT is typically positive with polyspecific and anti-C3 reagents.

In vivo hemolysis is the result of binding of antibody to a patient's RBCs in the peripheral vessels of the extremities, which are cooler (32° C and lower). As the cells recirculate to the body core and warm to 37° C, complement is activated and cells are destroyed. Hemolysis of cells may occur intravascularly but occurs more commonly via extravascular (C3b) pathways by macrophages in the reticuloendothelial system. Hemolysis may be chronic or episodic, depending on the thermal range of the antibody, and may be triggered by exposure to cold temperatures.

Because anti-I reacts broadly with virtually all adult RBCs, the antibody can cause great difficulty in compatibility testing. As with warm autoantibodies, one of the primary concerns is to detect and identify any potential underlying IgG alloantibodies. Techniques to circumvent the autoanti-I in serum testing may include prewarming, cold autoadsorption, adsorption with REST, or treatment of the serum with sulfhydryl reagents such as DTT or 2-ME (see Special Antibody Identification Techniques section).

Anti-i and anti-Pr are two additional specificities associated with CAD. Anti-i can be observed in patients with infectious mononucleosis and certain lymphoproliferative disorders. Up to 10%–20% of patients with infectious mononucleosis will have elevated cold agglutinin titers; however, few will actually develop clinical hemolysis (Eder, 2005; Cooling, 2010). Anti-i is usually an IgM, reacting more strongly with cord cells than with adult cells. Distinguishing anti-i from anti-I may require titrating patient sera with group O adult and cord red cells at 4° C, 24° C, and 37° C (Roback, 2008).

Anti-Pr specificities may initially react similarly to anti-I, but may be differentiated by equally strong reactions with cord and adult RBCs (see Table 35-48). In addition, anti-Pr is nonreactive with enzyme-treated red cells, whereas anti-I is enhanced by enzyme treatment. Anti-Pr in patients with CAD is usually monoclonal and may be IgG, IgM, or IgA (Issitt, 1998).

Paroxysmal Cold Hemoglobinuria

PCH is an autoimmune hemolytic syndrome most often seen in children following infection by mumps, chickenpox, measles, and other viruses. Historically, PCH was also seen in syphilitic patients. It can present suddenly with severe hemolysis with an initial Hg of 7 g/dL or lower. In addition to laboratory findings of intravascular hemolysis, PCH patients may have erythrophagocytosis on peripheral blood smear. The latter is highly unusual and should trigger an investigation for possible PCH (Eder, 2005).

TABLE 35-48

Differentiating Characteristics of Cold Red Cell Autoagglutinins

Antibody specificity	Clinical significance	IAT antibody screen*	Ig class	RELATIVE REACTION STRENGTHS WITH SELECTED RED CELLS AT ROOM TEMPERATURE†				
				O adult	O cord	A ₁ adult	A ₂ adult	Autologous
I	Acute CAD associated with <i>Mycoplasma pneumoniae</i> with antibody titers >1000 at 4° C	Pos	IgM	3+	w+	3+	3+	3+
i	Acute CAD associated with mononucleosis	Pos	IgM	w+	3+	w+	w+	Weaker than O cord
Pr	Rare cause of CAD‡	Pos	Reported cases of IgM, IgA, IgG	3+	3+	3+	3+	3+
P	PCH associated with certain viral infections in children	Neg	IgG§	Negative in routine agglutination tests; autoanti-P is a biphasic hemolysin (Donath-Landsteiner antibody)				
H	Benign except as alloantibody in Bombay phenotype	Weak to neg	IgM	3+	3+	1+	2+	0 to w+
IH	Benign	Weak to neg	IgM	3+	1+	1+	2+	0 to w+

CAD, Cold agglutinin disease; Ig, immunoglobulin; Neg, negative; PCH, paroxysmal cold hemoglobinuria; Pos, positive.

*Antigen expression: O adult (I+/- H+s); O cord (I+/- H+s); A₁ (I+/- H+w); A₂ (I+/- H+).

†Reagent cells showing agglutination in 37° C phase may be much weaker after conversion to indirect antiglobulin test (IAT).

‡May be differentiated from anti-I by enzymes or increasing pH; anti-Pr reactivity is decreased by both techniques.

§Autoanti-P is the only pathologic cold autoantibody known to be routinely of the IgG class to IAT.

Autoanti-P, also known as the Donath-Landsteiner (DL) antibody, is the most common causative antibody in PCH. It is an IgG, biphasic auto-hemolysin capable of binding to RBCs at cold temperatures and causing intravascular hemolysis of those cells at body temperature (see Table 35-48). This characteristic can be demonstrated in vitro by the diagnostic DL procedure to aid in the confirmation of PCH. In this test, three sets of tubes containing patient serum and group O cells are incubated—one at 4° C followed by 37° C, one only at 4° C, and one only at 37° C. If the first set shows hemolysis, but the other two do not, this indicates the presence of the biphasic hemolysin characteristic of PCH. The DL test requires that a fresh blood sample be used to ensure that an adequate supply of complement is available, because complement is relatively unstable and deteriorates during storage. The sample should be drawn and immediately stored at 37° C until clot formation. It is also important not to draw the blood into an anticoagulant such as EDTA because chelation of calcium ions will prevent complement activation and thus in vitro hemolysis.

Because the autoantibody in PCH rarely reacts above 4° C in vitro, routine antibody detection tests are usually negative, and crossmatches are compatible. Patient RBCs sensitized by the DL antibody will most commonly give a positive DAT owing to C3 only. In addition, the DAT is positive only during or immediately after an episode of hemolysis (Eder, 2005). Because the antibody dissociates easily from RBCs during washing, the DAT is usually negative with anti-IgG. IgG may be detected, however, if the cells are washed with cold saline and tested with cold anti-IgG reagent (Roback, 2008).

Because the antibody is biphasic, many clinicians recommend keeping the patient warm and utilizing a blood warmer for transfusion. Although PCH is due to an autoanti-P, it is not necessary to transfuse the patient with rare, P-negative red cells. Most patients will have an acceptable transfusion response with routine allogeneic red cells (Eder, 2005).

Mixed-Type AIHA

A “mixed” AIHA occurs in <10% of patients and is characterized by the presence of warm and cold autoantibodies (Eder, 2005). The DAT is usually positive with both C3 and IgG, and the patient’s serum will react in all phases of testing (at room temperature and at 37° C) in the IAT. The cold-reactive antibody is typically anti-I or anti-i, and the warm-reactive antibody is typically a 37° C reactive IgG autoantibody. To adsorb autoantibody in a mixed AIHA, the sample is sequentially adsorbed at 37° C to adsorb warm-reactive autoantibody, followed by incubation in an ice bath for 30 minutes to adsorb cold-reactive antibody. Clinically, mixed AIHA usually is similar to WAIHA, although some patients may have symptoms of both WAIHA and CAD.

POSITIVE DIRECT ANTIGLOBULIN TESTS AND HEMOLYTIC ANEMIA INDUCED BY MEDICATION

At this time, more than 130 drugs have been implicated in drug-induced hemolytic anemia, with an incidence of 1 in 1–2 million individuals (Salama, 2009). An even larger number of therapeutic drugs can be associated with a positive DAT (Table 35-49). It is also well documented that a positive DAT may be produced in patients receiving high-dose intravenous gammaglobulin therapy owing to passively acquired specific blood group antibodies, as well as nonspecific binding to RBCs by IgG dimers and aggregates in the gammaglobulin preparation (Knezevic-Maramica, 2003). Several theories regarding the immunologic process underlying drug-induced antibodies have been put forth, many of which remain unproven. Moreover, some drugs appear to work by more than one mechanism, further complicating the picture. An example of the latter is the group of cephalosporins, which now account for 93% of drug-induced hemolysis (Garratty, 2004).

Historically, drug-induced hemolytic anemia has been subclassified into four types, based on its serologic characteristics. Drug-independent antibodies do not require the addition of drug into the test system for detection, even though the drug is responsible for inducing hemolytic anemia. Drug-dependent antibodies, on the other hand, require the presence of the drug for serologic reactivity. Drug-dependent antibodies can be subclassified into two types, depending on whether antibody reactivity requires drug-coated red cells or simply the presence of drug in serum. Antibody reactivity against drug-coated red cells appears to be directed against the drug itself. Alternatively, reactivity observed after concurrent incubation of red cells, serum, and free drug is believed to reflect immune complex formation between drug and “anti-drug” antibody. Finally, non-immunologic protein adsorption proposes that a change in the red cell membrane causes immune globulins and other plasma proteins to be adsorbed nonspecifically to the red cell membrane.

A unifying model has been suggested that may be applicable to many different drugs thought to be operating via the mechanisms mentioned previously (Garratty, 2004). The hypothesis suggests that the immune process is initiated by a primary interaction between RBCs and the drug or its metabolites, even though the drug may be only loosely bound to RBCs in vivo. This provides the composite determinants (or neoantigen) necessary for production of drug-dependent antibodies, as in the drug adsorption and immune complex mechanisms, or of drug-independent autoantibodies that recognize subtle alterations in the RBC membrane.

TABLE 35-49

Selected Drugs Associated With a Positive DAT and/or Hemolysis Due to Drug-Induced Autoantibodies

Reported mechanism	Drug
Drug-independent autoantibody induction	Cladribine, fludarabine, levodopa, mefenamic acid, methyl dopa, procainamide
Drug dependent (reactivity with drug-coated cells)	Aminopyrine, amoxicillin, carbromal, cefamandole, cefazolin, cephalixin, erythromycin, insulin, nafcillin, penicillin, tetracycline, tolbutamide
Drug dependent (reactivity with uncoated cells)	Acetaminophen, amphotericin B, antazoline, butizide, ceftriaxone, chlorpropamide, diethylstilbestrol, etodolac, 9-hydroxy-methyl-ellipticinium, naproxen, phenacetin, probenecid, propylphenazone, quinine, sodium pentothal, stibophen, sulfamethoxazole, sulfasalazine, trimethoprim
Nonimmunologic protein adsorption	Clavulanate potassium, diglycoaldehyde, sulbactam sodium, suramin, tazobactam sodium
Combination mechanisms	Ampicillin, carbimazole, carboplatin, cefixime, cefotaxime, cefotetan, cefoxitin, ceftazidime, ceftizoxime, cephalothin, chlorinated hydrocarbons, chlorpromazine, cisplatin, cyanidanol, diclofenac, dipyrone, fenopropen, fluorescein, hydrochlorothiazide, isoniazid, mefloquine, methotrexate, nomifensine, oxaliplatin, piperacillin, quinidine, ranitidine, rifampicin, streptomycin, sulindac, suptofen, teicoplanin, teniposide, ticarcillin, tolmetin, triamterene, zomepirac

DAT, Direct antiglobulin test.

Stimulation of Red Cell Autoantibody Production

Drug-Independent Autoantibodies. About 20% of hypertensive patients who receive methyl dopa (Aldomet) for longer than 3–6 months will eventually develop a positive DAT, but only 0.8% will develop a hemolytic anemia (Petz, 1993). The DAT gradually becomes negative after stopping methyl dopa treatment, although it may take months to longer than 2 years. Serologically, autoantibodies eluted from RBCs, or free in the serum, are indistinguishable from autoantibodies found in patients with WAIHA. The antibodies are usually of the IgG class, with both κ and λ light chains, and many show Rh specificity. The antibody reactivity is independent of the drug being added to the laboratory test system. Drug-independent antibodies may be found alone as warm autoantibodies (methyl dopa, procainamide, and fludarabine) or in combination with drug-dependent antibodies (cefotetan). About 10% of patients with Parkinson's disease receiving L-dopa, a closely related drug, develop RBC autoantibodies, but these rarely result in overt hemolysis (Petz, 1993).

Drug-Dependent Autoantibodies (Two Types)

Reactivity With Drug-Coated Cells. About 3% of patients receiving large doses of penicillin intravenously ($>10 \times 10^6$ IU/day) develop a positive DAT, although only a few of these patients will have hemolytic anemia (Salama, 2009). Breakdown products of benzyl penicillin exhibit a high binding affinity for the RBC membrane, which results in the formation of haptenic benzylpenicilloyl determinants. Certain patients can form high-titered antibodies against penicillin metabolites and, to a lesser extent, red cell membrane components. The resulting antibody–drug–RBC complex yields a positive DAT with IgG and sometimes with anti-C3. The DAT becomes negative again within days to several weeks after discontinuing penicillin. Both the patient's serum and eluates prepared from the patient's RBCs usually react only with penicillin-coated RBCs in in vitro testing.

Penicillin antibodies may consist of IgM or IgG. IgM antibodies are very common if a sensitive method is used for detection. Those antibodies

associated with immune hemolytic anemia are usually of IgG isotype (Salama, 2009). Hemolysis occurs usually through extravascular destruction mediated by cells of the RE system, although rare cases of complement-mediated intravascular hemolysis have been reported. Several cases of acquired hemolytic anemia have also been reported in association with cephalosporins through a mechanism similar to that of penicillin (Garratty, 2004; Salama, 2009).

Reactivity With Uncoated Cells. A wide variety of drugs may cause hemolytic anemia via the so-called immune complex mechanism (see Table 35-49). In the unifying concept, these drugs loosely bind to the RBC membrane with subsequent formation of antibodies reacting with both drug and membrane components. The cell–drug–antibody complex then may stimulate activation of the complement cascade. Drugs acting by this mechanism most often are associated with episodes of acute intravascular hemolysis with hemoglobinemia and hemoglobinuria that may prove fatal (Petz, 1993). The DAT in these cases is usually positive with anti-C3d only. The antibodies implicated may be IgM or IgG (Roback, 2008). They can be detected only in test systems where serum/eluate, test cells, and free drug are all present simultaneously. Although the mechanism leading to antibody production may be similar to that of so-called drug adsorption, the drugs in this category are classified separately primarily by the DAT result (C3d+) and characteristic severe intravascular hemolysis.

Nonimmunologic Adsorption of Serum Proteins. Patients taking high-dose cephalothin (6–14g/day) for prolonged periods have been reported to develop a positive DAT, with a frequency ranging widely from 3%–81% (Garratty, 2004). Hemolysis is rarely, if ever, associated with the phenomenon (Roback, 2008). It was subsequently shown that RBCs exposed to cephalothin in vitro are able to nonspecifically adsorb plasma and serum proteins (albumin, Igs, complement). In the case of some cephalosporins, a decrease in CD55 and CD58 can be documented (Garratty, 2004). These proteins can be detected by polyspecific AHG sera in the DAT. It has been hypothesized that adsorption occurs because of a change in erythrocyte membrane properties induced by cephalothin and other drugs.

KEY POINTS

- Criteria for blood donor eligibility are established by the U.S. Food and Drug Administration to minimize risks to both the donor and the transfusion recipient.
- Blood components (red blood cells, platelet concentrates, fresh frozen plasma, cryoprecipitate) are manufactured and stored in a manner to minimize functional loss of desired constituents.
- Leukocyte reduction of blood components reduces alloimmunization to human leukocyte antigens, cytomegalovirus transmission, and febrile reactions. Irradiation of blood components can prevent graft-versus-host disease.
- Accurate identification of the pretransfusion blood sample and the intended recipient is the most important step in preventing acute hemolytic transfusion reactions.
- Restrictive red cell transfusion (hemoglobin target 7–9 g/dL) is associated with improved survival in critically ill patients younger than 55 years old or with lower Acute Physiology and Chronic Health Evaluation II scores.
- Platelet transfusion is generally indicated for microvascular bleeding, platelet count <10,000/μL, or platelet count <50,000/μL before an invasive procedure.
- Failure to respond to platelet transfusion may be due to immune causes (human leukocyte antigens or platelet-specific antibodies), nonimmune clinical causes (bleeding, splenomegaly, disseminated intravascular coagulation, medications), or product-specific causes (ABO incompatibility, age of component).
- Plasma transfusion is generally indicated for coagulation factor deficiency, disseminated intravascular coagulation, dilutional coagulopathy, urgent warfarin reversal, and thrombotic thrombocytopenic purpura.

- Potentially severe adverse effects of transfusion include hemolytic reactions, allergic reactions, transfusion-related acute lung injury, bacterial contamination, and graft-versus-host disease.
- Current risks of transfusion-transmitted human immunodeficiency virus or hepatitis are very low, but the risks of other transfusion-transmitted diseases (cytomegalovirus, parvovirus B-19) may be significant in some populations.

BACKGROUND

Transfusion medicine is a multidisciplinary specialty encompassing all aspects of blood donation, blood component preparation, blood cell serology, and blood transfusion therapy. The term **blood banking** has largely been superseded by transfusion medicine to emphasize the importance of patient care and clinical outcomes.

Operationally, transfusion medicine is divided between blood centers and transfusion services. Blood centers recruit and collect blood from donors and manufacture and distribute blood components. Transfusion services perform pretransfusion compatibility testing, select and issue blood components for patients, and provide medical support for blood transfusion. Most hospital transfusion services do not collect their own blood, but rather rely on regional blood centers.

Blood centers and transfusion services (collectively known as blood establishments) are regulated by the FDA. All blood establishments must be registered with the FDA, and blood centers that manufacture blood components must be licensed. Criteria for the acceptability of blood donors, performance of pretransfusion testing, manufacture of blood components, donor infectious disease testing, and evaluation and reporting of adverse events associated with transfusion are all defined by the FDA. Blood establishments are subject to periodic unannounced inspections by the FDA. Compliance with federal regulations is an essential aspect of

TABLE 36-1

Requirements of Allogeneic Donor Qualification

Category	Criteria
Age	At least 17 years
Whole blood volume collected	Maximum of 10.5 mL/kg
Donation interval	8 weeks after whole blood donation 16 weeks after two-unit red cell collection 4 weeks after infrequent apheresis At least 2 days after plasma, platelet, or leukocyte apheresis
Blood pressure	≤180 mm Hg systolic ≤100 mm Hg diastolic
Pulse	50–100 beats per minute, without pathologic irregularities <50 acceptable if an otherwise healthy athlete
Temperature	≤37.5° C orally
Hemoglobin/hematocrit	≥12.5 g/dL/0.38
Drug therapy	Finasteride, isotretinoin—defer 1 month after last dose Dutasteride—defer 6 months after last dose Acitretin—defer 3 years after last dose Etrinate—defer indefinitely Bovine insulin manufactured in the United Kingdom—defer indefinitely Ingestion of medications that irreversibly inhibit platelet function (aspirin) within 36 hours of donation precludes use of donor as sole source of platelets
General medical history	Free of major organ disease, cancer, abnormal bleeding tendency Family history of CJD or recipient of dura mater or human pituitary growth hormone—defer indefinitely
Pregnancy	Defer for 6 weeks
Recipient of blood transfusion or tissue transplant	Defer for 12 months
Vaccinations and immunizations	Recipient of toxoid, synthetic or killed viral, bacterial, or other vaccine—no deferral Recipient of life attenuated viral or bacterial vaccine—2- or 4-week deferral Smallpox vaccine—refer to current FDA guidance Other vaccines including unlicensed vaccines—12-month deferral
Infectious diseases— indefinite deferral	Viral hepatitis after 11th birthday Positive test for hepatitis B surface antigen Repeat reactive test for anti-HBc on more than one occasion Clinical or laboratory evidence of HCV, HTLV, or HIV infection by current FDA regulations Previous donation associated with hepatitis, HIV, or HTLV transmission Behavioral risk factors for HIV infection according to current FDA guidance History of babesiosis or Chagas' disease Stigma of parenteral drug use Injection of nonprescription drugs Risk of vCJD according to current FDA guidelines
Infectious diseases—12-month deferral	Mucous membrane exposure to blood Nonsterile skin or needle penetration Sexual contact with an individual with a confirmed positive test for hepatitis B surface antigen Sexual contact with an individual with viral hepatitis Sexual contact with an individual with HIV infection or at higher risk for HIV infection Incarceration in a correctional institution for longer than 72 consecutive hours History of syphilis or gonorrhea
West Nile virus	Defer according to current FDA guidance
Malaria	Confirmed diagnosis—defer for 3 years after becoming asymptomatic Travel to or residence in an endemic area as defined by the CDC—defer according to FDA guidance

CDC, Centers for Disease Control and Prevention; CJD, Creutzfeldt-Jakob disease; FDA, U.S. Food and Drug Administration; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HTLV, human T cell lymphotropic virus; vCJD, variant of Creutzfeldt-Jakob disease.

transfusion medicine. In addition, professional organizations such as AABB (formerly known as the American Association of Blood Banks), the College of American Pathologists, and The Joint Commission have put forth accreditation standards for transfusion services and conduct voluntary peer inspections.

BLOOD COLLECTION

Approximately 60% of the adult U.S. population is eligible to donate blood, although only about 5% actually do so annually. Approximately 16 million units of whole blood and red blood cells (RBCs) are collected annually in the United States (U.S. Department of Health and Human Services, 2009). Virtually all donors are voluntary and noncompensated. The average blood donor is a college-educated male between the ages of 30 and 50, who is married and has above average income. However, donations among women and minority groups are increasing. As the utilization of blood components increases and donor eligibility requirements are

tightened, efforts to recruit additional donors will be critical to ensure an adequate blood supply.

Donor criteria are established for the protection of the blood donor and the transfusion recipient. Current (2010) donor qualification criteria are listed in Table 36-1. Criteria for donor protection include a minimum age of 17 years, a minimum weight of 110 pounds, normal vital signs, a minimum hemoglobin (Hb) concentration, and a specified donation interval. Criteria for the protection of the recipient include history or risk factors for infectious disease transmission (hepatitis, human immunodeficiency virus [HIV], malaria, and others), risk of bacteremia, ingestion of certain medications, and history of malignancy. Blood centers are required to maintain a registry of deferred donors, and each donor must be checked against this registry before any donation is made. Finally, every donation must be tested for infectious disease markers as defined by FDA regulations. Current (2010) donor testing requirements are indicated in Table 36-2.

Blood must be collected in a manner to minimize the risk of bacterial contamination. The skin at the venipuncture site must be prepared with

an antibacterial scrub. Whole blood is collected into sterilized bag sets containing anticoagulant and attached satellite bags to facilitate component manufacture in a closed system. The rate of blood flow must be sufficient to prevent clot formation during phlebotomy. The volume of blood withdrawn is less than 10.5 mL/kg, including samples for testing. Typically, whole blood donations are 450 or 500 mL.

Blood components can also be collected by apheresis. The advantage of apheresis donation is that a greater volume of the desired components may be obtained from a single donation. The most common use of the apheresis donation is the collection of platelets (commonly called single donor platelets). Plasma may also be collected, typically concurrently with platelets. Apheresis donation allows for the collection of two units of RBCs from suitable donors. Leukocytes may also be collected by apheresis. This is most commonly utilized for the collection of hematopoietic progenitor cells for autologous or allogeneic transplantation. Granulocytes or mononuclear cells may be collected by apheresis for special applications.

Autologous donation is the collection of blood from a patient in advance of scheduled surgery for transfusion during or after the procedure to compensate for expected blood loss. Autologous transfusion prevents the transmission of blood-borne pathogens from allogeneic donors and is desired by some patients. It is not completely free of risk, however, particularly of bacterial contamination. Whether or not autologous transfusion actually decreases the need for allogeneic transfusion or improves patient outcome is controversial. Benefit in reducing allogeneic blood exposure or improving outcome has not been shown in controlled prospective randomized trials. Candidates for autologous donation must not have underlying disease that would put them at risk from this procedure. They must not be significantly anemic, although a lower Hb level than allowed for allogeneic donation may be acceptable. They must not be at risk for bacteremia because the most serious adverse consequence of autologous transfusion is bacterial contamination. Patients with heart disease, particularly aortic stenosis, may be unable to tolerate phlebotomy. Pregnancy does not itself constitute a contraindication to autologous donation; however, the value of autologous donation except in certain high-risk situations such as placenta previa is minimal. Autologous donations can occur more frequently than allogeneic donations. Typically, two or three units may be collected several weeks before surgery. Optimally, there should be sufficient time from donation to surgery to allow for recovery of a substantial portion of the collected red cell mass. This may require iron supplementation. Erythropoietin stimulation has been used as an adjunct to autologous donation.

Some patients desire to select donors for themselves (directed or designated donation) rather than receiving blood from the community blood supply. This provides some patients with the perception of greater safety, although no evidence suggests that directed donation reduces the risk of transfusion-transmitted disease. Directed donors must meet all criteria for allogeneic blood donation. In addition, directed donors must be compatible with the intended recipient. In certain situations, directed donation is contraindicated. Donation of any plasma-containing blood component from a mother to her child is particularly problematic because the formation of human leukocyte antigens (HLA) antibodies to fetal antigens is common in pregnancy, and transfusion of such antibodies can precipitate transfusion-related acute lung injury (see later). Transfusions from close relatives should be avoided in recipients of hematopoietic progenitor cell transplants because of the risk of immunization to HLA and other

histocompatibility antigens, which may endanger graft survival. There are rare circumstances under which directed donation may be desirable. These include rare blood group compatibility requirements and limitations of donor exposure for patients with long-term expected transfusion requirements such as aplastic anemia. In cases of neonatal alloimmune thrombocytopenia, collection of maternal platelets may be the best way of providing compatible antigen-negative platelets. In the past, donor-specific transfusion was utilized in kidney transplantation. However, with current immunosuppressive regimens, the value of donor-specific transfusion in prolonging renal graft survival is questionable.

Adverse effects of donations may occur. Minor reactions, mostly presyncope, occur in 2.5% of whole blood donations (Eder, 2009). Major reactions, including loss of consciousness, nerve or arterial injury, allergic reaction, and citrate reaction, occur in about 0.07% of whole blood and 0.05% of apheresis platelet collections. Up to 36% of donors interviewed 3 weeks after donation report some adverse effect, mostly minor, such as arm bruise or soreness (Newman, 2003). More serious adverse effects such as vasovagal symptoms occur in about 5%, and nausea and vomiting in about 1%. Repeat donors are less likely to have reactions than first-time donors. Smaller donors are at greater risk of postdonation syncope. Most syncope reactions occur shortly after donation. However, delayed reactions can occur, and if the donor is at work or is driving, these can be very serious. Seizures following blood donation have been reported, although it is unlikely that there is a causal relationship (Krumholz, 1995). Some highly apprehensive donors hyperventilate, leading to respiratory alkalosis and tetany. This can usually be managed easily by having the donor breathe into a paper bag.

Personnel at a collection site should be prepared to treat donor reactions. Vasovagal syncope can usually be managed easily by placing the donor into a supine position and applying a cold compress to the forehead. It is rare that intravenous fluids are required. A physician should be available to donor site personnel for consultation, and emergency medical support should be available, if necessary. Vasovagal reactions can be minimized by prior hydration of the donor, or by the use of caffeine (Sauer, 1999; Newman, 2007).

BLOOD COMPONENT MANUFACTURE

Whole blood donations are commonly manufactured into components. This facilitates the treatment of different patients with requirements for RBCs, plasma proteins, or platelets. The goals of component manufacture are to maintain viability and function, and to prevent detrimental changes or contamination of desired constituents.

RED BLOOD CELLS

RBCs are prepared from whole blood by centrifugation and removal of plasma. The most commonly used anticoagulant-preserved solution for RBC is CPDA-1. This is supplemented with dextrose and adenine to preserve red cell adenosine triphosphate levels. RBCs in CPDA-1 may be stored for up to 35 days at 1°–6° C. RBCs may also have an additive solution containing glucose and other substrates added during manufacture. Such additive solutions permit a longer storage period (42 days) and have a lower hematocrit (Hct). During storage, red cells undergo senescence changes similar to aging in vivo, such that a portion of transfused red cells are rapidly cleared by the spleen. The maximum allowable storage time for RBCs is defined by the requirement for recovery of 70% of transfused cells 24 hours after transfusion. Leakage of intracellular potassium occurs during red cell storage. The potassium concentration in the supernatant of RBCs can reach levels of 76 mmol/L, which may appear alarmingly high. However, the total amount of potassium in a unit of RBC at outdate is small compared with daily physiologic requirements, and hyperkalemia following transfusion is rare except in special circumstances (see later). Red cells lose intracellular 2,3-diphosphoglycerate (2,3-DPG) during storage, resulting in a shift of the Hb-oxygen dissociation curve to the left. Thus, shortly after transfusion, stored red cells have relatively high oxygen affinity. Normal levels of 2,3-DPG are restored within 24 hours of transfusion. The shift in oxygen association with storage is rarely clinically significant.

PLASMA

Plasma may be stored in the liquid state at 1°–6° C, or it may be frozen for extended preservation. In the liquid state at refrigerator temperatures, there is loss of labile clotting factors, particularly factor VIII and factor V.

Fresh frozen plasma (FFP) is separated from the RBCs and is placed at -18°C within 8 hours of collection. Plasma frozen within 24 hours after phlebotomy (FP24) is manufactured similarly to FFP but may not be frozen for up to 24 hours after collection. The coagulation factor content of FP24 is equivalent to FFP (Scott, 2009). Frozen plasma may be stored for up to 1 year at -18°C or lower. Before transfusion, both FFP and FP24 are thawed at 37°C and must be transfused within 24 hours. Thawed plasma not used within 24 hours may be relabeled as "Thawed Plasma." Thawed plasma can be kept at refrigerator temperatures for up to 5 days, while adequate levels of factors V and VIII are maintained (Downes, 2001; Scott, 2009).

CRYOPRECIPITATED ANTIHEMOPHILIC FACTOR

Cryoprecipitated antihemophilic factor (cryoprecipitate or cryo) is the cold insoluble portion of plasma remaining after FFP has been thawed at refrigerator temperatures. It contains approximately 50% of the factor VIII and 20%–40% of the fibrinogen present in the original plasma unit. Cryo also contains von Willebrand factor (vWF) and factor XIII. FDA regulations require that a unit of cryoprecipitate contain at least 80 IU of factor VIII, although most blood centers achieve higher levels routinely. A unit of cryoprecipitate contains approximately 250 mg of fibrinogen, but testing for the fibrinogen content is not required. Cryoprecipitated antihemophilic factor was a major advance in the treatment of hemophilia A before the development of safe purified clotting factor concentrates. Currently, cryo is used mainly as a source of fibrinogen.

PLATELET CONCENTRATES

Platelet concentrates (PCs) are prepared from whole blood by centrifugation of platelet-rich plasma and expression of platelet-poor plasma. Platelet concentrates must contain at least 5.5×10^{10} platelets per unit. They are stored at room temperature (20° – 24°C) because platelets stored at refrigerator temperature (1° – 6°C) have greatly diminished posttransfusion survival. Current FDA regulations allow PCs to be stored for up to 5 days with continuous gentle agitation. At the end of storage, the pH of the PCs must be 6.0 or higher. Platelet concentrates typically contain a small number of red cells, which are visibly apparent and can cause alloimmunization to red cell antigens. PCs contain 30–50 mL of plasma. It is typically necessary to pool five or more PCs to obtain a therapeutic dose for a typical adult patient.

PCs that are pooled using an open system must be transfused within 4 hours. PCs can be pooled and leukocyte reduced at the time of manufacture, using a system that maintains sterility, often referred to as pre-pooled platelets. Because the integrity of the container is not compromised in this process, pre-pooled platelets can be stored for up to 5 days.

PCs prepared by apheresis (platelets, pheresis, or single-donor platelets) are stored and handled in the same manner as platelet concentrates prepared from whole blood. Each apheresis platelet unit should contain a minimum of 3.0×10^{11} platelets. It is possible to collect two platelet units in a single apheresis session from some donors. One apheresis platelet unit will typically provide a therapeutic dose for an adult patient.

LEUKOCYTE COMPONENTS

Granulocytes can be prepared by apheresis. Granulocytes may be stored at room temperature for up to 24 hours. However, after even brief *in vitro* storage, granulocytes may have reduced ability to circulate and migrate to areas of inflammation (McCullough, 1983). It is desirable that they be transfused as soon as possible after collection. Donor stimulation with granulocyte colony-stimulating factor (G-CSF) is usually necessary to obtain a sufficient number of granulocytes to be a therapeutic dose for an adult patient (Heuft, 2002). Granulocyte units contain a substantial number of RBCs and must be ABO compatible with the recipient.

Mononuclear cells collected by apheresis can be a source of hematopoietic progenitor cells (HPCs) for autologous or allogeneic transplantation. The number of circulating HPCs can be increased by growth factor (G-CSF or granulocyte-macrophage colony-stimulating factor [GM-CSF]) stimulation, recovery from chemotherapy, or the chemokine receptor blocker plerixafor (Cashen, 2009; Nakasone, 2009). Autologous HPCs for transplantation in patients with lymphoma or other malignancies are typically collected when the bone marrow is recovering from chemotherapy because there are relatively high numbers of circulating

stem cells at that time. HPCs may be stored frozen after addition of a cryoprotective agent, such as DMSO, for an extended period of time. After thawing at 37°C , HPCs should be transfused as soon as possible. Mononuclear cells can also be used as a source of lymphocytes for induction of graft-versus-tumor effect, known as donor lymphocyte infusion (Gilleece, 2003).

LEUKOCYTE-REDUCED BLOOD COMPONENTS

Leukocytes present in blood components, particularly RBCs and PCs, may cause adverse effects. Such untoward effects include febrile nonhemolytic transfusion reactions, immunization to leukocyte (particularly HLA) antigens with subsequent refractoriness to platelet transfusions, transmission of leukocyte-associated viruses, and graft-versus-host disease. To minimize most of these adverse impacts, many blood centers and transfusion services have instituted the use of leukocyte-reduced components for all transfusions (universal leukocyte reduction). It must be noted that leukocyte reduction has not been shown to prevent posttransfusion graft-versus-host disease and is not used for this purpose. To be considered leukocyte reduced, blood components must be prepared by a method known to reduce the total number of residual leukocytes to fewer than 5×10^6 per unit for RBC and fewer than 8.3×10^5 for whole blood-derived PC (Fridey, 2003).

Leukocyte reduction is typically accomplished by filtration at the time of component manufacture (prestorage leukocyte reduction) or at the time of transfusion (poststorage leukocyte reduction). Both methods are effective for removing leukocytes. However, prestorage leukocyte reduction has the advantage of preventing accumulation of leukocyte-derived biological response modifiers, particularly cytokines, which may cause adverse reactions (Heddle, 1999). In addition, filtration at the time of manufacture allows for better process control. Certain apheresis devices can reliably produce platelet concentrates containing fewer than 1×10^6 leukocytes. Subtle differences have been noted in the distribution of leukocyte subsets between such components and those produced by filtration (Pennington, 2001). These differences, however, are unlikely to be clinically significant.

Leukocyte reduction failures may occur during filtration of blood from donors with sickle trait. Such filtration failures are due to Hb S polymerization in an environment of low oxygen tension and high osmolality (Beard, 2004). Leukocyte reduction is not an effective means of preventing graft-versus-host disease (Hayashi, 1993). Clearly, granulocytes and hematopoietic progenitor cells cannot be leukocyte reduced.

SPECIAL COMPONENTS

Cryoprecipitate-reduced plasma (cryopoor plasma) is the supernatant remaining from the production of cryoprecipitate. It is relatively deficient in high molecular weight forms of vWF but retains normal levels of the vWF-cleaving metalloprotease ADAMTS 13 (Blackall, 2001). For these reasons, cryoprecipitate-reduced plasma is an attractive alternative to FFP for the treatment of patients with thrombotic thrombocytopenic purpura. However, at present, no definitive evidence indicates that plasma exchange with cryoprecipitate-reduced plasma results in improved patient outcome.

Red blood cells can be stored in the frozen state after addition of a cryoprotective agent, such as glycerol. Frozen RBCs can be stored in mechanical freezers or liquid nitrogen for up to 10 years. Frozen units are thawed rapidly at 37°C . The cryoprotective agent must be removed by progressive addition of washing solutions with decreasing osmolality. Failure to properly deglycerolize frozen RBCs can result in hemolysis. Cryopreservation and deglycerolization of sickle trait red cells by standard methods can result in the formation of a jelly-like mass. This can be overcome by using a modified process (Meryman, 1976). After deglycerolization, red cells can be stored for up to 1 day at 1° – 6°C if processed by an open method, or up to 14 days if processed by a closed method. The main use of frozen RBCs is to maintain an inventory of rare antigen-negative units.

RBCs and PCs can be washed to remove plasma proteins and electrolytes. Washing can be accomplished by manual or automated methods. Loss of cells during the washing process can be substantial. In addition, washing of platelets can result in clumping and activation with reduced viability (Pineda, 1989). Because this is an open process, washed red cells may be stored for 24 hours at refrigerator temperatures, and washed platelets must be transfused within 4 hours of preparation. The main use of washed components is the prevention of severe allergic reactions. Washing is not an effective means of leukocyte reduction.

TABLE 36-3

ABO Compatibility

Donor type	RECIPIENT TYPE			
	O	A	B	AB
O	R P	R	R	R
A	P	R P		R
B	P		R P	R
AB	P	P	P	R P

P, Plasma-containing components (platelets, fresh frozen plasma) are compatible;
R, red cells are compatible.

Transfusion-associated graft-versus-host disease (TA-GVHD) can be prevented by irradiation of components containing viable lymphocytes (RBCs, PCs, granulocytes, and nonfrozen plasma). This can be accomplished by exposure to γ -rays or X-rays. The minimum dose should be 25 Gy delivered to the center of the blood container and no less than 15 Gy to the periphery. Irradiation causes chromosomal damage, which prevents replication of transfused lymphocytes in the recipient. However, irradiated cells are immunogenic. Thus, irradiation is not equivalent to leukocyte reduction. Irradiation also causes damage to red cell membranes with increased potassium leakage and decreased posttransfusion survival (Moroff, 1999). Irradiated red cells must have the outdate shortened to no more than 28 days from the date of irradiation. Platelets appear to sustain minimal damage from irradiation, and so their expiration date need not be altered, although the increment in platelet count may be reduced (Sweeney, 1994; Slichter, 2005). Clearly, hematopoietic progenitor cells must not be irradiated. Irradiation is not sufficient to prevent transmission of viral infections, including cytomegalovirus, or bacterial contamination.

PATHOGEN REDUCTION

Although great progress has been made in reducing the risks of transfusion-transmitted diseases, some risk remains. In addition, it is possible that a new transmissible disease may emerge as a threat to blood safety. For these reasons, strategies to inactivate contaminating microorganisms (pathogen reduction) are presently under active development. Blood derivatives such as albumin, coagulation factor concentrates, and immunoglobulins are commonly treated by a variety of methods, including heat and solvent-detergent, which are highly effective against viruses, including HIV, hepatitis B virus (HBV), and hepatitis C virus (HCV). The solvent-detergent treatment process disrupts the lipid envelope of viruses such as HIV, HBV, and HCV. However, it is ineffective against nonlipid-enveloped viruses. In addition, it destroys cell membranes and so is not applicable to cellular blood components. Solvent-detergent-treated plasma is available in Europe and is approved by the FDA, although it is not presently available in the United States. Solvent-detergent-treated plasma contains predictable levels of all coagulation factors and is effective in the treatment of thrombotic thrombocytopenic purpura (TTP) (Horowitz, 1992; Moake, 1994). It may, however, contain reduced levels of protein S and has been associated with thrombotic complications (Doyle, 2003).

Presently, two pathogen reduction methods for platelets and plasma, not available in the United States but marketed elsewhere, are Intercept (Cerus Corporation, Concord, Calif.) and Mirasol PRT (Navigant Biotechnologies, Lakewood, Colo.) (McClaskey 2009). Psoralen compounds used in the Intercept system intercalate between bases of RNA and DNA and, when exposed to ultraviolet (UV) light, form covalent cross-links that prevent replication. Both treatments are effective against viruses, bacteria, and protozoans (Lin, 2004; Ruane, 2004). Intercept-treated platelet concentrate has been shown to be safe and effective in a randomized trial (McCullough, 2004). The treatment process does result in a statistically significant, and possibly clinically significant, reduction in posttransfusion platelet recovery. Riboflavin, used in the Mirasol PRT system, causes strand cleavage of nucleic acids when activated by UV light. Because these methods require exposure to light, their applicability to RBCs is limited. Both the Intercept and Mirasol processes have been shown to preclude the need for irradiation of blood components to prevent transfusion-associated graft versus host disease (Mintz, 2009). Although each of these techniques is promising, questions of efficacy, toxicity, and immunogenicity remain.

SELECTION OF BLOOD COMPONENTS

Blood components must be serologically compatible with the recipient. ABO compatibility is the primary consideration. Transfused red cells must be compatible with recipient antibodies, and transfused plasma must be compatible with recipient red cells. Therefore, whole blood must be of identical ABO type to the recipient. Red blood cells contain a limited amount of plasma and need to be compatible but not necessarily identical to the ABO type of the recipient. Similarly, plasma and platelet concentrates contain few, if any, red cells. ABO-compatible blood component selection is summarized in Table 36-3. Red blood cells must also be negative for clinically significant antigens when transfused to alloimmunized recipients. It is highly desirable to transfuse only Rh-negative red cells to Rh-negative recipients because there is approximately a 30% risk of immunization to Rh(D) (Frohn, 2003). This is particularly important for women of childbearing potential because of the risk of hemolytic disease of the newborn in subsequent pregnancies.

Special considerations apply to recipients of ABO-incompatible hematopoietic progenitor cell transplants. During the course of transplantation, such individuals will change their blood type. Transfused red cells should be compatible with both donor and recipient isohemagglutinins, and transfused plasma-containing components should be compatible with both donor and recipient red cells. Thus, the optimal choice for such a patient will depend on current and expected future typing results.

RED BLOOD CELLS

The primary consideration in selection of RBCs is serologic compatibility for the prevention of hemolytic transfusion reactions. Because the post-transfusion survival of red cells is inversely related to length of storage, it is desirable to select fresh (typically less than 10 days old) units in situations where it is particularly desirable to limit the number of transfusions, such as intrauterine and neonatal transfusion. For large-volume transfusions of pediatric patients (such as exchange transfusion or cardiac surgery), it may be desirable to select Hb S-negative (sickle-negative) units. It is also preferable to select sickle-negative red cells for transfusion to patients with sickle cell disease because the presence of Hb S in donor red cells may complicate monitoring of the effectiveness of transfusion therapy. However, it has never been shown that red cell transfusion from asymptomatic sickle trait donors is deleterious, and in some cases such as rare blood requirements, the use of a sickle trait donor may be the only option. Heavily transfused patients, particularly those with sickle cell disease, are at risk of alloimmunization and hemolytic transfusion reactions (Vichinsky, 1990). Such patients may benefit from prophylactic administration of antigen-matched red cells, particularly Rh and Kell (Ambruso, 1987; Castellino, 1999).

Exchange transfusion of the neonate with hemolytic disease of the newborn (HDN) is a special case. In this situation, antigen-negative red cells and plasma (for oncotic pressure and bilirubin-binding capacity) are needed. Red cells must be compatible with the maternal antibodies, including ABO antibodies. Reconstituted whole blood, prepared by combining RBC and compatible FFP to a desired Hct (typically 50%), is commonly used, although whole blood may be used if available.

PLATELETS

Major ABO compatibility is less of an issue in platelet transfusion than in red cell transfusion. ABO antigens are expressed weakly on platelets. ABO-incompatible platelet transfusions may result in lower posttransfusion survival, although this usually is not clinically significant. Transfusion of isohemagglutinins contained in the plasma of apheresis platelets from donors with high-titer anti-A or anti-B can cause an acute hemolytic reaction (Larsson, 2000). Therefore, if non-ABO-identical platelets must be transfused, overriding consideration is typically given to plasma compatibility with the recipient. Some centers will screen apheresis platelets to ensure that high-titer incompatible anti-A or anti-B (e.g., $<1:200$ reactivity at immediate spin) is not transfused.

Failure to achieve an expected platelet count increment after platelet transfusion on two or more occasions is commonly considered refractoriness. Failure to respond with an appropriate increase in platelet count after transfusion (platelet refractoriness) may be due to immune causes (HLA or platelet-specific antibodies), nonimmune clinical causes (bleeding, splenomegaly, disseminated intravascular coagulation [DIC], medications), product-specific causes (ABO incompatibility; older products give lower increments), or the fact that some donors' platelets store poorly. A poor

increment following a single platelet transfusion must not be presumed to be due to alloimmunization. The refractoriness is often multifactorial and changes with the patient's underlying condition and therapy. HLA antibodies are the most common cause of immune-mediated platelet refractoriness. HLA class I antigens are expressed on platelets, and class I antibodies are common in patients who have been previously pregnant or transfused with non-leukocyte-reduced blood components. Leukocyte reduction has been shown to effectively prevent both alloimmunization and platelet refractoriness in previously unexposed patients with leukemia (Trial to Reduce Alloimmunization to Platelets Study Group, 1997). Antibodies to platelet-specific antigens are a relatively rare cause of platelet refractoriness. Several effective strategies are known for selection of platelets for the alloimmunized refractory recipient. The use of cross-match-compatible platelets is usually the first line (O'Connell, 1990). If the patient's HLA antibody specificities can be defined, it may be possible to select antigen-negative donors (Petz, 2000). Donors matched for HLA class I antigens may be selected. However, owing to constraints of donor availability, finding optimal matches may be very difficult. Even with a large donor base, many "HLA-matched" transfusions are mismatched for at least one antigen (Dahlke, 1984).

PRETRANSFUSION TESTING

The most critical step in pretransfusion testing is proper collection and identification of the recipient blood sample. The most common cause of an acute hemolytic transfusion reaction is misidentification of the sample or patient (Sazama, 1990; Linden, 2000). Each transfusion service must develop and implement policies and procedures for patient identification and specimen collection. The pretransfusion samples should be labeled at the time of phlebotomy by comparison with the patient's permanent identifier (typically a wristband). The label should contain at least two unique identifiers, such as patient name and hospital registration number. The date of sample collection and the identity of the phlebotomist must also be documented. In emergency situations when the patient's identity is unknown, a unique identifier must be assigned. This identifier must remain with the patient throughout the course of transfusion even if the patient is subsequently identified. Policies and procedures must be in place for management of patients with confidential or alias names.

Samples for pretransfusion testing should be collected no more than 3 days before transfusion, unless it is known that the patient has not been pregnant or transfused within the preceding 3 months. The common practice of patient admission on the same day as elective surgery presents special challenges. In this setting, pretransfusion samples may be collected during a preceding outpatient visit. One option is to require such patients to wear an identification wristband, although many patients find this undesirable. Another alternative is to assign a unique number to the pretransfusion specimen and affix this number to an identification form that the patient must provide on the day of surgery (Butch, 1994). Pretransfusion samples must be retained until at least 7 days after each transfusion. Typically, transfusion services retain pretransfusion samples for a fixed time.

Routine pretransfusion testing consists of ABO and Rh(D) typing and screening for unexpected red cell antibodies. If the antibody screen is positive, antibody identification tests should be performed. Results of current testing should be compared with records of the previous testing, if available. Clinically significant red cell antibodies may become undetectable over time but may cause delayed hemolytic reactions owing to an anamnestic response. Therefore, a history of a clinically significant red cell antibody should be honored by providing only antigen-negative red cells for transfusion. Any discrepancy in current testing or disagreement with previous records must be resolved before pretransfusion testing can be concluded.

Some patients present particular challenges in pretransfusion testing. Newborns typically have weak or absent isohemagglutinins. Expected ABO antibodies may not be present until 6 months of age. Recently transfused patients may show a mixture of circulating red cells, if they have not received ABO-identical units. Unexpected red cell antibodies can be acquired passively from transfusion of platelet concentrates or immunoglobulins. Some patients may lack expected isohemagglutinins because of disease or immunosuppressive therapy. Recipients of allogeneic HPC transplants may have complex and variable typing results, which necessitate conclusion of a "declared" blood type. In urgent situations when the blood type cannot be concluded, selection of group O red cells and group AB plasma is usually safe. If antibody identification tests cannot be completed, a medical judgment must be made regarding the urgency of transfusion and the risks of incompatibility. It may be desirable to issue red cells

lacking antigen specificities that cannot be excluded, if available. The occurrence of a weakly expressed Rh(D) antigen may complicate pretransfusion testing.

The final step of pretransfusion compatibility testing is the cross-match. The purpose of the cross-match is a final check of ABO compatibility and, to a lesser extent, detection of unidentified antibodies. A major cross-match is performed between the recipient's serum or plasma and donor red cells. A minor cross-match, between recipient red cells and donor or plasma, is usually unnecessary. In the absence of unexpected red cell antibodies, a cross-match can be performed by direct agglutination ("immediate spin") for detection of ABO incompatibility. When unexpected red cell antibodies are present, the cross-match should be performed by antiglobulin technique. For antibodies judged to be clinically significant, antigen-negative cells are selected for cross-match. An alternative for ensurance of ABO compatibility is the so-called computer cross-match. This is applicable when at least two determinations of the recipient's ABO group have been made, at least one on a current sample, and there are no unexpected antibodies (Butch, 1997). A validated computer system can then ensure that issued blood complements are ABO compatible. The presence of red cell autoantibodies presents a special problem. In this setting, it is essential that alloantibodies be excluded. Typically, the cross-match will be positive. Many transfusion services have a policy of issuing "least reactive" units, although the value of this policy has been called into question (Petz, 2003).

In urgent situations, emergency release of blood complements before completion of compatibility testing may be indicated. The goals of emergency release are to provide red cells for oxygen-carrying capacity and plasma for coagulation factor content to a rapidly bleeding patient. ABO compatibility is the first priority (see earlier discussion of component selection). Antibodies to other blood group antigens typically do not cause acute hemolytic reactions and therefore are of lower priority. However, when there is a history of prior antibodies, or when antibody identification tests are partially complete, it may be preferable to select antigen-negative RBCs, if available. Finally, documentation of the medical order for emergency release of blood components should be obtained, usually after the fact.

TRANSFUSION ADMINISTRATION

The transfusion service is responsible for developing and implementing policies and procedures for the administration of blood components. A physician's order is required to prepare, dispense, and administer blood components. Optimally, venous access should be established before a blood component is issued. The selection of location and type of access depends on the volume, timing, and expected duration of transfusion therapy. Peripheral access with an 18-gauge needle or catheter is typically sufficient. Smaller catheters may be used; however, high-pressure flow through a small lumen may cause hemolysis (de la Roche, 1993). Central venous access is desirable for high-volume administration or long-term therapy.

Before administration of a transfusion, accurate identification of the component and the intended recipient is essential. This process should include at least two unique identifiers, such as name and registration number, and comparison with a permanent identifier, such as a wristband. Additionally, the unit identifier on the blood container should be checked against the associated documentation (transfusion form or attached tag). The ABO and the Rh type on the unit label must agree with the associated documentation, and compatibility with the patient's recorded blood type should be verified. The expiration time and date of the blood component should be verified as acceptable. Many institutions require that two qualified individuals perform the identity check before transfusion. The physician's order and the patient's consent for transfusion should also be verified.

All blood components must be administered through a filter intended to retain clots and particles, typically 170–260 μm pore size. Administration sets should contain a drip chamber, attached compatible intravenous solution, and a means of controlling the flow rate. During surgery, it is routine practice to add a microaggregate filter through which the blood component flows first. This decreases the metabolic burden placed on the recipient to process aggregates of fibrin and cellular debris that accumulate during storage, and helps to preserve the patency of the intravascular line. Care should be taken to avoid admixture of the blood components with incompatible intravenous solutions. Normal saline is the preferred solution for all transfusions. Calcium-containing solutions should be avoided, as these may precipitate clotting. RBCs should not be administered with 5% dextrose, as this may cause hemolysis. Medications should not be added to

blood components. Leukocyte reduction filters may be used for transfusion of RBCs or PCs to reduce the incidence of febrile transfusion reactions, HLA alloimmunization, or cytomegalovirus (CMV) transmission. The appropriate filter must be selected for the blood component because clogging or filter failure may occur if improperly used.

It may be desirable to administer refrigerated blood components (RBCs or plasma) through a blood-warming device. Transfusion of cold components faster than 100 mL per minute for 30 minutes may increase the risk of cardiac arrest (Boyan, 1963). Blood-warming devices should have a visible thermometer and an audible alarm to avoid exceeding temperature limits. Blood components should never be warmed by the use of tap water, conventional microwave ovens, or any other nonapproved warming device.

The desirable rate of administration depends on the patient's blood volume, cardiac status, and hemodynamic state. Except for urgent resuscitation, the transfusion should be started slowly (approximately 2 mL/minute for the first 15 minutes). The patient should be carefully observed for the first 15 minutes of infusion because severe reactions such as hemolysis, anaphylaxis, or sepsis may manifest after a small volume has entered the circulation. Subsequently, the administration rate may be increased. In general, it is desirable to complete a red cell transfusion within 2 hours and a platelet or plasma transfusion within 30–60 minutes. Any transfusion should be completed within 4 hours of initiation. Patients at risk of volume overload may require slower administration. If the total administration time exceeds 4 hours, smaller-volume blood components should be provided. When high flow rates are required, such as in some resuscitation or surgical situations, a pressure infusion device may be used. When such devices are used, care must be taken to avoid mechanical hemolysis or air embolism. During transfusion, the patient's vital signs should be checked at regular intervals, and any suspected reaction should prompt interruption of the transfusion and immediate investigation.

BLOOD COMPONENT THERAPY

All transfusion decisions are clinical judgments that should be made while taking into account clinical and laboratory data. There are no absolute indications, and few contraindications, to blood transfusion.

Red Cell Transfusion

Red blood cells provide oxygen-carrying capacity. Red cell transfusion may be used to treat acute or chronic anemia. A patient's ability to tolerate anemia depends on the degree of anemia, physiologic adaptive mechanisms, and cardiac or respiratory disease. Normal physiologic adaptations to anemia include increased cardiac output, redistribution of blood flow, increased oxygen extraction, and increased red cell 2,3-DPG, resulting in rightward shift of the oxygen-Hb dissociation curve. General guidelines for red cell transfusion are summarized in Table 36-4. Symptomatic anemia, regardless of Hb concentration, in a euvolemic patient is an indication for transfusion. Symptoms of anemia include fatigue, tachycardia, tachypnea, dyspnea on exertion, postural hypotension, and impaired mentation. Anemia may precipitate angina in patients with coronary artery disease. Generally, acute blood loss of greater than 15% of a patient's blood volume may be an indication for red cell transfusion. Studies of postsurgical morbidity in patients who refused blood transfusion have indicated that for patients with a preoperative Hb of at least 6 g/dL, without underlying coronary artery disease, and sustaining operative blood loss of less than 2 g/dL of Hb, there is little relationship between mortality and degree of

preoperative anemia (Carson, 1996). Mortality increases with preoperative Hb levels below 6 g/dL (Spence, 1990). However, with a Hb loss of 2–4 g/dL, perioperative mortality increases with preoperative Hb levels below 10 g/dL. This risk is magnified by the presence of cardiovascular disease (angina, myocardial infarction, congestive heart failure, or peripheral vascular disease). One study of patients undergoing elective operations demonstrated no mortality despite Hb levels as low as 6 g/dL, provided that the blood loss was less than 500 mL (Carson, 1988).

The Transfusion Requirements in Critical Care (TRICC) study has been the largest randomized prospective trial to date comparing restrictive and liberal transfusion strategies (Hebert, 1999). The TRICC trial enrolled 838 critically ill patients with Hb levels <9.0 g/dL. Subjects were randomized to receive liberal or restrictive transfusion regimens. The liberal regimen was a transfusion trigger of 10 g/dL with a target of 10–12 g/dL. The restrictive regimen was a transfusion trigger of 7.0 g/dL with a target of 7.0–9.0 g/dL. The primary result was no statistically significant difference in 30-day mortality, although a trend favoring lower mortality was noted in the restrictive strategy group (18.7% vs. 23.3%; $p = 0.11$). Cardiac events, primarily pulmonary edema and myocardial infarction, occurred more frequently in the liberal than in the restrictive transfusion group (21.0% vs. 13.2%; $p < 0.001$). Subgroup analysis showed lower mortality in the restrictive strategy group among patients with lower disease severity measured by APACHE II scores (8.7% vs. 16.1%; $p = 0.03$) and among patients younger than 55 years of age (5.77% vs. 13.07%; $p = 0.02$). Thus, it appears that many critically ill adult patients can tolerate Hb levels less than 10 g/dL.

Whether the results of the TRICC trial are generalizable to patients with acute coronary syndromes is open to debate. A large retrospective cohort study of patients >65 years of age with acute myocardial infarction has examined the association between admission Hb and 30-day mortality (Wu, 2001). This showed a clear relationship between increasing mortality and lower initial Hb. Furthermore, among patients who received transfusion, lower adjusted odds of 30-day mortality were noted when the admission Hct was less than 33%, whereas the odds of death were higher for transfused patients with admission Hct >36% after adjustment for clinical factors, medication, and predictors of transfusion. These results suggested that red cell transfusion may result in lower short-term mortality among elderly patients with acute myocardial infarction who survived at least 2 days, if the Hct on admission is 30% or lower. However, inherent drawbacks of the retrospective study design, such as survivor bias, limit the conclusions that can be drawn from this study. An analysis of transfusion effects on 30-day mortality in patients with acute coronary syndromes presented somewhat different results (Rao, 2004). This was a reanalysis of three interventional drug trials with the primary outcome measure being 30-day mortality. Ten percent of subjects in the study were transfused. Transfused subjects were more likely to have comorbidities, including a higher Killip class, than nontransfused subjects. Cumulative mortality among transfused subjects was greater than in nontransfused subjects ($p < 0.001$). For subjects with a nadir Hct of 20%, no statistically significant difference in odds of death was observed between transfused and nontransfused individuals.

The recent Transfusion Trigger Trial for Functional Outcomes in Cardiovascular Patients Undergoing Surgical Hip Fracture Repair (FOCUS) addressed the red cell transfusion trigger in surgical patients with cardiac disease (Carson, 2006). The goal of this randomized clinical trial was to determine whether a more aggressive transfusion strategy in patients with cardiovascular disease or cardiovascular disease risk factors undergoing surgery for repair of hip fracture is associated with improved functional recovery and decreased risk of adverse postoperative outcomes. Subjects were randomly allocated to a 10 g/dL transfusion threshold or a symptomatic strategy. The study population consisted of patients 50 years of age or older who underwent surgical repair of a hip fracture, with Hb concentrations below 10 g/dL within 3 days after surgery, and who had clinical evidence of cardiovascular disease or cardiovascular risk factors. The primary outcome measure was ability to walk 10 feet (or across a room) without human assistance at 60 days after randomization, and the major secondary outcome measure was in-hospital acute coronary syndrome or death within 30 days. The FOCUS trial enrolled more than 2600 subjects, making it the largest and best powered clinical trial to date in transfusion medicine. The results of this trial will likely have a major impact on red cell transfusion in the surgical patient.

Transfusion of the patient with sickle cell disease (SCD) presents unique challenges. The indications for transfusion are to augment oxygen-carrying capacity in severe anemia and to improve microvascular circulation by decreasing the proportion of sickle red cells. Oxygen delivery in

TABLE 36-4

Red Cell Transfusion Guidelines

Symptomatic anemia in a euvolemic patient
Acute blood loss of >15% of estimated blood volume
Preoperative Hb <9.0 g/dL with expected blood loss >500 mL
Hb <7.0 g/dL in a critically ill patient
Hb <8.0 g/dL in a patient with an acute coronary syndrome
Hb <10.0 g/dL with uremic or thrombocytopenic bleeding
Sickle cell disease:
Acute sequestration: Hb <5.0 g/dL or decrease of 20% from baseline
Acute chest syndrome: Target Hb = 10 g/dL, HbS fraction <30%
Stroke prophylaxis: Target HbS fraction <30%
General anesthesia: Target Hb = 10.0 g/dL, HbS fraction <60%

Hb, Hemoglobin.

TABLE 36-5

Platelet Transfusion Guidelines

Thrombocytopenia due to decreased production
Stable patient: platelet count <10,000/ μ L
Fever: platelet count <20,000/ μ L
Bleeding, invasive procedure, or surgery: platelet count <40,000–50,000/ μ L
Retinal or central nervous system (CNS) bleeding: platelet count <100,000/ μ L
Microvascular bleeding due to platelet dysfunction

SCD represents a balance between oxygen-carrying capacity and blood viscosity. Optimal oxygen delivery is usually achieved when the posttransfusion Hct is about 30% (Schmalzer, 1987). No universally accepted laboratory parameters are available for transfusion in SCD. Hb values less than 5 g/dL and an acute drop of 20% from baseline during an acute illness are general indications for red cell transfusion. Acute splenic sequestration can produce sudden hypovolemia and cardiovascular collapse, necessitating prompt transfusion. In this setting, the rise in Hb following transfusion may be greater than expected because of release of sequestered red cells. Careful monitoring is essential to avoid overtransfusion (Powell, 1992). Acute chest syndrome may be life threatening. Prompt transfusion may prevent progression to respiratory failure (Mallouh, 1988). Exchange transfusion with a goal of achieving Hb S level of 30% or less and Hct of 30% is a typical approach. Long-term transfusion therapy can reduce the risk of stroke in SCD. In children, transfusion with the goal of maintaining Hb S levels below 30% can reduce the risk of stroke (Adams, 1998). How long a chronic transfusion regimen must be maintained is an open question. Termination, even after several years of therapy, can result in reversion to high risk of stroke (Adams, 2004). Before general anesthesia is administered, transfusion is indicated to achieve an Hb of 10 g/dL and an Hb S level of approximately 60% (Vichinsky, 1995). In uncomplicated pregnancy, prophylactic red cell transfusion is not beneficial. However, transfusion may be indicated in high-risk pregnancy or with a history of previous fetal loss (Seoud, 1994).

In autoimmune hemolytic anemia, transfusion may be indicated if cardiac or neurologic symptoms are present. Most patients with autoimmune hemolytic anemia tolerate transfusion of incompatible red cells, if alloantibodies have been excluded (Salama, 1992). Transfused red cells usually are not cleared any more rapidly than the patient's own red cells. It is important to note that a necessary red cell transfusion must never be withheld because of cross-match incompatibility. It is far more dangerous not to give such a transfusion to a patient with autoimmune hemolytic anemia than it is to provide it.

Red cell transfusion may be beneficial in bleeding associated with uremia. An inverse relationship between Hct and bleeding time has been noted in patients with chronic renal failure. Transfusion to an Hb of 10 g/dL may be beneficial in the bleeding uremic patient (Fernandez, 1985).

Transfusion of one unit of RBCs to an adult patient can usually be expected to raise the Hb by 1 g/dL and the Hct by 3%. However, the expected Hct increase may range from about 2%–9%, depending on the patient's vascular volume (Gorlin, 2000).

Platelet Transfusion

Platelet transfusion is indicated for prevention or treatment of hemorrhage due to thrombocytopenia or platelet dysfunction, as summarized in Table 36-5. Prophylactic transfusion is indicated when the platelet count is lower than 5000/ μ L. For stable patients undergoing chemotherapy, a prophylactic platelet transfusion threshold of 10,000/ μ L is often used (Rebulla, 1997). The goal of prophylactic therapy is to achieve platelet counts above 25,000/ μ L (Schlossberg, 2003). If the patient is febrile, a threshold for prophylactic transfusion of 20,000/ μ L is typically used. For bleeding patients, or for those undergoing an invasive procedure, including endoscopy or surgery, the goal of platelet transfusion therapy is to achieve sustained levels above 40,000–50,000/ μ L (British Committee for Standards in Haematology, Blood Transfusion Task Force, 2003). This usually ensures hemostasis, although it may take longer than normal to achieve. For this reason, for patients experiencing bleeding in critical spaces, such as the retina or central nervous system, a target of 100,000/ μ L is the standard of practice, as this level typically ensures no abnormal delay in hemostasis. In bleeding associated with platelet dysfunction, or thrombocytopenic bleeding associated with coagulopathy, there is no single transfusion threshold, and therapy must be guided by the patient's clinical

condition. Cardiopulmonary bypass may result in a transient acquired platelet dysfunction that may manifest as microvascular bleeding. The platelet count is not usually a useful indicator in such situations. Prophylactic platelet transfusion in routine cardiopulmonary bypass is not indicated.

The recent Prophylactic Platelet Dose (PLADO) trial addressed the optimal prophylactic platelet dose in patients with hypoproliferative thrombocytopenia from stem cell transplantation or chemotherapy (Slichter, 2010). Subjects were randomized to one of three arms: a low platelet dose of 1.1×10^{11} platelets/ m^2 (half the medium dose), a medium dose of $2.2 \times 10^{11}/m^2$, or a high dose of $4.4 \times 10^{11}/m^2$ (twice the medium dose). The primary outcome measure was the percentage of patients in each dose arm who had at least one episode of World Health Organization (WHO) grade 2 or higher bleeding. The incidence of grade 2 bleeding, higher grade bleeding, and other adverse events was similar among the three groups. The median number of platelets transfused in the low-dose group was significantly lower than in the other groups, but the number of platelet transfusions was higher. Bleeding events were more common on days when the platelet count was 5,000/ μ L or lower, regardless of treatment assignment. This trial demonstrated that low-dose prophylactic platelet transfusion is safe in hypoproliferative thrombocytopenia, but may not reduce total platelet transfusions.

The platelet transfusion is relatively contraindicated in immune thrombocytopenic purpura. In this setting, posttransfusion platelet survival is extremely brief, and platelet transfusion is indicated only if there is severe hemorrhage. Clearly, transfusion in the setting of intravascular platelet consumption should be undertaken with great caution. Platelet transfusion in heparin-induced thrombocytopenia or thrombotic thrombocytopenic purpura can be deleterious (Harkness, 1981; Gordon, 1987).

Transfusion of one apheresis platelet unit, or an equivalent pool of whole blood-derived platelet concentrates, can typically be expected to raise the platelet count of an adult by 20,000–40,000/ μ L. As a practical matter, it can be estimated that approximately 1 hour post transfusion, the blood platelet count should increase by 8000–10,000/ μ L for each 1×10^{11} platelets transfused for each square meter of body surface area (Strauss, 1995). However, there are many reasons why this increment may not be achieved. Consumption or bleeding, splenomegaly, platelet antibodies, and drugs are all causes of a poor response to platelet transfusion. Drugs that can cause an inadequate platelet increment include antibiotics, heparin, antiplatelet agents (clopidogrel, tirofiban), quinidine, and antithymocyte globulin, along with many others. In assessing platelet transfusion effectiveness, it is useful to take into account dose and body size by calculating the corrected count increment (CCI).

$$CCI = \frac{\text{Platelet count increment} \times BSA}{\text{Number of platelets transfused} (\times 10^{11})}$$

where BSA is the body surface area (m^2).

Example

Pretransfusion platelet count = 8000/ μ L
 Posttransfusion platelet count = 36,000/ μ L
 BSA = 1.5 m^2
 Platelet dose = 3.0×10^{11}

$$CCI = \frac{24,000 \times 1.5}{3} = 12,000$$

A CCI >7500 at 1 hour or a CCI >4500 at 24 hours generally indicates a successful transfusion. Obtaining a platelet count within 1 hour of completing the transfusion may be helpful in distinguishing immune from nonimmune causes of platelet refractoriness. Typically, immune refractoriness will result in an inadequate platelet increment when measured at 1 hour. Typical nonimmune refractoriness will manifest as an adequate CCI at 1 hour but shortened survival time, so that the platelet count by 24 hours may be back to baseline. It must be appreciated that the CCI does not indicate that an adequate platelet count has been achieved. It indicates only the adequacy of a platelet count increment in relation to the number of platelets transfused.

Plasma Transfusion

Guidelines for plasma transfusion are summarized in Table 36-6. Plasma may be used to replace any plasma protein deficiency. Purified protein concentrates, such as factor VIII, albumin, or immunoglobulin, are preferable for replacement of specific deficiencies because these are highly

purified and standardized, and carry extremely low risk of infectious disease transmission. Plasma is most commonly used for replacement of coagulation factor deficiencies when no factor concentrate is available. Multifactorial deficiencies are common in liver disease, massive bleeding, multiorgan system failure, and warfarin therapy. The degree to which factor deficiency may contribute to bleeding in such cases is controversial. Standard coagulation tests such as prothrombin time (PT) and activated partial thromboplastin time (APTT) are commonly used to assess the need for plasma transfusion; however, these tests are poorly predictive of bleeding risk. In general, if the PT and APTT are less than 1.5 times the midpoint of the reference range, no benefit will be obtained from plasma transfusion. If the international normalized ratio (INR) is used, in general, no benefit will be derived from plasma transfusion if it is less than 1.5, although for nervous system and retinal hemorrhage, plasma may be reasonably used unless the INR is less than 1.3. For maximal hemostatic effect, plasma should be transfused immediately before an invasive procedure is performed. For the bleeding patient, plasma transfusion may have to be repeated every 3–4 hours to maintain adequate coagulation factor levels. In general, a dose of 10–20 mL per kilogram is necessary to achieve a hemostatic effect. Plasma is the preferred choice for rapid reversal of warfarin, although factor IX complex concentrate is also effective (Boulis, 1999). Plasma is a source of vWF protease activity, which may be deficient in thrombotic thrombocytopenic purpura.

Cryoprecipitate Transfusion

General guidelines for the transfusion of cryoprecipitate are summarized in Table 36-7. Cryo can be used for factor VIII or vWF replacement. High purity or recombinant factor concentrates, however, are better alternatives. Cryo is a good source of fibrinogen and factor XIII. Most patients with hypofibrinogenemia also have deficiencies of other coagulation factors and are better treated with FFP. Some evidence suggests that cryo may be effective in the treatment of uremic bleeding, possibly by providing high molecular weight forms of the vWF (Triulzi, 1990). Desmopressin (DDAVP) is a preferred therapy for this situation, however. DDAVP may become ineffective after repeated short-term use, at which point cryo transfusion could be initiated. Cryo, when mixed with calcium and thrombin, can be used to make a topical fibrin sealant for surgery, although more concentrated, virally inactivated commercial products are available. Each unit of cryoprecipitate can be assumed to contain at least 80 units of factor VIII activity and 250 mg of fibrinogen, although the actual content is variable.

MASSIVE TRANSFUSION

Massive transfusion, usually defined as replacement of one blood volume within 24 hours, necessitates a systematic approach. Large-volume blood loss is often due to trauma but also occurs in gastrointestinal hemorrhage (particularly with chronic liver disease), ruptured aortic aneurysms, and

some surgical procedures such as liver transplantation. No single massive transfusion protocol will be optimal for all patients, although establishing an institutional policy is helpful because these cases can become chaotic. Special attention should be paid to patient and sample identification to avoid transfusion errors.

The priorities in transfusion management of massive bleeding are prevention or treatment of hypovolemic shock, maintenance of adequate oxygen-carrying capacity, maintenance of oncotic pressure, correction or prevention of coagulopathy, and avoidance of adverse effects of transfusion. Initial patient evaluation should include pertinent medical history (especially liver, kidney, cardiovascular, and hematologic diseases), history of previous transfusions or pretransfusion testing problems, examination for microvascular bleeding, complete blood count (CBC), and coagulation profile (PT, APTT, fibrinogen). Note that in hypovolemia, the CBC will underestimate blood loss. A sample for pretransfusion testing should be obtained and processed as soon as possible. Initial resuscitation is usually provided with crystalloid fluids. Red cell transfusion should be considered if greater than 15% loss of estimated blood volume (about 1000 mL in a typical adult) occurs with ongoing bleeding. RBC transfusions should be fully crossmatched if possible; however, the patient should not suffer adversely for want of serologically compatible RBCs. Transfusion can be started with group O uncrossmatched RBCs. If the patient's Rh type is unknown, Rh(D)-negative RBCs are preferable, especially for females with childbearing potential.

Coagulopathies may occur during massive transfusion as the result of dilution, consumption, or dysfunction. During resuscitation with RBCs and fluids, measured factor levels and platelet counts are often higher than would be expected on a purely dilutional basis (Counts, 1979; Murray, 1995), with considerable variation between patients. Consumptive coagulopathies occur with DIC, burns, brain injury, hyperthermia, and sepsis. These usually manifest by prolonged PT and APTT, lower than expected fibrinogen and platelet counts, and the presence of fibrin degradation products or D-dimers. Platelet or coagulation factor dysfunction can occur in hypothermia, acidosis, liver disease, or renal failure.

No single protocol has been established for plasma or platelet transfusion in massive bleeding. However, in retrospective studies, several protocols have been associated with improved outcomes (Cotton, 2009; Dente, 2009; Riskin, 2009). Such protocols call for transfusion of RBCs, plasma, and platelets in fixed ratios. Several retrospective studies in both military and civilian acute trauma resuscitation have suggested that more aggressive plasma transfusion is associated with lower mortality and improved outcomes (Holcomb, 2008; Cotton, 2009; Zehtabchi, 2009; Zink, 2009; Mitra, 2010). However, many confounding factors in these studies make causal inference problematic. Lacking randomized clinical trials, it is not possible to say definitively that a protocol-driven approach is superior to individualized clinical judgment. In a laboratory-driven approach, plasma is typically given if PT or APTT is greater than 1.5 times the reference range, and platelets are typically given for counts less than 50,000. It may be prudent to reserve platelet transfusion until after surgical control of major bleeding has been attained because it is likely to be ineffective during rapid blood loss. Cryoprecipitate may be given if the fibrinogen is less than 100 mg/dL, but hypofibrinogenemia is usually accompanied by deficiency of other factors, so plasma is often a better choice. Therapy is best guided by frequent assessment of coagulation parameters.

Complications of massive transfusion include hypothermia, hypocalcemia, and acid-base disorders. Hypothermia can be avoided with the use of high-flow warming devices. When the transfusion rate exceeds about 100 mL/minute, a clinically significant drop in ionized calcium may occur as the result of accumulation of citrate, and calcium supplementation may be indicated. Liver disease, hypotension, and hypothermia may exacerbate hypocalcemia. Monitoring the corrected QT interval is useful. Measurement of total calcium will not accurately indicate the level of ionized calcium. During rapid transfusion of RBCs, a modest decrease in arterial pH may be seen (Vretzakis, 2000); metabolic alkalosis is common after massive transfusion because of metabolism of citrate.

NEONATAL AND PEDIATRIC TRANSFUSION

Neonates particularly receive RBC transfusions because of anemia of prematurity, HDN, or iatrogenic blood loss. The unique physiology of the neonatal period and the relative fragility of the developing brain vasculature necessitate some differences from the approach to older children or adults. Guidelines for neonatal transfusion are summarized in Table 36-8. RBC transfusion of 15 mL/kg will typically increase the Hb by 2–3 g/dL, and platelet transfusion of 10 mL/kg will typically increase the platelet

count by 40,000–50,000/μL. For large-volume transfusion, as in exchange transfusion or cardiac surgery, selection of fresh RBCs (typically <10 days old) may be indicated. However, with transfusion of 15 mL/kg, most infants tolerate transfusion of RBCs stored until outdate, without adverse effects (Strauss, 1996). For a premature infant with an expected ongoing transfusion requirement, the use of aliquots of a single unit until outdate can significantly reduce donor exposures. Premature and low-birthweight infants are at greater risk of CMV infection and graft-versus-host disease (see later).

Exchange transfusion of the neonate for hyperbilirubinemia is usually indicated if the total bilirubin is greater than 25 mg/dL. Relating the total bilirubin to hours since birth is predictive of kernicterus risk (Bhutani, 1999). A two-blood volume exchange is typically used, which can be expected to reduce the total bilirubin by 25% and the fetal red cell mass by about 70%. Whole blood or RBCs reconstituted with compatible plasma to Hct of 45% can be used.

TRANSFUSION REACTIONS

Transfusion reactions are a diverse group of adverse reactions to transfusion that usually present during or shortly after transfusion. The workup and treatment of a transfusion reaction must be predicated on the clinical picture, especially in atypical cases. If a transfusion reaction occurs while a transfusion is in progress, the transfusion should be stopped immediately, and the intravenous line should be kept open with saline. It is important to recognize that the unit a patient is reacting to is not necessarily the one that is being infused. All suspected transfusion reactions should be reported to the blood bank or transfusion service.

FEBRILE NONHEMOLYTIC REACTIONS

A febrile transfusion reaction is defined as a rise in temperature of 1° C or greater, possibly accompanied by chills or rigors. Symptoms usually occur during the transfusion but may be delayed for up to 1 hour after the procedure has been completed. A patient who is hypothermic at the start of a transfusion and then manifests an expected temperature rise to normal, without symptoms, is not having a febrile reaction. In some patients, it may be impossible to distinguish between a febrile transfusion reaction and disease-related fever.

It is important to rule out a hemolytic transfusion reaction or bacterial contamination of the unit. Antipyretics, such as acetaminophen (325–500 mg) can be administered. Antipyretics are not necessarily required, as the fever of nonhemolytic transfusion reactions is self-limited and usually resolves within 2–3 hours. Diphenhydramine (50–100 mg) is commonly administered in this setting but probably has no effect on the course of febrile reactions.

Controversy continues as to whether the transfusion can be restarted after a reaction has been diagnosed and the patient has been treated. The principal argument in favor of restarting the transfusion is the reduction in the number of donor exposures, especially if pooled platelet

concentrates are involved (Oberman, 1994). Arguments against restarting the transfusion include the possibility that the patient may have a continued febrile reaction to the unit, and, if a hemolytic reaction or bacterial contamination has not been definitely excluded, a severe reaction may ensue (Widmann, 1994). The decision to restart the transfusion should be driven by the clinical condition of the patient and the results of transfusion reaction testing.

Premedication with antipyretics is often used to prevent febrile reactions, although the efficacy of premedication has not been established. A randomized, placebo-controlled trial failed to show prevention of febrile reactions by acetaminophen and diphenhydramine, but the number of subjects may have been insufficient to demonstrate a relatively small difference (Wang, 2002).

Some, but not all, studies have shown a reduction in the incidence of febrile reactions since the introduction of universal leukocyte reduction (Uhlmann, 2001; Dzik, 2002; Iboje, 2002). It is clear though that leukocyte reduction does not prevent all febrile reactions. Febrile reactions also have been attributed to the accumulation of pyrogenic cytokines in units during storage (Muylle, 1993). These biological mediators are produced primarily by leukocytes. Febrile reactions to platelet transfusion can be reduced by using platelet concentrates less than 4 days old (Kelley, 2000). Filtration at the time of transfusion will not remove pyrogenic cytokines from blood units, although it may remove other cytokines and activated complement components (Snyder, 1996). The use of prestorage leukocyte reduction has been shown to reduce the generation of cytokines in stored platelets and red cells and may be more effective than poststorage leukocyte reduction in preventing febrile reactions (Federowicz, 1995). Accumulated cytokines can be removed by plasma reduction or the washing of cellular blood components (Heddle, 1994). Plasma removal appears to be equivalent to prestorage leukocyte reduction in prevention of febrile reactions (Heddle, 2002). Plasma removal will not prevent all febrile reactions.

ALLERGIC REACTIONS

Mild allergic reactions to transfusion are commonplace. They may occur with any type of blood component, including autologous RBCs (Domen, 2003). Presenting symptoms include pruritus, urticaria, erythema, and cutaneous flushing. About 10% of allergic reactions have pulmonary signs and symptoms but not cutaneous involvement. Gastrointestinal involvement may include nausea, vomiting, abdominal pain, and diarrhea.

Should an allergic reaction occur, the transfusion should be discontinued and intravenous access maintained. If there is upper airway involvement, prompt intubation may be necessary. Oxygen should be administered if there is dyspnea or evidence of desaturation. Mild allergic reactions usually will respond to intravenous antihistaminics such as diphenhydramine (50–100 mg). More severe reactions may require epinephrine. In mild cutaneous reactions, the transfusion usually can be restarted after treatment without recurrence or worsening of the symptoms. In more serious reactions, particularly if there is airway involvement, restarting the transfusion is not advisable.

With the exceptions of IgA and haptoglobin deficiencies, the specific antigen to which the patient is reacting cannot usually be identified. Premedication with an antihistaminic, such as diphenhydramine, 25–50 mg, administered orally or intravenously, may prevent mild allergic reactions. Steroids such as methylprednisolone (125 mg) may help patients who manifest repeated allergic reactions, although the efficacy of steroids has not been proven.

Patients who have had repeated or significant allergic reactions may benefit from the concentration of cellular blood components through the removal of most of the plasma or by the washing of red cells and platelets. However, the routine use of washed components for patients with cutaneous allergic reactions is unwarranted.

SEVERE ALLERGIC (ANAPHYLACTIC) REACTIONS

In addition to the signs of typical milder allergic reactions, anaphylactic or anaphylactoid reactions manifest cardiovascular instability, including hypotension, tachycardia, loss of consciousness, cardiac arrhythmia, shock, and cardiac arrest. Respiratory involvement with dyspnea or stridor may be more pronounced than is seen usually in typical allergic reactions.

If an anaphylactic reaction occurs, the transfusion should be discontinued and intravenous access maintained. Supportive care, including

intubation, oxygen, intravenous fluids, and placement of the patient in the Trendelenburg position, should be instituted promptly. Epinephrine should be available immediately. For hypotension unresponsive to supportive measures or for significant bronchospasm, subcutaneous epinephrine 0.3–0.5 mg (0.3–0.5 mL of a 1:1000 solution) can be given. This dose can be repeated every 20–30 minutes for up to three doses. Alternatively, 0.5 mg of epinephrine may be given intravenously (5 mL of a 1:10,000 solution) and repeated every 5–10 minutes for refractory hypotension.

An antihistamine such as diphenhydramine, 50–100 mg, can be given intravenously, particularly when there are cutaneous manifestations such as urticaria. Aminophylline (6 mg/kg loading dose) may be useful when there is bronchospasm. Steroids are probably not effective in the acute situation, but if symptoms persist, a drug such as hydrocortisone (500 mg) may be given.

Patients with IgA deficiency who develop anti-IgA can have anaphylactic reactions (Vyas, 1969). Patients who have significant allergic reactions should be evaluated for their quantitative IgA levels. Recent transfusion may elevate serum IgA levels falsely. However, if IgA deficiency has been established, anti-IgA testing should be done, usually by a reference laboratory. IgA-deficient plasma can be obtained from rare donor registries, if necessary. Red cells and platelets can be washed to remove sufficient amounts of IgA to prevent reactions.

Patients with haptoglobin deficiency can have similar anaphylactic transfusion reactions due to IgG or IgE anti-haptoglobin (Shimada, 2002). Haptoglobin deficiency is rare in North American populations but is more common than IgA deficiency among Japanese patients suffering anaphylactic reactions.

ACUTE HEMOLYTIC REACTIONS

Acute hemolytic transfusion reactions (AHTRs), by definition, present within 24 hours of transfusion. Intravascular hemolysis is much more common in acute hemolytic reactions than is extravascular hemolysis. Presenting signs include fever and chills, nausea, vomiting, pain, dyspnea, tachycardia, hypotension, bleeding, and hemoglobinuria. Fever may be the initial sign of an AHTR. Therefore, any increase in temperature of 1° C or greater should result in a red cell transfusion being stopped and a laboratory evaluation initiated. Renal failure is a later complication. Pain during an AHTR has been reported as localizing to the flanks, back, abdomen, chest, head, and infusion site. A subjective feeling of distress is reported sometimes. Unexpected bleeding may be due to DIC. During surgery, hypotension and excessive bleeding may be the only signs of an AHTR. Both may be attributed to other causes; therefore, physicians must be mindful of the possibility of a hemolytic reaction in this circumstance.

Laboratory findings in AHTRs include hemoglobinemia, hemoglobinuria, elevated lactate dehydrogenase, hyperbilirubinemia, and low haptoglobin. The blood urea nitrogen and creatinine will be elevated if renal injury has occurred. The direct antiglobulin test (DAT) may show positive results with a mixed-field pattern if transfused incompatible red cells are present in the circulation. Red cell antibody identification studies may or may not show positive results, depending on the specificity of the antibody involved and the amount of antibody in the serum. ABO incompatibility due to a clerical error is the most common cause of AHTRs.

In the event of an AHTR, the transfusion should be discontinued and intravenous access maintained. The identity of the patient and the unit or units of RBCs should be reconfirmed, and other units of RBCs that have been dispensed for the patient should be located and quarantined. The reaction must be reported to the blood bank promptly. If a misidentification is discovered, another patient (e.g., with a similar name) may also be at risk of receiving incompatible blood.

Treatment of an AHTR must be guided by the clinical response of the patient. Patients who have minimal symptoms may be managed best by careful observation. However, in severe reactions, early vigorous intervention may be lifesaving. It bears repeating that the severity of AHTRs is related directly to the volume of incompatible blood transfused. Thus, early recognition, discontinuation of the transfusion, and prevention of the transfusion of additional incompatible units are the essential first steps of treatment. Initial attention must be paid to cardiovascular support. If hypotension is present, fluid resuscitation and pressor support may be indicated. Care should be taken to avoid fluid overload, however, especially in patients with impaired cardiac or renal function.

Because the load of incompatible red cells in the circulation dictates the severity and course of AHTRs, an exchange transfusion with antigen-negative blood may be considered. Again, the decision to perform an exchange transfusion must be guided by the clinical response of the patient.

It is not appropriate to expose a patient to the added risk of infectious disease if the hemolytic process is well tolerated. With ABO incompatibility, however, an exchange transfusion may greatly reduce the chance of morbidity or death.

Because renal failure is a significant problem in some patients, attention should be given to prevention. Early treatments of hypotension and DIC are the most important interventions to limit the extent of possible renal impairment. Maintenance of urine output with intravenous fluids and diuretics, mannitol or furosemide, early in the course of the reaction has been used successfully. Hydration with normal saline and 5% dextrose (1:1 ratio) at a rate of 3000 mL/m² per day and administration of sodium bicarbonate to maintain the urine pH above 7.0 have been recommended (Nussbaumer, 1995). Infusion of an initial dose of 20% mannitol 100 mL/m² given over 30–60 minutes followed by 30 mL/m² per hour for the next 12 hours has also been recommended (Slavc, 1992). However, if oliguria in the face of euolemia is present, fluid loading may be contraindicated.

Further transfusion of red cells should be avoided until the cause of the reaction has been established. Foremost, however, no patient should be allowed to exsanguinate for lack of serologically compatible blood. Group O RBCs lacking other known clinically significant antigens to which the patient currently has an antibody should be obtained, if possible. The results of serologic tests performed up to this point must be considered, and clinical judgment exercised. Although the focus of attention in most AHTRs is on red cells, care should be taken to avoid the transfusion of plasma or platelets that may aggravate hemolysis, especially when ABO incompatibility is a possible cause. Undue haste in both serologic evaluation and decision-making must be avoided because human errors are committed most often under pressure.

DELAYED HEMOLYTIC REACTIONS

By definition, delayed hemolytic transfusion reactions (DHTRs) occur at least 24 hours after transfusion of the offending unit. The time from transfusion to diagnosis of a DHTR is variable. Most patients present within the first 2 weeks after receiving the transfusion. However, clinical DHTR may be recognized more than 6 weeks later. Almost all DHTRs are due to an anamnestic response to a red cell antigen to which the patient has previously made an antibody, the concentration of which was too low to detect in pretransfusion testing. Rarely, a DHTR may be due to primary alloimmunization to a red cell antigen. Typically, hemolysis is extravascular, but intravascular hemolysis may occur also. Fortunately, these reactions tend to be much less severe than AHTRs; accordingly, they may be overlooked. Some patients will present with only unexpected anemia. Other clinical signs include fever or chills, jaundice, pain, or dyspnea. Rarely renal failure may ensue. In patients with sickle cell disease, DHTRs may precipitate a sickle crisis (Mintz, 1986).

Laboratory findings in DHTRs include anemia, elevated lactate dehydrogenase, hyperbilirubinemia, low haptoglobin, leukocytosis, the presence of a new red cell antibody, and a positive reaction on a DAT. The degree of hyperbilirubinemia will depend on the rate and amount of hemolysis, as well as on liver function. Typically, unconjugated bilirubin levels are elevated during active hemolysis. Depressed haptoglobin levels do not necessarily indicate intravascular hemolysis, as they may be seen with extravascular hemolysis as well.

Many patients tolerate DHTRs well and may need only to be followed carefully. Generally, fluid loading and diuresis are not indicated unless there is active intravascular hemolysis. Complications, such as renal failure or sickle crisis, should be treated as such. If there is a large burden of antigen-positive red cells, an exchange transfusion should be considered. In general, transfusion should be avoided until the causative antibody can be identified and antigen-negative units obtained. However, as with AHTRs, a patient should not be allowed to have significant morbidity from anemia for lack of serologically compatible blood. The selection of red cells for transfusion needs to be based on the results of serologic testing and good communication between the medical director of the blood bank and the patient's physician.

Because extravascular hemolysis is similar to autoimmune hemolytic anemia, in which high-dose intravenous immunoglobulin (IVIG) infusion may be useful, IVIG may be considered in the treatment of DHTRs also. A single dose of IVIG, 400 mg/kg, infused within 24 hours of transfusion, has been used successfully to prevent transfusion reactions in alloimmunized patients for whom compatible blood could not be obtained (Kohan, 1994). Five patients so treated had sustained increases in Hct. No transfusion reaction developed in any of the cases.

BACTERIAL CONTAMINATION OF BLOOD COMPONENTS

The clinical presentation of a transfusion reaction caused by bacterially contaminated blood components is usually dramatic. Onset of symptoms in most cases occurs during the transfusion or shortly after it; delayed presentation of more than 1 day has rarely been reported with contaminated platelet transfusions. Fever, chills, hypotension, shock, nausea, and vomiting are the most commonly reported symptoms (Kuehnert, 2001; Perez, 2001). Dyspnea, pain, and diarrhea also may occur. High fever and hypotension during or shortly after transfusion are particular clues that a contaminated unit may have been transfused. The clinical complications due to bacterial contamination are significant, often resulting in shock, renal failure, DIC, and death. The mortality rate is high and depends on the type of component involved, the identity and amount of the causative organism, and the clinical condition of the patient. Patient factors associated with clinical reactions include thrombocytopenia and pancytopenia. Risk factors for fatality include contamination by gram-negative rods, greater patient age, smaller volume of component transfused, and younger age of stored platelet concentrate. The latter two factors most likely reflect greater numbers of organisms in the component. The organism involved depends on the type and storage of the blood component. RBCs have been found to contain *Acinetobacter*, *Escherichia*, *Staphylococcus*, *Yersinia*, and *Pseudomonas* species. Gram-positive cocci such as *Staphylococcus* and *Streptococcus*, gram-negative rods such as *Acinetobacter*, *Klebsiella*, *Salmonella*, *Escherichia*, and *Serratia*, and gram-positive rods such as *Propionibacterium* have been reported in platelet concentrates (Kuehnert, 2001; Andreu, 2002). Some transfusion services culture for bacteria all platelet concentrates that have caused a febrile transfusion reaction because, if a red cell concentrate from the same donation exists, it can be withdrawn.

Usually, treatment must be initiated before the causative organism has been identified. If a reaction occurs, the transfusion should be discontinued, the unit with its associated tubing should be removed, and any other blood bags that have been recently transfused should be recovered. Supportive care of circulation and respiration should be initiated as required. Antibiotic therapy initially should include broad-spectrum coverage such as a β -lactam and an aminoglycoside until microbiological stains or cultures indicate the causative organism.

AABB standards require that blood banks and transfusion services have methods to detect and limit bacterial contamination of platelets. FDA approved methods include culture, measurement of oxygen consumption, and rapid qualitative immunoassay (AuBuchon, 2002; Ortolano, 2003). Measurements of pH or glucose and inspection for "swirling" have been used as indicators of contamination but are not sufficiently sensitive to meet current AABB standards (Wagner, 1996). Some studies have found that apheresis platelets have a lower incidence of septic reactions than pooled whole blood-derived platelets (Ness, 2001). Because skin flora, if present, enter the collection at venipuncture, diversion of the first 8 mL decreases the risk by 50% (Eder, 2009). Most blood centers culture apheresis platelets and pre-pooled platelets at the time of manufacture. The components then are held for a brief time (typically 12 hours) and are released for distribution if the culture is negative. Although this approach is operationally efficient, it is not optimal in that the culture is taken at a time when the bacterial load is low. The residual risk of a septic reaction with culture-negative apheresis platelets is approximately 1:75,000 (Eder, 2007). A rapid immunoassay has recently been approved by the FDA for detection of bacterial contamination in platelets (Platelet PGD Test, Verax Biomedical Incorporated, Worcester, MA). Although this test holds promise for significantly reducing the risk of septic reactions, this has not yet been shown in peer-reviewed publications. Pathogen reduction technology in the future may significantly reduce, if not eliminate, bacterial contamination.

TRANSFUSION-RELATED ACUTE LUNG INJURY

Transfusion-related acute lung injury (TRALI) usually presents during or within hours of transfusion. Its symptoms include dyspnea, hypoxemia, tachycardia, fever, hypotension, and cyanosis (Kleinman, 2004). Fever and hypotension, when present, are usually moderate and respond quickly to antipyretics and fluids. Characteristically, there is a lack of abnormal breath sounds. A chest X-ray usually shows pulmonary edema. By definition, there are no signs of cardiac failure. Patients with hematologic malignancy or cardiac disease appear to be at higher risk for TRALI (Silliman, 2003).

This may reflect the fact that these patient groups receive the majority of platelet transfusions. Reported mortality is approximately 20%, depending on the severity of the lung injury and the underlying clinical status of the patient. A wide range of severity is seen in this transfusion reaction; milder forms may not be readily recognized.

The differential diagnosis includes circulatory overload, bacterial contamination, allergic reactions, acute respiratory distress syndrome (ARDS), pulmonary embolism, and pulmonary hemorrhage. The diagnosis is established by findings of noncardiogenic pulmonary edema. Pulmonary artery wedge pressure is not elevated. Characteristically, TRALI resolves within 48–96 hours from outset (Popovsky, 1992). Failure of the patient to improve substantially after this time should call the diagnosis into question. Although chest X-ray findings may persist beyond 7 days, unlike with ARDS, no permanent pulmonary sequelae are evident. A decrease in leukocyte or platelet count may be a useful clue in TRALI caused by transfusion of HLA class I antibodies (Cooling, 2002).

The treatment of TRALI is supportive. If a transfusion is in progress, it should be discontinued, and blood bags from recently transfused units should be recovered. The blood bank should be consulted regarding the evaluation of TRALI. Usually, oxygen is indicated. Severely affected patients may require mechanical ventilation. Corticosteroids appear to be of little, if any, value. Diuresis is not indicated in the absence of signs of fluid overload.

TRALI has been attributed to the presence of antibodies in the plasma of the transfused unit that are directed against HLA or granulocyte antigens present on recipient leukocytes (Kopko, 2002). Plasma from multiparous female donors may carry a greater risk of TRALI (Palfi, 2001). It also has been attributed to the presence in the unit of lipid inflammatory mediators that activate already primed recipient neutrophils (from surgery, trauma, or inflammation) to cause capillary injury and leakage (Silliman, 2003).

GRAFT-VERSUS-HOST DISEASE

Transfusion-associated graft-versus-host disease can occur when viable donor T cells proliferate, are not recognized by the recipient's immune system as foreign, but recognize and reject the host as foreign. Patients with marked cellular immunodeficiencies are at risk of TA-GVHD (Table 36-9). These include congenital cellular immunodeficiencies (DiGeorge syndrome, severe combined immunodeficiency syndrome), immaturity of the immune system (intrauterine transfusions, very-low-birthweight infants), disease-associated immunodeficiencies (Hodgkin lymphoma), and therapy-associated cellular immunodeficiencies (hematopoietic progenitor cell transplantation, fludarabine treatment). Humoral immunodeficiencies, such as common variable immunodeficiency (CVID), are not a risk factor for GVHD. HIV infection, although it may cause marked T cell dysfunction, does not increase the risk of TA-GVHD. Common immunosuppressive regimens for solid organ transplantation and typical chemotherapy regimens for solid tumors do not increase the risk of TA-GVHD. However, TA-GVHD has been reported with highly aggressive chemotherapy for neuroblastoma and some other tumors. Patients with normal immunity may be at risk of TA-GVHD if the recipient is homozygous for an HLA haplotype and the donor is heterozygous but shares one haplotype. In this case, recipient lymphocytes are unable to recognize transfused lymphocytes as foreign, but transfused cells see recipient cells as foreign (Fig. 36-1). This is most likely to occur with donations from close (first- or second-degree) relatives but may also occur owing to chance, particularly in populations that are relatively homogeneous (Aoun, 2003).

TA-GVHD typically manifests 2–50 days after transfusion. Characteristic findings include rash, diarrhea, fever, liver dysfunction, and pancytopenia. Mortality is greater than 90%, with most patients dying of infection. In contrast to the expected GVHD of allogeneic HPC transplantation, the bone marrow in TA-GVHD is of recipient type and is a target organ. Aggressive immunosuppressive treatments have been tried but with rare exceptions have been unsuccessful. Thus, preventive measures are of paramount importance.

The minimum number of viable transfused T cells necessary to cause TA-GVHD has not been established, but it is clear that current leukocyte reduction methods are not sufficient (Hayashi, 1993). Exposure to ionizing radiation (γ -rays or X-rays) can cause chromosomal damage and prevent replication of transfused leukocytes. Current FDA guidance suggests a midplane dose of 25 Gy, with a minimum dose of 15 Gy to any point of the blood container (see earlier discussion of special components). It is possible that pathogen reduction technology based on nucleic acid modification may be effective in preventing TA-GVHD, but this remains to be established.

TABLE 36-9

Indications for Irradiation of Blood Components for Prevention of TA-GVHD

Absolute Indications

Congenital cellular immunodeficiency
Hematopoietic progenitor cell transplantation
Hodgkin lymphoma
Granulocyte transfusions
Intrauterine transfusions (IUTs)
Transfusion to neonates who have received IUT
Transfusions from biological relatives
Chemotherapy with purine analogs (fludarabine)

Probable Indications

Low-birthweight infants (<1200 g)
Hematologic malignancies other than Hodgkin lymphoma
HLA-matched platelet concentrates
High-dose chemotherapy, radiation therapy, and/or aggressive immunotherapy

Controversial Indications

Solid organ transplantation
Large-volume or exchange transfusion of infants who did not receive IUT
Aplastic anemia
Absolute lymphopenia (Absolute lymphocyte count <500/mL)

Irradiation NOT Indicated

HIV infection
Hemophilia
Small-volume transfusions of term infants who did not receive IUT
Elderly patients
Typical dose immunosuppressive therapy (other than purine analogs)
Immunocompetent surgical patients
Pregnancy
Red cell membrane, metabolic, or hemoglobin disorders (e.g., thalassemia, SCD)

Adapted from Gorlin JB, Mintz PD. Transfusion-associated graft-vs-host disease. In: Mintz PD, editor. Transfusion therapy: clinical principles and practice. 3rd ed. Bethesda, Md: AABB Press; 2011, p. 650.

HIV, Human immunodeficiency virus; SCD, sickle cell disease; TA-GVHD, transfusion-associated graft-versus-host disease.

HYPOTENSIVE REACTIONS

Transfusion-associated hypotension is defined as hypotension that occurs during transfusion in the absence of signs or symptoms of other transfusion reactions, such as fever, chills, dyspnea, urticaria, or flushing. The degree of hypotension required for the diagnosis is controversial but could be defined reasonably as a drop of at least 10 mm Hg in systolic or diastolic arterial blood pressure from the pretransfusion baseline. However, if the immediate pretransfusion blood pressure is elevated from the patient's typical blood pressure and the arterial pressure does not fall below the patient's usual blood pressure, this should not be considered a hypotensive reaction. Hypotension begins during the transfusion and resolves quickly when the transfusion is discontinued. If hypotension persists beyond 30 minutes after discontinuation of the transfusion, another diagnosis should be strongly considered. Hypotensive reactions have been associated with red cell and platelet transfusions. Some reactions have been associated with the use of leukocyte reduction filters (Fried, 1996; Abe, 1997).

If hypotension occurs, the transfusion should be discontinued and intravenous access maintained. The patient should be positioned with head down and feet elevated (Trendelenburg position), and isotonic fluids should be administered. Pressor support is indicated only if the hypotension is severe and refractory to intravenous fluids.

The cause of transfusion-associated hypotension has not been established definitively. However, the condition is most likely due to the release of bradykinin through activation of the contact pathway of coagulation. Some reactions have been associated with angiotensin-converting enzyme (ACE) inhibitor drugs in the recipient and/or the use of leukocyte reduction filters. ACE is the major enzyme that breaks down bradykinin in the circulation. Some filters, particularly those with a net-negative surface charge, appear to cause activation of kallikrein and cleavage of high

Figure 36-1 Mechanism of TA-GVHD in immunocompetent patients. The donor is homozygous at the HLA class I locus. The recipient is heterozygous and shares one haplotype with the donor. Engrafted donor T cells recognize the recipient as foreign, but the recipient's T cells do not identify donor T cells as foreign. (HLA, Human leukocyte antigens; TA-GVHD, transfusion-associated graft-versus-host disease.)

molecular weight kininogen, which results in the release of bradykinin (Davenport, 1997; Shiba, 1997; Mair, 1998). However, there is variability because not all such filtered units show activation.

NONIMMUNE HEMOLYSIS

Lysis of red cells can occur as a result of storage, handling, or transfusion conditions. Hyperosmotic or hypo-osmotic fluids mixed with red cells can result in significant lysis. Patients who receive lysed red cells may tolerate them remarkably well. However, transient hemodynamic, pulmonary, and renal impairment may occur, and death due to transfusion of lysed red cells has been reported (Sazama, 1990). The transfusion of autologous blood from a patient with sickle Hb can result in hemolysis and death (DeChristopher, 1990). The clinical signs are usually hemoglobinemia and hemoglobinuria. Hyperkalemia may occur, particularly in patients with renal failure. Fever also may occur. Finding lysis of RBCs in the transfused unit and excluding other causes, such as hemolytic transfusion reactions, establishes the diagnosis. All RBC units will show a slight degree in hemolysis with prolonged storage, but this will not result in clinical signs after transfusion. The principal reported complications of nonimmune hemolysis are renal failure and cardiac arrhythmia due to hyperkalemia. Hemolytic transfusion reactions can rarely occur when no red cell antibody is identifiable (Davey, 1980). Differentiation of this condition from nonimmune hemolysis may be impossible without careful investigation of the transfusion circumstances.

Should nonimmune hemolysis occur, the transfusion should be discontinued and intravenous access maintained. The blood bag, together with attached tubing and intravenous fluids, should be saved for further investigation. A hemolytic transfusion reaction needs to be ruled out. The serum potassium level should be checked and an electrocardiogram obtained to assess hyperkalemia. Care is supportive. Urine output should be maintained with hydration unless there is a contraindication such as renal failure.

TRANSFUSION-ASSOCIATED CIRCULATORY OVERLOAD

Circulatory overload is an all-too-common and preventable transfusion reaction. It presents as congestive heart failure during or shortly after transfusion. Signs and symptoms can include dyspnea, orthopnea, cyanosis, tachycardia, elevated blood pressure, pulmonary edema, jugular venous distention, pedal edema, and headache. The differential diagnosis includes TRALI, allergic reactions, and causes of congestive failure not related to transfusion, such as valvular heart disease. Clearly, patients with preexisting heart disease are at risk of circulatory overload with transfusion. The diagnosis of circulatory overload on clinical and radiologic examination may be difficult. Elevation of brain natriuretic peptide can be helpful in making the diagnosis (Zhou, 2005; Tobian, 2008).

TABLE 36-10

Approximate Current Per-Unit Risks of Infectious Disease Transmission

HIV	1:1,467,000
HBV	1:280,000–1:357,000
HCV	1:1,149,000
HTLV-I/II	1:641,000–1:1,900,000
West Nile virus	≈1:7,000,000

Data from Busch (2005), Zou (2009) and Zou (2010).

HBV, Hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HTLV, human T cell lymphotropic virus.

Volume overload should be anticipated in at-risk patients and prevented readily. Blood should be transfused slowly. Although a transfusion usually should be completed within 4 hours, the duration may be extended if medically indicated. If longer than 6 hours is required, however, alternative strategies should be considered. Small volumes can be transfused with adequate time between transfusions to allow for diuresis. To avoid additional donor exposures, a unit can be split using sterile technique and a portion retained in the blood bank for later transfusion. Units can also be concentrated by plasma removal. A diuretic can be administered before or during the transfusion.

TRANSFUSION-TRANSMITTED DISEASE

Improvements in donor screening and testing have resulted in dramatic reductions in transfusion-transmitted disease risk over the past two decades. For example, the risk of transmitting HIV by blood transfusion in the United States has been reduced from approximately 1 in 100 in certain urban areas in the early 1980s to approximately 1 in 1,500,000 throughout the country at present. It is virtually impossible to accurately measure current risks of hepatitis and HIV transmission by epidemiologic methods. Risk estimates for HIV, HBV, and HCV are now based on mathematical models that take into account the probability of marker-negative window-phase donations, viral strains not reliably detected by current assays, persistent antibody-negative carriers, and testing errors (Dodd, 2002). Current (2010) risk estimates are summarized in Table 36-10.

Hepatitis

Historically, HCV has accounted for the majority of cases of posttransfusion hepatitis (PTH). Approximately 10% of chronic HCV is attributable to blood transfusion (Alter, 1999). PTH is asymptomatic in the majority of cases. Three patterns of transaminase elevation have been observed: monophasic, polyphasic, and plateau (Pastore, 1985). Approximately 75%–85% of individuals have persistent HCV infection, and about 50% of these have evidence of chronic hepatitis. As many as 10% of patients with HCV PTH eventually manifest clinical liver disease (Seeff, 1992). Acute PTH due to HBV is typically more severe, with 25%–30% of individuals having jaundice, and with an incubation time of 40–60 days (Walsh, 1970; Seeff, 1975). Less than 10% of infected individuals progress to chronic hepatitis. If acquired before the age of 5 years, acute HBV infection is usually less severe, but the risk of chronic hepatitis is much greater. Hepatitis D virus (HDV) requires coinfection with HBV for replication. If acquired simultaneously with HBV, HDV can cause severe hepatitis and liver failure. If acquired during chronic HBV infection (superinfection), HDV significantly increases the risk of severe chronic liver disease. Transfusion-transmitted HDV is rare, and screening methods for HBV are also effective against HDV. Hepatitis A virus and hepatitis E virus have relatively short periods of viremia and do not progress to a chronic carrier state. Transmission of these viruses by transfusion is rare but has occurred (Sherertz, 1984; Matsubayashi, 2004). Hepatitis G virus (GBV-C) has a prevalence rate of about 1% in asymptomatic blood donors (Roth, 1997). Although it is clearly transmissible by transfusion, no causal relationship between GBV-C infection and hepatitis or chronic liver disease has been established (Alter, 1997).

Human Immunodeficiency Virus

The clinical manifestations of transfusion-transmitted HIV are similar to those of HIV infection acquired through other routes. An acute viral syndrome occurs in about 60% of cases. Untreated, asymptomatic infection persists for about 10 years before acquired immunodeficiency syndrome (AIDS)-defining illness occurs, although progression tends to be

more rapid in older individuals (Blaxhult, 1990). The time to AIDS progression for transfusion recipients may be shorter than that for the implicated donor, but this may reflect the effects of age and other cofactors (Busch, 1994). Until recently, Group O viral isolates were not reliably detected by enzyme immunoassay (EIA) tests. Currently, the prevalence of group O HIV in the United States is low, but it is endemic in some parts of western Africa, and transfusion-transmission by emigrants from such areas has occurred (Pau, 1996). Therefore, residence in or emigration from such areas has been a reason for permanent donor deferral. However, a combined immunoassay for simultaneous detection of HIV p24 antigen and HIV-1 and HIV-2 antibodies that detects group O HIV has been FDA approved for donor testing (Sickinger, 2008). Blood centers implementing this test can discontinue geographic deferral for HIV group O.

Human T Cell Lymphotropic Virus

Human T-cell lymphotropic virus type I (HTLV-I) is causally associated with adult T cell lymphoma/leukemia and HTLV-associated myelopathy (HAM) (Hall, 1996; Manns, 1999). Most carriers are asymptomatic. ATL or HAM develops in a small minority of cases after a latent period of many years. HTLV-I is rare in the United States. HTLV-II is prevalent in intravenous drug users in the United States and is also associated with HAM (Murphy, 1997). Blood donors who are HTLV-II positive have a higher incidence of acute bronchitis, pneumonia, bladder or kidney infection, and arthritis; HTLV-I-positive donors have a higher incidence of bladder or kidney infection and arthritis (Murphy, 2004).

Cytomegalovirus

CMV is common in the general population. In immunologically competent individuals, it causes minor symptoms but becomes latent in virtually all cases (Larsson, 1998). Approximately 50% of blood donors are CMV seropositive, although the estimated risk of transmission by a seropositive transfusion is about 1% (Preiksaitis, 1988). In patients with cellular immunodeficiency, CMV can cause pneumonitis, hepatitis, retinitis, and multi-system organ failure. CMV transmission can be minimized by the use of seronegative blood components, although many studies have shown a low rate of CMV infection in such patients. Whether this is due to failure to detect potentially infectious donors or whether viral transmission occurred by other routes is unclear. Several studies, including a prospective randomized trial, have shown that leukocyte-reduced blood components are as effective as seronegative components in reducing the risk of CMV transmission (Bowden, 1995).

Parvovirus B-19

Parvovirus B-19 is also common in the general population. The incidence of viremia among blood donors is variable, with episodic peaks, but it averages around 1:5000 (Hitzler, 2002). In most individuals, parvovirus B-19 causes a mild self-limited febrile illness. However, it is trophic for erythrocyte precursors in the bone marrow and can cause aplasia, particularly in the setting of accelerated erythropoiesis. Transfusion-transmitted parvovirus infection has been implicated in causing chronic anemia after bone marrow transplantation and in thalassemia (Zanella, 1995; Cohen, 1997).

West Nile Virus

West Nile virus (WNV) arrived in the United States in 1999. From its initial outbreak in New York, it has spread across the country. Birds are the natural reservoir, with mosquitoes serving as the vector of transmission. Humans are an accidental host, with infection occurring during times of mosquito activity. Most acute WNV infections are asymptomatic, with a febrile illness occurring in about 1 in 5 infections and neuroinvasive disease in about 1 in 150 infections (Petersen, 2002). In 2002, 23 confirmed cases of transfusion-transmitted WNV were reported by the Centers for Disease Control and Prevention (Pealer, 2003). In areas of peak WNV activity in 2002, the estimated rate of viremia among blood donors was 1.5 in 1000 (Biggerstaff, 2002). Donor screening for WNV by nucleic acid testing (NAT) was implemented in July of 2003 in North America. Subsequently, rare cases of WNV transmission by blood transfusion have been reported, most likely due to the low viral copy number that escaped detection (Macedo de Oliveira, 2004).

Malaria

About 1300 cases of malaria are reported annually in the United States. Transfusion-transmission of malaria still occurs rarely (1–2 cases annually). Implicated donors usually have a history of travel to an endemic area (Mungai, 2001).

Babesiosis

Babesia species are endemic in North American mammals and are transmitted by ticks of the genus *Ixodes*. Many cases of babesiosis are asymptomatic or mild. However, it may be more severe in the asplenic or immunosuppressed patient. The parasite is capable of survival in refrigerated red cells. About 40 cases of transfusion-transmitted babesiosis have been reported in the United States, although it is possible that transmission in endemic areas may be as high as 1 in 1800 red cell units (Cable, 2001; Lux, 2003).

Trypanosoma cruzi

T. cruzi is the cause of Chagas' disease and is endemic in parts of Central and South America. There may be 50,000–100,000 chronic carriers of *T. cruzi* in the United States, largely as the result of immigration (Kirchhoff, 1987). Rare cases of transfusion-transmitted Chagas' disease have been reported in the United States (Nickerson, 1989). The risk is dependent on the demographics of the donor population. Seropositivity rates among blood donors have been estimated to be 1:25,000 nationally and as high as 1:2000 in Los Angeles (Leiby, 2002; Centers for Disease Control and Prevention, 2006–2007). Since the FDA approval of a donor screening EIA test, more than 1000 confirmed positive donors have been detected in the United States (AABB Chagas Biovigilance Network, 2010). Estimates of the residual risk of transfusion-transmitted Chagas' disease since implementation of donor testing in the United States have not been published to date.

Transmissible Spongiform Encephalopathies

Transmissible spongiform encephalopathies are caused by a protein, called a prion, that is capable of assuming an abnormal configuration that is

resistant to enzymatic degradation and serves as a template for further abnormal prion deposition. Variant Creutzfeldt-Jakob disease (vCJD) is a human TSE that emerged from an epidemic of bovine spongiform encephalopathy, probably as a result of entry of the pathogenic prion into the human food supply from affected cattle. The transmissibility of vCJD by blood in experimental models suggests a possible risk of transmission by transfusion. The magnitude of such a risk is presently unknown. However, four cases of prion acquisition have been reported in individuals who received transfusions from donors who were themselves diagnosed with vCJD (Chohan, 2010). However, it is notable that no cases of transfusion transmission of sporadic or familial CJD have been found to date, despite ongoing surveillance (Dorsey, 2009).

CONCLUSION

Discovery of the A, B, and O blood groups by Carl Landsteiner in 1900 led to the widespread use of blood transfusion therapy early in the 20th century. This treatment directly afforded a remarkable evolution in surgical, trauma, and medical care. Although remarkable progress has been made in identifying and reducing transfusion-transmitted infection, the incidence of the principal noninfectious risks—TRALI and mistransfusion due to clerical error—has remained stable for many years. Increasing attention has been focused recently on these latter hazards, and it is hoped that this will lead to a substantial reduction in their occurrence. Despite the continuing risks of transfusion, a much greater threat is posed by withholding a blood component that is clinically indicated than by transfusing it.

KEY POINTS

- Hemapheresis is the process of removing normal or abnormal components from circulating blood.
- Cytopheresis involves the removal of cellular components; plasmapheresis involves the removal of plasma, the liquid component.
- Separation of the blood components is based on size (filtration instruments), density (centrifugation instruments), or a combination of both.
- Donor apheresis maximizes the collection of a scarce resource by allowing donors to donate only what is needed, returning the remaining components back to the donor.
- Donor apheresis is highly regulated. Donor eligibility requirements, frequency of donation, and amount of product allowed to be collected vary according to the components being collected, the instruments being used for the collection, and the frequency of the apheresis donations.
- Hematopoietic progenitor cell-apheresis collection has advantages over hematopoietic progenitor cell-marrow harvest, including faster time to engraftment, avoidance of general anesthesia for the donor, quicker donor recovery, and decreased expense.

- There is a dearth of randomized placebo-controlled clinical trials involving apheresis. To address this, the American Society for Apheresis categorizes diseases treated with apheresis according to the strength of the evidence supporting its use.
- Therapeutic cytoreduction for leukocytosis or thrombocytosis is indicated for primary disorders where symptoms of hyperviscosity or risk factors for complications are present.
- A 1–1.5 plasma volume plasma exchange will remove 70% of a substance located within the plasma. The treatment of additional plasma volumes results in the removal of a fixed percentage of the remaining substance, leading to diminishing returns in treating greater than 1.5 plasma volumes.
- Plasma exchange is nonselective, removing pathologic substances as well as beneficial substances such as coagulation factors and protein-bound drugs.
- Complications of donor apheresis are less common than complications seen with whole blood donation, although the rate of reactions requiring hospitalization has been reported to be greater.

Continued

- The most common reactions to donor apheresis, in decreasing frequency, are hematoma/pain; hypocalcemia due to the citrate anticoagulant; vasovagal reactions with syncope; and vasovagal reactions without syncope.
- Complications have been reported to occur in approximately 5% of patients undergoing therapeutic apheresis treatments. If complications due to central venous access placement are included, the complication rate has been reported to be 17%.
- The most common reactions due to therapeutic apheresis procedures, in decreasing frequency, are transfusion reactions from replacement fluids; hypocalcemia due to citrate anticoagulant; hypotension; vasovagal reactions; tachycardia; respiratory distress; tetany/seizure; and rigors/chills.

OVERVIEW

DEFINITIONS

The word **apheresis** is derived from the Greek word “aphaeresis,” which means “to separate,” “to take away by force,” or “to remove.” Hemapheresis is the process of removing normal or abnormal blood constituents from circulating blood. It can be divided into cytapapheresis, removal of the cellular component of blood, and plasmapheresis, removal of the plasma fraction. Cytapheresis can be selective with removal of red blood cells (erythrocytapheresis), platelets (plateletapheresis), or white blood cells (leukocytapheresis). If the red blood cells removed during an erythrocytapheresis are replaced with donor red blood cells in a therapeutic procedure, this is referred to as a red blood cell exchange. When a plateletapheresis procedure is performed as a therapeutic procedure, it is referred to as a thrombocytapheresis. If during a plasmapheresis procedure the removed plasma is replaced with a replacement fluid, the procedure is referred to as a plasma exchange. It is important to realize that the terms **plasmapheresis** and **plasma exchange** are not equivalent, even if they are commonly used in this way.

BASIC PRINCIPLES

All of the early apheresis instruments separated whole blood into its components by centrifugation. Centrifugal force is applied to whole blood such that the various components separate according to their specific gravity (density), with the most dense component layering the farthest from the axis of rotation and the least dense layering closest. Those components with intermediate densities would layer in between in order of increasing density. The order of density of blood components from least to most dense is shown in [Figure 37-1](#) as follows: plasma, platelets, lymphocytes,

granulocytes, and red blood cells (Burgstaler, 2010). Some mixing does occur at the interfaces of the various layers, resulting in some contamination with components of the adjacent layers. For example, red cells are present within the granulocyte layer and vice versa.

Centrifugation separators can be divided into two classes: intermittent flow and continuous flow centrifuges. In intermittent flow centrifuges, the bowl is filled with the whole blood to be separated and centrifugal force is applied. After the components are separated, the component of interest is removed. The centrifuge is then stopped and the bowl is emptied with contents returned to the patient/donor. The cycle is then repeated with whole blood being processed in discrete batches. In continuous flow centrifuges, each of the individual component layers is removed, with the layer of interest being retained, while the others are mixed together outside of the separation chamber and returned. This means that as volume is removed from the separation chamber, it can be continually replaced by whole blood, resulting in continuous separation. The chamber is not emptied until the entire procedure has been completed (Burgstaler, 2010).

In addition to centrifugation, apheresis can be accomplished by filtration. In this method, components of whole blood are separated based not on density but on size. The whole blood flows over a membrane containing pores that are of a size such that only the component of interest can pass through. The remaining elements are then returned. These separators may be hollow fiber or flat plate systems. The former consists of bundles of tubes containing pores within their walls. The blood enters into the tubes with the plasma exiting through the pores, where it is then collected, while the cellular elements exit from the opposite end of the tubes. The flat plate separators consist of two porous membranes. Whole blood flows between the membranes with the cellular elements being retained and collected at the opposite end of the plates, while the plasma passes through the membranes and is collected from the exterior surface of the plate (Burgstaler, 2010).

Centrifugation and filtration can be combined. In these instruments, blood enters a stationary chamber containing a central rotating filter. As the filter rotates, the blood begins to move and separate into layers. The result is that the more dense elements move away from the filter with the plasma being located directly adjacent to the filter. The plasma can then pass through the filter and can be drawn off while the cellular elements are collected from the periphery of the stationary chamber. The advantage of the combination of centrifugation and filtration in this arrangement is that the cellular elements cannot clog the pores of the filter. This means that filters with smaller surface areas, in comparison with filtration instruments, and lower *g* forces, in comparison with centrifugation instruments, can be used (Burgstaler, 2010).

Another basic aspect of apheresis involves determining the blood volume of the donor/patient. This is necessary because of the need to limit the amount of blood within the instrument and tubing connected to the donor/patient—the extracorporeal circuit—to avoid hypotension and complications. Previously, Standards for Blood Banks and Transfusion Services limited the extracorporeal blood volume for donors to 15% of total blood volume (Standards Committee of the American Association of Blood Banks, 1997). It was therefore necessary to determine the donor's blood volume. This is most often accomplished through nomograms or as a calculation performed by the instrument used for the procedure. This requires the input of donor/patient-specific data by the instrument operator, typically height, weight, gender, and hematocrit (Hct). A number of equations and rules are available for this determination (Nadler, 1962; Gilcher, 1996). For example, [Equations 37-1 and 37-2](#) can be used to determine blood volume in males and females, respectively (Nadler, 1962):

$$\text{Males: } BV = (0.3669 \times H^3) + (0.03719 \times W) + 0.6041 \quad (37-1)$$

$$\text{Females: } BV = (0.3561 \times H^3) + (0.03308 \times W) + 0.1833 \quad (37-2)$$

where

BV is blood volume in liters.

H is height in meters.

W is weight in kilograms.

Because the blood volume of tissues varies according to the ratio of adipose tissue present, such calculations may overestimate the blood volume in obese patients and underestimate it in muscular patients. These biases are partially corrected by formulas that cube the height of the patient (Mollison, 1998). The regulatory necessity to calculate blood volume has been simplified, beginning with the 19th edition of Standards for Blood Banks and Transfusion Services. Instead of limiting the

Figure 37-1 Separation of blood components within a centrifugal separation chamber. Blood components placed in a centrifuge are separated based on their density. The densest elements (red blood cells) are farthest from the axis of rotation, and the least dense element (plasma) is closest. (Image courtesy of Sergio Torloni, MD, Director of Transfusion Medicine, Mayo Clinic, Scottsdale, Ariz.)

extracorporeal volume to 15%, the maximum amount allowed to be within the extracorporeal circuit is 10.5 mL/kg of the donor's weight (Standards Committee of the American Association of Blood Banks, 2009). Calculations of blood volume, however, are still necessary to "prescribe" appropriate processing volumes during therapeutic cytappheresis. Additionally, for plasma exchanges, the blood volume can be used to further calculate the plasma volume, as given by Equation 37-3 (Buffalo, 1983):

$$PV = BV[1 - (0.91)(0.96)VCH/100] \quad (37-3)$$

where PV is plasma volume in liters, and VCH is venous centrifuge Hct.

Finally, the plasma volume can be used to calculate the exchange volume, the volume processed in a plasma exchange procedure as given by Equation 37-4 (Buffalo, 1983):

$$EV = PV \times PVE \quad (37-4)$$

where EV is exchange volume in liters, and PVE is desired number of plasma volumes to exchange.

These equations allow for the determination of appropriate volumes to be processed in the various therapeutic procedures described in this chapter.

The final basic aspect of hemapheresis that is applicable to all procedures, therapeutic and donor, is venous access. In donor hemapheresis, peripheral venous access is used, usually the veins of the antecubital fossa. The use of central venous access in this setting, with the potential for serious complications, would be too risky for the donor. If a donor's peripheral venous access is such that it cannot be used, then another donor should be located. The possible exception to this would be the setting of allogeneic peripheral hematopoietic progenitor cell harvest, where an alternative donor may not be available. Obviously, the risks to the donor and the benefits to the recipient must be carefully considered, and the donor must give informed consent before central venous access can be used.

In the setting of therapeutic hemapheresis procedures, it is often assumed that central access is essential because of damage to peripheral veins from previous medical treatment (e.g., chemotherapy), as well as the need for long-term therapy for some diseases. The Canadian Cooperative Multiple Sclerosis Study Group (Noseworthy, 1989) found that among 294 multiple sclerosis patients undergoing weekly plasma exchange procedures for 20 weeks, only 4.4% of patients could not be treated because of poor peripheral venous access. Of those who started the course of therapy, only 5.4% lost peripheral venous access such that the course could not be completed (Noseworthy, 1989). In a similar study, Grishaber (1992), looking at 46 patients with neurologic diseases requiring hemapheresis, found that 50% of patients could complete their course of therapy using peripheral access alone. Factors associated with the requirement of central venous access included Guillain-Barré syndrome or hospitalization within a medical intensive care unit (Grishaber, 1992). Contrary to popular belief, these authors also found no difference between peripheral venous access and central venous access with regard to the time required to perform the therapeutic procedures (Grishaber, 1992). These studies indicate that peripheral venous access, with its lower rate of complications, should be tried initially in therapeutic hemapheresis. Central venous access should be reserved for occasions in which peripheral access fails.

When peripheral venous access is not possible, then both the hemapheresis service and the physician placing the catheter must determine the type of central catheter to be placed. Many routinely used central venous catheters are inadequate for hemapheresis because their walls are too soft and collapse, their length is too long, or their diameter is too small. These characteristics result in pressure alarms from the instruments. The ideal catheters have relatively rigid walls to prevent collapse and large diameter with relatively short length to allow for maximum flow. Appropriate catheters include the Mahurkar dual-lumen catheter (Kendall, Mansfield, Mass.), PermCath (Kendall), Hickman Hemodialysis and Plasmapheresis Catheters (C.R. Bard, Inc., Cranston, R.I.), and the Neostar Pheres-Flow catheter (Horizon Medical Products, Inc., Manchester, Ga.). Other catheters may be used, such as the Hickman dual-lumen vascular access catheter (C.R. Bard, Inc.) or triple-lumen catheters, but often these can be used only as return lines and not as draw lines, requiring peripheral access as well. Grishaber (1992) found unacceptable failure rates with these catheters and could not recommend their insertion solely for apheresis procedures. A rule of thumb is that if a catheter can be used for dialysis where flow rates are greater than those seen in apheresis, it can be used for apheresis.

DONOR CYTAPHERESIS

DONOR PLATELETPHERESIS

Benefits of Apheresis Platelets

The use of apheresis platelets has increased from 25% of platelets transfused in 1987 (Wallace, 1993) to 83% in 2006 (Whitaker, 2008). In part, this is due to the inability to increase platelets derived from whole blood donations. In addition, there is a perception that apheresis platelets offer advantages over those produced from whole blood. The reported benefits of apheresis platelet products are given in Table 37-1.

An additional advantage of apheresis platelets over pooled nonapheresis products is simplification of inventory management. Pooled products, because they are prepared in an open system, have a 4-hour shelf life after pooling. Apheresis products do not need to be pooled and as a result retain their 5-day shelf life. In situations where platelet products are initially requested but then are not transfused, the use of apheresis products could avoid wastage. The disadvantages of apheresis platelets are the additional expense to obtain them and limited availability in some areas.

Platelet Product Requirements

Standards for Blood Banks and Transfusion Services require that the minimum number of platelets in an apheresis product be 3.0×10^{11} in 90% of units tested (Standards Committee of the American Association of Blood Banks, 2009); the Food and Drug Administration (FDA) requires a minimum of 3.0×10^{11} in 75% of units tested (CFR, 2009). The result of these requirements, however, is that an apheresis platelet product contains at least as many platelets as a pool of platelets from six whole blood donations.

Plateletpheresis Donor Selection

The donor requirements for plateletpheresis are the same as those for whole blood donation (Standards Committee of the American Association of Blood Banks, 2009). The FDA has issued additional requirements, as outlined in guidance issued in December of 2007, "Guidance for Industry and FDA Review Staff: Collection of Platelets by Automated Methods" (Division of Blood and Blood Products, Center for Biologics Evaluation and Research, 2007). FDA guidance includes a proscription on the collection of apheresis platelets from a donor who has ingested aspirin or piroxicam (Feldene) within 2 days of donation. Standards for Blood Banks and Transfusion Services (2009) also require that the use of platelets from a donor taking "medications known to irreversibly inhibit platelet function shall be evaluated." Finally, donors who have taken clopidogrel (Plavix) or ticlopidine (Ticlid) are deferred from apheresis platelet donation for 14 days after the last dose (Division of Blood and Blood Products, Center for Biologics Evaluation and Research, 2007).

Additional plateletpheresis-specific requirements include restrictions on the frequency and number of donations, as well as on the number of products donated. First, donors can donate as often as twice per week, but there must be a 2-day interval between hemapheresis procedures. A donor cannot donate more than 24 times in 12 months. This limit on the number of donations is based on the fact that early instruments produced platelet products containing significant numbers of lymphocytes (Strauss, 1994). This resulted in concerns that long-term platelet donation could result in lymphocyte depletion with subsequent disturbance in immune function. Finally, if a donor donates multiple plateletpheresis products, such as a double- or triple-platelet product, the donor is deferred from additional hemapheresis donation for 1 week. This restriction arises from concern

TABLE 37-1

Reported Benefits of Apheresis Platelet Products

Decreased donor exposure with decreased risk of transfusion-transmitted disease
Decreased donor exposure with delay in alloimmunization to HLA (Sint Nicolaas, 1981)
Decreased risk of septic platelet transfusion reactions (Ness, 2001)
Prestorage leukocyte reduction with delay in alloimmunization to HLA (Trial to Reduce Alloimmunization to Platelets Study Group, 1997), decreased febrile transfusion reactions (Heddle, 1995), and decreased cytomegalovirus infection (Bowden, 1995)

HLA, Human leukocyte antigen.

about exhaustion of platelet production with frequent donation and high product yields. Both of these concerns will be discussed further in the section dealing with **plateletpheresis donor concerns**.

Donors must have a minimum platelet count of 150,000/ μ L to be eligible to donate. FDA guidance requires that a sample for a platelet count be drawn prior to collection. This count should be used for eligibility determination (current collection or future collections) and to program the hemapheresis instrument to determine the platelet yield of the collection. The count may be completed before the procedure starts or immediately following the start of the procedure. If the platelet count cannot be obtained before the collection starts or immediately afterward (e.g., collections on a mobile drive), an average of previous measurements from the donor or a default count can be used to program the instrument. If one of these surrogate counts is used, a triple-platelet collection cannot be performed. The sample collected, however, must be tested. Finally, the FDA also requires that the hemapheresis device be programmed such that the donor's platelet count will not fall below 100,000/ μ L (Division of Blood and Blood Products, Center for Biologics Evaluation and Research, 2007).

Individuals donating after whole blood donation, or after an instrument failure resulting in the inability to return the extracorporeal blood volume, must wait 8 weeks before donating by apheresis. Exceptions are if the extracorporeal volume of the instrument is less than 100 mL, or if the loss of red cells is less than 200 mL. In these cases, the donor is eligible to donate by apheresis after the normal deferral period (Standards Committee of the American Association of Blood Banks, 2009). The FDA has provided further guidance on donor eligibility after red blood cell loss, as outlined in Table 37-2. Finally, the FDA has also defined limits on the total amount of plasma that can be removed during an apheresis platelet collection. Donors weighing less than 175 lb can have no more than 500 mL removed; in those weighing greater than or equal to 175 lb, 600 mL can be collected. An exception to these limits exists in that the manufacturer of the plateletpheresis collection device can define a different volume in the labeling of the device (Division of Blood and Blood Products, Center for Biologics Evaluation and Research, 2007).

Donor selection for plateletpheresis may be influenced by a number of factors, in addition to regulatory considerations. The yield of a plateletpheresis procedure is determined, to a large extent, by the platelet count of the donor, with higher counts associated with a higher yield (Glowitz, 1980; Goodnough, 1999). Some collection centers will screen whole blood donors for high normal platelet counts and will recruit these individuals for plateletpheresis to maximize the yield of each collection procedure. Female donors, on average, have higher platelet counts than males (Glowitz, 1980; Goodnough, 1999). Some authors have found higher platelet yields in female donors compared with males (Glowitz, 1980). In addition, the presence of a higher plasma volume in females enhances the separation and collection of platelets by some instruments, and this could also contribute to the higher yield. The difficulty with female donors is that because of prior pregnancies, they are at increased risk of sensitization against human leukocyte antigen (HLA) and neutrophil antigens. Antibodies toward these antigens have been implicated in the development of transfusion-related acute lung injury (TRALI). The American Association of Blood Banks (AABB) issued association bulletin #06-07 in November 2006 to address the risk of TRALI. In this bulletin, the AABB requires collection centers to "implement interventions to minimize the preparation of high plasma-volume components from donors known to be

leukocyte-alloimmunized or at increased risk of leukocyte alloimmunization" (Strong, 2007). Because of this, collection centers have adopted policies of deferring all females from plateletpheresis donation, deferring females who have been pregnant from plateletpheresis donation, or testing female donors for the presence of HLA and neutrophil antibodies (Powers, 2008).

Additional donor considerations arise in the selection of platelet products for alloimmunized patients. These patients, through transfusion or previous pregnancies, develop antibodies to antigens expressed on platelets, most frequently antibodies to HLA class I. The result is the development of an immune refractory state as defined by inadequate post-transfusion platelet increments as measured by platelet count collected between 10 minutes and 1 hour after the completion of a platelet transfusion. Antibodies toward platelet antigens are solely or partially responsible for a third of patients being refractory to platelet transfusion (Doughty, 1994). The presence of such a state requires the search for compatible platelet donors. Three general strategies have been employed to achieve this. First, if the specificities of the HLA alloantibodies and the HLA class I phenotype of the plateletpheresis donor are known, attempts can be made to obtain platelets from a donor lacking these antigens (Schiffer, 1987; Hussein, 1996). A second strategy that is used if the HLA class I type of the patient is known and the HLA antibody specificities are unknown or broad, is to attempt to match the HLA type of the patient and of the donor as closely as possible (Duquesnoy, 1978). Finally, if the HLA class I types of the recipient or potential donors are unknown, or if poor increments continue despite HLA matching, platelet cross-matching can be performed. Such testing involves combining donor platelets with recipient serum in a solid-phase red blood cell adherence assay (Schiffer, 1987; Bock, 1989; Murphy, 1991; O'Connell, 1992).

Plateletpheresis Donor Concerns

The typical platelet donor experiences a drop in platelet count following donation of 20%–29% (Szymanski, 1973; Katz, 1981; Heyns, 1985), with that among females typically being greater (Rogers, 1995; Dettke, 1998). The fall in platelet count does not correlate with the yield of the plateletpheresis procedure, that is, the fall is less than that predicted by the yield and represents mobilization of platelets from the spleen (Heyns, 1985). The time required for return to baseline following apheresis platelet donation is 4 days in males. A delay in increase of thrombopoietin levels causes delayed return to normal platelet counts in females (Dettke, 1998). In donors undergoing alternate day collections, platelet count and apheresis yields have been shown to return to baseline levels by day 10 of collection, with stable counts and yields obtained during subsequent collection procedures (Glowitz, 1980). A rebound elevation in platelet count with increased platelet yield following repeat procedures has also been seen (Szymanski, 1973). In donors with low platelet counts (150,000–180,000/ μ L), plateletpheresis using prolonged collection times to achieve the platelet yield required by regulations demonstrated no clinically significant problems in 291 procedures, despite postprocedure platelet counts as low as 69,000/ μ L (Rogers, 1995). The results of these studies indicate that even in donors undergoing repeated plateletpheresis, platelet counts return to normal levels promptly, and bleeding complications are uncommon.

Although studies have shown that platelet counts recover quickly following platelet donation, initial studies of the long-term effects of platelet donation suggested that donation could result in declines in baseline platelet counts (Lazarus, 2001). Lazarus retrospectively studied 939 donors who had donated 11,464 platelets over 4 years and found a significant and sustained decrease in platelet count that directly correlated with donation frequency (Lazarus, 2001). Although regular donation resulted in lower platelet counts, clinically significant thrombocytopenia was not seen (Lazarus, 2001). These findings raised concerns that frequent apheresis platelet donations could produce thrombocytopenia, and prompted the FDA to suggest restrictive policies on donation. Subsequent studies have failed to demonstrate declines in platelet count with long-term donation or with donation of high-yield products such as double- or triple-platelet products (Richa, 2008). As a result, less restrictive guidance was provided by the FDA in the form of the 2007 guidance document mentioned previously.

Plateletpheresis using early hemapheresis instruments was associated with losses of donor lymphocytes as great as $5\text{--}10 \times 10^9$ per procedure (Strauss, 1994). Based on studies involving therapeutic lymphocytapheresis and chronic thoracic duct drainage, it had been shown that abnormal cell-mediated immunity could be achieved by the loss of $1\text{--}1.5 \times 10^{11}$ lymphocytes within a few weeks (Strauss, 1994). As a result of this and studies

TABLE 37-2

Donor Eligibility Following Red Blood Cell Loss

Initial red blood cell loss	Second red blood cell loss within 8 weeks	Eligibility
<200 mL	<200 mL	No deferral
<200 mL	>200 mL but ≤ 300 mL	Defer for 8 weeks from second donation
>200 mL but ≤ 300 mL	NA	Defer for 8 weeks from first donation
<200 mL	Total loss from first and second loss >300 mL	Defer for 16 weeks from second loss
≥ 300 mL	NA	Defer for 16 weeks from loss

Division of Blood and Blood Products, Center for Biologics Evaluation and Research, 2007.

NA, Not available.

showing decreased total lymphocytes, T lymphocytes, and immunoglobulin (Ig)G levels 8 months after donation, concerns about inducing immune suppression arose. This resulted in regulations limiting the number of plateletpheresis donations to 24 per year (Standards Committee of the American Association of Blood Banks, 2009) and warning potential plateletpheresis donors about the possibility of lymphocyte depletion (Division of Blood and Blood Products, Center for Biologics Evaluation and Research, 1988), as well as some authors suggesting that donors should be deferred if their lymphocyte counts were below $1.2 \times 10^9/L$ (Strauss, 1994). More recent studies of donors donating with newer hemapheresis instruments have shown no differences in lymphocyte counts, lymphocyte subsets, or IgG levels when nondonors, plateletpheresis donors, and whole blood donors were compared (Lewis, 1999). In fact, the loss of lymphocytes over the course of 24 donations using modern hemapheresis equipment is equivalent to the loss of lymphocytes in a single whole blood donation (Strauss, 1994).

DONOR LEUKOCYTAPHERESIS

Granulocyte Transfusions

Granulocytes are sometimes transfused to neutropenic patients with infections that are refractory to antibiotic therapy, but clinical trials testing their efficacy are few. Seven controlled trials comparing antibiotics versus antibiotics and granulocyte transfusions have appeared in the literature and were reviewed by Strauss (1993). In these studies, the granulocyte donors were stimulated with steroids, and granulocyte colony-stimulating factor (G-CSF) was not used. Five of seven trials reported at least partial success of granulocyte transfusion in treating infections in neutropenic patients whose infections were unresponsive to antibiotics. The data from these studies were subsequently analyzed by quantitative meta-analysis and demonstrated that the dose of neutrophils transfused, as well as the survival rate of the controls, was primarily responsible for the differing success rates reported in the studies (Vamvakas, 1996). The authors stated that granulocyte transfusions should be considered in neutropenic patients with infections carrying a high mortality rate, and that the highest possible granulocyte doses ($>4 \times 10^{10}$ neutrophils) should be used (Vamvakas, 1996). Since these early studies, only one randomized trial involving G-CSF-stimulated donors has been published. This study demonstrated no difference between study groups with regard to survival (Hubel, 2002). Most of the studies and reports describing granulocyte transfusions in adults have dealt with neutropenic patients with unresponsive bacterial infections. Studies have looked at the utility of granulocyte transfusions in patients with fungal infection, but the results of such trials have been mixed (van Burik, 2003).

Another group of patients frequently considered for granulocyte transfusions are septic neonates. Six controlled studies have been published evaluating granulocyte transfusions in this setting, four of which found benefit (Laurenti, 1981; Christensen, 1982; Baley, 1987; Cairo, 1987, 1984; Wheeler, 1987). Quantitative meta-analysis of these studies identified granulocyte dose as the primary reason for disagreement in study outcomes. Those studies using buffy coat-derived granulocytes demonstrated no advantage, and those using leukocytapheresis-derived granulocytes demonstrated benefit (Vamvakas, 1996). Again, all of these trials were conducted before G-CSF became available. No trials of transfusion of G-CSF-stimulated granulocytes have been reported.

Granulocyte transfusions may benefit neutropenic patients, especially if large doses can be collected. Recommendations regarding who should be considered for granulocyte transfusions include adult patients who are profoundly neutropenic and are anticipated to remain neutropenic for at least 1 week, and those whose infections have progressed despite appropriate antibiotic therapy (Schiffer, 1990). In addition, the patient should have a possibility of recovery of granulocyte production. In neonates, indications for granulocyte transfusion include evidence of bacterial sepsis with an absolute neutrophil count below $3000/\mu L$ and decreased marrow store of neutrophils with less than 7% (of nucleated cells) metamyelocytes or more mature forms (Blanchette, 1991; Strauss, 1991).

Granulocyte Product Requirements

One of the critical factors in the success of granulocyte transfusions is the dose of granulocytes provided. Standards for Blood Banks and Transfusion Services require that 75% of granulocyte components collected have a minimum of 1.0×10^{10} granulocytes (Standards Committee of the American Association of Blood Banks, 2009). It must be realized that this dose represents a minimum, and that higher doses are desirable.

Granulocytes are stored at room temperature (20° – 24° C) without agitation and have an expiration date of 24 hours (Standards Committee of the American Association of Blood Banks, 2009). Neutrophils, however, undergo apoptosis throughout storage. Accumulation of transfused granulocytes at sites of inflammation decreases with increasing time of storage; they should therefore be transfused as soon as possible after collection (Price, 1979).

Granulocyte Donor Selection

As with plateletpheresis, leukocytapheresis donors must fulfill all of the requirements applicable to whole blood donation. In addition, platelets are removed during the collection, and application of the $150,000/\mu L$ platelet count requirement to granulocyte donors may be prudent. Another consideration in selecting donors is the ABO type of both recipient and donor. Significant numbers of red blood cells are present within granulocyte products. Because the red cell content is greater than 2 mL, Standards for Blood Banks and Transfusion Services require that the product be cross-match compatible (Standards Committee of the American Association of Blood Banks, 2009). If a granulocyte product could be generated with less than 2 mL of red cells, then ABO type could be ignored, as it does not influence transfused granulocyte survival or migration (McCullough, 1988).

Another consideration in donor selection is the cytomegalovirus status of the donor and recipient. Granulocyte transfusions have been linked to cases of cytomegalovirus (CMV) infection in CMV seronegative recipients (Winston, 1980; Buckner, 1983). Therefore, donors for CMV seronegative patients must also be CMV seronegative.

Finally, it is critical that HLA- or crossmatch-compatible donors be selected for alloimmunized patients. Studies of alloimmunized patients have demonstrated minimal to no recovery, survival, or localization to sites of infection using granulocytes from random donors (Dutcher, 1983; McCullough, 1986).

Granulocyte Donor Stimulation

Granulocyte dose is critical for the effectiveness of granulocyte therapy. The most commonly used method to increase granulocyte yield is to administer steroids to donors 10–12 hours before collection. Administration of oral prednisone (MacPherson, 1976; Jendiroba, 1998) or dexamethasone (Higby, 1977) increases granulocyte yield up to twice that of unstimulated donors. The effects of steroids appear to result from mobilization of granulocytes from marrow stores. Studies have shown no effect of steroid stimulation on the ability of neutrophils to phagocytose particles, phagocytose fungi, kill bacteria, or undergo chemotaxis when compared with granulocytes from nonstimulated donors (Glasser, 1977). In addition, steroid stimulation has been shown not to affect accumulation of transfused granulocytes at sites of injury (Price, 1979), and it inhibits apoptosis during storage (Liles, 1995).

The availability of G-CSF has resulted in the ability to generate even larger granulocyte doses and has led to a resurgence of interest in granulocyte transfusions. Administration of $5 \mu g/kg$ of G-CSF every other day resulted in granulocyte collections four to five times those seen in unstimulated donors and greater than those seen with prednisone stimulation (Jendiroba, 1998). The use of G-CSF-stimulated granulocyte transfusions has been shown to result in significant and sustained increments in neutrophil counts in patients (Adkins, 1997b). The optimum timing for granulocyte collection in G-CSF-stimulated donors is 12 hours after administration of the G-CSF (Price, 1998).

As with steroids, concerns have arisen over the function of G-CSF-stimulated granulocytes. Studies have demonstrated normal phagocytosis, chemotaxis, chemiluminescence, and superoxide anion production (Caspar, 1993) and normal accumulation at sites of injury (Adkins, 1997a). G-CSF has been shown to enhance microbicidal activity (Lieschke, 1992), as well as inhibit neutrophil apoptosis during storage (Adachi, 1994). Concern has also been raised as to whether repeated doses of G-CSF will adversely affect granulocyte function. Again, enhanced phagocytosis and oxidative burst were seen with multiple G-CSF administrations (Joos, 2002).

Studies have been performed to evaluate the effect of the combination of steroids and G-CSF (Dale, 1998; Liles, 1997). Eight milligrams of dexamethasone with 300 or 600 μg of G-CSF resulted in higher granulocyte yields than either agent alone, leading to a 10-fold increase in neutrophil count at 12 hours. The combination of dexamethasone and 600 μg resulted in a significantly greater yield than dexamethasone and 300 μg of G-CSF (Liles, 1997). Granulocyte function with this combined regimen demonstrated no defects (Dale, 1998). Subsequent studies comparing 450- μg versus 600- μg doses of G-CSF with 8 mg of dexamethasone found

TABLE 37-3

Short-Term Side Effects of Medications Used in Granulocyte Mobilization

Medication	Side effects

equivalency with regard to both the donor's absolute neutrophil count (ANC) at 12 hours and donor side effects (Liles, 2000).

Finally, the route of administration of G-CSF, when given with dexamethasone, also influences granulocyte kinetics. Subcutaneous administration gives a higher sustained ANC compared with IV administration (Stroncek, 2002).

Granulocyte Collection Procedure

Granulocyte yields can also be increased by enhancing the separation of red blood cells and granulocytes during the centrifugation process. Red blood cells and granulocytes have similar densities and sedimentation rates, resulting in poor separation during centrifugation. The addition of sedimenting agents such as hydroxyethyl starch (HES) can improve this separation and thereby enhance granulocyte collection (Iacone, 1981). The mechanism of action of HES is the induction of rouleaux formation among red blood cells. The resulting greater red cell sedimentation rate and a greater upward flow of plasma during centrifugation enhance separation (Lee, 1995b). Different types of HES include the high molecular weight hetastarch and the low molecular weight pentastarch. Both of these agents have been shown to have equivalent safety profiles (Strauss, 1986, 1987), although pentastarch has the benefit of being rapidly excreted. As a result, there is less danger of accumulation of the HES and possible complications (see discussion at end of chapter). Although the safety profile of pentastarch may be superior, a controlled study has shown greater granulocyte yields with hetastarch (Lee, 1995b).

Granulocyte Donor Concerns

In addition to granulocytes, platelets and significant numbers of red blood cells are present in the leukocytapheresis product. The donor's Hct typically drops by 7% following a granulocyte collection (Hester, 1995). This drop is due not only to loss of red blood cells but also to dilutional effects of volume expansion caused by the HES used during the procedure. Platelet count typically drops by 22% after each procedure—an equivalent drop to that seen with plateletpheresis (Hester, 1995). Again, a degree of dilutional effect is present. An additional cause for a fall in platelet count is seen in donors stimulated with G-CSF (Bensinger, 1993). Healthy donors receiving G-CSF for 10 days typically have a decline in platelet count starting at day 8, with significant differences from baseline at days 10 and 11. The mechanism behind this effect is uncertain and may represent changed platelet distribution, decreased platelet production, or increased intravascular volume (Korbling, 1998). In addition, recovery of platelet count appears to be prolonged, requiring 7–10 days among stem cell donors versus 4–6 days among platelet donors (Stroncek, 1996b).

G-CSF and corticosteroids can cause a number of other side effects (Table 37-3). These side effects are very common, occurring in 90% of allogeneic donors receiving G-CSF for apheresis collection of hematopoietic progenitor cell (HPC-A) (Stroncek, 1996a), are usually mild, and are treated symptomatically. For example, bone pain and headache, which tend

TABLE 37-4

G-CSF, Granulocyte-colony stimulating factor.

to be dose related (Stroncek, 1996a; Murata, 1999), typically respond to mild analgesics. Nausea and vomiting are more common in women, and headache is more common in those younger than 35 years (Murata, 1999). More significant but rare side effects of G-CSF include splenic rupture, anaphylaxis, acute iritis, marginal keratitis, gouty arthritis, autoimmune thyroiditis, rheumatoid arthritis exacerbation, thrombosis, erythema multiforme, acute lung injury, and capillary leak syndrome (Korbling, 1998; Volk, 1999; Azevedo, 2001; Arimura, 2005; Tighe, 2007; Veerappan, 2007). These are believed to represent exacerbation of underlying donor/patient illnesses. Donors, whether for granulocyte or HPC-A collection, should be evaluated for these illnesses in determining suitability for donation (Table 37-4).

Although the short-term effects of G-CSF are predominantly mild, the long-term effects are uncertain. Concerns have been expressed over the possibility of recipients developing hematologic diseases such as myelodysplasia or chronic myelogenous leukemia (CML) (Korbling, 1998; Volk, 1999). This is due in part to the occurrence of leukemic transformation after G-CSF therapy in 10%–15% of patients with congenital neutropenia receiving long-term G-CSF therapy (Bonilla, 1994). In addition, studies of normal donors receiving G-CSF have demonstrated the induction of a small population of tetraploid myeloid cells (Kaplinsky, 2003); temporary asynchronous allele replication and persistent aneuploidy, up to 265 days following G-CSF administration (Nagler, 2004); abnormal DNA relaxation and de novo DNA synthesis (Shapira, 2003); and alterations in gene expression (Hernandez, 2005; Amariglio, 2007). These findings were similar to those that have been seen in hematologic malignancies. It has been estimated that to detect a 10-fold increase in the frequency of leukemia above the population background of 0.05%, a study following 2000 stimulated donors for a minimum of 10 years would be needed (Pamphilon, 2008). Two registries have published data that almost meet these requirements. The European Bone Marrow Transplant Registry examined unstimulated bone marrow donors and HPC-A donors collected between 1990 and 2003. Among bone marrow donors, 9 of 28,134 (0.032%) donors developed hematologic malignancies compared with 5 of 16,432 (0.030%) stimulated HPC-A donors (Grupp, 2006). The National Marrow Donor Program examined 4015 healthy unrelated allogeneic donors who had donated between 1997 and 2007. Twenty cases of malignancy were identified, and this incidence was consistent with the age-adjusted U.S. incidence of cancer in adults. No cases of hematologic malignancy were seen (Confer, 2007). Despite these reassuring findings, donors undergoing G-CSF stimulation should give informed consent before stimulation, and appropriate institutional review should be obtained for use of G-CSF in this non-FDA-approved role.

Long-term steroid treatment is associated with a number of well-known side effects, including the development of posterior subcapsular cataracts (PSCs). Because these complications appear with long-term use, it would seem that short-term steroid stimulation of granulocyte donors should not be associated with them. This may not be the case, however. A single-center double-blind study compared the presence of cataracts in 9 apheresis platelet donors and 11 granulocyte donors matched for age, gender, and number of respective donations (Ghods, 2001). The frequency of cataracts not associated with steroid administration was equivalent between the two groups, but those associated with steroid administration—PSCs—were statistically more frequent in the granulocyte donors when all eyes were considered (5 of 22 eyes vs. 0 of 18; $p = 0.040$) (Ghods, 2001). A subsequent multicenter study examined 89 granulocyte donors and 89 control donors (Burch, 2005). The granulocyte donors had donated a mean of 13 donations (range, 5–39). Six of the granulocyte donors and 4 of the control donors had evidence of PSC

TABLE 37-5

Advantages and Disadvantages of Double Red Blood Cell Collections

Advantages

- Decreased incidence of donor reactions compared with whole blood donation (Wiltbank, 2002)
- Decreased number of donors necessary to produce a given number of red blood cell units (Gilcher, 2003)
- Standardized red blood cell dose (Gilcher, 2003)
- Decreased amount of component processing (i.e., one set of laboratory tests for two units of red blood cells) (Beeler, 1997)
- Decreased donor exposure if a patient receives both parts of a double red cell collection (Gilcher, 2003)

Disadvantages

- Greater complexity of collection (Gilcher, 2003)
- Greater time necessary for donation (Gilcher, 2003)

on photographic examination. This was not a statistically significant difference (Burch, 2005). This better powered study suggests that cataract formation may not be a concern among granulocyte donors.

DONOR ERYTHROCYTAPHERESIS**Benefits of Erythrocytapheresis**

A single unit of red blood cells or the equivalent of two units of red blood cells can be collected by apheresis. With the current shortages of red blood cells in the United States and the decreasing size of the donor pool, the collection of red blood cells, with the concurrent collection of other blood products or as double red blood cells, can maximize collection of this scarce resource. Advantages and disadvantages of double red blood cell collections are given in Table 37-5.

Erythrocytapheresis Product Requirements

The Standards for Blood Banks and Transfusion Services requires that apheresis red blood cells be collected and prepared by a method that is known to result in a mean hemoglobin (Hb) >60 g or a packed red cell volume of 180 mL. In addition, at least 95% of the units sampled must have >50 g of Hb or 150 mL packed red cell volume (Standards Committee of the American Association of Blood Banks, 2009). If the red blood cell units are leukocyte reduced, then the mean Hb must be >51 g or 153 mL packed red cell volume. Here, at least 95% of tested units must have >42.5 g of Hb or 128 mL packed red blood cell volume (Standards Committee of the American Association of Blood Banks, 2009).

The FDA does not define product requirements for red blood cells—single or double—collected by apheresis but instead states that 95% of the products collected must meet “expected or target RBC volume” and “any other target parameters specified in the device’s operator manual” (Division of Blood and Blood Products, Center for Biologics Evaluation and Research, 2001). The FDA also defines how such validation and testing is to be performed, with the initial validation consisting of testing “100 consecutive RBC units,” while subsequent testing must include at least 50 units per month, consisting of both single and double red blood cell products. If a center collects less than 50 units, all units must be tested (Division of Blood and Blood Products, Center for Biologics Evaluation and Research, 2001).

Erythrocytapheresis Donor Selection

Allogeneic apheresis red blood cell donors must meet the criteria defined by the FDA and the AABB for whole blood donation. In addition, they are required to meet any other selection criteria defined by the device’s operator manual (Division of Blood and Blood Products, Center for Biologics Evaluation and Research, 2001).

The FDA and the AABB do not define a minimum Hb/Hct for double red cell donation. Instead, it is required that the collection center follow the instrument manufacturer’s recommendations (Division of Blood and Blood Products, Center for Biologics Evaluation and Research, 2001; Standards Committee of the American Association of Blood Banks, 2009). The FDA does, however, require that the Hb/Hct be determined by a quantitative method (Division of Blood and Blood Products, Center for Biologics Evaluation and Research, 2001). As a result, the copper sulfate method cannot be used to qualify a donor for double red cell donation.

The AABB limits the total volume of red blood cells removed, such that the donor’s Hct and Hb are not <30% and <10 g/dL, respectively, after volume replacement (Standards Committee of the American Association of Blood Banks, 2009). The FDA makes no specific limitations, requiring that the manufacturer’s recommendations be followed (Division of Blood and Blood Products, Center for Biologics Evaluation and Research, 2001).

The type of product collected determines the donation interval following hemapheresis red blood cell donations. Donors donating a single unit of red blood cells are deferred for 8 weeks. The exception to this would be that, as described in the section on **donor plateletpheresis**, they could donate platelets or platelets with concurrent plasma, as long as the extracorporeal red blood cell volume of the collecting instrument is less than 100 mL (Division of Blood and Blood Products, Center for Biologics Evaluation and Research, 2001). Donors donating two units of red blood cells are deferred for 16 weeks, and no automated or manual collections are allowed during this time (Division of Blood and Blood Products, Center for Biologics Evaluation and Research, 2001).

If a donor experiences an incomplete procedure, that is, the targeted collection is not reached, the FDA defines the length of deferral based on the absolute loss of red blood cells during the initial collection and subsequent collections, as outlined in Table 37-2 (Division of Blood and Blood Products, Center for Biologics Evaluation and Research, 2007).

Erythrocytapheresis Donor Concerns

Owing to the removal of two units of red blood cells, one of the most frequent concerns is whether reactions are more frequent with double red blood cell collections when compared with whole blood collections. Studies have demonstrated no increase in reactions with automated double red cell collections when compared with whole blood donation (Wiltbank, 2002; Gorlin, 2003). Wiltbank reported lower rates of moderate and severe reactions with automated double red blood cell collection (6.8/10,000 and 1.2/10,000 collections, respectively) compared with whole blood donations (14.5/10,000 and 1.2/10,000 collections, respectively) (Wiltbank, 2002). The lower rate of reactions, despite the removal of a greater red blood cell mass, results from the fact that donors are isovolemic at the end of the collection as a result of the infusion of saline.

Donors undergoing double red cell donation experience a transient fall in Hct of 9% (Taylor, 2002). This is due to red cell loss, as well as volume expansion from saline administration. Despite this fall, studies have shown minimal effects on donors following double red blood cell donations. Meyer (1993) found in a study of 40 blood donors that double red blood cell donors took 1–2 days longer than whole blood donors to regain their baseline sense of well-being. Smith (1996) found no significant differences in ambulatory monitored blood pressure and pulse among one-unit red blood cell collections, two-unit red blood cell collections, and sham collections (Smith, 1996). Quintana (1995) found that double red blood cell donation did not have a significant effect on exercise capacity, as determined by examining maximal oxygen consumption decrease, anaerobic threshold, maximum heart rate, respiratory exchange ratio, and maximum power on days 0, 2, 7, and 14 following donation.

A final concern with double red blood cell donations is whether donors making such donations are at greater risk of developing iron deficiency than whole blood donors. Meyer (1993) followed double red blood cell donors and whole blood donors for 1 year, measuring serum ferritin, serum iron, total iron-binding capacity, transferrin saturation, and zinc protoporphyrin/heme ratios. Half of the donors in each group received iron supplementation. No significant differences were found in iron balance between double red cell donors and the whole blood donors (Meyer, 1993).

MULTICOMPONENT APHERESIS DONATION

With current instrumentation, different combinations of blood products can be collected from the same donor. This allows for the optimum utilization of each donor. For example, the maximum amount of plasma would be collected from an AB donor, while his or her red blood cells, which frequently outdate before they are transfused, would not be collected. An O Rh-negative or Rh-positive donor would provide a double red blood cell collection, but plasma, which is usually in adequate supply, would not be collected. The various combinations of collections currently available are given in Table 37-6. It should be mentioned that all of the various regulations that apply to individual apheresis collections with regard to donor criteria and donor frequency apply to multiple-component collections. For example, a donor undergoing a double red cell collection with

TABLE 37-6

Combinations of Blood Products Available for Multicomponent Collections

- | | |
|----------------------------------------|----------------------------------------|
| • Red blood cell and plasma | • Double or triple platelet |
| • Red blood cell and platelet | • Platelet and single or double plasma |

| • Double red blood cell | • Double or triple plasma |

a concurrent plasma collection would have to meet the requirements for a double red cell collection, as well as the requirements for frequent or infrequent plasma collection, as applicable. This would include tracking red blood cell loss (see Table 37-2) and total plasma volume loss (see discussion of plasma donation later).

HEMATOPOIETIC PROGENITOR CELL COLLECTION BY APHERESIS

Benefits of Hematopoietic Progenitor Cell Collection

HPC-A provides a number of advantages for both the donor and the recipient that have resulted in replacement of the collection of hematopoietic progenitor cells by bone marrow harvest (HPC-M) in many patients. Donors tolerate hemapheresis better than bone marrow harvest as it does not require an operative procedure with the need for general anesthesia. As a result, the procedure is less expensive, is more convenient as it can be undergone as an outpatient, and avoids the potential complications seen with general anesthesia and surgery. Also, the donor recovers more quickly from the procedure without the pain and temporary disability that often accompany bone marrow harvest (Lee, 1995a). The use of peripheral blood HPCs in transplantation restores hematopoietic and immune function more rapidly than bone marrow. This means fewer days of immune suppression and fewer exposures to allogeneic blood products in the recipient (Moog, 1998; Bensinger, 2001). Additionally, in autologous transplantation, collection of peripheral HPCs by hemapheresis can be performed when marrow involvement by malignancy or prior pelvic irradiation is present and would preclude bone marrow harvest (Lee, 1995a).

Although HPC-A collection provides a number of benefits over bone marrow harvest, it also has disadvantages when compared with bone marrow harvest. Disadvantages include possible adverse effects of mobilization regimens, a greater length of time required for collection, the possibility of a larger volume of component to be transfused at the time of transplantation, and the necessity for central venous access in many cases, along with the accompanying risks and complications (Lee, 1995a). In addition, conflicting evidence in allogeneic transplantation suggests a greater frequency of chronic graft-versus-host disease (GVHD) (Duhrsen, 1988; Brown, 1997) or GVHD more refractory to standard therapy (Flowers, 2002). This may result from the larger number of T cells within peripheral blood stem cell products compared with bone marrow.

Autologous versus Allogeneic Hematopoietic Progenitor Cell Harvest

At first, HPC-A collections were limited to autologous transplantation. This was due to the use of chemotherapy as the method for mobilizing HPCs. Transplantation of HPCs collected in this way was limited to diseases such as solid malignancies, Hodgkin disease and non-Hodgkin lymphomas, and multiple myeloma. The use of HPCs has subsequently expanded to include transplantation for leukemias, including CML (Lee, 1995a; Gillespie, 1996; Moog, 1998). As methods for mobilization that do not depend upon chemotherapy have become available, HPC-A collection has been used for allogeneic donations as well. Initial use of HPC-A collection in this setting was limited to retransplant in recipients with recurrent disease or failure to engraft (Lee, 1995a; Gillespie, 1996; Moog, 1998). Currently, the use of allogeneic HPC-A in initial transplants is widespread.

Hematopoietic Progenitor Cell Dose

An important factor in determining the success of HPC transplantation is the dose of HPCs infused. Unfortunately, a method for definitively

enumerating HPCs is not available. It is known that HPCs are found within the mononuclear cell component of blood; as a result, the mononuclear cell count (MNC) has been used as an indicator of when to discontinue HPC collection. Studies have shown that a total dose of $6.0\text{--}6.5 \times 10^8$ MNC/kg is sufficient to produce rapid engraftment (Kessinger, 1989, 1995). Although MNC does not correlate directly with HPC dose, it is convenient and easily measured.

A more exact way of measuring HPC dose is by assessing colony-forming unit granulocyte-macrophage (CFU-GM) colonies grown on soft agar. HPC collections that contain $0.5\text{--}2.0 \times 10^5$ CFU-GM/kg are associated with rapid engraftment (Bender, 1992). Unfortunately, CFU-GM assays are technically challenging and difficult to standardize. As a result, direct comparison of data between institutions and studies should be made with caution. In addition, the assay requires 2 weeks to complete.

A third method of determining HPC dose is the measurement of CD34+ cell count within the product. HPCs represent a subset of CD34+ cells. As a result, the measurement of CD34+ cells gives a better indication of HPC dose than MNC and also correlates with CFU-GM (Lee, 1995a). A minimum dose of CD34+ cells necessary for engraftment appears to be 2.5×10^6 CD34+ cells/kg (Bensinger, 1995; Korblyng, 1995). This dose of CD34+ cells results in prompt engraftment of white blood cells. Bensinger (1995), however, found that the higher dose of 5.0×10^6 CD34+ cells/kg resulted in an equivalent engraftment of white blood cells, as well as more rapid engraftment of platelets. Although CD34+ cell content is easier to measure than CFU-GM, it has been plagued by difficulties in standardization due to variations in methods used (Lee, 1995a). Fortunately, the availability of kits and instruments from numerous manufacturers appears to have solved this problem. It should be mentioned that in the setting of allogeneic HPC transplantation, as with many things in life, too much of a good thing may be bad. Although minimal numbers of CD34+ cells/kg are needed for prompt engraftment, too many cells have been associated with an increased risk of chronic graft-versus-host disease in some studies (Zauch, 2001; Heimfeld, 2003). Zaucha (2001) found a higher incidence of extensive chronic graft-versus-host disease in allogeneic transplant patients receiving greater than 8.0×10^6 CD34+ cells/kg.

Some authors have suggested that the dose of CD34+ cells needed for engraftment may vary with the number of HPC collection procedures performed (Smolowicz, 1999). It is thought that a higher total dose is necessary when CD34+ cells are collected over multiple procedures. This is believed to be due to changes in CD34+ cell subsets seen during the course of multiple collections (Smolowicz, 1999).

Hematopoietic Progenitor Cell Mobilization

Early attempts at harvesting hematopoietic progenitor cells from peripheral blood were successful but labor and resource intensive. Peripheral blood contains only 10% of the fraction of CD34+ cells found in bone marrow (Lee, 1995a). This means that when HPCs are collected during steady state (i.e., without mobilization), the number of procedures necessary to achieve a sufficient dose may be large, for example, 12 procedures in one study (Moog, 1998). This limits the utility of hemapheresis collection of HPCs during steady state. The discovery that peripheral hematopoietic progenitor cells could be mobilized from the bone marrow meant that therapeutic doses of HPCs could be collected by hemapheresis in fewer procedures, making the method more attractive. Chemotherapy, cytokines, or a combination of chemotherapy and cytokines can mobilize HPCs from bone marrow (Lee, 1995a; Gillespie, 1996; Moog, 1998). Table 37-7 gives a general comparison of the effectiveness of these three mobilization regimens.

The regimen initially used for mobilization was chemotherapy. During the period of rebound hematopoiesis following chemotherapeutic treatment, the number of HPCs present within the peripheral blood increases dramatically (see Table 37-7). This allows for the effective collection of HPC-A and serves to decrease the tumor burden within the donor/recipient. The limitation of such a method of mobilization, however, is that it can be applied only to autologous transplants.

Cytokines such as G-CSF and granulocyte-macrophage colony-stimulating factor (GM-CSF) dramatically increase the presence of HPCs within the peripheral blood and have the additional benefit of providing minimal short-term toxicity (see Table 37-3). This therefore allows for the mobilization of HPCs in normal donors and the use of hemapheresis in allogeneic transplantation. The mechanism of action of these cytokines is an indirect one with regard to their effects on HPCs. HPCs in the marrow are bound to stromal cells by adhesion molecules. These molecules include VLA-4 and CXCR4 on the HPCs and VCAM-1 and SDF-1 on the stromal

TABLE 37-7

Comparison of Mobilization Regimens

Regimen	Approximate day when peak HPC concentrations are reached	Increase in HPCs above steady state
Chemotherapy	Day 14 after completion of chemotherapy	5–15×
Cytokines (G-CSF and GM-CSF)	Day 5 after initiation of cytokine therapy	60×
Chemotherapy and cytokines	Day 5 after initiation of cytokine therapy	1000×

Data from Gillespie TW, Hillyer CD. Peripheral blood progenitor cells for marrow reconstitution: mobilization and collection strategies. *Transfusion* 1996;36:611–24.

G-CSF, Granulocyte-colony stimulating factor; GM-CSF, granulocyte-macrophage colony stimulating factor; HPC, hematopoietic progenitor cell.

cells. G-CSF increases the number of neutrophils in the marrow. This results in increases in proteolytic enzymes such as elastase and MMP-9, which are released by the neutrophils. These enzymes cleave VCAM-1 and SDF-1, resulting in the release of HPCs from the stromal cells, allowing them to enter the peripheral circulation (Lapidot, 2002).

Overall, the magnitude of increase in CD34+ cells with G-CSF and GM-CSF is the same, but differences in recipient recovery of hematopoiesis and donor side effects exist between the two agents. Recipients of GM-CSF-mobilized HPCs experience a longer time until recovery of platelet production than do recipients of G-CSF-mobilized HPCs (13 days vs. 18 days) (Gillespie, 1996). Although donors receiving GM-CSF experience the same symptoms as those receiving G-CSF, they tend to have more severe side effects (Bolwell, 1994). The use of G-CSF or GM-CSF in normal donors is associated with a peak in CD34+ cells at approximately 5 days following initiation of cytokine therapy (Bensinger, 1996). The use of G-CSF in normal donors for periods longer than 5 days has been associated with a decrease in the number of CD34+ cells collected after day 10 of stimulation (Stroncek, 1996a).

In December of 2009, a new medication was approved by the Food and Drug Administration for the mobilization of HPC-A from patients with non-Hodgkin lymphoma and multiple myeloma. This medication, plerixafor, is a CXCR4 inhibitor that was initially investigated as an anti-human immunodeficiency virus (HIV) medication. As described earlier, CXCR4 on the HPCs binds to SDF-1 on marrow stromal cells. Plerixafor blocks this interaction, resulting in mobilization of HPCs from the marrow (Cashen, 2009). Currently, plerixafor has been approved for the mobilization of HPC-A from patients who have failed previous mobilization and is given in addition to G-CSF. Plerixafor cannot be used to mobilize stem cells in patients with leukemia, as it has been shown to mobilize leukemic cells (Cashen, 2009).

In addition to G-CSF and GM-CSF, a number of other cytokines and monoclonal antibodies against stem cell adhesion molecules are being evaluated for their effects on HPC mobilization. These include stem cell factor, Gro- β , and hrPTH (Pusic, 2008).

Finally, the effects of chemotherapy and cytokine mobilization are independent of one another. This means that by combining the two mobilization regimens, even greater numbers of HPCs can be collected than when either regimen is used alone. In healthy allogeneic donors, the optimum mobilization regimen appears to be 10–16 $\mu\text{g}/\text{kg}$ of G-CSF split into two doses and administered subcutaneously (Kroger, 2002). Although G-CSF demonstrates a dose response, doses larger than 10–16 $\mu\text{g}/\text{kg}$ result in more donor adverse effects without significant improvement in CD34+ cell yield. If a donor is a poor mobilizer, however, higher doses can be given (Kroger, 2002). Twice-daily dosing has been shown to be superior to single dosing in this setting. This is thought to be due to the relatively short half-life of G-CSF of 3–4 hours (Kroger, 2002).

In autologous donors, mobilization is complicated by the underlying disease, as well as by previous therapy. In autologous HPC collection, G-CSF doses >16 $\mu\text{g}/\text{kg}$ are needed. If poor mobilization occurs, the patient/donor may need to be remobilized with chemotherapy followed by growth factor, higher doses of growth factor, sequential stimulation with G-CSF and GM-CSF, or the use of plerixafor (Kessinger, 2003; Pusic, 2008; Cashen, 2009).

In addition to these mobilization regimens, HPCs are mobilized by the collection procedure itself. Studies of the kinetics of HPCs during hemapheresis procedures have shown that larger numbers of HPCs are

TABLE 37-8

Factors That Negatively Influence Mobilization in Autologous Stem Cell Collections

- Age*
- Presence of marrow involvement
- Follicular NHL compared with diffuse NHL
- Prior radiation therapy
- Greater number of cycles of chemotherapy
- Low platelet count
- Low NK cell numbers
- Prior rituximab therapy

NHL, Non-Hodgkin lymphoma; NK, natural killer.

*Not important if mobilized by chemotherapy. When granulocyte-colony stimulating factor (G-CSF) is given alone, younger donors/patients mobilize better than older ones (Bensinger, 1995; Moog, 1998).

recovered than would be expected based solely on the number of cells present in the peripheral blood. This means that during the procedure, as HPCs are removed, additional HPCs are released from the marrow (Smolowicz, 1999).

Unfortunately, despite attempts to optimize mobilization regimens, not every patient collects a dose of peripheral blood HPCs sufficient for transplantation. Factors that have been found to adversely affect HPC harvest are given in Table 37-8. Some authors have found that the number of CD34+ cells within the bone marrow is a predictor of the ability of a patient to mobilize and could be used to assist in deciding whether a patient should undergo hemapheresis or bone marrow harvest (Passos-Coelho, 1995a).

Although mobilization increases the number of HPCs present in the peripheral blood, it can also have detrimental effects on the donor and on the HPC product. As discussed in the section on donor concerns in granulocyte collection, the use of G-CSF is associated with minimal short-term side effects, as well as unknown long-term side effects. In the setting of autologous harvest, these effects and concerns are unimportant relative to the risks that the patient faces from the disease. In addition, the use of such agents in this setting accelerates white cell recovery following chemotherapy—a beneficial effect. In the setting of allogeneic donation, the uncertainty of long-term risks of cytokine mobilization must be explained to the donor during the consent process. The delay in platelet recovery seen following G-CSF treatment and granulocyte collection is also seen with HPC harvest (Gillespie, 1996; Stroncek, 1996b). In autologous donors, this combined with marrow suppression from recent chemotherapy may result in the need for platelet transfusion. Mobilization is also associated with increased risk of catheter thrombosis (Lee, 1995a). Finally, in addition to mobilizing HPCs, the regimens described previously have been shown to mobilize tumor cells into the peripheral blood by some (Brugger, 1994; Gazitt, 1996) but not all authors (Passos-Coelho, 1995b). The study by Brugger (1994) demonstrated mobilization of tumor cells on days 1 through 7 following the start of chemotherapy in patients without bone marrow involvement, and on days 9 through 16 in those with marrow involvement. Mobilization of tumor cells in these latter patients occurred within the time frame of HPC collection. Similarly, Gazitt (1996) found that mobilization of plasma cells in multiple myeloma patients occurred later—days 5 and 6—than mobilization of stem cells—days 1 through 3. Differences in mobilization of tumor cells versus HPCs have led many to suggest that single collections early in the course of mobilization may be better than multiple collections. It should be realized that although tumor contamination does occur, the effect of this contamination on relapse is uncertain.

Hematopoietic Progenitor Cell Collection Procedure

One of the first things to consider in performing an HPC collection is when to initiate the collection. In allogeneic donors, initiating collection on the fifth day after the start of G-CSF administration appears to be the preferred practice. This is due to the relatively reproducible response of healthy allogeneic donors to G-CSF administration (Kroger, 2002). For autologous donors, a number of criteria can be used in determining whether to initiate therapy. Criteria that have been used include myelocytosis and rising monocyte levels (Lee, 1995a), a twofold increase in total white blood cell count in 24 hours (Lee, 1995a), time of first platelet count

increase (Gillespie, 1996), day 14 after initiation of chemotherapy (Gillespie, 1996), and a white blood cell (WBC) count of 10,000/ μ L (Dreger, 1993). With regard to this last indicator, Dreger (1993) demonstrated a peak in CFU-GM 1–2 days after the WBC count reached 10,000/ μ L. Starting collection at this time avoided missing the subsequent peak in CFU-GM. Another widely used method is serial CD34+ cell counts by flow cytometry. This can be used to detect a rise in CD34+ cells and to trigger HPC harvest. Trigger levels described in the literature should be viewed with caution because of the current lack of standardization in CD34+ cell measurements (Lee, 1995a). Individual institutions must determine their own trigger criteria.

Once the decision to initiate collection has been made, a number of aspects of the procedure can be modified that will influence the quality of the product. First, the instrument used to collect the HPCs determines the characteristics of the product. A number of instruments are available, including the Amicus (Fenwal Inc., Lake Zurich, Ill.), the CS3000 Plus (Fenwal Inc.), and the COBE Spectra (CaridianBCT Inc., Lakewood, Colo.). Direct comparison of the CS3000 Plus and the COBE Spectra demonstrated no differences in their efficiency of collecting CD34+ cells (Stroncek, 1997). It was found that the product produced by the COBE Spectra contained more neutrophils (Stroncek, 1997). Studies comparing the Amicus and the COBE Spectra demonstrated similar CD34+ cell collection efficiency, but the COBE Spectra removed significantly more platelets from the donor (Ikeda, 2003; Adorno, 2004). The Amicus HPC-A product contains fewer neutrophils than the COBE Spectra (Snyder, 2000). The presence of fewer neutrophils could be a significant finding if the HPC product is to be modified, such as T cell depleted, as these additional cells can interfere with the depletion process. In addition, studies have found a correlation between HPC-A neutrophil content and adverse reactions at the time of stem cell transplant (Calmels, 2007).

Another variable to consider is the whole blood flow rate during the procedure. It would seem that higher flow rates would result in a higher volume processed and a concurrent larger number of HPCs collected. With the COBE Spectra, this does appear to be the case (Lin, 1995). With the CS3000, however, increased flow rates were associated with the detrimental effect of decreased mononuclear cell content of the product, as well as the beneficial effect of decreased platelet count (Lin, 1995). This may have resulted from insufficient dwell time within the centrifugal field to allow adequate centrifugation at the higher flow rate.

Although the whole blood flow rate can adversely affect collection efficiency, the concept of increasing the amount of blood processed to increase the HPC yield is a valid one. Standard HPC collection involves the processing of approximately 1.5–3 blood volumes per procedure (Lee, 1995a). Alternatively, large-volume leukocytapheresis (LVL) involves processing more than 5 blood volumes, or more than 15 L (Reik, 1997). The benefits of such procedures include the collection of large numbers of HPCs per procedure, with the resulting need for fewer collection procedures, as well as greater mobilization of HPCs during the procedure (Lee, 1995a; Moog, 1998). In addition to these, improved yield of HPCs in patients who mobilize poorly has been seen (Smolowicz, 1997). Disadvantages of LVL include longer time required to complete the procedure and an increased incidence of citrate reactions (see discussion at the end of the chapter) (Moog, 1998). In standard leukocytapheresis procedures, thrombosis of central catheters is the most common complication (Goldberg, 1995), but in LVL, citrate reactions predominate, occurring in 33% of donations (Lin, 1995). This is due to the greater amount of citrate anticoagulant that is infused. Some authors have attempted to minimize this by adding heparin to the anticoagulant before the procedure (Reik, 1997) and/or providing IV calcium supplementation during the procedure (Bolan, 2002; Buchta, 2003).

Hematopoietic Progenitor Cell Donor Concerns

In addition to the reactions associated with G-CSFs, as described in the section on granulocyte collections, and concerns seen with large-volume leukocytapheresis, thrombocytopenia is a matter of concern in both autologous and allogeneic HPC collections. Schlenke (2000) reported average platelet losses of $24.2 \pm 12.5\%$ during large-volume peripheral blood hematopoietic progenitor cell collections using the CS3000. Smaller platelet loss has been reported using the Amicus (Burgstaler, 2004). In addition, patients undergoing autologous peripheral blood stem cell collections may be thrombocytopenic from the chemotherapy routinely used as part of the mobilization regimen. Bleeding complications in these patients are uncommon (Goldberg, 1995). However, patients may require platelet transfusions before or after collections, depending on their platelet count, to avoid bleeding complications.

DONOR PLASMAPHERESIS

PLASMA PRODUCTS

Two types of plasma products are collected by donor plasmapheresis: fresh frozen plasma and source plasma. Source plasma is plasma that is subsequently used to manufacture derivative products. These derivative products include albumin, Igs, coagulation factor concentrates, and laboratory reagents. Fresh frozen plasma (FFP) is the liquid component of whole blood that has been frozen within 6–8 hours after collection. The benefit of collecting FFP by plasmapheresis is that 600–700 mL of plasma can be collected from a single donor. This can then be divided into multiple units of a volume equivalent to FFP derived from whole blood donations. Alternatively, the entire volume can be frozen as “jumbo plasma.” These large units have the benefit of limiting donor exposure in patients requiring large volumes of FFP, such as in plasma exchange for thrombotic thrombocytopenic purpura (TTP). An additional benefit is that the large volume of collection can maximize the production of frequently used or rare products such as type AB FFP or IgA-deficient FFP.

PLASMA DONOR SELECTION

The donor criteria for plasmapheresis vary according to the frequency of donation. Donors donating plasma less frequently than every 4 weeks are classified as “infrequent” donors and must fulfill whole blood donor requirements. In addition, AABB Standards require that donors taking warfarin be deferred from plasma donation for 1 week following their last dose of medication (Standards Committee of the American Association of Blood Banks, 2009). This is due to the fact that the plasma of individuals taking this medication will have decreased vitamin K–dependent coagulation factor activity.

If the donor donates more frequently than every 4 weeks, he or she is classified as a “frequent” donor and must fulfill criteria outlined in the Code of Federal Regulations (CFR) (Standards Committee of the American Association of Blood Banks, 2009). These requirements are similar in many ways to those for whole blood donation, with differences in deferrals for malaria and transfusion-transmitted disease exposure (CFR, 2009). In addition, the CFR requires that frequent plasma donors have a total serum protein of at least 6.0 g/dL; this is determined before each donation. Donors must also have a serum protein electrophoresis or quantitative immunodiffusion performed every 4 months, as well as an annual physical examination by a physician (CFR, 2009). Frequent plasma donors are limited to two donations within a 7-day period with at least 2 days between donations (CFR, 2009).

Both frequent and infrequent plasma donors, as well as those donors donating multicomponent collections or plateletpheresis, are limited in the amount of plasma that they can donate within a 12-month period. Donors weighing 110 to 175 lb can donate up to 12 L; those weighing more than 175 lb can donate 14.4 L (Division of Blood and Blood Products, Center for Biologics Evaluation and Research, 1995).

PLASMA DONOR CONCERNS

The risks of donor plasmapheresis are those common to any hemapheresis procedure. In addition, concern arises over possible depletion of Igs or removal of coagulation factors faster than they can be replenished, especially in frequent donors. Studies of long-term donors (Wasi, 1991), as well as donors undergoing frequent donations (Ciszewski, 1993), have not supported these concerns.

INDICATIONS FOR THERAPEUTIC HEMAPHERESIS

Therapeutic apheresis procedures, both cytappheresis and plasma exchange, have been used to treat a wide variety of illnesses, often without a clear scientific basis for expecting any benefit. Limited numbers of randomized controlled trials have been conducted (Shehata, 2002). In this way, apheresis has been analogous to the bloodletting of the early 18th century, with which it has frequently been compared. As a result, it is difficult in some cases to determine for which diseases and disorders hemapheresis is truly indicated. To help determine when hemapheresis procedures are indicated, the American Society for Apheresis (ASFA) publishes regularly updated recommendations and guidance on the use of apheresis (Szczipiorkowski, 2010). Diseases are grouped into four indication categories, as given in

TABLE 37-9

ASFA Categorization of Apheresis Indications

Category	Description
I	Disorders for which apheresis is accepted as first-line therapy, either as a primary standalone treatment or in conjunction with other modes of treatment.
II	Disorders for which apheresis is accepted as second-line therapy, either as a standalone treatment or in conjunction with other modes of treatment.
III	Disorders for which published available evidence does not permit definitive determination of the role of apheresis. Treatment decisions should be highly individualized.
IV	Disorders for which published evidence demonstrates or suggests apheresis to be ineffective or harmful. Institutional review board (IRB) approval is desirable if apheresis is undertaken in these circumstances.

From Szczepiorkowski (2010).
ASFA, American Society for Apheresis.

TABLE 37-10

ASFA Recommendation Grades

Recommendation grade	Description
1A	Strong recommendation with high-quality evidence. Can apply to most patients in most circumstances without reservation.
1B	Strong recommendation with moderate-quality evidence. Can apply to most patients in most circumstances without reservation.
1C	Strong recommendation with low-quality or very-low-quality evidence. May change when higher-quality evidence becomes available.
2A	Weak recommendation with high-quality evidence. Best action may differ depending on circumstances or patient or societal values.
2B	Weak recommendation with moderate-quality evidence. Best action may differ depending on circumstances or patient or societal values.
2C	Weak recommendation with low-quality or very-low-quality evidence. Other alternatives may be equally reasonable.

From Szczepiorkowski (2010).
ASFA, American Society for Apheresis.

Table 37-9. In addition, each indication is assigned a recommendation grade that indicates the strength of the ASFA recommendation, as well as the quality of the evidence supporting the recommendation. These are defined in Table 37-10. Table 37-11 lists diseases that have been categorized by ASFA in the most recent publication of the categorization.

A discussion of all of the disorders listed in Table 37-11 is beyond the scope of this chapter. The interested reader is referred to three sources: the textbooks *Apheresis: Principles and Practice* (McLeod, 2010) and *Therapeutic Apheresis: A Physician's Handbook* (Winters, 2008), both published by the AABB, and the special issue of the *Journal of Clinical Apheresis* entitled "Guidelines on the Use of Therapeutic Apheresis in Clinical Practice—Evidence-Based Approach from the Apheresis Applications Committee of the American Society for Apheresis" published by the ASFA (Szczepiorkowski, 2010).

A final consideration is that not every possible disorder that has or could be treated by hemapheresis is included in the resources mentioned here. Similarly, not every potential disorder has been classified by the ASFA. In circumstances where requests are made to perform therapeutic hemapheresis procedures for category III indications, or for those indications that have not been categorized, a physician must evaluate the pathophysiology of the disease process and whether hemapheresis makes sense, the evidence that exists in the medical literature supporting the use of hemapheresis, and the risks of the hemapheresis procedure to the patient, including financial risks (Shaz, 2007). Hemapheresis procedures should not be attempted solely because, "We tried everything else," or

because "When in doubt, pheresis it out." The interested reader is referred to the article "How We Approach an Apheresis Request for a Category III, Category IV, or Noncategorized Indication" (Shaz, 2007), for a discussion of clinical decision-making in such circumstances.

THERAPEUTIC CYTAPHERESIS

Therapeutic Plateletpheresis

Thrombocytosis

Thrombocytosis is defined as an increase in the number of platelets present in the blood. This can range from mild increases to increases resulting in platelet counts greater than 1,000,000/ μ L. It is in these latter patients that concern arises. Thrombocytosis can result from a number of disease processes (Table 37-12). These processes can be primary or secondary (reactive); the latter type accounted for the majority (82%) in one study of patients with platelet counts greater than 1,000,000/ μ L (Buss, 1994).

Both thrombotic and hemorrhagic events may complicate thrombocytosis. Hemorrhagic complications consist predominantly of mucocutaneous bleeding (Schafer, 1996). Thrombotic complications include both microvascular thrombosis, such as erythromelalgia, and macrovascular thrombosis, such as myocardial infarction. Of cases of macrovascular thrombosis, arterial thrombosis predominates, with the most frequent sites including the cerebrovascular, peripheral vascular, and coronary artery circulations (Schafer, 1996). These complications are rare in cases of secondary thrombocytosis (4%) but are relatively common in primary cases (56%) (Buss, 1994). Risk factors found to be associated with these complications in primary thrombocytosis are given in Table 37-13.

Because of concern over the occurrence of these complications, studies have focused on efforts to reduce elevated platelet counts. Treatments include chemotherapeutic agents such as alkylating agents, radiophosphorus (32 P), and hydroxycarbamide (hydroxyurea), as well as medications such as interferon- α and anagrelide (Schafer, 1996). All of these agents have been found to be effective in reducing platelet counts over a period of days to weeks; they also have significant side effects, including leukemogenesis with alkylating agents, 32 P, and hydroxycarbamide. As a result, and because of the low risk of complications in patients with secondary disorders, these interventions to reduce platelet count are not used in this setting, and the underlying disorder is treated (Buss, 1994). In primary disorders, however, the decision is more difficult and controversial. Still, unless the patient is symptomatic from the elevated platelet count, many authors recommend not treating. This is due in part to studies that have shown no convincing evidence that reducing the platelet count prevents complications (Schafer, 1984), as well as the fact that the platelet count does not correlate with the risk of thrombosis (Tefferi, 1994).

Therapeutic Thrombocytapheresis Indications

The role of hemapheresis in the treatment of thrombocytosis is to intervene when patients become symptomatic and to stabilize patients' condition until medical management reduces the platelet count. As stated previously, platelet count does not correlate with the risk of thrombosis, even when the count is >1,000,000/ μ L (Schafer, 1984, 1996; Buss, 1994; Tefferi, 1994). As a result, thrombocytapheresis should be used to treat those who are symptomatic from their elevated platelet counts. Additionally, thrombocytapheresis can be used in the preoperative setting to reduce the platelet count and possibly prevent bleeding, and in the treatment of pregnant women (Isbister, 1997). The benefit of thrombocytapheresis in this latter patient group is again uncertain, as there is a lack of correlation between platelet count and pregnancy outcome (Schafer, 1996). Although hemapheresis is an adjunct to therapy and not a primary treatment modality, Baron (1993) did note that apheresis appeared to increase the sensitivity of patients to busulfan therapy. This produced a greater platelet response but also a greater danger of pancytopenia (Baron, 1993). It must be stressed that the effects of thrombocytapheresis in thrombocytosis are temporary, lasting hours to days, and medical management must be instituted at the same time.

Thrombocytapheresis procedures in this setting can be performed on any instrument that can collect platelets from donors. Typically, the goal of the procedure is to process 1–1.5 blood volumes (Baron, 1993), or to process for a defined length of time such as 3 hours (Burgstaler, 1994). In a study comparing the ability of apheresis systems to reduce platelet counts, Burgstaler and Pineda (1994) found that processing for 3 hours resulted in a 43% reduction in platelet count using the COBE Spectra. Just as there is no defined level at which thrombosis occurs, no target for

platelet reduction has been defined. The patient's symptoms should be treated, with improvement/resolution being the desired endpoint.

Thrombocytapheresis for symptomatic thrombocytosis is a category II indication with a 2C recommendation grade, and prophylactic thrombocytapheresis for asymptomatic thrombocytosis is a category III indication with a 2C recommendation grade, according to the ASFA (Szczepiorkowski, 2010).

Therapeutic Leukocytapheresis

Hyperleukocytosis

Hyperleukocytosis is an extreme elevation in white blood cell count. The causes of such elevations include malignant and nonmalignant disease, with the former resulting in the highest counts. This can produce a number of syndromes, including central nervous system (CNS) leukostasis, characterized by neurologic deficits, and pulmonary leukostasis, characterized by poor oxygenation and chest pain (Isbister, 1997). Traditionally, extremely elevated white blood cell counts have been believed to result in increased viscosity with changes in blood flow within the microvasculature. White blood cells, especially granulocytes, are more rigid than red blood cells

TABLE 37-13

Factors Associated With Complications in Primary Thrombocytosis

Thrombosis	Increasing age Previous thrombotic event Longer duration of thrombocythemia
Hemorrhage	Platelet count >2,000,000/ μ L NSAID ingestion

NSAID, Nonsteroidal anti-inflammatory drug.

(Isbister, 1997). It has been believed that, at these very high white blood cell counts, occlusion of the microvasculature can occur, resulting in leukostasis and ischemia. However, this may not represent the entire picture. White blood cell count does not necessarily correlate with the onset of symptoms. More recent evidence suggests that the interactions of adhesion molecules expressed on the leukemic blasts and endothelial cells may also contribute to vascular occlusion and endothelial injury (Liesveld, 1997; Porcu, 2000; Stucki, 2001).

In addition to vascular occlusive symptoms of hyperleukocytosis, another potential problem resulting from markedly elevated white blood cell count is the tumor lysis syndrome (Isbister, 1997). This occurs during the patient's initial chemotherapy and results from the release of tumor cell breakdown products, producing damage to the kidneys and/or initiating disseminated intravascular coagulation.

Higher mortality rates occur during the first week of therapy among patients with white blood cell counts greater than 100,000/ μ L. These deaths were associated with a significantly greater number of CNS hemorrhages than in those with white cell counts <50,000/ μ L (Dutcher, 1987). Similarly, the presence of pulmonary leukostasis is also associated with early mortality (Lester, 1985). In one study, average survival of patients with pulmonary leukostasis was 0.2 months versus 15.4 months in those with CNS leukostasis and 10.8 months in patients lacking leukostasis (Lester, 1985). As in thrombocytosis, the definitive treatment of these elevated white blood cell counts is to treat the underlying disease, in this case leukemia.

Therapeutic Leukocytapheresis Indications

As in therapeutic thrombocytapheresis, the role of leukocytapheresis in hyperleukocytosis is to decrease the white cell count to relieve symptoms and/or prevent tumor lysis syndrome. As with thrombocytapheresis, the indication for treating a patient is the presence of symptoms indicating leukostasis. Additionally, leukocytapheresis can be used to treat pregnant women to prolong pregnancy until the child can be delivered and the mother started on chemotherapy. Again, hemapheresis represents an adjunct to therapy and not a primary treatment modality. The definitive therapy is chemotherapy that should be begun at the same time or shortly after hemapheresis is initiated, as the reduction in white blood cell counts with leukocytapheresis is temporary. With this said, two things should be stated. Although hemapheresis can reverse or lessen leukostasis symptoms in some patients, no correlation has been found between the degree of leukoreduction, as an absolute value or as a percentage, and overall survival (Porcu, 1997). In addition, although leukocytapheresis may improve 2- to 3-week mortality rates after diagnosis, it does not appear to affect the long-term or overall survival rates of these patients (Thiébaud, 2000; Giles, 2001).

Leukocytapheresis procedures share similarities with granulocyte collections, as previously described. HES can be used to enhance the separation of cellular components during centrifugation, resulting in more efficient white cell removal. This is especially important when the cells are more mature granulocytes, as seen in chronic phase CML. The total blood volume processed is usually 8–10 L or two blood volumes (McLeod, 1993). With this strategy, reductions in white blood cell count of 50%–85% have been reported (Steeper, 1985; Burgstaler, 1994). As in therapeutic thrombocytapheresis, no goal has been defined for the reduction in white blood cells, and improvement/resolution of the patient's symptoms is the endpoint. Hyperleukocytosis with leukostasis is a category I indication with a 1B recommendation grade for leukocytapheresis. Prophylactic leukocytapheresis for asymptomatic hyperleukocytosis is a category III indication with a 2C recommendation grade, according to the ASFA (Szczepiorkowski, 2010).

Red Cell Exchange

Red cell exchange (RCE), or therapeutic erythrocytapheresis, is a form of cytapheresis that removes the patient's red blood cells and replaces them with allogeneic red blood cells. This form of hemapheresis has been used occasionally to treat hyperparasitemia in malaria and other parasitic infections of red blood cells such as babesiosis (Powell, 2002). It is most commonly used in the treatment of sickle cell anemia.

Sickle Cell Anemia

Sickle cell anemia is an autosomal recessive disorder present in 1 in 200–500 African American newborns (Wayne, 1993); it is also seen in people from sub-Saharan and Western Africa, Arab countries, the Mediterranean basin, and India (Davies, 1997). Sickle cell anemia results from a mutation that substitutes a valine for a glutamic acid at position six of the β -globin chain of Hb, producing Hb S (Davies, 1997). This change decreases the solubility of Hb when deoxygenated, such that crystals form which alter the shape of the red blood cell and damage its membrane. Repeated episodes lead to irreversible sickling of the cell. Even in the absence of sickling, the red cells in sickle cell anemia are abnormally “sticky.” The combination of this “stickiness” and sickling leads to occlusion of small vessels, endothelial damage, and thrombosis (Wayne, 1993; Davies, 1997).

Sickle cell anemia is characterized by chronic hemolytic anemia and crises—episodes of acute illness. Crises are most often due to vascular occlusion and infarction and include crises of pain, aplasia, splenic sequestration, hemolysis, cerebrovascular accidents, acute chest pain syndrome, and priapism. They are treated by correcting factors that enhance sickling, namely, dehydration, hypoxia, and acidosis. This is done through hydration, alkalization, and the administration of supplemental oxygen (Wayne, 1993; Davies, 1997). In addition, painful crises are treated by the administration of analgesics. These crises can also be treated by red blood cell transfusion.

Red cell transfusion in sickle cell anemia can be divided into three categories: acute simple transfusion, chronic simple transfusion, and red cell exchange transfusion. Acute simple transfusion consists of the transfusion of red blood cells to increase oxygen-carrying capacity and is indicated for the treatment of symptomatic anemia, splenic sequestration crisis, aplastic crisis, blood loss, accelerated hemolysis, and preoperative preparation (Wayne, 1993). Chronic simple transfusion consists of regular

TABLE 37-14

Benefits of Red Blood Cell Exchange by Apheresis Compared With Simple or Chronic Transfusion

Decreased amount of hemoglobin S without increasing hematocrit and, therefore, viscosity
Use of fewer units of red blood cells to achieve the same percentage of hemoglobin S
Decreased contribution to iron overload in chronically transfused patients

transfusions of red blood cells in an attempt to suppress endogenous red cell production with the goal of keeping the percentage of red cells containing Hb S below 30%. This form of therapy is indicated for cerebrovascular disease and debilitating vaso-occlusive symptoms. It can also be used to treat sickle cell disease complicated by pulmonary disease, cardiac disease, high-risk pregnancy, and preoperative preparation (Wayne, 1993).

RCE in sickle cell anemia is used to remove Hb S-containing red blood cells, while replacing them with Hb A-containing red cells. The goal of RCE is to leave the patient with a Hct of approximately 30% and a “sicklecrit”—the percentage of cells containing Hb S—of less than 30% (Wayne, 1993; Davies, 1997). To do this, the fraction of red cells remaining (FCR) must be calculated based on the patient's current Hb S percentage and the desired Hb S percentage. This can be calculated by Equation 37-5. If the patient's Hct is to be increased by the procedure, then the adjusted FCR must be calculated according to Equation 37-6 (COBE BCT, 1997). It should be noted that increasing the Hct too much can result in decreased oxygen delivery as a result of increased viscosity. This results from the fact that the sickle cells, as well as the endothelium, of these patients are “stickier” than normal.

$$\text{Desired FCR} \% = (\text{Desired Hb S} / \text{Current Hb S}) \times 100 \quad (37-5)$$

$$\text{Adjusted FCR} \% = \text{Desired FCR} \% \times (\text{Current Hct} / \text{Desired Hct}) \times 100 \quad (37-6)$$

These are then entered into the hemapheresis instrument along with other values to determine the volume of red blood cells necessary to perform the procedure. The benefits of RCE over the other strategies of transfusion are given in Table 37-14.

Acute chest syndrome is a crisis characterized by respiratory symptoms, chest and abdominal pain, infiltrates on chest radiograph, and an abnormal chest examination. It is thought that pain from rib splinting or fat embolism results in hypoventilation leading to atelectasis. This, in turn, causes hypoxia leading to occlusion of small vessels in the lung and possible thrombosis of the pulmonary arteries (Davies, 1997). It occurs in 20%–50% of sickle cell patients and has a mortality rate of 2%–14%. Repeated episodes may progress to chronic pulmonary disease (Wayne, 1993). RCE is used to remove Hb S-containing cells and has been associated with marked improvement (Wayne, 1993).

Priapism is a painful, sustained erection that results from occlusion of vessels in the corpus cavernosum by sickled cells. It is associated with dehydration and acidosis and is treated with supplemental oxygen, hydration, and analgesics (Wayne, 1993). If prolonged (over 6 hours), priapism is referred to as fulminant priapism and may require surgical intervention or RCE. A significant percentage of patients will suffer from impotence if not treated (Davies, 1997). Although RCE has been reported as effective in treating priapism, it is not without risks. A syndrome of neurologic events called ASPEN syndrome (association of sickle cell disease, priapism, exchange transfusion, and neurologic events) has been reported to occur in some patients treated with RCE. It consists of neurologic events ranging from headache and seizure activity to obtundation requiring ventilator support. The syndrome is thought to be due to decreased cerebral blood flow from the abrupt elevation in Hct, as well as the release of vasoactive substances from the penile detumescence. Aggressive treatment has been associated with complete neurologic recovery (Siegel, 1993). Patients suffering from priapism undergoing RCE should be monitored for symptoms of ASPEN syndrome.

Additional crises and disorders in sickle cell patients for which RCE is indicated include cerebrovascular accident, retinal artery vaso-occlusion, hepatic failure, and septic shock. RCE has also been used to decrease the

percentage of Hb S at the initiation of chronic simple transfusion therapy, to prevent sickling due to contrast dye during cerebral angiograms, and in preparation for surgery (Wayne, 1993). It should be noted that a study has shown no benefit of RCE versus a conservative transfusion regimen designed to increase Hb to 10 g/dL in preventing complications of surgery (Vichinsky, 1995).

Stroke in sickle cell anemia is a category I indication with a 1C recommendation grade for RCE. Acute chest syndrome, stroke prophylaxis, and prophylaxis for iron overload in sickle cell anemia are all category II indications with 1C recommendation grades for RCE. Primary or secondary stroke prevention is a category II indication for RCE with a 1C recommendation grade. Finally, multiorgan failure in sickle cell anemia is a category III indication with a 2C recommendation grade for RCE according to the ASFA. Severe malaria is a category II indication with a 2B recommendation grade for RCE. Severe babesiosis is a category I indication with a 1B recommendation grade, and treatment of high-risk patients without severe symptoms is a category II indication with a 2C recommendation grade for RCE (Szczepliorowski, 2010).

Extracorporeal Photopheresis

Extracorporeal photopheresis, also called extracorporeal photochemotherapy (ECP) or photopheresis, is a form of leukocytapheresis. In this procedure, a small percentage of a patient's white blood cells are collected by hemapheresis. These cells are then treated by incubation with a psoralen compound and are exposed to ultraviolet A (UVA) irradiation within the instrument. Following this, the cells are reinfused into the patient (Zic, 1999). This then appears to result in an immunomodulatory effect. Depending on the disease being treated, this may stimulate or suppress an immune response. Currently, this therapy is approved by the FDA only for the treatment of cutaneous T cell lymphoma (CTCL). In December of 2006, the Centers for Medicare Services approved coverage of the use of photopheresis for the treatment of chronic graft-versus-host disease and acute cardiac allograft rejection. Previously, Medicare had covered the use of photopheresis in the treatment of CTCL.

Extracorporeal Photopheresis Indications

Cutaneous T Cell Lymphoma. The first disease treated by photopheresis was CTCL—a skin-based T cell lymphoma characterized by a long premalignant phase (4–10 years) of eczematous skin lesions. Following this, the disease progresses through a series of phases characterized by increasing skin involvement until the development of the tumor phase, characterized by cutaneous masses. CTCL may then progress to a leukemic phase known as Sézary syndrome, in which malignant T cells are found circulating in the blood. Median survival depends on the stage of the disease at diagnosis; 10-year survivals range from 20% for the tumor stage to 85% for the initial plaque phase (Zic, 1999).

In 1987, Edelson reported responses in 64% of 37 CTCL patients treated with photopheresis. Subsequently, the use of photopheresis for the treatment of CTCL received FDA approval (Zic, 2003). Combined analysis of more than 400 patients reported in the literature has found an overall response rate of CTCL to photopheresis of 55.7%, with 17.6% of patients having a complete response. Response rates vary from 64% for stage IB patients (generalized patches and plaques) to 27.3% for stage IVB patients (visceral involvement) (Zic, 2003). Factors predictive of response to photopheresis are given in Table 37-15. The median time until clearing of skin lesions in such patients is 11 months; patients who show an early response (clearing in 6–8 months) maintain their response (Zic, 1999). Extracorporeal photopheresis has also been associated with longer survival

TABLE 37-16

Factors Associated With the Development of Chronic Graft-Versus-Host Disease

- | | |
|-------------------------------------------|------------------------------------------------|
| • Increased donor age | • Unrelated donor |
| • Increased recipient age | • Prior acute graft-versus-host disease (GVHD) |
| • Human leukocyte antigen (HLA) disparity | • Alloimmunized female donor |

from time of diagnosis (longer than 60 months among photopheresis-treated patients vs. 31 months for patients receiving chemotherapy) (Christensen, 1991).

The mechanism of action of photopheresis in CTCL has not been completely elucidated. Extracorporeal photopheresis is known to induce a CD8+ T cell response toward expanded pathologic T cell clones within the patient (Zic, 2003). It is thought that this is due to the fact that upon exposure to UVA, 8-methoxypsoralen (8-MOP) reacts with cellular constituents, irreversibly binding to DNA, proteins, and lipids. This induces an increase in the number of HLA class I molecules present on the exposed cell, as well as apoptosis. It is interesting to note that apoptosis occurs in exposed lymphocytes, including malignant T cells, but not monocytes. Monocytes, as a result of their exposure to subphysiologic temperatures and contact with walls of the tubing during collection and photoactivation, differentiate into immature dendritic cells (DCs). These DCs are then capable of phagocytosing the apoptotic malignant T cells and can present the tumor antigens from these cells within their HLA class I molecules. Upon reinfusion of the UVA-exposed photopheresis product, these antigen-presenting cells can then activate cytotoxic T cells, resulting in an immune response toward abnormal T cell clones (Zic, 2003). This is associated with a shift in the patient's cytokine profile from that of a Th2 response to a Th1 response (Zic, 2003). The beneficial effects of the procedure do not result from direct cytotoxicity of 8-MOP and UVA on abnormal T cells or tumor cells, as only 10%–15% of the lymphocyte pool is harvested, and less than 5% of cutaneous T cell lymphoma cells are treated (Christensen, 1991).

Erythrodermic CTCL is a category I indication with a 1B recommendation grade for extracorporeal photopheresis, according to the ASFA (Szczepliorowski, 2010). Nonerythrodermic CTCL is a category III indication with a 2C recommendation grade for extracorporeal photopheresis (Szczepliorowski, 2010).

Graft-Versus-Host Disease and Solid Organ Rejection. Chronic graft-versus-host disease (cGVHD) occurs in 27%–50% of matched related sibling donor transplants and in 42%–72% of unrelated bone marrow or peripheral blood stem cell transplants (Foss, 2002). Factors associated with cGVHD are given in Table 37-16.

A number of studies have reported the use of extracorporeal photopheresis in cGVHD (Foss, 2002). In these studies, patients with cGVHD unresponsive to other therapies have shown improvement in skin, oral, and visceral (hepatic) lesions. These have been associated with normalization of CD4/CD8 ratios and decreased numbers of NK cells. Treatment allowed for tapering of steroid doses and maintenance of the response for a median of 12 months. No increase in infection rates or CMV activation was noted in the patients studied (Foss, 2002). Those patients who were more likely to respond were those who started therapy within 10 months of transplant.

As with CTCL, the mechanism behind photopheresis in cGVHD is unclear. It is remarkable that therapy associated with immune activation in one disease is associated with immune suppression in another. In cGVHD patients, photopheresis is associated with a decrease in antigen recognition and processing by DC, as well as decreased numbers of DCs. This, in turn, decreases CD8 stimulation, with a shift in Th1 response to a Th2 response through inhibition of Th2 cytokine secretion (Foss, 2002). The result is decreased alloreactivity by T cells.

Similar to cGVHD, solid organ rejection is a disorder of alloreactive T cells. Extracorporeal photopheresis has similarly been used to treat rejection in heart, lung, kidney, and liver transplant. In cardiac transplantation, the use of extracorporeal photopheresis has been reported to histologically reverse 89% of treated rejection episodes without side effects. Similar rates have been reported with other transplant types (Dall'Amico, 2002).

Chronic cutaneous GVHD is a category II indication with a 1B recommendation grade. Acute cutaneous GVHD is a category II indication with a 2C recommendation grade. GVHD involving organs other than the skin, whether acute or chronic, is a category III indication with a 2C recommendation grade for extracorporeal photopheresis, according to ASFA (Szczepiorkowski, 2010). Treatment of cardiac allograft rejection is a category II indication with a 1B recommendation grade for extracorporeal photopheresis, and prophylaxis of rejection is a category I indication with a 1A recommendation grade (Szczepiorkowski, 2010).

Other Diseases. Additional diseases that have been treated with extracorporeal photopheresis are listed in Table 37-17. Many, but not all, of these diseases have a common thread of T cell alloreactivity or autoreactivity. Some of these diseases have been assigned categories and recommendation grades by ASFA; the reader is referred to Table 37-11.

Extracorporeal Photopheresis Procedure

The extracorporeal photopheresis procedure is performed using the UVAR XTS or CELLEX photopheresis system (Therakos, Inc., Exton, PA) with the UVAR XTS scheduled for discontinuation by 2016. For the UVAR XTS, following venipuncture, 125 mL or 225 mL of whole blood is collected in a Latham centrifuge bowl, where the components are separated. Heparin or acid-citrate-dextrose (ACD) can be used as the anticoagulant. The buffy coat is retained in a collection bag, and the remaining blood components are returned to the patient. Because this is an intermittent centrifuge, six cycles (125 mL bowl) or three cycles (225 mL bowl) of whole blood collection are performed to collect a 270-mL MNC suspension. This consists of 80 mL of plasma, 90 mL of saline, and 100 mL of MNC. After completion of the collection, 8-MOP is added to the bag. The MNC suspension is then pumped through a photoactivation chamber. This consists of transparent acrylic plates between which is sandwiched a tortuous channel. Adjacent to the plate is a UVA light source that irradiates the 8-MOP-containing buffy coat. The MNC suspension is photoactivated for 30 minutes. Following completion of photoactivation, the buffy coat is then reinfused. The general process for the CELLEX device is similar to that for the UVAR XTS, in that a buffy coat is harvested, exposed to 8-MOP, photoactivated, and reinfused to the patient. CELLEX differs from UVAR XTS, however, in that it is a continuous flow device, can be used to perform a double- or single-needle procedure, and has peristaltic pumps, as opposed to pneumatic pumps. This device also has only a single-size centrifugation bowl. Results of these changes are that the extracorporeal volume of the CELLEX is less than that of the UVAR XTS (216–266 mL for the CELLEX vs. 220–620 mL for the UVAR XTS), and the total procedure time is less (1.5 hours for the CELLEX vs. 3 hours for the UVAR XTS). In addition, the CELLEX provides greater flexibility in programming of the device (Burgstaler, 2010). This means that much smaller patients, including pediatric patients, who could not be treated previously can now receive photopheresis. A typical course of photopheresis for CTCL consists of two treatments on consecutive days every 4 weeks

(Christensen, 1991). Following improvement in disease symptoms, the interval between procedures may be prolonged, and the patient weaned from extracorporeal photopheresis. For other indications, the frequency of treatment varies; the reader is referred to the ASFA guidelines for additional information (Szczepiorkowski, 2010).

An important aspect of this procedure is the clean separation of whole blood into plasma and buffy coat. The product must allow the transmission of UVA light to photoactivate the 8-MOP. The presence of significant numbers of red blood cells within the leukocytapheresis product will reflect or absorb the UVA irradiation, resulting in failure to photoactivate the product. As a result, it is critical that the Hct of the leukocytapheresis product be less than 7% (Zic, 1999). Similarly, it is important that excess plasma not be present. Excess plasma will dilute the white blood cells, resulting in fewer passages of each cell through the photoactivation chamber (Zic, 1999).

Two complications of this procedure are photosensitivity and possible leukemogenesis. Patients undergoing extracorporeal photopheresis are sensitive to sunlight (Knobler, 1993). They should avoid direct or indirect sunlight exposure for 24 hours following completion of the procedure by covering exposed skin, using sunscreen, and wearing wrap-around ultraviolet (UV) protective eyewear. Another possible complication of extracorporeal photopheresis could be mutagenesis from DNA damage caused by photoactivation of the 8-MOP. This theoretically could result in the reinfusion of cells with damaged DNA still capable of cell division. These cells could then give rise to hematologic malignancies. Although evidence has not been found to support this concern, it is still a theoretical risk of the procedure (van Iperen, 1997).

THERAPEUTIC PLASMA EXCHANGE

Efficacy of Removal

The goal of therapeutic plasma exchange is to remove a pathologic substance present within the plasma by removing the patient's plasma and replacing it with a substitution fluid. The removal is nonspecific in that all of the substances present in the plasma, including normal substances, are removed. Removal of a substance can be predicted by Equation 37-7, as shown in Figure 37-2 (Derksen, 1984b):

$$Y/Y_0 = e^{-x} \quad (37-7)$$

where

Y is the final concentration of the substance

Y_0 is the initial concentration of the substance

x is the total number of times the patient's volume is exchanged.

This model assumes that the intravascular compartment is closed, and that exchange between the intravascular and extravascular compartments does not occur. Based on this equation, 30% of the initial quantity of a substance will remain within the patient's plasma after one plasma volume exchange, and 10% will remain after the exchange of two plasma volumes.

Figure 37-2 Removal of substances during plasma exchange. The removal of substances limited to the intravascular compartment, whether pathologic or normal, can be predicted by an exponential equation (see Equation 37-7). A fixed percentage of the remaining substance is removed with each blood volume. This means that as the number of blood volumes processed increases, a progressively smaller amount of the substance is removed, resulting in diminishing returns.

TABLE 37-17

Diseases in Which Extracorporeal Photopheresis Has Been Reported as Effective

Malignancy	Cutaneous T cell lymphoma (CTCL)
Graft-versus-host disease (GVHD)	Mucocutaneous GVHD Hepatic GVHD
Organ rejection	Heart Kidney Lung
Autoimmune diseases	Systemic lupus erythematosus Rheumatoid arthritis Juvenile dermatomyositis Pemphigus vulgaris Epidermolysis bullosa acquisita
Infectious diseases	Chronic Lyme arthritis AIDS-related complex (ARC)
Other diseases	Severe atopic dermatitis Psoriasis Nephrogenic systemic fibrosis

From van Iperen (1997), Zic (1999), and Mathur (2008).

As more plasma volumes are exchanged, a fixed percentage of the remaining substance is removed (approximately 70%), such that a smaller and smaller total amount is removed. As can be seen in [Figure 37-2](#), the marginal benefit of removing additional plasma volumes declines after 1.5–2 plasma volumes, so most therapeutic plasma exchange procedures are limited to 1–1.5 plasma volume exchanges.

The assumption that no exchange occurs between intravascular and extravascular compartments during the procedure is not valid for all substances. As a result, the amount removed as well as the concentration in the plasma at the end of the procedure may not match that predicted. For example, IgM is located predominantly within the intravascular space (76%), with negligible influx from the extravascular space (Derksen, 1984b). As a result, during a plasma exchange procedure, the equation will accurately predict the removal of IgM. IgA, however, is evenly distributed between the intravascular space and the extravascular space and can move between the two compartments. During plasma exchange, as the concentration of IgA within the intravascular space falls, IgA within the extravascular space follows its concentration gradient and moves into the intravascular space. The result of this is that after the procedure has been completed, the plasma concentration of IgA is not as low as predicted; this would lead one to believe that the procedure was not as efficient as expected (Derksen, 1984b). If one looks at the amount of substance removed by measuring the IgA within the collection bag, one would see that the total amount of IgA removed was greater than predicted, and that the procedure was more efficient than expected. Not only was IgA being removed from the intravascular compartment, it was also being removed from the extravascular compartment (Derksen, 1984b).

Four patterns of removal in plasma exchange using 5% albumin as the replacement fluid have been identified. In the first pattern, seen with fibrinogen and C3, the concentration decreases to a greater extent than expected. This is probably due to the combination of removal and consumption of these factors during the hemapheresis procedure. In the second pattern, such as with IgM, cholesterol, and alkaline phosphatase, the change in concentration is what is predicted. These substances are confined to the intravascular space or have little exchange between compartments. In the third pattern, as seen with lactate dehydrogenase (LD) and creatinine phosphokinase (CPK), the concentration is less than predicted owing to movement of these substances between compartments. Finally, in the fourth pattern, concentrations are much greater than predicted or do not change at all, which may be due to rapid equilibration. This pattern is seen with small inorganic and organic molecules such as potassium, bicarbonate, and glucose (Orlin, 1980).

The pattern of removal of Igs during plasma exchange depends on whether normal Ig or a paraprotein is involved. The removal of normal IgG has been reported to be predictable by [Equation 37-7](#); it behaves as if it is entirely intravascular (Chopek, 1980; Orlin, 1980). Others, however, have reported behavior similar to that of a substance equilibrating between the two compartments (Derksen, 1984b). In the case of paraproteins, the removal of Igs may appear to be half of what is expected when looking at plasma concentrations (Chopek, 1980). This difference is attributed to expansion of the patient's plasma volume due to the presence of the paraprotein (Chopek, 1980). In other words, the plasma volume of the patient is greater than what is predicted by standard equations (e.g., [Equation 37-3](#)), such that if these are used to calculate a 1.5 plasma volume exchange, the real volume exchanged will be less.

In addition to the effect on removal of the substance from the plasma, the distribution between the intravascular and extravascular compartments and the ability to move between these compartments will influence the rise in plasma levels of the substance following plasma exchange. The concentrations of substances that diffuse rapidly and have a large extravascular component will rise rapidly. The increase in concentrations of those substances that are predominantly intravascular will depend on the rate of synthesis of the substance. Most substances return to normal levels within 48–72 hours. Exceptions to this include fibrinogen, complement, and Igs, for which mean recoveries at 48 hours were 65%, 65%, and 44% of initial values, respectively. Cholesterol also shows a slow recovery, with 67%–72% of preapheresis values achieved 1 week after hemapheresis (Orlin, 1980).

For the majority of substances removed by plasma exchange, the rate of synthesis does not increase following the procedure (Derksen, 1984a). For some substances, especially the Igs, rebound may occur. Rebound is an increase in concentration after completion of a procedure to a level greater than that seen initially (Derksen, 1984a; Dau, 1995). This may result from the removal of inhibitory substances by the procedure or the removal of negative feedback on the responsible cell. As a result of this,

concurrent treatment with cytotoxic agents during the procedure is suggested to prevent rebound (Dau, 1995). In addition, plasma exchange may enhance the efficacy of cytotoxic agents by increasing the metabolic activity of autoreactive immune cells, making them more sensitive to such agents (Dau, 1995). Another point related to this is that plasma exchange will only temporarily decrease the level of a pathologic substance unless additional therapy is instituted to stop its production. This means that in most cases, plasma exchange should be viewed as an adjunct to other therapies.

Replacement Fluids

In therapeutic plasma exchange, 1–1.5 plasma volumes are removed; therefore, this volume must be replaced with another fluid. A number of replacement fluids are available, each of which has advantages and disadvantages. Replacement fluids used in plasma exchange include 5% albumin, FFP, plasma cryoprecipitate reduced (cryopoor plasma), saline, and HES.

Albumin in a concentration of 5% is the most widely used replacement fluid. It is a hyperoncotic fluid for most patients and therefore will result in the net flow of fluid from the extravascular space. This can result in a mild dilutional anemia (Chopek, 1980). The main advantage of 5% albumin is that it does not transmit viral diseases. Disadvantages, however, are that it is expensive and has at times been in short supply because of FDA-mandated recalls. Hypotensive reactions due to prekallikrein activation (Alving, 1978) and febrile reactions due to pyrogens have been reported (Pool, 1995). Both of these reactions are rare. In addition, the albumin may not function comparably to the albumin present in the plasma before exchange. Although exchange with 5% albumin provides physiologic concentrations of the protein, the drug- and metabolite-binding sites of this albumin are occupied by preservatives such as sodium caprylate and may not be available for normal physiologic functions (Koch-Weser, 1976). Standard practice is to use a 5% albumin solution for 60%–70% of the replacement volume. The remaining volume is replaced by crystalloid (normal saline).

FFP is used as the primary replacement fluid in treating TTP (see later discussion of this disease) and may also be used to prevent the dilutional coagulopathy seen with repeated plasma exchanges. FFP can be used in the treatment of severe factor XI deficiency in a patient known to bleed from this defect who is to undergo a surgical procedure. Because a concentrate for factor XI is not available and the quantity of FFP that would need to be infused to reach therapeutic levels would cause volume overload, exchange with FFP immediately before the surgical procedure can provide hemostasis. Advantages of FFP are that it is relatively inexpensive and provides physiologic concentrations of coagulation factors. Disadvantages include the danger of transmission of transfusion-transmitted viral diseases, transfusion reactions, the need to have an ABO-compatible product, and an increase in the frequency of citrate reactions (see discussion at the end of the chapter). This last disadvantage results from the fact that the patient is infused not only with citrate anticoagulant but also with the citrate within the FFP. When used to treat TTP, 60%–70% of the replaced volume will be FFP, and the remainder will be normal saline. When used to prevent coagulopathy, two units of FFP can be given at the end of the procedure, with most of the replacement volume being 5% albumin.

Plasma cryoprecipitate reduced is also used in the treatment of TTP, specifically in those unresponsive to plasma exchange with FFP. The advantages and disadvantages of plasma cryoprecipitate reduced are the same as those for FFP, with the exception that plasma cryoprecipitate reduced does not provide physiologic concentrations of all coagulation factors, thereby lacking fibrinogen and factor VIII.

Saline is used for a portion of most plasma exchange procedures (30%–40%); it is used to prime the instrument and to make the anticoagulant solution. The use of saline for greater volumes is problematic in that it is a crystalloid and not a colloid and can redistribute into the extravascular space, resulting in hypotension and edema following the procedure. The advantages of saline are that it is inexpensive and does not carry the risks of transmitting disease.

The final option is the use of synthetic colloidal fluid such as HES. HES is derived from plant starches and consists of large starch molecules that can be added to saline to generate a colloidal solution. Plasma exchanges using HES as the replacement fluid have been described (Burgstaler, 1990; Rock, 1997). The benefits of HES are that it is inexpensive and does not transmit disease. A disadvantage is that a small percentage of individuals will have an allergic reaction to HES (see discussion at end of chapter). Also, high molecular weight HES hetastarch has a half-life of 25.5 hours, so significant amounts can persist after frequent plasma

TABLE 37-18

Effects of Plasma Exchange on Medications as Reported in the Literature

Medications That Do Not Require Dose Supplementation Because of Insignificant Removal, Redistribution From Tissue Stores, or Drug Binding to Red Blood Cells

- Acyclovir
- Azathioprine
- Carbamazepine
- Cyclophosphamide
- Cyclosporine
- Digoxin
- Digoxin
- Oxcarbazepine
- Phenobarbital
- Phenytoin
- Prednisolone
- Prednisone
- Propranolol
- Quinine
- Tacrolimus
- Valproic acid
- Vancomycin

Medications That Are Removed and May Require Dose Supplementation

- Basiliximab
- Ceftazidime
- Ceftriaxone
- Chloramphenicol
- Cisplatin
- Diltiazem
- Interferon- α
- Intravenous immune globulin (IVIg)
- Palivizumab
- Propoxyphene
- Propranolol
- Rituximab
- Tobramycin
- Verapamil
- Vincristine

From Kale-Pradhan (1997), Kintzel (2003), and Ibrahim (2007).

exchange procedures, resulting in volume expansion and alterations in partial thromboplastin time (PTT), total protein, albumin, Hct, and fibrinogen (Rock, 1997). These changes are less frequent with pentastarch, a low molecular weight HES, because of its shorter half-life. HES has been associated with changes in hemostasis (Rock, 1997) but is an alternative replacement solution for those who have reactions to albumin or FFP (Burgstaler, 1990). It can also be used in those who require plasma exchange, but whose religious beliefs preclude the use of replacement fluids derived from blood.

Patient Concerns

Plasma exchange is a nonselective method of removing substances from plasma; many of the concerns about patients undergoing plasma exchange involve the removal of unintended substances such as therapeutic drugs and coagulation factors. Despite the fact that plasma exchange has been a treatment modality for a variety of diseases for almost 30 years, little information is available regarding its effects on therapeutic drugs. Theoretically, drugs that are highly protein or lipid bound should be efficiently removed by plasma exchange. As in the previous discussion, the volume of distribution influences the removal of a drug. For example, a highly protein-bound drug that is limited predominantly to the intravascular compartment should be efficiently removed, and a highly protein-bound drug that is distributed throughout the body will not be efficiently removed. A poorly bound drug will also not be efficiently removed.

The effect of plasma exchange on drug concentrations can be determined by calculating the drug half-life during plasma exchange (Kintzel, 2003). These calculations could then be used to determine the additional dosing that might be needed following plasma exchange. This has not been done with the majority of medications. The effects of plasma exchange on a variety of medications are given in Table 37-18. From a practical standpoint, because plasma exchange may remove a portion of a drug dose, drugs that are given once daily should be withheld until after the procedure, if possible. Drugs that are administered more often should also be scheduled, so they are not given directly prior to plasma exchange.

Another possible way in which plasma exchange and therapeutic drugs may interact is through the removal of enzymes necessary for metabolism and proteins necessary for transport. Plasma pseudocholinesterase is removed during plasma exchange; as a result, neuromuscular blockade agents such as succinylcholine or mivacurium may have a prolonged effect in patients who have recently undergone plasma exchange (Wood, 1978; Naik, 2002). Such agents should be avoided immediately following plasma exchange.

Following plasma exchange using 5% albumin as a replacement fluid, decreases in the levels and activities of coagulation factors (Flaum, 1979; Orlin, 1980), as well as abnormal coagulation tests (Flaum, 1979), have been seen. Flaum (1979) demonstrated significant decreases in the levels of factors V, VII, VIII, IX, and X, and von Willebrand factor (vWF) activity following plasma exchange. These deficits returned to normal by 24 hours following plasma exchange, with the exception of factors VIII and IX and vWF activity, which had returned to normal at 4 hours (Flaum, 1979). Orlin (1980) noted reductions in fibrinogen levels to 25% of preapheresis levels. Fibrinogen levels had reached 66% of preapheresis levels at 72 hours (Orlin, 1980). These studies indicate that a risk of bleeding exists in hemostatically challenged patients following plasma exchange. This is especially true in patients undergoing serial procedures on consecutive days, when sufficient time for recovery of hemostatic levels may not be possible. At-risk patients, such as those who have undergone or will undergo surgical procedures or biopsies in proximity to their plasma exchange, may require FFP as a portion of their replacement fluid. This should be given at the end of the procedure to prevent its removal.

In addition to increased risk of bleeding, increased risk of thrombosis is possible. Because of the nonspecific nature of removal, inhibitors of coagulation, such as antithrombin, are also removed during plasma exchange (Chirnside, 1981; Volkin, 1982). This could theoretically lead to thrombosis.

Finally, platelets are also lost during therapeutic plasma exchange (Perdue, 2001). In a study of 71 patients undergoing therapeutic plasma exchange with the COBE Spectra, Fresenius AS104 (Fresenius HemoCare, Redmond, WA), or the Haemonetics LN9000 (Haemonetics, Braintree, MA), platelet losses ranged from 0–71% (Perdue, 2001). Factors found to influence platelet losses included the instrument used, with the Fresenius AS104 having the greatest losses (18.6% vs. 2.6% and 1.6% for the Haemonetics LN9000 and the COBE Spectra, respectively), and the disease for which patients are being treated. Of patients treated in the study, those with hyperviscosity syndrome due to dysproteinemia had the greatest losses (Perdue, 2001). In this study, however, no bleeding complications occurred (Perdue, 2001). Greater losses with the Fresenius AS104 in comparison with the COBE Spectra were felt to be due to differences in g force and dwell time between the two instruments (Burgstaler, 2001).

Procedures for Selective Removal of Plasma Components

As previously discussed, plasma exchange is nonselective. Each plasma exchange removes approximately 150 g of plasma proteins (110 g of albumin and 40 g of globulin) (Randerson, 1982; Lysaght, 1985) to eliminate 1–2 g of pathologic substance. Repeated plasma exchanges can result in bleeding due to loss of coagulation factors and immunodeficiency due to loss of IgG. If other replacement fluids are used, additional risks may be present, including disease transmission and allergic reactions. Because of these disadvantages, a number of procedures have been developed to selectively remove a plasma component, allowing return of the patient's "cleansed" plasma. The benefits of such procedures are that depletion of normal plasma components and the need for substitution fluids are avoided. The drawbacks to such procedures are that they are more expensive to perform than plasma exchange because of the costs of selective removal columns. In addition, although many devices are available worldwide to perform these types of procedures, only two are available in the United States and have been licensed by the Food and Drug Administration.

Selective removal procedures most often involve an initial separation step, in which the cellular elements of whole blood are separated from the plasma. The plasma is then perfused through the selective removal device, where the substance of interest is removed by chemical, physical, or immunologic means. The treated plasma is then recombined with the cellular components and reinfused. The selective removal device may then be regenerated, and the bound substance removed and diverted to a waste collection bag. Following this, the selective removal device is used to treat additional plasma. If the device cannot be regenerated, then it is discarded. Examples of selective removal procedures are discussed in the following sections.

Selective Removal of Low-Density Lipoproteins

Selective removal of low-density lipoproteins (LDLs), also called LDL-apheresis, is indicated for the treatment of familial hypercholesterolemia

TABLE 37-19

Criteria for Use of Low-Density Lipoprotein (LDL) Apheresis in Familial Hypercholesterolemia (FH)

U.S. Food and Drug Administration Criteria

- Functional FH homozygotes with an LDL cholesterol >500 mg/dL
- Functional FH heterozygotes with an LDL cholesterol \geq 300 mg/dL who have failed a 6-month trial of maximal drug therapy and an American Heart Association Step II diet
- Functional FH heterozygotes with an LDL cholesterol \geq 200 mg/dL and documented coronary artery disease who have failed a 6-month trial of maximal drug therapy and an American Heart Association Step II diet

German Committee of Physicians and Health Insurance Funds

- Homozygotes for FH
- Patients with severe hypercholesterolemia in whom maximal dietary and drug therapies for >1 year have failed to lower cholesterol sufficiently

International Panel on Management of FH

- Homozygotes for FH
- Heterozygotes for FH with symptomatic coronary artery disease in whom LDL cholesterol is >4.2 mmol/L or decreases by <40% despite maximal medical management

Heart—United Kingdom

- Homozygotes for FH in whom LDL cholesterol is reduced by <50% and/or >9 mmol/L with drug therapy
- Progressive coronary artery disease, severe hypercholesterolemia, and Lp(a) >60 mg/dL in whom LDL cholesterol remains elevated despite drug therapy.

Data from Thompson GR, HEART-UK LDL Apheresis Working Group. Recommendations for the use of LDL apheresis. *Atherosclerosis* 2008;198:247–55.

(FH) in homozygotes and in heterozygotes unresponsive to drug therapy (Thompson, 2008). This disorder results in accelerated atherosclerosis due to the inability of the liver to clear LDL cholesterol from the blood caused by mutations in the hepatic LDL receptor. Criteria for the treatment of patients with LDL apheresis vary worldwide and are given in Table 37-19. Comparisons of the life expectancy of patients treated with these techniques and their untreated siblings (Thompson, 1985), as well as series (Kamanabroo, 1988) and case reports (Leren, 1993) of treated patients, have been reported. Significant reductions in cholesterol, improvements in xanthomas, disappearance of electrocardiographic (ECG) abnormalities, regression of coronary artery lesions, improvement in exercise tolerance, and prolongation of life span have been seen (Thompson, 1985; Kamanabroo, 1988; Leren, 1993; Matsuzaki, 2002). A number of methods are available for the selective removal of LDL.

The first method used after plasma exchange was double-filtration plasmapheresis (DFPP). LDL is one of the largest plasma components; as such, filters can be constructed to allow its removal. In DFPP, plasma is separated from whole blood by filtration. The plasma is then passed through a second filter with a pore size too small to allow passage of the LDL. The resulting plasma filtrate contains 83% of the albumin, 68% of the IgG, and 47% of the HDL cholesterol present in the original plasma. The filter, however, retains 94% of the LDL cholesterol, 92% of the IgM, and 90% of the fibrinogen. In comparison with plasma exchange, secondary filtration produced a similar decrease in LDL cholesterol but resulted in a smaller loss of HDL cholesterol (Leitman, 1989). Because lipids in the plasma can clog the second filter, a heater is used in modern DFPP instruments to heat the plasma before it reaches the second filter. This keeps the lipids from gelling (Klingel, 2004).

A second method of LDL-apheresis is heparin-induced extracorporeal low-density lipoprotein precipitation (HELP) (B Braun Medical Inc., Bethlehem, PA). With this technique, plasma is separated from whole blood using a hollow fiber separator. A sodium acetate buffer of pH 4.84 containing heparin is added to the plasma to precipitate the LDL. This precipitate is then removed by filtration, with the heparin being adsorbed from the plasma by a diethylaminoethyl cellulose filter. The acetate and extra volume are then removed through bicarbonate dialysis/ultrafiltration. The treated plasma is combined with the cellular elements and returned to the patient (Bambauer, 2003). Results of treatment in one trial demonstrated reductions in LDL cholesterol of greater than 30%,

with reductions in HDL and fibrinogen of 15% and 58%, respectively (Lane, 1993).

A third method of removal is dextran sulfate absorption (Liposorber, Kaneka, Osaka, Japan). In this method, two columns of dextran sulfate are used to continuously remove LDL cholesterol. Plasma is separated from whole blood using a hollow fiber separator and is pumped through the dextran sulfate column. Treated plasma is then mixed with the cellular elements and returned to the patient. In the column, the negatively charged dextran sulfate interacts with the positively charged apolipoprotein B-100 of the LDL cholesterol, resulting in its removal. When the first column becomes saturated, flow is switched to the second column and the first is rinsed with 4.1% NaCl to remove the LDL cholesterol. Following this, the column is flushed with lactated Ringer's solution, then is ready to be used again. A salinometer monitors the effluent of the column to make certain that the hyperosmolar saline is not infused into the patient (Bambauer, 2003). Studies using this system have demonstrated a 53% reduction in cholesterol with one plasma volume exchange (Thompson, 1995), as well as a 36% reduction in fibrinogen and a 5% loss of high-density lipoprotein (HDL) (Schulzeck, 1992).

The fourth method of LDL removal is immunoadsorption (Therasorb-LDL, Miltenyi Biotec, Cologne, Germany). In this system, two columns containing agarose beads covalently linked to sheep polyclonal antihuman apolipoprotein B-100 antibodies are used. Similar to other methods, one column is perfused with plasma as the second one is regenerated. In this case, a glycine/HCl buffer is used to remove the bound ApoB-containing LDL (Bambauer, 2003). A study of the use of this form of LDL-apheresis demonstrated its ability to maintain cholesterol at levels of 165 mg%, as well as to increase HDL (Richter, 1993).

The fifth available method is direct adsorption of lipoproteins from whole blood (DALI, Fresenius, St. Wendel, Germany). This system consists of columns that contain polyacrylate-coated polyacrylamide beads. Similar to dextran sulfate, these beads are negatively charged, resulting in binding of the positively charged ApoB-containing LDL. For this column, plasma separation need not occur, as anticoagulated whole blood can be passed through the column. Unlike the systems previously described, the column is not regenerated but is used only once. Different sizes of columns are available to treat different blood volumes (Bosch, 2001a; Bambauer, 2003).

The final system is the dextran sulfate whole blood perfusion system (Liposorber D, Kaneka, Osaka, Japan). As with the DALI column, plasma separation is not needed because whole blood is perfused through the column. Using different dextran sulfate beads than those used in the Liposorber system, LDL binds to the negatively charged dextran. As with the DALI columns, these cannot be regenerated and are discarded once saturated. Again, the columns come in different sizes for use in treating different blood volumes (Otto, 2003).

Of all the systems described previously, only the dextran sulfate system and the HELP system are currently FDA approved for use in the United States. Comparisons of these systems have shown similar reductions in LDL cholesterol, lipoprotein a (Lp[a]), HDL, and other plasma components (Matsuda, 1994; Parhofer, 2000; Bambauer, 2003; Otto, 2007); reductions in HDL, fibrinogen, and other plasma components are less than those seen with plasma exchange. These systems have also demonstrated similar reaction rates but differ in terms of cost and simplicity of the operation (Matsuda, 1994).

Some systems, such as the HELP system and secondary filtration, remove additional plasma components such as fibrinogen. Because of the removal of large macromolecules other than LDL, these systems have been used to alter blood flow characteristics in certain disease states. This form of apheresis has been referred to as Rheophoresis. These devices have been used to treat age-related macular degeneration (Klingel, 2003), sudden sensorineural hearing loss (Suckfull, 1999, 2002), stroke (Jaeger, 1999), and myocardial ischemia (Jaeger, 1999).

According to ASFA, homozygous FH is a category I indication for LDL apheresis with a grade 1A recommendation. Heterozygous FH is a category II indication for LDL apheresis with a grade 1A recommendation. Plasma exchange is a category II indication with a grade 1C recommendation for FH homozygotes whose blood volume is too small for them to be treated with a selective removal system (Szczejporkowski, 2010).

Therapeutic Plasma Exchange Indications

Table 37-20 lists selected disorders for which plasma exchange is indicated and which will be briefly discussed.

TABLE 37-20

Conditions for Which Plasma Exchange Is Accepted

Neurologic disorders	Acute inflammatory demyelinating polyneuropathy (AIDP) Chronic inflammatory demyelinating polyneuropathy (CIDP) Myasthenia gravis
Hematologic disorders	Thrombotic thrombocytopenic purpura Hyperviscosity syndrome
Metabolic disorders	Familial hypercholesterolemia
Other disorders	Anti-basement membrane antibody disease (Goodpasture's syndrome) Cryoglobulinemia Glomerulonephritis Conditioning for renal transplant

Neurologic Disorders

Therapeutic plasma exchange (TPE) is well described for acute inflammatory and chronic demyelinating polyneuropathy and for myasthenia gravis; these diseases are common indications for TPE.

Acute Inflammatory Demyelinating Polyneuropathy. Guillain-Barré syndrome (GBS) is a neurologic disorder of immune origin and is the most frequently encountered paralytic disorder (Guillain-Barré Syndrome Study Group, 1985; Ropper, 1992). It affects males more frequently than females and is more common with increasing age (Hughes, 1993). The disorder is characterized initially by leg weakness, which progresses proximally to involve the arm, face, and oropharyngeal muscles (Ropper, 1992). Sensory loss is mild but may include paresthesias of fingers and toes. Disease progression stops by the third week of the illness and then improves after a variable period of stability (Ropper, 1992).

The pathophysiology of GBS is thought to be one of antibody-mediated damage to peripheral nerve myelin followed by inflammatory response. Complement-fixing antibodies to peripheral myelin have been identified in patients (Koski, 1985). The titers of these antibodies correlate with the clinical course of patients (Koski, 1986), as well as to the response to plasma exchange and relapse following plasma exchange (Vriesendorp, 1991). Treatment of GBS consists of supportive care to provide adequate nutrition, ventilatory support, and avoidance of infection and pulmonary embolism (Ropper, 1992). Intravenous immune globulin (IVIG) is also beneficial in the treatment of GBS (Plasma Exchange/Sandoglobulin Guillain-Barré Syndrome Trial Group, 1997), but corticosteroids are not (Hughes, 1978) and may interfere with the response to hemapheresis (Mendell, 1985).

Plasma exchange is associated with improvement in disability, greater likelihood of recovering function, and a shortened course (Guillain-Barré Syndrome Study Group, 1985). Unfortunately, patients requiring ventilation support for several days before initiation of plasma exchange are not likely to benefit immediately from the procedure. However, they have been found to have a shorter course of ventilator dependency (Guillain-Barré Syndrome Study Group, 1985). Plasma exchange should be initiated within 14 days of the onset of symptoms (Guillain-Barré Syndrome Study Group, 1985; Plasma Exchange/Sandoglobulin Guillain-Barré Syndrome Trial Group, 1997) and should consist of five to six procedures over 8–13 days (Guillain-Barré Syndrome Study Group, 1985; Plasma Exchange/Sandoglobulin Guillain-Barré Syndrome Trial Group, 1997). Replacement fluid should be albumin. Treatments should continue for at least 10–14 days, as cessation of plasma exchange during the active phase of the disorder is characterized by relapse (Ropper, 1988). Ten percent of patients may relapse 16–21 days after therapy (Ropper, 1988).

A review of the Cochrane Neuromuscular Disease Group Register summarized the results of randomized and quasirandomized trials of plasma exchange versus sham exchange or supportive therapy (Raphael, 2002). A total of six trials involving 649 patients were identified which fulfilled the criteria for evaluation. According to the authors of the review, results showed that TPE is the “first and only treatment that has been proven to be superior to supportive treatment alone” (Raphael, 2002). In addition, the authors found that TPE was most effective if started within 7 days of disease onset; two sessions of TPE are superior to none in mild acute inflammatory demyelinating polyradiculoneuropathy (AIDP), four sessions are superior to two in moderate AIDP, and six sessions are no better than four in severe AIDP (Raphael, 2002).

AIDP is a category I indication with a 1A recommendation grade for plasma exchange, according to the ASFA (Szczepiorkowski, 2010).

Chronic Inflammatory Demyelinating Polyneuropathy. Chronic inflammatory demyelinating polyneuropathy (CIDP) is a neurologic disorder, probably of autoimmune origin, characterized by progressive or relapsing motor and/or sensory peripheral nerve dysfunction involving more than one limb and developing over 2 months (Cornblath, 1991). Hyporeflexia or areflexia is also present, with nerve conduction studies indicating demyelination, and nerve biopsy showing demyelination and remyelination (Cornblath, 1991). Other causes of polyneuropathy, such as toxin exposure, must be excluded. Patients demonstrate a male predominance with peak age of onset in the fifth and sixth decades (Dyck, 1975). Patients typically present with burning dysesthesias, muscle pain, and shooting pain, as well as distal muscle weakness (Dyck, 1975). The pathophysiology is thought to be immune-mediated damage to peripheral nerve myelin, causing demyelination and subsequent nerve degeneration. Evidence in support of an immune mechanism includes the presence of demyelination in monkeys when given patient-derived immune globulin (Heininger, 1984), deposition of Ig in nerve biopsies (Dalakas, 1980a), and monoclonal IgG in the cerebrospinal fluid (CSF) of some patients (Dalakas, 1980b). Some CIDP patients respond to corticosteroids but are prone to the complications of these medications because of the need for long-term treatment (Dyck, 1975). IVIG has been found to be beneficial (van Doorn, 1990), especially in a select group of patients demonstrating specific findings (van Doorn, 1991).

The first double-blind, sham-controlled crossover study of plasma exchange in CIDP demonstrated an improvement in 5 of 15 patients undergoing two procedures per week for 3 weeks. The benefits of therapy gradually disappeared 10–14 days following discontinuation (Dyck, 1986). A more recent study involving more frequent procedures (four the first week, three the second week, two the third week, and one the fourth week) demonstrated improvement in 80% of patients, usually becoming apparent on the third to sixth days of treatment (Hahn, 1996). Unfortunately, 66% of responders relapsed after stopping therapy (Hahn, 1996). Comparison of plasma exchange and IVIG has demonstrated similar rapid response with both treatment modalities (Dyck, 1994). Therapy usually consists of an initial intensive course of four to six procedures over 2 weeks, followed by one to two treatments per week or at longer intervals as tolerated. Improvement is usually seen within a week (Hahn, 1996) but lasts only 2 weeks (Dyck, 1986). Five percent albumin is used as the replacement fluid.

CIDP is a category I indication with a 1B recommendation grade for plasma exchange, according to the ASFA (Szczepiorkowski, 2010).

Myasthenia Gravis. Myasthenia gravis (MG) is an autoimmune disorder characterized by weakness of voluntary muscle groups. It may involve only the extraocular muscles or may be generalized, involving appendicular and trunk muscles. The presence of bulbar muscle weakness can lead to aspiration in the setting of a weakened diaphragm. This can result in severe respiratory compromise and was the major cause of death in these patients in the past. MG is caused by autoantibodies directed against the acetylcholine receptor on the motor endplate. These autoantibodies prevent normal functioning of the receptor by increasing receptor turnover, blocking the binding of acetylcholine, and fixing complement with degradation of the receptor (Lindstrom, 1976; Maselli, 1994). The disorder can be associated with other autoimmune phenomena and is associated with thymic abnormalities, including thymoma (Sanders, 1994). Treatment of myasthenia gravis is directed toward increasing the amount of acetylcholine at the motor endplate through the use of acetylcholine esterase inhibitors such as pyridostigmine and neostigmine, as well as decreasing antibody production through immunosuppressive medications such as corticosteroids or azathioprine (Sanders, 1994). In addition, IVIG has been used to treat MG with beneficial effects and has been found to produce effects similar to plasma exchange (Gajdos, 1997).

Plasma exchange is performed to lower the level of anti-acetylcholine receptor antibody, although it has also been reported to be successful in 10%–15% patients with symptoms of MG who do not have detectable antibody. Intensive courses of plasma exchange are recommended for those patients with MG who have severe disease with impaired respiratory function, swallowing, and locomotion (Sanders, 1994), as well as to prepare patients for thymectomy or surgery (Iwasaki, 1993). This may consist of 1–1.5 plasma volume exchanges performed daily for 5–6 days (Dau, 1977). Patients with stable chronic disease who experience mild exacerbations can be treated with shorter courses of 2–3 plasma exchanges (Antozzi, 1991); some patients can be treated with as few as 1–4 exchanges per month (Dau,

1980). The course of therapy should be individualized to the needs of the patient. Five percent albumin is used as the replacement fluid. Concurrent immunosuppressive therapy is also performed to prevent rebound of the antibody (Dau, 1977).

Moderate to severe myasthenia gravis is a category I indication with a 1A recommendation grade for plasma exchange, according to the ASFA. Prophylactic treatment prior to thymectomy is a category I indication with a 1C recommendation grade (Szczepiorkowski, 2010).

Hematologic Disorders

Thrombotic Thrombocytopenic Purpura. TTP is a disorder characterized by thrombocytopenia, microangiopathic hemolytic anemia, neurologic dysfunction, fever, and some degree of renal dysfunction. Laboratory abnormalities, in addition to thrombocytopenia, include schistocytes and nucleated red blood cells on peripheral smear, as well as elevated LD. Although it has been assumed that the elevation in LD is due to hemolysis, a study of 10 patients has demonstrated that in the majority of patients, it is of hepatic origin (Cohen, 1998). TTP can also be divided into primary (idiopathic) and secondary TTP. Causes of secondary TTP include systemic lupus erythematosus (Nesher, 1994), bone marrow transplant (Pettitt, 1994), cyclosporine (Wiener, 1997), pregnancy (McCrae, 1997), ticlopidine (Bennett, 1998), HIV infection (Hymes, 1997), and a number of chemotherapeutic agents.

Primary TTP can be divided into several variants. Idiopathic initial episode TTP consists of a single episode not associated with any other cause. Intermittent TTP is characterized by relapses following the initial episode. Chronic relapsing TTP also consists of recurring episodes, but these begin during childhood and recur at predictable intervals (Moake, 1995).

Histologic study of tissue from patients with TTP has demonstrated the presence of platelet thrombi within the microvasculature. Immunohistochemistry has demonstrated these to consist of platelets and vWF with little fibrin (Asada, 1985). In addition, studies have shown that early in the course of TTP, unusually large multimers of vWF (UL vWF) circulate in the patient's plasma (Moake, 1989). These multimers have an increased affinity for glycoprotein Ib-IX on platelets and are thought to induce platelet aggregation under high shear stress conditions. Normally, these UL vWF multimers are located within the endothelium, and when released into the circulation are cleaved into smaller fragments by a metalloprotease called *adisin* and *metalloprotease* with *thrombospondin* Type I motifs 13 (ADAMTS13) (Levy, 2001a). It has been demonstrated that in patients with idiopathic initial TTP, intermittent TTP, and ticlopidine-associated TTP, an autoantibody is present that decreases ADAMTS13 enzyme activity (Furlan, 1998a,b; Rice, 1998; Tsai, 1998). In idiopathic TTP, autoantibodies are present in 44%–83% of cases (Moake, 2002; Zheng, 2004), with severe deficiency of ADAMTS13 activity (<5%) specifically associated with idiopathic TTP (Moake, 2002; Vesely, 2003; Zheng, 2005). In chronic relapsing TTP, ADAMTS13 activity has been shown to be absent without the presence of an autoantibody representing a genetic deficiency in enzyme production (Furlan, 1997). This congenital syndrome of TTP is also known by the eponym of Schulman-Upshaw syndrome. Other than in patients with ticlopidine-induced TTP, and possibly HIV-induced TTP, neither autoantibodies nor a deficiency in ADAMTS13 enzyme activity appears to be involved in secondary TTP. A study of bone marrow transplant-associated TTP showed normal ADAMTS13 activity (van der Plas, 1999). It is postulated that endothelial damage in many secondary cases results in release of UL vWF that may overwhelm protease activity. Similarly, studies of patients with diarrhea-associated hemolytic-uremic syndrome also show normal ADAMTS13 activity (Tsai, 2001).

The primary treatment of TTP is plasma exchange. Prior to the use of plasma exchange, the mortality rate of TTP was 95%. Following the widespread use of plasma exchange, the mortality rate has decreased to 15% (Rock, 1991). The mechanism of plasma exchange is thought to be the combination of autoantibody removal, UL vWF removal, and ADAMTS13 infusion. An alternative therapy to plasma exchange is plasma infusion. In most cases, however, this is not as effective as plasma exchange (Rock, 1991). This is due to the fact that the volume of plasma that can be infused is limited by the ability of the patient's cardiovascular system to withstand the volume. Coppo (2003) studied large-volume plasma infusion compared with plasma exchange. In their trial, they sought to infuse as much plasma as was given during a plasma exchange. They demonstrated no significant difference with regard to outcome between patients randomized to plasma exchange and those assigned to plasma infusion. They did, however, see greater complications in the plasma infusion group due to

volume overload, and 8 of the 19 patients in that arm had to be switched to plasma exchange because of this complication (Coppo, 2003). There are two settings in which plasma infusion is indicated in the treatment of TTP. First, patients with a genetic deficiency of ADAMTS13 expressed as chronic relapsing TTP can be given regular fresh frozen plasma infusion to prevent exacerbation. In addition, plasma infusion can be used to treat a patient while arrangements are being made to perform plasma exchange. Additional therapies for TTP include antiplatelet medications (Amorosi, 1977), vincristine (Gutterman, 1982), splenectomy (Crowther, 1996), IVIG (Centurioni, 1995), cyclosporine (Hand, 1998), corticosteroids (Bell, 1991), and rituximab (Elliott, 2009).

Treatment of TTP consists of daily plasma exchange of 1–1.5 volumes using FFP as a replacement fluid until the platelet count is greater than 150,000/ μ L, the LD is normalizing, and no evidence of neurologic dysfunction is present (Bell, 1991; Dawson, 1994). If the patient remains stable for 48 hours on plasma exchange, then tapering can be started by performing apheresis every other day (Dawson, 1994). It should be noted, however, that the benefits of tapering have not been proven (Bandarenko, 1998), and at some centers this is not done. Because patients may have an abrupt worsening of signs and symptoms with a longer course following early cessation of plasma exchange (Bell, 1991), many recommend tapering. Regardless, close monitoring of neurologic status, platelet count, and LD should be performed during and after plasma exchange. It is important to note that the presence or absence of schistocytes at the time that plasma exchange is discontinued does not affect relapse and is not a criterion for the discontinuation of treatment (Egan, 2004). In patients not responding to plasma exchange with FFP, switching to plasma cryoprecipitate reduced as the replacement fluid may be beneficial and has been shown to induce remission in some patients (Rock, 1996). This is thought to be possibly due to the lack of vWF in plasma cryoprecipitate reduced. Because of this finding, a frequent question is whether plasma cryoprecipitate reduced should be routinely used as the replacement fluid in plasma exchange for TTP. The North American TTP Group performed a multiinstitutional prospective randomized trial comparing FFP and plasma cryoprecipitate reduced as replacement fluids in primary TTP during initial presentation. This trial showed the two replacement fluids to be equivalent in this population (Zeigler, 2001). A second trial by the Canadian Apheresis Study group also found no benefit of plasma cryoprecipitate reduced compared with FFP in the treatment of idiopathic TTP (Rock, 2005). In addition, plasma cryoprecipitate reduced is not routinely available in many blood centers, as it is discarded as a byproduct of cryoprecipitate production.

Although plasma exchange is effective in treating idiopathic TTP, its role in secondary cases lacking deficiency of ADAMTS13 is uncertain. Studies of plasma exchange in the setting of bone marrow transplant-induced TTP have shown it to be ineffective (Ho, 2005).

TTP is a category I indication with a 1A recommendation grade for plasma exchange, according to the ASFA (Szczepiorkowski, 2010).

Hyperviscosity Syndrome. Hyperviscosity syndrome is characterized by mental status changes, a bleeding diathesis involving the mucosa and gastrointestinal tract, retinopathy with hemorrhage and papilledema, and hypervolemia with congestive heart failure (Foerster, 1993b). Hyperviscosity syndrome occurs in less than 5% of multiple myeloma patients but in as many as 70% of patients with Waldenström's macroglobulinemia (Foerster, 1993b). It may rarely be seen with polyclonal increases in Ig. Differences in frequencies in plasma cell disorders are due to differences in the monoclonal proteins produced in these two diseases. In multiple myeloma, the Ig produced is usually IgG or IgA, but in Waldenström's macroglobulinemia, the protein is IgM. In hyperviscosity syndrome, the presence of large concentrations of paraprotein increases blood viscosity by causing sludging of the red blood cells and results in occlusion of the microcirculation with organ ischemia (McGrath, 1976). Symptoms usually occur when the viscosity increases to 4–6 Ostwald units (normal blood viscosity is 1.5–1.8 Ostwald units), but patients may be asymptomatic at very high protein concentrations and viscosities (Bloch, 1973). Although the viscosity is dependent on the concentration, demonstrating an exponential relationship (Bloch, 1973), it is also dependent on the nature of the protein. The exponential nature of the relationship between concentration and viscosity means that after a critical concentration, small changes result in a large increase or decrease in viscosity.

The treatment of hyperviscosity syndrome is twofold. First, the long-term goal is to decrease paraprotein production with chemotherapy. The second goal is to decrease the protein concentration and improve blood flow. This second goal can be achieved with plasma exchange by exchanging 1–1.5 plasma volumes with 5% albumin or equal volumes of albumin

and saline. In hyperviscosity syndrome due to an IgM monoclonal protein, one to two plasma exchanges may be sufficient to remove enough protein to improve viscosity, as IgM is located almost entirely within the intravascular space. With IgG or IgA paraproteins, the Ig is also present within the extravascular space, and more procedures may be necessary to decrease paraprotein levels. The goal of therapy should be relief of symptoms, with the subsequent frequency tailored to the needs of the patient. In instances of Waldenström's macroglobulinemia resistant to therapy, repeated plasma exchange alone has been used to control hyperviscosity for extended periods of time—as long as 17 years (Salmon, 1997). It should be noted that because of the presence of extravascular Ig in multiple myeloma, patients might experience hypovolemia following procedures, as oncotic pressure results in movement of fluid from the intravascular space.

Symptomatic hyperviscosity is a category I indication and a 1B recommendation grade for plasma exchange, according to the ASFA. Prophylactic plasma exchange to treat hyperviscosity prior to the administration of rituximab is a category I indication with a 1C recommendation grade (Szczepiorkowski, 2010).

Myeloma With Acute Renal Failure

Acute renal failure occurs in multiple myeloma patients who excrete free light chains—Bence Jones proteins—in their urine. It occurs in 3%–9% of multiple myeloma patients (Bear, 1980; Johnson, 1980; Solling, 1988) and is associated with a poor prognosis. Myeloma with acute renal failure may be caused by the filtration of monoclonal light chains with deposition in the renal tubules leading to cast nephropathy. This eventually leads to dilation of the tubules, as well as tubular atrophy and renal failure (DeFronzo, 1978; Bernstein, 1982; Cohen, 1984). Unlike in hyperviscosity syndrome, the amount or characteristics of the light chain do not correlate with the disease. The diagnosis of cast nephropathy is made by renal biopsy, as other causes of renal failure may be seen in patients with multiple myeloma (Leung, 2008). Development of this complication is prevented by treatment of the underlying disease. Additional treatment includes alkalization of the urine to enhance excretion of the protein.

Plasma exchange is used in the treatment of cast nephropathy in multiple myeloma to decrease the quantity of light chains present. Although this can also be accomplished with dialysis, plasma exchange has been found to be more effective (Bear, 1980; Johnson, 1980; Solling, 1988). Renal failure in multiple myeloma is associated with poor prognosis; however, two controlled trials (Zucchelli, 1984; Johnson, 1990) have demonstrated recovery of renal function in some patients on dialysis with cast nephropathy by using the combination of chemotherapy and plasma exchange. A larger multicenter randomized controlled trial, however, failed to demonstrate efficacy of plasma exchange in myeloma kidney (Clark, 2005). This trial was criticized for using composite endpoints, failing to biopsy patients to ensure that cast nephropathy was present, and obtaining lower rates of dialysis dependency compared with other trials (Leung, 2006). The role of plasma exchange in myeloma kidney remains controversial (Leung, 2008). In cast nephropathy, the plasma exchange is performed daily to three times per week for 1–4 weeks until renal function improves. Subsequent therapy is performed as needed to maintain renal function (McGrath, 1976).

Multiple myeloma cast nephropathy is a category II indication with a 2B recommendation grade for plasma exchange, according to the ASFA (Szczepiorkowski, 2010).

Nephrologic Disorders

Anti-Basement Membrane Antibody Disease. Anti-basement membrane antibody disease (Goodpasture's syndrome) is a rare disorder characterized by the combination of pulmonary and renal hemorrhage. It affects men more commonly than women and is most frequent between 18 and 35 years of age. The disorder is autoimmune with an antibody directed against type IV collagen within the glomerular and pulmonary basement membrane. The antibody is usually transient and may be triggered by damage to the respiratory system, as the syndrome is frequently preceded by an infectious or chemical insult. Patients usually present with pulmonary symptoms of cough, hemoptysis, and dyspnea. Laboratory values show evidence of renal failure and renal inflammation. Mortality rate may be as high as 50%. Treatment of Goodpasture's syndrome focuses on suppressing antibody production and inflammation and removing the antibody. The former goals are accomplished through the use of immunosuppressive agents such as cyclophosphamide and prednisone (Wiseman, 1993).

Plasma exchange is used to remove the anti-basement membrane antibody. Treatment consists of 1–1.5 plasma volume exchanges using 5%

albumin for replacement. Therapy is usually performed daily for 7–14 days and, in the presence of concurrent immunosuppression, results in decreased antibody levels and clinical improvement (Erickson, 1979; Pusey, 1983; Johnson, 1985). Because the antibody is only transiently present, treatment longer than 6 months is uncommon (Pusey, 1983). It should be noted that plasma exchange should be started early, as recovery of renal function is unlikely once scarring and atrophy of glomeruli and tubules occur (Johnson, 1978). Patients who present needing dialysis, who have a creatinine >6.8 mg/dL, who are oliguric, and who have 100% crescentic glomeruli on renal biopsy are unlikely to benefit from plasma exchange (Levy, 2001b). In this setting, plasma exchange may be reserved for the onset of pulmonary hemorrhage (Levy, 2001b). Patients with a creatinine of <5.7 g/dL and who have less than 50% crescentic glomeruli on renal biopsy have overall and “renal” survivals at 1 year of 100% and 95%, respectively (Levy, 2001b).

Anti-basement membrane antibody disease in dialysis-independent patients is a category I indication with a 1A recommendation for plasma exchange, according to the ASFA. If patients are dialysis dependent and lack pulmonary hemorrhage, plasma exchange is a category IV indication with a 1A recommendation grade. In patients with pulmonary hemorrhage, irrespective of renal function, plasma exchange is a category I indication with a 1B recommendation grade (Szczepiorkowski, 2010).

Cryoglobulinemia. Cryoglobulins are Igs that reversibly precipitate at cold temperature. Three categories of cryoglobulins exist. Type I cryoglobulin consists of a single monoclonal protein and is usually seen in multiple myeloma, Waldenström's macroglobulinemia, or other lymphoproliferative disorders. Usually, the immunoglobulin is IgG or IgM (Foerster, 1993a). Type II cryoglobulin consists of a mixture of polyclonal immunoglobulins with a monoclonal protein, usually IgM, directed toward polyclonal IgG. Type II cryoglobulinemia is associated with chronic hepatitis C infection, autoimmune disorders, and IgM-producing malignancies (Foerster, 1993a). Finally, Type III cryoglobulin consists of polyclonal immunoglobulins, usually IgM, that have activity toward polyclonal IgG. They are associated with autoimmune conditions, as well as infections (Foerster, 1993a). Cryoglobulins produce symptoms by precipitating in areas of low temperature, such as the skin or extremities, resulting in vascular occlusion. This produces a wide variety of symptoms, including acrocyanosis, Raynaud's phenomenon, skin ulcers, skin purpura, and glomerulonephritis (Foerster, 1993a).

Cryoglobulin precipitation is dependent on the concentration of the Ig. As the concentration of the Ig increases, the temperature at which the protein precipitates rises (Hillyer, 1996). As a result, some patients may experience symptoms with only small decreases in temperature, such as those occurring in the distal extremities when patients are exposed to the outdoor environment.

Treatment of cryoglobulinemia is directed at the underlying disease (Berkman, 1980). In addition, plasma exchange can be used to reduce the protein concentration, thereby decreasing the temperature at which precipitation occurs (Berkman, 1980; McLeod, 1980). Treatment usually consists of 1–1.5 volume exchanges using 5% albumin. Again, the intensity, duration, and frequency of therapy are determined by patient symptoms. As these proteins precipitate at room temperature, blood warmers (on both the draw and return lines) may be necessary to prevent precipitation in the apheresis instrument. In some patients with high cryoglobulin concentrations and resulting precipitation at higher temperatures, it may be necessary to perform hemapheresis procedures at room temperature of 37° C or higher to prevent precipitation (Hillyer, 1996).

Severe symptomatic cryoglobulinemia is a category I indication with a 1B recommendation grade for plasma exchange, according to the ASFA. Cryoglobulinemia secondary to hepatitis C viral infection is a category II indication with a 2B recommendation grade for the use of immunoadsorption (Szczepiorkowski, 2010).

Glomerulonephritis. Many of the glomerulonephritides result from deposition of antigen-antibody complexes within the glomeruli, leading to glomerular damage. These complexes, as well as their constituent components, can be found circulating within the bloodstream. Because of this, it is theoretically possible for plasma exchange to be used to remove these substances, thereby halting and possibly reversing further glomerular injury. A number of glomerulonephritides have been treated with plasma exchange. As with many of the diseases treated by hemapheresis, investigations have been limited to case studies and small case series without randomized, controlled trials. Treatments for some selected glomerular kidney diseases are given in Table 37-21.

TABLE 37-21

Glomerulonephritides Treated With Plasma Exchange

Disease	Putative substance removed	Reported efficacy
Primary focal segmental glomerulosclerosis (Bosch, 2001b)	50 kD permeability factor	Partial or complete remission of proteinuria in 44% of patients
Recurrent focal segmental glomerulosclerosis following renal transplant (Bosch, 2001b)	50 kD permeability factor	Long-term remission in 44% of adults and 74% of children
Lupus nephritis (Mistry-Burchardi, 2001)	Antinuclear antibodies, anti-DNA antibodies	No benefit over immunosuppression alone or as adjunct therapy
Pauciimmune rapidly progressive glomerulonephritis (Gaskin, 2001)	Antineutrophil cytoplasmic antibodies (ANCA)	Possible benefit when renal function is impaired to the point where dialysis is required
Immune complex rapidly progressive glomerulonephritis (Walters, 2008)	Variety of antibodies, including immunoglobulin (Ig)A	No conclusive evidence supporting use in rapidly progressive glomerulonephritis due to immune complex deposition

Conditioning Therapy for Renal Transplantation

Kidney transplantation represents the current optimal therapy for chronic renal failure, and plasma exchange plays an adjunctive role by reducing ABO isoagglutinins. Unfortunately, the supply of deceased donor kidneys is inadequate to meet the need for organs in the United States, with approximately 86,728 people listed on the deceased donor kidney waiting list as of November 5, 2010 (Organ Procurement and Transplantation Network, 2010). The waiting time for deceased donor kidney transplantation exceeds 4 years (United Network for Organ Sharing, 2008). If a patient is blood group O or blood group B, the average waiting time is even longer. In addition, in 2007, 5000 of the 50,000 listed on the waiting list have panel reactive alloantibodies (PRA) >80% (United Network for Organ Sharing, 2008). Fewer than 300 of these patients are transplanted each year, with many of the most highly sensitized patients requiring a perfect HLA-matched kidney. Because so few of these highly sensitized patients receive deceased donor kidneys, a waiting time cannot be calculated for this group (Stegall, 2002).

While these individuals await an ABO- or HLA-compatible deceased donor kidney, their medical condition deteriorates. This wait is associated with a 5%–8% mortality rate per year. Attempts to transplant ABO- or cross-match incompatible kidneys have, in the past, been associated with the development of hyperacute rejection. Pre-formed ABO isoagglutinins or anti-antibodies bind to target antigens present upon the vascular endothelium of the incompatible organ at the time of reperfusion of the graft. The result is fixation of complement followed by endothelial injury, thrombosis, and occlusion of the microvasculature of the organ, resulting in immediate loss of the organ. To circumvent hyperacute rejection and increase the availability of organs, a number of protocols have been developed that use plasma exchange or immunoabsorption in combination with immunosuppression to reduce ABO isoagglutinin or anti-HLA antibody titers. These protocols have been reported to allow successful transplantation of incompatible kidneys from living donors.

Tanabe (1998) used three to four immunoabsorption procedures and/or one to two double-filtration plasma exchange procedures in an attempt to reduce ABO isoagglutinin titers to fewer than 16 before transplantation of ABO-incompatible living donor kidneys. This treatment, in conjunction with intensive immunosuppression and splenectomy at the time of transplantation, resulted in no instances of hyperacute rejection among 67 patients. Patient survival among ABO-incompatible transplant recipients was equivalent to that of ABO-compatible recipients. Graft survival was significantly less up to 3 years after transplant (79%) but showed equivalence at 4 years after transplant and beyond (Tanabe, 1998). Our group reported on the use of four plasma exchanges before transplant to reduce isoagglutinin titers to fewer than 4. This, and an intensive immunosuppression regimen with splenectomy, allowed for successful transplantation without hyperacute rejection among 26 ABO-incompatible transplants (Winters, 2004). One-year graft and patient survivals were slightly lower than in ABO-compatible transplants performed during the same time period (89 vs. 96% and 94 vs. 99%, respectively) (Gloor, 2003b).

Plasma exchange is associated with reductions in isoagglutinin scores and titers at the time of transplantation (Aikawa, 2001; Winters, 2004). Following transplant, however, titers will rise to levels greater than those seen at transplant but less than those seen initially (Aikawa, 2001; Winters, 2004). In addition, ABO antigen levels are maintained on the graft (Aikawa, 2001). Despite these increases in antibody titers, rejection episodes are limited to the early transplant course and can be reversed with plasma

exchange and increased immunosuppression (Winters, 2004). Studies have suggested that “accommodation” occurs in the setting of ABO-incompatible kidney transplantation (Delikouras, 2003). This appears to be due to active self-protection of the graft through the alteration of gene expression (Park, 2003).

ABO-incompatible renal transplantation is a category II indication with a 1B recommendation grade for plasma exchange, according to ASFA (Szczeniowski, 2010).

A number of groups have reported success in transplanting cross-match incompatible living donor kidneys using the combination of plasma exchange, IVIG, immunosuppression, and splenectomy (Montgomery, 2000; Schweitzer, 2000; Gloor, 2003a). Four to six plasma exchanges with concurrent immunosuppressive therapy and IVIG were successful in converting patients with low-titer anti-HLA antibodies (<16) to cross-match compatibility on the day of transplantation. None of the patients treated developed hyperacute rejection. Acute humoral rejection episodes were seen in 43% of patients treated by Gloor (2003a), but these episodes were reversed with additional plasmaphereses and steroids. Graft survivals of 100% (Schweitzer, 2000) and 79% (Gloor, 2003a) have been reported at 12 months following transplantation. Unlike ABO-incompatible transplants, reports have described durable, sustained loss of donor-specific HLA antibodies following conditioning for and transplantation of cross-match incompatible kidneys (Zachary, 2003). In addition, as in ABO-incompatible accommodated transplants, cross-match incompatible accommodated transplants demonstrate altered gene expression that results in downregulation of apoptosis of the graft's endothelial cells (Salama, 2001).

Plasma exchange for desensitization in cross-match incompatible renal transplantation with a living donor kidney is a category II indication with a 1B recommendation grade, according to ASFA. Plasma exchange for desensitization in high-PRA patients awaiting a cadaveric renal transplant is a category III indication with a 2C recommendation grade (Szczeniowski, 2010).

DONOR/PATIENT COMPLICATIONS COMMON TO ALL HEMAPHERESIS PROCEDURES

Hemapheresis procedures, both donor and therapeutic, are safe procedures with minimal risk of complications. Those which do occur are generally traumatic and associated with venous access or physiologic complications that include citrate-mediated, allergic-type, and volume-related problems. Because citrate-mediated reactions are common and may require the attention of the physician, they are discussed in some detail in the following paragraphs. The reaction rates among donors undergoing hemapheresis procedures have been found to be 2.18% (McLeod, 1998) and 0.81% (Despotis, 1999), respectively. This is less than the 11%–21% reaction rate reported for whole blood donation (Newman, 1997). However, the rate of serious reactions—those requiring hospitalization—has been found to be 0.01% (2 out of 19,736 donations) (Despotis, 1999), which is 20 times greater than that reported to occur with allogeneic whole blood donation (1 out of 198,119 donations; 0.0005%) (Popovsky, 1995). Therefore, although apheresis donation appears to have a lower reaction rate than whole blood donation, the risk of serious reactions is greater.

TABLE 37-22

Reaction Rates Among Apheresis (McLeod, 1998) and Whole Blood (Newman, 1997) Donors

Reaction	Apheresis donations (%)	Whole blood donations (%)
Hematoma or pain	1.15	9–16
Citrate toxicity	0.4	N/A
Mild vasovagal	0.05	2–5
Vasovagal with syncope	0.08	0.1–0.3

N/A, Not available.

The most common of reactions seen by McLeod among apheresis donors were injuries due to venipuncture (McLeod, 1998). Table 37-22 lists the adverse effects to apheresis donation reported by McLeod, their frequency, and comparable frequency among whole blood donors. As with whole blood donation, first-time donors had reactions more frequently than repeat donors. Reactions were found to be more frequent among platelet donors than among plasma or granulocyte donors (5.9% and 9.4%, respectively, vs. 12%), which may have been due to a greater number of first-time donors in this group (McLeod, 1998). Despotis (1999) found associations of citrate and hypotensive reactions with donor weight, gender, and type of collection instrument used. For venipuncture-related complications, only female gender was associated as a risk factor (Despotis, 1999). The instrument used for collection also influenced reaction rates. McLeod found that the Fenwal CS3000 had fewer reactions than other instruments. This could possibly be due to lower citrate infusion rates with this instrument, as well as the ability to perform single-needle procedures with the other instruments. Such single-needle procedures, which alternate between drawing and returning through the single intravenous line, result in larger extracorporeal volumes (McLeod, 1998). Despotis (1999) noted that the relationship between donor weight and citrate reactions was different when the COBE Spectra and the Fenwal CS3000 were compared. Donors with lower weights had a higher probability of citrate reactions on the Fenwal CS3000, and those with higher weights had a higher probability on the COBE Spectra. The authors of this study believed that this was due to the methods by which these instruments determine the anticoagulant infusion rate (Despotis, 1999).

Reactions among therapeutic hemapheresis procedures have been reported to occur in 4.75% of procedures (McLeod, 1999). The reactions identified and their overall frequencies are given in Table 37-23. The rate of reactions varied with regard to procedure, replacement fluid, and patient. For example, the reaction rate for plasma exchange using albumin was 3.35% as compared with 7.81% for plasma exchange using plasma as the replacement fluid. Leukocytapheresis demonstrated a reaction rate of 5.71%, HPC-A collection had a rate of 1.66%, and no reactions occurred in the 18 patients who underwent therapeutic thrombocytapheresis. Patients with neurologic disorders were more likely than other categories of patients to experience vasovagal reactions (McLeod, 1999).

Shemin (2007) in a more recent review examined the frequency of complications during the performance of plasma exchanges. Of 1727 plasma exchanges in 174 patients, 614 procedures (36%) were complicated by a reaction. Most complications were mild, and no deaths occurred. Of the reactions, 0.2% required discontinuation of the procedure, and 0.1% required additional medical management beyond that available in the apheresis unit. The most common reactions were fever (7.7%), urticaria (7.4%), and hypocalcemic symptoms (7.3%). Similar to what was reported by McLeod, differences were seen based on the replacement fluid used. Urticaria and pruritus were more common with the use of FFP as a replacement fluid; hypotension was more common with the use of albumin and saline (Shemin, 2007).

It should be noted that the study by McLeod did not include complications or reactions due to venous access, but that by Shemin did. Studies that included these data have noted higher reaction rates with therapeutic hemapheresis. For example, Couriel (1994) noted adverse effects in 17% of therapeutic apheresis procedures. These were predominantly mild, consisting of citrate reactions, but 6.15% of procedures were complicated by severe reactions, reactions that were life threatening, or reactions that resulted in termination of the procedure. All of these reactions were due to central venous access and consisted of a pneumothorax, a hemopneumothorax, catheter-related bacteremia, and a sternocleidomastoid hematoma. The patient with the hemopneumothorax exsanguinated because of the complication (Couriel, 1994). Of the two severe reactions requiring

TABLE 37-23

Reaction Rates Among Patients Undergoing Therapeutic Apheresis Procedures

Reaction	Frequency (%)
Transfusion reactions	1.6
Citrate toxicity	1.2
Hypotension	1.0
Vasovagal reactions	0.5
Pallor and diaphoresis	0.5
Tachycardia	0.4
Respiratory distress	0.3
Tetany and seizure	0.2
Chills or rigors	0.2

Data from McLeod BC, Sniecinski I, Ciavarella D, et al. Frequency of immediate adverse effects associated with therapeutic apheresis. *Transfusion* 1999;39:282–8.

additional medical intervention reported by Shemin (2007), one was due to arterial puncture during central line placement. Although only one death due to therapy was reported by Couriel, and no deaths attributable to therapeutic hemapheresis were reported in the studies by McLeod and Shemin, additional deaths have been reported by other authors. A majority of such deaths have been ascribed to cardiopulmonary arrest during hemapheresis; additional causes have included anaphylaxis, pulmonary embolus, and vascular perforation due to central venous access. Huestis (1989) estimated a mortality rate for therapeutic hemapheresis of 3 per 10,000 procedures (0.03%), and Mokrzycki (1994) estimated the mortality rate, based on a review of the literature available to that time, to be 0.05% of procedures.

As discussed under the description of each procedure, specific complications are associated with specific procedures, such as those due to G-CSF administration in granulocyte harvest. A discussion of complications and risks common to all hemapheresis procedures follows.

ELECTROLYTE AND ACID-BASE DISTURBANCES

Citrate is used as the primary anticoagulant in both donor and therapeutic apheresis procedures because it effectively prevents coagulation while being short acting and easily reversible, unlike heparin. Citrate ions chelate calcium ions, producing a soluble complex. As a result, the chelated calcium ions are unavailable for biological reactions such as the coagulation cascade. Within the apheresis instrument, plasma citrate concentrations reach 15–24 mmol/L, lowering the calcium ion concentration below 0.2–0.3 mmol/L, the level necessary for coagulation (Strauss, 1996). This ionized calcium level requires the infusion of approximately 500 mL of ACD-A solution and would be incompatible with life. Death does not occur, however, because of compensatory mechanisms in the donor/patient. Upon return of blood from the apheresis instrument to the donor/patient, the citrate is diluted throughout total extracellular fluid. In addition, the liver, kidneys, and muscles rapidly metabolize citrate, releasing the bound calcium (Strauss, 1996). The body responds to the decrease in ionized calcium by increasing parathyroid hormone levels, resulting in mobilization of calcium from skeletal stores and increased absorption by the kidneys (Silberstein, 1986). Finally, calcium bound to albumin is also mobilized and buffers the decline (Bolan, 2003a).

In therapeutic plasma exchange procedures, the volume of plasma removed must be replaced by a similar volume of replacement fluid. In plasma exchange using FFP or plasma cryoprecipitate reduced as replacement fluid, an additional source of citrate is infused in the form of the anticoagulant present in these solutions. It is therefore common for symptoms of citrate toxicity to be seen in these patients. In plasma exchange using albumin as a replacement fluid, it would be expected that citrate toxicity would be less of a problem. However, this is not always the case. Normally, 40%–55% of serum calcium is bound to albumin, with the unbound portion representing the physiologically active ionized calcium. Albumin preparations are depleted of this calcium and, as a result, bind calcium when infused during plasma exchange. This can lead to a drop in ionized calcium with the subsequent appearance of symptoms due to hypocalcemia. Goss (1999) demonstrated a higher incidence of citrate reactions and greater decreases in ionized calcium levels in neurology patients receiving plasma exchange with 5% albumin as the replacement fluid when

compared with those receiving 10% pentastarch as the replacement fluid. A subsequent study demonstrated that the addition of calcium gluconate to the albumin preparation before administration more effectively reduced the incidence of citrate toxicity when compared with IV calcium gluconate or oral calcium carbonate (Weinstein, 1996). The effect was due to the saturation of calcium binding sites on the albumin, thereby maintaining ionized calcium levels in the patient.

Despite compensatory mechanisms, citrate infusion can result in a decrease in ionized calcium levels to the point where symptoms develop in the donor/patient. These result from a decrease in ionized calcium to levels at which the excitability of nerve membranes increases to the point where spontaneous depolarization can occur (Strauss, 1996). Resulting signs and symptoms can include perioral paresthesias, acral paresthesias, shivering, light-headedness, twitching, and tremors. In addition, some patients experience nausea and vomiting. As the ionized calcium levels fall farther, these symptoms may progress to carpopedal spasm, tetany, and seizure (Strauss, 1996). It is therefore important to elicit the presence of early symptoms from the donor/patient, so that interventions can occur before the more severe symptoms. In addition to the symptoms described previously, prolongation of the QT interval on electrocardiogram, depressed myocardial contraction, and fatal arrhythmias have been reported (Strauss, 1996). Hypotension may also be seen with citrate reactions (Goodnough, 1999) and may be due to the depressed myocardial function mentioned and to vascular smooth muscle relaxation (Bunker, 1962).

Factors that have been found to influence the rate of citrate reactions in donor and therapeutic apheresis include alkalosis due to hyperventilation (Strauss, 1996); the type of anticoagulant solution used, with ACD-A having more reactions than ACD-B (Szymanski, 1978); the rate of infusion of the anticoagulant solution (Strauss, 1996); the amount of citrate infused (Strauss, 1996); and the donor's serum albumin level before the start of the procedure (Bolan, 2003a). It should be noted that intermittent flow hemapheresis procedures tend to have a greater frequency of citrate reactions, as the rate of citrate infusion is higher when the separation chamber is emptied than during continuous apheresis procedures. Also, the method by which an instrument calculates the dose of anticoagulant may influence the rate of reactions among certain donor subgroups (Despotis, 1999).

The treatment of citrate reactions is relatively simple when reactions are identified early. Treatment includes slowing the reinfusion rate to allow for dilution and metabolism of the citrate, increasing the donor/patient blood/citrate ratio to decrease the amount of citrate infused, giving oral calcium in the form of calcium antacids, and giving intravenous calcium (Strauss, 1996).

Administration of oral calcium carbonate and its effects on citrate toxicity in apheresis platelet donors were studied by Bolan (2003a, 2003b). It was found that administration of 2 g of calcium carbonate was associated with a statistically significant reduction in the severity of paresthesias (Bolan, 2003b). Physiologically, this dose was also associated with the greatest improvement in ionized and total calcium levels among the doses examined (Bolan, 2003a), but it was not associated with a reduction in overall symptom development, and it did not affect the occurrence of more severe symptoms (Bolan, 2003b).

Administration of intravenous calcium, in the form of calcium gluconate or calcium chloride, usually is not necessary in donor procedures but is common in the setting of therapeutic apheresis procedures. In HPC-A collections, the continuous infusion of calcium gluconate or calcium chloride has been found to prevent hypocalcemic symptom development (Bolan, 2002; Buchta, 2003), with calcium chloride maintaining higher ionized calcium levels (Buchta, 2003). In a comparison of infusion of calcium gluconate continuously, prophylactically at the start of HPC collection, or at the time of symptom development, continuous infusion maintained higher calcium levels, and changes in calcium levels were insignificant with the other two modes of administration (Kishimoto, 2002). When given to treat symptoms, the usual dose is 10 mL of calcium gluconate IV infused over 10–15 minutes (Hester, 1983). In patients with low ionized calcium levels before the start of the procedure, calcium gluconate can be given prophylactically.

Magnesium is another physiologically important divalent cation. Similarly to calcium, magnesium is bound by citrate. As a result, the infusion of citrate in the setting of plateletpheresis decreases ionized magnesium by 30% (Mercan, 1997). Mercan (1997) also found that magnesium levels fall more rapidly than calcium levels during citrate infusion, and they recover more slowly. Hypomagnesemia can induce signs and symptoms similar to hypocalcemia, including muscle spasms, muscle weakness, decreased vascular tone, and impaired cardiac contractility. In addition,

hypomagnesemia can impair calcium and potassium homeostasis, including inhibition of the release of parathyroid hormone when markedly decreased (Mercan, 1997). As a result, patients with low magnesium levels before undergoing apheresis may exhibit signs and symptoms of citrate toxicity due to hypomagnesemia and not hypocalcemia. Patients who cannot rapidly metabolize citrate, thereby releasing the bound cations, may also be at risk (Kamochi, 2002). These symptoms may be unresponsive to the administration of calcium supplementation. To avoid hypomagnesemia, it is common at some institutions to measure magnesium levels before initiation and to supplement magnesium before performing procedures if indicated. Reports have described the use of prophylactic magnesium infusions similar to those done with calcium. Haddad (2005) investigated prophylactic administration of magnesium to allogeneic HPC-A donors. Supplementation was associated with normal ionized magnesium levels during the procedure, as well as greater parathyroid hormone response and higher blood glucose levels. However, no differences were seen with regard to the symptoms (mild paresthesias, coldness, and nausea) (Haddad, 2005).

As described, citrate is rapidly metabolized. This process consumes hydrogen ions; as a result, metabolic alkalosis due to citrate infusion may develop. The risk of this occurrence is greatest in patients with renal disease, who cannot adequately excrete bicarbonate (Kelleher, 1987), and in those receiving replacement fluids containing citrate (Kelleher, 1987; Dzik, 1988). A study comparing patients with TTP undergoing plasma exchange with FFP replacement versus patients with myasthenia gravis undergoing plasma exchange with albumin demonstrated increased frequency of metabolic alkalosis in the former group (Marques, 2001). Patients with TTP demonstrated a mean creatinine level of 1.3 mg/dL and a mean blood urea nitrogen of 24.8 mg/dL (Marques, 2001). Although the metabolic alkalosis seen in these patients did not reach critical levels (>35 mEq/L HCO_3^-) and resolved following cessation of plasma exchange, it was associated with critical drops in potassium (<3.0 mEq/L) during the procedures (Marques, 2001). The presence of alkalosis can worsen hypocalcemia (Edmondson, 1975) and slow citrate metabolism (Dzik, 1988). Unfortunately, the symptoms of metabolic alkalosis are nonspecific, usually presenting as worsening symptoms of hypocalcemia. Alkalosis resolves with time or dialysis and can be avoided by reducing the amount of citrate infused by adjusting the blood/citrate ratio and/or using replacement fluids that lack citrate (Pearl, 1985).

Metabolic alkalosis results in a shift in hydrogen ions from intracellular locations (in an attempt to compensate pH) with a concurrent flux of potassium into these cells to maintain electrical neutrality. The result is that significant drops in potassium can occur during large-volume hematopoietic progenitor cell collections, in addition to those seen in the TTP patients described previously. Schlenke (2000) found an average drop in potassium levels of $11.3 \pm 7\%$ in a study of 96 large-volume leukaphereses. Despite this decline, none of the patients in this study experienced symptoms attributable to hypokalemia. Symptoms of hypokalemia include weakness, hypotonia, and cardiac arrhythmia (Schlenke, 2000). Treatment of such complications would consist of replacement of the potassium, orally or intravenously. A prudent option would be to prevent the reaction by determining the potassium level before the start of the procedure and supplementing if indicated.

ALLERGIC, ANAPHYLACTOID, AND ANAPHYLACTIC REACTIONS

Allergic, anaphylactoid, and anaphylactic reactions result from the release of vasoactive substances such as histamine, leukotriene C4, leukotriene D4, prostaglandin D2, and platelet-activating factor from mast cells and basophils. The release of these substances is mediated by the presence of IgE antibodies on the surface of these cells. When the target antigen binds to the IgE molecule, the substances listed previously are released. This in turn results in a variety of symptoms by causing contraction of smooth muscle, increased vascular permeability, and vasodilation. Mast cells and basophils can also be activated by complement-derived factors such as C3a and C5a, which can be produced by antigen-IgG interactions and other mechanisms (Vamvakas, 2001). These types of reactions can range from mild urticarial reactions to life-threatening anaphylactic reactions. Signs and symptoms of these reactions include pruritus, urticaria, erythema, flushing, angioedema, upper airway obstruction, lower airway obstruction, hypotension, shock, nausea, vomiting, and diarrhea (Vamvakas, 2001).

Allergic reactions have been reported in both donors and patients undergoing hemapheresis procedures. Among donors, reactions have been

reported among platelet, plasma, and granulocyte donors. In platelet and plasma donors, reactions to ethylene oxide gas used to sterilize the tubing sets used for the procedures have been described (Leitman, 1986; Muylle, 1986). These reactions have occurred predominantly in donors who had undergone numerous previous procedures. It is thought that during the procedures, ethylene oxide present within the plastic binds to proteins within the plasma. The proteins serve as carrier molecules and the ethylene oxide as a hapten, with the result being an immune response with the generation of IgE antibodies toward ethylene oxide. In most of the donors who experienced allergic phenomena, IgE antibodies to ethylene oxide were identified (Leitman, 1986). Reactions ranged from urticaria, flushing, and periorbital edema (Leitman, 1986) to an anaphylactic reaction consisting of wheezing, flushing, swelling of the lips, and hypotension (Muylle, 1986). The overall rate of reaction in one study was 1.0% of platelet donors. The reactions also showed an increased frequency with the Fenwal CS3000 than with the Haemonetics V-50 (Haemonetics, Braintree, Mass.). This was thought to be because, at the start of processing with the CS3000, a mixture of saline and anticoagulant that was used to prime the bag was infused into the patient. This was not the case with the V-50. It was postulated that this resulted in a bolus of ethylene oxide that produced the symptoms (Leitman, 1986).

Reactions have been reported among granulocyte donors as well. Besides ethylene oxide reactions, another mechanism is possible. Granulocyte donors are exposed to low molecular weight or high molecular weight HES to enhance red cell sedimentation. Although these substances are poor immunogens and have not been able to induce antibody formation, allergic reactions have occurred in the setting of HES use in hemapheresis (Dutcher, 1984) and as a volume expander (Ring, 1977). The mechanism behind the production of anaphylactoid reactions with HES is thought to be due to the ability of HES to activate the alternative complement cascade. This would result in the production of C3a and C5a, both of which can cause mast cell and basophil release (Dutcher, 1984). Reactions reported to occur with HES include mild urticarial reactions and severe reactions with respiratory and cardiac arrest. The rate of reaction in a study of patients receiving HES for volume expansion was 0.085%, with severe (anaphylactic) reactions occurring in 0.006% (Ring, 1977). Reactions have occurred with both high molecular weight (hetastarch) (Ring, 1977) and low molecular weight (pentastarch) (Kannan, 1999) HES. Because of this risk, Dutcher (1984) recommended excluding people with a history of allergies as granulocyte donors.

Among therapeutic hemapheresis patients, reactions to ethylene oxide or HES could occur. In addition, therapeutic plasma exchange procedures frequently use plasma products—FFP or plasma cryoprecipitate reduced—as replacement solutions. As a result, patients are also at risk for allergic and anaphylactic reactions due to transfusion reactions. The most common allergic reaction within the setting of plasma product infusion is the urticarial reaction. This reaction occurs in 1%–3% of plasma infusions and consists of hives scattered over the body. In 1 in 20,000–47,000 transfusions, anaphylaxis occurs (Vamvakas, 2001). The most common cause of this last reaction is the infusion of plasma containing IgA into an IgA-deficient individual who possesses anti-IgA antibodies (Vamvakas, 2001).

The treatment of allergic, anaphylactoid, and anaphylactic reactions depends on their severity. In donor reactions, the procedure should be stopped. Simple reactions such as urticaria can then be treated with oral antihistamines (e.g., diphenhydramine). The same treatment can be provided with therapeutic procedures, although in this case the procedure can be restarted following antihistamine administration. In addition, the patient can be premedicated with antihistamines before subsequent procedures are performed.

Anaphylactic reactions are life threatening. The procedure, whether donor or therapeutic, must be immediately discontinued. Vascular access should be kept open using saline. For less severe reactions, epinephrine 0.3–0.5 mg can be given subcutaneously, with the dose repeated every 20–30 minutes for up to three doses. In addition, aminophylline 6 mg/kg can be given for bronchospasm. This loading dose should be followed by an infusion of 0.5–1 mg/kg/hour. Volume expansion with normal saline or lactated Ringer's solution can be given for hypotension. Oxygen should be given for respiratory distress. For severe reactions, epinephrine 0.5 mg can be given intravenously, with repeated dosing every 5–10 minutes. Dopamine can also be given for hypotension unresponsive to volume. The airway must be protected, and endotracheal intubation may be indicated (Vamvakas, 2001).

Obviously, the best course of action is to avoid such reactions. Donors who have experienced such reactions should be deferred from future donation. Patients with mild reactions should be premedicated with

antihistamines. Those with severe reactions due to IgA should receive IgA-deficient replacement fluids. For most procedures, this could be albumin or saline. For procedures requiring plasma as a replacement fluid, as in plasma exchange for TTP, IgA-deficient plasma products must be used.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

The use of angiotensin-converting enzyme (ACE) inhibitors by patients undergoing hemapheresis procedures is associated with reactions similar in many respects to the allergic reactions described previously. These reactions consist of flushing, hypotension, bradycardia, and dyspnea (Strauss, 1996) and have been seen in patients undergoing therapeutic plasma exchange (Owen, 1994), LDL-apheresis using dextran sulfate columns (Agishi, 1994), and treatment with staphylococcal A protein columns (Owen, 1994). These reactions result from activation of the kinin system and generation of bradykinin when patient plasma comes in contact with the negatively charged plastic of the apheresis set. Normally, bradykinin is rapidly inactivated by kininase I and II. ACE inhibitors, however, block the actions of these enzymes such that high levels accumulate, producing the symptoms described previously (Strauss, 1996). During plasma exchange with albumin, prekallikrein-activating factor present in the albumin can trigger the formation of bradykinin (Owen, 1994). Again, the presence of ACE inhibitors prevents degradation of this substance. These reactions can be avoided by withholding ACE inhibitors for 24–48 hours before hemapheresis procedures (Owen, 1994). Some newer ACE inhibitors have longer half-lives; withholding these drugs for longer periods or switching to ACE inhibitors with shorter half-lives may be necessary.

HYPOVOLEMIA AND VASOVAGAL REACTIONS

Hypotension can be seen during both donor and therapeutic hemapheresis procedures. This can be the result of two different pathophysiologic mechanisms. In the first, hypotension results from intravascular volume depletion due to too much volume being present within the extracorporeal circuit. Such reactions are characterized by both increased vascular tone and increased cardiac output as the sympathetic nervous system attempts to compensate for the hypovolemia (Strauss, 1996). Increasing both heart rate and contractility produces the increase in cardiac output. These reactions are not common among hemapheresis donors, as Standards for Blood Banks and Transfusion Services limit the amount of volume that can be present within the extracorporeal circuit to 10.5 mL/kg (Standards Committee of the American Association of Blood Banks, 2009), and the donors fulfill health and weight requirements. In therapeutic procedures, the patient has an underlying disease that may make hypovolemia more likely. For example, the presence of hypotension has been found to be more common in patients with neurologic disease (McLeod, 1999). Standards for Blood Banks and Transfusion Services do not prescribe limits on extracorporeal volume during therapeutic hemapheresis procedures, although application of the limits used during donor hemapheresis procedures would seem prudent (Strauss, 1996).

The second mechanism causing hypotension during hemapheresis procedures is the vasovagal reaction. In this reaction, hypovolemia results in a decrease in blood pressure. As stated previously, the compensatory response is to increase cardiac output and vascular tone. During a vasovagal reaction, parasympathetic output, which normally counteracts sympathetic output, increases disproportionately, resulting in slowing of heart rate and decreased vascular tone, leading to hypotension (Strauss, 1996). Factors that have been associated with such reactions in whole blood donors include younger age, low weight, first-time donation, and inattentive staff (Newman, 1997). Tomita (2002) examined the incidence of vasovagal reactions among apheresis donors and whole blood donors at the same collection center. They noted that the incidence of these reactions among apheresis donors increased with age, unlike what has been reported with whole blood donors. The age-related increase in vasovagal reactions was even more common in women and was thought to result from a lower circulating blood volume in these populations (elderly and women), leading to a greater percentage of the donor's blood being within the extracorporeal circuit during collection. The resulting greater drop in blood pressure during collection leads to additional reactions. It was also

noted that the incidence increased with increasing cycles during a collection, and it was theorized that hypocalcemia was involved in the onset of vasovagal reactions (Tomita, 2002).

Hypovolemic and vasovagal reactions are treated similarly. The procedure should be temporarily interrupted, and a fluid bolus should be infused. If the reaction is due to hypovolemia, blood pressure should increase and pulse rate should decrease in response to this intervention. If the reaction is due to a vasovagal reaction, this may not occur. Additional treatments for vasovagal reactions include placing the donor/patient in the Trendelenburg position (head down), applying cold compresses to the forehead and neck, and reassuring the donor/patient (Strauss, 1996).

HYDROXYETHYL STARCH AND COAGULOPATHY

As discussed under the section dealing with plasma exchange, removal of plasma from a patient during a therapeutic hemapheresis procedure and replacement of the volume with albumin or some other fluid that does not contain coagulation factors can result in mild, temporary abnormalities in coagulation. These changes are usually short lived, with return of most coagulation factors to normal levels within 24–48 hours. The use of HES as volume replacement or as a sedimenting agent is also associated with changes in coagulation factor levels. Both high molecular weight HES, such as hetastarch, and low molecular weight HES, such as pentastarch, result in prolongation of the PTT, as well as decreases in fibrinogen levels. This is thought to result from the dilutional effects produced when these substances are infused. High molecular weight, but not low molecular weight, HES is also associated with decreases in factor VIII activity, factor VIII antigen, and vWF antigen, as well as with prolongation of bleeding time (Strauss, 1988). It is thought that this last effect is a result of the decrease in vWF antigen levels and may represent an acquired von Willebrand disease–like state. Because of these changes, a risk of coagulopathy exists with the use of these agents. This risk appears to be dose dependent. In the setting of volume expansion in critical care, the maximum dose of HES needed to avoid such complications has been suggested to be 20 mL/kg/24-hour period. Doses up to 3600 mL have been given in this setting without difficulty (Nearman, 1991). The danger in hemapheresis procedures is that multiple collections or therapeutic procedures may be necessary in a given donor/patient over consecutive days. Because HES, especially high molecular weight HES, has a long half-life, this may result in an accumulation of HES over the course of the hemapheresis procedures and the potential danger of coagulopathy.

Comprehensive review of the use of therapeutic apheresis. Includes one-page summaries describing treatment recommendations and technical considerations for more than 50 diseases. Also provides categorization and strength of evidence for the use of apheresis in the diseases discussed.

HYDROXYETHYL STARCH AND OTHER SIDE EFFECTS

As has been mentioned, HES has a long half-life. This is dependent upon the metabolism of HES by α -amylase and subsequent renal excretion of the breakdown products (Yacobi, 1982). Persistent pruritus due to deposition of HES in the skin has been reported as one of the most frequent complications of HES administration. Skin deposits have been detected for up to 4 years following administration (Sirtl, 1999; Stander, 2001).

In addition to skin deposition, a case report has described marrow and organ failure in a patient undergoing chronic plasma exchange (20 months) with HES used as the replacement fluid. In this patient, foamy macrophages containing HES were found replacing bone marrow, as well as infiltrating duodenal mucosa, liver, peritoneum, and dura mater. These cells were also present in ascitic fluid (Auwerda, 2002).

AIR EMBOLUS

Air embolus is a rare complication of hemapheresis procedures. It occurs when air enters the venous system through a leak in the hemapheresis instrument or the venous access. Air entering the right ventricle and pulmonary artery results in obstruction to right ventricular output and pulmonary artery vasoconstriction (Montacer-Kuhssari, 1994). Symptoms of air embolism include dyspnea, tachypnea, cyanosis, tachycardia, and hypotension. The reason for the rarity of this complication is that all modern hemapheresis instruments possess sensors that can detect air within the extravascular circuit and stop the procedure. Should air embolism occur, however, treatment consists of placing the donor/patient in the Trendelenburg position on the left side. This traps the air in the apex of the right ventricle, away from the pulmonary outflow tract, improving right ventricular outflow. Over time, the air will dissolve.

SUMMARY

In summary, hemapheresis represents a safe and effective technique for the production of needed blood components, as well as for the treatment of a variety of diseases. Although hemapheresis is often compared with the 18th century practice of bloodletting, it shares little with this practice. Hemapheresis is selective in what is removed from the donor/patient. In addition, hemapheresis is grounded in evidence-based medicine. Hemapheresis procedures are safe; however, they are not without risk and should be applied only to those diseases and disorders for which the possibility of benefit exists, and for which evidence in support of this benefit has been shown.

KEY POINTS

- Appreciate the wide range of allogeneic tissues used for transplantation.
- Allograft tissue is screened, tested, and processed to improve its safety.
- Allograft tissue is stored by a variety of methods, including cryopreservation.
- Risks and complications are associated with the use of allograft tissue.
- A wide range of assisted reproductive techniques are available to infertile couples and individuals.
- Hematopoietic progenitor cells can be derived from multiple sources and transplanted in different ways, depending on the needs of the recipient.
- Appreciate the balance between the graft-versus-host reaction and the graft-versus-leukemia effect.

Throughout the United States, tissue banks routinely provide hundreds of products that not only extend life but also in many instances significantly improve the quality of life for the patients they serve. More than 400,000 bone allografts (American Association of Tissue Banks, 2008) and 50,000 corneas (Eye Bank Association of America, 2008) are transplanted annually in the United States—a number that far exceeds the approximately 25,000 solid organ transplants per year (United Network for Organ Sharing, 2008). Clinical applications of allogeneic and autologous tissue and the types of tissue available have grown exponentially in the last two decades. Yet, aside from the patients and physicians served by these tissue banks, many people are unaware of the vast scope of activities in today's health care environment that are under the umbrella of tissue banking. Over the past 20 years, tissue banking in the United States has evolved from a system of incidental hospital bone or sperm banks to a system of regulated, accredited facilities, much like blood banks, providing an expanding variety of high-quality, carefully screened and tested products for use by physicians (Table 38-1).

Many tissue banks provide a wide range of products and services in skin, bone, and heart valve procurement, processing, and storage. Other tissue banks focus their services in specialized areas such as reproductive tissue or hematopoietic progenitor cells (HPCs). One bank may recruit donors and procure and process tissue such as skin for burn patients or bone for orthopedic repairs; another may collect, process, and store HPCs for life-saving bone marrow transplants. Processing of musculoskeletal tissues and cardiac valves, which requires extensive equipment, personnel,

and quality assurance, is performed primarily by a few large tissue banks that subcontract with other tissue banks, which, in turn, collect, store, and issue these products. In addition, an exponential growth has occurred over the past two decades in reproductive banks that provide assistance to infertile couples or individuals.

SOURCES OF TISSUE

Tissues used for transplantation come from two primary sources: living donors and deceased donors. Living donors may be individuals who donate for their own use (autologous HPCs or sperm), as directed donors for a given individual (allogeneic HPCs or sperm donation), or altruistically for unknown recipients (surgical discard bone, sperm donation, allogeneic HPCs through the National Marrow Donor Program). A large majority of bone, skin, and cardiac valves used for transplantation, as well as eye tissue, come from deceased donors. Unlike solid organ donation, where there is a need for the organs to be obtained while circulation is maintained, deceased donor tissue can be obtained for several hours after death and up to 24 hours later if the body is refrigerated. This substantially increases the number of available tissue donors. Because corneal tissue has relatively minimal contact with the circulatory system, some individuals who would otherwise be excluded as tissue donors may still be eye donors.

Deceased donor tissue is procured primarily from hospital operating rooms or morgues and medical examiners' offices. Harvesting of tissue is performed in a sterile or clean environment using aseptic techniques. Many tissues, such as bone, are then frozen for subsequent processing and refreezing or freeze-drying. Specialized tissues such as cornea are processed immediately and stored for only a short time (48 to 72 hours) before use. Tissue from living donors is procured in the operating room (surgically salvaged bone or bone marrow) or in specialized clean environments that hemapheresis centers and sperm banks are equipped to provide. These tissues are collected under sterile conditions, processed immediately, and used in less than 24 hours or frozen for subsequent use.

TISSUE BANK ACTIVITIES

The major activities of tissue banks are outlined in Table 38-2. A major impetus for the movement to formal, accredited tissue banks in our nation was the concern about transfusion-transmitted disease. As with blood banks and transfusion services (see Transfusion Medicine and Hemapheresis chapters), donor recruitment, screening, and testing are critical functions of the tissue bank. Since the early 1990s, cases involving disease transmission documented that careful screening by both medical record review and serologic testing, as well as maintenance of detailed records, was critical to safe tissue banking practices and thus acceptance of allograft tissue by both the public and health care providers. Concerns still remain

that physicians who utilize these tissues recognize and report these adverse reactions, primarily infection, to the originating tissue bank. The Joint Commission (TJC) has standards for tissue banking practices that are targeted primarily at the transplantation facility. These standards focus on the necessity for implantation facilities to keep clear, precise records regarding tissue receipt, storage, and use, so that all allogeneic tissues can be traced from donor to recipient. TJC standards also require institutions to establish a mechanism for physicians to report adverse reactions and the originating tissue bank to be notified. Accredited full service tissue banks, in the same manner as blood banks, investigate suspected reactions or complications extensively. “Look-back” reviews should include reviews of the complications associated with other tissue from the same donor, the current health of the donor, if living, and quarantining of other tissue from the same donor. The American Association of Tissue Banks (AATB)* provides strict standards and accreditation for organizations involved in any area of tissue banking. Several states also require tissue banks to be licensed, and the U.S. Food and Drug Administration (FDA) regulates the screening of donor tissue used for transplantation purposes (FDA CFR, 2009).

DONOR SCREENING

Tissue donors are carefully screened to prevent the transmission of bacterial, viral, and/or genetic disease, as well as to ensure the quality of the tissue obtained (Table 38-3). With deceased tissue donors, unlike blood

donors, information regarding medical and social history is obtained from the family or close friends, as well as from physicians' records.

Reports of tissue transplant complications in the early 1990s focused on the transmission of human immunodeficiency virus (HIV) (Simonds, 1992) and hepatitis C (Conrad, 1995). More recently, attention has been focused on testing of tissue donors for additional disease transmission vectors (*Trypanosoma cruzi*, West Nile virus, and H1N1), as well as for transmission of nonscreened viruses such as Creutzfeldt-Jakob disease (Centers for Disease Control, 2003) and others (Kainer, 2004) by serologically negative tissue. It is likely, however, that there will continue to be isolated case reports of transmission of uncommon pathogens by tissue and organ donors. The impracticality of screening for all transmissible diseases emphasizes the continued need for careful screening of tissue and organ donors by medical history and family interview, as well as laboratory testing. Asking the right questions in the correct manner is a critical function that needs to be performed by well-trained, experienced individuals who are able to identify possible risks in the donor medical history, in information about possible risk behaviors, or in available laboratory data.

Other parts of the review process are targeted at ensuring the quality of the donated tissue. Musculoskeletal donors need to be carefully screened for any history of trauma that might result in a weakened structural bone graft. Sperm donations are reviewed not only for genetic disease but also to ensure viable sperm that will have a reasonable chance of resulting in successful fertilization. The use of umbilical cord blood for unrelated allogeneic bone marrow and peripheral blood transplantation requires screening and testing of the mother and of the cord blood. When tissue is procured from living donors, with the exception of HPC, the tissue is frozen and quarantined for a minimum of 180 days, at the end of which the donor serologic testing is repeated. This prevents the use of tissue from any donor who was in the “window” period for HIV or hepatitis C, that is, those who had been exposed to the virus but did not demonstrate antibody at the time of donation. The addition of nucleic acid testing for hepatitis C and HIV1/2 has also increased the safety of donated allograft tissue by decreasing the time between donor exposure and a positive laboratory test (AABB). Because of concerns about the sensitivity of testing specimens from deceased donors, tissue banks that process these tissues must utilize test kits that have been approved by the FDA for the testing of deceased donors (CFR, 2009).

CRYOPRESERVATION

Tissues such as HPCs, sperm, and skin and some types of musculoskeletal tissue require the presence of viable cells and have a very short shelf life at refrigerator temperatures, thus requiring cryopreservation. The goal of

*AATB, 1350 Beverly Rd., #220A, McLean, Va.

all cryopreservation techniques is to extend the usable storage period of the material being frozen by reducing the metabolic demand of cells at lower temperatures with no loss of viability due to the freezing or thawing procedures. Cryopreservation of animal sperm has been an established agricultural practice for decades, and human researchers have been able to gain from their experiences. Generally, cryopreservation of human tissues makes use of cryoprotectant agents such as dimethyl sulfoxide (DMSO) or glycerol, balanced tissue culture media, and some form of protein supplementation such as autologous plasma, albumin, or other colloidal suspensions. The actual freezing is often performed using a controlled-rate freezer, a mechanical device that controls the rate at which freezing of the tissue takes place, usually $-1^{\circ}\text{C}/\text{minute}$ down to temperatures of -80°C . DMSO is the cryoprotective agent of choice for tissues such as skin, HPCs, and other nucleated cell suspensions or tissues; glycerol is generally used for the freezing of sperm. Cryoprotectant agents function by preventing the formation of intracellular ice crystals during freezing and balancing the osmotic pressure and concentration of intracellular versus extracellular water during the thawing process. The formation of extracellular ice crystals or too rapid an increase in extracellular osmotic pressure with resulting dehydration of the cell during thawing can result in damage to the cells and thus loss of viability. Cryoprotectant agents, such as DMSO, work by slowing the rate at which this change occurs (Gorin, 1986). Most tissue banks make use of liquid nitrogen and controlled-rate freezing processors that are programmed to compensate for the heat released, called the **heat of fusion**, at the change from the liquid state to the frozen state (Gorin, 1986). Uncompensated, the heat of fusion can result in decreased viability of the cells or frozen tissue.

Once frozen, cryopreserved tissues are stored at varied temperatures from -80°C in a mechanical freezer to vapor (-100°C) or liquid (-196°C) phase liquid nitrogen. Expiration dates for cryopreserved tissues are generally 5 years after collection, although these are arbitrary limits and the actual length of storage possible for many tissues has not been determined. Other tissues that do not require the presence of viable cells, such as structural bone, may be frozen or freeze-dried by a variety of other methods. Some freeze-dried tissues have expiration dates of 5 years, and others may be stored indefinitely.

SKIN BANKING

The most common use of allogeneic skin grafts is as a temporary cover for patients with extensive third-degree burns, until autologous or autogeneic skin can be recovered and grafted. Because of the concentrations of histocompatibility antigens and antigen-presenting cells (APCs), all allogeneic skin grafts are eventually rejected (Medawar, 1946). When used to cover burns, the grafts are generally replaced periodically until autografting can be performed. Most deceased donor skin provided as an allograft is a split-thickness graft with a thin layer of epidermis without dermis, and therefore ABO matching is not required (Eastlund, 1998). As a temporary graft, however, split-thickness skin grafts provide vital, immediate cover, as a barrier against infection plus fluid, electrolyte, and heat loss from extensive burns, allowing for patient stabilization and eventual autografting.

Generally, skin is harvested from deceased donors with uninfected, unblemished skin who have a body surface area less than 1.75 m^2 . The skin is harvested with a dermatome from areas of the back, legs, and upper arms. The skin is generally disinfected before harvest and is soaked in antibiotic-containing tissue culture solution until it is used or until it is frozen.

Skin can be stored at $2^{\circ}\text{--}8^{\circ}\text{C}$ for several days (Kagan, 2005) or cryopreserved and stored for several years. Because of today's need for extensive review of the donor's history and laboratory records, skin grafts are more commonly frozen for subsequent use. The cryoprotectant of choice is 10%–15% glycerol (American Association of Tissue Banks, 2002), and the graft is generally incubated for a period of time (20–30 minutes) in the freezing solution to allow the solution to permeate the graft. The skin is then frozen in strips supported by gauze mesh and is frozen flat (Eastlund, 1998). Skin can be frozen with or without controlled-rate freezing and is easily stored at -50°C to -80°C ; however, lower temperatures are commonly used for longer storage by many tissue banks (Kearney, 1998). Frozen skin allografts are thawed rapidly at 37°C and are used immediately or washed with physiologic solutions to dilute the cryoprotectant.

The limited supply of human skin allografts has stimulated efforts targeted at xenogeneic substitutions, such as pigskin and artificial barriers. More recently, attempts have been made to culture epithelial cells to expand the available supply of autologous skin (Wang, 2007). Another

homologous tissue product, which has gained widespread use, is Allo-derm,* an acellular dermal matrix graft that is processed from human allograft skin. The tissue is enzymatically processed to remove the immunologically active cells, leaving behind an acellular collagen framework. It allows for fibroblast infiltration, collagen deposition, and neoeptithelization. Because the immunologically active cells are removed, the graft is tolerated (not rejected) significantly longer than traditional human skin allografts. It not only has been employed as skin graft for burns, it also has applications in ophthalmic; plastic; ear, nose, and throat; and dental surgeries (Shorr, 2000). It is a product made from allogeneic human tissue that must be used with the identical patient consents and tracking required for other human tissue products.

MUSCULOSKELETAL TISSUES

Bone banking began several decades ago, when physicians first stored surgical discard bone, mostly femoral heads from joint replacement surgery, for future use in spinal fusions and other orthopedic procedures. Generally, this involved simple storage of the bone in an unmonitored freezer somewhere in the hospital. Often, no testing or processing of the surgical discard bone was performed, nor were monitoring of storage conditions and tracking of tissue sources or recipients conducted. In some situations, the original donor/patient was not even asked for consent. Today, these practices have been almost eliminated by the use of musculoskeletal tissue from registered, accredited tissue banks, so that patients can confidently elect to have a bone allograft as part of a surgical procedure (Tomford, 1993). In addition to autogeneic bone grafts, living donor bone donation is still used as a source of some types of bone. Living donors are now screened and tested and must provide informed consent. In addition, the bone tissue obtained is further processed to reduce the risk of infectious disease transmission, and detailed records of the source donor and recipient are kept for tracking and follow-up purposes.

Surgical discard bone and deceased donor bone are processed in a similar fashion. Extraneous tissue, blood, and marrow elements are removed by high-pressure pulse washing, and the tissue is soaked in antibiotic solutions. Bacteriologic culturing of the tissue is done at collection, during processing, and before freezing. Tissue that requires the presence of viable cells such as cartilage, femoral head, tibia, whole bone, or tendon is usually washed, soaked, and frozen at temperatures between -60° and -150°C . With other tissues, where viability is not an issue, ethanol soaks may be used to remove lipid content, generally in the preparation of demineralized, lyophilized bone, which also decreases the infectivity of the tissue. Most bone tissue is further sterilized by the use of low-dose irradiation. In addition, lyophilization, which is possible with bone products such as cancellous and cortical bone chips, appears to reduce the immunogenicity and the infectivity of these products. The use of ethylene oxide to end-sterilize bone tissue has been generally eliminated, as adverse reactions were reported in multiple recipients (Jackson, 1990). The bone tissue is cut and shaped and then is preserved by freezing or freeze-drying.

Bone allografts serve mainly as a mechanical support and a framework for the host's bone-forming cells to replace lost tissue. The osteoinductive function of the allograft bone is dependent in part on the presence of certain growth factor glycoproteins (Mohan, 1991), but they do not appear to cause any significant allograft reaction on the part of the host. Because bone tissue is processed to remove blood, marrow, and other extraneous tissue, most studies have failed to demonstrate the presence of ABO antigens (Ezra-Cohn, 1961). The antigenicity of the resulting product is low, thus histocompatibility or blood type matching is not required. Because large osteoarticular grafts, such as whole bone-patellar-tendon grafts, are not extensively processed, they may contain residual red blood cells, and instances of immunization to Rh system antigens have been reported (Hill, 1974). Many surgeons using these larger grafts will attempt to provide Rh-compatible tissue to Rh-negative females of childbearing age.

In addition to autogeneic bone, allograft bone is used for spinal fusion surgery, replacement of failed prosthetic joints, packing of benign bone cysts, reconstruction of maxillofacial deficits, restoration of alveolar bone in periodontal pockets, and even replacement of resected bone for tumors such as osteosarcoma (Kagan, 2005). Tendon and cartilage allografts are used primarily for knee repair surgery. Some patients will be confronted with the option of having autologous tissue recovered from their iliac crest for many elective orthopedic procedures, or of receiving allograft tissue from a tissue bank. Advantages and disadvantages are associated with each

*Lifecell Corporation, The Woodlands, Tex.

(i.e., autograft vs. allograft). Autografts appear to incorporate quicker, are not immunogenetic, and do not transmit disease; however, they are associated with longer anesthesia time, increased blood loss, and prolonged recovery from the donor site. Because of the wide supply of allografts, an exact fit can usually be made. No donor site recovery is needed, and the surgical procedure is generally shorter. However, although the risk of transmitted disease is greatly reduced by today's procedures, it is still present. Allografts also have a poorer capacity for osteoconduction and osteoinduction (Torrioni, 2009), which makes them unsatisfactory for larger grafts.

Recent investigation and clinical trials have focused on the use of synthetic scaffolds or cages infused with the patient's own bone marrow stromal cells and various bone morphogenetic proteins to create a graft which is almost identical to an autologous graft without the necessity of a donor site (Torrioni, 2009). Bone morphogenetic proteins allow the marrow stromal cells to differentiate into osteoprogenitor cells, eventually resulting in the formation of new bone.

CARDIAC VALVES

Aortic valve replacement may utilize human heart valves or pig valves. With the use of human valve tissue, anticoagulants are not required, and the incidence of thromboembolism or infection is lower. Human valves are ideal for use in children, pregnant women, or patients with a history of bacterial endocarditis. They are, however, utilized less often overall because procedures to place them are more technically difficult. Aortic and pulmonic valves are commonly procured from deceased organ donors when the whole heart is rendered unsuitable for transplantation because of events such as cardiac arrest that do not affect the integrity or function of the aortic or pulmonic valves. Procurement is performed in the operating room. The valves are carefully dissected with a cuff of myocardium, inspected for valve integrity, and frozen by controlled-rate freezing in liquid nitrogen using DMSO as the cryoprotective agent (O'Brien, 1988). Although blood group antigens have been demonstrated on the endothelium of cryopreserved hearts, the major mechanical function of these is dependent only on the nonviable connective tissue. After transplantation, host cells eventually replace the donor endothelium. Several studies have documented that neither ABO compatibility (Weipert, 1995) nor human leukocyte antigen (HLA) compatibility (Yap, 2006) is necessary for long-term function of these allograft valves. However, the use of allograft valves does induce the formation of HLA antibodies, especially in children, and may create difficulty in identifying a compatible donor for those patients later requiring whole heart transplantation (Hooper, 2005).

Recently, some cardiothoracic surgeons have attempted the use of saphenous vein allografts for performing coronary artery bypass procedures or for bypassing obstructed lower limb arteries when autografts are not available. Because the role of ABO matching in the long-term function of these tissues has been controversial, ABO-compatible tissue is generally used (Laub, 1992). Because thawing of the allograft valves is generally performed by operating room personnel, and not by experienced tissue bank technologists, detailed instructions and protocols are necessary to prevent cracking of the valve. Although the use of allograft valves has been a successful practice for several years, the results of most vein allograft studies to date are disappointing (Fahner, 2006).

CORNEA

Corneal transplantation has been regularly performed in the United States since 1961, although the first corneal transplant is recorded to have taken place in 1905. Presently, more than 55,000 corneal transplants are performed each year (Eye Bank Association of America, 2008). There are 86 accredited eye banks in the United States involved in recruitment, screening, procurement, and transplantation of corneal tissue, as well as public and professional education. Loss of vision due to corneal disease can result from infection, trauma, burns, or congenital disease. Long-term (>10 years) success rates for corneal allografts are well above 90%.

Corneal donation is possible from many donors when other tissues are not retrievable because of age, trauma, or disease. Corneal tissue is recovered from donors up to 80 years of age. Generally, eye enucleation is performed in the operating room or morgue from deceased donors within 6 hours of death. Subsequently, the cornea is then removed in a sterile environment in the eye bank and is placed in supplemented, sterile tissue culture media. The corneas are stored at 4° C and are transplanted within 48–72 hours. This allows for appropriate serologic screening of the donor but ensures maximum viability of the graft.

The corneal graft has long been considered an “immunologically privileged site” (Medawar, 1948). Because the cornea is almost entirely avascular, host APCs and effector lymphocytes do not circulate through the allograft cornea. Histocompatibility and blood group matching therefore are not required. In a small percentage of corneal grafts, vascularization occurs, and some grafts are rejected. The use of HLA-matched corneal transplants in an attempt to provide successful grafts for this group of patients has met with varying success rates (Volker-Dieben, 1987).

REPRODUCTIVE TISSUE

Because of the exponential growth in knowledge of fetal development and reproductive technologies, particularly in vitro fertilization (IVF), 1%–3% of births in most Western countries now occur with assisted reproductive technologies (Evers, 2002). Reproductive banks are currently able to assist more individuals and couples who wish to maintain or achieve fertility. Most reproductive banks in the United States today function as for-profit corporations. Despite this, and because of a number of factors including consumer demand, the need for consumer confidence, and government regulation, sperm banks in the 21st century function in keeping with the highest medical and ethical standards, and physicians and patients can make use of their services without concern. Guidelines and standards for anonymous-donation sperm banking have been established by the American Society for Reproductive Medicine and the American Association of Tissue Banks.

Reproductive banks serve two types of donors: client-directed donors and anonymous bank donors. These include men and women who are about to undergo chemotherapy, radiation therapy, or surgery for malignant diseases that will affect their reproductive ability. Client-directed sperm donations are generally targeted to intimate partners of men who, for a variety of reasons, are concerned about future fertility. Other men will predeposit their sperm before vasectomy as insurance against life changes when they may wish to father additional children. Individuals with low sperm counts may bank their sperm to allow collection of sufficient gametes for fertilization of the intimate partner. Less frequently, males who have occupational exposure (such as nuclear power plant employees) that may lead to infertility or the potential for genetic defects may elect to store their sperm. Sperm collected and stored for intimate partners is tested in the same manner in which anonymous donor collections are screened. Semen from infected donors, which still may be usable by the intimate partner, must be quarantined and stored separately from other client deposits. Directed donations are also made to sperm banks for specific individuals who are not intimate partners.

Attempts at ova banking (egg banking) have not been as successful as embryo cryopreservation. Unfertilized ova have a very low rate of fertilization when they are subsequently thawed and attempts at IVF are made. Recently, attempts have been made at cryopreserving ovarian tissue for future implantation with very limited success in humans. One major concern is an increase in chromosomal abnormalities in both ova and ovarian tissue banking. Continuing research is needed in this area to provide women with the opportunity for future fertility with a chosen partner (Porcu, 2008).

Female patients confronted with loss of fertility due to age, disease, or chemotherapy, who have an intimate partner, are still frequently guided to IVF with cryopreservation of the resulting embryos for later implantation. Donor sperm and IVF are often recommended for females without an intimate partner until oocyte cryopreservation demonstrates more promising results. Many reproductive banks also provide donor ova collection for infertile individuals. These donors are screened in the same manner in which anonymous sperm donors are tested.

Sperm banks also provide sperm from anonymous donors for infertile couples or individuals. Sperm banks maintain libraries of sperm donors, so that individuals can select donors with similar physical characteristics such as hair and eye color, race, and the like. Anonymous sperm donors are rigorously screened not only to ensure the safety of the recipient and potential offspring, but also to provide the highest probability of successful fertilization. Sperm collected from anonymous donors is quarantined for 180 days before issue. During these 180 days, the donor is tested monthly, not only by the standard serologic assays employed for all tissue donors, but also for infections such as cytomegalovirus, *Neisseria gonorrhoeae*, and *Chlamydia*. Sperm donors are tested for genetic diseases such as Tay-Sachs disease, cystic fibrosis, sickle cell disease, and thalassemia. Generally, complete genetic karyotyping is performed on anonymous sperm donors. Collections are also examined for sperm number, function, and viability.

Not until all of these criteria have been met and reviewed by the medical director of the sperm bank are tissues released for use.

In vitro fertilization and embryo banking are also offered by many reproductive banks, as well as hospital-based fertility centers. Since the original success attained with IVF as a treatment for tubal obstruction in 1983 (Steptoe, 1983), significant advances have been made in this area which improve the success rate of IVF. They include technical innovations in culture media, embryo cryopreservation, and morphologic criteria for selection of the best embryo to transfer (Houghton, 2002). In addition to its use for women with fallopian disease, the success of intracytoplasmic sperm injection of the oocyte (Palermo, 1992) has made IVF the preferred technique for many infertile couples, utilizing either partner's sperm or donor sperm, as it results in higher fertilization rates as compared with artificial insemination (Boyle, 2004). In addition, IVF offers couples with certain genetic diseases, such as hemophilia and cystic fibrosis, the opportunity for preimplantation genetic diagnosis with subsequent selection of embryos in an attempt to reduce the risk of disease transmission to their offspring.

Collected semen is mixed with a glycerol-egg yolk solution that acts as a cryoprotectant, the egg yolk providing supplemental protein that assists in preserving the sperm during the thawing process. The semen-preserved mixture is aliquoted into straws or vials, precooled to a temperature of 5° C, frozen by controlled-rate freezing with liquid nitrogen, and stored in the liquid phase of liquid nitrogen at -196° C. Cryopreserved sperm can be used for artificial insemination or in vitro fertilization. Client-directed donations are kept indefinitely, and anonymous sperm bank donor samples are usually stored for 5 years. For those individuals desiring artificial insemination, these attempts are not always successful, and individuals are counseled to deposit adequate sperm for several reproductive procedures.

The advent of all these technologies has raised many ethical and scientific issues related to disposition of unused embryos, preimplantation screening of embryos, multiple gestations, and the possibility of unknown genetic risks to the health of children conceived through IVF (Lucifero, 2004). Thus a multidisciplinary approach to this field is needed to include members of the public, as well as scientific and medical professionals (Cetin, 2003).

HEMATOPOIETIC PROGENITOR CELL BANKING

Hematopoietic cell transplantation had its beginning about 50 years ago with bone marrow transplants performed between genetically identical individuals (identical twins) in the setting of high-dose, myeloablative chemotherapy and/or radiation therapy as an attempt to cure hematopoietic malignancies (Thomas, 1959). Earlier work had demonstrated the presence of colony-forming units (CFUs) or cells in the spleen or marrow of mice that were able to restore hematopoietic function to their lethally irradiated, genetically identical littermates (Lorenz, 1951). Restoration of hematopoiesis in the human recipient is dependent on the transplantation of sufficient numbers of pluripotent HPCs that make up about 1% of normal marrow cells and are capable of both replication and differentiation into all lineages of blood cells (see Chapter 31, Hematopoiesis). Identification of the HLA system as the major histocompatibility system in man and the ability of tissue-typing laboratories to identify individuals' HLA types at the allele level allowed bone marrow transplantation to be performed between HLA-matched individuals, generally first-degree relatives, who

were not genetically identical. Today, progenitor cell banks exist as highly specialized tissue banks that collect, process, store, and reinfuse HPC products obtained from bone marrow, peripheral blood, or even umbilical cord blood for patients with a wide variety of diseases (Table 38-4). Today, HPC grafts are performed in the traditional manner with the use of otherwise lethal doses of chemotherapy and/or radiation therapy (myeloablative transplants) in patients with malignant disease, and to restore normal function in patients with defects of hematopoiesis (aplastic anemia, sickle cell anemia). Hematopoietic transplants are also performed following minimal induction therapy in some patients (nonmyeloablative transplants). The success of these transplants depends on the "graft-versus-disease" effect of donor T lymphocytes to eliminate residual disease in patients with malignant disease. In the year 2000, approximately 18,000 patients worldwide were treated with some form of a hematopoietic graft (Storb, 2003). Terminology in transition is shown in Table 38-5. Data from both autologous and allogeneic hematopoietic transplants are now maintained by the Center for International Blood and Marrow Transplant Research (CIBMTR), which is a joint effort of the National Marrow Donor Program in the United States and the International Bone Marrow Transplant Registry. CIBMTR has been funded since 2006 by a contract from Heath and Human Services to gather and maintain data on clinical and research activities in hematopoietic transplantation (www.CIBMTR.org).

SOURCES OF HEMATOPOIETIC GRAFTS

Hematopoietic tissue for transplanting may come from one or more sources (Table 38-6). Individuals who have autologous or autogeneic grafts

TABLE 38-4

Indications for Hematopoietic Transplantation

Acute myeloid leukemia	Neuroblastoma
Acute lymphoblastic leukemia	Ewing's sarcoma
Chronic myelogenous leukemia	Rhabdomyosarcoma
Multiple myeloma	Aplastic anemia
Non-Hodgkin lymphoma	Sickle cell anemia
Myelodysplastic syndromes	Thalassemia
Hodgkin disease	Severe combined immunodeficiency

TABLE 38-5

Terminology in Transition

HPC	Hematopoietic progenitor cells, formerly hematopoietic stem cells
HPC, apheresis	Hematopoietic progenitor cells, apheresis, formerly peripheral blood progenitor cells or hematopoietic stem cells
HPC, marrow	Bone marrow-derived hematopoietic progenitor cells
HPC, umbilical cord blood	Cord blood-derived hematopoietic progenitor cells

HPC, Hematopoietic progenitor cell.

TABLE 38-6

Comparison of Hematopoietic Progenitor Cell Sources and Products with Collection and Complications

	Cord blood (HPC, UCB)*	Autologous (HPC, apheresis + marrow)*	Allogeneic (HPC, apheresis + marrow)*
Type of donor	Umbilical cord blood	Patient	Related or unrelated matched donor
Product	Cord blood progenitor/stem cells	Bone marrow or peripheral blood progenitor cells	Bone marrow or peripheral blood progenitor cells
Collection	Placenta umbilical cord at birth	Intraoperative marrow or hemapheresis	Intraoperative marrow or hemapheresis
Major complication	Insufficient progenitor cells	Recurrence of original disease	Graft-versus-host disease

*HPC (hematopoietic progenitor cell), apheresis = PBPCs (peripheral blood hematopoietic progenitor cells); HPC, marrow = BMPCs (bone marrow hematopoietic progenitor cells); and HPC, UCB (umbilical cord blood) = UCPCs (umbilical cord blood hematopoietic progenitor cells).

donate their own cells, which are frozen and thawed before high-dose chemotherapy and/or radiation therapy. Immediately following this myeloablative therapy, the patient's own cells are thawed and reinfused. The patient's own hematopoietic progenitor cells in the transplant will home and reengraft in the marrow stroma and differentiate into mature blood cell-forming elements. Other patients who are not candidates for autologous transplantation, because of the presence of circulating tumor cells as in acute leukemia, will be candidates for an allogeneic transplant, where the hematopoietic tissue comes from a closely HLA-matched individual. Hematopoietic tissue contains viable lymphocytes that are capable of recognizing the foreign HLA antigens of the host and creating a graft-versus-host (GVH) reaction. This immune response of the graft to the host can vary from mild (Grade 1) to severe (Grades 3 and 4). The GVH reaction, particularly grades 3 and 4, remains one of the most significant morbidity and mortality risks associated with allogeneic hematopoietic cell transplantation. For this reason, donors are selected who are the best HLA match available. Donors may be HLA-matched siblings or other family members, or the patient may receive a graft from an unrelated HLA-matched individual identified through one of several worldwide donor registries. These registries, the largest in the United States being the National Marrow Donor Program, recruit healthy individuals who are willing to altruistically donate their bone marrow or peripheral blood progenitor cells (PBPCs) for an individual needing a transplant who does not have an HLA-matched related donor. Marrow or PBPCs from registry donors are obtained at a hospital or blood center close to their own home, and the graft is then transported by courier to the transplant center. Anonymity is maintained for both donor and recipient. Because of the need for an almost perfect HLA match, registries must have millions of volunteers if they are to have a reasonable chance of finding a match for a given patient. Because pluripotential hematopoietic progenitor cells do not express ABO antigens, they will engraft in the marrow stroma of ABO-incompatible individuals, thus abrogating the need for donors to be ABO compatible, but requiring the removal of mature red cells from these grafts.

Bone Marrow

Bone marrow is harvested from the iliac crest of the donor in the operating room under sterile conditions. Donors will elect to have general or spinal anesthesia. The amount of marrow to be collected is dependent on the recipient size. Generally, sufficient marrow is collected to provide 2×10^8 nucleated cells per kilogram of recipient body weight. For a 70-kg adult, this will generally require the collection of about 700 mL of marrow. The technique involves the collection of approximately 3–5 mL per aspiration into a heparinized syringe. Aspirating too large a volume from one site will result in dilution of the marrow with peripheral blood. Usually, two individuals will harvest marrow at the same time from each side of the donor iliac crest. As it is collected, the aspirated marrow is filtered through large-pore filters to remove bone spicules or clots, and supplemental anticoagulant is added. Because the hematopoietic progenitor cells are contained within the nucleated cell fraction, the collected marrow is often further processed to reduce the volume by separating the buffy coat from a large proportion of the red cells and plasma volume. The buffy coat may be further processed to remove all red cells if the donor and the recipient are ABO incompatible or T cell depleted if desired. Generally, bone marrow from allogeneic marrow donations is collected immediately before transplant, but it can be successfully frozen and stored for later use.

Although bone marrow harvested from the iliac crest was the original and long-standing source of HPCs for transplantation, the last 20 years have seen the development of technologies that allow the collection of these cells from the peripheral blood of both patients and normal donors and even from placental or cord blood.

Peripheral Blood Progenitor Cells

The stimulation for the development of technologies that would allow the collection of HPCs from peripheral blood was the potential for use in the autologous transplant setting, where concerns about marrow contamination with tumor cells are high. Because of the relative ease of hemapheresis collection over marrow harvest and the increased rate of engraftment, progenitor cells obtained from the peripheral blood are increasingly being used in the allogeneic setting as well. Currently, about 70% of allogeneic hematopoietic transplants employ HPCs from peripheral blood, and approximately 20% are obtained from marrow. This has positively affected

the recruitment of volunteer donors in that more individuals may volunteer for the national marrow donor programs when hemapheresis is offered as an option over traditional bone marrow harvest. The instrumentation and procedures used for peripheral blood progenitor cell harvest are described in Chapter 37, Hemapheresis.

Clearly, the greatest advantage of peripheral blood progenitor cells over marrow is the time to neutrophil and platelet engraftment, averaging 8–12 days for mobilized peripheral blood progenitor cells compared with 2–4 weeks for bone marrow (Gianni, 1989). This rapid recovery clearly reduces morbidity and mortality associated with profound neutropenia/thrombocytopenia and reduces the costs associated with hospital stay, transfusion support, treatment of complications, and so forth.

HPCs were known three decades ago to be present in the peripheral blood following chemotherapy recovery (Richman, 1976). It was later, however, when hemapheresis systems were developed that would allow the safe collection of adequate numbers of these cells to provide for engraftment of the recipient after chemotherapy (Kessinger, 1988). In most patients undergoing autologous transplantation, large-volume apheresis collection (14–20 L/procedure) is now well established as an efficient means of collecting adequate numbers of HPCs in a reasonable number of procedures to provide for adequate hematopoietic recovery.

HPCs are morphologically indistinguishable from other mononuclear cells seen in the marrow or peripheral blood, yet collection of adequate numbers of cells is essential to ensuring marrow engraftment in the recipient. Bone marrow collections have traditionally been targeted at collecting sufficient nucleated cells to ensure a minimum number of progenitor cells. Bone marrow grafts could be assayed for progenitor cell activity by the use of colony-forming assays (Iscoe, 1971). With this technique, a sample of mononuclear cells from the graft is cultured in methylcellulose media supplemented with hematopoietic growth factors and essential amino acids for 10–14 days. At the end of this period, the plates are examined for the numbers and types of characteristic CFUs, including burst-forming unit-erythroid, granulocyte-macrophage (CFU-GM), and mixed colonies—granulocyte, erythrocyte, monocyte, megakaryocyte. Clusters containing more than 50 cells are scored as a colony. Collections containing greater than 1×10^5 CFUs per kilogram of recipient weight are considered adequate.

With increasing use of peripheral blood hemapheresis procedures to obtain progenitor cell grafts, it became necessary to develop an assay that could be completed on the same day and used to determine the number of hemapheresis collections required. Quantitation of the number of cells bearing the CD34 antigen by flow cytometry has become the widely accepted method for assessing the adequacy of peripheral blood progenitor cell collections. The CD34 antigen is restricted to primitive cells of all lineages (Civin, 1989). Collection of hemapheresis products using CD34+ cell enumeration as an index of graft efficacy has proved to result in enduring hematopoietic engraftment (Berenson, 1991). Standardization of the CD34 cell assay and availability of flow cytometric analysis have resulted in the use of CD34+ cell measurements by most programs to determine the number and adequacy of peripheral blood progenitor cell collections (Keeney, 2004). Generally, peripheral blood progenitor cell collections containing greater than 3×10^6 CD34+ cells per kilogram of recipient body weight are considered adequate to provide for neutrophil engraftment in 8–10 days.

Collection of HPCs in the nonmobilized patient or donor would require multiple apheresis procedures or collections, as the numbers of HPCs in the peripheral blood are about $\frac{1}{10}$ to $\frac{1}{100}$ of the number in the marrow. Thus, **mobilization** therapies are required to increase the numbers of circulating HPCs and thus improve the efficiency of hemapheresis collection. Richman (1976) recognized that although there was a drop in the number of circulating CD34+ cells following chemotherapy, this was followed by a fourfold to fivefold increase in the percentage of circulating CD34+ cells just as the absolute neutrophil count began to recover, usually around 14–21 days following therapy. This increase in circulating CD34+ cells is greatest with chemotherapeutic agents such as cyclophosphamide and etoposide. If hemapheresis collection is performed in this window, large numbers of HPCs can be recovered with a limited number of procedures, even though the total white count may be less than 10,000/ μ L. Because the period of increased numbers of circulating CD34+ cells is short (2–3 days), close monitoring of the patient's white count and peripheral blood CD34+ cell counts and timing of the hemapheresis collection are critical. In addition, some investigators have felt that collecting autologous HPCs in the recovery phase of chemotherapy decreases the likelihood of tumor cells contaminating the apheresis product. The use of hematopoietic growth factors such as granulocyte-macrophage

colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF) also results in a significant increase in the numbers of circulating CD34+ cells in peripheral blood (Siena, 1989). Doses of 5–10 µg/kg of body weight for 4–5 days will result in a fivefold to 10-fold increase in the number of HPCs in the peripheral blood. The use of G-CSF alone has proved to be more efficient than chemotherapy priming for the collection of CD34+ cells. The combination of chemotherapy priming and the use of growth factors (primarily G-CSF) results in the maximum mobilization of PBPCs and the need for the fewest number of hemapheresis procedures to collect a transplant dose of HPCs—a strategy employed by most autogeneic transplant programs.

The use of G-CSF in the healthy allogeneic donor to mobilize HPCs has been investigated and, aside from mild effects such as bone pain and headache, is well tolerated (Anderlini, 1997). Increasingly, transplant programs are using peripheral blood instead of marrow as a source of HPCs for their allogeneic and autogeneic transplants. The higher risk of GVHD in allogeneic recipients of peripheral blood HPCs versus marrow (Cutler, 2001) has stimulated trials of new technologies to modify these grafts (see [T Cell Depletion](#)).

Umbilical Cord Blood

The fact that higher numbers of CFU cells or progenitor cells were present in umbilical cord blood was known for many years, but it was not until 1989 that the first attempts were made to use cells recovered from placenta umbilical cords for hematopoietic transplantation (Gluckman, 1989). The apparent success of many of these early cord blood transplants led to the organization of several cord blood banks in this country and in Europe in an attempt to provide another source of progenitor cell tissue for patients requiring an allogeneic transplant from an unrelated donor. The Cord Blood Transplantation Study (COBLT), which collected data from 1997–2004, established standardized procedures for donor screening, HLA matching, cord blood processing, and storage and data collection. These data clearly established that cord blood transplants in children with a wide range of malignant and nonmalignant conditions could result in a high degree of engraftment and 2-year event-free survivals of 55% for children with high-risk malignancies and 78% for children with nonmalignant conditions (Martin, 2006; Kurtzberg, 2009). In addition, because the progenitor cells are obtained from cord blood, there appears to be a greater degree of tolerance for some degree of HLA incompatibility between donor and recipient without the appearance of a Grade 3 or 4 GVH reaction; thus, hematopoietic transplantation might become available for some patients who otherwise have no HLA-matched donor (Barker, 2005). An additional advantage of cord blood HPC over both bone marrow and apheresis products is that the cord blood is banked and is more immediately available for use, thus reducing the time to transplantation.

Umbilical cord progenitor cells are harvested by cannulation of the placental vessels while the placenta is still in utero or, more commonly, following delivery, or by direct expression, of the cord blood from the placenta following delivery. The number of HPCs recovered is directly proportional to the volume of cord blood collected, which varies with the size of the infant/placenta and with the experience of the individual performing the collection (Wagner, 1992). Volumes ranging from 40–150 mL are common for experienced centers. This will result in the harvesting of approximately $4\text{--}11 \times 10^8$ nucleated cells. Collections that are not adequate in volume (<40 mL) are usually discarded. Generally, umbilical cord blood collections are not further processed to reduce their volume, and they are frozen directly with DMSO and liquid nitrogen storage. Specially trained staff deployed to the delivery room are not distracted by the care of the mother and/or the infant, and they also reduce the risk of bacterial contamination of the cord blood.

Careful screening and testing of the mother are essential to ensure the safety of the cord blood product, as well as the absence of genetic disease. In addition to standard laboratory measurements for serologically transmissible disease, testing is performed for viral and bacteriologic diseases.

Although umbilical cord blood banking offers the exciting potential for a lesser degree of histocompatibility and thus availability for more patients, the remaining critical issue is the lack of sufficient hematopoietic progenitor cells in most cord bloods to successfully engraft adults. Research efforts to expand these cells in vitro have met with limited success and are not yet ready for clinical trials. More recently, investigative efforts have focused on the use of more than one cord blood to provide sufficient HPCs to transplant adults (Haspel, 2008).

REDUCED-INTENSITY CONDITIONING OF HEMATOPOIETIC GRAFTS

Ablative conditioning regimens using high-dose chemotherapy and/or radiation therapy are not always successful in eliminating neoplastic cells before HPC transplant. These high-dose regimens are associated with increased morbidity and mortality, and many patients are excluded as candidates for traditional HPC grafts because of comorbidities. These factors, along with data demonstrating greater benefit from allogeneic versus autologous HPC grafts, led to the investigation of nonmyeloablative transplant protocols, now more commonly referred to as reduced intensity allogeneic HPC grafts.

Early murine studies had shown that recipients of allogeneic grafts had better survival than recipients of syngeneic grafts (Barnes, 1957). Later studies in humans showed a “graft-versus-leukemia effect” in patients transplanted for acute leukemias that appeared to correlate with the development of chronic graft-versus-host disease in the recipient (Weiden, 1981). That this effect was dependent upon donor T lymphocytes was further demonstrated by the high relapse rate that occurred in patients receiving T cell-depleted HPC grafts (Marmont, 1989). Initial efforts focused on the infusion of donor T lymphocytes after HPC grafting in patients who had relapsed (Kolb, 1990). This technique became known as donor lymphocyte infusion (DLI). Because these patients received no additional chemotherapy, the next approach was to attempt HPC peripheral blood grafts with no conditioning (Porter, 1999). It quickly became clear that some conditioning therapy, primarily immunosuppressive, was necessary to allow donor cells to engraft. Conditioning regimens in reduced-intensity conditioning of HPC transplants are now focused on providing sufficient immunosuppression to allow engraftment of donor cells without complete elimination of the tumor burden. The larger number of T lymphocytes in peripheral blood HPC grafts versus marrow appears to decrease the risk of graft rejection by overwhelming host T lymphocytes and favoring the development of a graft-versus-leukemia effect. DLI may also be given at a later date if insufficient donor T cell engraftment or disease relapse is evident.

In the reduced-intensity conditioning of HPC grafts, disease control is mediated by recognition of host residual tumor cells by donor T cells and requires establishment of at least partial donor T lymphocyte chimerism, if not full replacement by donor T cells. The kinetics of T cell engraftment in nonmyeloablative HPC transplants is such that up to a year may be required for the patient to achieve complete disease remission (Childs, 1999). Therefore, this therapy is not appropriate for patients with acute leukemia who are not in remission or for those with other aggressive malignancies likely to relapse at an early date. Although the morbidity and mortality associated with the conditioning regimen in nonmyeloablative HPC grafts are lower, the risk of GVHD is the same as that seen following high-dose conditioning regimens. Because of the higher risk of GVHD and graft rejection in unrelated HPC grafts, particularly HLA-mismatched ones, it remains to be seen whether this group of patients will benefit from nonmyeloablative HPC grafts (Koreth, 2009).

Reduced toxicity of the preparative regimen allows its use in older patients and is associated with less transfusion burden and shorter hospital stays (Weissinger, 2001). Studies are currently under way to look at the efficacy of reduced-intensity conditioning in such diseases as multiple myeloma (Cook, 2009), in which the patient population tends to be older. Reduced toxicity and improved outcomes seen with this therapy have contributed to its rapid growth in the hematopoietic transplant community.

PURGING

Once hematopoietic progenitor cells are collected from the marrow or from peripheral blood, it is often advantageous to further process the collected HPC product in an attempt to reduce possible tumor cell contamination or, in the allogeneic setting, to reduce the number of T lymphocytes. Two approaches, not mutually exclusive, have been taken. The first employs techniques targeted at eliminating tumor cells, so-called purging or negative-selection techniques. The second approach utilizes methods to separate and collect only the CD34+ hematopoietic progenitor cells, discarding the remaining cell fraction, which presumably contains contaminating tumor cells. These methods are usually referred to as **positive-selection techniques** (Table 38-7).

Purging techniques originally employed a variety of specific and non-specific methods to remove the unwanted cell population. Original

methods used cytotoxic drugs such as 4-hydroperoxycyclophosphamide (4-HC) and etoposide to remove contaminating tumor cells (Yeager, 1986). These methods are the *in vitro* equivalent of high-dose chemotherapy, and thus the major negative effect is damage to HPCs. Other technologies included the use of lectins and/or rosetting to remove unwanted cell populations, particularly T cells. More recently, monoclonal antibodies targeted at a specific cell receptor have been used with complement or coupled to immunotoxins such as ricin to actually lyse the contaminating tumor cell population. Also, with the advent of immunomagnetic bead technology, the monoclonal antibody can be coupled to an immunomagnetic bead. The antibody-bead-tumor cell complex is then removed by passing the cell suspension over a magnetic field, where the unwanted cell populations will be retained, while the HPCs are rinsed through and collected.

Positive-selection techniques focus on the presence of CD34 on hematopoietic progenitor cells and the availability of monoclonal antibodies targeted to this antigen. Although the original technology used a column to which the monoclonal antibody was bound, current methods utilize an immunomagnetic bead or sphere. The mononuclear cell fraction from the bone marrow harvest or the progenitor cell hemapheresis collection is incubated with the monoclonal anti-CD34 or another monoclonal antibody of interest. A suspension of immunomagnetic beads labeled with a secondary antibody is then added that binds to the monoclonal anti-CD34, creating a bead-target cell complex. When the cell suspension is subsequently passed over a magnetic field, the CD34+ cell-magnetic bead complex will be retained, and the remaining mononuclear cell suspension containing unwanted tumor cells, T cells, and others will be removed. The CD34+ progenitor cells are then freed from the magnetic beads with the use of a releasing agent, and the beads are removed by reapplication of the magnetic field, leaving a cell suspension that is approximately 90% CD34+ cells. The reduction in total number of CD3+ T cells is about 3.5 log₁₀ depletion. The median recovery of CD34+ cells is approximately 50% of the starting numbers of CD34+ cells in the hemapheresis product. The benefits of positive- and negative-selection purging of HPC grafts to reduce tumor cell contamination and reduce disease relapse rates have been controversial (de Lima, 2004). These techniques, with the exception of T cell depletion, have been widely investigated but are still considered experimental.

T Cell Depletion

Techniques to reduce the numbers of T lymphocytes in allogeneic hematopoietic grafts, primarily marrow, have been targeted at reducing the incidence and severity of GVHD. Many of the techniques mentioned previously for purging of tumor cells, such as positive selection for CD34+ cells, have also been applied to the reduction of T cells in the graft (Table 38-8). Other techniques specifically targeting T cells have included soybean lectin agglutination, E-rosette formation, combinations of the two, counterflow elutriation, monoclonal antibodies, and the application of monoclonal antibodies *in vivo* in the recipient post transplant to reduce donor T cells.

Soybean lectin produces an agglutinin specific for the CD2 receptor on lymphocytes, thus agglutinating CD2+ T cells. The addition of a rosetting step with sheep erythrocytes removes the remaining T cells not agglutinated by the soybean lectin. This method results in a 2 to 3 log₁₀ depletion of T cells (Reisner, 1982). Current trials with monoclonal antibodies have focused on the use of anti-CD52 antibodies for *in vitro*

treatment of the HPC product and *in vivo* to reduce host T lymphocytes (Chakraverty, 2002).

Counterflow elutriation is a method used for the depletion of T cells that utilizes the separation characteristic of cells in a centrifugal field, based on the size and density of various cell populations. One of the advantages of the system is that no chemotherapeutic agents or antibodies are added to the hematopoietic progenitor cell population; thus, there is no impairment of cell function. Buffy coat concentrates from harvested marrow are introduced into the centrifuge at different flow rates, allowing for the collection of cell fractions of different sizes and densities. The system is highly efficient at separating a CFU-GM-rich fraction from a CD3+ lymphocyte fraction. Because no changes are made to the cells, the CD3+ fraction can be enumerated and partially added back to the CFU-GM fraction to provide a controlled dose of CD3+ cells, if clinically desired (Noga, 1990). Cell recovery is high, and because elutriation media are biocompatible, the product(s) can be reinfused without additional wash steps. The major disadvantages of the procedure are the cost of the required equipment and the need for experienced operators.

The introduction of immunomagnetic bead techniques for the positive selection of CD34+ cells has also led to the use of these techniques in the allogeneic setting for the resultant depletion of CD3+ T cells, particularly from peripheral blood progenitor cell collections. Immunomagnetic bead technology is easily applied to hemapheresis progenitor cell products and to the larger-volume bone marrow harvest products. Many centers have reported success with these newer methods to reduce CD3+ T cells in allogeneic transplantation, particularly when reduced-intensity conditioning is desirable (Handgretinger, 2008). Other centers have focused on *in vivo* protocols employing anti-T cell agents such as alemtuzumab for reduction of the donor T cell population in the recipient (Malladi, 2009).

One additional advantage of purging or positive-selection techniques is that they result in a significantly reduced volume of progenitor cell product to be frozen, thawed, and reinfused in the patient. This greatly reduces toxicities associated with the reinfusion of DMSO-containing products, as well as decreasing freezing and storage costs for the progenitor cell laboratory. Presently, licensed technologies for purging and/or positive selection to reduce tumor cell contamination are costly, and additional data are needed to assess the clinical efficacy of these procedures for tumor cell reduction.

Both positive- and negative-selection techniques incur a concomitant loss of as much as 50% of the original number of CD34+ cells from agent toxicity (chemotherapeutics, complement), entrapment by magnetic bead complexes, or loss during required wash steps. The initial hemapheresis or bone marrow collection of CD34+ cells must be increased to allow for subsequent loss in processing. This may be difficult to accomplish in patients who are hard to mobilize.

The major disadvantage of T cell depletion is the resultant increase in the incidence of disease relapse. Patients who demonstrate mild GVHD appear to have a lower incidence of relapse of neoplastic disease than do those patients who have no GVHD. The presence of the donor T cell population is apparently critical to "graft-versus-leukemia effect," with recognition of host antigens by donor T cells generating an immune response that eliminates residual host tumor cells. More recent studies have demonstrated a role for natural killer (NK) cells in the graft-versus-leukemia effect. Others have used combinations of techniques such as CD34+ selection and counterflow elutriation to create a CD34+ cell-rich fraction and an NK cell-rich/T cell-depleted fraction, taking advantage of the fact that NK cells do appear to have antitumor effects but do not contribute to GVH effects (Handgretinger, 2008).

CRYOPRESERVATION OF HEMATOPOIETIC GRAFTS

HPC grafts from all autogeneic and many allogeneic collections are cryopreserved and stored before use. The most common protocol involves the

use of 10% DMSO as a cryoprotective agent, controlled-rate freezing, and liquid nitrogen storage, either vapor or liquid phase. The use of DMSO provides significant improvement in postthaw viability over agents such as glycerol. Because toxicities are associated with the postthaw infusion of progenitor cell products containing DMSO, other investigators have looked to the use of lower concentrations or the addition of hetastarch or other additives, but DMSO currently remains in use by most programs. Attempts to wash products following thaw to reduce the amount of DMSO present resulted in significant loss of progenitor cells; strategies are now targeted at reducing the volume of the prefreezing product, thus lowering the amount of DMSO necessary.

REINFUSION OF PROGENITOR CELL PRODUCTS

Regardless of the source of the progenitor cell graft, HPCs are infused to the recipient in a manner very similar to that of any blood product transfusion. Pluripotential progenitor cells, with their unique membrane receptors, will home to the marrow space, engraft, and replicate. Products that have been cryopreserved with DMSO in most cases are thawed and immediately reinfused without washing. HPCs collected by hemapheresis that are not further processed may contain large numbers of red blood cells. Cryopreservation in DMSO does not maintain red blood cell membrane integrity, and these products will contain a large amount of free hemoglobin when thawed. Recipient reactions will vary from mild, characterized by nausea, chills, or headache, to more severe reactions that can include

TABLE 38-9 Adverse Reactions Observed in Patients Transfused with Cryopreserved Progenitor Cell Products	
Common	Contributing Factors
Chills	Volume of product reinfused
Nausea	Type and amount of cryoprotectant reinfused
Emesis	Volume of incompatible red cells (allogeneic products)
Fever	Bacterial contamination
Headache	
Dyspnea	
Uncommon	
Renal failure	
Cardiac arrest	
Hypotension	
Sepsis	

hypotension, sepsis, renal failure, or even cardiac arrest (Stroncek, 1991). Such adverse reactions are shown in Table 38-9. Recipients of cryopreserved progenitor cell products are generally premedicated with antihistamines and/or antiemetics. Adequate hydration and the use of diuretics are indicated to decrease renal toxicities associated with free hemoglobin and larger-volume infusions.

KEY POINTS

- Physiologic hemostasis consists of the plasma coagulation, fibrinolysis, and anticoagulation protein systems.
- Physiologic hemostasis is initiated by factor VIIa and tissue factor; thrombosis is also initiated by factor VIIa and tissue factor, but it is amplified by factor XII activation on injured tissue and platelet thrombus.
- The adequacy of physiologic hemostasis cannot be fully assessed by current assays to detect coagulation abnormalities such as the activated partial thromboplastin time and prothrombin time.
- Current assays to assess coagulation protein abnormalities have good diagnostic power to recognize specific defects in coagulation proteins.
- Acquired coagulation protein defects more commonly reflect general medical disorders than specific protein defects.

OVERVIEW OF COAGULATION AND FIBRINOLYSIS

Hemostasis, or cessation of bleeding, occurs within the intravascular compartment lined with endothelium. Normal hemostasis and thrombosis involve a number of factors. These factors include platelets, granulocytes, and monocytes, as well as the coagulation (clot forming), fibrinolytic (clot lysing), and anticoagulant (regulating) protein systems. The coagulation system serves to form thrombin that initiates the proteolysis of fibrinogen,

leading to fibrin clot formation. The role of the fibrinolytic system is to lyse the clot formed by thrombin. The role of the anticoagulation system is to regulate all enzymes of the coagulation and fibrinolytic systems, so that no inappropriate excess of clotting or bleeding occurs. These three protein systems, together with the vessel wall endothelium, are in delicate balance to ensure adequate hemostasis with limitation on thrombosis formation.

Recent years have seen an evolution in our understanding of the physiologic hemostatic system (Fig. 39-1). For decades, the hemostatic system has been referred to as the **coagulation cascade**, based on the waterfall hypothesis of Ratnoff and Davies and MacFarland, who published, almost simultaneously, a sequence of proteolytic reactions starting with factor XII (Hageman factor) activation and ending with formed thrombin proteolyzing fibrinogen to form a clot (MacFarland, 1964; Ratnoff, 1964). However, at the onset, this hypothesis for physiologic hemostasis was untenable because it was known that factor XII (FXII) deficiency was not associated with bleeding (Ratnoff, 1955). Thus the physiologic basis of this pathway was questioned because FXII is not essential for hemostasis. Further, by the mid-1970s, the cofactors for FXII activation, that is, prekallikrein and high molecular weight kininogen, were identified, and deficiencies of these proteins were not associated with a bleeding state (Weuppers, 1972; Colman, 1975; Saito, 1975). Other mechanisms for physiologic hemostasis were sought. In 1977, Osterud and Rappaport recognized that FVIIa is able to activate FIX to FIXa (Osterud, 1977). Later, Broze and colleagues recognized that the kinetics of tissue factor pathway inhibitor (TFPI) was such that under physiologic circumstances the FVIIa-tissue factor complex cannot directly activate FX, but instead requires the involvement of FIX (Broze, 2003). These latter two studies indicate the important role of the FVIIa-tissue factor pathway in physiologic hemostasis. A key remaining question was how does FXI, whose deficiency is associated with bleeding,

Figure 39-1 Schematic diagram of physiologic blood coagulation. Note that labels for the “contact phase” factors constituting factor XII (FXII), high molecular weight kininogen (HK), and prekallikrein (PK) are shown grayed. Although FXI is activated by FXIIa on a surface under artificial in vitro conditions, such as in the activated partial thromboplastin time (APTT), this pathway is not believed to contribute to normal physiologic hemostasis. Similarly, whereas tissue factor (TF)/FVIIa can directly activate X to Xa in the in vitro prothrombin time (PT) test under conditions in which supraphysiologic concentrations of TF are employed, this reaction is shown as grayed because it does not contribute significantly to clot formation under normal in vivo physiologic conditions. Normal clotting in vivo is initiated when sufficient TF/FVIIa becomes available to activate FIX to FIXa. Subsequently, FIXa in the presence of FVIIIa activates FX to FXa, which, in turn, activates prothrombin to thrombin in the presence of FVa. Thrombin not only then proceeds to clot fibrinogen and to activate platelets, but additionally exerts critically important positive feedback by activating both factor VIII and factor V. Physiologic amplification of thrombin formation is believed to result from thrombin activating FXI to FXIa, thereby providing an additional pathway for the activation of FIX. Phospholipid (PL) protein complexes present on the surface membranes of platelets in vivo; and Ca^{++} , calcium ions.

become activated under physiologic circumstances? In 1991, Gailiani and Broze found that formed thrombin activates FXI in the presence of dextran sulfate and high molecular weight kininogen, resulting in amplification of the coagulation system under stress (Gailiani, 1991). More recent evidence indicates that if FXI is poorly activated by thrombin, if FIX is poorly activated by FXIa, or if an antibody prevents FXIa activation of FIX, thrombin generation in plasma is reduced (Kravtsov, 2009). Under the same conditions, an antibody to FXIIa activation of FXI does not influence thrombin generation (Kravtsov, 2009). Furthermore, mice with total deficiency of FXII and low tissue factor (TF) are viable and phenotypically similar to low-TF mice with normal FXII expression. In contrast, superimposed FXI deficiency on the low-TF background results in death in utero (Spronk, 2009). Thus, FXII is not essential for hemostasis, but FXI is. Presently, physiologic hemostasis is understood to be an interacting system of activation and amplification of several zymogens that become serine proteases. The initiator of physiologic hemostasis is FVIIa when bound to its cofactor, tissue factor. Regulation of expression of tissue factor constitutes a major modulation of physiologic hemostasis. Thrombin in

turn amplifies the process by activating FXI, leading to additional FIX activation.

It is important for the reader to understand the physiologic basis of hemostasis. However, clinical laboratory assays used to examine the coagulation system are based on the original coagulation cascade hypothesis. Although these tests do not represent physiologic hemostasis, they are still very useful for diagnosis of potential bleeding disorders. Thus one needs to understand the distinction between physiologic coagulation, fibrinolysis, and anticoagulation and the tests that we use to measure these systems. This chapter endeavors to clarify this distinction for the reader. In the first part of this chapter, the details of physiologic coagulation, fibrinolysis, and the regulation of coagulation will be presented. In the second part of this chapter, a description of the assays performed to measure bleeding disorders will be presented, together with a discussion of the limitations of these assays for characterizing physiologic hemostasis. In the third part of this chapter, an overview of congenital bleeding disorders will be presented. Last, this chapter will present the acquired bleeding disorders, the most common forms of bleeding states one actually encounters in clinical practice.

PHYSIOLOGIC HEMOSTASIS

The physiologic hemostatic system, a tightly regulated balance between formation and dissolution of hemostatic plugs modulated by a series of enzymes and scaffolding proteins, has two major parts. The first part is its cellular component, which consists mostly of platelets and endothelial cells but also includes neutrophils and monocytes. The second part is a large group of plasma proteins, which participate in clot formation (coagulation), dissolution of clots (fibrinolysis), and the action of naturally occurring serine protease inhibitors (anticoagulation) that terminate activity of a number of enzymes of the coagulation and fibrinolytic systems.

ENDOTHELIUM AND PLATELETS

Normal hemostasis involves interplay among the cellular components and proteins involved in clot formation and lysis. Endothelium that lines the vascular compartment contributes to its constitutive anticoagulant nature. Endothelial cells have glycosaminoglycans that bind antithrombin (Marcum, 1984). Thrombomodulin on endothelial cell membranes is a locus at which protein C is activated by low levels of thrombin (Esmon, 1981). Intact endothelial cells secrete an ectonucleotidase, CD39, that degrades adenosine diphosphate (Pinsky, 2002). Endothelial cells also secrete prostacyclin and nitric oxide, which prevent platelet activation, thereby reducing the risk of arterial thrombosis (Hong, 1980; Palmer, 1987; Shariat-Madar, 2006). Endothelial cells additionally bind plasminogen, tissue plasminogen activator, and single-chain urokinase, all of which contribute to fibrinolysis and maintenance of an anticoagulant state (Barnathan, 1988; Cesarman, 1994). When a vessel wall is injured, collagen is exposed, and platelets adhere to the site of injury (van der Meijden, 2009). von Willebrand factor helps platelets adhere to the injured vessel wall by binding both to this exposed collagen and to the platelet receptor GP Ib/IX/V complex (He, 2003). This adhesion event activates platelets, initiating a signaling cascade within them (Zaffran, 2000). The stimulated platelets release the contents of their granules, recruit additional platelets to aggregate to those already adherent, and provide a surface favoring the activation of multiple coagulation factors. Furthermore, in flowing blood, factor XII autoactivates if exposed to collagen or in the milieu of activated platelets, leading to the cascade of proteolytic events producing thrombin (van der Meijden, 2009). Together, these events promote hemostatic plug formation as a physiologic event, and in pathophysiologic states may lead to thrombus formation.

Once prothrombin has been activated to thrombin in the intravascular compartment, the resulting thrombin stimulates endothelium to upregulate TF, and TF forms a complex with FVIIa. The complex of FVIIa-TF activates FIX to FIXa, which converts zymogen FX to enzymatically active FXa (see Fig. 39-1). In the presence of FVa from liver or injured endothelium, FXa activates prothrombin (FII) to thrombin (FIIa). Under normal circumstances, the rate-limiting component of prothrombinase complex formation and the ultimate generation of thrombin activity is the concentration of FXa (Rand, 1996). Thrombin then proteolyzes fibrinogen to form fibrin. In static, in vitro systems, as little as 5–10 pM TF is sufficient to induce clot formation, leading to a 1000–2000-fold amplification of the process that increases the concentration of thrombin to 10–20 nM, which is sufficient to initiate clot formation (Mann, 2003). In a static model of blood coagulation, the addition of 5 pM TF results in an average clot time

TABLE 39-1

Proteins of the Plasma Coagulation System

	Factor II	Fibrinogen
	Protein C	Protein S

of ≈ 5 minutes—a time sufficiently fast for physiologic hemostasis. Thrombin also is a major physiologic activator of platelets, together with other agonists such as collagen, ADP, platelet-activating factor, and epinephrine. Unactivated platelets probably circulate without promoting coagulation. When platelets are activated (see Chapter 40), their membranes become a site for additional thrombin formation. This pathway for thrombin formation conjoins with FXII autoactivation on exposed vessel collagen and downstream elaboration of thrombin as well (van der Meijden, 2009). Critical reactions to form FXa and thrombin are accelerated 300,000-fold on the platelet surface. Physiologically important coagulation and fibrinolytic reactions are likely to occur on the surface of cells in the intravascular compartment.

COAGULATION PROTEIN SYSTEM

Characterization of Coagulation Proteins

The proteins that constitute the coagulation system consist of zymogens and cofactors (Table 39-1). The zymogens (proenzymes) of the coagulation system can be grouped into the phospholipid-bound and the surface-bound. Phospholipid-bound zymogens make up the physiologically important hemostatic system. These proteins are vitamin K-dependent. Vitamin K is required for an essential γ -carboxylation reaction that takes place on the glutamic acid residue of each of these proteins located in their amino-terminal regions (see Chapter 42, Fig. 42-1). This carboxylation reaction allows these proteins to bind to phospholipid and cell membranes, where they are activated. Without this carboxylation reaction, these proteins do not function normally in the hemostatic system. Proenzymes include FX, FIX (Christmas factor), FVII, and FII (prothrombin). Protein C is a vitamin K-dependent phospholipid-bound zymogen, but when activated, it functions as an inhibitor (see later and Chapter 41). Protein S is a vitamin K-dependent cofactor for activated protein C.

The surface-bound proenzymes are proteins of the plasma kallikrein/kinin system (see Table 39-1). Surface-bound proenzymes include FXII (Hageman factor), prekallikrein (Fletcher factor), and FXI. These protein zymogens are also known as the **contact system** because FXII autoactivates when associated with a negatively charged surface such as a glass tube and several physiologic substances (see later) (Wiggins, 1979; Miller, 1980). The autoactivation phenomenon of FXII allows for a common laboratory test, the activated partial thromboplastin time (APTT), which is used to assess the integrity of the coagulation system (see later). This assay is an important diagnostic test that is performed more than 200 million times annually in the United States alone to assess many coagulation proteins. Thus, it is important to be aware that assays to assess coagulation proteins (e.g., APTT, activated clotting time) are based on the event of FXII autoactivation. Although absolutely essential for a normal APTT, the proteins of the plasma kallikrein/kinin system do not have a physiologic role in hemostasis. These proteins do participate in blood pressure regulation, fibrinolysis, inflammation, angiogenesis, and arterial thrombosis (Schmaier, 2002, 2003, 2004; Shariat-Madar, 2006; Maas, 2008; LaRusch, 2010). Under physiologic circumstances in vivo, prekallikrein when assembled on endothelial cells may be first activated by an endothelial enzyme, prolylcarboxypeptidase ($K_m = 9$ nM) with FXII activation secondary to the formed plasma kallikrein (Rojkjaer, 1998; Shariat-Madar, 2002). Finally, the role of the surface-activated proteins that participate in in vitro blood coagulation assays has been reevaluated. Although deficiencies of FXII, prekallikrein, and high molecular weight kininogen are not associated with bleeding, investigations suggest that they do have a role in arterial thrombosis. Mice deficient in FXII, kininogen, and the bradykinin B2 receptor are protected from arterial thrombosis (Renne, 2005; Shariat-Madar, 2006;

Merkoulov, 2008). FXII participates in in vivo thrombus formation presumably by autoactivation on released polysomes from activated platelets, extracellular ribonucleic acid, aggregated proteins, or exposed collagen in the intravascular compartment in flowing blood (Smith, 2006; Kannemeier, 2007; Maas, 2008; van der Meijden, 2009). In the absence of the bradykinin B2 receptor, increased angiotensin II binds to the angiotensin receptor 2 to increase nitric oxide and prostacyclin to reduce arterial thrombosis risk (Shariat-Madar, 2006).

The hemostatic cofactors for the enzymatic reactions of the coagulation system may be considered to act as receptors for coagulation proteins. For example, high molecular weight kininogen serves as a receptor for prekallikrein binding to endothelial cells (Schmaier, 1988; Motta, 1998). Factors VIIIa and Va function as coreceptors of factors IXa and Xa, respectively (Miletich, 1978; Ahmad, 2000). All three of these proteins serve as cofactors that accelerate the reactions in which they participate. For example, high molecular weight kininogen accelerates the activation of prekallikrein and FXI by FXIIa. Factors VIIIa and Va accelerate FX and prothrombin activation, respectively, by factors IXa and Xa. Each cofactor also functions as a substrate of one or more enzymes that participate in their formation and inactivation. High molecular weight kininogen accordingly is a substrate of FXIIa, plasma kallikrein, and FXIa. Factors VIII and V are substrates of thrombin, and factors VIIIa and Va of activated protein C. Fibrinogen is a substrate of thrombin.

FVIII (antihemophilic factor) is a 330-kDa protein. When activated to FVIIIa, it is a cofactor for FIXa in the activation of FX. Its absence is associated with the most severe clinically recognized bleeding disorder, hemophilia A. FV is also a 330-kDa protein with homology to FVIII. When activated to FVa, it serves as a cofactor for FXa in the activation of FII (prothrombin) to thrombin. Fibrinogen is a 330-kDa protein that not only is the main substrate of thrombin (FIIa) but is also the principal adhesive molecule subserving platelet aggregation. When it is proteolyzed by thrombin, a fibrin monomer is formed. This monomer associates end-to-end and side-to-side to form a fibrin clot. The clot is stabilized by activated FXIII, a tissue transglutaminase that cross-links the strands of associating fibrin (Fig. 39-2). TF (47-kDa protein) is an essential cofactor for activated FVIIa. It is found in most tissues and cells. Upregulation of TF results in the formation of complexes with FVII that produce the initiation of hemostatic reactions. Last, high molecular weight kininogen (HK, also known as Fitzgerald factor or Williams factor) is a 120-kDa protein that acts as a cofactor for the activation of FXII, prekallikrein, and FXI.

Physiologic Protein Assemblies

Certain critical protein assemblies in hemostatic reactions accelerate these proteolytic events. The proteins of the coagulation system that are essential for hemostasis or control of bleeding were originally identified by observation of affected patients, and more recently through mouse knockout studies. Deficiencies in coagulation factors VIII and IX are the most prominent bleeding disorders that occur in patients who survive gestation and birth. The rare patients who have apparent congenital deficiencies of coagulation factors VII, X, V, and II usually do not have severe bleeding states. In contrast, murine models have demonstrated that mouse embryos containing complete genetic knockouts of factor VII, X, V, or II die of massive hemorrhage during gestation or at birth (Cui, 1996; Rosen, 1997; Sun, 1998; Dewerchen, 2000). This information suggests that the human patient who has a deficiency of factor VII, X, V, or II may have some factor, albeit less than 1%, to allow for a milder clinical phenotype than that seen in mouse models, or, alternatively, other compensatory mechanisms may be operative in the human patient. All of these proteins participate in two critically important assemblies that are essential for normal hemostasis: **tenase** and **prothrombinase**.

The tenase complex comprises the assembly of FIXa and thrombin-activated FVIIIa on phospholipid surfaces or cell membranes in an ordered structure, with FX to accelerate its activation to FXa. When all of these components are present, the rate of FX activation by FIXa is increased 1.4×10^8 -fold over the rate of FX activation by FIXa alone. The prothrombinase complex in analogous fashion comprises the assembly of FXa and thrombin-activated FVa on phospholipid membranes or cell membranes in an ordered structure with FII (prothrombin) to accelerate its activation to FIIa (thrombin). When all of these components are present, the rate of FII activation by FXa is increased 1.7×10^8 -fold over the rate of FII activation by FXa alone. Because these coagulation reactions occupy critical regulatory points within the physiologic hemostatic system, they are also the target of a number of anticoagulant agents for venous thrombosis that are currently in use or are being developed.

Figure 39-2 Formation of a fibrin clot. **A**, Schematic of fibrinogen. **B**, Thrombin proteolyzes fibrinopeptides A and B from fibrinogen to leave soluble fibrin monomer. Soluble fibrin monomer then associates side-to-side (**C**) and end-to-end (not shown, for clarity) to form fibrin polymers. **D**, Thrombin-activated factor XIII (factor XIIIa) covalently cross-links the fibrin polymers into an increasingly complex structure and an ultimately insoluble clot (**E**). Note that “E” corresponds to the central domain of the original fibrinogen molecule, and “D” to the peripheral domains. (Modified with permission from Doolittle RF. *Fibrinogen and fibrin*. *Sci Am* 1981;245:126–35.)

THE FORMATION OF FIBRIN AND THE FIBRINOLYTIC SYSTEM

The six peptide chains of the fibrinogen molecule are organized into a structure described as having a central E domain and two terminal D domains. When thrombin is formed, it cleaves fibrinopeptide A from the A α chain and fibrinopeptide B from the B β chain of fibrinogen in the E domain region (Doolittle, 1981). The remainder of this thrombin-proteolyzed fibrinogen is called soluble fibrin monomer. Soluble fibrin monomers then assemble with end-to-end and side-to-side association to form a noncovalent fibrin polymer (see Fig. 39-2). Activated FXIII, a transglutaminase, cross-links fibrin monomeric subunits into an insoluble, cross-linked fibrin clot. When insoluble, cross-linked fibrin is made, a new linkage between the D domains of two adjacent fibrin monomers occurs, and in the process a neo-epitope of interaction is formed (see Fig. 39-2).

The fibrinolytic protein system consists of the zymogen plasminogen and its naturally occurring activators. Plasminogen is activated to the main clot-lysing enzyme, plasmin, by endogenous tissue plasminogen activator (tPA), single-chain urokinase plasminogen activator (ScuPA), and two-chain urokinase plasminogen activator (TcuPA). These activators are found in the endothelium as well as in granulocytes and monocytes. The natural plasminogen activators tPA, ScuPA, and TcuPA convert zymogen plasminogen to the active enzyme plasmin (Fig. 39-3). tPA is produced constitutively, and ScuPA is increased in inflammatory states. Plasminogen activator inhibitor-1 (PAI-1) is the major inhibitor of tPA and TcuPA. α_2 -Antiplasmin, a serine protease inhibitor (serpin), is the major inhibitor of formed plasmin. However, the plasma concentration of α_2 -antiplasmin is only about half the plasma concentration of plasminogen.

Following its activation from plasminogen, the active plasmin molecule recognizes multiple substrates. Plasmin will degrade soluble fibrinogen to produce fibrinogen degradation products (Fig. 39-4, A). Plasmin cleaves fibrinogen into an X fragment of similar molecular mass by eliminating portions of the α -chain (Marder, 1974). Plasmin then cleaves the X fragment asymmetrically between the D and E domains to produce fragment

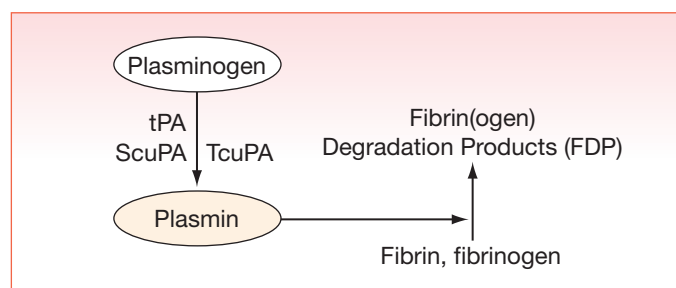

Figure 39-3 Fibrinolysis. Zymogen plasminogen is converted to plasmin by tissue plasminogen activator (tPA), single-chain urokinase plasminogen activator (ScuPA), and two-chain urokinase plasminogen activator (TcuPA). Formed plasmin degrades fibrinogen or fibrin to form fibrinogen or fibrin degradation products, respectively.

Y. Plasmin further degrades the Y fragment to produce soluble D and E domains that are called soluble fibrinogen degradation products or, in the case of fibrin digestion by plasmin, fibrin degradation products. Their presence indicates that plasmin has been formed. Plasmin will also degrade insoluble, cross-linked fibrin (Fig. 39-4, B). When it does so, it liberates a D–D-dimer domain formed as result of the neo-epitope between these two domains (see Fig. 39-4, B) (Marder, 1976). The presence of soluble D-dimer indicates that first thrombin has been formed, then clotting has occurred, then the clot has been cross-linked by FXIIIa, and, finally, plasmin has been formed and has cleaved the insoluble, cross-linked fibrin clot.

THE ANTICOAGULATION PROTEIN SYSTEMS (Fig. 39-5)

Three major anticoagulant systems regulate the enzymes of the coagulation protein system to help to inhibit clot formation. These systems are

Figure 39-4 **Panel A**, Plasmin-cleaved soluble fibrinogen or fibrin. When plasmin cleaves fibrinogen, initially small portions from the α -chain (α C) are removed to make Fragment X. Fragment X is then asymmetrically cleaved into Fragment D and Fragment Y. Fragment 5Y is further cleaved by plasmin into Fragments D and E. (Modified with permission from Greenberg CS, Lai T-S. Fibrin formation and stabilization. In: Loscalzo J, Schafer AI, editors. *Thrombosis and hemorrhage*. 3rd ed. Philadelphia: Lippincott, Williams & Wilkins; 2003, p. 83, Fig. 5-3, B.) **Panel B**, Plasmin-cleaved insoluble, cross-linked fibrin. When insoluble, cross-linked fibrin is proteolyzed by plasmin, the neo-epitope between the D-domains is preserved, and the liberated fragment consists of the D-dimer together with an E domain. (Modified with permission from Doolittle RF. *Fibrinogen and fibrin*. *Sci Am* 1981;245:126–35.)

the protein C/protein S system, the plasma serine protease inhibitor system, and TFPI, a Kunitz-type serine protease inhibitor. Antithrombin (antithrombin III) is the main serine protease inhibitor of coagulation enzymes of the plasma serine protease inhibitor system. Each of these systems plays a critical role in proper regulation of the coagulation system. Moreover, in murine deletion models, complete deficiencies of protein C, protein S, antithrombin, and TFPI are incompatible with survival of mammalian gestation, delivery, or life ex utero (Huang, 1997; Jalbert, 1998; Hayashi, 2006; Burstyn-Cohen, 2009).

Protein C/Protein S System

When activated, protein C, a 62-kDa vitamin K-dependent protein, is an enzyme that functions as an inhibitor. Protein C is activated by thrombin when bound to an endothelial cell protein called thrombomodulin. Thrombomodulin forms a trimolecular complex with protein C and thrombin. Activated protein C inactivates factors Va and VIIIa to decrease the rate of thrombin formation. Protein S, a 69-kDa vitamin K-dependent protein, is not an enzyme. It is a cofactor, or receptor, for activated protein C on cell membranes. It allows activated protein C to bind to cell surfaces in such a manner as to orient itself to inactivate factors Va and VIIIa. The enzyme uses this cofactor as a receptor to localize its activity to perform its inhibitory function. Plasma protein S is in equilibrium between the free

form and a bound form that is complexed to C4b-binding protein; only the free form functions as a cofactor for activated protein C. Activated protein C also binds to three receptors on endothelial cells: (1) endothelial cell protein C receptor to activate (2) protease-activated receptor (PAR)1 and (3) apolipoprotein E receptor 2 (ApoER2) (Esmon, 1999; Coughlin, 2000; Yang, 2009). Activation of PAR1 on endothelial cells may contribute to the anticoagulant function of activated protein C by liberating tPA. Activated protein C on endothelial cells also has an inflammatory effect via activation of sphingosine-1-phosphate receptor transactivation and activation of ApoER2 (Finigan, 2005; Yang, 2009). Thus activated protein C reduces thrombin formation, stimulates fibrinolysis, and initiates inflammation to reduce thrombosis risk.

Antithrombin

This serpin is a 58-kDa protein that inhibits each of the following hemostatic enzymes: IIa, Xa, VIIa, IXa, XIa, kallikrein, and XIIa. It exerts its anticoagulant effect primarily by inhibiting factors IIa and Xa (see Fig. 39-5). The ability of antithrombin to function as an inhibitor of coagulation protein enzymes is potentiated by heparin. In fact, it is the presence of antithrombin that gives heparin its anticoagulant properties. In the presence of heparin, antithrombin is 1000-fold more effective as an inhibitor of factor IIa. In addition to antithrombin, other serpins regulate the

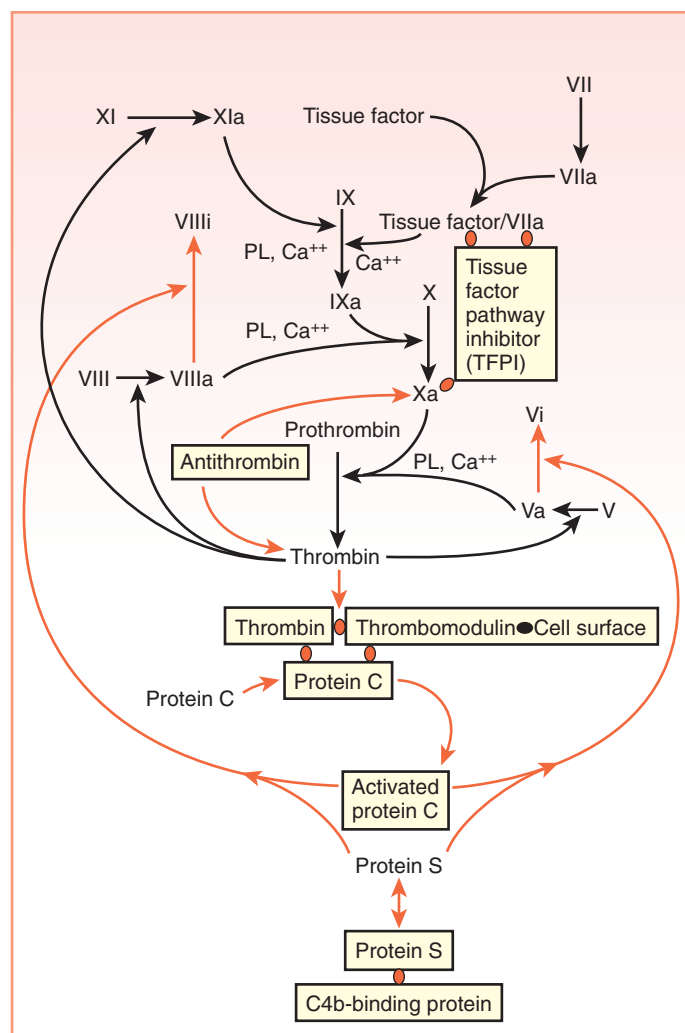

Figure 39-5 Natural inhibitors of coagulation: antithrombin (AT); components of the protein C pathway (thrombomodulin, protein C, protein S); and tissue factor pathway inhibitor (TFPI). Three major anticoagulant systems are recognized. Antithrombin inhibits factor Xa and thrombin to prevent thrombosis. It is important to note that antithrombin inhibits every enzymatic form of blood coagulation serine proteases (factor XIIa, plasma kallikrein, factor XIa, factor IXa, and factor VIIa), even though this is not indicated in the figure for readability purposes. The protein C system requires that this zymogen is activated to activated protein C by thrombin when bound to the endothelial cell membrane protein thrombomodulin. Protein S is a cofactor for activated protein C to inactivate factors Va and VIIIa. C4b binding protein regulates protein S activity. TFPI makes a quaternary complex with tissue factor/factor VIIa and factor Xa to inhibit both enzymes.

enzymes of the hemostatic and inflammatory systems. Heparin cofactor II is a serpin that specifically inhibits thrombin in the presence of dermatan sulfate. Protein Z inhibitor is a serpin that specifically inhibits factor Xa in the presence of its cofactor protein Z—a vitamin K-dependent protein. C1 inhibitor (C1 esterase inhibitor) is the most potent inhibitor of FXIIa, kallikrein, and FXIa in plasma. Its main function is to regulate the amount of free bradykinin in the intravascular compartment and reduce inflammatory events (Han, 2002; Schmaier, 2002; Maas, 2008).

Tissue Factor Pathway Inhibitor

In addition to the serpins, there is the Kunitz-type serine protease inhibitor, TFPI (Crawley, 2008). TFPI is the most potent inhibitor of the FVIIa-tissue factor complex. Under physiologic conditions, TFPI exerts its inhibitory effects by forming a quaternary complex with FVIIa, TF, and FXa (see Fig. 39-5). It is noteworthy that the murine TFPI knockout is embryonically lethal (Jalbert, 1998). Another family of Kunitz-type serine protease inhibitors, the amyloid β -protein precursor (A β PP) and related members, is present in platelets and brain and regulates factors XIa, IXa, Xa, VIIa/TF, and plasmin (Van Nostrand, 1990; Schmaier, 1993, 1995; Mahdi, 1995, 2000). This inhibitor does not inhibit thrombin. The exact function of this inhibitor is not completely known, but it is believed to be a cerebral anticoagulant (Del Zoppo, 2009). A β PP and amyloid

precursor-like/protein 2 gene-deleted mice survive gestation but have an accelerated rate of thrombosis in a carotid artery thrombosis model (Xu, 2009).

CURRENT HYPOTHESIS FOR INITIATION OF THE HEMOSTATIC SYSTEM

More proteins participate in coagulation reactions in vitro than are critical for hemostatic reactions in vivo. The original coagulation cascade waterfall hypothesis initiated by FXII has been replaced by one whereby TF and FVIIa are initiators (Gailiani, 1991). TF is ubiquitous throughout the body, although it is rich in brain, lung, and placenta. Its expression is upregulated after injury. Regulation of the expression of TF is a major control mechanism for the initiation of hemostasis. Some investigators believe that a circulating form of TF is also present. The FVIIa-TF complex activates FIX, leading in turn to FX activation. It must be noted that at the concentrations of factors ordinarily present in the body, VIIa/TF does not directly activate appreciable amounts of FX because of the presence of TFPI—a point emphasized diagrammatically in Figure 39-1 by the graying of this reaction. Once FX has been activated to FXa, this Xa in turn contributes to the activation of thrombin from prothrombin. Thrombin then proteolyzes fibrinogen to form fibrin. Although TF-dependent coagulation reactions are rapidly inhibited by TFPI, if the stimulus for thrombin formation is sufficiently strong, coagulation is maintained through the activation of FXI by thrombin (Meijers, 2000). Activation of FXI to FXIa results in increased activation of FIX and eventually increased formation of thrombin. Further modulation of hemostatic balance in the direction of clot formation is exerted by TAFI, the thrombin-activatable fibrinolysis inhibitor (also known as carboxypeptidase U). Among its actions, TAFI cleaves C-terminal lysine residues from fibrin, thereby decreasing the binding of plasminogen to the clot and diminishing clot lysis (Leurs, 2005).

CLINICAL LABORATORY HEMOSTASIS

When faced with a bleeding patient, one must use an analytic diagnostic approach to determine the cause of the problem. The underlying cause in almost all cases will derive from a defect or deficiency in a plasma protein, a defect in platelet number or function, or a defect in adhesive interactions between platelets and the vessel wall.

Any coagulation protein defect can be a true protein deficiency, an inhibitor to the active site of the protein, an abnormal protein that cannot participate in its physiologic function(s), or an apparent deficiency that arises as the result of enhanced clearance of protein. In general, inhibitors to a coagulation protein are immunoglobulins, although hypergammaglobulinemic states or abnormal production of endogenous heparin, fibronectin, or cryoglobulins as acquired inhibitors to coagulation proteins have also been reported. Abnormal proteins that are present but do not function normally occur as a result of missense or deletion mutations, or translocations of DNA. Last, enhanced clearance of coagulation proteins usually occurs as a result of antigen-antibody complex formation. Resultant increased clearance of the protein gives the appearance of a deficiency, but the real mechanism is enhanced clearance.

Typical clinical presentations of bleeding disorders are shown in Table 39-2. In general, hemarthrosis and spontaneous soft tissue and intramuscular hemorrhage characterize plasma protein defects such as hemophilia A and B (factors VIII and IX deficiency). Soft tissue petechiae, purpura, or ecchymosis characterizes von Willebrand disease, or disorders of platelet number or function. However, at times, it is difficult to distinguish the potential mechanism for bleeding. Thus the clinical laboratory is essential for definitive diagnosis of a bleeding disorder in the patient.

PHYSIOLOGIC HEMOSTASIS VERSUS CLINICAL ASSAYS

In the practice of clinical hemostasis, a dichotomy is seen between physiologic hemostasis and assays used in the clinical laboratory to recognize coagulation protein defects. As indicated previously in Figure 39-1, physiologic hemostasis is initiated by an increase in the formation of TF-FVIIa complexes. At present, no good assays are available in the clinical laboratory to assess this early event specifically. Instead, the relatively late event of actual clot formation is monitored. The two assays most commonly used to examine the coagulation system are (1) the APTT induced by surface

TABLE 39-2
Patterns of Clinical Bleeding in Disorders of Hemostasis

Characteristics	Primary hemostasis (platelet/vascular problem)	Secondary hemostasis (coagulation factor problem)
Onset	Spontaneous, immediate after trauma	Delayed after trauma
Sites	Skin, mucous membranes	Deep tissues
Form	Petechiae, ecchymosis	Hematomas
Mucous membrane	Common (nasal, oral, gastrointestinal, genitourinary)	Less common
Other sites	Rare	Joint, muscle, central nervous system, retroperitoneal space
Clinical examples	Thrombocytopenia, platelet defects, von Willebrand disease, scurvy	Factor deficiency, liver disease, acquired inhibitors

(contact) activation of the system, and (2) the prothrombin time (PT) induced by the addition of excess tissue factor. Contact activation of the coagulation system occurs because FXII in the presence of artificial, negatively charged particles in the reagent autoactivates to FXIIa, which in turn initiates the cascade of proteolytic reactions of the coagulation system. As is discussed later, this test measures more proteins than those necessary for hemostasis. With the PT test, the addition of excess TF creates a very unphysiologic change in the normal stoichiometric relationships of factors, thereby allowing FVIIa to overcome the inhibitory effect of TFPI and favoring direct activation of FX to FXa. Both assays are extremely useful for assessing the integrity of the blood coagulation system and for recognizing potential bleeding problems in a patient (see later).

SCREENING TESTS FOR COAGULATION DISORDERS

When a patient with a bleeding problem is addressed in the clinical laboratory, several screening tests are used to classify and diagnose the basis of this disorder. The term **primary hemostasis** refers to platelet reactivity at the site of vessel injury; this topic is covered in Chapter 40. The platelet count is an example of a screening assay for primary hemostasis. This section describes assays for what has been called **secondary hemostasis**, that is, the coagulation of plasma. However, more recent studies employing animal model systems suggest the need for caution in accepting this distinction too literally, for example, in vivo visualization studies of arterial thrombus formation in at least some models suggest that platelet accumulation and fibrin generation may actually occur simultaneously (Falati, 2002; Furie, 2009). Regardless of the true order of events occurring in vivo, however, when performed simultaneously on a sample of plasma, these coagulation assays identify almost all of the diagnostic categories for a coagulopathy. The 50-year-old cascade hypothesis for hemostasis still has merit in explaining the mechanism(s) for clot formation seen in the screening tests for coagulation reactions. In this hypothesis, coagulation proteins are classified as members of the so-called **intrinsic system**, **extrinsic system**, or **common pathway** (Fig. 39-6). This approach allows for a practical differential diagnosis of which protein(s) may be affected, based on the results of a series of screening tests. The specific coagulation factors involved in each test are shown schematically in Figure 39-6. Methodologic aspects of these tests (Fig. 39-7) are discussed in the following paragraphs.

Activated Partial Thromboplastin Time

(Fig. 39-7, A)

To perform this common coagulation assay, a mixture of a negatively charged surface, phospholipid, and anticoagulated patient plasma is incubated for several minutes. The recommended anticoagulant is 3.2 g% sodium citrate because less variation is seen in blood specimens from normal patients and those on anticoagulants collected in this concentration of anticoagulant (Adcock, 1997, 1998). Sodium citrate is a reversible chelator of calcium that prevents coagulation protein activation. When whole blood is collected, the ratio of anticoagulant to whole blood is 1 part

Figure 39-6 Organization of the coagulation system based on current assays. The **intrinsic** coagulation system consists of the proteins factors XII, XI, IX, and VIII and prekallikrein (PK) and high molecular weight kininogen (HK). The **extrinsic** coagulation system consists of tissue factor (tissue thromboplastin) and factor VII. The **common pathway** of the coagulation system consists of factors X, V, and II, and fibrinogen (I).

anticoagulant to 9 parts whole blood. After incubation of patient plasma with reagent for a prescribed time, depending on the assay, the sample is recalcified with excess calcium chloride, and the time required for clot formation is measured. The APTT assesses the coagulation proteins of the so-called intrinsic system and common pathways (see later). This assay is commonly referred to as the partial thromboplastin time (PTT), but it is really an “activated” PTT, in that its reagents contain a negatively charged surface that accelerates the rate of the reaction (Proctor, 1961).

Prothrombin Time (Fig. 39-7, B)

To perform this common coagulation assay, tissue thromboplastin (recombinant human or isolated animal tissue factor) and patient plasma are incubated for several minutes, after which the citrated plasma mixture is recalcified by the addition of excess CaCl_2 , and the time required for clot formation is measured. The PT assesses the coagulation proteins of the so-called extrinsic system and common pathway (see later) (Quick, 1935). Tissue thromboplastin traditionally has been a crude preparation of animal brain TF. Presently, recombinant TF is used in the preparation of several commercial PT reagents. In general, the range of prolongation of time of an abnormal PT increases when recombinant TF is used. This fact makes for a more sensitive assay. The PT serves as the basis for the international normalized ratio (INR) value used to monitor patients on warfarin. As discussed in Chapter 42, the INR is the ratio of patient PT divided by geometric mean normal PT for the local laboratory (based on a population of normal individuals assessed with identical sample collection, reagents, and machines), raised to the power of the international sensitivity index. Although the INR is clearly the most appropriate measure to use in conjunction with oral anticoagulant monitoring, for hemostatic evaluation of the nonwarfarinized patient, actual PT values in seconds may be used, referencing the laboratory’s locally established reference interval for the PT test.

Thrombin Time (Fig. 39-7, C)

To perform the thrombin time (also referred to as thrombin clotting time), purified exogenous thrombin is added to plasma to determine the time to clot formation. It is a direct measure of fibrinogen function and may be used to ascertain if there is a defect in fibrinogen function. The thrombin time will be prolonged in hypofibrinogenemic states, if an abnormal

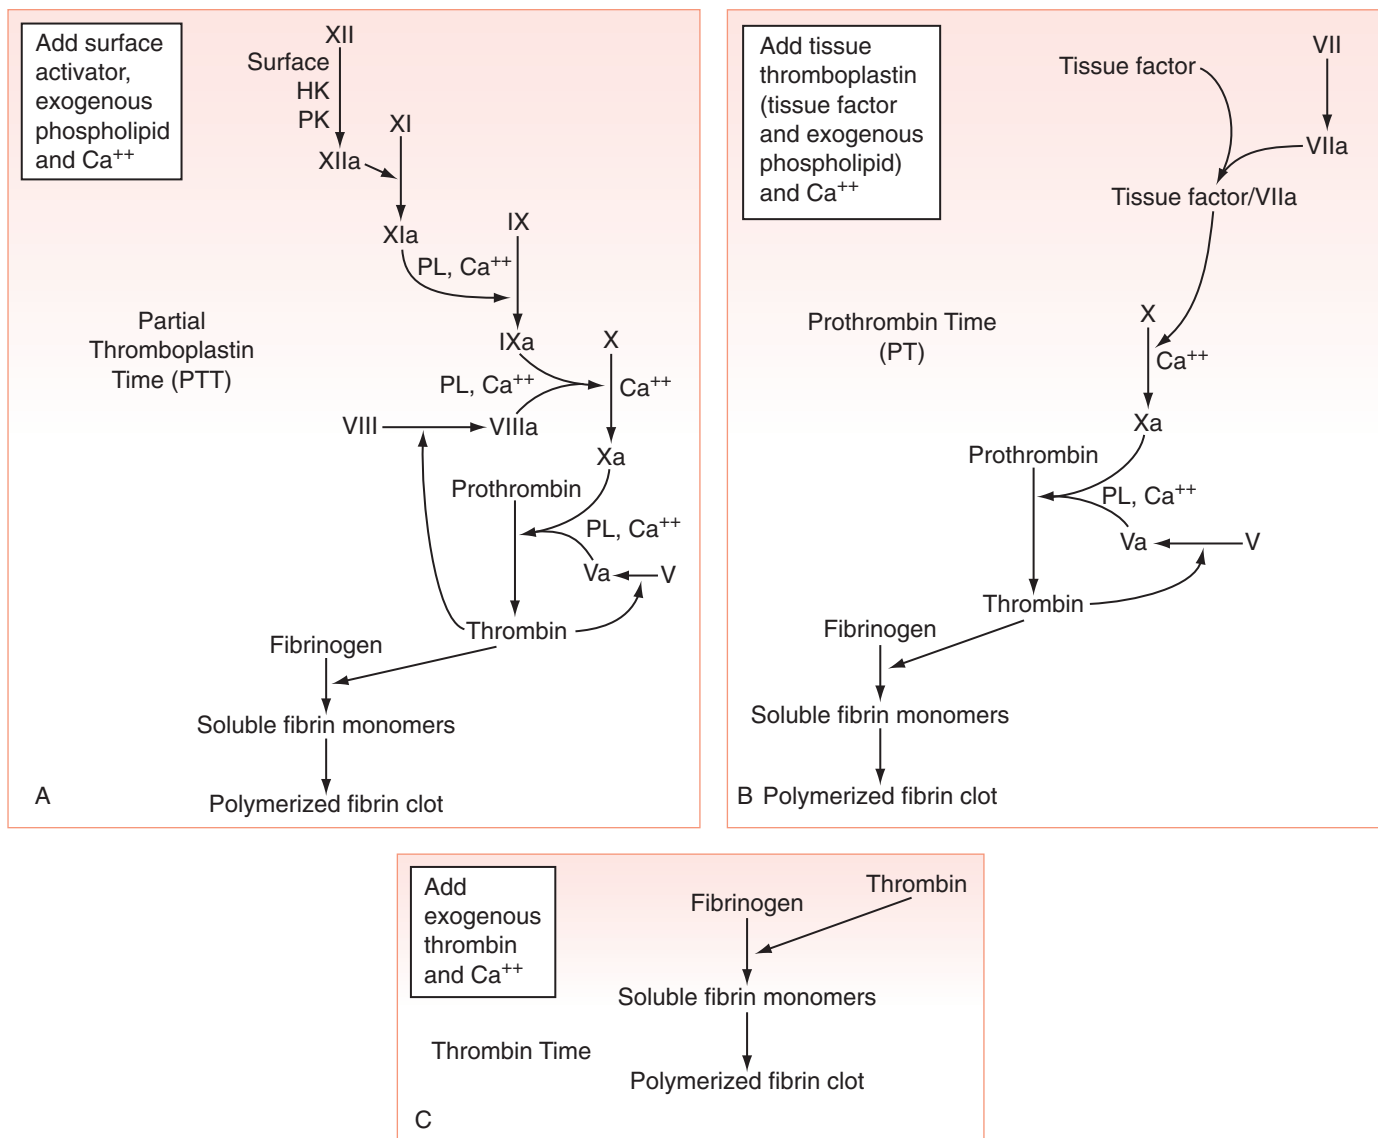

Figure 39-7 Coagulation screening tests. **Panel A**, Activated partial thromboplastin time (APTT, "PTT" on the figure) requires the presence of every protein except tissue factor and factor VII. **Panel B**, Prothrombin time (PT) requires tissue factor and factors VII, X, V, and II and fibrinogen. **Panel C**, In the thrombin time (or thrombin clotting time), exogenous thrombin is added to plasma to proteolyze (clot) fibrinogen. The endpoint in each of these tests is the number of seconds until detection of a clot, following addition of the indicated reagents to citrated platelet-free patient plasma. Because virtually all measuring systems employed detect the formation of a polymerized fibrin clot, whether or not any cross-linking of fibrin occurs, none of these tests will provide information with respect to factor XIIIa activity.

protein fibrinogen (dysfibrinogenemia) is present, or if a thrombin inhibitor is present.

ASSAYS USED IN CLINICAL COAGULATION TESTING

Clinical coagulation testing is based on functional assays that examine the rate of clot formation. In these assays, a sequence of proteolytic reactions takes place, leading to thrombin formation and its proteolysis of fibrinogen (Mann, 2003). Proteolysis of fibrinogen results in clot formation, precipitation of soluble proteins, which is detected by increased impedance or turbidity, or decreased optical clarity, based on the instrumentation used to measure the result. Any defect along the pathway to clot formation will give an abnormal final result. Furthermore, because a series of reactions need to take place for final clot formation to occur, any defect below a specific factor will lead to an abnormal result in measuring that factor. For example, a high-titer inhibitor of FVIII will produce an abnormal FXI assay. Similarly, deficient or abnormal fibrinogen will affect the results of all clotting tests.

All coagulation factors of the intrinsic system (XII, prekallikrein, high molecular weight kininogen, XI, IX, and VIII) are measured in assays using the APTT as its platform. These specific factor assays became readily available because of the recognition of patients and the commercial

availability of specific factor-deficient plasmas that serve as substrate for them. For example, a FVIII assay is a mixture of APTT reagent, FVIII-deficient plasma, and test (unknown) plasma from the patient (Landell, 1953). After incubation for a few minutes, the time to clot is initiated by the addition of calcium chloride. FVII, together with coagulation factors of the common pathway (X, V, and II), is usually measured by assays using the PT as the platform. For example, an FX assay is a mixture of PT reagent that contains TF (thromboplastin), FX-deficient plasma, and test or patient (unknown) plasma. After incubation for a few minutes, time to clot is initiated by the addition of calcium chloride. The amount of factor present in a given patient sample is determined by comparing the patient sample against a standard curve made with plasma samples containing varying amounts of the specific factor to be assayed mixed with factor-deficient plasma, as well as the appropriate APTT or PT reagent for the assay.

Coagulation-based assays are sensitive and specific. They are much simpler to perform than antigen assays for each of the coagulation proteins. These assays provide information on the functional presence of the coagulation protein. Additional coagulant-based assays such as thrombin time (see earlier) and reptilase time (see later) specifically examine the integrity of fibrinogen to liberate its fibrinopeptides, resulting in fibrin clot formation. When establishing a clinically useful thrombin time, it is important to reduce the thrombin concentration to about 1–2 NIH U/mL (≈ 8 –16 nM human α -thrombin at 3000 U/mg specific activity), so that the time of a normal assay is about 20 seconds. Such an assay will allow for

reproducibility and sufficient sensitivity to detect subtle protein abnormalities. Coagulation-based assays examine the function of the protein; antigen assays establish the presence of the proteins; combined, the two assays characterize any protein with reduced function but with normal antigen. A dysfunctional protein has reduced protein function with normal levels of antigen. Such a situation arises commonly when fibrinogen is examined. The most useful means to determine whether fibrinogen is abnormal (i.e., dysfibrinogenemia) is to measure clottable fibrinogen and fibrinogen antigen. If fibrinogen clottability is less than 90% of the amount of fibrinogen antigen present, this finding would suggest that the protein produced is abnormal in some way.

Chromogenic assays are used to measure certain enzymes (plasmin, activated protein C) and various plasma protease inhibitors (antithrombin, C1 inhibitor, α_2 -antiplasmin, PAI, tPA). Neutralizing the enzymatic activity of FXa or thrombin is a useful way to assay for the level of anticoagulants that inhibit FXa or thrombin (see Chapter 42). Presently, such assays are used to measure the therapeutic levels of unfractionated heparin, low molecular weight heparin, or fondaparinux. An assay for any future parenteral or oral FXa or thrombin inhibitor can be developed by using the agent's ability to neutralize its enzymatic activity. Last, a direct chromogenic assay for FXa has been useful in assessing the degree of anticoagulation for the occasional patient on warfarin who has a lupus anticoagulant (see Chapter 41) of sufficient potency to interfere not only with the APTT, but with the PT as well.

PRACTICAL APPROACH TO PATIENTS WITH COAGULATION DISORDERS

Using the coagulation cascade hypothesis and its grouping of proteins of the coagulation system, screening tests for coagulation proteins can identify various deficiencies or abnormalities among coagulation proteins (Table 39-3; see Fig. 39-6).

With the APTT, FXII autoactivation on an artificial, negatively charged surface initiates the sequence of reactions of the coagulation cascade. The APTT (labeled "PTT" in the figure) measures proteins of the intrinsic coagulation system (FXII, prekallikrein, high molecular weight kininogen, FXI, FIX, and FVIII) and proteins of the common pathway (factors X, V, II, and fibrinogen) (see Fig. 39-7, A). It is important to realize that a coagulation factor has to be decreased to different levels before screening assays are sensitive and show an abnormality. For example, most commercial APTT reagents will detect a decrease in FVIII when the level of the protein is down to 35%–45% of normal (i.e., 0.35–0.45 U/mL). In contrast, FXII and high molecular weight kininogen at a level of 10%–15% may not prolong an otherwise normal APTT. When evaluating new lots of coagulation reagents, it is important to determine their level of sensitivity to detect coagulation protein deficiencies. Additionally, very high levels of FVIII can mask a defect in other coagulation factors. High levels of FVIII can also mask a low protein C level in a clot-based activated protein C assay.

The PT measures the extrinsic coagulation pathway of coagulation, which consists of activated FVII (FVIIa) and TF and proteins of the common pathway (factors X, V, II, and fibrinogen) (see Fig. 39-7, B). FVII levels below 35%–40% will begin to be detected by prolongation of the PT. The thrombin time measures only the ability of exogenous thrombin to proteolyze (clot) fibrinogen (see Fig. 39-7, C). It is used to characterize fibrinogen function.

With knowledge of what each test measures, the following approach can be used to evaluate bleeding risk among patients who have one or more

of these assays prolonged (see Table 39-3 and Fig. 39-6). For example, if a patient has an isolated prolonged APTT, determination of the patient's risk to bleed can begin with the addition of some historical information. If isolated prolongation of the APTT in a male patient is associated with bleeding, then the differential diagnosis in decreasing likelihood of frequency is FVIII, FIX, or FXI deficiency. These disorders will be discussed in the next section. If the APTT alone is prolonged and there is no history of bleeding, the most common cause is a lupus anticoagulant. The specific proteins of the so-called intrinsic coagulation system associated with a prolonged APTT but no bleeding history include, in decreasing frequency, FXII, prekallikrein, and high molecular weight kininogen. Knowing about these latter three proteins is essential in evaluating a prolonged APTT even though the patient is not at bleeding risk, so that patients neither get unnecessary plasma replacement therapy nor experience unnecessary delays in scheduled surgical procedures.

Alternatively, if the patient has an isolated PT prolongation that is associated with bleeding, this finding usually indicates partial FVII deficiency. Of note, FVII Padua (a substitution of glutamine for arginine at residue 304) renders the human FVII molecule less activatable in the presence of some nonhuman forms of TF (Girolami, 1979; Pollak, 2006). Individuals who may not even have a true bleeding disorder typically come to attention owing to a long PT performed with nonhuman TF. FVII assayed using this same source of TF may also appear to be decreased. Repeat assays employing recombinant human TF should provide more normal results for these tests. At times, defects in some common pathway proteins (fibrinogen, factors II, V, and X) may first produce an isolated PT prolongation, although, if severe, these latter protein defects will lead to prolongations of the PT and APTT. This arises because when a sensitive TF is used in the assay, a subtle abnormality in the common pathway proteins is first observed in PT-based assays. Usually, however, defects in the common pathway proteins (fibrinogen, factors II, V, X) result in prolonged PT and APTT. When confronted with patient laboratory results of prolonged PT and APTT, it is important not simply to consider the specific proteins mentioned earlier but also to address the differential diagnosis from general medical states such as anticoagulation therapy, disseminated intravascular coagulation, liver disease, vitamin K deficiency, and massive transfusion. Each of these entities will be described later in the section on acquired bleeding disorders.

A few rare bleeding disorders will not be recognized on routine blood coagulation and platelet screening tests. In order of frequency, these entities include FXIII defects, α_2 -antiplasmin defects, PAI-1 defects, and α_1 -antitrypsin_{PITTSBURGH} (Aoki, 1980; Owen, 1983; Fay, 1992; Anwar, 1999; Hua, 2009). FXIII deficiency will be discussed below. α_2 -Antiplasmin defects and PAI-1 defects, both congenital and acquired (see later), produce hyperfibrinolytic states as a result of reduced inhibition of plasmin, tPA, or urokinase. α_1 -Antitrypsin_{PITTSBURGH} is a rare entity and is a bleeding disorder that may result from a mutation in antitrypsin that leads to potent thrombin inhibition, thereby preventing any clot from forming.

When presented with a prolonged coagulation assay, the differential diagnosis is often between a true deficiency and inhibition of a specific coagulation protein. Two approaches can be used to obtain a specific diagnosis. In the first approach, the specific defect of a prolonged coagulation assay can be identified by performing all relevant coagulation factor assays. If any one test is decreased, then a specific coagulation factor inhibitor assay can be performed for that factor. One general approach to a specific inhibitor study can be employed by mixing various ratios of patient plasma to normal plasma (e.g., 1:1, 2:1, 4:1, 1:2, 1:4), incubating the samples for 2 hours at 37° C, and assaying the level of the specific factor in the mixture. Simultaneously, patient plasma and normal plasma used in the mixing study are also incubated under the same conditions. At the time of assay, the percentages of activity of the specific factor under study in normal plasma, patient plasma, and each of the mixtures are obtained. If the observed value at any given ratio of patient plasma to control plasma is less than the calculated expected value of mixing the two plasmas at various ratios (e.g., 1:1, 2:1, 1:2), then one can conclude that an inhibitor is present in patient plasma that transfers to the normal plasma sample. For example, if 100% activity (1 U/mL) of the factor being studied is observed in an undiluted sample, then a 1:1 dilution of normal plasma with factor-deficient plasma should yield a level of about 50% activity. If the same normal plasma was incubated with patient plasma at a 1:1 ratio, and the value came back as 32% activity, one should conclude that there is something in patient plasma that transfers and inhibits the factor's activity in normal plasma (i.e., the definition of an inhibitor). This approach serves as a general, nonquantitative method of assessing a coagulation factor inhibitor. In the section on hereditary coagulation protein defects

TABLE 39-3

Differential Diagnosis of Abnormal Coagulation Screening Tests

Abnormal Activated Partial Thromboplastin Time (APTT) Alone

Associated with bleeding: VIII, IX, and XI defects

Not associated with bleeding: XII, prekallikrein (PK), high molecular weight kininogen, lupus anticoagulants

Abnormal Prothrombin Time (PT) Alone

Factor VII defects

Combined Abnormal APTT and PT

Medical conditions: Anticoagulants, disseminated intravascular coagulation (DIC), liver disease, vitamin K deficiency, massive transfusion

Rarely dysfibrinogenemia; factor X, V, and II defects

(later), a specifically quantitative method for determining inhibitors to FVIII will be presented; this approach is applicable to any factor that is measured by coagulant assay.

A second way to approach the problem of determining a specific coagulation factor defect is to begin with a mixing test of patient and normal plasma. Mixing studies based on the PT or APTT are interpreted with knowledge of the fact that a 50% level of any coagulation factor alone gives normal PT and APTT values. The reason that 50% of any coagulation factor will have normal PT and APTT values is that both of these screening assays have hyperbolic sensitivity curves (i.e., a decrease in any one factor does not lead to linear prolongation of either of these two assays). Only with values well below 50% will the PT and APTT start to be prolonged. As indicated earlier, the sensitivity of the PT and APTT to prolongation with lowering of clotting factors varies as to the factor and the reagent made by the manufacturer. Thus, if patient plasma is mixed 1:1 with normal plasma, the PT or APTT should be normal if no inhibitory factor was present in the patient plasma. If, however, the mixture does not correct to within normal values, one can consider that something in patient plasma interferes with function of the protein in normal plasma.

How one does screening assays for inhibitors has been somewhat subjective for individual laboratories; this is the main problem when a screening inhibitor assay is used as the first step in patient disease diagnosis. Almost no studies have provided evidence-based laboratory medicine on how to proceed with inhibitor screening studies. Some approaches to the use of mixing studies have been developed for testing for lupus anticoagulants, which has its own peculiar aspects (Brandt, 1995a, b). Critical issues in performing mixing studies include the ratio of patient plasma to normal plasma (1:1–4:1), the time of incubation from mixing to assay (immediate–2 hours), and the assays to be used to measure the result (PT, APTT). One investigation aimed to examine the sensitivity and specificity of mixing studies in assessing factor deficiencies and anticoagulants (Chang, 2002). In this study, patient plasma and normal plasma were incubated at 37° C for 1 hour before assay at a ratio of 1:1 or 4:1 (patient:normal). With an APTT mix of 1:1 and a percent correction of 70%–75% calculated by a specific formula (see reference for formula), the sensitivity/specificity for recognizing a factor deficiency or anticoagulant was 100%/33% or 33%/100%, respectively. When the percent correction was 50%, calculated from a ratio of 4:1 (patient:normal) in the plasma mix for APTT, the sensitivity/specificity in recognizing a factor deficiency or anticoagulant improved to 88%/100% or 100%/88%, respectively (Chang, 2002). Similarly, on a PT mix of 1:1 with a percentage correction of 70%–75% calculated by a specific formula (see reference for formula), the sensitivity/specificity in recognizing a factor deficiency or anticoagulant was 95%/50% or 50%/95%, respectively. When the percentage correction was greater than 40%, as calculated from a ratio of 4:1 (patient:normal) in the plasma mix for PT, the sensitivity/specificity for recognizing a factor deficiency or anticoagulant improved to 96%/100% or 100%/96%, respectively (Chang, 2002). Additional studies showed that the assay after an immediate mix versus 1-hour incubation at 37° C had lower sensitivity and specificity.

Multiple factor deficiencies, such as those seen when a patient is on warfarin, often do not correct, owing both to deficiencies in plasma levels of multiple proteins and to the production of abnormal coagulant molecules resulting from the carboxylation inhibition defect that proceed to function as inhibitors in coagulant-based assays. Once it is determined that an inhibitor is present, specific factor assays still need to be performed to isolate the specific protein toward which the inhibitor is directed. In general, most institutions start with a mixing study to diagnose a novel coagulation protein defect. Regardless of the diagnosis of a deficiency or inhibitor, all relevant factors that could be producing that defect need to be assessed. The alternative approach is to assay for all relevant factors initially to isolate the defect, and then to determine, if appropriate, whether an inhibitor is present. The latter approach usually speeds the time to patient diagnosis. If multiple factors are low, consideration should be given to the possibilities of factitious warfarin, heparin, myeloma proteins, hypodysfibrinogenemia, cryoglobulins, and so forth.

HEREDITARY COAGULATION PROTEIN DEFECTS

As described earlier, protein or factor deficiencies can be quantitative or qualitative. In quantitative disorders, the factor level determined by routine clot-based methods (functional activity assays) is similar to that obtained by immunologic (antigen) assays. In qualitative disorders, the functional assay result is decreased, but the antigen level is significantly higher or

normal, indicating the presence of a dysfunctional protein or an inhibitor to the function of that protein.

DEFICIENCY OF FACTOR VIII (HEMOPHILIA A) OR FACTOR IX (HEMOPHILIA B)

Hemophilia A (FVIII deficiency) is the most common severe congenital bleeding disorder that allows for normal gestation and delivery, affecting 1 in 5000–10,000 males. Hemophilia B (FIX deficiency, Christmas disease) is also a severe congenital bleeding disorder, affecting 1 in 25,000–30,000 males. The factor VIII and IX genes are both located on the X chromosome, with the result that hemophilia A and B are X-linked recessive disorders primarily affecting males. Females carrying a hemophilia mutation on one of their two X chromosomes are carriers. Hemophilia A can affect females when carriers have imbalanced Lyonization of the normal X chromosome or Turner's syndrome (XO), or when they are daughters of an affected male and a carrier female.

Bleeding manifestations of hemophilia A and B, which are coagulation factor problems, include hemarthrosis; soft tissue hematomas into muscles; easy bruising; excessive bleeding with surgery, trauma, dental extraction, and circumcision; bleeding in the gastrointestinal or genitourinary tract; epistaxis; poor wound healing; and, uncommonly, umbilical stump bleeding (see Table 39-2). Intracranial hemorrhage can occur, particularly following trauma. The severity of hemophilia is classified on the basis of plasma factor level (Table 39-4). Severe hemophilia presents with spontaneous bleeding two to four times per month and requires frequent treatment or prophylactic therapy with replacement factor products. At the other end of the spectrum, mild hemophilia presents with prolonged bleeding after trauma or major surgery, and patients rarely need intravenous factor replacement.

Hemophilia is suspected on the basis of bleeding symptoms or a family history of hemophilia. About one third of hemophilia A cases arise from spontaneous mutations. Laboratory evaluation of patients with such a bleeding history should include an APTT and PT. Diagnosis is confirmed by a FVIII or FIX assay. It is important to appreciate that two levels of the standard curve for FVIII coagulant activity assays need to be prepared to fully characterize patients with severe FVIII deficiency, because the curve is not linear at lower values. FVIII levels above 10% are evaluated with a standard curve that spans 10%–150% FVIII activity. Low FVIII levels are evaluated with a standard curve, e.g., that might range between 0.24% and 15% levels. The most common cause of severe hemophilia A is partial inversion of the FVIII gene up to and including intron 22, which accounts for up to 40%–45% of such patients (Naylor, 1992; Lakich, 1993). These inversions are due to homologous recombination between the region that includes the *F8A* gene in intron 22 and one of the two other homologous regions located more than 400kb 5' (telomeric) to the FVIII gene (Lakich, 1993; Kaufman, 2001). Several types of these inversions have been described (Kaufman, 2001). If the intron 22 inversion is not detected, definition of the responsible mutation is difficult because of the large size of the FVIII gene (approximately 186,000 bp long). In contrast, the FIX gene is one-fifth the size of the FVIII gene, and the mutations responsible for hemophilia B are easier to define by genetic analysis.

More diagnostic testing may be required for patients with mild to moderate deficiency of FVIII for whom a diagnosis of hemophilia A may be less apparent (e.g., a female patient with low FVIII and apparent

TABLE 39-4
Classification of Hemophilia A and B

	CLASSIFICATION		
	Severe	Moderate	Mild
Percentage of patients	50–70	10	30–40
Factor VIII or factor IX activity, %	<1	1–5	6–30
Pattern of bleeding episodes	≈2–4 per month approximately	≈4–6 per year approximately	Uncommon
Cause of bleeding	Spontaneous	Minor trauma	Major trauma Surgery

autosomal inheritance). In patients with von Willebrand disease, a secondary deficiency of FVIII may occur (see Chapter 40) because FVIII is normally bound to von Willebrand factor in the plasma (Weiss, 1977). Further, a unique von Willebrand factor abnormality has been described in which a missense mutation in von Willebrand factor impairs the capacity of von Willebrand factor to bind to and promote FVIII secretion into plasma. This abnormality, first described in a French patient from Normandy, has been named von Willebrand disease “Normandy,” or type 2N. It should be suspected in a patient with normal von Willebrand factor antigen and functional studies (see Chapter 40), but reduced FVIII levels, whose inheritance is autosomal recessive rather than sex-linked (Schneppenheimer, 1996).

FIX activity levels during childhood remain at about 75% of adult levels. A 25% increase in FIX expression begins at puberty in both sexes (Andrew, 1992). It has been assumed that this is a result of steroid hormone action. It is interesting to note that a rare form of FIX deficiency, hemophilia B Leyden, undergoes postpubertal phenotypic resolution. Patients with this condition present with hemophilia B in early childhood, with FIX activity ranging from less than 1%–13% of normal. Plasma levels rise to as high as 70% of normal after the onset of puberty with resolution of bleeding complications (Reitsma, 2001). Mutations in hemophilia B Leyden have been identified in the promoter region of the FIX gene, within which a consensus sequence for steroid receptor binding is located (Crossley, 1992).

Evaluation of Carriers

Detection of carriers is useful for prediction of symptoms and prenatal counseling. Carriers may have low enough FVIII or FIX levels to be symptomatic with easy bruising, menorrhagia, and hemorrhagic complications of surgery and trauma (Arun, 2001). In hemophilia A, if the mutation is known, the potential carrier may be tested for that mutation. Otherwise, the woman should be tested for the common intron 22 inversion. Detailed genetic analysis of the woman, the affected male, and intervening family members may define the mutation. These techniques provide an extremely high likelihood of detection of carriers when all family members are available for study. Otherwise, the woman's ratio of FVIII activity to the level of von Willebrand factor antigen may be used to predict carrier status. Abnormally decreased ratios have been reported to identify 91%–99% of hemophilia A carriers (Fishman, 1982; Graham, 1986; Green, 1986). Prenatal diagnosis of the hemophilias can be performed at a number of high-risk obstetric centers by chorionic villous sampling at 12 weeks' gestation or by amniocentesis after the 16th week. If the genetic basis of the disease is known within a family, then mutational analysis or examination for the intron 22 inversion can be performed on the cell samples (Ljung, 1999; Arun, 2001). Fetoscopic blood sampling can be performed at 20 weeks' gestation for coagulation factor analysis, although it carries a higher risk and is less precise. In hemophilia B, 30%–40% of carriers will be missed by measurement of FIX activity, and mutation analysis is important for defining carrier status (Graham, 1979; Ljung, 1999). Similar to hemophilia A, hemophilia B arises spontaneously in one third of patients.

Treatment of Hemophilia

Recombinant factor products are now the standard of care for treatment of hemophilia A and B in developed countries. Clotting factors are dosed on the basis of weight and desired plasma activity. Plasma with 100% clotting factor activity has 1 U/mL of that clotting factor. By convention, one unit of a coagulation factor is the amount of that factor present in 1 mL of normal pooled human plasma. Each unit of recombinant FVIII/kg raises the plasma FVIII activity by about 2%, and each unit of recombinant FIX/kg raises the plasma FIX activity by about 1%. To raise the FVIII plasma activity of a 70-kg man by 100%, the calculated dose will be as follows:

$$\begin{aligned} &\text{Body weight (kg)} \times 0.5 \text{ international units/kg} \\ &\quad \times \text{FVIII activity increase desired (\%)} = \text{Dose required, or} \\ &(70 \text{ kg}) (0.5) (100) = 3500 \text{ units to be infused.} \end{aligned}$$

The plasma half-life of FVIII is about 12 hours. To raise the FIX plasma activity of a 70-kg man by 100%, the calculated dose will be as follows:

$$\begin{aligned} &\text{Body weight (kg)} \times \text{desired FIX increase (\%)} \\ &\quad \times 1 \text{ international unit/kg} = \text{Dose required, or} \\ &(70 \text{ kg}) (100) = 7000 \text{ units to be infused (Shapiro, 2005).} \end{aligned}$$

About one third of FIX-deficient patients have a lower recovery after recombinant FIX infusion, requiring 20% higher dosing. The plasma half-life of FIX is about 24 hours.

Complications of Treatment

Inhibitor antibodies to FVIII or FIX represent significant complications of therapy. The incidence of inhibitors in patients with severe hemophilia A is approximately 15%–35%, and the incidence of inhibitors in patients with hemophilia B is approximately 1%–4%.

Studies to detect the emergence of an inhibitor may be undertaken periodically, and most particularly when doses of replacement factor therapy thought sufficient to control a bleeding challenge prove unsuccessful. It can be very helpful when trying to assess the emergence of an inhibitor to draw blood at multiple times following the infusion of the replacement factor. An acceleration in the fall-off rate of factor level plotted against time will typically occur with the development of an inhibitor against that factor.

Characterization of a specific inhibitor to FVIII or FIX or any other coagulation protein requires careful quantitation. This is important to perform because the degree of inhibitor titer has a major bearing on the choice of therapy for the patient. In general, lower-titer FVIII inhibitors (less than 5 Bethesda units [BU], see later) can be treated with replacement factor; in contrast, higher-titer inhibitors (above 10 BU, see later) typically can be treated effectively only with recombinant FVIIIa or with a FVIII bypassing concentrate (activated prothrombin complex concentrates) (Hay, 2006). A simple mixing test as described previously for the APTT can underestimate the presence of an inhibitor. Further, as indicated earlier, there is no unanimity on how such mixing assays should be performed. In order to diagnose the presence of a FVIII or FIX inhibitor, a formal FVIII or FIX “Bethesda” inhibitor assay should be performed (Kasper, 1975). In general, this approach to assay for coagulation factor inhibitors is reliable for all coagulation protein inhibitors. This assay standardizes the amount of plasma in the mixture and the time of incubation and normalizes interpretation of the inhibitor, so that it is universally interpretable. In the classic Bethesda assay, 1 part patient plasma is mixed with 1 part normal plasma and is incubated for 2 hours at 37° C. The control is a 1:1 mix of normal plasma with buffer. In a variation of the original Bethesda assay, known as the Nijmegen modification, the control of pooled normal plasma is incubated with FVIII-deficient plasma, and the pooled normal plasma used in the assay is buffered to prevent pH shifts during the 2-hour incubation (Verbruggen, 1995). This modification is used less commonly in the United States (Peerschke, 2009). After incubation, the patient mixture and the control mixture are assayed for FVIII activity, and the percentage of residual FVIII activity is determined at each dilution by the ratio of patient mixture to control mixture. An arbitrary BU has been devised to quantify coagulation factor inhibitors determined by this method. Thus, in the case of FVIII, 1 BU is defined as the amount of patient plasma that destroys half the FVIII activity in the control plasma (Fig. 39-8). Therefore, patient plasma producing a residual FVIII activity of 50% is considered to contain 1 BU of inhibitor per milliliter. If this same plasma had been diluted tenfold before assaying for the inhibitor, then this result would indicate an inhibitor value of 10 BU/mL. This assay is sensitive, but at times is difficult to reproduce. A common observation is that varying dilutions of plasma may yield different estimates of the inhibitor titer. For assigning the level of BUs, the dilution that comes closest to the 50% residual factor is chosen for calculation of the FVIII inhibitor titer. Values on the standard curve should be read only at between 25% and 75% residual FVIII activity. If below 25%, higher dilutions of the sample are needed. If residual activity using the least diluted patient specimen is above 75%, a demonstrable inhibitor may not be present. It is in fact important for the laboratory to determine a lower limit of sensitivity for this assay, typically in the range of <0.4 to <0.6 BU, below which it reports lack of laboratory evidence for the presence of inhibitor. It is additionally of note that a plot made of residual FVIII activity versus increasing volume of original patient plasma in the Bethesda assay may distinguish between an inhibitor capable of reducing FVIII activity into the unmeasurable range (type I inhibitor) and an inhibitor that preserves some degree of residual FVIII activity, even at high inhibitor titer (type II inhibitor), presumably reflecting a target epitope at a less critical region of the FVIII molecule (Gawryl, 1982; Luna-Zaizar, 2009).

HEREDITARY DEFICIENCIES OF OTHER COAGULATION FACTORS

The other hereditary deficiencies of coagulation factors have autosomal inheritance (Table 39-5). With the exception of FXI deficiency, these disorders are very rare. However, they have a higher prevalence in areas where consanguineous marriage is practiced (Mannucci, 2004). In general,

TABLE 39-5

Characterization of Coagulation Factors and Their Deficiencies

Figure 39-8 Expression of factor VIII inhibitor titer in Bethesda units. In this assay for an inhibitor to factor VIII, the percent residual factor VIII activity in normal plasma is determined after incubation with patient plasma. By convention, 1 international Bethesda unit of inhibitor is the amount of antibody that destroys 0.5 U factor VIII activity after 2 hours' incubation at 37° C. As shown in the figure, the percent residual factor VIII activity on a log scale is plotted against Bethesda units/mL in a linear scale. For a sample to be evaluable in this assay, the level of factor VIII activity should fall between 25% and 75%. Patient samples that produce residual factor VIII activity below 25% need to be diluted further so the 50% residual factor VIII activity point can be found. (Redrawn with permission from Bockenstedt PL. *Laboratory methods in hemostasis*. In: Loscalzo J, Schafer AI, editors. *Thrombosis and hemorrhage*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2003, p. 370, Fig. 21-7.)

most patients with coagulation protein deficiencies of factors VII, X, V, and II probably have partial defects because they have relatively mild bleeding disorders. Most coagulation-based assays have difficulty detecting these factors once their levels are below 5%–10%. In vivo, however, the presence of even this small level of coagulation factor can greatly influence bleeding risk. In contrast, findings with knockout mice indicate that a true null of each of these proteins is associated with virtually 100% mortality from hemorrhage before or at the time of birth. With hereditary factor deficiencies, heterozygous deficient individuals have approximately 50% (most commonly 30%–60%) of the normal level of the affected factor. The symptoms of these disorders are quite variable. Coagulation factor deficiencies may be suspected on the basis of symptoms, family history, or abnormal screening tests, and the laboratory confirms this diagnosis by specific factor assays. Once a specific protein deficiency is recognized, clinical history usually distinguishes a congenital from an acquired defect (see later).

Disorders With Prolonged APTT and Normal PT

Factor XI

Factor XI deficiency is common in Ashkenazi Jews, in whom heterozygote frequency is 8% (Asakai, 1991; Emsley, 2010). This ethnic population constitutes about 50% of the FXI-deficient patients seen in the United States. Most patients with FXI deficiency rarely have spontaneous hemorrhage. Bleeding typically occurs following injury or surgery, particularly involving areas of the body with high fibrinolytic activity (mouth, nose, genitourinary tract). Women can experience menorrhagia and postpartum hemorrhage. Bleeding can occur in heterozygotes and does not necessarily correlate with the residual FXI level (Leiba, 1965; Bolton-Maggs, 1988). However, the bleeding tendency may be modified by additional defects such as hemophilia, von Willebrand disease, and platelet function defects (Brenner, 1997). Diagnosis depends on determination of FXI activity below the reference range. Most widely used APTT reagents will have prolonged APTT results for patient samples with FXI activity below 20%–25% and mixed results when levels are 25%–60%. The lower limit of the normal range is probably between 60% and 70% (Bolton-Maggs, 1995). Therefore, a normal APTT does not rule out a mild FXI deficiency. In cases where marked elevation of FVIII may be present, the APTT can be normalized even when other factors are reduced (Lawrie, 1998). In all patients with FXI deficiency, preoperative management is critical to prevent bleeding complications. Patients with severe deficiency (FXI <10%–20%) should receive treatment with fresh frozen plasma to raise their FXI levels. Usually, replacement therapy of 20 mL/kg loading dose with a maintenance dose of 5–10 mL/kg every 24 hours is sufficient to cover patients with severe FXI deficiency through elective surgery (Kessler, 1996). Patients with levels from 20%–70% may bleed. A bleeding history

and the nature of the proposed surgery will then guide management. The development of inhibitors to FXI in patients with FXI deficiency has been described, although these are rare (Salomon, 2003).

FXII, Prekallikrein, and High Molecular Weight Kininogen

As discussed previously, FXII, prekallikrein, and HK deficiencies are associated with prolonged PTT but are not associated with any bleeding risk. FXII deficiency is most common, occurring in all racial and ethnic backgrounds. It is associated with a very long PTT. Prekallikrein deficiency is less common but is seen in the United States in all ethnic groups. It is associated with a slightly prolonged APTT that corrects to normal when sitting on the bench for 1 hour at 37° C. HK deficiency is a rare disorder that also is associated with a very long APTT. These protein deficiencies are not associated with bleeding—a point emphasized diagrammatically in Figure 39-1 by graying of this portion of the coagulation “cascade.” Because no replacement therapy for hemostasis is necessary for FXII, PK, or HK deficiency, it is important to recognize these defects to prevent unnecessary transfusion. Although deficiencies of FXII and HK have been associated with thrombosis risk, deletions of these proteins in mice are associated with delayed times to thrombosis in arterial thrombosis models (Renne, 2005; Merkulov, 2008). When a deficiency in the proteins of the kallikrein/kinin system is suspected, a FXII assay should be performed first, because it is the most common.

Disorders With Prolonged APTT and PT

Observation of prolonged PT and APTT most commonly is due to general medical conditions described later under acquired disorders of blood coagulation. When hereditary disorders are considered, the following list, although much less common, should be considered.

Disorders of Fibrinogen

Fibrinogen deficiencies may prolong the PT and APTT if the plasma concentration of the protein is sufficiently low, usually less than 100 mg/dL. Afibrinogenemia is autosomal recessive and represents the total absence of fibrinogen. It results in a bleeding disorder of variable severity (Fried, 1980; Lak, 1999). Umbilical stump and mucosal bleeding are most common, as is an increased incidence of musculoskeletal and central nervous system bleeding. Patients also exhibit poor wound healing. Hypofibrinogenemia is a decreased level of normal fibrinogen and has a similar but milder pattern of bleeding. Both afibrinogenemia and hypofibrinogenemia are associated with recurrent miscarriage, as well as with antepartum and postpartum hemorrhage (Goodwin, 1989; Kobayashi, 2000). Paradoxically, reports have described thrombotic events in patients with afibrinogenemia (Chafa, 1995; Lak, 1999; Dupuy, 2001).

Dysfibrinogenemia is a qualitative fibrinogen deficiency characterized by the production of a dysfunctional fibrinogen (Miesbach, 2010). Most patients with congenital dysfibrinogenemia are heterozygous because of molecular defects in produced protein, although rare homozygous cases have been reported. Dysfibrinogenemias are most commonly acquired in association with liver disease. Acquired dysfibrinogenemias are most commonly due to posttranslational modifications of the fibrinogen protein as a result of synthesis in an abnormal liver. These defects are common in patients with hepatitis B and C. Patients with dysfibrinogenemia are usually asymptomatic or have mild bleeding, but in some cases, thrombosis has been reported, with or without a bleeding history (Hanss, 2001). The thrombin time and reptilase time, which measure clotting time during the conversion of fibrinogen into fibrin, are often prolonged in dysfibrinogenemia. When thrombin proteolyzes fibrinogen in the thrombin time, fibrinopeptides A and B are released from the $\alpha\alpha$ and $\beta\beta$ chains of fibrinogen. Reptilase clots fibrinogen by liberating only fibrinopeptide A (Funk, 1971). Proteolysis of fibrinopeptide A from fibrinogen is sufficient to induce clot formation. Fibrinopeptide B liberation increases the rate of association of the fibrin monomers, but not the actual physiologic clot (Martinelli, 1980; Nawarawong, 1991). Bleeding risk is associated only with fibrinopeptide A release defects, not with fibrinopeptide B release defects. Therefore, a patient can have long PT and APTT from a fibrinopeptide B release defect and not have any bleeding risk, hence the reason for using both the thrombin time and reptilase time to assess dysfibrinogenemias. Assays that measure clottable fibrinogen will show lower levels than assays that measure fibrinogen antigen. A normal fibrinogen has a ratio of clottable fibrinogen activity to fibrinogen antigen greater than 95%. Ratios less than this raise the possibility of a dysfibrinogenemia. For many years, cryoprecipitate has served as a good source of fibrinogen when replacement is

needed. A fibrinogen concentrate is now available for therapeutic administration both in Europe and in North America.

FII Deficiency

Prothrombin deficiency may be the rarest inherited coagulation factor deficiency (1:2,000,000) (Bolton-Maggs, 2004). A true prothrombin deficiency in the mouse is incompatible with life after birth (Sun, 1998). Hypoprothrombinemia (type I deficiency) manifests as a concomitant reduction in prothrombin activity and antigen levels. Bleeding symptoms include mucosal bleeding, hematomas, and hemarthrosis. Dysprothrombinemia (type II deficiency) presents with reduced activity and normal antigen levels. The clinical presentation of dysprothrombinemia is less predictable, and patients may be asymptomatic or may have only mild bleeding manifestations (Bolton-Maggs, 2004). Depending on the sensitivity of the reagents, both PT and APTT may be prolonged in prothrombin deficiency. However, a specific factor II assay is best if there is clinical suspicion or a positive family history in the presence of normal screening tests. A PT reagent-based prothrombin assay with factor-deficient plasma is most convenient. Prothrombin complex concentrates are the treatment of choice, although fresh frozen plasma can serve as an alternative source of prothrombin. Because the half-life of the protein is long, replacement every few days is typically sufficient.

FV Deficiency

Heterozygous FV deficiency is asymptomatic. Homozygous FV deficiency is rare (1:1,000,000), presenting in children with easy bruising and mucosal bleeding (Girolami, 1998; Lak, 1999). These individuals may well have some functional FV, considering that 50% of true null mice die at the time of development of the cardiovascular system (days 9–11), and the other half die at birth from hemorrhage (Cui, 1996). Hematomas and hemarthrosis may occur with injury but rarely spontaneously. It is associated with prolongation of both the APTT and PT (but a normal thrombin time) and is confirmed by a PT reagent-based, single-stage FV assay. Patients with FV deficiency should also have a FVIII assay performed to evaluate for combined deficiency of factors V and VIII (see later) (Nichols, 1998; Zhang, 2004). The only suitable replacement product available is fresh frozen plasma. It is interesting to note that human platelets contain 20% of total plasma FV and can also be a source of this protein for a bleeding state (Tracy, 1982). The replacement goal should be to elevate the FV level to at least 10%–15% (Peyvandi, 1999). Acquired inhibitors to FV are relatively common from the surgical use of topical bovine thrombin to aid incision hemostasis. Most cases are not severe, but the few encountered can be very serious and life-threatening owing to the lack of specific replacement therapy.

FX Deficiency

Heterozygous FX deficiency is asymptomatic. Homozygous FX deficiency is a severe bleeding disorder that presents in infancy. Symptoms include umbilical cord bleeding, mucosal bleeding, severe soft tissue hematomas, and hemarthroses (Peyvandi, 1998a). One-stage PT-based FX assays are sufficient for diagnosis, although additional assays are commercially available. As with all vitamin K-dependent clotting factors, it is important to exclude vitamin K deficiency or other acquired cause for the FX deficiency before the diagnosis of an inherited deficiency is made. For example, FX deficiency is the most common factor deficiency associated with primary amyloidosis, occurring in <10% of patients and probably due to adsorption of FX onto amyloid fibrils (Uprichard, 2002). Current therapy for factor X deficiency includes prothrombin complex concentrates, although recombinant FVIIa has been used successfully to treat FX deficiency associated with amyloidosis (Boggio, 2001).

Combined Deficiency of FV and FVIII

Combined FV and FVIII deficiency is a rare autosomal recessive disorder that results from a single gene defect rather than from coinheritance of defects in both FV and FVIII genes. Patients typically have FV and FVIII levels between 5% and 30%. In two thirds of patients, this results from null expression of LMAN1 (previously known as ERGIC-53) (Nichols, 1998). LMAN1 shuttles between the endoplasmic reticulum and the Golgi and is believed to facilitate protein trafficking through the secretion pathway (Zhang, 2003). Other patients have a mutation of *MCFD2*, which directly interacts with LMAN1 (Zhang, 2003). Bleeding manifestations include epistaxis, easy bruising, menorrhagia, and postpartum hemorrhage, as well as bleeding following surgery, dental extraction, and trauma (Seligsohn, 1982; Peyvandi, 1998b). Testing usually demonstrates disproportionate prolongation of the PTT compared with the PT. Replacement

therapy includes both FVIII concentrates and fresh frozen plasma (as a source of FV).

Combined Deficiency of Vitamin K–Dependent Clotting Factors

Vitamin K–dependent clotting factor deficiency affecting multiple vitamin K–dependent coagulation factors (II, VII, IX, and X) occurs with vitamin K deficiency and hepatic dysfunction, but it also results from heritable dysfunction of hepatic enzyme γ -glutamyl carboxylase (type I) or the vitamin K epoxide reductase enzyme complex (type II) (Brenner, 1998; Zhang, 2004). Severely affected individuals may present as neonates with umbilical stump bleeding or spontaneous intracranial hemorrhage; in infancy or early childhood with hemarthroses, soft tissue hematomas, or gastrointestinal hemorrhages; or as adults with easy bruising, mucosal bleeding, and bleeding following surgery. Diagnosis is established by prolongation of both the APTT and PT and associated reductions in levels of vitamin K–dependent clotting factors. These patients may respond to vitamin K (oral or parenteral) with normalization of the APTT, PT, and factor levels, as well as resolution of bleeding symptoms. This fact makes the establishment of a diagnosis of an inherited abnormality difficult, in that other acquired causes of vitamin K deficiency (hemorrhagic disease of the newborn, liver disease, and prolonged use of broad-spectrum antibiotics) or factitious warfarin administration could present similarly. For patients who do not respond fully to vitamin K administration, fresh frozen plasma can be used for acute bleeding or surgery.

Disorders With Normal APTT and Prolonged PT

FVII Deficiency

FVII deficiency is common compared with the other rare hereditary coagulation factor deficiencies (Mariani, 2009). The bleeding manifestations are variable, with epistaxis, mucosal bleeding, and menorrhagia commonly reported (Peyvandi, 1997). Severe FVII deficiency is autosomal recessive, often presenting shortly after birth, and may have dramatic presentation with intracranial hemorrhage in 15%–60% of cases (Ragni, 1981). The diagnosis is suspected with the finding of isolated prolongation of the PT. However, FVII, a vitamin K–dependent clotting factor, is low in the newborn period and will also be low in the presence of vitamin K deficiency. Therefore, reevaluation of infants with mild deficiencies is required after they reach a few months of age, or after vitamin K replacement in older patients. Functional FVII activity is measured by a PT-based, FVII-deficient plasma clotting assay. The use of recombinant human thromboplastin will yield results that are more likely to reflect *in vivo* FVII levels. Samples for FVII testing should not be stored at 4° C, as this can lead to cold activation of FVII as result of C1 inhibitor inactivation and FXIIa formation in the tube with FVII activation (Kitchen, 1992). Cold activation of FVII results in an overestimation of the actual plasma FVII level. Therapeutic options include fresh frozen plasma, prothrombin complex concentrates, and recombinant FVIIa. For major surgery, plasma FVII levels of at least 20% are sufficient (Bolton-Maggs, 2004).

Disorders With Normal APTT and PT

FXIII Deficiency

FXIII stabilizes the clot after a fibrin clot has formed (Hsieh, 2008). Therefore, the PT and APTT will be normal even with a severe FXIII deficiency. Testing for FXIII deficiency is suggested for individuals with a positive bleeding history, particularly with features such as delayed bleeding, umbilical stump bleeding, or miscarriage, in which the PT and APTT are normal (Anwar, 1999). Thirty percent of severely FXIII-deficient patients die in middle age from spontaneous intracerebral hemorrhage unless they are receiving prophylactic therapy (Lorand, 1980). The diagnosis of severe FXIII deficiency (<5% activity) can be confirmed with the 5M urea clot solubility test or a chromogenic assay. Clots formed with normal FXIII activity remain stable in 5M urea, whereas clots from FXIII-deficient patients dissolve in urea. The reason for this is that FXIIIa initiates the formation of a new intermolecular γ -glutamyl- ϵ -lysine bridge between fibrin molecules (Lorand, 1980). This new interaction augments the mechanical rigidity of the clot structure and increases its resistance to lysis. The urea clot solubility assay is simple to perform but is sensitive only to very low levels of FXIII. More robust quantitative activity assays are based on cross-linking of glycine-ethyl ester into a specific peptide (Fickenscher, 1991), incorporation of an amine substrate into fibrinogen (Kohler, 1998), or incorporation of a biotinylated peptide to spermine

attached to microtiter plates (Hitomi, 2009). Acquired deficiency of FXIII has been described in a variety of diseases, including Henoch-Schönlein purpura, isoniazid treatment for tuberculosis, various forms of colitis, erosive gastritis, and some forms of leukemia (Board, 1993), although FXIII level determination and therapeutic management are controversial. Because the half-life of FXIII is very long, replacement with fresh frozen plasma is usually sufficient for most patients. FXIII concentrates and recombinant FXIII are currently being evaluated in clinical trials (Lusher, 2010).

Hereditary Hemorrhagic Disorders of Fibrinolysis

Hereditary bleeding disorders resulting from excessive fibrinolysis are rare. Deficiency of α_2 -antiplasmin has been reported in a few families with a bleeding tendency (Fay, 1992; Aoki, 1980). Although not recommended for routine use as a screening assay, the whole blood clot lysis time can be helpful as a first-order test to detect deficiencies of α_2 -antiplasmin. In brief, whole blood is allowed to clot; following this, the time to clot lysis is recorded. In normal individuals, the presence of α_2 -antiplasmin effectively prevents lysis from occurring in this *in vitro* setting, even 24 hours after initial clot formation. In contrast, in the presence of a severe deficiency of α_2 -antiplasmin or in some fibrinolytic states, clot lysis can be observed after several hours. In such instances, follow-up testing specific for α_2 -antiplasmin activity should be employed. Acquired α_2 -antiplasmin deficiency commonly occurs in acute leukemia (Schwartz, 1986; Okajima, 1994). Also, plasma can be admixed with dilute acid to precipitate a fraction relatively rich in plasminogen activator, plasminogen, and fibrinogen but relatively poor in antiplasmins. This **euglobulin** fraction is then redissolved in buffer and clotted by recalcification, and the time for clot lysis is then measured. Euglobulin clot lysis is normally complete in 2–5 hours, but the time may be shortened with increased fibrinolysis associated with increased plasminogen activator activity. Plasminogen activator, plasminogen, and plasminogen activator inhibitor may be assayed directly.

ACQUIRED COAGULATION DISORDERS

Acquired bleeding disorders are due to anticoagulation, disseminated intravascular coagulation (DIC), liver disease, vitamin K deficiency, massive transfusion, and unique inhibitors to coagulation proteins. The topic of anticoagulation is addressed extensively in Chapter 42. In general, prolongations of the PT and APTT arising in a patient should raise the possibility, as discussed in the following sections, of anticoagulants, DIC, liver disease, vitamin K deficiency, and massive transfusion. Only after these clinical states have been excluded should attention be directed to specific protein defects influencing the PT and PTT.

THROMBOTIC DISORDERS AND DISSEMINATED INTRAVASCULAR COAGULATION

Risk factors underlying the development of thrombosis are discussed in detail in Chapter 41. Regardless of origin, however, the formation of a fibrin clot, cross-linking of that clot, and subsequent lysis of that clot by the fibrinolytic system are central features of the process.

DIC is a clinicopathologic condition in which activation of the coagulation and fibrinolysis systems results in the simultaneous formation of thrombin and plasmin with consumption of coagulation factors and inhibitors of the system, resulting in the clinical laboratory phenotype of prolonged PT, APTT, and thrombocytopenia. It arises in patients with sepsis, malignancy, obstetric complications, or massive tissue injury (Schmaier, 1991). DIC can arise during surgery as a result of the release of thromboplastic material within the tissue. In circulatory arrest operations on the arch of the aorta or the main pulmonary arteries, DIC is a frequent complication related to chilling of the patient and tissue destruction. Abruptio placentae and placenta previa are associated with acute hemorrhagic DIC, whereas retained dead fetus is associated with a DIC that is not hemorrhagic but prothrombotic. DIC due to sepsis can also occur in the post-operative period. DIC with sepsis is most commonly seen with gram-negative infection but can occur with gram-positive infection and in the immunosuppressed patient with fungemia. The balance between thrombin and plasmin formation in the individual patient clinically translates into a prothrombotic versus hemorrhagic state, respectively.

The diagnosis of DIC depends on appropriate clinical test results in the correct clinical setting. The finding of a prolonged PT and APTT with reduced fibrinogen and platelet count is highly suspicious for DIC in the

hospitalized patient until proven otherwise (Colman, 1972). This clinical laboratory phenotype of DIC most probably results from a hyperfibrinolytic state and is the form of DIC most commonly recognized. A prothrombotic state as the result of DIC is usually associated with normal PT and APTT with mildly reduced platelet count and normal or elevated fibrinogen. The diagnosis of DIC is made by using a confirmatory test that shows the simultaneous presence of thrombin and plasmin formation. Currently, the D-dimer assay is the confirmatory test that, if positive, shows that both thrombin and plasmin have been formed. The D-dimer measures plasmin-cleaved, insoluble, cross-linked fibrin that originally arose from thrombin cleavage of fibrinogen (see Figs. 39-2 and 39-4, B). The D-dimer can be performed by immunonephelometric assay or by latex agglutination assay, and results can be obtained rapidly, facilitating the use of this test in clinical decision-making (Reber, 2009). As would be anticipated, the D-dimer is elevated in a wide variety of thrombotic conditions, including DIC (Koracevic, 2009). By careful establishment of a cutoff value, the D-dimer may be judiciously used in concert with clinical findings as a negative predictive test to exclude deep vein thrombosis or pulmonary embolism (Ceriani, 2010). The level of D-dimer may decrease in response to anticoagulation. In the past, fibrin degradation (split) products (FDPs) were used to recognize DIC (see Fig. 39-4, A). However, depending on the specificity of epitopes recognized by antibodies employed in the particular test systems, FDP may variably represent plasmin-cleaved fibrinogen, soluble fibrin, or insoluble fibrin. The finding of increased FDPs accordingly does not necessarily translate into a measure of plasmin-cleaved, insoluble, cross-linked fibrin equivalent to that obtained with the D-dimer assay. Fibrin monomer is the large molecular mass protein of fibrinogen that remains after fibrinopeptides A and B are liberated. It can be elevated in DIC, but if DIC is severe, it may be absent. Thus, it is an unreliable assay for use in recognizing DIC. A scoring system that combines in a quantitative fashion the results of four commonly employed laboratory tests that may be helpful, in the appropriate clinical setting, to evaluate the likelihood of DIC is presented in Table 39-6 (Levi, 2009).

LIVER DISEASE

It is important for liver disease to be recognized in patients because most coagulation factors are synthesized in the liver. Thus, patients with liver disease will have increased risk of bleeding. Patients with serious liver disease will have a prolonged PT and APTT. Not only is the synthesis of these proteins reduced, but the proteins made are at times abnormal, functioning as inhibitors of normal coagulation proteins. For example, abnormal fibrinogens (dysfibrinogenemias) are very common in patients with liver disease. As already mentioned, if these proteins have defects in fibrinopeptide A or B release, the thrombin time will be abnormal; the reptilase time is abnormal only in fibrinopeptide A release defects. Overall, abnormal fibrinogens can be appreciated by an abnormal ratio of clottable

fibrinogen (an activity measure) to fibrinogen antigen (measured by radial immunodiffusion or another immunoassay). Finding less activity in relation to the mass of the protein is characteristic of an abnormal molecule. Similarly, all vitamin K-dependent proteins (factors II, VII, IX, and X and proteins C, S, and Z) are decreased in liver disease. These proteins may have abnormal γ -carboxylation reactions of the glutamic acid residues within their amino-terminal portion, thus producing reduced factor activity with relatively higher levels of that factor's antigen (see next section). In general, PK is one of the first proteins, and fibrinogen one of the last proteins, to be decreased in liver disease. Factors VIII and V become absent in the anhepatic stage of liver transplantation, but FVIII is elevated in patients with inflammatory hepatocellular disease. Moreover, anti-thrombin and other serpin plasma protein inhibitors are also decreased in liver disease.

VITAMIN K DEFICIENCY

Vitamin K, a lipid-soluble vitamin, is provided by dietary intake of leafy green vegetables and by synthesis of intestinal flora. In clinical medicine, vitamin K deficiency is seen most often in the very ill patient on antibiotics who has subsisted on parenteral nutrition. Not infrequently, intravenous fluids are not supplemented with vitamin K. After 4–6 weeks of parenteral nutrition and antibiotic treatment, the patient becomes vitamin K-deficient. Vitamin K deficiency can also be seen in patients who have anatomic bypass of the small intestine, malabsorption, biliary tract obstruction, and, rarely, reduced dietary intake. For example, alcoholics are often vitamin K-deficient. Warfarin also inhibits the enzymatic pathway necessary for vitamin K utilization (see Fig. 42-1 in Chapter 42). Vitamin K has a critical role in the γ -carboxylation reaction of a number of glutamic acid residues within coagulation factors II, VII, IX, and X and proteins C, S, and Z. This γ -carboxylation is critical for the proteins to bind to cells and phospholipids, so that they can participate in physiologic coagulation reactions. Thus patients will have reduced clottable factor levels for the vitamin K-dependent factors II, VII, IX, and X. If antigen levels of these patients are measured, they will frequently be higher. In general, patients with a therapeutic level of warfarin (i.e., an INR between 2 and 3) have \approx 5%–15% clottable factor activities, whereas their antigen factor levels are in the range of 25%–40%.

MASSIVE TRANSFUSION

Massive transfusion has been defined as the replacement of more than 1.5 blood volume in 24 hours. For example, in a 70-kg man, 7% of body weight, or 4.9 kg or L, is the blood volume (\approx 16–19 units, assuming that a unit of blood is 250–300 mL). Hemostatic failure can result from dilution of clotting factors, DIC, or acquired platelet dysfunction. Dilutional coagulopathy results from replacement with packed red blood cells and normal saline and lack of clotting factors or platelets. Tests of hemostasis typically show prolongation of the PT and APTT, reduced fibrinogen, and thrombocytopenia (Leslie, 1991). Additionally, in the massively transfused patient, an anticoagulant effect is seen as well, resulting from citrate in the transfused blood products.

ACQUIRED COAGULATION PROTEIN INHIBITORS AND LUPUS ANTICOAGULANT

Acquired inhibitors to coagulation proteins occur and, in some cases, increase the risk of bleeding. The clinical laboratory phenotype of these patients depends on the protein toward which the coagulation protein inhibitor is directed. The most common severe acquired coagulation protein inhibitor is that against FVIII. These patients present with bleeding and a long APTT. Characteristically, one sees this inhibitor in elderly patients, patients with B-cell malignancies, patients with connective tissue disorders such as systemic lupus erythematosus, and postpartum patients. These patients are managed acutely with high-dose FVIII, activated vitamin K-dependent coagulation factor concentrates, or rVIIa, but long term, management may require immunosuppression with Cytoxan, prednisone, or rituximab (Lian, 1989; Aggarwal, 2005). Management decisions in these patients are influenced by the severity of bleeding and by the titer of the inhibitor to FVIII, as determined by the Bethesda assay.

Acquired deficiencies or inhibitors are also seen in a number of medical conditions. Systemic amyloidosis is associated with decreases in plasma factor X or IX as a result of adsorption of the coagulation proteins onto the amyloid protein (McPherson, 1977; Furie, 1981; Mumford, 2000;

TABLE 39-6

ISTH Diagnostic Scoring System for DIC

Risk assessment: Does the patient have an underlying disorder known to be associated with overt DIC?

- If yes, proceed.
- If not, do not use this algorithm.

Order global coagulation tests (PT, platelet count, fibrinogen, D-dimer)

Score the test results:

- Platelet count (>100 k/ μ L = 0, <100 k/ μ L = 1, <50 k/ μ L = 2)
- Elevated D-dimer (<0.4 μ g/mL = 0, 0.4–4.0 μ g/mL = 2, >4.0 μ g/mL = 3)
- Prolonged PT (<3 sec = 0, >3 sec but <6 sec = 1, >6 sec = 2)
- Fibrinogen level (>100 mg/dL = 0, <100 mg/dL = 1)

Calculate score:

- If ≥ 5 , compatible with overt DIC: Repeat score daily.
- If <5 , suggestive (not affirmative) for nonovert DIC: Repeat next 1–2 days.

DIC, Disseminated intravascular coagulation; ISTH, International Society on Thrombosis and Haemostasis; PT, prothrombin time.

Note that in this example of score implementation, a D-dimer test having an upper normal limit of 0.4 μ g/mL was employed. More generally, for the particular analyte employed as an “elevated fibrin marker,” no increase = 0, moderate increase = 2, and strong increase = 3.

Thompson, 2010). In the case of factor X, the PT and APTT may be affected; in the case of factor IX, only the APTT. Hypergammaglobulinemic states seen with multiple myeloma or Waldenström's macroglobulinemia (IgM) can be associated with pan-inhibitors to coagulation protein function (Glaspy, 1992). Dysfibrinogenemias are also common in these patients.

The last type of inhibitor seen is the lupus anticoagulant or antiphospholipid antibody that influences coagulation protein reactions. Briefly, these inhibitors are antibodies directed to epitopes of proteins bound to phospholipids (Lafer, 1981; Levine, 2002). Lupus anticoagulants variably

interfere with the APTT and, less commonly, with the PT. The degree of interference depends on the nature of the commercial reagent. Paradoxically, unless these patients have additionally developed an inhibitor against a specific coagulation factor, they are not at bleeding risk; rather, they may be at risk for thrombosis, which at times can be a vicious prothrombotic state (Mueh, 1980; Rand, 2003). Antiphospholipid antibodies may also interfere with several anticoagulation mechanisms such as annexin V, thus enhancing prothrombinase on endothelial cells and prostacyclin production from endothelial cells. For a more detailed discussion of lupus anticoagulants and the antiphospholipid syndrome, see Chapter 41.

KEY POINTS

- Platelets are highly complex cells that participate in critical steps central to hemostasis and thrombosis, including adhesion to subendothelium, secretion of granule contents, aggregation, and provision of membrane surface for activation of coagulation factors.
- Abnormalities of platelet number or of platelet function can play an important role in the balance of hemostasis and thrombosis.
- Almost unique to laboratory medicine and pathology, platelet pathology may be assessed in real time upon living cells obtained from the patient.
- von Willebrand factor is a multimeric protein synthesized by endothelial cells and megakaryocytes that plays a central role in platelet adhesive interactions.
- Platelet counts and platelet function are affected by a number of acquired disorders and autoimmune processes and by numerous drugs.

NORMAL PLATELET BIOLOGY

PLATELET STRUCTURE

Blood platelets are highly complex, anucleate cells that derive from bone marrow megakaryocytes. A well-prepared peripheral blood film offers the opportunity for evaluation of platelet number, size, distribution, and structure under the light microscope. Although subtle abnormalities of platelet structure usually require electron microscopy, gross absence or asymmetry of granules and grossly aberrant platelet surfaces may be evident. In films from nonanticoagulated fingerstick specimens, some platelet clumping is an expected feature. In instances of observed abnormalities, artifacts resulting from improper specimen collection or handling should always be considered, and a repeat specimen should be obtained if a satisfactory explanation for the abnormality is not apparent.

In cases of suspected platelet structural abnormalities, electron microscopy allows much more precise characterization of the defect (White, 2004) with the opportunity to examine in great detail each of the specific organelles within the platelet (Clauser, 2009). It is essential that established

Figure 40-1 Discoid platelets. The diagram summarizes ultrastructural features observed in thin sections of discoid platelets cut in the equatorial plane. Components of the peripheral zone include the exterior coat (EC), the trilaminar unit membrane (CM), and the submembrane area containing specialized filaments (SMFs) that form the wall of the platelet and line channels of the surface-connected canalicular system (also referred to as the open canalicular system, or OCS). The matrix of the platelet interior is the sol-gel zone containing actin microfilaments, structural filaments, the circumferential band of microtubules (MTs), and glycogen (Gly). Formed elements embedded in the sol-gel zone include mitochondria (M), granules (G), and dense bodies (DBs). Collectively, they constitute the organelle zone. The membrane systems include the OCS and the dense tubular system (DTS), which serve as the platelet sarcoplasmic reticulum. The electron micrograph shows a platelet sectioned in the equatorial plane ($\times 30,000$) which reveals most of the structures indicated on the diagram. (With permission from White JG, Bloom AL, Forbes CD, Thomas DP, Tuddenham EGD, editors. *Hemostasis and thrombosis*. New York: Churchill Livingstone; 1994.)

protocols for the collection and processing of platelet specimens for ultrastructural study be followed meticulously to avoid attributing changes that occur because of inadvertent *in vitro* activation to abnormalities truly characteristic of platelets *in vivo*.

Normal features of the platelet that may be visualized ultrastructurally are shown in Figure 40-1. The outer surface of the platelet, the **glycocalyx**, is rich in glycoproteins. A submembranous band of **microtubules**, composed of the protein tubulin, provides structural support for the normally discoid cell. Contractile **microfilaments** may also be seen. These are composed principally of platelet actin and platelet myosin. An extensive **open canalicular system** within the platelet has been demonstrated by a variety of methods to be in direct communication with the extracellular environment. Often seen in close proximity to the open canalicular system is the **dense tubular system**. This system, apparently derived from the smooth endoplasmic reticulum, shows positive staining for platelet peroxidase activity (Breton-Gorius, 1972), in accord with its role as a site for

arachidonic acid metabolism within the platelet. The dense tubular system also functions as a calcium-sequestering pump, providing low levels of cytoplasmic calcium within the resting platelet.

A variety of inclusions may be recognized within the platelet cytoplasm. Both **mitochondria** and **glycogen** may be identified. Lighter staining **α -granules**, less frequent **dense core** (or “bull’s eye”) **granules**, **lysosomes**, and **peroxisomes** may also be seen. The α -granules contain a number of different proteins, including platelet fibrinogen, platelet-derived growth factor (PDGF), von Willebrand factor (vWF), the factor V binding protein multimerin (Hayward, 1991, 1993), P-selectin (Stenberg, 1985; Berman, 1986), β -thromboglobulin (β TG), and the heparin-neutralizing platelet factor (PF)4. Dense core granules are known to be the locus of stored, nonmetabolic pools of adenosine diphosphate (ADP), adenosine triphosphate (ATP), 5-hydroxytryptamine, and calcium.

PLATELET MEMBRANE GLYCOPROTEINS AND PHOSPHOLIPIDS

Detailed study of the platelet membrane glycoproteins has led to an improved understanding of platelet function. Radioactive and biotin labeling (Fabris, 1992; Solum, 1995; Sachs, 2000) of surface glycoproteins and electrophoretic separation of solubilized proteins on polyacrylamide gels have permitted assessment of various platelet glycoproteins. In fact, application of this method to the platelets of patients with congenital bleeding disorders led to the discovery that some of these disorders were due to an absence of critical membrane glycoproteins, and that several major platelet glycoproteins existed as multichain complexes. A summary of platelet membrane glycoproteins that function as receptors for adhesive ligands is included in Table 40-1. Quantitatively, the glycoprotein (GP)IIb/IIIa receptor complex (also referred to as α IIb β 3) consists of two distinct proteins and dominates, with approximately 50,000 copies per platelet, followed by the GPIb/IX receptor complex at approximately 25,000 copies per platelet. (Note that this receptor complex may also be referred to as GPIb/IX/V or GPIb/V/IX, because GPV forms a tight, noncovalent association with GPIb and GPIX.) The copy number for other GP complexes is much lower.

Platelet membranes contain several phospholipids, including phosphatidylinositol, phosphatidylcholine, phosphatidylserine (PS), and phosphatidylethanolamine, that play a major role in platelet function. Phosphatidylinositides are the source of signaling molecules inositol triphosphate and diacylglycerol that are produced following platelet activation. Negatively charged PS is expressed in the inner membrane leaflet of the resting platelet (Fig. 40-2) (Zwaal, 2005); on platelet activation, PS translocates to the outer leaflet—an essential step in the formation of a procoagulant platelet surface that is critical in several blood coagulation mechanisms (Solum, 1999). This activation-associated change in PS exposure can be assessed using flow cytometry as increased binding of annexin V to the platelet surface.

ROLE OF PLATELETS IN HEMOSTASIS AND PLATELET ACTIVATION MECHANISMS

Following injury to the blood vessel, platelets adhere to exposed subendothelium by a process (adhesion) which involves the interaction of a plasma protein, vWF, and a specific glycoprotein complex on the platelet surface, glycoprotein Ib-IX-V (GPIb-V-IX) (Fig. 40-3), which binds vWF, particularly under conditions of high shear stress. Adhesion is followed by recruitment of additional platelets, which interact with each other to form clumps in a process called aggregation. This involves binding of fibrinogen to specific platelet surface receptors—a complex comprising glycoproteins IIb/IIIa (GPIIb/IIIa, integrin α IIb β 3). GPIIb/IIIa is platelet- and megakaryocyte-specific and has the ability to bind vWF as well. Resting platelets do not bind fibrinogen. Platelet activation induces a conformational change in the GPIIb/IIIa complex, which leads to fibrinogen binding, a prerequisite for aggregation. Activated platelets release contents of their granules (secretion or release reaction) such as ADP and serotonin from the dense granules, which cause recruitment of additional platelets. In addition, platelets play a major role in coagulation mechanisms; several key enzymatic reactions occur on the platelet membrane lipoprotein surface. During platelet activation, the negatively charged phospholipids, especially PS, become exposed on the platelet surface; this is essential for the role of platelets in accelerating specific coagulation reactions by

Figure 40-2 Transporter-controlled exchange of phospholipids between both lipid leaflets of the cell membrane. Unidirectional phospholipid transport by flippase is directed inward, whereas floppase promotes outward-directed transport. Both transporters are adenosine triphosphate (ATP) dependent and frequently move phospholipids against their respective concentration gradients. For example, aminophospholipid translocase (flippase) rapidly shuttles PS and PE from outer to inner leaflet, while ABCB1 (floppase) moves both cholinephospholipids and aminophospholipids more slowly toward the outer leaflet. The concerted action of both transporters is thought to create a dynamic asymmetrical steady state, in which the outer monolayer is rich in cholinephospholipids, whereas aminophospholipids predominantly occupy the inner leaflet. Bidirectional phospholipid transport is catalyzed by a scramblase, activation of which may occur following Ca^{++} influx or when cells go into apoptosis. Because scramblase activity moves all major phospholipid classes back and forth between the two leaflets, it promotes the collapse of membrane phospholipid asymmetry, with appearance of PS at the cells' outer surface. promoting the binding of vitamin K–dependent factors (platelet coagulant activity). These events involving platelets are discussed in greater detail later.

Platelet Activation and Signaling Events

(see Fig. 40-3).

A number of physiologic agonists interact with specific receptors on the platelet surface to induce numerous events that culminate in well-recognized responses, including change in platelet shape from discoid to spherical (shape change), aggregation, secretion, and thromboxane A_2 (TxA_2) production (Shattil, 2004; Smyth, 2010). These agonists include ADP, collagen, thrombin, TxA_2 , epinephrine, and platelet-activating factor, and they induce signaling events in platelets. Platelets possess at least three well-defined purinergic receptors that mediate responses to ADP: P2Y₁, P2Y₁₂, and P2X₁. The P2Y₁ receptor mediates the rise in cytoplasmic Ca^{++} . The P2Y₁₂ receptor mediates inhibition of adenylyl cyclase to lower cyclic adenosine monophosphate levels in platelets and is the receptor targeted by the thienopyridine group of antiplatelet agents, including clopidogrel, ticlopidine, and prasugrel. A possible role in amplifying the initial phase of a platelet activation event is presently the subject of investigation of P2X₁, which has attributes of an ion channel (Hu, 2010).

Thrombin induces platelet responses through interaction with protease-activated receptors (PARs); human platelets possess PAR1 and PAR4 receptors. GPVI is the principal collagen receptor in platelets and is a member of the immunoglobulin receptor superfamily. Ligation of platelet receptors by agonists such as thrombin, TxA_2 , and ADP initiates the production and release of several intracellular messenger molecules, including products of hydrolysis of phosphoinositides by phospholipase C, diacylglycerol, and inositol 1,4,5-triphosphate (IP_3) and conversion of arachidonic acid to TxA_2 . These mediators induce or modulate the various platelet responses of Ca^{++} mobilization, protein phosphorylation, aggregation, secretion, and thromboxane production. The interaction between platelet surface receptors and key intracellular enzymes (e.g., phospholipases A_2 and C, adenylyl cyclase) is mediated by a group of distinct proteins (called G-proteins), which bind and are modulated by guanosine triphosphate. As in most secretory cells, platelet activation results in a rise in cytoplasmic ionized calcium concentration; inositol triphosphate functions as a messenger to mobilize Ca^{++} from intracellular stores. This increase in cytoplasmic Ca^{++} levels regulates other events, such as activation of phospholipase A_2 ,

Figure 40-3 Platelet proteins and molecular pathways important for hemostasis. The stages of hemostatic plug formation are broadly divided into platelet adhesion and initial signaling events, platelet aggregation, degranulation, soluble agonist receptor activation, and subsequent signaling. (For discussion in greater depth of these molecules and their roles in platelet activation, see Wei AH, Schoenwaelder SM, Andrews RK. *New insights into the haemostatic function of platelets*. *Brit J Haematol* 2009;147:415–30, from which this figure is reproduced with permission.) leading to TxA_2 production, and phosphorylation by myosin light chain kinase of the myosin light chain, which is involved in shape change and secretion.

Diacylglycerol activates the protein kinase C (PKC) family of enzymes, which phosphorylate several proteins, including pleckstrin. PKC activation

is considered to play a major role in platelet responses, including secretion and activation of GPIIb/IIIa. Platelets possess several families of G-proteins that function as molecular switches in transmitting the signal from surface receptors to intracellular effectors. For example, phospholipase activation and calcium mobilization on activation by ADP (P_2Y_1), TxA_2 , or thrombin

are mediated by Gq, and signaling through the P2Y₁₂ ADP receptor and inhibition of adenylyl cyclase are mediated by G_i.

Another well-recognized response of platelets to activation is synthesis of TxA₂. The initial and rate-limiting step in TxA₂ production is the mobilization of arachidonic acid from phospholipids (predominantly phosphatidylcholine) by phospholipase A₂. Free arachidonic acid is converted by cyclooxygenase to prostaglandins G₂ and H₂, which are converted by thromboxane synthase to TxA₂. Binding of fibrinogen to the GPIIb/IIIa complex results in activation of tyrosine kinases and associated events, a process called **outside-in signaling** (Shattil, 2004). Numerous other mechanisms and events occur in platelets on activation, involving small GTPases, tyrosine kinases, and phosphatases; these are beyond the scope of the present review. Although the agonists mentioned previously activate platelets to function in hemostasis, other agonists, such as prostacyclin (PGI₂), produced by endothelial cells, inhibit platelet responses. PGI₂ does this by increasing platelet cAMP levels by activating adenylyl cyclase.

Through activation of the coagulation system, thrombin is produced and serves as a very potent stimulus for platelet activation. Upon stimulation by thrombin, collagen, or various other agents, platelets change in shape from discoid to spherical, extend pseudopods, undergo internal contraction resulting in centralization of their α -granules and dense core granules, and ultimately release from the cell the contents of these granules. Depending on the strength of the stimulus, the contents of the α -granules, dense core granules, or even lysosomal granules may be released. As a result of platelet activation, conformational changes in the glycoprotein IIb/IIIa complex occur (Frelinger, 1991; Phillips, 1991; Sims, 1991; Calvete, 1999), resulting in the formation of receptors capable of binding several plasma proteins, most notably fibrinogen (Bennett, 1979; Cox, 2004).

Following vascular injury, blood platelets rapidly adhere to the exposed subendothelium. Under lower shear conditions, such as those characteristic of the venous circulation, platelets may bind directly to exposed collagen by means of GPVI and GPIa/IIa ($\alpha 2\beta 1$). Under higher shear conditions present in the arterial circulation, adhesion is believed to be initiated by binding of circulating vWF to exposed subendothelial collagen, followed by binding of surface-bound vWF to the platelet via the GPIb/IX receptor complex of the platelet (Auger, 2005).

Platelet Coagulant Activity

Platelets play a vital role in coagulation. The α -granules possess several coagulation factors, including factor V, fibrinogen, and several others. Most important, several of the key enzymatic reactions leading to activation of coagulation factors and thrombin generation require the platelet membrane surface to proceed at an optimum rate (Smyth, 2010). Following stimulation of platelets by agonists, progressive loss of platelet membrane phospholipid asymmetry results from increased bilayer movement, or “flip-flop,” of PS and other phospholipids from the internal to the external surface of the membrane (see Fig. 40-2) (Hemker, 1983; Zwaal, 2005). A proline-rich, transmembrane protein termed **scramblase** (see Fig. 40-2) (Comfurius, 1996; Zhou, 1997) is believed to be involved in this process (Zwaal, 2005). The availability of highly ordered phospholipoprotein surfaces permits activation of factors IX and X and prothrombin to occur on the platelet surface. Platelet activation (e.g., by ADP or collagen) results in the generation of high-affinity binding sites for factor XI. High molecular weight kininogen and prothrombin may then serve as cofactors for activation of platelet-bound factor XI by thrombin (Baglia, 1998; Oliver, 1999). Platelets additionally contain endogenous factor V, which appears to play a key role in the formation of a receptor on the platelet surface for activated factor X (Miletich, 1978). Effector cell protease receptor-1, a platelet activation-dependent membrane protein (Bouchard, 1997), together with activated factor V, is required to mediate factor Xa binding to the surface of activated platelets to form a functional prothrombinase complex. Functional coagulation complexes are described further in the preceding chapter.

LABORATORY EVALUATION OF PLATELET FUNCTION DISORDERS

INITIAL LABORATORY EVALUATION

The initial laboratory evaluation of platelet disorders includes a platelet count. This measurement has become a routine component of the complete blood count in an era of electronic particle counting. The normal platelet count is 150–400 $\times 10^9/L$. Many instruments additionally provide

the mean platelet volume (MPV) and display a histogram of MPV. In healthy individuals the MPV varies inversely with platelet count, so that interpretation of MPV as low or high is best done with reference to the patient's platelet count (Bessman, 1981). Some automated instruments additionally assess platelet maturity, as reflected by the RNA content of **reticulated platelets**—analogous to reticulocyte measurements in the erythroid series. Such measurements offer the opportunity to detect a thrombopoietic response from the bone marrow 1 or more days earlier than it might be detected by more traditional approaches. Evaluation of the peripheral blood film provides a rough corroboration of the platelet count and size distribution.

Because platelets may undergo activation and spreading during preparation of the blood film, the apparent size distribution of platelets in the blood film in some cases may deviate significantly from actual volume distributions. In cases of severe thrombocytopenia below the established linearity of a given automated instrument, or whenever cellular fragments may be spuriously affecting the automated count, a manual phase contrast count with a hemocytometer chamber may be required. However, such manual counts performed on a relatively small number of platelets have a much higher coefficient of variation than is obtained when automated instruments are used within their linear ranges, and unless such counts are performed by an experienced individual, the counts may be unreliable.

SCREENING STUDIES OF PLATELET FUNCTION

No currently available laboratory test faithfully reflects the ability of platelets to accomplish their enormously complex series of functions in hemostasis. For many years, the template bleeding time test has been used by many laboratories as a global test for the adequacy of primary hemostasis. In this procedure, a disposable device is used that consists of a spring-loaded blade that descends vertically into the epidermis (described in detail by Hoyer [1982]) or a blade that cuts the epidermis as it makes a rotary arc (Buchanan, 1989). With these tests, a blood pressure cuff is placed around the upper arm and is inflated to maintain a pressure of 40 mm Hg. A standardized cut is then made on the volar surface of the forearm, a timer is started, and at 30-second intervals, the resulting drops of blood are blotted with filter paper (without directly touching the wound edge). When blood no longer stains the filter paper, the timer is stopped. At platelet counts above 100 $\times 10^9/L$, bleeding times should fall within the laboratory's established reference interval. Prolonged bleeding times in such cases are associated with prior ingestion of drugs with an antiplatelet action (e.g., aspirin, clopidogrel), von Willebrand disease, and congenital and acquired disorders of platelet function (discussed later).

Whereas a carefully performed bleeding time test provides useful information during the evaluation of a patient with a history of bleeding manifestations, its usefulness is less clear in the context of preoperative hemostatic screening of asymptomatic patients. In an extensive review of publications reporting the extent of clinical bleeding in a wide variety of settings, Rodgers and Levin (Rodgers, 1990) concluded that the available data did not provide convincing evidence that the relationship between platelet count and bleeding time was predictively useful in the individual patient typically encountered in clinical practice. They additionally concluded that the degree of bleeding from a standardized template cut in the skin could not be relied upon in an individual patient to predict the risk of bleeding elsewhere in the body, such as at operative sites. A prospective study of 40 patients without a bleeding history and with no recent intake of nonsteroidal antiinflammatory drugs who underwent coronary artery bypass surgery found no predictive relationship between the preoperative bleeding time test and perioperative or postoperative bleeding (De Caterina, 1994). Although a dramatically prolonged bleeding time provides strong suspicion for an underlying disorder of primary hemostasis, the interpretation of mildly or moderately prolonged bleeding times is less clear. Because of the limitation in predictive value, the risk of scarring, and the considerable technical expertise and performance time associated with performance of bleeding times, use of this procedure has declined considerably in recent years. In parallel with this decline, the popularity of *in vitro* measures has increased, most notably the platelet function analyzer (PFA-100) instrument. With this instrument, anticoagulated whole blood is flowed under high shear force through a narrow hole punched out of a membrane coated with collagen and epinephrine or ADP. The combination of biophysical shear and chemical stimulation initially promotes platelet adhesion to the outer edges of the cut membrane; subsequently, platelet-platelet aggregation leads to full occlusion of the channel, which

Modified with permission from Hayward CPM, Harrison P, Cattaneo M, et al. Platelet function analyzer (PFA)-100 closure time in the evaluation of platelet disorder and platelet function. *J Thromb Haemost* 2006;4:312–9.

Note: The data reported with CADP (collagen and ADP) and CEPI (collagen and epinephrine) cartridges, indicated as normal (N) or prolonged (P), are based on small numbers of reported cases.

is recorded as **closure time**. This process is dependent on plasma levels of vWF.

Whereas inhibition of the platelet cyclooxygenase by aspirin and other mild to moderate impairments of platelet function prolong closure times with the collagen/epinephrine membranes, only more profound impairment of platelet function or of vWF prolongs closure times with collagen/ADP cartridges. Thrombocytopenia or anemia also prolongs closure times. Although abnormal in some platelet disorders, the PFA-100 does not have sufficient sensitivity or specificity to be relied upon as a screening tool for platelet disorders (Table 40-2) (Hayward, 2006). Definitive identification of abnormalities of platelets or vWF requires more specialized studies.

Several additional ex vivo experimental systems have been developed in which shear forces play a major role. These include variations of cone-and-plate viscometers and parallel plate flow chambers (Michelson, 2002). These devices offer the potential to detect inherited and acquired disorders related to both platelets and vWF, but their role in clinical practice needs to be defined.

PLATELET AGGREGATION AND SECRETION STUDIES

Further evaluation of a suspected defect of platelet function can be performed through study of platelet aggregation and secretion in response to a battery of platelet-stimulating agents. These studies are performed using platelet-rich plasma (PRP) harvested from blood collected using sodium citrate as the anticoagulant. Sodium citrate lowers Ca⁺⁺ in the blood to prevent clotting of blood, but not to the extent that it is lowered by ethylenediaminetetraacetic acid (EDTA), which is routinely used to collect samples for blood counts. EDTA dissociates the GPIIb/IIIa complexes on the platelet surface; thus, aggregation studies cannot be performed when such a sample is used. When citrated PRP is continuously stirred in a platelet aggregometer and a light beam is passed through the suspension, platelet aggregation in response to added agonists can be monitored by changes in light transmittance (Zucker, 1989). Discoid-to-spheroid shape change is seen as an initial decrease in transmittance, whereas subsequent formation of platelet clumps allows more light to pass through the suspension to the photodetector and is recorded as an increase in light transmittance. When instruments equipped with a second channel are used for monitoring secretion, the release of adenosine triphosphate (ATP) from platelet-dense granules is simultaneously measured (Fig. 40-4). This is

accomplished by adding the firefly luminescence substrate and enzyme—luciferin and luciferase—to the PRP; released ATP then functions as a cofactor in the light-producing luciferin–luciferase reaction, and light emission is recorded with a second photodetector. Because of separation of wavelengths, the aggregation and release channels can be monitored independently (Miller, 1984). The release of ATP in most cases may be assumed to reflect the release of other constituents of dense granules, which are less easily measured (i.e., ADP, serotonin, calcium). Direct measurements of serotonin, ATP, and ADP can also be performed (Holmsen, 1989). As an alternative to lumiaggregometry studies, platelet secretion may be studied in parallel with aggregation by initially labeling platelets with radioactive serotonin and then measuring the release of radioactivity from platelets on activation (Lan, 2005).

Platelets have receptors for several agonists on their surface (see Figs. 40-3, 40-5, and 40-6). A number of these agonists may be used in the diagnostic laboratory to determine whether response to one or more of these agonists is impaired. Frequently employed agonists include collagen, epinephrine, ADP, U46619 (a TxA₂ analog), arachidonic acid, ristocetin, and the calcium ionophore A23187. Platelet responses to these agonists with the exception of ristocetin are dependent on active metabolic processes in platelets. In contrast, ristocetin-induced clumping of platelets occurs to a large degree even in the presence of metabolic inhibitors and in formalin-fixed platelets; therefore, it is often referred as **agglutination**.

Although of paramount importance as a platelet stimulus in vivo, thrombin is difficult to employ with PRP because of interference from the formation of fibrin. The partially trypsinized γ -thrombin, however, retains platelet-stimulating activity but largely lacks clotting activity and can be useful (Charo, 1977). Platelet responses to thrombin are mediated by a G-protein-coupled seven-transmembrane receptor that is cleaved by thrombin. Thus, thrombin receptor activating peptide, consisting of amino acid sequence SFLLRN, derived from the extracellular **tethered ligand** region of the thrombin receptor (Furman, 1998), is useful in platelet function testing. Agonists such as collagen, thrombin, and TxA₂ are capable of directly inducing secretion and further TxA₂ synthesis, in addition to inducing aggregation. In contrast, secretion and TxA₂ synthesis following platelet stimulation with the agonists ADP or epinephrine may be considered secondary responses after a threshold level of aggregation has first been achieved (Cattaneo, 2009). Mezzano and coworkers have recently reviewed the potential diagnostic yields and the limitations of aggregation and secretion studies (Mezzano, 2009).

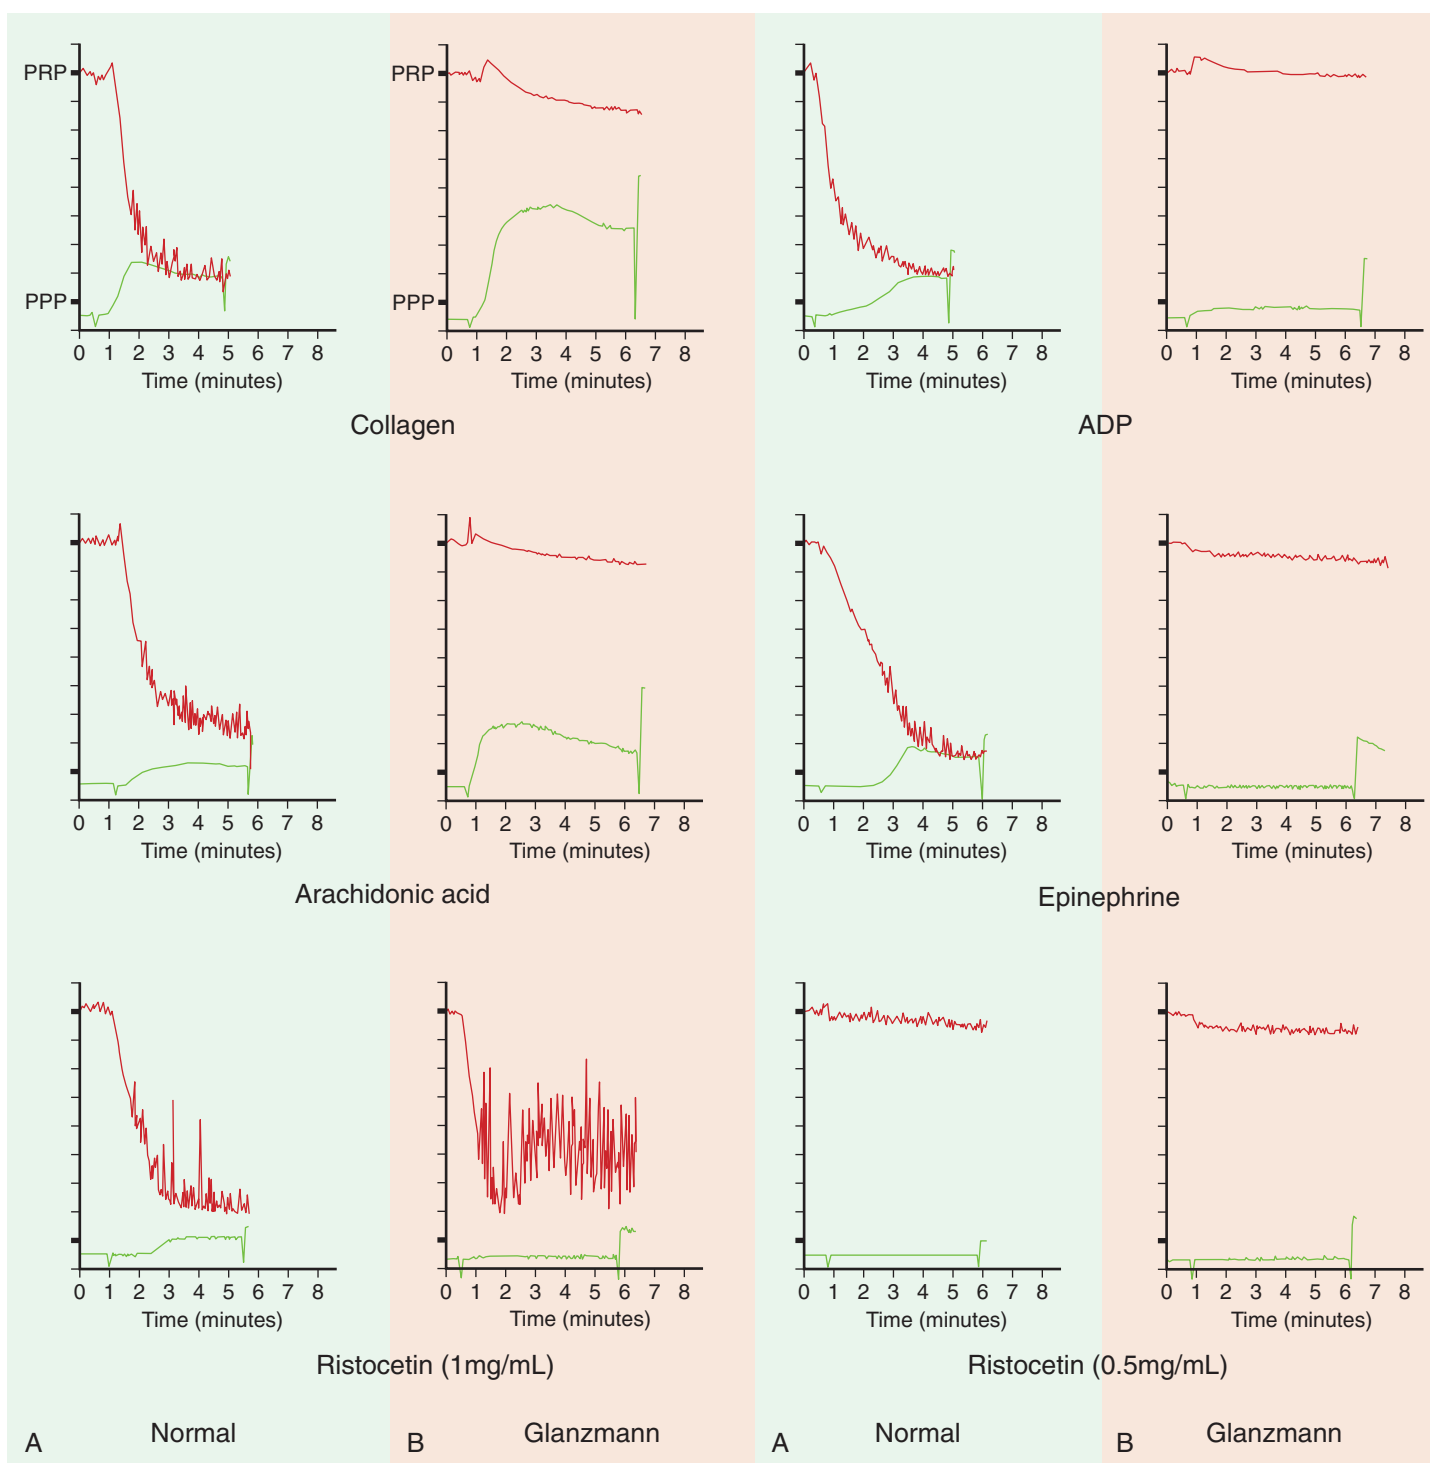

Figure 40-4 Platelet studies with lumiaggregometry in Glanzmann thrombasthenia. **A**, Normal pattern. Simultaneously measured platelet aggregation and secretion of adenosine triphosphate (ATP) (lumiaggregometry) in Glanzmann thrombasthenia. In each panel, the upper tracing displays platelet aggregation, with increasing light transmittance and aggregation shown as downward deflection. With platelet-rich plasma (PRP) initially set at 90% full vertical scale, and platelet-poor plasma (PPP) at 10%, the maximum possible downward deflection would be to the level of the PPP line. The lower tracing in each panel displays platelet secretion of ATP (monitored as luminescence when secreted ATP reacts with luciferin-luciferase reagent present in the cuvet) as an upward deflection. **B**, Patient with Glanzmann thrombasthenia. Simultaneous measurement of aggregation and a marker of dense granule secretion provide information on two responses of platelets to activation: aggregation and secretion. Note that the Glanzmann patient's platelets do aggregate in response to ristocetin: Even in the absence of glycoprotein (GP)IIb/IIIa, which functions as a receptor for platelet bridging by fibrinogen, ristocetin can facilitate the bridging together of platelets through the binding of plasma von Willebrand factor to the GPIb α chains present in normal numbers in Glanzmann platelets (see Fig. 40-6). (Modified with permission from Miller JL, Schumackher H, Rock W, Stass S, editors. *Handbook of hematologic pathology*. New York: Marcel Dekker; 2000.)

Other methods have also been developed to test platelet function. Impedance measurements, as opposed to monitoring of light transmission, have been used to study platelet aggregation, not only in PRP but also in whole blood (Cardinal, 1980). Following the addition of a platelet agonist to the stirred sample, conductance between two electrodes falls as platelets aggregate upon electrode surfaces. The resulting curves of electrical impedance over time share many similarities to those of light transmittance

recordings, although characteristic differences between these two approaches have been noted (Ingeman-Wojenski, 1984; Joseph, 1987). When impedance aggregometry is combined with ATP secretion measurement on whole blood samples (Ingeman-Wojenski, 1984), relatively rapid evaluation of platelet function, requiring only a small volume of blood, may be performed (McGlasson, 2009). Additionally, platelet aggregation in whole blood may be monitored optically by means of the coaggregation

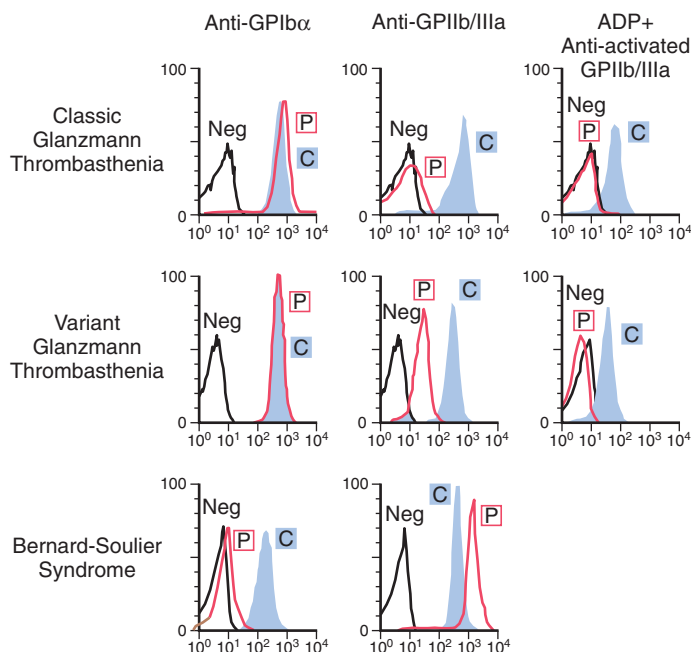

Figure 40-5 Flow cytometric evaluation of platelet membrane glycoprotein disorders. Platelets from normal controls (C) or from patients (P) were incubated with monoclonal antibodies against glycoprotein (GP)Ib α , GPIIb/IIIa, or a monoclonal antibody (Pac1) that recognizes only the conformationally altered active form of GPIIb/IIIa that normally occurs following platelet stimulation with agonists (e.g., adenosine diphosphate [ADP]). In the patient with classic Glanzmann thrombasthenia shown in the upper panel, there is virtual absence of GPIIb/IIIa, although GPIb α is present at normal levels. In the variant of Glanzmann thrombasthenia shown in the middle panel, although an intermediate level of expression of GPIIb/IIIa is apparent, a more severe loss of ability to adopt the active conformation of this receptor occurs upon stimulation of the platelets with ADP. In the patient with Bernard-Soulier syndrome shown in the lower panel, a severe deficiency of GPIb α expression but no decrease in GPIIb/IIIa expression is seen. (Modified with permission from Nurden AT, George JN. *Inherited disorders of the platelet membrane: Glanzmann thrombasthenia, Bernard-Soulier syndrome, and other disorders*. In: Colman RW, editor. *Hemostasis and thrombosis: basic principles and clinical practice*. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2001.)

of fibrinogen-coated beads impregnated with a dye that absorbs light in the infrared region of the electromagnetic spectrum. This approach has been introduced recently for assessing the effect of treatment with platelet inhibitors (see later).

The contractile abilities of activated platelets also result in contraction (or **retraction**) of formed clots. In the test tube, **clot retraction** may be quantitatively assessed (Taylor, 1970). In thrombocytopenia or Glanzmann thrombasthenia, clot retraction is delayed or incomplete. GPIIb/IIIa appears required for clot retraction (Coller, 1983). Although the tripeptide recognition sequence Arg-Gly-Asp (RGD) binding sites of fibrinogen play a major role in the binding of fibrinogen to GPIIb/IIIa with subsequent fibrinogen-mediated platelet aggregation, specific sites have been identified within the fibrinogen γ -chain that appear to subserve clot retraction (Podolnikova, 2003).

EVALUATION OF PLATELET FUNCTION USING FLOW CYTOMETRY

Flow cytometry has proved useful not only for measuring the expression of major glycoprotein receptors on the platelet surface, but also for assessing the ability of GPIIb/IIIa to undergo conformation change upon challenge of platelets with appropriate agonists (see Fig. 40-5). Owing to the small volumes of blood required to perform flow cytometry, this technique can be particularly valuable in diagnostic evaluations of small children and neonates (Israels, 2009). In vivo, aggregates of platelets developing within vessels are termed thrombi.

Platelet activation also leads to remarkable translocation of P-selectin from its intracellular α -granule storage site to the outer membrane surface of the platelet, where it may be readily assessed by flow cytometry. Under conditions of platelet activation in which microparticles bud off from the platelet membrane, P-selectin is also exposed on the outer surface of the microparticles. Microparticle P-selectin, or P-selectin derived from other sources, is capable of binding to P-selectin glycoprotein ligand (PSGL)-1 expressed by monocytes, which, in turn, leads to expression of circulating tissue factor (Cambien, 2004). Platelet P-selectin may also bind to PSGL expressed by neutrophils, injured endothelial cells, and a variety of other cells in particular disease states (Shattil, 1987; Rao, 1998; Evangelista, 1999; Andre, 2004; Cambien, 2004; Furie, 2004; Michelson, 2006; Michelson, 2007).

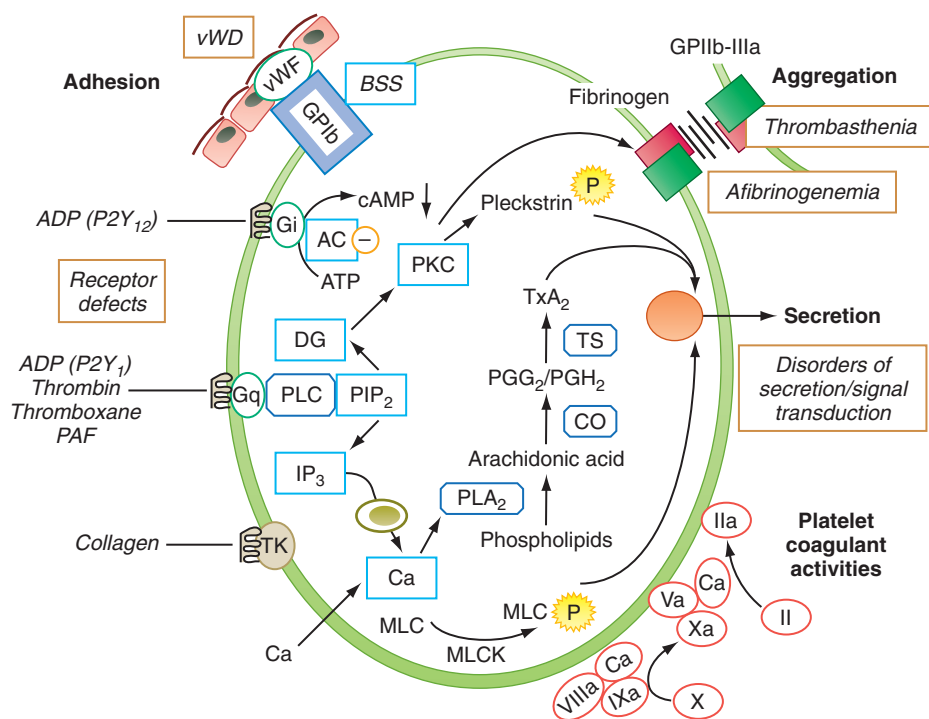

Figure 40-6 A schematic representation of selected platelet responses to activation and congenital disorders of platelet function. The Roman numerals in the circles represent coagulation factors. (Modified with permission from Rao AK. *Congenital disorders of platelet function: disorders of signal transduction and secretion*. *Am J Med Sci* 1998;316:69-76.) AC, Adenyl cyclase; BSS, Bernard-Soulier syndrome; CO, cyclooxygenase; DAG, diacylglycerol; G, GTP-binding protein; IP₃, inositol trisphosphate; MLC, myosin light chain; MLCK, myosin light chain kinase; P2Y₁, P2Y₁₂, G-protein-coupled adenosine diphosphate (ADP) receptors; PAF, platelet-activating factor; PGG₂/PGH₂, prostaglandin arachidonic pathway intermediates; PIP₂, phosphatidylinositol bisphosphate; PKC, protein kinase C; PLA₂, phospholipase A₂; PLC, phospholipase C; TK, tyrosine kinase; TS, thromboxane synthase; vWD, von Willebrand disease; vWF, von Willebrand factor.

TABLE 40-3

Mechanisms of Platelet Destruction

Type of thrombocytopenia	Specific example(s)
Immune Mediated	
Autoantibody-mediated platelet destruction by reticuloendothelial system (RES)	Primary immune thrombocytopenic purpura; secondary immune thrombocytopenia associated with lymphoproliferative disease; collagen vascular disease; infections such as infectious mononucleosis; human immunodeficiency virus syndrome
Alloantibody-mediated platelet destruction by RES	Neonatal alloimmune thrombocytopenia; posttransfusion purpura; passive alloimmune thrombocytopenia; alloimmune platelet transfusion refractoriness
Drug-dependent, antibody-mediated platelet destruction by RES	Drug-induced immune thrombocytopenic purpura (e.g., quinine)
Platelet activation by binding of immunoglobulin G (IgG) Fc of drug-dependent IgG to platelet FcγIIa receptors	Heparin-induced thrombocytopenia
Non-Immune Mediated	
Platelet activation by thrombin or proinflammatory cytokines	Disseminated intravascular coagulation; septicemia/systemic inflammatory response syndromes
Platelet destruction via ingestion by macrophages (hemophagocytosis)	Infections; certain malignant lymphoproliferative disorders
Platelet destruction through platelet interactions with altered von Willebrand factor	Thrombotic thrombocytopenic purpura; hemolytic-uremic syndrome
Platelet losses on artificial surfaces	Cardiopulmonary bypass surgery; use of intravascular catheters
Decreased platelet survival associated with cardiovascular disease	Congenital and acquired heart disease; cardiomyopathy; pulmonary embolism

Modified with permission from Warkentin TE, Kelton JG. Thrombocytopenia due to platelet destruction and hypersplenism. In: Hoffman R, Benz EJ Jr, Shattil SJ, et al, editors. Hematology: basic principles and practice. Philadelphia: Elsevier Churchill Livingstone; 2005, p. 2305–25.

QUANTITATIVE PLATELET DISORDERS

THROMBOCYTOPENIA

Decreased platelet production and increased platelet destruction (Table 40-3) constitute two of the major causes of thrombocytopenia. Additionally, decreased numbers of circulating platelets may be seen with splenomegaly of any cause, because of the resulting increase in sequestration of platelets by the spleen.

Congenital Thrombocytopenia

Congenital thrombocytopenias are being recognized with increasing frequency, and several distinct genetic abnormalities have been documented in such patients (Drachman, 2004; Althaus, 2009). Patients with these entities may present with isolated thrombocytopenia or with this disorder in conjunction with characteristic syndromes. From a practical point of view, they may be characterized based on inheritance patterns or on the size of the platelets. A diverse group of autosomal dominant syndromes, referred to as **MYH9-related macrothrombocytopenias**, include the May-Hegglin anomaly, Fechtner syndrome, Epstein syndrome, and Sebastian syndrome and share features of increased platelet size, cytoplasmic inclusions in leukocytes (Döhle bodies), and premature release of platelets. These entities arise from mutations in the *MYH9* gene encoding non-muscle myosin heavy chain IIA, a contractile cytoskeletal protein. All of the *MYH9* syndromes have macrothrombocytopenia; other features such as nephritis, sensorineural deafness, and cataracts serve to distinguish them (Althaus, 2009).

Other congenital thrombocytopenias inherited in an autosomal dominant manner include the velocardiofacial syndrome (VCF) and the DiGeorge syndrome, which arise owing to deletions within chromosome 22q11 and are associated with cardiac abnormalities, parathyroid and thymus insufficiencies, cognitive impairment, and facial dysmorphism (VCF only); and the Paris-Trousseau/Jacobsen syndrome, which is characterized by psychomotor retardation and facial and cardiac abnormalities, and arises as the result of deletion of a portion of chromosome 11,11q23–24, which encompasses the transcription factor *FLI-1* gene. Platelets in the latter disorder are increased in size and have giant α -granules. In patients who have the familial platelet disorder with predisposition to acute myeloid leukemia, autosomal dominant thrombocytopenia occurs secondary to mutations in the *RUNX1/CBF42/AML1* gene. In these patients, platelet function is also abnormal (Song, 1999), and the platelets are of normal size. Patients with the Bernard-Soulier syndrome (BSS) have macrothrombocytopenia, which is inherited in an autosomal recessive manner, and the primary abnormality is a deficiency of the GPIb/IX/V complex on platelets (discussed later).

It is interesting to note that a dominant form of macrothrombocytopenia (Mediterranean macrothrombocytopenia) has been described in

southern Europe; this has been associated with mutations in GPIb α and is considered a heterozygous form of the BSS (Savoia, 2001). Congenital amegakaryocytic thrombocytopenia is an autosomal recessive disorder associated with mutations in the thrombopoietin receptor *Mpl* and is characterized by severe thrombocytopenia and absence of megakaryocytes in the bone marrow. Patients with the Wiskott-Aldrich syndrome (WAS) and related X-linked thrombocytopenia have mutations in the *WAS* gene and characteristically have small platelets. Other causes of congenital thrombocytopenia include the gray platelet syndrome (GPS) (see later) and thrombocytopenia with absent radii syndrome, which is associated with skeletal abnormalities and is inherited in an autosomal recessive manner. In general, patients with congenital thrombocytopenia may have associated defects in platelet responses, in addition to decreased counts. Establishing the diagnosis of congenital thrombocytopenia is important because many patients with these entities often get labeled as having **chronic immune thrombocytopenia** and are subjected to inappropriate therapy.

Acquired aplastic anemias involving the erythroid and granulocytic lines, as well as the megakaryocytic line, are seen more commonly than are pure megakaryocytic aplasias. Toxic chemical exposures, viral illnesses, and, frequently, unexplained causes may underlie the aplasia.

Study of the bone marrow may be required to assess whether the thrombocytopenia is due to failure of platelet production. Bone marrow aspirates are often less reliable than bone marrow biopsies for enumerating the megakaryocytes present. In some instances, abnormalities in megakaryocyte structure may be found. In contrast to estimations of megakaryocyte numbers, it is usually difficult to assess abnormalities in megakaryocyte size or lobulation pattern from biopsy or clot sections. This is because one section may sample only a small portion of the relatively large megakaryocyte cell. For such purposes, a well-prepared Wright-Giemsa stain on an aspirate smear or on a biopsy touch preparation is typically most helpful.

Immune Thrombocytopenic Purpura

One of the most important and frequently encountered forms of enhanced consumption of platelets is the acquired disorder, immune thrombocytopenic purpura (ITP). As recently defined by an international consensus conference (Rodeghiero, 2009), **primary** ITP is a diagnosis of exclusion, made in the absence of other causes or disorders associated with thrombocytopenia—which, by contrast, would favor a diagnosis of **secondary** ITP (Table 40-4, *upper panel*). The clinical history is usually helpful in arriving at a tentative diagnosis, and in particular in distinguishing between the newly diagnosed, persistent, chronic, and severe forms of secondary ITP, as defined in Table 40-4. This group also recommended that a platelet count of <100,000 platelets/ μ L should be employed as a threshold for diagnosis. This threshold seeks to avoid overdiagnosis of disease in apparently healthy people with platelet counts of 100,000–150,000/ μ L and also to avoid inclusion of most women with pregnancy-related thrombocytopenia. A companion consensus conference report

TABLE 40-4

Immunologic Thrombocytopenic Purpura (ITP)

PROPOSED DEFINITIONS OF DISEASE

Primary ITP:

- Primary ITP is an autoimmune disorder characterized by isolated thrombocytopenia (peripheral platelet count $<100 \times 10^9/L$) in the absence of other causes and disorders that may be associated with thrombocytopenia.
- The diagnosis of primary ITP remains one of exclusion; no robust clinical or laboratory parameters are currently available to establish this diagnosis with accuracy.
- The main clinical problem with primary ITP is an increased risk of bleeding, although bleeding symptoms may not always be present.

Secondary ITP:

- All forms of immune-mediated thrombocytopenia except primary ITP*

Phases of the disease:

- Newly diagnosed ITP: within 3 months from diagnosis
- Persistent ITP: between 3 and 12 months from diagnosis; includes patients not reaching spontaneous remission and not maintaining complete response off therapy
- Chronic ITP: lasting for longer than 12 months
- Severe ITP: presence of bleeding symptoms at presentation sufficient to mandate treatment, or occurrence of new bleeding symptoms requiring additional therapeutic intervention with a different platelet-enhancing agent or an increased dose

RECOMMENDATIONS FOR THE DIAGNOSIS OF ITP IN CHILDREN AND ADULTS

Basic evaluation

- Patient history
- Family history
- Physical examination
- Complete blood count and reticulocyte count
- Peripheral blood film
- Quantitative immunoglobulin measurement*
- Bone marrow examination (in selected patients)
- Blood group (Rh)
- Direct antiglobulin test
- *Helicobacter pylori*†
- HIV†
- HCV†

Tests of potential utility in the management of an ITP patient

- Glycoprotein-specific antibody
- Antiphospholipid antibodies (including anticardiolipin and lupus anticoagulant)
- Antithyroid antibodies and thyroid function
- Pregnancy test in women of childbearing potential
- Antinuclear antibodies
- Viral PCR for parvovirus and CMV

Tests of unproven or uncertain benefit

- TPO
- Reticulated platelets
- PaltG
- Platelet survival study
- Bleeding time
- Serum complement

Upper panel: ITP: Proposed definitions of disease.

Modified with permission from Rodeghiero F, Stasi R, Gernsheimer T. Standardization of terminology, definitions and outcome criteria in immune thrombocytopenic purpura of adults and children: report from an international working group. *Blood* 2009;113:2386–93.

*The acronym ITP should be followed by the name of the associated disease (for thrombocytopenia after exposure to drugs, the term “drug-induced” should be used) in parentheses, for example, “secondary ITP (lupus-associated),” secondary ITP (HIV-associated),” and “secondary ITP (drug-induced).”

Lower panel: Recommendations for the diagnosis of ITP in children and adults.

Modified with permission from Provan D, Stasi R, Newland AC. International consensus report on the investigation and management of primary immune thrombocytopenia. *Blood* 2010;115:168–86.

CMV, Cytomegalovirus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; PaltG, platelet-associated immunoglobulin G; PCR, polymerase chain reaction; Rh, rhesus; TPO, thrombopoietin.

*Quantitative immunoglobulin level measurement should be considered in children with ITP and is recommended in those children with persistent or chronic ITP as part of the reassessment evaluation.

†Recommended by the majority of international consensus panel members for adult patients regardless of geographic locale.

(Provan, 2010) proceeded to address a number of critical issues concerning the diagnosis and management of ITP. No single laboratory test for the diagnosis of ITP was awarded “gold standard” status by this group.

A variety of laboratory approaches were deemed to be of “potential utility” or of “unproven or uncertain benefit,” as shown in Table 40-4 (*lower panel*). Of particular interest, antecedent infectious diseases appear to be present in approximately 60% of pediatric patients with ITP. Molecular mimicry, in which immune responses initially directed against an infectious organism cross-react with platelet antigens in both children and adults, appears likely in a number of instances, including infection with human immunodeficiency virus (Karparkin, 1992, 1995) and hepatitis C virus (HCV) (Stasi, 2009; Zhang, 2009). In recent years, increasing attention has also been paid to the association between *Helicobacter pylori* infection and ITP (Semple, 2009; Stasi, 2009). A possible mechanistic explanation for the thrombocytopenia is that *H. pylori* organisms may trigger P-selectin-dependent platelet aggregation and increased PS expression (Yeh, 2010).

In addition to accelerated destruction of platelets in ITP, evidence suggests impairment in the production of new platelets by megakaryocytes (McMillan, 2007; Cines, 2009). This may be due to detrimental effects on megakaryocytes by infectious agents, as well as to immunologic mechanisms affecting platelet precursors. The observation that a number of patients with chronic forms of ITP do respond to new thrombopoietin mimetic agents would appear to add further support for suppression of platelet production as an important mechanism in some patients with ITP (McMillan, 2007).

The study of platelet-associated immunoglobulins in patients suspected of having ITP has been widely employed in an effort to identify immune-mediated processes. However, the predictive value of positive findings in such cases remains in serious question because immunoglobulins that do not influence platelet survival or function may be associated with platelets in various clinical settings (Kelton, 1982), and platelet-associated IgG may be nonspecifically elevated in disorders associated with elevated plasma IgG. Alternatively, a number of enzyme-linked immunosorbent assays (ELISAs) are available, whereby antibodies eluted from patient platelets or serum are reacted against purified glycoprotein complexes typically immobilized in wells by murine monoclonal antibodies. Many pathologic antibodies may fail to recognize their epitopes within the glycoprotein targets provided in this artificial manner (especially in the case of GPIb). Additionally, false-positive results may occur when patient serum is used if human antimouse antibodies are present in sufficient titer. Some laboratories have also used the monoclonal antibody immobilization of platelet antigen (MAIPA) approach to detect autoantibody obtained directly from patient serum or eluted from patient platelets, which is directed at specific platelet glycoprotein complexes (Kiefel, 1987; Hewitt 1994; Clouet-Sanchez, 1996; Cordiano, 1996). MAIPA assays preserve platelet target antigens in a more native form than most preceding techniques. Results closely matching those of the MAIPA assay have been reported by using a multicolor flow cytometric technique (Nguyen, 2004). However, a true “gold standard” assay for ITP still appears to be a goal for the future, rather than a present reality.

Drug-Induced Thrombocytopenia

Drug-induced thrombocytopenia must always be considered as a cause of acute thrombocytopenia. This disorder can be particularly difficult to identify in patients who are on multiple drugs. Certain drugs such as heparin, quinidine, gold, and sulfa antibiotics, however, have had a relatively higher frequency of causing thrombocytopenia than most other drugs. In this context, the laboratory may play a helpful role if a drug-dependent antibody interacting with the platelets can be demonstrated. It is interesting that whereas normal platelets possess a binding site for anti-platelet antibodies implicated in thrombocytopenia associated with quinidine or quinine, platelets from patients with BSS do not appear to have this receptor (Kunicki, 1978b). Berndt (1985) has provided evidence that such antibodies may be binding to GPIX, to the β -subunit of GPIb, or to a region defined by the association of GPIb and GPIX. It has been suggested by Pfueller (1988), however, that quinine- and quinidine-induced thrombocytopenia may result from antibodies that are heterogeneous among patients, with recognition of neoantigens composed of various epitopes on the platelet surface and the drug, or of new conformations of platelet glycoproteins induced by the drug. Additionally, in some patients, quinidine-dependent antibodies may be directed against epitopes present within the GPIIb/IIIa complex (Pfueller, 1988; Chong, 1991; Visentin, 1991; Nieminen, 1992).

Immune thrombocytopenia has been well described with administration of the platelet GP IIb/IIIa antagonist drugs abciximab, eptifibatide, and tirofiban. All three agents can cause acute severe thrombocytopenia, even following first exposure to the drug (Aster, 2007). Acute thrombocytopenia results from drug-dependent, preexisting antibodies that bind to the GPIIb/IIIa complex; additionally, drug-dependent antibodies may subsequently arise as an immune response to the drug administration (Aster, 2004).

Heparin-Induced Thrombocytopenia

See Chapter 42 for an extensive discussion of this entity.

Thrombotic Thrombocytopenic Purpura

The microangiopathic disorders referred to as thrombotic thrombocytopenic purpura (TTP) and the hemolytic-uremic syndrome (HUS) have long been considered to be close relatives better distinguished on the basis of clinical presentation than upon laboratory findings. This situation changed dramatically in 1998, with two independent groups (Furlan, 1998; Tsai, 1998) demonstrating that the pathogenesis of TTP was related to deficient activity of a plasma metalloproteinase, known as ADAMTS-13, which normally cleaves unusually large vWF molecules (so called ULvWF) released by endothelial cells. This enzyme deficiency results in the persistence of unusually large vWF molecules that are capable of binding both to endothelial cells and to platelets, leading to a meshwork of platelet-rich thrombi in the microcirculation (Moake, 1986; Tsai, 1998). Although an earlier study (Padilla, 2004) had suggested that P-selectin might function as the endothelial anchor for ULvWF, a more recent study using P-selectin-deficient mice concludes that P-selectin appears unnecessary for anchoring to occur, and raises an alternative hypothesis that electrostatic charges presented by endothelial glycosaminoglycans may serve as anchoring sites for ULvWF (Chauhan, 2007).

In HUS, plasma vWF-cleaving protease activity is not severely decreased as observed in TTP (Furlan, 1998). Nevertheless, in typical forms of *Escherichia coli*- or *Shigella* toxin-associated diarrheal HUS, long vWF strings have been observed to bind both to endothelial cells and to platelets, and the possibility has been raised that the toxin may interfere with ADAMTS-13 binding to vWF strings (Moake, 2009).

Application of ADAMTS-13 testing results has increasingly been found to be helpful both for the purpose of prognostication and for guidance in treatment, such as the decision to institute anti-B lymphocyte immunotherapy (Coppo, 2010; Hovinga, 2010; Zheng, 2010). However, both the sensitivity and the specificity of plasma ADAMTS-13 levels for the diagnosis of TTP have been called into question in a number of studies. Thus, neither the presence of a normal level of ADAMTS-13 (implying normal gene product) nor the absence of demonstrable neutralizing antibodies in the plasma of patients otherwise meeting clinical criteria for TTP is sufficient to exclude this diagnosis (George, 2004; Peyvandi, 2004). Patients with systemic connective tissue disorders (Mannucci, 2003), as well as those with ITP, disseminated intravascular coagulation (DIC), and a variety of other disorders, have also been found to have decreased levels of ADAMTS-13 (Moore, 2001). The extent to which these findings reflect idiosyncrasies of the particular testing approaches employed, as opposed to reflecting shared or distinct pathophysiologic mechanisms among

TABLE 40-5

Reactive Conditions in Which Elevated Platelet Counts May Be Found

Transient processes	• Connective tissue disorders
• Acute blood loss	• Temporal arteritis
• Recovery (rebound) from thrombocytopenia	• Inflammatory bowel disease
• Acute infection or inflammation	• Tuberculosis
• Response to exercise	• Chronic pneumonitis
Sustained processes	• Drug reactions
• Iron deficiency	• Vincristine
• Hemolytic anemia	• All-trans-retinoic acid
• Asplenia (e.g., after splenectomy)	• Cytokines
• Cancer	• Growth factors
• Chronic inflammatory or infectious diseases

these diverse disorders, is presently unresolved. The assays originally developed involved a number of steps in the testing process, including reacting the patient's plasma with a protease-free vWF substrate previously denatured with guanidine or urea, performing gel electrophoresis on degraded vWF, immunoblotting, and demonstrating an abnormal persistence of higher molecular weight vWF multimers. Continual efforts have been made to simplify the ADAMTS-13 assays. Early modification of this method was applied to the final step, where a technically less demanding ELISA of the residual ability of vWF to bind to a collagen-coated surface was substituted for vWF multimeric analysis (Gerritsen, 1999). Subsequently, efforts were directed toward the development of one-step, simplified assays of plasma proteolytic activity against molecules recapitulating the critical residues of vWF required for proteolysis by ADAMTS-13 (Kokame, 2004; Whitelock, 2004). Such assays offer the advantage of rapid turnaround times; their potential role in such diagnostic decision-making is not yet clear.

THROMBOCYTOSIS

Increased platelet count, or thrombocytosis, may arise as a result of a benign, reactive process (Table 40-5) or alternatively be a manifestation of a neoplastic disorder (Griesshammer, 1999; Schafer, 2004) (see later). The blood film should be reviewed to confirm the increase in platelets. Clues as to whether one is dealing with an autonomous clonal process or a reactive secondary process may be provided by a number of clinical and laboratory findings (Table 40-6).

It has been stated that reactive processes typically do not produce platelet counts over $1000 \times 10^9/L$; this criterion is not reliable for diagnosis. Patients with myeloproliferative syndromes may develop bleeding or thrombotic events. In a meta-analysis reviewing patients with essential thrombocythemia, platelet counts repeatedly failed to achieve significance as a risk factor for thrombosis (Finazzi, 2008). Unless additional risk factors are present, thrombotic events are less likely to occur in secondary than in primary thrombocytosis (Griesshammer, 1999). Patients with myeloproliferative syndromes may have abnormalities in platelet and megakaryocyte structure and platelet function (reviewed later). The abnormalities in aggregation studies do not have the ability to predict bleeding or thrombotic events. Despite statistically significant abnormalities when populations of patients with myeloproliferative disorders or with reactive thrombocytosis are compared, in the individual patient platelet sizing parameters and platelet function studies are unlikely to be capable of differentiating these disorders (Sehayek, 1988).

INHERITED DISORDERS OF PLATELET FUNCTION

OVERVIEW

Table 40-7 provides a classification based on platelet functions or responses that are abnormal (see Fig. 40-6). Although several of these disorders are

TABLE 40-6
Clinical Findings That May Distinguish Between Clonal and Secondary (Reactive) Thrombocytosis

Finding	Clonal thrombocytosis*	Secondary (reactive) thrombocytosis
Underlying systemic disease	No	Often clinically apparent
Digital or cerebrovascular ischemia	Characteristic	No
Large-vessel arterial or venous thrombosis	Increased risk	No
Bleeding complications	Increased risk	No
Splenomegaly	Yes, in about 40% of patients	No
Peripheral blood smear	Giant platelets	Normal platelets
Platelet function	May be abnormal	Normal
Bone marrow megakaryocytes:		
• Number	Increased	Increased
• Morphologic features	Giant, dysplastic forms with increased ploidy; associated with large masses of platelet debris	Normal

Reprinted with permission from Schafer AL. Thrombocytosis. *N Engl J Med* 2004;350:1211–9.
 *Clonal thrombocytosis includes essential thrombocythemia and other myeloproliferative disorders.

TABLE 40-7
Classification of Inherited Disorders of Platelet Function

- Defects in platelet–vessel wall interaction (disorders of adhesion)
 - von Willebrand disease (deficiency or defect in plasma von Willebrand factor)
 - Bernard-Soulier syndrome (deficiency or defect in glycoprotein [GP] Ib/IX)
- Defects in platelet–platelet interaction (disorders of aggregation)
 - Congenital afibrinogenemia (deficiency of plasma fibrinogen)
 - Glanzmann thrombasthenia (deficiency or defect in GPIIb/IIIa)
- Disorders of platelet secretion and abnormalities of granules
 - Storage pool deficiency
 - Quebec platelet disorder
- Disorders of platelet secretion and signal transduction defects (primary secretion defects)
 - Defects in platelet–agonist interaction (receptor defects)
 - Receptor defects: thromboxane A₂, collagen, adenosine diphosphate (ADP), epinephrine
 - Defects in G-protein activation
 - Gα_q deficiency
 - Gα_s abnormalities
 - Gα_{i1} deficiency

rare, they shed enormous light on platelet physiology. Of note, not all of these disorders are due to a defect in the platelets per se. Some, such as vWD and afibrinogenemia, result from deficiencies of plasma proteins essential for normal platelet function. Moreover, in most patients with inherited abnormalities in platelet aggregation responses, the underlying

molecular mechanisms remain unknown. In patients with defects in platelet–vessel wall interactions (adhesion disorders), adhesion of platelets to subendothelium is abnormal. The two disorders in this group are von Willebrand disease (vWD), due to a deficiency or abnormality in plasma vWF, and the BSS, in which platelets are deficient in GPIb (and GPV and GPIX); in both disorders, platelet–vWF interaction is compromised. Binding of fibrinogen to the GPIIb/IIIa complex is a prerequisite for platelet aggregation. Disorders characterized by abnormal platelet–platelet interactions (aggregation disorders) arise because of a severe deficiency of plasma fibrinogen (congenital afibrinogenemia) or because of a quantitative or qualitative abnormality of the platelet membrane GPIIb/IIIa complex, which binds fibrinogen (Glanzmann thrombasthenia). Patients with defects in platelet secretion and signal transduction constitute a heterogeneous group lumped together for convenience of classification, rather than on the basis of an understanding of the specific underlying abnormality. The major common characteristics in these patients, as currently perceived, are abnormal aggregation responses and an inability to release dense granule contents upon activation of PRP with agonists such as ADP, epinephrine, and collagen. In aggregation studies, the second wave of aggregation is blunted or absent. Platelet dysfunction in such patients may arise from diverse mechanisms. A small proportion of these patients have a deficiency of dense granule stores (storage pool deficiency). In some of the other patients, impaired secretion results from aberrations in signal transduction events that lead to secretion and aggregation. Another group consists of patients who have an abnormality in interactions of platelets with proteins of the coagulation system; the best described is the Scott syndrome, characterized by impaired transmembrane migration of procoagulant phospholipid PS. Defects related to platelet cytoskeleton or structural proteins may also be associated with platelet dysfunction, as, for example, in WAS. Recent studies document impaired platelet function associated with mutations in transcription factors (RUNX1, GATA1) that regulate expression of important platelet proteins. In addition to the groups discussed previously, some patients have abnormal platelet function associated with systemic disorders, such as Down syndrome and the May-Hegglin anomaly, where specific aberrant platelet mechanisms are unclear.

DISORDERS OF PLATELET ADHESION

Bernard-Soulier Syndrome

BSS is a rare autosomal recessive platelet function disorder resulting from an abnormality in the platelet GPIb/V/IX complex, which consists of four polypeptides and distinct gene products (GPIbα, GPIbβ, GPV, and GPIX). This complex mediates the binding of vWF to platelets and thus plays a major role in platelet adhesion to the subendothelium, especially at higher shear rates. GPIb exists in platelets as a complex consisting of GPIb, GPIX, and GPV. Approximately 25,000 copies of GPIb/V/IX complex are present on platelets, and these are reduced or abnormal in the BSS. Although GPV is also decreased in BSS platelets, it is not required for platelet surface GPIb/IX expression. Bleeding time is markedly prolonged, platelet counts

are moderately decreased, and, on the peripheral smear, platelets are increased in size. In platelet aggregation studies, responses to the commonly used agonists ADP, epinephrine, thrombin, and collagen are normal. Characteristically, the aggregation in PRP in response to ristocetin is decreased or absent—a feature shared with patients with vWD. However, plasma vWF and factor VIII are normal in BSS. Secretion (dense granules) on activation with thrombin may be decreased.

The blood film from a patient with BSS may resemble that from ITP patients in terms of thrombocytopenia and enlarged platelet size. Findings in the aggregometer are almost the reciprocal of those in Glanzmann thrombasthenia: Aggregation and secretion are normal with all agents *except* ristocetin. In addition, the release reaction induced by thrombin may be decreased. Unlike vWD, in which platelet agglutination is diminished in response to ristocetin, in BSS the addition of exogenous vWF (present in plasma cryoprecipitate fractions) does not restore ristocetin-induced agglutination of platelets. This important difference is attributable to the finding that, whereas vWD is characterized by a deficiency in plasma vWF, in BSS the deficiency is seen in the platelet membrane receptor for vWF.

When platelet surface membrane glycoproteins from patients with BSS are analyzed, a striking decrease in GPIIb is noted (Nurden, 1975; Whitelock, 2004). Molecular studies have identified a variety of specific point mutations or deletions in GPIIb α , GPIIb β , and GPIIX that, when present in homozygous or doubly heterozygous fashion, result in a classic BSS phenotype. Mutations in the gene encoding GPIIb α are most common. A point mutation in the leucine-rich region of the GPIIb α chain may also produce a Bernard-Soulier phenotype, even when expressed only by a single allele (Miller, 1992; Ware, 1993).

von Willebrand Disease

See later section on von Willebrand factor and von Willebrand disease.

DISORDERS OF PLATELET AGGREGATION

Glanzmann Thrombasthenia

Glanzmann thrombasthenia is a rare autosomal recessive disorder characterized by markedly impaired platelet aggregation, prolonged bleeding time, and relatively more severe mucocutaneous bleeding manifestations than most platelet function disorders (Nurden, 2001). It has been reported in clusters in populations where consanguinity is common. Normal resting platelets possess approximately 50,000–80,000 GPIIb/IIIa complexes on the surface. The primary abnormality in thrombasthenia is a quantitative or qualitative defect in the GPIIb/IIIa complex, a heterodimer consisting of GPIIb and GPIIIa whose synthesis is governed by distinct genes located on chromosome 17. Thus, thrombasthenia may arise owing to a mutation in either gene, with decreased platelet expression of the complex. Because of this, fibrinogen binding to platelets on activation and aggregation is impaired. A variety of distinct mutations involving GPIIb and GPIIIa have been described in patients with thrombasthenia (Franchini, 2010). Clot retraction, a function of the interaction of GPIIb/IIIa with the platelet cytoskeleton, is also impaired. The history of investigation of Glanzmann thrombasthenia has set the paradigm for the application of emerging technologies to platelet pathophysiology, as recently chronicled in a historical review of this topic (Coller, 2008).

In non-anticoagulated blood films prepared from patients with Glanzmann thrombasthenia, platelets are present in normal number and appearance but show a characteristic tendency to remain isolated, without the platelet-platelet clumping seen in normal blood films. The diagnostic hallmark of thrombasthenia is absence or marked decrease of platelet aggregation (see Fig. 40-4) in response to virtually all platelet agonists (except ristocetin), with absence of both primary and secondary waves of aggregation; the shape change response is preserved. Platelet-dense granule secretion may be decreased with some agonists (e.g., ADP) but normal on activation with thrombin. Heterozygotes have approximately half the number of platelet GPIIb/IIIa complexes, but platelet aggregation responses are completely normal.

Because the platelet antigen PI^{AI} is associated with glycoprotein IIIa, this antigen is typically decreased in patients with Glanzmann thrombasthenia (Kunicki, 1978a; Von dem Borne, 1981). Relative estimation of platelet GPIIb/IIIa molecules through binding of specific monoclonal antibodies permits diagnosis of Glanzmann thrombasthenia by flow cytometry requiring only small volumes of blood (Kunicki, 1978a; Montgomery, 1983; Kempfer, 1991). Flow cytometry has become a very

useful tool for the diagnosis of both inherited and acquired Glanzmann thrombasthenia (Giannini, 2008; Miller, 2009), as illustrated in Figure 40-5. Definitive characterization of true homozygosity or compound heterozygosity for mutations in GPIIb or GPIIIa may be undertaken by molecular techniques (Bray, 1994; French, 1998; Rosenberg, 1998; Ruan, 1998; Gonzalez-Manchon, 1999; Franchini, 2010). As recently emphasized by Nurden and coworkers, identification of mutations or deletions in the specific genes that produce abnormalities in a multichain receptor complex such as GPIIb/IIIa will become essential in gene therapy for such disorders (Nurden, 2009). Although congenital afibrinogenemia is characterized by a similar absence of platelet aggregation, in this disorder, prothrombin time, activated partial thromboplastin time, and thrombin time are markedly prolonged, although they are normal in thrombasthenia.

DISORDERS OF PLATELET GRANULES, SECRETION, AND SIGNAL TRANSDUCTION

As a unifying theme, patients lumped into this heterogeneous group generally manifest impaired secretion of granule contents and absence of the second wave of aggregation upon stimulation of PRP with ADP or epinephrine; responses to collagen, thromboxane analog (U46619), arachidonic acid, and platelet-activating factor (PAF) may also be impaired. Conceptually, platelet function is abnormal in these patients when granule contents are diminished (storage pool deficiency [SPD]), or when an aberration occurs in the activation mechanisms governing aggregation and secretion (see Table 40-7).

Deficiency of Granule Stores

The term SPD refers to patients with deficiencies in platelet content of dense granules (δ -SPD), α -granules (α -SPD), or both types of granules ($\alpha\delta$ SPD) (Hayward, 1997; Rao, 2005; Nurden, 2009).

δ -Storage Pool Deficiency

Patients with δ -storage pool deficiency (δ -SPD) have a mild to moderate bleeding diathesis associated with prolonged bleeding time. In platelet studies, the second wave of aggregation in response to ADP and epinephrine is absent or blunted, and the collagen response is markedly impaired. However, both impaired (Weiss, 1981) and normal (Ingerman, 1978) aggregation responses to arachidonic acid have been noted. Responses to epinephrine may also be variable; a second wave of aggregation is noted in some patients (Weiss, 1988). It is interesting to note that δ -SPD has been documented (Nieuwenhuis, 1987; Israels, 1990) in a number of patients with prolonged bleeding times and normal aggregation responses. Thrombin-induced secretion of acid hydrolases is also impaired in SPD platelets; this is corrected by addition of exogenous ADP.

Normal platelets possess three to eight dense granules/platelet (each 200–300 nm in diameter) (Nieuwenhuis, 1987; Israels, 1990). Under the electron microscope, dense granules are decreased in SPD platelets (White, 1971; Israels, 1990). Other methods to demonstrate a decrease in dense granules include (1) fluorescence microscopy after staining of platelets with mepacrine (quinacrine), which localizes in dense granules because of high affinity for ATP; and (2) specific staining by uranyl ions (uranaffin reaction) of both the membrane and the core of dense granules. Flow cytometry can also be applied to assess fluorescent staining of dense granules (Linden, 2004). By direct biochemical measurement, total platelet and granule ATP and ADP contents are decreased (Holmsen, 1979) along with other dense granule constituents such as calcium, pyrophosphate, and serotonin. Two thirds of platelet ATP and ADP resides in the dense granules and a smaller amount in the metabolic pool; proportionately more ADP than ATP is present in dense granules (Holmsen, 1979). Thus, in δ -SPD platelets, the ratio of total ATP to ADP is increased (>2.5) compared with that in normal platelets. Incubation of normal platelets with carbon-14-serotonin results in its incorporation into dense granules and subsequent secretion upon activation. In SPD platelets, the initial rate of uptake of carbon-14-serotonin is normal, but saturation levels and retention over 4–6 hours are decreased.

Other abnormalities reported in δ -SPD include decreased synthesis of prostaglandins, TxA_2 , and malondialdehyde in platelets activated with collagen and epinephrine, but not arachidonic acid (Weiss, 1988); impaired liberation of arachidonic acid from membrane phospholipids (Rendu, 1978); and an enhanced ADP- but not thrombin-induced rise in cytoplasmic Ca^{++} levels (Lages, 1997). Platelet procoagulant activity

(prothrombinase activity) induced upon activation has been reported to be impaired in association with an inability to maintain elevated intracellular Ca^{++} levels (Weiss, 1997).

δ -SPD has been reported in association with other inherited disorders such as the Hermansky-Pudlak syndrome (HPS) (oculocutaneous albinism and increased reticuloendothelial ceroid), the Chédiak-Higashi syndrome, WAS, thrombocytopenia with absent radii syndrome, and the Griscelli syndrome (Menasche, 2000; Gunay-Aygun, 2004). The simultaneous occurrence of δ -SPD and defects in skin pigment granules, as in HPS, points to the interrelatedness of the two types of granules with respect to genetic control—a concept further advanced by animal models (Novak, 1984; Menasche, 2000; Huizing, 2001; Gunay-Aygun, 2004).

Dense granule membranes possess the lysosomal proteins, lysosome-associated membrane protein 2 and CD63 (granulophysin or LAMP3) (Nishibori, 1993; Israels, 1996), as well as P-selectin and GPIIb/IIIa. Granulophysin is deficient in HPS platelets (Gerrard, 1991). Studies with antigranulophysin antibody demonstrated the presence of a normal number of granules in platelets of two nonalbino patients with SPD (McNicol, 1994); therefore, these patients have the granules but with reduced contents.

A substantial amount of information on SPD has been obtained from patients with HPS, which is characterized by oculocutaneous albinism, platelet SPD, and lipofuscinosis (Gunay-Aygun, 2004; Huizing, 2008). A large group of HPS patients reside in Northwest Puerto Rico, where HPS occurs in 1 in every 1800 individuals (gene frequency, 1 in 21) (Witkop, 1990). At least eight HPS-causing genes are known, leading to various subtypes of human HPS, with most patients being in HPS-1 and coming from Puerto Rico (Gunay-Aygun, 2004; Huizing, 2008). At least 14 mouse models of HPS have been reported to date; seven of these constitute models for the human subtypes (Gunay-Aygun, 2004). Together, human and mouse models have served as an invaluable source of information about vesicle formation and trafficking. Human HPS subtypes are autosomal recessive, and heterozygotes have no clinical findings. In addition to albinism, which is variable between HPS subtypes, most patients have congenital nystagmus and decreased visual acuity. Two additional manifestations have been noted in patients with HPS: granulomatous colitis and pulmonary fibrosis (Gunay-Aygun, 2004).

Chédiak-Higashi syndrome is a rare autosomal recessive disorder characterized by SPD, oculocutaneous albinism, immune deficiency, neurologic dysfunction, and the presence of giant cytoplasmic inclusions in different cells (Huizing, 2001). Chédiak-Higashi syndrome patients have defective cytotoxic T and natural killer cell function. It arises from mutations in the lysosomal trafficking regulator (*LYST*) gene on chromosome 1. The protein coded by this gene interacts with several proteins, including the SNARE complex protein HRS and signaling proteins, and participates in intracellular membrane fusion reactions and vesicle trafficking (Huizing, 2001; Tchernev, 2002).

Gray Platelet Syndrome

The term **gray platelet syndrome (GPS)** has been derived from the initial observation by Raccuglia (1971) of a gray appearance of platelets, with a paucity of granules in peripheral blood smears from a patient with a life-long bleeding disorder. Characterized by an isolated deficiency of α -granule contents, GPS patients have a lifelong bleeding diathesis of autosomal recessive inheritance, mild thrombocytopenia, and prolonged bleeding time (Weiss, 1979; Gerrard, 1980; Nurden, 2008). Under the electron microscope, platelets and megakaryocytes reveal absent or markedly decreased α -granules (Levy-Toledano, 1981). Platelets are severely and selectively deficient in α -granule proteins such as platelet factor four (PF4), β -thromboglobulin, vWF, thrombospondin, fibronectin, factor V, high molecular weight kininogen, and PDGF (Gerrard, 1980; Nurden, 1982). Platelet aggregation responses have been variable. Responses to ADP and epinephrine were normal in most patients; however, in some patients, aggregation responses to thrombin, collagen, and ADP have been impaired. Impaired thrombin-induced Ca^{++} mobilization and an increase in Ca^{++} transport have been reported in some patients. GPS is a heterogeneous disorder associated with abnormalities in α -granule formation and maturation (Nurden, 2008).

Plasma levels of PF4 and β TG have been found to be raised in some patients (Gerrard, 1980), suggesting that the defect is not in their synthesis by megakaryocytes but in their packaging into granules. Studies on megakaryocytes cultured from peripheral blood of three GPS patients show that vWF is synthesized but is secreted into extracellular space instead of normal α -granule packaging (Drouin, 2001). The neutrophils from these patients also had decreased granules. Reticulin is increased in the bone

marrow from GPS patients (Breton-Gorius, 1981; Levy-Toledano, 1981), which can be attributed to elevated plasma PDGF levels. Using complementary DNA (cDNA) microarrays, Hyman (2003) found upregulation of cytoskeletal proteins, including fibronectin 1, thrombospondins 1 and 2, and collagen VI α , in fibroblasts from a patient with GPS.

Quebec Platelet Disorder

The Quebec platelet disorder (QPD) is an autosomal dominant disorder associated with delayed bleeding and abnormal proteolysis of α -granule proteins caused by increased amounts of platelet urokinase-type plasminogen activator (Kahr, 2001; McKay, 2004). Patients are characterized by normal to reduced platelet counts, proteolytic degradation of soluble and membrane proteins of α -granules, deficiency of an α -granule factor V-binding protein called multimerin, and selective defective aggregation with epinephrine. Platelet factor V but not plasma factor V is degraded along with other α -granule proteins, fibrinogen, vWF, thrombospondin, osteonectin, fibronectin, and P-selectin. QPD appears to derive from pathologically increased expression of the urokinase plasminogen activator (uPA) in megakaryocytes caused by a *cis* regulatory defect linked to the *uPA* gene (Diamandis, 2009). This leads to an increase in platelet uPA stores, which are only partially inhibited, and in turn increased intraplatelet generation of plasmin, which degrades several platelet α -granule proteins. Additionally, the uPA released by activated QPD platelets leads to increased platelet-dependent fibrinolysis, which may contribute in a major way to the bleeding observed in QPD. Patients with QPD suffer from mucocutaneous bleeding, which often is delayed by 12–24 hours following injury and is unresponsive to platelet transfusions but responsive to fibrinolytic inhibitors (McKay, 2004).

Defects in Receptors, G-Proteins, and Platelet Signal Transduction

Signal transduction mechanisms encompass processes that are initiated by the interaction of agonists with specific platelet receptors and include responses such as G-protein activation and activation of effector enzymes such as phospholipase C and phospholipase A₂ (see Figs. 40-3 and 40-6, and also section on platelet activation and signaling events). If the key components in signal transduction are the surface receptors, the G-proteins, and the effectors, evidence now exists for specific platelet abnormalities at each of these levels.

Patients with defects in platelet-agonist interaction have impaired responses caused by an abnormality in the platelet surface receptor for a specific agonist. Such receptor defects have been documented for epinephrine, collagen, ADP, and TxA₂ (Rao, 2004; Collier, 2010). Hirata (1994) described an Arg 60-to-Leu mutation of the human TxA₂ receptor in a dominantly inherited bleeding disorder. Several patients with a defect in the P2Y₁₂ ADP receptor, which is coupled to inhibition of adenylyl cyclase, have been described (Cattaneo, 1992; Nurden, 1995; Cattaneo, 1997; Daly, 2009). Because ADP and TxA₂ play a synergistic role in platelet responses to several agonists, patients with receptor defects manifest abnormal responses to multiple agonists. Specific deficiencies in the P2Y₁ (Oury, 1999) and P2X (Oury, 2000) ADP receptors have been documented but are less well characterized.

A few patients with isolated blunting of platelet responses to collagen associated with deficiencies in platelet GPIa and GPVI have been described (Nieuwenhuis, 1985, 1986; Kehrel, 1988; Khan, 2004). Reduced surface expression by flow cytometry of GPIa on the platelets of 18 individuals from two unrelated families with an autosomally dominant bleeding disorder has been reported; Western blot analysis also showed mildly reduced GPIa. However, no mutations in GPIa or GPIIa could be demonstrated (Noris, 2006). Abnormalities of GPVI have been associated with increased bleeding tendency (Khan, 2004). Deficiency of platelet GPVI in some patients has been attributed to anti-GPVI antibody-mediated loss of this GP (Boylan, 2004). A familial defect in GPVI signaling has been described, the characterization of which involved flow cytometry, studies of aggregation and secretion, tyrosine immunoblotting, and GPVI shedding (Arthur, 2007; Dunkley, 2007). It has been proposed that metalloproteinase-mediated ectodomain shedding of GPVI may constitute a regulatory control on the reactivity of this receptor (Berndt, 2007). Last, polymorphisms of GPVI are being studied as possible risk factors for thrombosis (Moroi, 1989; Arai, 1995; Nieswandt, 2001; Cabeza, 2004; Nurden, 2004; Yee, 2004).

G-proteins make up a heterogeneous group of proteins that link surface receptors and intracellular effector enzymes; defects in G-protein activation can impair signal transduction (see Chapter 74). Patients with

deficiencies at the level of $G\alpha_q$ (Gabbeta, 1997) and $G\alpha_i$ (Patel, 2003) have been described. A patient with the $G\alpha_q$ deficiency had a mild bleeding disorder, abnormal aggregation and secretion responses to a number of agonists, and diminished GTPase activity (a reflection of G-protein α -subunit function) on activation. Essentially identical abnormal platelet findings have been reported in $G\alpha_q$ -deficient knockout mice (Offermanns, 1997). Additionally, impaired platelet responses have been reported in association with $G\alpha_s$ hyperfunction (which leads to increased cAMP levels) and alterations in the $G\alpha_s$ gene (*GNAS1*) (Freson, 2001b).

Platelet signal transduction is also impaired by defects in phospholipase C activation, calcium mobilization, and protein phosphorylation. Several patients have been identified who have a relatively mild bleeding diathesis and impaired dense granule secretion, although their platelets have normal granule stores and, in general, synthesize substantial amounts of TxA_2 . On laboratory testing, these patients have abnormal aggregation and secretion, particularly in response to some agonists (ADP, epinephrine, PAF); the response to other agonists such as arachidonate and high concentrations of collagen may be normal. Such patients appear to be more common than those with SPD or defects in TxA_2 synthesis. Defects in early platelet activation events, including Ca^{++} mobilization, phosphatidylinositol hydrolysis, and phosphorylation of pleckstrin (a protein phosphorylated by protein kinase C), have been described (Rao, 2004; Collier, 2010). Specific deficiencies at the level of phospholipase C- β_2 (Lee, 1996; Yang, 1996) and protein kinase C- θ (Sun, 2004) have been documented. Activation of GPIIb/IIIa and platelet fibrinogen binding is a prerequisite for aggregation and is a signal transduction-dependent process. Defects in GPIIb/IIIa activation due to upstream signal transduction defects have been noted in some patients (Gabbeta, 1996). A major platelet response to activation consists of liberation of arachidonic acid from phospholipids and its subsequent oxygenation to TxA_2 , which plays a synergistic role in the response to several agonists. Patients have been described with impaired liberation of arachidonic acid from membrane phospholipids related to an abnormality in phospholipase A₂ (Adler, 2008), as well as with congenital deficiencies of cyclooxygenase and thromboxane synthase (Rao, 2004; Collier, 2010); these lead to diminished TxA_2 production on platelet stimulation.

DEFECTS IN CYTOSKELETAL ASSEMBLY

WAS is an X-linked inherited disorder affecting T lymphocytes and platelets and characterized by thrombocytopenia, immunodeficiency, and eczema (Remold-O'Donnell, 1996). Bleeding manifestations are variable. Several platelet abnormalities, including dense granule deficiency and deficiencies of platelet GPIb, GPIIb/IIIa, and GPIa have been reported. WAS arises from mutations in the gene coding for the WAS protein of 502 amino acids that binds to several other signaling proteins, including Cdc42 (a GTPase) and p47nck (a SH3-containing adapter protein) (Remold-O'Donnell, 1996; Zigmond, 2000). This protein constitutes a link between the cytoskeleton and signaling pathways and is a key regulator of cytoskeletal assembly.

DISORDERS OF PLATELET PROCOAGULANT ACTIVITIES

Platelets play a major role in blood coagulation by providing the surface on which several specific key enzymatic reactions occur. As discussed previously, in resting platelets, asymmetry is seen in the distribution of some of the phospholipids, such that PS and phosphatidylethanolamine are located predominantly on the inner leaflet, and phosphatidylcholine has the opposite distribution. Platelet activation results in redistribution with expression of PS on the outer surface, mediated by phospholipid scramblase (see Fig. 40-2). Exposure of PS on the outer surface is an important event in the expression of platelet procoagulant activities. A few patients have been described in whom the platelet contribution to blood coagulation is impaired, but aggregation and secretion responses are normal; this is referred to as Scott syndrome (Weiss, 1994; Solum, 1999; Weiss 2009). In these patients, who have a bleeding disorder, bleeding time and platelet aggregation responses have been normal, as have PT and partial thromboplastin time. In a patient described by Weiss (1994), platelet factor Xa-binding sites and binding of factors IXa and VIIIa were diminished; this was associated with decreased surface expression of PS following platelet activation. A review of additional patients presenting with forms of Scott syndrome has recently been presented (Weiss, 2009).

TRANSCRIPTION FACTOR MUTATIONS AND ASSOCIATED PLATELET DYSFUNCTION

Transcription factors regulate the expression of proteins in platelets and megakaryocytes, megakaryopoiesis, and platelet production. Several reports have demonstrated impaired platelet function and congenital thrombocytopenia in patients with mutations in specific transcription factors.

RUNX1/CBFA2 (Familial Platelet Disorder With Predisposition to Acute Myelogenous Leukemia)

An association between inherited platelet function abnormalities, thrombocytopenia, and a predisposition to acute myeloid leukemia (AML) has been reported in several families and has been linked to mutations in the gene *RUNX1* (*AML1*, *CBFA2*) (Song, 1999; Sun, 2004; Collier, 2010) (see Chapter 77 for a discussion of *RUNX1* in AML). This disorder is inherited as an autosomal dominant trait. Platelet abnormalities include impaired aggregation and secretion, granule deficiency, abnormal α Ib β 3 activation, decreased platelet myosin light chain and pleckstrin phosphorylation, decrease in platelet protein kinase C- θ and 12-lipoxygenase, and decreased platelet thrombopoietin receptors (Mpl) (Song, 1999; Sun, 2004; Collier, 2010; Kaur, 2010). *RUNX1* regulates expression of several genes including *MYL9* (myosin light chain) (Jalagadugula, 2010), *PF4* (Aneja, 2011), 12-lipoxygenase (*ALOX12*) (Kaur, 2010), and protein kinase C- θ .

GATA-1

GATA-1 is a major transcription factor regulating both megakaryopoiesis and thrombopoiesis. *GATA-1* mutations have been associated with an X-linked syndrome consisting of dyserythropoiesis, anemia, thrombocytopenia, and large platelets (Drachman, 2004); selectively impaired responses to collagen and ristocetin related to abnormalities in GPIIb β ; diminished levels of platelet $G\alpha_s$ protein and messenger RNA (mRNA); and a form of GPS (Freson, 2001a; Drachman, 2004; Hughan, 2005; Tubman, 2007).

RELATIVE FREQUENCIES OF VARIOUS INHERITED PLATELET DEFECTS

The relative frequency of various disorders remains unknown. The entities commonly thought about—Glanzmann thrombasthenia, BSS, and SPD—are distinctly uncommon, with the exception of some local pockets on a worldwide basis. Thrombasthenia and BSS are rare disorders. Although no data have been published, patients currently lumped into the heterogeneous category of defects in platelet secretion and signal transduction probably exhibit the more frequently encountered inherited platelet function abnormalities, excluding vWD. In our experience, in most of them, the underlying mechanisms are unknown. SPD is present in less than 10%–15% of patients with congenital platelet defects. Abnormalities in thromboxane production occur in about 20% of these patients. A large proportion of remaining patients with abnormal aggregation and secretion demonstrate adequate dense granule stores and produce substantial amounts of TxA_2 . In some of these patients, evidence suggests defects in the signaling mechanisms (Rao, 2004).

EVALUATION OF PATIENTS WITH SUSPECTED PLATELET DISORDERS

The evaluation of patients with a clinical history or symptoms suggesting a bleeding tendency involves consideration of the coagulation and fibrinolytic systems, as well as of the blood platelets. A carefully conducted history and physical examination can be the single most important factor leading to a diagnosis in many patients. Determination of whether the disorder is likely to be congenital or acquired is important, and a family history is critically important. A platelet count may help determine whether the bleeding tendency is explicable by decreased platelet numbers alone. Prolonged PFA-100 or bleeding time may help determine whether a platelet defect is present. However, both may be normal in patients with platelet function defects. Because vWD may be more common than congenital platelet defects in patients with mucocutaneous bleeding manifestations, simultaneous evaluation of plasma factor VIII and vWF would be indicated.

Bleeding manifestations in patients with inherited platelet function defects are highly variable. The usual reasons for referral for evaluation

include mucocutaneous bleeding manifestations, excessive bleeding following a procedure or surgery, and prolonged bleeding time or PFA-100 with a reasonable platelet count. In patients suspected of having a platelet function defect, possible studies include platelet count, bleeding time, PFA-100, and studies to assess platelet aggregation and secretion responses in vitro. Platelet studies are usually performed using PRP harvested from anticoagulated blood, and responses to various agonists, including ADP, epinephrine, collagen, arachidonic acid, a TxA_2 analog (U46619), thrombin receptor peptides, and ristocetin, are monitored. The patterns of response observed may often provide clues to the nature of the underlying platelet defect, although specific techniques, largely available in research laboratories, are required to delineate the precise platelet mechanisms that are altered. Patients with classical thrombasthenia are characterized by the absence of both primary and secondary waves of aggregation in response to all commonly used agonists (except ristocetin) with a normal shape change response. Impaired or absent response to ristocetin with normal aggregation response to other agonists suggests vWD or BSS. In the latter disorder, platelet counts are decreased and platelet size is increased. Although these findings may occur in some variants of vWD (e.g., type 2B), plasma levels of vWF and factor VIII, as well as the multimeric pattern of vWF, are normal in BSS but abnormal in vWD. Patients with impaired granule secretion or diminished dense granule contents generally show a decreased or absent second wave of aggregation in response to ADP, epinephrine, and PAF, along with blunted responses to other agonists (collagen, U46619) associated with markedly decreased release of granule contents.

THERAPY FOR CONGENITAL PLATELET FUNCTION DEFECTS

Platelet transfusions and 1-desamino-8D-arginine vasopressin (DDAVP) administration have been the mainstays of therapy for patients with inherited platelet defects. Because of wide disparity in bleeding manifestations, therapeutic approaches need to be individualized. Platelet transfusions are effective in controlling bleeding manifestations but are associated with potential risks involving blood products, including alloimmunization. Patients with thrombasthenia may develop antibodies against GPIIb/IIIa that compromise the efficacy of subsequent platelet transfusions. A viable alternative to platelet transfusions is intravenous administration of DDAVP, which was shown to shorten bleeding time in a substantial number of patients with platelet function defects (Rao, 1995; Mannucci, 1998). The effect on bleeding time lasted about 4–5 hours. This response appears to be dependent on the abnormalities leading to platelet dysfunction. Most patients with Glanzmann thrombasthenia have not responded to DDAVP infusion with shortening of the bleeding time. Responses in patients with disorders of platelet secretion, signal transduction, or storage pool deficiency have been variable, with shortening of bleeding time reported in some patients.

DDAVP administration induces a rise in plasma vWF, factor VIII, and tissue plasminogen activator. Abnormal in vitro platelet aggregation or secretion responses in patients with platelet defects are not corrected by DDAVP (Rao, 1995). Recently, recombinant factor VIIa has developed into an important drug for the management of bleeding events in patients with Glanzmann thrombasthenia and some other inherited defects (Poon, 2000; Almeida, 2003). Additional approaches that have been utilized to improve hemostasis in patients with inherited platelet defects include a short (3–4 day) course of prednisone (20–50 mg) (Mielke, 1981) and administration of antifibrinolytic agents such as ϵ -aminocaproic acid or tranexamic acid. Allogeneic bone marrow transplantation has now been successfully performed with complete correction in patients with thrombasthenia, although the development of antibodies directed against the GPIIb/IIIa complex remains a potential problem (Flood, 2005; Fujimoto, 2005).

VON WILLEBRAND FACTOR AND VON WILLEBRAND DISEASE

VON WILLEBRAND FACTOR BIOLOGY

von Willebrand factor is a pivotal protein in hemostasis, playing key roles both in primary hemostasis and in secondary hemostasis. In the latter role, vWF serves as a carrier protein for factor VIII; in the absence of vWF, factor VIII is rapidly cleared from the plasma (see Chapter 39). With respect to primary hemostasis, vWF serves as an adhesive platelet ligand that tethers the platelet to exposed collagen at sites of vascular injury. vWF circulating

Figure 40-7 Structure of von Willebrand factor (vWF) and mutations in von Willebrand disease (vWD) type 2. The vWF precursor consists of a signal peptide (residues 1–22), a propeptide (residues 23–763), and the mature subunit (residues 764–2813). The locations are indicated for repeated domains (A, B, C, D, CK); binding sites for factor VIII (FVIII), platelet glycoprotein Ib (GPIb), collagen, and integrin $\alpha\text{Ib}\beta 3$; intersubunit disulfide bonds (S–S); and the Tyr–Met bond cleaved by ADAMTS13 (Y1605–M1606). Below, the schematic structure of vWF is shown, along with the locations of mutations that cause specific subtypes of vWD type 2. (Sadler JE. New concepts in von Willebrand disease. *Annu Rev Med* 2005;56:175, Figure 1. Reprinted, with permission, from the Annual Review of Medicine, Volume 56, © 2005 by Annual Reviews at www.annualreviews.org.)

in the blood plasma is derived from secretion by endothelial cells. This secretion has a major constitutive component, but a releasable pool of vWF is also stored in the endothelial Weibel–Palade bodies. Megakaryocytes also synthesize vWF, which is stored in the platelet α -granules. This pool of vWF is released only upon platelet activation, as part of the more general platelet release reaction. Although such released vWF generally would not be capable of appreciably raising the overall level of vWF in the plasma, local increases in vWF at sites of injury may be significant.

The vWF gene is located on chromosome 12 and is 178 kB long, extending over 52 exons. The presence of a partial, but nonfunctional, duplication of the vWF gene on chromosome 22 (vWF pseudogene) is an important consideration in the design of primers for amplification of the vWF gene. Following cleavage of an N-terminal propolypeptide fragment, the mature 2050 amino acid vWF protein is composed of a series of functional domains, as shown in Figure 40-7. Individual vWF monomeric units are bound together by a series of disulfide bonds, which occur near both N-termini and C-termini (Tsai, 2003). The resulting multimers may achieve molecular weights exceeding 20 MDa. Soon after their secretion into the blood, however, vWF multimers undergo proteolytic trimming by the metalloproteinase ADAMTS13. Although a potential cleavage site exists between Tyr842 and Met843 within the A2 domain of each vWF multimer, following a certain degree of proteolysis, the ADAMTS13 proteolysis of potential sites within vWF comes to a halt—presumably as the result of steric hindrance of the ADAMTS13 penetrating deeper into the vWF multimeric structure. Deficiency of ADAMTS13, due to a congenital abnormality or to the formation of autoantibodies against the enzyme, results in the circulation of unusually large vWF multimers in the plasma. These forms are capable of spontaneously aggregating platelets, as well as forming large strands anchored to the endothelial surface that can result in RBC fragmentation—two characteristic attributes of the associated disorder, TTP.

At sites of vessel injury, vWF binds to exposed subendothelial collagen. Particularly under conditions of high shear, where relatively high blood flow occurs through smaller-diameter vessels, bound vWF and GPIIb α on the surface of circulating blood platelets are able to bind together, effectively tethering the platelet to the injury site. This ligand–receptor interaction further produces outside-to-inside signaling across the platelet membrane, leading to platelet activation. One component of this platelet activation consists of a subsequent inside-to-outside signaling event within GPIIb/IIIa that makes this receptor complex competent to bind the aggregatory ligand fibrinogen. In the clinical laboratory, vWF may be assayed antigenically, functionally, and even structurally. Although vWF antigen was formerly quantified by a variety of gel electrophoretic approaches, it may now be measured with high precision by rapid methods such as ELISA or immunoturbidometric procedures.

TABLE 40-8

vWD Classification and Laboratory Values

Condition	Description	vWF:Rco (IU/dL)	vWF:Ag (IU/dL)	FVIII	vWF:Rco/vWF:Ag Ratio
Type 1	Partial quantitative vWF deficiency	<30*	<30*	↓ or Normal	>0.5–0.7
Type 2A	↓vWF-dependent platelet adhesion with selective deficiency of high molecular weight vWF multimers	<30*	<30–200‡	↓ or Normal	<0.5–0.7†
Type 2B	Increased vWF affinity for platelet GPIb; ± ↓platelet numbers	<30*	<30–200‡	↓ or Normal	Usually <0.5–0.7†
Type 2M	↓vWF-dependent platelet adhesion without selective deficiency of high molecular weight vWF multimers	<30*	<30–200‡	↓ or Normal	<0.5–0.7†
Type 2N	Markedly decreased vWF binding affinity for FVIII	30–200	30–200	↓↓	>0.5–0.7
Type 3	Virtually complete deficiency of vWF	<3	<3	↓↓↓ (<10 IU/dL)	Not applicable
"Low vWF"*		30–50	30–50	Normal	>0.5–0.7
Normal		50–200	50–200	Normal	>0.5–0.7

Modified with permission from Nichols WL. Am J Hematol 2009;84:366–70. Note that these values represent prototypical cases. Exceptions occur, and repeat testing may be necessary.

FVIII, Coagulation factor VIII activity; GPI, glycoprotein; vWD, von Willebrand disease; vWF, von Willebrand factor; vWF:Ag, vWF antigen; vWF:Rco, vWF ristocetin cofactor activity; ↓, decrease in function or in the test result compared with the laboratory reference range.

*<30 IU/dL (or 30%) is recommended as the "cutoff" level for a definitive diagnosis of vWD, although some patients with type 1 or type 2 vWD will have levels of vWF:Rco and/or vWF:Ag of 30–50 IU/dL. This "cutoff" is recommended because (1) There is a high frequency of blood type O in the United States, which is associated with "low" vWF levels; (2) bleeding symptoms are reported by a significant proportion of normal individuals; (3) no abnormality in the vWF gene has been identified in many individuals who have mildly to moderately low vWF:Rco levels. This does not preclude the diagnosis of vWD in patients with vWF:Rco of 30–50 IU/dL if supporting clinical and/or family evidence of vWD is present, nor does this preclude the use of agents to increase vWF levels in those who have vWF:Rco of 30–50 IU/dL, and who may be at risk for bleeding.

†Until more laboratories clearly define a reference range, the vWF:Rco/vWF:Ag ratio of <0.5–0.7 is recommended to distinguish type 1 vs. type 2 vWD variants (A, B, or M).

‡Note that despite the higher value occasionally observed, the vWF:Ag in the majority of individuals with type 2A, 2B, or 2M vWD is <50 IU/dL.

VON WILLEBRAND DISEASE AND ITS SUBTYPES

As shown in Table 40-8, a variety of clinical conditions may be associated with vWF abnormalities. In type 1 vWD, qualitatively normal vWF molecules are present in the plasma but are quantitatively decreased. Accordingly, a normal distribution of vWF multimers is seen across the entire size spectrum, albeit lower than normal amounts of each multimer (Fig. 40-8). In one sense, type 3 vWD represents an extreme extent of the quantitative abnormality in that total absence of vWF gene product is evident. However, whereas inherited type 1 vWD is typically expressed in an autosomal dominant fashion, type 3 is autosomal recessive, with neither parent of an affected patient typically showing symptomatic disease. Because one of the key functions of vWF is to serve as a carrier molecule for factor VIII, type 3 patients not only suffer with respect to platelet function but are at further hemostatic risk because of vanishingly low amounts of circulating factor VIII.

Patients with type 2 vWD have one or another of the many described qualitative abnormalities of this complex protein. For practical purposes, these abnormalities have been grouped into a small number of subtypes. In type 2A vWD, lack of higher molecular weight multimers is seen (see Fig. 40-8), with corresponding loss of vWF functionality due to mutations that prevent proper multimerization or to mutations that increase the susceptibility of fully formed vWF to proteolysis by ADAMTS13 or other proteolytic enzymes. In some instances, vWF synthesized by megakaryocytes and stored in platelet α -granules appears to have a fuller complement of vWF multimers than does plasma vWF derived from secretion by endothelial cells; this may reflect the protective effects resulting from proteolysis due to sequestration within the α -granules. In type 2B vWD, point mutations within the vWF molecule actually confer an increase-of-function capability with respect to its ability to bind the platelet GPIb receptor. Binding of abnormal type 2B vWF molecules to circulating platelets in the absence of appropriate hemostatic insult leads to uncompensated depletion of the higher molecular weight multimers of plasma vWF (see Fig. 40-8) and typically also to mild to moderate thrombocytopenia. In the clinical laboratory, this increase-of-function can be demonstrated by the ability of abnormally low concentrations (typically 0.3–0.5 mg/mL) of the modulator ristocetin (a glycopeptide antibiotic produced by *Amycolatopsis lurida*) to aggregate the PRP of such patients.

In contrast, in the case of type 2A vWD or type 1 vWD, the extent and rate of aggregation are decreased to below normal at standard ristocetin concentrations of 1.0–1.5 mg/mL. Patients with type 2M vWD share

Figure 40-8 Multimer patterns in selected variants of von Willebrand disease (vWD). Plasma samples were analyzed for von Willebrand factor (vWF) by sodium dodecyl sulfate (SDS)-agarose gel electrophoresis and Western blotting. Patterns are shown for pooled normal plasma (NP) and patients with the indicated types of vWD. Note that in the 2A and 2B examples, there is relative loss of higher molecular weight multimers, although to varying extents. Of note, the extent of multimer loss is highly variable in each subtype, and the differences in extent of multimer loss between the 2A and 2B subtypes illustrated in these particular examples do not distinguish between these subtypes in diagnostic studies. Instead, functional studies are required to distinguish between the decrease-of-function 2A subtype and the increase-of-function 2B subtype (see text). (Adapted with permission from Sadler JE. New concepts in von Willebrand disease. Annu Rev Med 2005;56:173–91; and Sadler JE. von Willebrand disease. In: Bloom AL, Forbes CD, Thomas DP, Tuddenham EGD, editors. Hemostasis and thrombosis. New York: Churchill Livingstone; 1994, p. 843–57.)

a similar decrease-of-function phenotype with type 2A vWD, but the mutations responsible for this vWD subtype do not result in loss of normal vWF multimeric structure. If, in contrast to testing the patient's own PRP, the patient's platelet-free plasma is tested for ristocetin cofactor activity, the observed level is decreased not only in type 1, type 2A, and type 2M, but also in type 2B, because of acquired deficiency of high molecular weight multimers actually remaining in the patient's plasma. In type 1 vWD, the levels of vWF antigen and ristocetin cofactor activity generally

decline in parallel. In contrast, in type 2 patients, a more dramatic decrease in ristocetin cofactor activity than in vWF antigen level is typically seen, because it is precisely the missing higher molecular weight multimers that are critical to the vWF–platelet interaction measured by this functional assay. A similar discrepancy may be observed between vWF collagen-binding activity and vWF antigen. Finally, patients with type 2N (Normandy) vWD have point mutations within the vWF molecule that specifically impair the ability of this molecule to bind factor VIII. Type 2N patients accordingly may show normal levels of vWF antigen and even of ristocetin cofactor activity, but will have abnormally low levels of circulating factor VIII. Because the vWF gene is transmitted autosomally, type 2N vWD should be suspected in cases where an autosomal inheritance pattern of factor VIII deficiency is noted. Definitive diagnosis is made by demonstrating impaired binding of normal factor VIII to the patient vWF, such as by ELISA assay and by molecular diagnostic methods.

Whereas, at least conceptually, the basis for diagnosing type 2 and type 3 vWD seems clear, the same cannot be said for type 1 vWD (Sadler, 2003, 2005). The level of circulating vWF is a result of multigenic influences. Not only genes encoding vWF, but also genes encoding intracellular transporter proteins, ABO genes affecting posttranslational modifications of the vWF molecule, genes affecting vWF proteolysis, and doubtless still other genetic factors may influence the quantity and functionality of vWF. For example, individuals inheriting the same vWF genes may be anticipated to have 20% or lower circulating levels of vWF if they are of type O rather than type AB blood group type. In some instances, this could mean the difference between being considered normal or deficient in vWF level. Additionally, Sadler (2003) has argued that, because of the relatively high prevalence of mild bleeding symptoms and of mild deficiencies of vWF, it may be erroneous to conclude that simple demonstration of a mild to moderate decrease in plasma vWF level is actually the *cause* of an individual patient's increased bleeding tendency. Thus, in such instances, it may be important to investigate additional possible causes for an apparent disorder of primary hemostasis, specifically, an abnormality of platelet aggregation or secretion in response to one or more platelet agonists. The approach to patients with mild deficiencies of vWF has continued to be debated (Gudmundsdottir, 2007; Onundarson, 2008). It has been proposed (Nichols, 2009; Sadler, 2009) that unless more diagnostic family or personal information is available for an individual presenting with a vWF level in the range of 30–50 U/dL, this condition may be better considered to be “low vWF” rather than “type 1 vWD” (see Table 40-8).

In the autosomal dominant bleeding disorder termed platelet-type von Willebrand disease (Miller, 1982; Weiss, 1982), patients characteristically have low-normal platelet counts, normal factor VIII coagulant activity, normal or decreased vWF antigen, and decreased plasma ristocetin cofactor activity. On agarose gel electrophoresis of plasma, a selective decrease in higher molecular weight multimers is seen, similar to that noted in type 2B vWD. However, unlike platelets from patients with type 2B vWD, platelets from patients with platelet-type vWD show an increased ability to bind normal vWF (Miller, 1983). In the diagnostic laboratory, this increased binding is reflected by the ability of unusually low concentrations of ristocetin (0.3–0.5 mg/mL) to produce strong aggregation of the patient's PRP in this disorder—a finding also observed in type 2B vWD (Ruggeri, 1980). Cryoprecipitate (which contains vWF), however, when added to platelet-type vWD platelets without additional aggregating agents, is capable of inducing aggregation; cryoprecipitate added to normal or type 2B vWD platelets, in contrast, does not produce aggregation. Platelets from patients with platelet-type von Willebrand disease also show unique agglutination reactions with desialylated vWF (asialo vWF) (Miller, 1987).

The molecular basis of platelet-type vWD has been shown to be due to a single base mutation resulting in the replacement of glycine by valine at amino acid residue 233 of the GPIb α -chain (Miller, 1991). Substitution of valine for methionine just 6 amino acids away at residue 239 has subsequently been reported in two additional kindreds (Russell, 1993; Takahashi, 1995). Each of these mutations is believed to produce conformational changes in the receptor, leading to abnormally heightened vWF binding (Pincus, 1991; Miller, 1996). Additionally, heightened binding in vivo between the mutant platelet protein and circulating vWF may induce a conformational change in the vWF that permits enhanced access for ADAMTS13 proteolysis (Nishio, 2004). Recently, a similar phenotype has been reported to result from a 9 amino acid deletion in an unexpectedly distant region of the GPIb α -chain (Othman, 2005). The incidence of platelet-type vWD is difficult to determine but appears to be far lower than even that of the relatively uncommon type 2B vWD disorder (Othman, 2010).

LABORATORY TESTS OF VON WILLEBRAND FACTOR

As is apparent from consideration of the domain structure of vWF (see Fig. 40-7), vWF is potentially capable of binding to a number of different molecules. Assessment of such binding comprises a group of functional tests of the vWF molecule. The principal functional tests of vWF currently employed in the evaluation of patients center around the binding of vWF to platelets, to collagen, and to factor VIII.

Although, as with a number of other plasma proteins, vWF does contain an RGD tripeptide sequence through which it can potentially bind to the platelet integrin GPIIb/IIIa, the major platelet receptor for vWF that is evaluated in the clinical laboratory is the GPIb/IX/V complex. Specifically, vWF binds to the α -chain of the GPIb molecule (GPIb α). Because platelets themselves contain a releasable store of vWF in their α -granules, and because the binding of exogenous vWF to normal, healthy platelets may lead to the release of that stored vWF (see earlier), assays of plasma vWF need to be designed to avoid the contribution of such released vWF. Fortunately, fixation of normal platelets with formalin preserves the reactivity of GPIb α to vWF, while effectively destroying the metabolic responses of the cell required to support secretion. Moreover, such fixed platelets may even be lyophilized and then reconstituted at the time of testing. When such platelets are incubated under stirring conditions with ristocetin, the rate and extent of their aggregation becomes a function of the amount of vWF contained in plasma samples used in the assay. This test of vWF reactivity with platelets is termed **vWF ristocetin cofactor activity** and may be performed manually in a standard platelet aggregometer or through a variety of more automated approaches.

Because measurements of ristocetin cofactor activity have traditionally suffered a relatively high coefficient of variation (i.e., low precision) compared with other tests performed in the coagulation laboratory (Kitchen, 2006), alternative measures of the interaction between vWF and platelet-associated GPIb α have been pursued, including assays based on ELISA, immunoturbidometric agglutination, flow cytometry, and other technologies (Vanhoorelbeke, 2000, 2002; Lattuada, 2004; Popov, 2006; Strandberg, 2006; Sucker, 2006; Pinol, 2007; Chen, 2008; Truss, 2009). As discussed earlier, it is characteristically the higher rather than the lower molecular weight multimers that are most active in binding to platelets, so that ristocetin cofactor activity will be expected to be diminished in instances where deficiency of the higher molecular weight multimers occurs, even if the total amount of vWF is normal (i.e., in instances where there is a relative abundance of only lower molecular weight multimers). Efforts to use recombinant GPIb α in functional ELISA assays to evaluate vWF functional activity (Federici, 2004; Hui, 2007; Flood, 2009) have also shown promise. Such assays may not always provide concordant results with traditional ristocetin cofactor assays, for example, not reporting out a comparably decreased value for some patient samples lacking the higher molecular weight multimers. On the other hand, an assay employing increase-of-function mutations in GPIb α corresponding to those seen in platelet-type vWD and that does not require the addition of ristocetin for vWF binding may be useful in demonstrating phenotypically normal variations in vWF that otherwise would be classified as a type 2M vWD by virtue of their failure to bind to the commonly employed reagent, ristocetin (Flood, 2009).

Measurement of the collagen-binding activity of vWF is more straightforward than ristocetin cofactor activity, usually assayed as the binding of vWF to collagen-coated wells by immunoassays such as ELISA. This activity is also greater in higher rather than lower molecular weight vWF multimers, so that frequently, vWF collagen-binding activity and vWF ristocetin cofactor activity will be similar. vWF collagen-binding activity, however, is generally considered a supplementary test rather than a replacement for tests assessing the interaction of vWF with platelets (Favaloro, 2007).

vWF multimeric analysis contributed significantly to the original foundation for defining the various phenotypes of vWD discussed previously. This technique traditionally has been sufficiently labor intensive to preclude its performance by all but a small number of reference laboratories, although the emergence of more automated approaches could potentially allow the performance of such analysis to become more widespread. At low resolution, multimeric analysis determines the relative distribution of vWF by molecular weight range. At higher resolution, abnormal patterns of multimers within a narrow size range may also be resolved. For example, vWF isolated from platelets will reveal higher multimers (also seen within endothelial cells) that are typically lost when vWF released into the circulating plasma comes in contact with ADAMTS13. Also apparent in these

images is the production of additional bands reflecting proteolytic activity by ADAMTS13 that has not yet occurred on circulating vWF, along with vWF that had been protected within the platelet α -granules. Typical patterns of vWF multimers seen in the major vWD variants were discussed previously.

ACQUIRED VON WILLEBRAND DISEASE

Most patients with acquired vWD (AvWD) have been older than 40 years of age without previous manifestations or family history of a bleeding diathesis. Diverse associated disorders in these patients include both benign and malignant hematologic disorders (Federici, 2000; Kumar, 2002). About half of patients have had an underlying lymphoproliferative disorder or plasma cell proliferative disorder (Federici, 2000). In patients with myeloproliferative disease (chronic myelogenous leukemia, essential thrombocythemia, polycythemia vera) and with reactive thrombocytosis, an impressive correlation has been noted between abnormalities in plasma vWF and elevated platelet counts (Budde, 1997). AvWD has been reported in patients with autoimmune disorders, including systemic lupus erythematosus, scleroderma, mixed connective tissue disease, hypothyroidism, and antiphospholipid antibody syndrome (Federici, 2000; Kumar, 2002). Several therapeutic agents have been associated with AvWD: ciprofloxacin (Castaman, 1995), valproic acid, griseofulvin, and a plasma expander, hydroxyethyl starch. AvWD has been reported in patients with solid tumors, most notably Wilms' tumor, but case reports have associated AvWD with others as well (adrenocortical carcinoma, lung carcinoma, gastric carcinoma). Patients with aortic stenosis and congenital valvular heart disease may have excessive bleeding (particularly gastrointestinal), and several reports have documented AvWD in such patients (Gill, 1986; Vincentelli, 2003); of note, plasma abnormalities are corrected after surgery.

AvWD arises by diverse mechanisms. These include antibodies directed against functional domains of vWF (Kumar, 2002) with inhibition by patient plasma of ristocetin cofactor activity in normal plasma; enhanced clearance of vWF mediated by antibodies that are not targeted to a functional vWF region; increased proteolysis of vWF, induced by exposure of vWF to high stress, as, for example, in severe aortic stenosis (Sadler, 2005); and cellular adsorption and removal of vWF by malignant cells or by other cells (including platelets in myeloproliferative disease). Last, decreased vWF synthesis has been invoked in patients with hypothyroidism (Levesque, 1993) and in those receiving valproate (Kreuz, 1990).

ACQUIRED DISORDERS AFFECTING PLATELET FUNCTION

Alterations in platelet function occur in many acquired disorders of diverse origins (Rao, 2006). The specific biochemical and pathophysiologic aberrations leading to platelet dysfunction are poorly understood in most. In some, such as the myeloproliferative disorders (MPDs), intrinsically abnormal platelets are produced by the bone marrow. In others, dysfunction results from the interaction of platelets with exogenous factors, such as pharmacologic agents, artificial surfaces (cardiopulmonary bypass), compounds that accumulate in plasma owing to impaired renal function, and antibodies. In these disorders of platelet dysfunction, bleeding is usually mucocutaneous with a wide and often unpredictable spectrum of severity. The usual laboratory tests that identify platelet dysfunction include abnormal bleeding time, prolonged PFA-100 closure time, and abnormal *in vitro* platelet aggregation studies. Neither the PFA-100 nor the bleeding time is a reliable indicator of risk of clinical bleeding. For example, aspirin ingestion impairs platelet aggregation and secretion responses to usually used agonists (such as ADP, epinephrine, arachidonic acid, and low doses of collagen) in almost all individuals but prolongs bleeding time in only about half of subjects (Mielke, 1969; Mielke, 1983). Similarly, PFA-100 results may be normal in some patients with platelet defects (Hayward, 2006). In general, the correlation between abnormalities observed in bleeding time, PFA-100, or platelet aggregation studies and clinical bleeding remains weak.

MYELOPROLIFERATIVE DISORDERS

Bleeding tendency, thromboembolic complications, and qualitative platelet defects are all recognized in MPDs, which include essential thrombocythemia, polycythemia vera, chronic idiopathic myelofibrosis, and chronic myelogenous leukemia (Schafer, 1984; Landolfi, 1997) (see Chapter 33). Platelet abnormalities reflect their development from an abnormal clone

of stem cells, but some of the alterations may be secondary to enhanced platelet activation *in vivo*. The clinical impact of *in vitro* qualitative platelet defects, which occur even in asymptomatic patients, is often unclear.

Numerous studies have examined platelet function and morphology in patients with MPD (Schafer, 1984; Landolfi, 1997). Under the electron microscope, platelet findings include reduction in dense and α -granules, alterations in open canalicular and dense tubular systems, and reduction of mitochondria (Maldonado, 1974). Bleeding time is prolonged in a minority ($\approx 17\%$) of MPD patients and does not correlate with increased risk of bleeding (Schafer, 1984). Platelet aggregation responses are highly variable in MPD patients and often vary in the same patient over time. Decreased platelet responses are more common, although some patients demonstrate enhanced responses to agonists. In one analysis (Schafer, 1984), responses to ADP, collagen, and epinephrine were decreased in 39%, 37%, and 57% of patients, respectively. In patients with abnormally high circulating platelet counts, it has been a common laboratory practice to dilute patients' PRP with their own platelet-poor plasma to allow standardization of platelet aggregometry. However, recent studies have cautioned that decreases in aggregation observed in these patients may be at least partially artifactual, owing to inhibitory factors that appear to be present in the platelet-poor plasma employed as diluent (Cattaneo, 2007; Grignani, 2009). Impaired aggregation in response to epinephrine is more commonly encountered than with other agonists; however, a diminished response to epinephrine is not pathognomonic of an MPD. Impaired responsiveness to epinephrine in MPD has been attributed to a decrease in the number of platelet α_2 -adrenergic receptors. Diminished epinephrine-induced Tx_2 production, dense granule secretion, and Ca^{++} mobilization have also been reported in patients with impaired epinephrine-induced aggregation response. On the platelet surface, decreases in GPIIb/IIIa complexes, GPIb, and GPIa/IIa have been documented in MPD. Evidence also reveals impaired signal transduction-dependent activation of GPIIb/IIIa (Kaplan, 2000). Platelet GPIV (CD36), another membrane GP related to platelet-collagen and platelet-thrombospondin interactions, has been noted to be increased in essential thrombocythemia (Legrand, 1991). Platelet receptors for the Fc portion of IgG have been reported to be increased in MPD platelets (Moore, 1981).

Platelet activation results in the release of free arachidonic acid, which is metabolized by two well-recognized pathways: the cyclooxygenase pathway, leading to Tx_2 production, and the 12-lipoxygenase pathway, leading to formation of 12-hydroperoxyeicosatetraenoic acid and 12-hydroxyeicosatetraenoic acid. Reduced platelet formation of lipoxygenase products has been reported in MPD patients (Schafer, 1982); this was associated with enhanced Tx_2 production (Schafer, 1982).

MPD patients have been reported to have defects in platelet signaling mechanisms, including calcium mobilization (Fujimoto, 1989), signaling through the Tx_2 receptor (Ushikubi, 1992), and protein phosphorylation due to deficiency of cyclic guanosine monophosphate-dependent protein kinase (Eigenthaler, 1993). Cooper (1978) reported a decrease in PGD_2 -induced activation of adenyl cyclase associated with a 50% reduction in platelet PGD_2 receptors, indicating impairment in platelet inhibitory mechanisms. Platelets from patients with polycythemia vera and idiopathic myelofibrosis, but not essential thrombocythemia or chronic myelogenous leukemia, have been shown to have reduced expression of the thrombopoietin receptor (Mpl) and reduced thrombopoietin-induced tyrosine phosphorylation of proteins (Molitero, 1998).

Abnormalities in plasma vWF have been documented in MPD patients (and probably contribute to the hemostatic defect). Plasma vWF, particularly with large vWF multimers, is decreased, which is inversely related to platelet count, and has improved following cytoreduction (Budde, 1997). Changes in plasma vWF occur in patients with reactive thrombocytosis as well. Observed increases in the 140-kDa and 167-kDa proteolytic fragments of vWF raise the suspicion that enhanced vWF proteolysis by ADAMTS13 may be occurring, possibly because of platelet-induced conformational effects on the plasma vWF (Elliott, 2005).

ACUTE LEUKEMIAS AND MYELOYDYSPLASTIC SYNDROMES

The major cause of bleeding in these conditions is thrombocytopenia. However, in patients with normal or elevated platelet counts, bleeding complications may be associated with platelet dysfunction (Rao, 2005). Acquired platelet defects associated with clinical bleeding are more common in AML but have been reported in acute lymphoblastic and myelomonoblastic leukemias, hairy cell leukemia, and myelodysplastic syndromes. Reduced aggregation responses to ADP, epinephrine, and

collagen have been reported, along with diminished nucleotide secretion, TxA_2 production, and platelet PDGF and βTG . Acquired forms of vWD and a Bernard-Soulier-like platelet defect have been described in hairy cell leukemia and myelodysplastic syndromes. In acute leukemias and myelodysplastic syndromes, platelets may be morphologically abnormal, and ultrastructural studies have shown decreased microtubules, reduced number and abnormal size of dense granules, and excessive membranous systems. The megakaryocytes exhibit dysplasia.

DYSPROTEINEMIAS

Excessive clinical bleeding may occur in patients with dysproteinemias; this appears to be related to multiple mechanisms, including platelet dysfunction, specific coagulation abnormalities, hyperviscosity, and alterations in blood vessels due to amyloid deposition. Qualitative platelet defects occur in some of these patients and have been attributed to coating of platelets by the paraprotein.

UREMIA

The pathogenesis of the hemostatic defect in uremia remains unclear, but platelet dysfunction and impaired platelet-vessel wall interaction are considered the major causes. Patients on dialysis have increased numbers of circulating reticulated platelets, indicating accelerated platelet turnover (Himmelfarb, 1997). Bleeding time was demonstrated many years ago to be prolonged in uremia. One major reason for this is the anemia frequently seen in uremia, and in fact, prolonged bleeding times are typically shortened following red cell transfusions or treatment with erythropoietin (Livio, 1982; Moia, 1987). Multiple platelet abnormalities are recognized in uremia (Boccardo, 2004). Adhesion of platelets to the subendothelium, an initial step in hemostasis, involves the interaction of vWF, platelets, and the subendothelium. Adhesion of platelets from uremic whole blood perfused over deendothelialized rabbit aorta has been reported to be impaired (Castillo, 1986). Most studies have found normal or increased plasma vWF antigen levels and activity (ristocetin cofactor), although in some vWF activity was consistently lower than the antigen level. The multimeric structure of vWF has been shown to be normal. The numbers of GPIIb and GPIIb/GPIIIa sites per platelet have been reported to be normal in uremia (Gralnick, 1988). However, decreased platelet GPIIb levels and a functional defect in vWF interaction with GPIIb/IIIa have been noted.

Many studies have shown impaired platelet aggregation responses to several agonists in uremia, sometimes with conflicting results. Plasma levels of PF4 and βTG are elevated in uremia and increase further with hemodialysis, reflecting reduced renal clearance, as well as platelet activation by membrane dialyzers. Several studies have shown reductions in products of arachidonic acid metabolism ($\text{PGG}_2/\text{PGH}_2$, TxA_2) in uremic platelets and have implicated these in observed defective aggregation and secretion. Reduced TXA_2 may arise as the result of a dysfunctional cyclooxygenase or through the liberation of arachidonic acid from phospholipids by phospholipase A_2 activation. Other platelet defects described in uremia include increased platelet cAMP levels and adenylyl cyclase (which can inhibit platelet responses), along with decreased agonist-induced Ca^{++} mobilization, clot retraction, and platelet procoagulant activity.

Convincing evidence suggests that pathogenesis of the hemostatic defect in uremia is linked to accumulation of dialyzable and nondialyzable molecules in the uremic plasma. One such compound, guanidinosuccinic acid, accumulates in uremic plasma, inhibits platelets in vitro, and stimulates generation of nitric oxide, which inhibits platelet adhesion and platelet responses by increasing levels of cellular cGMP (Boccardo, 2004). Exposure of human endothelial cells to uremic plasma leads to enhanced nitric oxide production. Enhanced prostacyclin-like activity has been observed in uremic plasma (Remuzzi, 1978). Aggressive dialysis is an important component of overall management and corrects the bleeding diathesis in some patients, but it is only partially effective in others. Elevation of the hematocrit with packed red blood cells or recombinant erythropoietin shortens bleeding time, improves platelet adhesion, and corrects mild bleeding in uremic patients.

ACQUIRED STORAGE POOL DISEASE

Several patients have been reported in whom the dense-granule SPD appears to be acquired (Rao, 2006). In general, this defect probably reflects in vivo release of platelet dense-granule contents due to activation or production of abnormal platelets by the marrow. Acquired SPD has been

TABLE 40-9

Drugs That Affect Platelet Function

Cyclooxygenase inhibitors

- Aspirin
- Nonsteroidal antiinflammatory agents
 - Indomethacin, phenylbutazone, ibuprofen, sulfinpyrazone, sulindac, meclofenamic acid

Adenosine diphosphate (ADP) receptor antagonists

- Ticlopidine, clopidogrel, prasugrel

Glycoprotein (GP)IIb/IIIa receptor antagonists

- c7E3 (abciximab), tirofiban, eptifibatide

Drugs that increase platelet cyclic adenosine monophosphate (cAMP) or cyclic guanosine monophosphate (cGMP)

Adenylate cyclase activators

- Prostaglandins I_2 , D_2 , E_1 , and analogs

Phosphodiesterase inhibitors

- Dipyridamole
- Cilostazol
- Anagrelide
- Milrinone
- Methylxanthines
 - Caffeine, theophylline, aminophylline

Nitric oxide and nitric oxide donors

Antimicrobials

- Penicillins
- Cephalosporins
- Nitrofurantoin
- Hydroxychloroquine
- Miconazole

Cardiovascular drugs

- β -Adrenergic blockers (propranolol)
- Vasodilators (nitroprusside, nitroglycerin)
- Diuretics (furosemide)
- Calcium channel blockers
- Quinidine
- Angiotensin converting enzyme inhibitors

Anticoagulants

- Heparin

Thrombolytic agents

- Streptokinase, tissue plasminogen activator, urokinase

Psychotropics and anesthetics

- Tricyclic antidepressants
 - Imipramine, amitriptyline, nortriptyline
- Phenothiazines
 - Chlorpromazine, promethazine, trifluoperazine
- Selective serotonin reuptake inhibitors
 - Fluoxetine, sertraline, paroxetine
- Local anesthetics
- General anesthesia (halothane)

Chemotherapeutic agents

- Mithramycin
- Carmustine
- Daunorubicin

Miscellaneous agents

- Dextran and hydroxyethyl starch
- Lipid-lowering agents (clofibrate, halofenate)
- ϵ -Aminocaproic acid
- Antihistaminics
- Ethanol
- Vitamin E
- Radiographic contrast agents
- Food items (omega-3 fatty acids, vitamin E, onions, garlic, ginger, cumin, turmeric, cloves, black tree fungus, ginkgo)

Modified with permission from Rao AK. Acquired disorders of platelet function. In: Colman RW, editor. Hemostasis and thrombosis: basic principles and clinical practice. Philadelphia: Lippincott Williams & Wilkins; 2006.

observed in patients with antiplatelet antibodies, systemic lupus erythematosus, chronic ITP, DIC, HUS, renal transplant rejection, multiple congenital cavernous hemangiomas, MPD, acute and chronic leukemias, and severe valvular disease, as well as in patients undergoing cardiopulmonary bypass and in platelet concentrates stored for transfusion.

ANTIPLATELET ANTIBODIES AND PLATELET FUNCTION

Binding of an antibody to platelets may induce several effects, including accelerated destruction, platelet activation, cell lysis, aggregation, secretion of granule contents, and outward exposure of PS. Platelet-antibody interaction may lead to impaired function, both as a consequence of activation and as a result of antibody binding to specific glycoproteins. Patients with ITP have decreased platelet survival and may have impaired platelet function and abnormally prolonged bleeding times, even at adequate counts. Antibodies can induce platelet dysfunction through multiple mechanisms. In many patients, antibodies are directed against specific platelet surface membrane glycoproteins GPIb (Woods, 1984), GPIIb/IIIa (Woods, 1984), GPIa/IIa (Deckmyn, 1994), and GPVI (Sugiyama, 1987; Boylan, 2004) and glycosphingolipids (van Vliet, 1987; Koerner, 1989). In one report, the anti-GPVI antibody induced clearance of the GPVI/FcR gamma complex from the platelet surface (Boylan, 2004). Some of these antibodies, in effect, induce acquired forms of BSS and thrombasthenia.

DRUGS THAT INHIBIT PLATELET FUNCTION

Many drugs may affect platelet function (Table 40-9). For several, the effects on platelets have been studied in vitro, and the relevance of such findings to drug levels achieved in clinical practice is not well established. Even among those shown to alter platelet responses *ex vivo*, the impact on hemostasis often remains unclear. Moreover, the impact of concomitant administration of multiple drugs, each with a mild effect on platelet function, is unknown, although it is clinically relevant. Because of their widespread use, aspirin and nonsteroidal antiinflammatory agents are an important cause of platelet inhibition in clinical practice. Aspirin ingestion results in inhibition of platelet aggregation and secretion upon stimulation with ADP, epinephrine, and low concentrations of collagen. Aspirin irreversibly acetylates and inactivates the platelet cyclooxygenase, leading to inhibition of synthesis of endoperoxides (PGG₂ and PGH₂) and TxA₂. Typically, 5–7 days is recommended after cessation of aspirin ingestion for studies intended to assess baseline platelet function. Several other nonsteroidal antiinflammatory drugs also impair platelet function by inhibiting the cyclooxygenase enzyme and may prolong bleeding time. Compared with aspirin, inhibition of cyclooxygenase by these agents is generally short-lived and reversible. In the case of ibuprofen, for example, 24 hours from cessation of this medication is a sufficient interval for testing of baseline platelet function.

- Ticlopidine, clopidogrel, and prasugrel are orally administered thienopyridine derivatives that inhibit platelet function by inhibiting the binding of ADP to the platelet P2Y₁₂ receptor. These drugs prolong bleeding time and inhibit platelet aggregation responses to several agonists, including ADP, collagen, epinephrine, and thrombin, to various extents depending on agonist concentrations. GPIIb/IIIa receptor antagonists constitute a class of compounds that inhibit fibrinogen binding and platelet aggregation. These include a monoclonal antibody against the GPIIb/IIIa receptor (abciximab), as well as a synthetic peptide (eptifibatide) and a peptidomimetic (tirofiban) whose mechanism of action is based upon mimicking arginine-glycine-aspartic acid (RGD) sequences within fibrinogen. These are potent inhibitors of aggregation (both primary and secondary) in response to all the usual agonists except ristocetin; they prolong bleeding time and are far more potent than aspirin as platelet inhibitors. Immune-mediated thrombocytopenia (secondary to drug-dependent antibodies) is a potential complication of the GPIIb/IIIa antagonists (Aster, 2007) (see Chapter 42).
- Growing evidence indicates that selective serotonin reuptake inhibitors (SSRIs) inhibit platelet function, and that this has clinical relevance. These include fluoxetine, setraline, paroxetine, fluvoxamine, citalopram, and escitalopram. Serotonin in plasma is taken up by platelets, incorporated into dense granules, and secreted on platelet activation. SSRIs inhibit uptake of serotonin and platelet aggregation and secretion responses to activation. In epidemiologic studies, patients on SSRIs have had increased gastrointestinal bleeding and increased bleeding with surgery (Movig, 2003; McCloskey, 2008).
- β-Lactam antibiotics, including penicillins and cephalosporins, inhibit platelet aggregation responses and may contribute to a bleeding diathesis at high doses (Rao, 2006). These include carbenicillin, penicillin G, ticarcillin, ampicillin, nafcillin, azlocillin, cloxacillin, mezlocillin, oxacillin, piperacillin, and apalcillin. The platelet inhibition appears to be dose dependent, taking about 2–3 days to manifest and 3–10 days to abate after drug discontinuation. Cephalosporins may also impair platelet function. Moxalactam has been reported to induce platelet dysfunction associated with prolonged bleeding times and clinical hemorrhage; it inhibits synthesis of vitamin-dependent coagulation factors as well. Other third-generation cephalosporins appear to show little effect on normal platelet function. In general, the clinical significance of the effect of antibiotics on platelet function remains unclear. Because of the presence of concomitant factors (thrombocytopenia, DIC, infection, vitamin K deficiency), the general context in which bleeding events are encountered in patients on antibiotics prevents identification of the precise role played by the antimicrobials. Discontinuation of a specifically indicated antibiotic is usually not an option and is not necessary.
- A host of other medications and agents, including food substances, inhibit platelet responses, but the clinical significance of many is unclear. They have been reviewed elsewhere (Rao, 2005). Given the increasing use of herbal medicines and food supplements, their role and interaction with pharmaceutical drugs need to be considered in the evaluation of patients with unexplained bleeding.

KEY POINTS

- The amount of clot formed is regulated by several important regulatory mechanisms. Under normal conditions, these mechanisms control excess clot formation and halt venous thrombosis. Major systems are the antithrombin mechanism, the protein C–protein S system, and the tissue factor pathway inhibitor mechanism.
- Deficiencies, genetic or acquired, of the main regulatory proteins (antithrombin, protein C, and protein S) increase the risk for venous thrombosis.
- Increased levels of procoagulant factors or polymorphisms (causing functional change) increase the risk for venous thrombosis. A very common polymorphism in factor V (factor V_{Leiden}) reduces the ability of factor V to be downregulated by activated protein C. Relatively high levels of prothrombin (due to a specific polymorphism at base pair 20210) and elevated levels of factor VIII also increase the risk for development of thrombosis.
- Other inherited or acquired defects in hemostasis (dysfibrinogenemia and fibrinolysis) and in nonhemostatic systems (homocysteine) also increase the risk of venous thrombosis.
- Antiphospholipid syndrome and lupus anticoagulant (LA) are autoimmune disorders that affect the coagulation system and increase the risk of venous and arterial thrombosis. The LA antibodies are heterogeneous and present with a variety of laboratory abnormalities which can be detected only with a battery of tests. An approach for the identification of antiphospholipid syndrome and LA is presented.
- When evaluating a patient for thrombotic risk, it is important to plan the timing of testing so as to avoid misinterpreting decreased natural anticoagulants secondary to consumption by thrombosis or to anticoagulation from inherited deficiencies.

PHYSIOLOGIC ANTICOAGULANT PATHWAYS

(For a schematic overview of physiologic anticoagulant pathways, see also Fig. 39-5 in Chapter 39.)

Antithrombin (formally termed antithrombin III) is a circulating plasma serine protease inhibitor which regulates thrombin and factor Xa, and to a lesser extent factors IXa, XIa, XIIa, and VIIa (Stassen, 2004). The function of antithrombin is greatly enhanced on the endothelial cell surface by cell-bound glycosaminoglycans (heparan sulfate, dermatan sulfate, and small amounts of heparin) (Fig. 41-1) and pharmacologically by heparin (discussed extensively in Chapter 42).

A second major antithrombotic regulatory system is the protein C pathway, with an apparent multiprong mechanism consisting of a major anticoagulant component (Fig. 41-2) and an indirect profibrinolytic component (Esmon, 2009). The pathway is complex, with multiple factors which interact to generate a multitiered mechanism (Esmon, 2003a, 2003b, 2009). The central protein, protein C, is a vitamin K–dependent plasma proenzyme. The system is initiated with the generation of excessive non-clot-bound thrombin, which rapidly and tightly binds to an endothelial cell transmembrane glycoprotein, thrombomodulin (TM in Fig. 41-2). Thrombin bound in this complex undergoes a dramatic change in substrate specificity. Whereas it formerly was the sine qua non procoagulant enzyme of the coagulation system and a potent activator of platelets, its new ability to activate protein C effectively renders thrombin a potent anticoagulant enzyme. Thrombomodulin-bound thrombin, together with the endothelial cell protein C receptor, rapidly cleaves a small activation peptide from the protein C molecule (Stearns-Kurosawa, 1996; Esmon, 2004; Esmon, 2009). This process generates an active serine protease enzyme, activated protein C (APC). A second vitamin K–dependent inhibitory plasma protein, protein S (see Fig. 41-2), serves as a critical cofactor for APC. Protein S is a nonenzymatic cofactor molecule that binds in equilibrium to a large complement protein, C4b-binding protein (Rigby, 2004). Only the unbound (or “free”) form of protein S possesses APC cofactor activity. The complex of APC and protein S on the phospholipid surface of platelets or other cells rapidly inactivates factor Va and factor VIIIa, thereby greatly diminishing thrombin generation in the procoagulant pathways (Esmon, 2003a, b). The protein C system also appears to exert significant, although indirect, profibrinolytic activity. This is believed to involve the thrombin-activated fibrinolytic inhibitor (TAFI) (van de Wouwer, 2004) and the plasminogen activator inhibitor-1 (PAI-1) (Madden, 1991; Meltzer, 2010). TAFI is a plasma carboxypeptidase which is rapidly activated by the thrombin–thrombomodulin complex (van de Wouwer, 2004). The active form of the carboxypeptidase cleaves C-terminal lysine residues from fibrin that has already undergone proteolytic cleavage by plasmin. Loss of these

Hemostatic regulatory mechanisms limit the amount, location, and duration of clot formation. Dysfunction in the major regulatory systems of blood coagulation may lead to the pathologic condition of excessive clot formation (thrombosis). Both genetic and acquired deficiencies or abnormalities of such regulatory factors are capable of increasing the risk for thromboembolism. This chapter will discuss a number of factors that influence the balance toward bleeding or toward thrombosis, as well as the role of the laboratory in identifying abnormalities associated with these factors.

residues impairs the efficient binding of plasminogen-activating proteins to fibrin, thereby downregulating the fibrinolytic process. APC, via inactivation of factor Va, causes a decrease in thrombin generation, thus slowing TAFI activation. PAI-1 is inhibited by APC, thereby increasing overall fibrinolytic activity (Madden, 1991). Based on in vitro and animal experiments, the protein C system may also have other important defense properties, including anti-inflammatory activity and regulation of complement activity (Esmon, 2003a; Castellino, 2009).

As shown in Figure 41-3, tissue factor pathway inhibitor (TFPI) is another regulatory system that controls initiation of the tissue factor pathway (also referred to as the **extrinsic pathway**) of coagulation

(Smithies, 2004; Crawley, 2008). This inhibitor has two reactive binding sites: one for factor Xa that has previously been activated by tissue factor–factor VIIa, and a second for the tissue factor–factor VIIa complex itself (Esmon, 2003b). After some factor Xa is generated, then and only then can TFPI inhibit the tissue factor–factor VIIa complex. Binding of these proteins by TFPI removes their ability to contribute further to clot formation. TFPI accordingly provides a negative feedback mechanism for downregulating the coagulation process (Esmon, 2003b). The protein C–protein S pathway and TFPI regulatory systems are interdependent, with some proteins playing multiple roles in several mechanisms (Marlar, 2007; Hackeng, 2009).

THROMBOPHILIC PROTEINS OR FACTORS

An imbalance between the procoagulant systems and the regulatory mechanisms can lead to bleeding or thrombosis. An increase in procoagulant factors or a decrease in regulatory factors will tip the balance to excessive fibrin production, resulting in thrombus formation. These imbalances can be caused by genetic or acquired factors, or by a combination of the two (Tables 41-1 and 41-2). However, the process leading to excessive fibrin formation is not as simple as a single factor being disproportionate to the other factors. Rather, it consists of a combination of moderately imbalanced factors, which leads to excessive fibrin formation at the initial site of injury (Marlar, 2007). This, in turn, leads to vessel occlusion and fibrin clot growth (Franco, 2001). This multifactorial model, in which these factors interact in a cooperative manner, will lead to significant risk for the development of thrombosis (Marlar, 2007). Therefore, a complete assessment of the recognized and established risk factors must be made to determine the overall risk potential for an individual (see Table 41-2). The following factors are the major known components involved in increased risk for thrombus development (see Table 41-1 for a summary of prevalence and relative risk).

ANTITHROMBIN

Both hereditary and acquired deficiencies of antithrombin have been identified (Egeber, 1965; Bloemenkamp, 2003; Patnaik, 2008). Genetic deficiency of antithrombin is a rare disorder (~1 in 10,000 individuals) in the general population, and about 1% of patients are diagnosed as having familial venous thrombosis (Adcock, 1997). Antithrombin is autosomal, having an apparent dominant expression and high penetrance, with a large

number of known mutants throughout the gene (Adcock, 1997; Lane, 1997). Heterozygous individuals have plasma antithrombin levels around 50% of normal and are usually symptomatic (compared with heterozygotes of coagulation factor deficiencies, who usually are asymptomatic). Both type I (decreased activity with concomitant decreased antigen) and type II (decreased activity with normal levels of antigen) mutations have been described in antithrombin-deficient individuals (Lane, 1997). Homozygous antithrombin deficiency is incompatible with life, except for unique type II mutations in the heparin-binding region, where patients typically manifest venous thrombosis (Kuhle, 2001). The most common clinical presentation is deep venous thrombosis in the lower extremities and pulmonary embolus. It is noteworthy that thrombi may also occur in the retinal, mesenteric, and splenic veins (Bloemenkamp, 2003). Acquired deficiencies of antithrombin occur in disseminated intravascular coagulation (DIC) (Asakura, 2001), liver disease, the nephrotic syndrome, the acute period following venous thrombosis, and during heparin therapy (Marlar, 1990b). In some cases, acquired defects can cause plasma levels to drop to 30%–50% of normal and may be mistaken for genetic deficiencies. In the

TABLE 41-2

Estimated Thrombotic Risk for Cooperativeness of Multiple Factors

Risk factor 1	Risk factor 2	Combined risk (fold greater)
Protein C	Factor V _{Leiden} (heterozygous)	25–45
Protein S	Factor V _{Leiden} (heterozygous)	25–50
Factor V _{Leiden} (heterozygous)	Elevated factor VIII	12–20
Factor V _{Leiden} (heterozygous)	Oral contraceptives	8–20
Factor V _{Leiden} (heterozygous)	Pregnancy	25–40

newborn period, antithrombin is also characteristically low, reaching adult levels by the age of 6 months (Streif, 1999).

Both antithrombin activity and antigen in plasma can be determined using commercial kits. Antithrombin activity is determined by a chromogenic method utilizing factor Xa or thrombin as the inhibited enzyme. Antithrombin antigen is typically determined by enzyme-linked immunosorbent assay or by nephelometry. The normal ranges for both antithrombin activity and antigen are fairly narrow, usually around 80%–120% of normal (Adcock, 1997; Kuhle, 2001).

PROTEIN C

Protein C, the central protein in the protein C pathway, is a vitamin K-dependent protein. Both genetic and acquired deficiencies of protein C increase the risk for thrombosis. Protein C is autosomal, with variable penetrance phenotype expression. More than 100 mutations have been described with both type I (decreased activity with concomitant decreased antigen) and type II (decreased activity with normal levels of antigen) proteins (Marlar, 1990a, b; Lane, 1996). As shown in Table 41-1, surveys of the general population have found significant numbers of individuals with decreased levels of protein C. When plasma protein C levels, types of mutations, and lifestyles are compared, no differences are noted between symptomatic and asymptomatic individuals. The difference between asymptomatic and symptomatic protein C deficiencies is likely due to the further influence of additional thrombotic risk factors present within the symptomatic population. In homozygous protein C deficiency, severely deficient (<1% protein C activity) individuals manifest neurologic and

ophthalmic complications during intrauterine development and subsequently develop purpura fulminans and DIC during the newborn period (Peters, 1988; Marlar, 1990c). This disorder is incompatible with life unless the patient is treated with protein C replacement (fresh frozen plasma [FFP] or protein C concentrate) and anticoagulant therapy. The plasma half-life of protein C is relatively short at 6–8 hours. The initiation of warfarin oral anticoagulant therapy (especially large loading doses) without overlap of prior heparin anticoagulation in individuals heterozygous for protein C deficiency can lead to an infrequent but devastating condition of thrombotic skin lesions known as warfarin-induced skin necrosis (Moll, 2004; Tai, 2004; Goldenberg, 2008).

Testing for protein C in plasma is performed using clotting activity or chromogenic activity assays, or one of several types of antigen assays. The activity assays measure the function of the molecule in plasma; however, chromogenic assays may erroneously report protein C molecules as functional that actually do not possess functionality with respect to their natural coagulant substrates (Marlar, 1990a). For this reason, a clotting-based assay is recommended to assess protein C functional activity (Rezende, 2004). In type I protein C deficiency, functional activity and antigen level are decreased to about 50% of normal, whereas in type II deficiency, the functional level is decreased on average to 50% of normal, but the antigen level is 100% of normal (Marlar, 1990a, b).

PROTEIN S

Both genetic and acquired deficiencies of protein S are associated with increased risk of thrombosis (Esmon, 2003a, 2009). As discussed previously, protein S together with APC binds to the phospholipid surface of a platelet or other cell, enhancing the enzymatic inactivation of factors Va and VIIIa (Hackeng, 1994; van Wijnen, 1996). About 40% of the protein S is free in plasma, whereas the remaining 60% is bound to the complement protein, C4b-binding protein (C4b BP) (Nelson, 1992). Many pathologic and physiologic conditions can change the ratio of free and bound protein S, thereby effectively modulating the protein C inhibitory pathway (Mackie, 2001). The level of protein S characteristically decreases during pregnancy, with values averaging only 60% of those of controls from the 10th week of pregnancy onward (Cerneca, 1997; ten Kate, 2008).

The autosomal gene encoding protein S is expressed with variable penetrance (Rezende, 2004). More than 50 mutations have been described with associated increased thrombotic risk (Simmonds, 1998). The traditional quantitative type I deficiency (decreased protein S activity with concomitant decreased total antigen) and a qualitative type II deficiency (decreased protein S activity with normal levels of free and total antigen) have been reported. Because of the equilibrium between protein S and C4b BP, a third type of mutation has been identified (Simmonds, 1998): Type III deficiency is similar to type I, but the decreased protein S activity is associated with normal free protein S, yet decreased total protein S. Several studies have shown, however, that these rare type III individuals actually may not have increased risk for thrombosis (Brouwer, 2005; Libourel, 2005). Homozygous protein S deficiency with severely decreased protein S activity (<1%) has been reported with the same presentation and similar treatment regimens as homozygous protein C deficiency (Brouwer, 2005). Symptoms include purpura fulminans and DIC during the newborn period, with ophthalmic and neurologic complications having developed in utero. This disorder is incompatible with life unless the patient is treated with replacement therapy (i.e., FFP) and anticoagulant therapy.

Plasma protein S levels are determined by protein S clotting activity assays, as well as by antigenic assays for free protein S and total protein S antigen. Definitive diagnosis of protein S deficiency can be very difficult owing to the complexity of protein S interaction with C4b BP (Nelson, 1992; Goodwin, 2002; Persson, 2003; ten Kate, 2008). The activity assay measures the functional fraction of protein S in the plasma sample, but falsely low protein S activity has been reported (Goodwin, 2002). Two types of antigen assays are available: Assays whose measurement includes both free protein S and the bound fraction are considered to be measuring the *total* amount of protein S in a plasma sample (**total protein S antigen**). Assays for free protein S measure only the unbound portion of protein S by employing a monoclonal antibody specific for unbound protein S or by including a precipitation step with polyethylene glycol in which the bound portion of the protein S molecules is removed (Comp, 1986; Goodwin, 2002; Persson, 2003; ten Kate, 2008). Because clot-based functional assays have been reported to produce artifactually low values, it is recommended that free protein S antigen assays be used for the initial assessment of protein S. If the level is found to be decreased, reflex testing of both protein S activity and total protein S antigen should then be performed. Reaching

a definitive diagnosis of congenital deficiency of protein S is challenging, given the complexity of the interaction of protein S with C4b BP, the acquired conditions which can change the equilibrium of free and bound forms, and the presence of vitamin K antagonists (Simmonds, 1998; Mackie, 2001; Goodwin, 2002; Rezende, 2004; ten Kate, 2008).

ACTIVATED PROTEIN C RESISTANCE AND FACTOR V_{LEIDEN}

Activated protein C resistance (APC-R) is said to be present when the addition of exogenous APC to plasma does not result in the anticipated prolongation of clotting time tests such as the activated partial thromboplastin time (APTT) (Dahlbäck, 1999; Castoldi, 2010). APC-R is considered one of the most common genetic risk factors for venous thrombosis; however, although the prevalence of this abnormality in the Caucasian population is on average 4%, prevalence is lower among African and Asian populations (Ridker, 1995; Heijmans, 1998). APC normally enzymatically inactivates factors Va and VIIIa, prolonging the clotting time of plasma. In APC-R, the ability of APC to enzymatically degrade factor Va is significantly reduced. The polymorphism at one of the cleavage sites in factor Va is an arginine residue substituted by a glutamine residue (R506Q) that renders the site resistant to APC cleavage (Aparicio, 1996). The amino acid substitution is due to a single nucleotide change in the gene, termed factor V_{Leiden} (Bertina, 1994). Factor V_{Leiden} increases the relative risk of thrombosis onefold to twofold in the heterozygous condition and tenfold to fifteenfold in the homozygous individual (Svensson, 1997; De Stefano, 1999; Castoldi, 2010). The presence of factor V_{Leiden} will typically produce a characteristic abnormality in functional APC-R assays. There are numerous variations of such assays, with an exogenous source of factor V-deficient plasma frequently employed to increase specificity for abnormalities attributable to a genetic abnormality of the patient's own factor V. Two clotting tests are performed: the first in the presence of added APC, and the second without the addition of APC. If the ratio of clotting time with added APC divided by clotting time in the absence of added APC is sufficiently high (usually >2.0), then APC-R or factor V_{Leiden} is excluded. Lower ratios, in contrast, suggest that the sample is APC resistant, and that the patient may have factor V_{Leiden} (or one of several other rare factor V mutations), which should be confirmed by genetic testing (Aparicio, 1996; Tripodi, 1997; Castoldi, 2010). Also of potential clinical importance, however, are those cases of acquired APC-R not associated with a genetic abnormality of the patient's factor V molecule. As shown in Figure 41-4, several abnormalities may affect regulation of the coagulation pathways and may additionally exert a prothrombotic influence by virtue of increasing APC-R (Cumming, 1995; Graf, 2003; Castoldi, 2010). Detection of such forms of APC-R will be more frequent when assays are employed that do not include the addition of exogenous factor V-deficient plasma.

PROTHROMBIN 20210

A polymorphism in the prothrombin gene at base pair number 20210 is a guanine-to-adenine substitution in the 3'-untranslated region of the gene (Colucci, 2004). Heterozygosity for this polymorphism imparts approximately a twofold greater risk for venous thrombosis (Eikelboom, 1999). Heterozygous individuals characteristically have levels of plasma prothrombin higher than those in individuals lacking this polymorphism, although even these higher levels usually fall within the established reference interval for prothrombin activity of most laboratories. Accordingly, molecular diagnostic procedures are required for the diagnosis of prothrombin 20210 (Poort, 1996; Grunwald, 2000). There is believed to be increased transcription of the gene into the gene product, probably as the result of an increase in time during which mRNA molecules are translated (De Stefano, 1999). Prothrombin 20210 is a common genetic risk factor for venous thrombosis in populations of European descent (about 3%), with lower prevalence in other, non-European populations (De Stefano, 1999).

ELEVATED COAGULATION FACTOR LEVELS

In addition to an elevated level of prothrombin acting as a risk factor for thrombosis, elevation of several other coagulation factors has been reported to impart an increased risk of thrombosis. As levels of factors VII, VIII, IX, XI, or fibrinogen are elevated, the relative risks for developing thrombosis are proportionately increased (one-and-one-half-fold to sixfold) (Kannel, 1987; O'Donnell, 1997; Kyrle, 2000; Meijers, 2000). The most

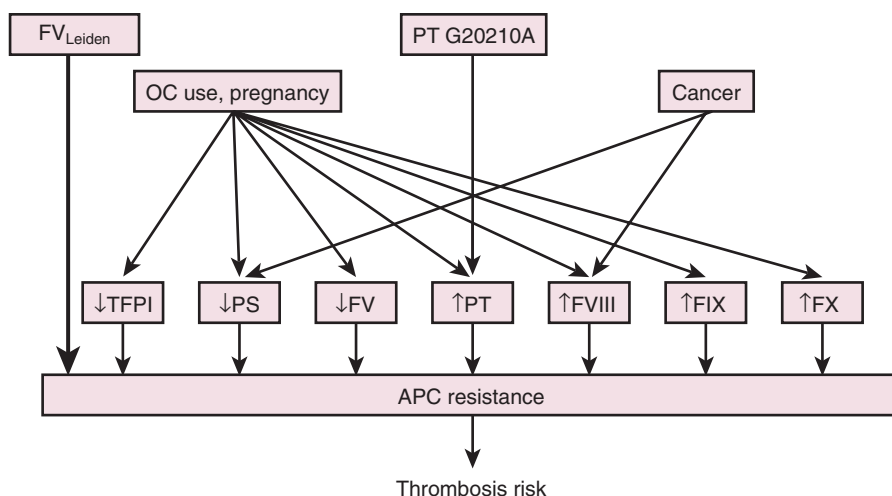

Figure 41-4 Activated protein C (APC) resistance as a complex phenotype. (Redrawn with permission from Castoldi E, Roseng J. APC resistance: biological basis and acquired influences. *J Thromb Haemost* 2010;8:445–53.)

studied and most complex of these reported risk factors is factor VIII. Factor VIII is regulated by genetic mechanisms and additionally by physiologic mechanisms that increase the release of stored factor VIII in times of stress and exercise. Some familial elevation of factor VIII has been reported, but transiently high levels can be seen in patients with a concomitant increase in plasma von Willebrand factor level and in patients with stress due to a variety of clinical conditions (Vormittag, 2009). Factor VIII levels of 120%–150% have a one-and-one-half-fold to twofold greater risk of thrombosis; levels of 300%–400% have an increased relative risk of threefold to sixfold (O'Donnell, 1997).

DYSFIBRINOGENEMIA

Fibrinogen is the final protein in the formation of a clot and the major component in a venous thrombus. Published reports of abnormalities associated with increased risk of thrombosis due to dysfunctional fibrinogen molecules are rare (Haverkate, 1995; de Moerloose, 2010). The incidence of recognized cases of dysfibrinogenemia in familial thrombosis is about 0.8%. Presently, the only assays commonly employed to assess fibrinogen are functional assays of clottability and antigenic assays. As discussed in Chapter 39, an imbalance in the ratio of such assays provides an indication of a decrease-of-function dysfibrinogenemia. Unfortunately, subtleties in the ability of fibrinogen—and perhaps more important, of the resulting fibrin—to bind proteins having an influence on the balance of hemostasis and thrombosis (e.g., tissue plasminogen activator) are not picked up by such assays. It is accordingly possible that the frequency by which dysfibrinogenemias underlie thrombotic events may be even higher than is presently recognized.

HYPOFIBRINOLYTIC MECHANISMS

Impaired function of the fibrinolytic system increases the risk of thrombosis, but there remains a lack of global clinical assays sufficiently robust to allow estimation of the degree of that risk (Collen, 1999; Meltzer, 2009). The euglobulin clot lysis time provides a measure of some aspects of the fibrinolytic system (Sartori, 2003). In brief, citrated plasma is diluted and acidified, resulting in the selective precipitation of many proteins that include fibrinogen, plasminogen activator, and plasminogen, whereas other molecules, including α_2 -antiplasmin, remain in solution. This precipitated **euglobulin fraction** is then redissolved in appropriate buffer and clotted by thrombin, and the time to clot lysis measured. An abnormal rate of euglobulin clot lysis helps direct the subsequent laboratory evaluation to an underlying abnormality of a critical component of the fibrinolytic system. Such a result adds support to the decision to proceed to more detailed testing of the fibrinolytic system, such as specific assays for plasminogen activator, plasminogen, and other proteins upregulating or downregulating fibrinolysis (Meltzer, 2009).

Although a variety of defects in the fibrinolytic system may well be contributing to the increased risk of thrombosis, consensus has been difficult to achieve with respect to assessment through system-based assays, specific component functional assays, or molecular analysis studies with respect to the individual patient. Deficiencies of plasminogen, the zymogen precursor of plasmin—the major enzyme responsible for fibrin clot

breakdown (see Chapter 39)—have been reported, but the association with increased thrombotic risk is not well founded (Schulman, 1996). Assessment of the mechanical properties of clots throughout the period of their formation and subsequent lysis with the Sonoclot, TEG thromboelastograph, or similar devices represents a quite different approach, which, with sufficient standardization, may permit the detection of abnormal fibrinolysis (Kamada, 2001; Salooja, 2001; Vig, 2001; Meltzer, 2009). These types of instruments work by detecting clot **rigidity** or **strength** during the clot formation and breakdown process (Kamada, 2001; Salooja, 2001; Vig, 2001; Meltzer, 2009; Kupesiz, 2010), and accordingly may offer the potential for real-time assessment of fibrinolytic state, which could be of particular benefit in conjunction with the monitoring of active antifibrinolytic therapy (Kupesiz, 2010).

OTHER POSSIBLE DEFECTS

Abnormalities in several other coagulation regulatory proteins and platelet proteins have been reported. However, difficulty in assessment of these proteins and lack of conclusive correlation with increased thrombotic risk have not yet established them as important risk factors for venous thrombosis.

Thrombomodulin (labeled as “TM” in Fig. 41-2) defects have been reported by several groups to have good association with thrombosis (2–6×). Numerous defects appear to span a large portion of the TM gene (Ohlin, 1995; Ohlin, 1997), with the result that it is still a challenge for clinical laboratories to detect such abnormalities.

Heparin cofactor II, a homologous inhibitor of antithrombin, has not been demonstrated to be associated with increased risk of thrombosis (Tollefsen, 2002). The PLA1/PLA2 polymorphism, as well as other platelet glycoprotein polymorphisms, has been of interest with respect to potential prothrombotic contributory roles (Lindoff, 1997; Heit, 2000; Robert, 2000; Paganin, 2003), with ongoing efforts to assess whether or not such variations actually achieve clinical significance (Ivanov, 2008; Zuern, 2010). Additionally, the non-O types of the ABO blood groups have been reported as increased thrombotic risk factors compared with type O, possibly owing to increased levels of von Willebrand factor and factor VIII (Wu, 2008).

ACQUIRED HYPERCOAGULABLE STATES

Numerous acquired conditions have been associated with increased risk of venous thrombosis. The relative risk for many of these has been determined and appears to combine with genetic causes to increase the overall risk for thrombosis. Common conditions that have a strong association with venous thrombosis include trauma, surgery and the postoperative state, pregnancy, immobility, obesity and diet, smoking, and previous thrombosis. Additionally, malignancy, chronic DIC, oral contraceptive use and hormone replacement use, heparin-induced thrombocytopenia, nephrotic syndrome, essential thrombocythemia, polycythemia vera, and inflammatory conditions have all been associated with increased risk of venous thrombosis. Finally, as discussed in Chapter 40, abnormalities of the enzyme ADAMTS13 have been associated with the thrombotic disorder thrombotic thrombocytopenic purpura.

ANTIPHOSPHOLIPID SYNDROME AND LUPUS ANTICOAGULANT

The antiphospholipid antibody syndrome (APS), a clinical disorder characterized by recurrent arterial and venous thrombotic events, is one of the most common risk factors for thrombosis, pregnancy complications, and fetal loss (Bizzaro, 2005; Palomo, 2009; Pengo, 2009). Venous or arterial thrombosis may occur, with venous manifestations being more common (Eby, 2009). The syndrome is an autoimmune disorder with antibodies directed against protein-phospholipid (PL) complexes. A strong association has been noted between immunoglobulin (Ig)G antibodies directed against domain I of β_2 -glycoprotein I (β_2 GPI) and thrombotic and obstetric complications in APS. Autoantibodies directed against additional PL-binding proteins such as prothrombin or annexin A2 may also be seen, although the clinical significance of these antibodies appears less clear. The binding of β_2 GPI to platelet plasma membranes and the subsequent interaction of anti- β_2 GPI involving both platelet GPIb α and a truncated splice variant of LRP-8 (a member of the low density lipoprotein-receptor family present on platelets, also known as ApoER2) may trigger platelet activation (de Groot, 2005; Giannakopoulos, 2007; de Groot, 2010). A potentially significant interaction between anti- β_2 GPI and β_2 GPI complexes with platelet factor 4 has recently been suggested (Sikara, 2010).

When PL-specific binding antibody interactions occur *in vivo*, there is a prothrombotic action. However, it is ironic that when these interactions occur *in vitro*, there is inhibition of procoagulant reactions. The term **lupus anticoagulant** (LA) is misleading since the presence of an LA raises concern for clinical thrombosis rather than for clinical bleeding, and most patients with LA in fact do not have systemic lupus erythematosus. The original studies identifying the antiphospholipid antibodies (APAs) used cardiolipin in the binding assays (anticardiolipin antibodies [ACAs]). In occasional cases, testing may include antiphospholipid-protein complexes specifically with phosphatidylethanolamine, phosphatidylserine, or phosphatidylinositol. Many of the ACAs are responsible for the false-positive results observed in Venereal Disease Research Laboratory testing for syphilis. In turn, many infections and autoimmune diseases and a variety of medications are associated with a positive ACA (McCrae, 2001; Galli, 2003; Riboldi, 2003).

In a number of studies, abnormal LA or ACA have been reported to occur in 1%–5% of an asymptomatic general population, with many of these being transitory (Biggioggero, 2010). Patients who maintain a persistent LA together with high titers of anti- β_2 GPI show the highest correlation with thrombosis (de Laat, 2009). The combination of anti- β_2 GPI, ACA, and LA test positivity has the highest association with recurrent venous thromboembolism (Pengo, 2006).

The mechanisms by which APA affect coagulation and hemostasis are multifactorial owing to the diversity of PL-associated proteins. Reports on the *in vivo* mechanism for hypercoagulability include downregulation of TM, interference with protein S, platelet activation, and endothelial perturbation. In particular, platelet-associated binding of antibodies against β_2 GPI may cause platelet activation (see earlier). Although there is no uniform approach for *in vitro* diagnosis of LA, it is clear that because of the heterogeneity of these antibodies, the presence of an LA cannot be excluded by simply failing to detect it in any single assay. Most commonly, the APTT and the dilute Russell viper venom time (dRVVT) are employed. Because these assays recognize different aspects of PL-dependent coagulation reactions, the combination is best for detecting LA. In the dRVVT test, the coagulation cascade is initiated later than in the APTT, with direct factor X activation by the venom in a PL-dependent fashion.

Several reagents for the APTT are designed to be more sensitive to LAs. The clotting time of plasma from LA patients is prolonged in these assays. When mixed with equal parts of normal pooled plasma, the plasma from LA patients will prolong the clotting time of the mixture beyond the clotting time of the normal control plasma itself. Whereas specific factor inhibitors, such as those directed against factor VIII, are typically time- and temperature-dependent (see Chapter 39), LAs more commonly are immediate-acting even at room temperature. Of particular note, LAs are notorious for interfering with quantitative measurement of coagulation factors assayed in an APTT-based system. A tell-tale pattern that should itself arouse suspicion of an LA is a persisting increase in apparent factor activity with increasing dilutions of patient plasma used in the assay: Such apparent increases in factor activity result from corresponding dilutions of LA.

Preincubation of LA plasma with an appropriate source of PL can neutralize the LA and result in significant shortening of a subsequently performed clotting time. Sources of neutralizing PL that have been used

for this purpose include purified hexagonal phase PLs and complex PLs derived from frozen and thawed washed platelets (platelet neutralization procedure [PNP]) (Favaloro, 2008, 2009).

Recent international consensus statements (Miyakis, 2006; Favaloro, 2009) combine the clinical criteria of vascular thrombosis and pregnancy complications with laboratory criteria. These laboratory criteria include a positive LA, an ACA of IgG or IgM of >40 IU and medium- or high-titer IgG or IgM anti- β_2 -glycoprotein I antibodies. The tests should be abnormal when repeated at least 12 weeks apart before a diagnosis of APA is made. The clinical course of high-risk patients diagnosed with APS reveals an extensive increase in recurrence of thrombosis, which can be markedly reduced by adequate anticoagulation (Pengo, 2010). Current approaches deriving from recommendations by the International Society on Thrombosis and Haemostasis related to the diagnosis of APS are shown in Table 41-3. Important considerations in implementing such an approach include (1) processing to ensure that the specimen is platelet-poor, (2) choosing two tests, such as the dRVVT or a silica-activated APTT with low PL content, (3) eliminating the influence of anticoagulants in mixing studies, (4) correcting prolonged clotting time in the presence of excess PL, and (5) ensuring that specific comments on the laboratory's reference ranges and interpretations accompany the LA profile and the ACA and β_2 GPI antibody assays (Ledford-Kraemer, 2008; Pengo, 2009, 2010).

HYPERHOMOCYSTEINEMIA

Homocysteine is an amino acid that is an intermediate molecule for the production and regulation of the sulfur-containing amino acid methionine (Guba, 1996; Refsum, 1998; Cattaneo, 2001). Perturbations, genetic or acquired, in the regulatory mechanism of this pathway can lead to elevated levels of homocysteine and to an associated increased risk of thrombosis. The most devastating of these is the cystathione- β -synthetase gene, which, in the homozygous state, leads to severe thrombosis and atherosclerosis (Mudd, 1985). Acquired causes mostly associated with diet and vitamin intake also are significant factors raising homocysteine levels in plasma. The associated risk for thrombosis with elevated homocysteine levels is a graded response, in which the higher the plasma level, the greater is the risk. Of note, two common polymorphisms associated with the homocysteine-metabolizing enzyme, methylenetetrahydrofolate reductase (MTHFR), were initially thought to be associated with increased risk of thrombosis. More recent studies have failed to establish MTHFR as an independent risk factor for thrombosis in adults (Tosetto, 1997; Franco, 1999), although a possible relationship with childhood stroke remains less clear (Prengrer, 2001). Accordingly, it is not presently recommended to evaluate MTHFR polymorphisms as a cause of venous thrombosis (Legnani, 1997; Franco, 1999) in adults; however, plasma levels of homocysteine often are determined as part of such an investigation.

GENERAL ASPECTS OF THE LABORATORY EVALUATION FOR THROMBOTIC RISK

Laboratory evaluation of thrombophilia is complex and rapidly changing, including the appropriate tests to order, when to order them, and on whom to perform the testing (Foy, 2009). There is no global test to grade the thrombotic risk status of an individual, so a series of individual tests must be ordered to obtain a good assessment of risk. Molecular diagnostic tests, in contrast, are not affected by such influences. From the laboratory perspective, appropriate assays to measure true functionality and concentration must be utilized. Whenever possible, activity assays should be performed to determine the functionality of the molecule; simply determining the antigen level may miss the type II molecule and misidentify the patient as normal (Rezende, 2004). A number of questions must be asked of every patient who is being considered for evaluation: Does the patient (and family) history justify an evaluation? Are the tests to be ordered appropriate for addressing major accepted risk factors? Is the timing appropriate to provide proper evaluation? Are there underlying therapeutic, pathologic, or physiologic conditions that interfere with interpretation of results?

Ideally, evaluations are performed when the patient is asymptomatic and is not on anticoagulation therapy. Unfortunately, during the immediate postthrombotic period before anticoagulation, plasma factors are consumed, thus inviting the potential for erroneous diagnoses. Heparin significantly decreases antithrombin levels, increases protein S levels, and

TABLE 41-3

Laboratory Detection of Lupus Anticoagulants (LAs)

- A. Blood collection
 1. Blood should be collected before the start of any anticoagulant drug regimen or a sufficient period after its discontinuation.
 2. Fresh venous blood in 0.109 M sodium citrate (ratio 9:1)
 3. Double centrifugation removes residual platelets.
 4. Quickly frozen plasma required if LA assays are postponed.
 5. Frozen plasma must be thawed at 37° C.
- B. Initial testing
 1. Use two separate screening tests based on different principles, each with a *low level of phospholipid (PL)*:
 - a. Dilute Russell viper venom time (dRVVT)
 - b. LA-sensitive activated partial thromboplastin time (APTT) (preferably with silica activator)
 2. Exclude the presence of heparin, LMW heparin, direct thrombin inhibitors, or factor Xa inhibitors.
 - a. Indirect (heparin) and direct thrombin inhibitors should be suspected from prolongation of the thrombin time.
 3. Results of screening tests are potentially suggestive of LA when their clotting times are longer than the local cut-off value.*
- C. Mixing studies for prolonged LA-sensitive APTT or dRVVT
 1. Pooled normal plasma (PNP) for mixing studies should ideally be prepared in-house. Alternatively, adequate commercial frozen or lyophilized PNP can be used.
 2. Plasma with prolonged screening values should be mixed as 1 part patient plasma with 1 part PNP and reassayed without incubation (i.e., <30 minutes after mixing).
 3. Results of mixing tests are suggestive of LA when their clotting times are longer than the local cut-off value.†
- D. Confirmatory tests for prolonged APTT or dRVVT
 1. Confirmatory tests are performed by increasing the PL concentration beyond that used in the screening tests.
 2. Bilayer or hexagonal (II) phase PL should be used to increase the concentration of PL.
 3. Results are confirmatory of LA if the % correction is above the local cut-off value.‡
- E. A report with an explanation of the results should be given.§

Subcommittee on Lupus Anticoagulant/Antiphospholipid Antibody of the Scientific and Standardisation Committee of the International Society on Thrombosis and Haemostasis. Update of the guidelines for lupus anticoagulant detection. *J Thromb Haemost* 2009;7:1737–40.

APTT, Activated partial thromboplastin time; LMW, low molecular weight.

*The cut-off value is the 99th percentile of the distribution of clotting times performed on plasmas from healthy donors. Testing described should be performed with the local reagent/instrument combination on plasmas from at least 40 adult healthy donors younger than 50 years of age. Cut-off values established elsewhere should not be substituted, even if they refer to the same method and instrument.

†In the case of mixing studies, the cut-off value would be the 99th percentile of the distribution of clotting times when plasmas from healthy donors are mixed in equal parts with PNP; alternatively, the distribution may be of a derived “index of circulating anticoagulant” = [(b-c)/a] X 100, where a, b, and c are the clotting times of the patient plasma, mixture, and PNP, respectively.

‡In the case of confirmatory testing, a distribution of values for “% correction” = [(screen – confirm)/screen] X 100, based upon testing of plasmas from healthy donors at low (screen) and high (confirm) PL concentrations is first obtained. A patient result above the cut-off value assigned to this distribution (e.g., above the 99th percentile) would then be considered as a positive confirmatory test. Note that the clotting time of the confirmatory test in LA-positive samples is not always shortened to within the normal range of controls. Accordingly, to avoid false-negative results, confirmatory tests are recommended to be performed in all normal controls, and these results used to establish the cut-off value.

§International Society on Thrombosis and Haemostasis (ISTH) guidelines further state, “Results should be expressed as ratio of patient-to-PNP for all procedures (screening, mixing and confirm).” Additional ISTH subcommittee explanations and qualifications are reported in detail in the original source of this table.

may mask LAs (unless a heparin-neutralizing molecule such as protamine or polybrene, or the enzyme heparinase, is included in the assay). Warfarin decreases protein C and protein S levels. Only genetic risk markers can be evaluated at any time by molecular diagnostic techniques. Attempts have been made to circumvent the test abnormalities produced by oral anticoagulation by using ratios of protein C or protein S to one or another of the vitamin K-dependent coagulation factors. However, the variability of such ratios is considerable, inviting the opportunity for misdiagnosis. Thus, this approach is not recommended. An erroneous diagnosis can be made when plasma factor levels decrease during a variety of acquired conditions such as pregnancy, hormone therapy, and post surgery.

Perhaps even more than in many other areas of clinical medicine, it is of critical importance to communicate the implications of these laboratory results to the patient in a manner that neither underestimates nor overestimates the role that thrombotic risk factors play in that patient's life. Decisions such as whether or not to take oral contraceptives, how to manage pregnancies, and whether or not to undergo chronic anticoagulant therapy can be difficult for both patient and provider. In the case of inherited disorders, genetic counselors may play a critical role as well. In all such instances, knowledge not only of available testing, but also of limits in interpretation of these tests, can contribute greatly toward reaching the most appropriate clinical decisions.

KEY POINTS

- Warfarin is the most commonly used oral anticoagulant. It acts as a vitamin K antagonist and blocks γ -carboxylation of a series of glutamic acid residues during the synthesis of factors II, VII, IX, and X, and proteins C and S. The resulting decreased functionality of the coagulation factors leads to prolongations of the prothrombin time, monitored by the international normalized ratio.
- Heparin binds to antithrombin and increases its ability to inhibit thrombin, factor Xa, and, to a lesser extent, other serine protease coagulation factors. Heparin is thus considered to be an “indirect” thrombin inhibitor. Heparin anticoagulant intensity is commonly monitored by prolongations of the partial thromboplastin time, with actual quantitation of heparin anticoagulant activity being assayed as anti-factor Xa activity. In instances where it is necessary to monitor low-molecular-weight heparin therapy, this must be done by measuring its anti-factor Xa activity.
- Heparin-induced thrombocytopenia (HIT) is a complication of heparin therapy in which antibodies develop against complexes of heparin and platelet factor 4. In the most severe cases, the resulting antibodies bind to platelets in such a manner as to cause activation, leading to arterial and/or venous thrombosis. Both immunologic and functional assays are employed in the evaluation of possible HIT.
- More recent anticoagulants function as direct thrombin inhibitors, or directly inhibit factor Xa. Effectively monitoring the activity of these inhibitors, as well as identifying possible interference by these inhibitors upon testing for other hemostatic abnormalities, presents new challenges to the diagnostic laboratory.
- Therapy directed toward inhibition of platelet reactivity is being used increasingly in both acute and chronic settings. The laboratory can monitor the resulting reactivity of platelets from treated patients, and in some instances can detect apparent resistance to aspirin or other therapeutic agents.

PREANALYTIC VARIABLES
AND CONTROLS

All standards for accuracy and precision in monitoring anticoagulant therapy are of little use if the blood sample is not obtained and processed in a defined manner (Adcock, 2009). The Clinical and Laboratory Standards Institute (CLSI) has provided useful guidelines for the collection, storage, and preparation of blood or plasma before coagulation testing is undertaken (summarized in an Appendix at the end of this chapter [CLSI, 2008]).

For optimal reporting, the time and date of the sampling, as well as the time of the last dose of the anticoagulant, should be recorded. Laboratory results for monitoring antithrombotic therapy need to be interpreted in conjunction with the clinical history for optimal regulation. Whenever there is a computed manipulation of the analytic data, such as the conversion of prothrombin time (PT) from seconds to the international normalized ratio (INR), a periodic check must ensure that the appropriate constants and data manipulations are being used, as defined by the standard operating procedures for the laboratory.

VITAMIN K ANTAGONISTS

Warfarin is the most commonly prescribed oral vitamin K antagonist. It is a racemic mixture of the stereoisomers S-warfarin and R-warfarin. S-warfarin is more potent in producing an anticoagulant effect. Warfarin inhibits vitamin K reductase (vitamin K 2,3-epoxide reductase) and blocks regeneration of the active form of vitamin K, which is necessary for the formation of γ -carboxy-glutamic acid in a sequence of amino acid residues (termed the **Gla domain**) within factors II, VII, IX, and X and proteins C and S (Fig. 42-1). With the decreasing extent of γ -carboxylation of glutamic acid within the Gla domains, there is in turn a decreased ability of the affected proteins to be bound into the highly ordered protein- Ca^{++} -phospholipid complexes that are critical components of the coagulation cascade (Ansell, 2004). Tests dependent on proper functioning of these factors will become more abnormal with increasing intensity of oral anticoagulant therapy (Ansell, 2008).

The degree of warfarin anticoagulation is typically measured in the PT testing system, although prolongations of the activated partial thromboplastin time (APTT) also are typically observed. Because fibrinogen synthesis is not vitamin K-dependent, the thrombin time (TT) remains normal. It must be stressed that *initial* prolongation of the PT upon institution of warfarin therapy does *not* faithfully reflect the overall intensity of anticoagulation. The reason for this unintuitive observation is that although the relatively short half-life of factor VII (4–6 hours) underlies the contemporaneous prolongation of the PT, the half-lives of other vitamin K-dependent factors actually extend to several days. Only when all of these factors have reached a steady-state level of decreased γ -carboxylation should one anticipate that overall diminution of the

A wide array of agents may alter the synthesis or action of coagulation factors, affect platelet function, or modify blood vessel responses. Prescribed and over-the-counter medicines with anticoagulant or antiplatelet activity are among the drugs most commonly used. Such agents may behave as a “double-edged” sword in that they may prevent formation or extension of a thrombus, but they can also produce or exacerbate bleeding. The clinical laboratory has a major role in the monitoring of some antithrombotic therapy.

Figure 42-1 The vitamin K-dependent γ -carboxylation system. The γ -carboxylase converts vitamin K-dependent proteins to γ -carboxyglutamic acid (Gla) containing proteins by adding carbon dioxide (CO₂) to glutamic acid (Glu) residues in newly synthesized proteins. The γ -carboxylase requires reduced vitamin K₁ (vitamin K₁H₂) as a cofactor for this posttranslational modification reaction. Concomitant with γ -carboxylation, vitamin K₁H₂ is converted to vitamin K₁ 2,3-epoxide (vitamin K₁>O). The epoxide is reduced by the warfarin-sensitive enzyme vitamin K₁ 2,3-epoxide reductase (VKOR) to the vitamin K₁H₂ cofactor. This cyclic interconversion of vitamin K metabolites constitutes the vitamin K cycle. At high tissue concentrations, vitamin K₁ quinone (vitamin K₁) can be reduced to vitamin K₁H₂ by the alternative pathway of the cycle. This pathway is catalyzed by NAD(P)H dehydrogenases (DT-diaphorases), which are not inhibited by warfarin (From Wallin R, Hutson SM. Warfarin and the vitamin K-dependent gamma-carboxylation system. *Trends Mol Med* 2004;10:299–302.)

coagulation system (as reflected by actual thrombin generation) has been obtained. For this reason, a minimum of 4–6 days of oral anticoagulant therapy is generally recommended before assuming that laboratory monitoring actually reflects the steady-state level of anticoagulation. When more rapid onset of effective anticoagulation is necessary, heparin is given before or along with warfarin. After at least 4 days of combined therapy, heparin can be discontinued, and the warfarin dose can be adjusted to the prescribed target INR. Although warfarin therapy ordinarily produces a net anticoagulant effect, in certain settings (e.g., active HIT), the resulting decrease in carboxylation and hence activity of protein C and/or protein S may dominate the hemostatic imbalance, resulting in purpura fulminans or other manifestations of venous thrombosis (Martin, 1998).

As discussed in Chapter 39, the PT is performed by adding a source of phospholipid and tissue factor (thromboplastin), as well as excess calcium, to the citrated platelet-free plasma. The time in seconds to subsequent clot formation then is determined by mechanical or optical measurements. However, the actual degree of PT prolongation in response to warfarin therapy is highly dependent on the particular thromboplastin reagent and instrument system employed. Cooperation among a number of laboratories in different countries resulted in the development of the INR and the international sensitivity index (ISI), both of which are now universally used to improve standardization of PT reporting worldwide. In brief, the logarithms of PTs obtained on prescribed series of normal and warfarinized patients, using the primary international reference thromboplastin, are plotted against the logarithms of PTs obtained using an individual thromboplastin reagent (Fig. 42-2). The resulting slope of this plot is the ISI for that thromboplastin reagent and instrument combination (Kitchen, 1999; Poller, 2004; Adcock, 2002; van den Besselaar, 2004; Favaloro, 2008). The ratio of patient PT divided by geometric mean normal PT for the local laboratory (based on a population of normal individuals in which identical sample collections, reagents, and analyzers are used), raised to the power of the ISI, defines the INR as follows:

$$INR = \left(\frac{\text{Patient PT in Seconds}}{\text{Mean of the Normal PT in Seconds}} \right)^{ISI} \quad (42-1)$$

Put in another way, the INR seeks to represent the PT ratio that would have been obtained if the international reference thromboplastin had

Figure 42-2 An example of a thromboplastin calibration using the World Health Organization (WHO) international sensitivity index (ISI) model. Prothrombin times were performed on a series of normal subjects and anticoagulated patients with a reference thromboplastin and a test thromboplastin under calibration. (From Kitchen S, Preston FE. Standardization of prothrombin time for laboratory control of oral anticoagulant therapy. *Semin Thromb Hemost* 1999;25:17–25.)

actually been used in patient testing. However, attainment of a fully assay-independent INR may be very difficult in practice (Ng, 1993; Cunningham, 1994; Favaloro, 2010).

Because of the importance of proper monitoring of oral anticoagulant therapy, several additional points regarding ISI and INR must be emphasized: The ISI must be correctly specified not only for each type of PT reagent, but also for each new lot of thromboplastin, in conjunction with the specific instrument model being used in a given laboratory. Less responsive thromboplastins (typically derived from nonhuman tissues) have ISI values in the range of 1.7–2.2, whereas more responsive human-derived tissue-derived reagents have ISI values in the range of 1.0–1.7. Recombinant tissue factor is the most responsive thromboplastin, with ISI values approaching 1.0. Most laboratories report results simply as INR, but some also give the results as PT in seconds. During initiation of anticoagulation, more frequent measurements of PT may be required until the INR has stabilized. In plasma from patients treated with both heparin and warfarin, the anticoagulant contribution of warfarin can be assessed if heparin is first removed or neutralized before PT testing is performed (see later). Unless a method becomes available for removal or neutralization of direct thrombin inhibitors (DTIs), the therapeutic intensities of such inhibitors can be sufficient to prolong PT, and accordingly influence the INR value (Tobu, 2004; Walenga, 2004). This should be assessed when warfarin is to be started after DTI therapy (Bartholomew, 2005). Although most lupus anticoagulants exert a more pronounced effect upon the APTT than the PT, the presence of a lupus anticoagulant in some patients may render the PT inaccurate as a means of monitoring warfarin therapy. This may depend on the reagents used (Moll, 1997). In such instances, a direct chromogenic assay for factor X (rather than a clotting assay) may aid in monitoring of anticoagulant intensity (Rosborough, 2004). An additional consideration is that use of nonhuman tissue factor in some patients may lead to prolongation of the PT (and hence increased INR) that would not

TABLE 42-1

Phenotype Characteristics of Warfarin Metabolism Genotype Combinations

Warfarin sensitivity	GENOTYPE COMBINATION		Prevalence	Clinical considerations
	VKORC1	CYP2C9		
Very high	A/A G/A	*1/*3, *2/*2, *2/*3, *3/*3 *3/*3	23 (2.6%)	Dose decrease and frequent INR monitoring
High	A/A G/A G/G	*1/*2 *2/*3 *3/*3	36 (4.0%)	Dose decrease and frequent INR monitoring
Moderate	A/A G/A G/G	*1/*1 *1/*2, *1/*3, *2/*2 *2/*3	238 (26.6%)	Dose decrease and frequent INR monitoring
Mild	G/G	*1/*2, *1/*3, *2/*2	109 (12.2%)	Frequent INR monitoring
Normal	G/A	*1/*1	262 (29.2%)	Likely to experience normal response to warfarin
Less than normal	G/G	*1/*1	228 (25.4%)	Dose increase may be required to maintain optimal INR
Total			896 (100%)

CI, Confidence interval; NS, not significant; SNP, single-nucleotide polymorphism.

Frequency values are reported for the variant allele at each SNP. CYP2C9 gene locations taken from <http://www.cypalleles.ki.se/cyp2c9.htm>

have been obtained had human tissue factor been employed. This phenomenon has been reported in patients with **factor VII Padua**, who have a nonpathogenic polymorphism in their factor VII molecule that supports normal interaction with human tissue factor, but diminished interaction with tissue factor of various animal origins, notably including rabbit (Pollak, 2006; Kirkel, 2010).

The half-life of warfarin is between 20 and 60 hours, with a mean plasma half-life of 40 hours. The maximum effect of a dose lasts for up to 48 hours after administration. S-warfarin is metabolized by CYP2C9, and R-warfarin is metabolized by the CYP1A2 and CYP3A4 enzymes. VKOR controls the levels of reduced vitamin K reductase. There are polymorphisms of CYP2C9 and VKOR, and knowledge of the patient's specific gene alleles may have predictive value in determining which patients need higher or lower doses of warfarin (Higashi, 2002; Linder, 2002; Adcock, 2004). Warfarin dosing incorporating genotyping results has been reported to reduce patient hospitalization rates (Moore, 2008; Epstein, 2010). Specific allelic combinations of CYP2C9 and VKORC1 are associated with a wide range of warfarin sensitivities (Table 42-1). Allelic frequencies and their relationships to race and therapeutic warfarin dose are shown in Table 42-2. Pharmacologic algorithms have been developed to help guide warfarin dosing (Gage, 2008; Lubitz, 2010). They have become increasingly successful in predicting variabilities in response to warfarin dosing (Klein, 2009), and even in reducing hospitalization (Epstein, 2010).

Genetic resistance to warfarin therapy is uncommon. In instances where inappropriate responses to warfarin are marked and persistent, the metabolites can be measured using high-performance liquid

chromatography (Lombardi, 2003). These measurements can also be used to check compliance. Drugs that affect S-warfarin metabolism may markedly alter the potency of warfarin treatment. Some drugs or herbal medications induce CYP2C9 and cause warfarin to be metabolized faster, thus decreasing the anticoagulant effect. Other drugs inhibit the metabolism of warfarin and thus enhance the effect of warfarin. Several hundred compounds are known to alter the metabolism of warfarin (Poller, 1996; Ansell, 2008). Antibiotics may interfere with the metabolism of warfarin, or they may suppress the gut flora, which supplies a significant amount of vitamin K in humans. Rifampin, e.g., may dramatically increase the metabolism of warfarin, thereby necessitating very high doses of warfarin to achieve anticoagulation (Krajewski, 2010). Foods, particularly green leafy vegetables rich in vitamin K, may make anticoagulation with warfarin more difficult. Warfarin products may have different potencies, so that switching between related medications may require more frequent monitoring and dosage adjustments (Bongiorno, 2004).

Warfarin is used most commonly for prevention of thromboembolic stroke in patients with atrial fibrillation. Additionally, warfarin is used both prophylactically and therapeutically in a wide range of clinical settings and may even be used on a lifelong basis in patients who are at particularly high risk for recurrent thrombotic events. The American Association of Chest Physicians periodically reviews the guidelines for anticoagulant therapy and publishes its consensus report in the journal *Chest* (Hirsh, 2008). The current recommendation for treatment targets an INR between 2 and 3 for most patients with venous thromboembolic disease and atrial fibrillation (Ansell, 2008).

Because warfarin is influenced by liver function, diet, absorption from the gut, and cotreatment with other drugs or herbal medications, it is not uncommon for patients to present with INRs that are elevated or decreased. Mild elevations of INR can be treated by changing the dosage schedule. More significant elevations can be treated with 2 mg of vitamin K given orally. If there is a high risk of bleeding, higher doses of vitamin K can be administered. However, the patient then may become resistant to further warfarin therapy, and another anticoagulant may have to be substituted. If the patient is bleeding, fresh frozen plasma, activated prothrombin complexes, or recombinant FVIIa may be transfused to achieve hemostasis (Ansell, 2008).

Extreme care should be used in treating patients with warfarin. Warfarin should not be used in patients with evidence of hemorrhage. If there is a suspicion of hemorrhage, a periodic assessment for blood loss and anemia should be made. Warfarin is teratogenic and should not be used in pregnant females (Bates, 2004). If a deficiency state of protein C is suspected, heparin or another anticoagulant should be started before or concomitantly with warfarin therapy. In patients with HIT, administration of warfarin is of particular concern, in that lowering the activity of protein C may potentially promote venous limb gangrene (Warkentin, 2008).

The INR is monitored to keep patients on warfarin therapy within a range that will prevent further thrombosis but will not lead to bleeding. Although an anticoagulant intensity goal INR of 2–3 defines the usual reference interval, still higher INRs may be sought in certain clinical settings. Patients, families, and caregivers should be educated about the therapy and should be informed about the importance of having the INR checked on a routine basis. In some instances, patients may be taught how to use point-of-care (POC) coagulometers to obtain an INR measurement (see following).

Many new developments have occurred in the technology of POC monitors for oral anticoagulant therapy. Mechanical technologies using the magnetic motion of iron filings, motion flow detectors, thrombin-cleavable fluorescent substrates, electrochemical detectors of impedance changes, and laser light dispersion technologies have been used to detect clot formation and to transform data into a reportable PT-INR. Each type of POC-PT measurement must be characterized for use with specific patients (NCCLS, 2004). Results obtained with different POC-PT instruments and laboratory-based instruments often are not comparable (Nutescu, 2004). Indeed, even the patient specimen itself will vary in terms of being whole blood directly sampled by a POC instrument, as opposed to the citrated plasma routinely used in the clinical laboratory setting. Quality assurance and quality control plans should be in place for POC coagulation testing (Gardiner, 2009; van Cott, 2009). Out-of-range POC INR should be retested by analyzing a sample of citrated blood in the clinical laboratory (Sunderji, 2005).

HEPARIN

Heparin is a natural polymer of sulfated glycosaminoglycans with a wide range of molecular weights. Unfractionated heparin (UFH) may be used prophylactically or therapeutically for venous and arterial thrombosis. The molecular weight of UFH ranges from 20,000–50,000 Da. UFH for systemic use is prepared from porcine intestine. Heparin is an **indirect** thrombin inhibitor that exerts its effects by binding to antithrombin in such a manner as to significantly increase the potency of the inhibitory action of antithrombin on the serine esterase activity of thrombin (Fig. 42-3). The anticoagulant effect is derived from inhibition of serine protease coagulation factors, with the most critical inhibition being that of factor IIa (thrombin) and factor Xa. However, additional effects of heparin include the release of tissue factor pathway inhibitor, an increase in tissue plasminogen activator and fibrinolysis, and impairment of platelet function (Salzman, 1980). Unfractionated heparin can be given subcutaneously or intravenously with a rapid onset of action (Bussey, 2004; Hirsh, 2004b). It is important to rapidly achieve effective anticoagulation in patients with veno-occlusive disease (e.g., venous thromboembolism [VTE]) because sequestered thrombin may allow subsequent propagation of the thrombus (Hull, 1997).

A variety of methods can be used to measure unfractionated heparin. These include the APTT, TT, protamine reversal, factor Xa inhibition, and activated clotting time (ACT). The APTT is the most commonly used assay. In contrast to the case of warfarin monitoring, for which the international community has established the INR to minimize performance variations in reagent/instrument combinations used by different laboratories, comparable standardization is presently lacking with respect to use of the APTT for monitoring heparin. This raises a particular problem for

Figure 42-3 Hypothetical mechanisms for heparin/heparan sulfate regulation of protein-protein interactions. Binding of a specific pentasaccharide sequence of heparin present in unfractionated heparin (UFH) and low-molecular-weight heparin (LMWH) or in isolated form (fondaparinux) to antithrombin (AT) produces a conformational change in AT sufficient for inhibition of the serine protease factor Xa. Effective inhibition of thrombin (factor IIa) additionally requires direct interaction with a region of the heparin molecule distinct from the pentasaccharide. Such thrombin binding regions are characteristically more available in UFH than in the LMWH products. (Modified from Nugent MA. Heparin sequencing brings structure to the function of complex oligosaccharides. *Proc Natl Acad Sci U S A* 2000;97:10301–3.)

the laboratory with respect to serving those clinicians whose professional societies quote a heparin goal range in terms of actual seconds measured by APTT testing. Although there does appear to be a degree of convergence toward an increasingly standardized range for the normal APTT adult reference interval when products from a number of manufacturers are used, APTT testing systems with significantly different performance attributes are also available. Accordingly, it is important for the individual laboratory to consider the potentially considerable implications with respect to use of the APTT in therapeutic drug monitoring of heparin when deciding upon which reagent/instrument combination to adopt. A classic approach used by many clinicians for monitoring heparin therapy is to aim for a 1.5- to 2.5-fold increase in APTT over the patient's baseline APTT, or, alternatively, over the midpoint of the laboratory's normal reference interval for the APTT. However, the approach currently in general usage by clinical laboratories, and in fact mandated for many laboratories by their accreditation process, comprises performing a linear regression analysis of the APTT plotted against anti-factor Xa heparin levels for patients undergoing therapeutic heparin anticoagulation. An example of such an analysis is shown in Figure 42-4. Because recommendations from a number of professional societies as to goals for intensity of heparin therapy are expressed in anti-Xa units, the laboratory then translates the range of anti-Xa units (e.g., 0.3–0.7 anti-Xa units is commonly recommended in conjunction with treatment of deep venous thrombosis) into the corresponding range of APTT values that has been obtained with current lots of reagents for both the anti-Xa assay and the APTT. This relationship must be reevaluated each time a change in reagent lot (or instrument) occurs for either of these tests. Additionally, it should be noted that, owing to the complex pharmacokinetics of heparin, plasma samples must be obtained from patients actually undergoing heparin therapy; it is not acceptable simply to add exogenous heparin to normal plasma samples and then perform regression analysis on the resulting APTT and anti-Xa values (Olson, 1998; Hirsch, 2004b). As is apparent from the wide degree of scatter seen in Figure 42-4 (and an even greater range of scatter apparent in examples presented by Cuker [2009]), the relationship between APTT and anti-Xa values obtained from real patients is far from tight. When one considers the many contributors to variation in the APTT (see Chapter 39) such as factor VIII level and levels of contact factors and lupus anticoagulants, it is not at all surprising that the APTT will have considerable variation between patients, even though heparin levels may be identical. Less intuitive, however, may be the variability observed among anti-Xa heparin assays performed with the various available reagent/instrument combinations. One contributor to such variability is whether or not the particular assay system includes the addition of exogenous antithrombin

TABLE 42-3

Comparison of the Properties of LMWH, Fondaparinux, and Idraparinux

Feature	LMWH	Fondaparinux	Idraparinux
Mode of administration	Subcutaneous	Subcutaneous	Subcutaneous
Bioavailability, %	80–90	100	100
Half-life, hours	4	17	80
Target	Factor Xa > thrombin (2–4 fold)	Factor Xa	Factor Xa
Renal clearance	Yes	Yes	Yes
Neutralized by protamine sulfate	Partial	No	No

Modified from Bates SM, Weitz JI. New anticoagulants: beyond heparin, low-molecular-weight heparin and warfarin. *Brit J Pharmacol* 2005;144:1017–28.
LMWH, Low-molecular-weight heparin.

Figure 42-4 Linear regression analysis of relationship between activated partial thromboplastin time (APTT) and anti-factor Xa (Xa) heparin level performed on plasma samples from patients undergoing heparin therapy. With this particular reagent/instrument combination, the regression analysis yields an APTT range of 66–108 seconds that would correspond to an anti-Xa range of 0.3–0.7 U/mL.

(Lehman, 2006). Providing an excess of antithrombin may produce a higher heparin level for the patient who is deficient in endogenous antithrombin. In a sense, this yields the more accurate measurement. Viewed from a different perspective, however, the more appropriate measurement to guide dosing may be the one that reflects the actual inhibitory ability of infused heparin, that is, the method that remains dependent on the patient's own antithrombin level. It is interesting to note that in a recent interinstitutional study, when heparin dose adjustments were guided by APTT target ranges defined by their relationship to anti-Xa assays, concurrence in dose adjustment proved more difficult to achieve than when these adjustments were guided by simple fold-increase in the APTT, as described previously (Cuker, 2009). Regardless of how the continuing debate regarding optimal monitoring of heparin therapy is resolved, however, all would agree that for patients who have a quite prolonged baseline the APTT before initiation of heparin therapy, a more specific method such as the anti-Xa assay must be employed.

Heparin contamination is a frequent cause of prolongation of the APTT and TT, and in fact can interfere with the performance of clot-based tests. This is particularly true when samples are drawn from intravenous catheters. Some commercial test kits contain polybrene or other agents to neutralize heparin. The presence of heparin can be determined if a prolonged APTT shortens following treatment with heparinase (obtained from *Flavobacterium heparinum*). In specimens with a very prolonged APTT value, a second treatment with heparinase may be necessary to remove all heparin and produce a true APTT value. A similar approach can be used in which heparin-binding cellulose absorbs heparin from patient plasma. This absorption procedure has only minimal effects on the other coagulation factors, except for a slight reduction in factor IX (Hutt, 1972; Thompson, 1976; Cowan, 1981; Newman, 1995).

Patients may appear to be resistant to heparin, although the definition of such resistance may be dependent on the specific clinical setting:

"In the context of venous thromboembolism, heparin resistance is defined as the need for more than 35,000 U 24 h⁻¹ to prolong the activated partial thromboplastin time into the therapeutic range. In contrast, during cardiac bypass procedures, the definition of heparin resistance is based on the ACT, with at least one ACT less than 400 s after heparinization and/or the need for exogenous antithrombin administration"

(Anderson, 2002).

Causes of heparin resistance include massive thrombosis with release of heparin-binding proteins; elevated factor VIII levels (often evidenced by short baseline APTT); treatment with nitroglycerin; severe obesity; antithrombin deficiency (<30%); HIT; and cancer (Edson, 1967; Bharadwaj, 2003; Francis, 2004a). In some instances of apparent heparin resistance as measured by the APTT, such as in the case of elevated factor VIII levels, simply changing to anti-factor Xa assays will provide a more accurate measure of the heparin level (Hirsh, 2004b). Additionally, a recent study has suggested that race may play a role in sensitivity to heparin (Shimada, 2010).

LOW-MOLECULAR-WEIGHT HEPARIN

Low-molecular-weight heparin (LMWH) (see Table 42-3) is derived from unfractionated heparin. LMWH does not as effectively inactivate thrombin as it does factor Xa. This has been explained by the observation that since distribution of the pentasaccharide with heparin chains is random, there will more frequently be insufficient room in adjacent regions for effective binding to thrombin in the shorter LMWH chains (Gray, 2008). Anti-Xa assays, rather than APTT, must be used when measurement of LMWH is needed (Boneu, 2001). The general therapeutic range for LMWH in patients being treated for venous thromboembolic disorders is different for each LMWH product. As a result of decreased binding to plasma proteins, a predictable response to LMWH can be expected in most cases, allowing LMWH to be given subcutaneously once or twice a day (Bounameaux, 2004; Harenberg, 2004). Plasma levels of LMWH usually are not monitored, except during treatment of children and newborns, pregnant women, markedly obese patients, and patients with renal failure. When monitoring is performed, blood is ordinarily drawn approximately 4 hours after the last dose because this is when the peak level is anticipated to occur (Bounameaux, 2004; Harenberg, 2004; Hirsh, 2008).

Complications of osteopenia and HIT (see later) occur less frequently when LMWH rather than UFH is used (Pettit, 2002; Schulman, 2002). However, patients with established HIT should not be anticoagulated with LMWH. Although LMWHs initially are less immunogenic, once antibodies have actually been produced following UFH administration, pathologic antigen-antibody interaction may occur upon subsequent administration of LMWH (Warkentin, 2007; Lobo, 2008).

FONDAPARINUX

Fondaparinux is a small synthetic pentasaccharide that targets factor Xa. This drug binds to antithrombin (AT) in an irreversible fashion, enhancing the reactive site of AT to complex with factor Xa. It has a longer half-life than heparin or LMWH and can be given subcutaneously once daily; dose is based on weight and does not ordinarily require measurement of blood levels. Fondaparinux is cleared by the kidneys, and its dose must be reduced in patients with compromised renal function (Weitz, 2010a). Only very

rarely has fondaparinux been associated with HIT (Warkentin, 2007; Lobo, 2008).

HEPARIN-INDUCED THROMBOCYTOPENIA

Thrombocytopenias arising in the setting of heparin therapy occur in two forms. Nonimmune HIT is believed to result from platelet activation following the direct binding of heparin to platelets (Horne, 2001). The degree of thrombocytopenia is generally mild and transient. Of far greater concern are immune-mediated processes, sometimes referred to as **type II HIT**, but more commonly simply as **HIT**. Additionally, when venous and/or arterial thrombosis arises in the context of HIT, the entity may be referred to as **heparin-induced thrombocytopenia and thrombosis (HITT)**. Studies have shown that UFH structures bind tetramers of PF4 into ultralarge complexes (ULCs) that are particularly antigenic (Rauova, 2005). If multiple IgG molecules bind to the ULC, the Fc regions of these antibodies may then be oriented in a manner favoring their binding to the Fc γ RIIA receptors of the platelet, thereby causing signal transduction and subsequent platelet activation. Manifestations of such platelet activation include secretion of granular material and release of platelet microparticles whose outwardly facing phosphatidylserine may potentially promote thrombin generation and hence increased clotting. Antibodies to other chemokines which have shared sequence structures with PF4 (the CXC family of chemokines), including interleukin-8 (IL-8), interferon-gamma-inducible protein (IL-10), platelet basic protein and its proteolytic product β -thromboglobulin, and neutrophil-activating protein-2, may also cause HIT (Greinacher, 1994; Amiral, 1996). HIT-associated antibodies may also cause endothelial cells and monocytes to activate and express tissue factor on their surface (Fig. 42-5). HIT is more likely to arise in patients experiencing major trauma (Lubenow, 2010; Warkentin, 2010).

HIT occurs more frequently with exposure to bovine heparin than to porcine heparin, and with lower frequency following LMWH (Fig. 42-6). In the usual presentation, the platelet count drops at 5–10 days after exposure to heparin, with platelets falling to below 150,000/ μ L or decreasing to levels of less than 50% of peak platelet count before initiation of heparin. When this occurs, all heparin treatment should be discontinued (including heparin flushes of catheters). In most cases, the platelet decrease is seen at 4–5 days from initiation of therapy, but in some cases thrombocytopenia may occur as early as 2–3 days, and may even arise within a week or 2 following discontinuation of heparin administration. Although a fall in platelet count can certainly be a matter of concern in various clinical contexts, by far the most serious concern arises in that minority of patients with HIT who actually progress to thrombotic events (see Fig. 42-6). Venous thromboses are more common than arterial thromboses, and the

lower limbs are more frequently involved. Formation of platelet microparticles with phosphatidylserine exposed on their outer surfaces, together with activation of monocytes that produce tissue factor, contributes to thrombin generation and subsequent venous thromboses (Kelton, 2008). Patients may have areas of skin necrosis at the site of heparin injections or acute systemic inflammatory reactions after a heparin bolus, and may show evidence of heparin resistance. Other causes of thrombocytopenia must be ruled out. If heparin is discontinued, thrombocytopenia frequently abates in 9–10 days. However, the patient can be at risk for thrombosis for several weeks after discontinuing heparin.

A presumptive diagnosis of HIT is often made on clinical grounds, particularly in cases where the time course and the extent of the drop in platelet count fit together convincingly with the patient's history of heparin therapy. In such cases, treatment decisions may be made independently of whether or not the results of laboratory testing also point in this direction (Warkentin, 2008). Several algorithmic approaches have been developed that attempt to assess the pretest likelihood of true HIT in the individual patient, most notably the **4T** system (Table 42-4). Establishing the correct diagnosis in a timely manner through laboratory testing has continued to represent a substantial challenge. As illustrated in Figure 42-6, a great many patients test positively on one or more immunologically based tests, and even a substantial number test positively on tests employing platelet functional responses, yet they may not actually have clinical HIT or HITT. Greinacher (2010) has postulated that a background level of antibody directed against PF4 bound to glycosaminoglycans may routinely arise as part of the body's antibacterial response to infectious organisms whose glycosaminoglycans also bind PF4. This hypothesis not only would account for a number of apparent biological false-positive results observed in HIT testing, but also would provide an explanation for what otherwise would appear to be an unusually short minimal time (\approx 5 days) to the appearance of antibodies following exposure to heparin.

Additionally, recent contributions by Rauova (2009), Kelton (2008), and others suggest that platelet content of PF4, in conjunction with the level of PF4 actually bound to the surface of both platelets and monocytes, may be a key determinant as to which patients will or will not manifest clinically significant HIT and HITT. Viewed from these perspectives, it may well be that present analytic approaches are not yet assessing critical pathophysiologic determinants. Until the time that such improved testing may become available, efforts will continue to establish algorithmic approaches intended to guide diagnosis using present technologies. Clearly, such algorithms must be expected to vary among themselves, based on the specific tests employed in a given laboratory. One example of such an algorithmic approach, as used in this instance by the Greinacher group in Greifswald, Germany, is illustrated in Figure 42-7.

Figure 42-5 Mechanistic basis of heparin-induced thrombocytopenia (HIT). (A) shows the platelets and monocytes from a patient with little released platelet factor 4 (PF4) on the left. Following heparinization (1), the small amount of surface-bound PF4 becomes complexed to the higher-affinity circulating heparin and induces anti-PF4/heparin antibody production (2). Because there are not many surface PF4/GAG complexes for the antibodies to bind, they largely remain unattached to cells and do not activate the platelets or the monocytes (3). The patient does not develop HIT. (B) is as (A), but with a great deal of released PF4 bound to the surface of both platelets and monocytes. After heparinization (1), some PF4/surface GAG complexes remain. Circulating free PF4/heparin induces antibody production (2), and because there remain antigenic targets on platelets and monocytes, the antibodies bind to these cells and activate them (3), resulting in both thrombocytopenia and the prothrombotic state seen in HIT. (Modified from Kowalska MA, Rauova L, Poncz M. Role of the platelet chemokine platelet factor 4 [PF4] in hemostasis and thrombosis. *Thromb Res* 2010;125:292–6.)

Considerations in the selection and interpretation of several of the more commonly used testing methods are discussed in the following paragraphs.

A test for HIT that had perfect sensitivity and specificity and that could be performed rapidly in a cost-effective fashion of course would be the ideal. Many laboratories, however, presently use a testing strategy in

which the initial (or only) test is a readily performed PF4–enzyme-linked immunosorbent assay (ELISA) that has high sensitivity but lower specificity. Such assays accordingly may provide results that can be helpful in the effort to exclude the likelihood of HIT, with the degree of test positivity increasingly being associated with thrombotic risk (Fig. 42-8). However, if the value is higher than the established cutoff value (and particularly if

Figure 42-6 The relationship among the clinical expression of heparin-induced thrombocytopenia (HIT) (thrombocytopenia with or without thrombosis), the type of heparin used, and the antibodies that cause HIT. This can be conceptualized as an “iceberg.” The visible component of the iceberg (the portion above the waterline) represents clinically evident features of HIT, such as thrombocytopenia and/or thrombosis. The mass of the iceberg corresponds to the entire spectrum of anti–platelet factor 4 (PF4)/heparin antibodies generated. Some of these antibodies will be biologically active (platelet activating), and others will be non–platelet activating, which may make them unlikely to cause clinical consequences. The type of heparin given to the patient determines the overall size of the iceberg, with unfractionated heparin (UFH) being the largest (most immunogenic), and low-molecular-weight heparin (LMWH) and fondaparinux having lesser immunogenicity. Also illustrated in this figure is in vivo cross-reactivity. UFH forms antigens that are readily recognized by HIT antibodies. In contrast, fondaparinux forms poorly recognized antigens. LMWH is intermediate. (Illustration by AY Chen, from Kelton JG, Warkentin TE. Heparin-induced thrombocytopenia: a historical perspective. *Blood* 2008;112:2607–16.)

TABLE 42-4

Pretest Scoring System for Heparin-Induced Thrombocytopenia: The 4 Ts

4 Ts	2 points	1 point	0 points
Thrombocytopenia	Platelet count fall >50% and platelet nadir ≥ 20 k/ μ L*	Platelet count fall 30%–50%, or platelet nadir 10–19 k/ μ L	Platelet count fall <30% or platelet nadir <10 k/ μ L
Timing of platelet count fall	Clear onset between days 5 and 10 or platelet fall ≤ 1 day (prior heparin exposure within 30 days) [†]	Consistent with day 5–10 fall, but not clear (e.g., missing platelet counts); onset after day 10 [‡] ; or fall ≤ 1 day (prior heparin exposure 30–100 days ago)	Platelet count fall <4 days without recent exposure
Thrombosis or other sequelae	New thrombosis (confirmed); skin necrosis [§] ; acute systemic reaction post intravenous unfractionated heparin (UFH) bolus	Progressive or recurrent thrombosis [¶] ; nonnecrotizing (erythematous) skin lesions [§] ; suspected thrombosis (not proven) [§]	None
Other causes for thrombocytopenia	None apparent	Possible**	Definite**

From Lo GK, Juhl D, Warkentin TE, et al. Evaluation of pretest clinical score (4 Ts) for the diagnosis of heparin-induced thrombocytopenia in two clinical settings. *J Thromb Haemost* 2006;4:759–65.

*Greifswald, Germany (GW): platelet count fall >50% or nadir 20–100 k/ μ L; Hamilton, Canada (but not GW): Platelet count fall >50% directly resulting from surgery counts as 1 point, rather than 2 points.

[†]GW: onset from days 5–14 (rather than days 5–10); platelet fall within 1 day (heparin exposure within 100 days).

[‡]GW: onset after day 14.

[§]Skin lesions at heparin injection sites.

[¶]Progression refers to objectively documented increase in thrombus size (usually, extension of deep vein thrombosis by ultrasonography); recurrence refers to newly formed thromboembolus in previously affected region (usually, new perfusion defects in a patient with previous pulmonary embolism).

[§]In GW, “suspected thrombosis (not proven)” was not included as a criterion.

**Determination of whether the presence of another apparent cause of thrombocytopenia was “possible” or “definite” was at the discretion of the investigator.

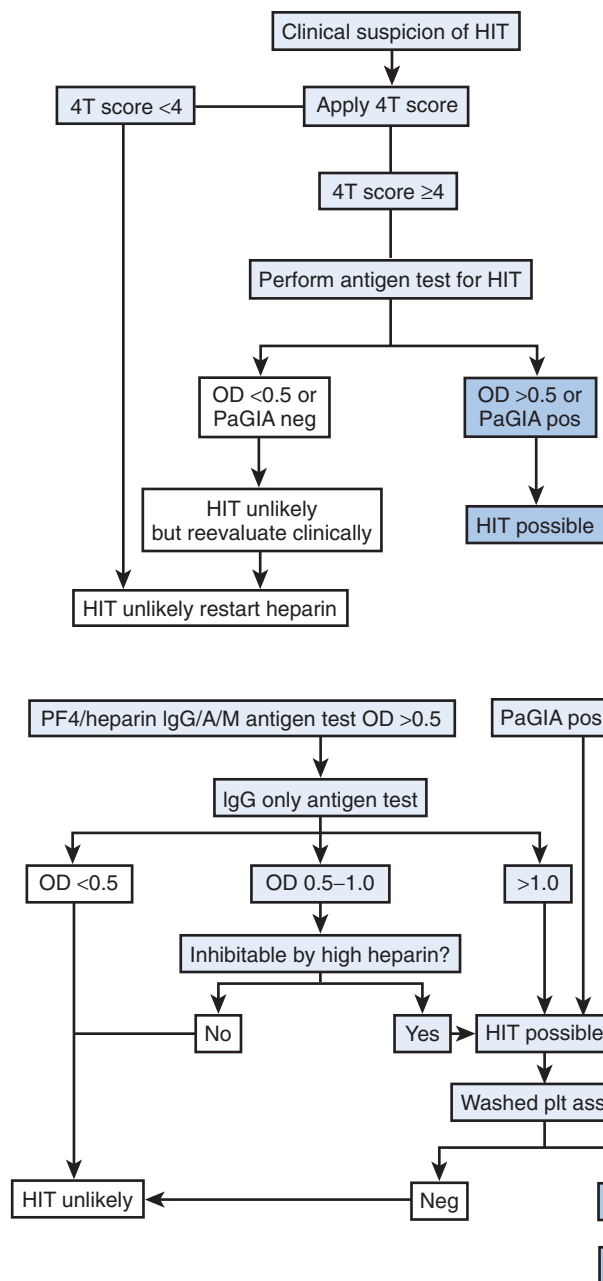

Figure 42-7 One example (among a variety of such efforts) of a diagnostic algorithm for heparin-induced thrombocytopenia (HIT):

1. Assess pretest probability for HIT (e.g., using the 4Ts). Patients with a low pretest probability (score ≤ 4) need no further testing, and heparin can be maintained.
2. If the enzyme immunoassay (EIA) or particle gel immunoassay (PaGIA) is negative, HIT is very unlikely, and heparin can be maintained. A positive result on a screening EIA or PaGIA indicates the presence of anti-platelet factor 4 (PF4)/heparin antibodies. If an immunoglobulin (Ig)G EIA is weakly positive (optical density [OD] <1.0), the antibodies are most likely non-platelet activating. A confirmatory step using high heparin should be performed; if reactivity is not inhibited, HIT is very unlikely, and heparin can be maintained.
3. An IgG EIA with OD >1.0 or positive PaGIA indicates increased risk for platelet-activating antibodies. These sera ideally should be assessed by a washed platelet activation assay. Demonstration of platelet-activating antibodies makes HIT very likely. A negative functional assay makes HIT unlikely, and heparin can be maintained/restarted.
4. Clinical reassessment should support final confirmation or exclusion of the diagnosis. However, it is a misconception to automatically retest patients whose EIA is negative (because EIA is positive even during the earliest phase of HIT). (From Greinacher A, Althaus K, Krauel K, Selleng S. Heparin-induced thrombocytopenia. *Hamostaseologie* 2010;30:17–8, 20–8.)

Figure 42-8 Relative risk of developing thrombosis related to quantitative results (mean \pm SD) from an anti-platelet factor (PF4)/heparin enzyme-linked immunosorbent assay (ELISA) performed on 500 patients 6 days after coronary artery bypass graft surgery. (From Mattioli AV, Bonetti L, Zennaro M, Ambrosio G, Mattioli G. Heparin/PF4 antibodies formation after heparin treatment: temporal aspects and long-term follow-up. *Am Heart J* 2009;157:589–95.)

it is very high), then a functional test becomes pivotal to providing further laboratory support for the presence of HIT. Functional tests typically are much more demanding to perform but enjoy higher specificity, in addition to high sensitivity. A critical issue in the design of functional HIT tests is the choice of target upon which antibodies present in the patient's blood will act. Early tests employed platelet-rich plasma (PRP) of normal donors. However, as has been analyzed in considerable detail (Warkentin, 2001), washing of these target platelets so as to remove the accompanying plasma can greatly improve test performance. In North America, the gold standard of functional testing for HIT has been the serotonin release assay, in which washed platelets that have taken up exogenous serotonin are challenged with patient plasma in the presence of optimal heparin concentrations, and the amount of released serotonin is taken as the endpoint. Interestingly, in a number of European laboratories quite comparable results are obtained when aggregation in microtiter wells is employed as the functional endpoint using similarly washed platelets (Warkentin, 2001). An additional endpoint that has been explored is the formation of platelet microparticles, detectable by flow cytometric methods (Mullier, 2010).

A host of technical issues must be addressed in setting up any of these assays, including selection of platelet donors and whether or not to test these donors with respect to polymorphisms in Fc γ RIIA. A number of studies have suggested that the use of serologic reagents in selectively detecting patient antibodies of the IgG (but not IgA or IgM) class may increase specificity for the diagnosis of HIT. However, concern that excluding IgA and IgM antibody detection may serve to decrease the sensitivity of HIT diagnostic testing still exists among a number of workers in the field. Because there appears to be a stoichiometric optimum for heparin interaction with PF4–glycosaminoglycan complexes, elimination of a proportion of false-positive reactions in some testing systems may be achieved by verifying that a (true positive) reaction is inhibited when the analysis is repeated in the presence of very strong heparin excess. Finally, it should be noted that in those instances where the target epitope is atypical (i.e., not the anticipated epitopes within platelet PF4), although the highly specific immunoassays may then fail to detect HIT-associated antibodies, this atypicality would not be expected to influence the functional assays. Correlation between ELISA heparin–platelet factor 4 (H-PF4) titers and the functional tests for HIT and heparin-induced platelet aggregation is greatest when H-PF4 antibodies are high (Javela, 2010). Given all of the complexities inherent in laboratory testing for HIT, it bears repeating that appropriateness of the clinical setting (most typically, falling platelet counts in a reasonable temporal relationship to heparin administration) remains of paramount importance with respect to evaluation of this disorder.

The laboratory sometimes will be called upon to perform HIT testing on presently asymptomatic individuals who have been positive for HIT at

some time in the past. Given variability among patients in the rate of disappearance of detectable antibodies (Fig. 42-9), together with variability in their manifesting an anamnestic response upon reexposure to heparin, testing may be required before reexposure to heparin is considered, and of course subsequent to the initiation of such therapy if instituted.

Figure 42-9 Rate of loss of demonstrable anti-platelet factor 4 (PF4)/heparin antibodies in a population of 131 serologically positive coronary artery bypass graft patients. The median time for persistence of measurable antibody was 90 days. (From Mattioli AV, Bonetti L, Zennaro M, Ambrosio G, Mattioli G. Heparin/PF4 antibodies formation after heparin treatment: temporal aspects and long-term follow-up. *Am Heart J* 2009;157:589–95.)

Guidelines to assist in monitoring of such patients have recently been endorsed by the American Society of Hematology, as presented in Figure 42-10. Although it has been demonstrated that most HIT-associated antibodies do not show an anamnestic reappearance if the patient is rechallenged with heparin more than 6 months following loss of detectable antibody, close laboratory monitoring of such rechallenged patients is critical. In the event that an anamnestic response does develop, the reemergence of antibody can be dramatic, requiring at least rapid detection of falling platelet counts, if not in fact more specific tests for HIT.

MONITORING OF HEPARIN THERAPY DURING PROCEDURES

Heparin is used extensively to prevent thrombi from forming during cardiac bypass surgery, as well as during a number of interventional vascular procedures. The ACT is frequently used to guide heparin therapy during the course of such procedures. In the ACT, glass beads, kaolin, or diatomaceous earth may be used to activate whole blood obtained from the patient. The ACT is used most frequently to monitor high levels of heparin (2–4 U/mL)—a range of heparin concentration beyond which the APTT does not perform optimally, and it is frequently used to monitor heparin reversal following injection of protamine. The importance of establishing local reference intervals using normal controls for ACT testing cannot be stressed too much. Only by this means can a testing

A. Cardiac and vascular surgery

Clinical picture	Laboratory profile		Recommended intraoperative anticoagulation [†]
	Immunologic assay	Functional assay	
Remote HIT	Negative	Negative	1. Use UFH (Grade 1B)
Subacute HIT	Positive	Negative	1. Delay surgery, if possible, until immunologic assay becomes negative (Grade 1B) 2. If surgery cannot be delayed, use UFH (Grade 2C)
Acute HIT	Positive	Positive	1. Delay surgery, if possible, until functional and immunologic assays become negative (Grade 1B) 2. If surgery cannot be delayed, use bivalirudin (Grade 1B)

B. Cardiac catheterization/percutaneous coronary intervention

Clinical picture	Laboratory profile		Recommended intraprocedural anticoagulation [†]
	Immunologic assay	Functional assay	
Remote HIT	Negative	Negative	1. Use a non-heparin anticoagulant [bivalirudin (Grade 1B), argatroban (Grade 1C), lepirudin (Grade 1C), or danaparoid (Grade 1C)] 2. If a non-heparin anticoagulant is not available, use UFH
Subacute HIT	Positive	Negative	1. Use a non-heparin anticoagulant [bivalirudin (Grade 1B), argatroban (Grade 1C), lepirudin (Grade 1C), or danaparoid (Grade 1C)]
Acute HIT	Positive	Positive	

Figure 42-10 American Society of Hematology (ASH) practice guidelines for heparin reexposure in patients with a history of heparin-induced thrombocytopenia (HIT). HIT laboratory testing should be used to determine the safety of exposing a patient with a history of HIT to intraoperative heparin. (From Cuker A, Crowther M. Quick reference: 2009 clinical practice guideline on the evaluation and management of heparin-induced thrombocytopenia. American Society of Hematology, 2009. Available from: <http://www.hematology.org/Practice/Guidelines/4678.aspx>) UFH, Unfractionated heparin.
*If preoperative and postoperative anticoagulation is indicated, a non-heparin anticoagulant should be used. [†]American College of Chest Physicians Grading System: 1 = strong recommendation; 2 = weak recommendation; A = based on high quality evidence; B = based on moderate quality evidence; C = based on low quality evidence.

facility gain the experience necessary to monitor patients undergoing heparin therapy during procedures. For example, it is vital to obtain a baseline ACT value before heparinization is instituted and to realize that for occasional patients with a markedly prolonged baseline ACT (such as one who may have a lupus anticoagulant, or another who may have a severe contact factor deficiency), an alternative approach to monitoring should be considered—typically, an anti-Xa heparin assay. LMWHs have little effect on the ACT. However, the ACT may be considered in conjunction with monitoring of DTIs, as discussed in the following section (Rössig, 2010).

DIRECT THROMBIN INHIBITORS

Hirudin originally isolated from the salivary glands of leeches is available as a recombinant protein (Refludan, lepirudin). It forms an essentially irreversible complex with thrombin. Lepirudin has been used in patients with HIT. The half-life of lepirudin is between 90 and 120 minutes, and it is cleared by the kidneys. Anticoagulant activity has been monitored using the APTT, with a target range of 1.5–2.5 times baseline APTT (Call, 2004; Hirsch, 2008). However, in instances where a patient's baseline APTT is abnormal (e.g., in the presence of a lupus anticoagulant), monitoring by means of the APTT may be unreliable. One alternative to the APTT for monitoring DTIs is the ecarin clotting time (ECT), which uses the venom from *Echis carinatus*. The active enzyme of this venom is a metalloproteinase that converts prothrombin to meizothrombin—a reaction that is blocked by DTIs. A calibration curve for the ECT can be generated by directly spiking normal plasma with DTIs in vitro (Nowak, 2001; Kolde, 2004). The dilute thrombin time may also be used to monitor DTI therapy (Love, 2007). DTI may inhibit the PT/INR, and anticoagulant monitoring during the bridging transition between DTI and vitamin K antagonist therapy is accomplished by using a chromogenic assay for Factor X, or by discontinuing the DTI for several hours and then measuring the INR in patients after several days of vitamin K antagonist therapy (Hoppensteadt, 1997; Tobu, 2004; Walenga, 2004; Castellone, 2010).

A related DTI, bivalirudin, is a reversible, relatively short-acting molecule that has been approved for use in patients undergoing coronary angioplasty who have or are at risk for developing HIT (Merry, 2004; De Luca, 2009). It binds to the anion-binding exosite of thrombin.

Argatroban, a semisynthetic derivative of hirudin, is a short-acting reversible DTI that has also been approved for use in HIT. A rather wide window of 1.5–2.0 times baseline APTT has been suggested for the target therapeutic range of argatroban (Call, 2004). Alternative monitoring methods may help to narrow this range (Love, 2007). Argatroban is metabolized in the liver and can be used in patients with impaired renal function.

Dabigatran etexilate (see below) is the first oral anticoagulant in the direct thrombin inhibitor class to have received FDA approval in the U.S.

Clearly, DTIs are enjoying an increasing role in anticoagulation. At the present time, they are used primarily in patients with HIT. However, in the future, they may be anticipated to be used in a wider variety of clinical settings, particularly in patients for whom it has proven difficult to stabilize their anticoagulant intensity with more traditional agents (Weitz, 2010a).

NEW ORAL ANTICOAGULANTS

Several newly developed oral anticoagulants have shown potential promise for their efficacy in preventing VTE and in treating VTE, for their role in stroke prevention with atrial fibrillation, and for their potential role in treating acute coronary syndrome (Weitz, 2010a, 2010b). The oral coagulation inhibitors include the DTI dabigatran etexilate and the Xa inhibitors rivaroxaban and apixaban (Turpie, 2009; Weitz, 2010b; Wittkowsky, 2010). These agents have relatively short half-lives of less than 15 hours, are significantly excreted by the kidney, and are irreversible; laboratory monitoring, although available, may not be required on a routine basis (Ng, 2009; Bounameaux, 2010; Mismetti, 2010). Dabigatran etexilate is actually a prodrug that requires activation to dabigatran. Rivaroxaban and apixaban are metabolized by CYP3A4, and drugs that inhibit or induce CYP3A4 may increase or decrease exposure to these drugs (Eikelboom, 2010; Wittkowsky, 2010).

ANTIPLATELET THERAPY

Several classes of compounds are currently employed to diminish platelet functionality. These include aspirin, other cyclooxygenase inhibitors, adenosine diphosphate (ADP) receptor antagonists, and glycoprotein (GP)

IIb/IIIa receptor antagonists. In contrast to treatment with oral anticoagulants or with heparin, antiplatelet therapy traditionally has not been as closely monitored in the laboratory. Increasingly, however, the laboratory is coming to play a greater role. Questions that can potentially be answered by laboratory testing include the following: (1) whether or not a patient's platelets are resistant to inhibition by a particular agent; (2) what dose of agent is required to achieve a desired intensity of inhibition; (3) when, following termination of therapy, platelet function has returned to an adequate level to subserve significant hemostatic challenges such as surgery; and (4) whether thrombocytopenia observed following antiplatelet therapy may reasonably be attributed to that therapy itself.

Certainly an agent that has enjoyed a long tenure in therapeutics is aspirin. As is widely known, aspirin irreversibly acetylates cyclooxygenase. In the case of the anucleate platelet, this effectively means that recovery from aspirin inhibition occurs only as platelets newly released from megakaryocytes enter the circulation. Although human platelets circulate in the blood for an average of 10 days, substantial normalization of platelet functional responsiveness occurs within 5–7 days following termination of aspirin therapy. This phenomenon may be due to the ability of thromboxane A₂, the active product from the platelet cyclooxygenase pathway of nonaspirinated platelets, to stimulate nearby platelets whose cyclooxygenase has been acetylated by aspirin. However, individual patient responses to therapeutic aspirin administration may vary (Mason, 2004; Sanderson, 2005). Because relative resistance to the platelet inhibitory effects of aspirin may imply the need for additional or alternative antiplatelet treatment in some clinical settings, the laboratory can play a useful role in measuring such resistance. Presently, two main approaches have been employed to assess platelet resistance to aspirin. Because platelets are the principal cell type to produce thromboxane, assay of this substance provides a measure of the activity of platelet cyclooxygenase. Because thromboxane A₂ undergoes conversion to thromboxane B₂ and thence to the more stable 11-dehydro-thromboxane B₂, plasma assay of this metabolite has been used as an indirect measure of platelet cyclooxygenase activity (Catella, 1986); subsequently, assay of urinary 11-dehydro-thromboxane B₂ was employed for this purpose (Eikelboom, 2002).

An alternative approach that more directly assesses actual platelet functionality is the measurement of platelet aggregation following stimulation of platelets in vitro by an agonist strongly dependent upon an intact cyclooxygenase pathway. Arachidonic acid and related compounds are frequently employed as agonists in such studies. Of great importance for the validation of such functional assays, if they are to be capable of identifying aspirin resistance, is very tight standardization of the testing procedure. Although this certainly may be accomplished by carefully performed platelet aggregometry on PRP (see Chapter 40), alternative methods have been developed to provide comparable information directly on anticoagulated whole blood. For example, the VerifyNow (Accumetrics, San Diego, Calif.) instrument permits optical platelet aggregation studies to be performed on a patient's whole blood. In this approach, fibrinogen-coated plastic beads impregnated with an infrared (IR) dye (i.e., a dye that absorbs light in the IR region of the electromagnetic spectrum) are added to citrated whole blood. Following addition of arachidonic acid, the fibrinogen-coated beads coaggregate with the platelets, presumably by virtue of the fibrinogen binding to the conformationally active forms of GPIIb/IIIa on stimulated platelets. Whereas absorbance by erythrocytes of light in the visible wavelength had previously precluded optical whole blood aggregometry, the introduction of IR techniques has permitted rapid quantitation of platelet aggregation (as increasing IR light transmittance) and of its inhibition by aspirin or other antiplatelet agents (Smith, 1999; Wang, 2003).

Whole blood or PRP aggregation studies have also proven helpful in defined clinical settings such as percutaneous transluminal coronary angioplasty (PTCA) for assessing the degree of residual platelet reactivity following inhibition of platelets by abciximab, eptifibatide, and other antagonists of the platelet GPIIb/IIIa complex (Hezard, 2000; Matzdorff, 2001). Detection of residual ADP purinergic receptors on the platelet surface following treatment by clopidogrel or other P2Y₁₂ antagonists may be assessed in a similar manner (see later).

In addition to aggregometry, other methods may be employed to detect activation of the platelet by agonists, and consequently inhibition of that activation by antiplatelet therapies. Flow cytometry may be used for this purpose through the detection of markers of platelet activation. Translocation of P-selectin from the intracellular α -granule of the resting platelet to the extracellular membrane following sufficient platelet stimulation provides one such marker, although the relatively small number of P-selectin molecules detectable even on the fully activated platelet limits the dynamic range of this marker. Antibodies sensitive to conformational

change in the GPIIb/IIIa molecule associated with platelet activation potentially offer a greater dynamic range of signal extending between fully nonactivated and fully activated platelets. Flow cytometric approaches have also been used to monitor residual functionality of the GPIIb/IIIa complex following treatment of patients with GPIIb/IIIa inhibitors (Hezard, 2000; Matzdorff, 2001), as well as to quantify platelet microparticles as an indicator of platelet activation (Craft, 2004).

Following the introduction of GPIIb/IIIa antagonists in PTCA and other invasive procedures, recognition that thrombocytopenia can complicate administration of this drug has been increasing (Abrams, 2004; Aster, 2009). In some instances, this fall in the platelet count appears to be due to an immediate interaction between drug and platelet, possibly caused by pre-formed drug-dependent antibodies (Aster, 2004). In other instances, the time course of the thrombocytopenia suggests the development of antibodies to the drug itself or to a neo-epitope formed by binding of the drug to its platelet target (Curtis, 2002, 2004; Nurden, 2004). Although definitively establishing such a drug-dependent cause by laboratory methods is difficult and at times may simply prove elusive, available methods currently employed for evaluation of such acquired thrombocytopenia include flow cytometry, monoclonal antibody-specific immobilization of platelet antigens, and related techniques.

Efforts to detect residual ADP purinergic P2Y₁₂ receptors on the platelet surface following treatment by clopidogrel, prasugrel, or other P2Y₁₂ receptor antagonists have arguably been more difficult still. The reasons for this difficulty are severalfold. First, the presence on the platelet surface of the additional P2Y₁ class of ADP receptors that remain responsive to ADP following P2Y₁₂ receptor antagonism complicates interpretation of residual responsiveness to ADP challenge in treated patients. Second, analysis of P2Y₁₂ receptor antagonist therapy is almost universally undertaken in the setting of patient platelets that are being inhibited additionally by aspirin therapy. Third, it has become increasingly common for patients to be started on combined P2Y₁₂ receptor antagonist and aspirin therapy very early in the course of their evaluation for possible acute coronary syndrome or other potentially catastrophic thrombotic disorders. Accordingly, there is no opportunity in such instances to establish a baseline platelet function study that might be used to assess reduction in responsiveness following initiation of P2Y₁₂ receptor antagonist therapy. Rather than identifying a true reduction in responsiveness that can reliably be attributed to antiplatelet therapy, the laboratory will be able to provide only a snapshot of platelet responsiveness for the patient already under treatment.

Through comparison of response to ADP by the patient's platelets versus their responsiveness to other platelet agonists, derived estimates of the inhibition attributable to P2Y₁₂ receptor antagonism have been proposed. As recently demonstrated, for levels of derived percent inhibition greater than ≈20%, the correspondence of these values to true percent reduction of posttreatment responses compared with pretreatment responses using the VerifyNow whole blood device (see earlier) (Fig. 42-11) appears reasonably good (Varenhorst, 2009). In addition to whole blood aggregation, assessments of responsiveness to ADP receptor antagonists may be made by traditional light transmittance aggregometry of patient PRP, arguably a gold standard for assessment of platelet function. Flow cytometric approaches have also been introduced that assess the phosphorylation of intracellular vasodilator-stimulated phosphoprotein—the degree of which reflects with some measure of specificity the downstream signaling following the binding of ADP to platelet P2Y₁₂ receptors.

Efforts to sort out the relative merits of these different methods have been described in a number of recent publications (Alstrom, 2009; Gremmel, 2009; Varenhorst, 2009; Bidet, 2010; Bouman, 2010; Cuisset, 2010). Nevertheless, caution is still in order with respect to how much reliance can be placed upon current assays of platelet function to guide therapy. Lordkipanidze (2008) remarked at the conclusion of a double-blind study assessing four different methodologic approaches in 116 patients with coronary artery disease, "The assessment of platelet function inhibition by clopidogrel is highly test-specific. Decision to increase clopidogrel dosage may vary on the basis of the assay used, thus highlighting the need for unambiguous guidelines with respect to assay selection, as platelet function assays are not interchangeable. At present, platelet function testing evaluating clopidogrel efficacy cannot be recommended in routine clinical practice." Based on a study of 1069 patients on clopidogrel undergoing elective coronary stent implantation, caution was also expressed by Breet (2010), who concluded, "None of the tests provided accurate prognostic information to identify low-risk patients at higher risk of bleeding following stent implantation." Accordingly, it appears fair to say that the clinical usefulness of platelet function testing related to P2Y₁₂ receptor

Figure 42-11 Association of “percent inhibition” reported by VerifyNow P2Y₁₂ (x-axis) based solely on posttreatment measurement and calculated percent inhibition (y-axis) based on decrease in PRU (P2Y₁₂ reaction units) posttreatment compared with pretreatment baseline PRU. Correlation coefficient (r) was calculated using Lin’s concordance method. ■ represents prasugrel; ▲, clopidogrel; filled line, unity line. (From Varenhorst C, James S, Erlinge D, et al. Assessment of P2Y₁₂ inhibition with the point-of-care device VerifyNow P2Y₁₂ in patients treated with prasugrel or clopidogrel coadministered with aspirin. *Am Heart J* 2009;157:562.e1–9.)

inhibition to date has been only modest at best. It is important to note that limitations of available approaches must not be forgotten despite the understandably intense pressure from clinicians facing dosage decisions that carry the risk of increased thrombosis on the one hand, and increased bleeding on the other hand.

Analogous to the use of pharmacogenetics to guide oral anticoagulant therapy (see earlier), significant effort is being devoted to developing a role for assessing genotypic variations affecting the metabolism of P2Y₁₂ inhibitors. Of particular note, clopidogrel is a prodrug that acquires its ability to antagonize P2Y₁₂ receptors only after it has been transformed in vivo to active metabolite. The potential significance of this was spotlighted by a new warning label mandated for Plavix (clopidogrel) by the U.S. Food and Drug Administration (FDA) in March of 2010, accompanied by the following announcement on the FDA website, <http://www.fda.gov/Drugs/DrugSafety/PostmarketDrugSafetyInformationforPatientsandProviders/ucm203888.htm>.

“The liver enzyme CYP2C19 is primarily responsible for the formation of the active metabolite of Plavix. Pharmacokinetic and antiplatelet tests of the active metabolite of Plavix show that the drug levels and antiplatelet effects differ depending on the genotype of the CYP2C19 enzyme. The following represent the different alleles of CYP2C19 that make up a patient’s genotype:

- *The CYP2C19*1 allele has fully functional metabolism of Plavix.*
- *The CYP2C19*2 and *3 alleles have no functional metabolism of Plavix. These two alleles account for most of the reduced function alleles in patients of Caucasian (85%) and Asian (99%) descent classified as poor metabolizers.*
- *The CYP2C19*4, *5, *6, *7, and *8 and other alleles may be associated with absent or reduced metabolism of Plavix but are less frequent than the CYP2C19*2 and *3 alleles.*

A patient with two loss-of-function alleles (as defined above) will have poor metabolizer status.”

Efforts to provide genotyping as referenced by the FDA announcement accordingly have intensified in the clinical laboratory arena, in an effort to keep pace with these rapidly moving developments. Additionally, as newer P2Y₁₂ antagonists become available, attention must be paid increasingly to the pharmacogenomics of these compounds as well. Within the class of thienopyridines, for example, significant differences may be seen in the effectiveness of clopidogrel and of prasugrel, depending on CYP2C19 alleles. The extent to which genotyping of individual patients actually contributes to their clinical outcome continues to be a subject of intense investigation (Mega, 2009; Shuldiner, 2009; Momary, 2010; Sibbing, 2010). Study of such genotypes may prove of increasing use for managing drug–drug interactions, such as the effect of proton pump inhibitors on clopidogrel efficacy in inhibiting platelet reactivity (Laine, 2010).

APPENDIX: CLINICAL AND LABORATORY STANDARDS INSTITUTE PREANALYTIC GUIDELINES (CLSI, 2008)

1. Blood should be collected directly into the tube containing anticoagulant. Small syringes may be used and blood may be drawn through a vascular access device if it is flushed with saline and six dead space volumes of the vascular access device are discarded.
2. In a direct draw, the PT and APTT are not affected if the first tube drawn is tested. Collection of blood through lines that have been flushed with heparin is to be avoided.
3. The blood should be placed into an anticoagulated tube within 1 minute and mixed well, inverting at least 4 times. The tube should not be vigorously shaken.
4. The anticoagulant should be 3.2% sodium trisodium citrate. The ratio should be 9 parts blood and 1 part citrate.
5. Inadequately filled or clotted specimens should be discarded.
6. The specimen should be centrifuged and should be platelet-poor, which is defined as less than $20 \times 10^9/L$.
7. Hemolyzed specimens are discarded.
8. Grossly icteric, lipemic or slightly hemolyzed specimens should be analyzed using a mechanical method to detect clotting or with an instrument with a wavelength outside of the interfering substances absorption wavelength.

STORAGE OF SPECIMENS

- Specimens for PT determinations can be kept at 18°–24° C either on separated plasma or spun cells and testing should be performed within 24 hours. Cold activation of factor VII may occur at 2°–4° C.
- Routine unheparinized specimens can be kept centrifuged or uncentrifuged in an unopened tube on the cells at 18°–24° C and tested within 4 hours. Specimens with UFH should be centrifuged within 1 hour of collection, and plasma should be tested within 4 hours.
- If testing is not done within 24 hours for the PT or within 4 hours for the APTT, the plasma should be removed and frozen at –20° C and tested within 2 weeks, or stored at –70° C and tested within 4 weeks. These frozen samples should be rapidly thawed at 37° C with gentle mixing and assayed immediately. They may be kept at 4° C and assayed within 4 hours.

QUALITY CONTROL

- The quality control program should have a peer group for comparison. The laboratory should participate in a proficiency survey. Samples for this survey should be analyzed in the same manner as patient plasma samples.

KEY POINTS

- The immune system consists of cellular and humoral components that defend the body against invading microorganisms. Deficiency of individual factors of the immune system can leave an individual susceptible to different infections.
- The lymphoid cells of the immune system are composed of T cells, which act directly against foreign antigens, and B cells, which synthesize immunoglobulins that combine with foreign antigens. Antigen-presenting cells are crucial for cell-to-cell communication during the direction of an immune response.
- The mechanisms by which lymphocytes differentiate into T cells and B cells involve rearrangement of genes for the T cell antigen receptor and of genes for immunoglobulins, respectively.
- Lymphocytes from patient specimens are characterized by detection of surface proteins, termed cluster of differentiation markers, which designate their subset and function.
- Additional cellular elements are natural killer lymphocytes plus neutrophils, eosinophils, and the effectors of immunoglobulin (Ig) E-mediated hypersensitivity—basophils and mast cells.
- In addition to immunoglobulins or antibodies, humoral elements include a cascading series of proteins in the complement system that result in enzymatic destruction of foreign cells and recruitment of cellular infiltrates by cytokine actions.
- Histocompatibility antigens play a major role in antigen presentation to T cells and form the immunologic identity of an individual, which is important in rejection of organ transplants.
- Immunologic injury can occur as the result of excessive response to specific antigenic exposures, such as from allergies or from circulating immune complexes.
- Autoimmune disease results when the mechanisms for maintaining immunologic tolerance to self-(auto)antigens fail, resulting in the formation of various autoantibodies plus activation of the cellular immune system against the patient's own tissues.
- Laboratory measurements of the immune system involve relatively simple techniques for counting lymphocytes and their subsets, as well as for quantifying overall concentrations of immunoglobulins and complement proteins. More complex methods such as detection of gene rearrangements, autoantibody characterization, and allergen reactivity with IgE are useful for diagnosing various disorders of the immune system.

- Therapeutic approaches to disorders of the immune system include stimulation or replacement of deficient components and reduction or removal of other factors that are abnormal or are present in excess.

The immune system is structured to recognize, respond to, and destroy a wide variety of invading organisms such as bacteria, viruses, fungi, and parasites that otherwise would be capable of promoting infection that is harmful to the body. Discovery of components of the immune system has very often followed investigation of serious infections and the specific reactions that the body uses to combat pathogenic organisms. In general, this immunologic function can be summarized as searching for foreign (or nonself) antigens that do not belong in the body and then destroying them. In this process, the immune system also maintains surveillance over the appearance of new or foreign antigens on tumor cells and attempts to destroy them while leaving unharmed the normal (or self) antigens on healthy cells. Disease states may arise as a result of various aspects of immunologic function going awry, as in hypersensitivity reactions, autoimmune disease, and various immunodeficiency disorders. When functioning properly, the immune system is responsible for rejection of allogeneic organ/tissue transplants and graft-versus-host disease; the quest for tolerance in transplantation continues. This overview highlights components of the immune system and their functions, along with some of the significant clinical disorders of immunity.

LYMPHOID CELLS

The lymphoid cells of the body reside in the lymph nodes, the spleen, the mucosal surfaces, and the circulation. They derive from multipotential hematopoietic stem cells, with their production moving progressively from the yolk sac in the embryo to the liver in the fetus, and finally to the bone marrow in the infant through adult ages (Weissman, 1994). The various lymphoid cells are conveniently identified by the presence of unique protein markers on their surfaces that endow those cells with particular functions.

T LYMPHOCYTES

T lymphocytes undergo differentiation in the thymus. After originating in the bone marrow, prothymocytes pass from the cortex to the medulla of the thymus, during which time they undergo maturation. This process involves a selection process such that self-reactive thymocytes are eliminated, while thymocytes that can recognize antigens through interactions

with molecules of the major histocompatibility complex (MHC) are retained (Nossal, 1994; von Boehmer, 1994). During maturation, they undergo genetic programming in which the gene for the T cell antigen receptor (TCR) is rearranged to produce protein receptors that are invariant in their antigen specificity for the life span of that T lymphocyte, as well as for all its descendent cells. T lymphocytes account for about 60%–70% of all lymphocytes in the blood; they are also found in paracortical areas of lymph nodes and within periarteriolar lymphoid sheaths in the spleen.

A majority (>95%) of T lymphocytes have antigen receptors made of α - and β -subunits linked with disulfide bonds to form a molecular heterodimer that resides on the outer membrane of the cell in association with the CD3 molecular complex (CD3 is a pan-T cell marker). The α - and β -subunit TCR proteins have variable, joining, and constant regions (α also contains a diversity region), with corresponding encoding regions in the *TCR* gene that undergo rearrangement, resulting in high specificity binding for a particular antigen. The CD3 proteins assist transduction of the signal to the interior of the cell when an antigen binds to the TCR on the lymphocyte surface (Janeway, 1994; Weiss, 1994). A small percentage of T lymphocytes have a TCR composed of γ - and δ -subunits that similarly interact with CD3; these cells are generally found at mucosal surfaces of the gastrointestinal and respiratory tracts. T cell proliferations may be characterized as neoplastic (clonal) or benign (polyclonal), according to whether their DNA shows predominantly a single form of *TCR* gene rearrangement or a complete spectrum of such rearrangements, as normally occurs in a heterogeneous lymphocyte population.

Examination of T lymphocytes by flow cytometry focuses on a variety of surface markers. CD4 is found on about 60% of CD3⁺ cells; these are helper/inducer T cells that direct the functions of other cells of the immune system by secreting cytokines that stimulate various functions. Two distinct subpopulations of CD4⁺ helper cells have been identified: Th1, which secrete interleukin (IL)-2 and interferon (IFN)- γ ; and Th2, which secrete IL-4 and IL-5. Th1 cells facilitate macrophage activation delayed-type hypersensitivity and the production of antibodies with opsonizing action; Th2 cells direct synthesis of other antibodies such as IgE and activate eosinophils. The marker CD8 is found on about 30% of T cells (thus the normal ratio of CD4⁺ to CD8⁺ cells in the blood is typically 2:1). These CD8⁺ T cells exhibit cytotoxicity and suppressor activity in the immune response.

The mechanism of antigen recognition is different between CD4⁺ and CD8⁺ subsets of T lymphocytes. CD4 molecules bind to the MHC class II molecules on antigen-presenting cells, whereas CD8 molecules interact with MHC class I molecules. Accordingly, CD4⁺ T cells recognize antigens only in the context of MHC class II antigens, and CD8⁺ T cells recognize them only through MHC class I antigens.

B LYMPHOCYTES

B lymphocytes make up roughly 10%–20% of peripheral lymphocytes in the blood; they also are found in the bone marrow, lymph nodes, spleen, and other lymphoid tissues. In the spleen and lymph nodes, they aggregate into lymphoid follicles. Differentiation of B lymphocytes occurs in the bone marrow, where both positive selection and negative selection take place, as well as at peripheral locations. Antigenic stimulation of B cells leads to the formation of plasma cells that secrete immunoglobulins—the basis of specificity in humoral immunity. The B cell antigen receptor complex uses surface IgM as the antigen-binding component. The antigen specificity of immunoglobulins derives from a rearrangement process in which both heavy and light chain genes are realigned. The heavy chain has variable, diversity, joining, and constant regions, whereas the light chain gene has variable, joining, and constant regions. Maturation of an antibody response entails switching from IgM to another heavy chain type (usually IgG) as the result of further gene rearrangement, although the light chain type remains fixed (Corcoran, 2005).

B cells have on their surfaces receptors for complement (CD21, which is also the receptor for Epstein-Barr virus [EBV] and thus makes these cells susceptible to EBV infection) and for the Fc region of immunoglobulins; they have CD19 and CD20, which are frequently used for immunologic identification of B cells.

ANTIGEN-PRESENTING CELLS

Macrophages function as mononuclear phagocytes in inflammation; they also process ingested antigens and present them to immune effector cells in association with MHC molecules on their membranes (Fig. 43-1).

T cells are not activated by soluble antigens, and so presentation of antigens in this manner is necessary for T cell stimulation and induction of cell-mediated immunity (Germain, 1994; Trombetta, 2005). Macrophages also secrete cytokines such as IL-1 for modulation of inflammatory processes; they can directly lyse tumor cells in their role of immunosurveillance, and they are effector cells for some types of cell-mediated immunity (e.g., delayed hypersensitivity).

Dendritic cells (found in lymphoid tissues and in interstitial regions of other organs) and Langerhans cells (found in the epidermis) have extensive dendritic cytoplasmic processes that are rich in MHC class II molecules. Consequently, they are very efficient at presenting antigens (although they probably are not phagocytic) and are considered to be extremely important in that task within the entire immune system (Park, 2005).

NATURAL KILLER CELLS

Natural killer (NK) cells constitute 10%–15% of lymphocytes in the peripheral blood. They are neither T cells nor B cells and were formerly called **null cells**. NK cells have the function of lysing other cells without prior sensitization. They can attack tumor cells, cells infected with viruses, and others as well; consequently, they form the initial defense against aberrant cells. NK cells are characterized by the surface markers CD16 and CD56, which are commonly used for their identification. CD16 is the Fc receptor for IgG; hence NK cells are able to lyse selectively those cells that are coated with antibodies (antibody-dependent cell-mediated cytotoxicity, which is important in some hypersensitivity reactions). NK cells also secrete cytokines such as IFN- γ . It is interesting to note that NK cells are recognizable on examination of standard stained blood smears as large granular lymphocytes (Kronenberg, 2005).

NONLYMPHOID CELLS

These cells are not genetically programmed to recognize specific antigens or to interact with lymphoid cells in the induction of an immune response. Instead, they are effectors of immune reactions that are triggered by various factors.

NEUTROPHILS AND EOSINOPHILS

Neutrophils are drawn to regions of inflammation by chemoattractants such as IL-8; they then release from their granules toxic substances and enzymes that digest cellular structures indiscriminately; neutrophils also ingest cellular debris, as do eosinophils, and remove it from tissue sites.

BASOPHILS AND MAST CELLS

Basophils (and their counterparts in tissues, the mast cells) have on their surfaces high-affinity Fc receptors that bind circulating IgE. Uptake of IgE onto the membranes of basophils apparently is not antigen dependent; instead, it is driven by mass action between the amount of total IgE and the available basophils. When the antigen (or allergen) comes into contact with basophil surface-bound IgE that recognizes it, those basophils become activated and release substances such as histamine, which mediate some hypersensitivity reactions. Thus, basophil specificity is directed by the particular IgE that is bound to its surface from the blood; theoretically, a basophil could have multiple different IgE molecules on its surface and so could react with many different allergens.

HUMORAL FACTORS IMMUNOGLOBULINS

Antibody molecules can be bound to B cell surfaces for stimulation of further immunoglobulin secretion; they also circulate in the blood and appear at mucosal surfaces of the respiratory and gastrointestinal tracts, where they are likely to come into contact with potentially pathogenic microorganisms. The major immunoglobulins in the blood are IgM, IgG, and IgA; these antibodies presumably arise following exposure to a multitude of foreign antigens and may remain for years with continued secretion to replace molecules that are lost through normal clearance of proteins from the circulation. At mucosal surfaces, the primary type of antibody is dimeric IgA, which is secreted at that site (Fagarasan, 2004) (see Chapter 46). The other immunoglobulins are IgD (which resides on B cell surfaces, where it may be involved in immune signal transduction but does not achieve substantial concentrations as free molecules in the blood) and IgE

Figure 43-1 Cellular interactions in the immune system. Antigen-presenting cells (APCs) process external or internal antigens (Ag) and present antigen peptide fragments, in association with a major histocompatibility complex (MHC) molecule, to T cells. On the T cell, a specific antigen receptor (TcR), along with the co-receptor CD4 or CD8 molecule, recognizes the antigen–MHC complex. Cellular activation proceeds through the CD3 complex and activation of tyrosine kinases (TKs). The B cell receptor is composed of membrane-bound immunoglobulin (Ig) complexed to associated membrane proteins, and the CD19/21 coreceptor. On antigen recognition, cellular TKs are also activated. Co-stimulatory activation of T cells or B cells is provided by cellular receptors binding their ligands (the ligand B7 or B7.2 for T cell co-stimulation through CD28 and CTLA-4 molecules, and the gp39 ligand for the B cell CD40 molecule). (Redrawn with permission from Paul W, Seder R. *Lymphocytic responses and cytokines*. Cell 1994;76:229; and Weiss A, Littman D. *Signal transduction by lymphocyte antigen receptors*. Cell 1994;76:263.)

(which functions by binding to surfaces of basophils and stimulates the release of vasoactive substances from those cells in the presence of specific allergens).

Immunoglobulins in the blood function by attaching to antigens on the surfaces of foreign cells, bacteria, viruses, and the like, and by facilitating their destruction through nonspecific effectors such as complement and NK cell activation. Disease monitoring by immunoglobulin testing includes qualitative analysis for clonal versus polyclonal detection (e.g., for diagnosis of multiple myeloma) and quantitative analyses both for overall concentrations of IgM, IgG, and IgA (to detect possible selective or combined deficiencies or overproduction of immunoglobulin classes) and for titers of specific antibodies against individual antigens (e.g., isohemagglutinins, *Pneumococcus*, *Haemophilus*, tetanus, diphtheria).

COMPLEMENT

This set of interacting proteins has the role of enzymatically destroying targets (e.g., cells, bacteria) to which they have been directed by antibodies or through other means (see Chapter 47). Measurements of complement components have two major uses in clinical diagnosis: to detect congenital deficiencies (which are relatively rare) that may predispose to certain disorders such as infection or progression to autoimmune disease, and to detect acquired complement level reductions that reflect current activity of systemic autoimmune diseases such as systemic lupus erythematosus (Wen, 2004).

CYTOKINES

These soluble substances are the means by which cellular immune responses are regulated; they are short-acting mediators that are elaborated by some cells and diffuse to other cells, where they act (Leonard, 2003). Many cytokines are pleiotropic in that they can act on different cell types. They can act in an endocrine manner by stimulating cells at a distance, they can act on cells in their immediate vicinity (paracrine), and they can stimulate the same cells that secreted them (autocrine). The specific actions of cytokines include hematopoiesis through colony-stimulating factors that induce granulocyte and macrophage production, natural

immune responses (through IL-1, tumor necrosis factor [TNF]- α , interferons, and IL-8), stimulation of lymphocyte growth and activation (through IL-2 and others), and activation of nonspecific inflammatory cells (see Chapter 47). Cytokines are still being discovered as more details emerge regarding cell-to-cell communication.

Clinical use of cytokines includes both suppression of the immune response in allogeneic organ transplantation by drugs such as cyclosporine, which blocks production of IL-2, and enhancement of the immune response in therapies against cancer or infection. These latter treatments are largely experimental, although it has been shown that pretreatment with antibodies against TNF- α can prevent deleterious Jarisch-Herxheimer reactions resulting from antibiotic treatment of *Borrelia recurrentis* infection in sheep (Fekade, 1996). This model very probably presages a host of new therapies by which immune responses will be selectively enhanced or suppressed according to particular clinical needs.

HISTOCOMPATIBILITY ANTIGENS

The MHC (also called the human leukocyte antigen [HLA] complex) is encoded on human chromosome 6 and includes class I molecules (HLA A, B, and C), class II molecules (HLA DP, DQ, and DR), and the intervening class III molecules of some complement components and TNF- α and - β (see Chapter 48). The functions of class I and class II antigens have already been discussed briefly in terms of how they participate in antigen presentation to T cells. These antigens were discovered and their highly polymorphic natures were described in studies of immune tolerance and rejection of transplanted allogeneic organs. Consequently, one of the most important clinical uses of HLA typing involves matching potential organ or tissue donors with recipients who are in need of a transplant. Another significant clinical application is seen in the typing of affected patients and their family members to establish their risk of developing some diseases that are associated with particular HLA types (e.g., ankylosing spondylitis with HLA B27) (see Chapter 49). Still another use of HLA typing involves providing matched platelets for patients who have become refractory to platelet transfusions as the result of HLA antibody formation after exposure to multiple donors (e.g., following transfusion support for chemotherapy or hematopoietic progenitor cell transplantation) (see Chapter 38).

MECHANISMS OF IMMUNOLOGIC INJURY

Immunologic responses can cause injury to normal tissues and to invading organisms that may have triggered a response. These injurious responses are conveniently classified into four types of hypersensitivity. Type I is anaphylactic or allergic in nature; it is mediated by IgE bound to the surface of basophils and mast cells. When specific antigens (or allergens) bind to surface IgE, the basophils are stimulated to release histamine and other vasoactive substances that are the immediate mediators of allergic reactions (Kemp, 2002). Clinical strategies for treatment of asthma and allergies have addressed different aspects of this sequence of events from counteracting the effects or release of histamine back to desensitization. Successful use of a recombinant humanized monoclonal antibody against IgE to treat such individuals has been demonstrated (Milgrom, 1999); in the future, this therapy could be based in part on measurement of IgE concentrations in serum.

Type II occurs when antibodies bind to antigens on the surfaces of cells; damage may occur as the result of binding and activation of complement (e.g., immune hemolysis), antibody-dependent cell-mediated cytotoxicity (e.g., lysis of tumor cells or parasites), or antibody-mediated interference with cellular functions (e.g., autoantibodies against acetylcholine receptors in myasthenia gravis).

Type III results from immune complex formation between exogenous antigens such as bacteria or viruses and antibodies, or between endogenous autoantigens and autoantibodies. Typical tissue damage occurs in organs that contain numerous small blood vessels wherein circulating immune complexes deposit, or in places where endogenous antigens naturally occur.

Type IV is cell-mediated or delayed hypersensitivity, which depends on functioning CD4⁺ T cells or other cytotoxicity from CD8⁺ T cells. Type IV is the basis of the immune reaction to viruses, fungi, protozoa, and parasites, and also to intracellular microbes such as mycobacteria. Patients with acquired immunodeficiency syndrome are susceptible to infection with these and other opportunistic agents when they lose CD4⁺ T cells.

LABORATORY APPLICATIONS OF IMMUNOLOGIC ASSESSMENT

Examinations of the immune system for evaluation of potential deficiencies or disorders are listed in Table 43-1.

Cellular immunity has several levels of investigation, beginning with leukocyte count and differential commonly available on automated hematology analyzers as part of the complete blood cell count. Deficiencies of neutrophils often occur with chemotherapy for malignancy, whereas elevation of neutrophils is a sign of acute infection, particularly with bacteria. Rare individuals may have normal numbers of neutrophils but may be susceptible to infection owing to defects of function (e.g., chronic granulomatous disease) that can be assessed by neutrophil activation (by oxidative burst) in response to stimuli, or by bacterial killing assays.

Different populations of lymphocytes are enumerated by flow cytometric techniques that quantitate cells according to the expression of surface protein markers specific for T cells (CD2, CD3), subsets of T cells (CD4, CD8), B cells (CD19, CD20), monocytes (CD14), and natural killer cells (CD16, CD56). Because the most common cause of lymphocyte disorder today is infection with the human immunodeficiency virus (HIV), the most frequently monitored lymphocyte surface markers are CD4 and CD8, for the effects of HIV infection and prediction of susceptibility to opportunistic infection. HIV infection is usually diagnosed by detection of anti-HIV antibodies confirmed by Western blot; monitoring of HIV infection also includes quantitative viral loads by molecular diagnostic methods such as reverse transcriptase polymerase chain reaction, and use of antiretroviral drugs is guided by HIV genotyping (and on rare occasion by phenotype testing of drug resistance). Lymphocyte function is not often measured directly, but this can be done by stimulation assays that look at lymphocyte proliferation (e.g., by incorporation of tritiated thymidine into DNA) or by cell cycle analysis performed with flow cytometry after stimulation. Of course, skin testing is a direct reflection of T cell response to antigens *in vivo*.

Humoral immunity is often assessed by quantitative immunoglobulin measurements of total IgG, IgA, and IgM; deficiency of one or more immunoglobulin classes can lead to increased susceptibility to infection. Measurement of IgG subclasses can also be useful in this type of evaluation. Serum protein electrophoresis and immunofixation electrophoresis provide additional information regarding the clonality of immunoglobulins. A monoclonal band of immunoglobulins indicates a clonal population of B cells or plasma cells that have escaped regulation and might result in a plasma cell dyscrasia such as multiple myeloma. In contrast, a polyclonal distribution of immunoglobulins is generally taken to indicate a reactive process of an otherwise normal immune system.

Direct measurement of immunoglobulin function is done by evaluating the titers of antibodies against specific antigens. The presence of isohemagglutinins against ABO blood group antigens is conveniently examined to detect anti-A and anti-B antibodies in persons who lack those blood

TABLE 43-1

Domains of Immunology Testing

Cellular Immunity

- Complete blood count and differential
- Lymphocyte enumeration (CD2, CD3, CD4, CD8, CD19, CD20, CD56) for T cells, B cells, NK cells
- HIV antibodies/viral load/genotype
- Skin testing for anergy
- Lymphocyte function/activation
- Neutrophil activation (oxidative burst)
- Lymphocyte adhesion defect (CD11a, CD11b, CD11c, CD18)

Humoral Immunity

- Quantitative immunoglobulins (IgG, IgA, IgM)
- IgG subclasses
- Immunoglobulin function/stimulation (protein antigens: tetanus, diphtheria; carbohydrate antigens: *Pneumococcus*, *Haemophilus*); ABO blood group isohemagglutinins

Complement

- C3, C4 for consumption
- Screening for deficiency: CH50
- Confirming deficiency: C1-C9
- C4d deposition
- Circulating immune complexes

Cytokines

- Interleukins
- Interferons
- Tumor necrosis factors

Human Leukocyte Antigens (HLAs)

- HLA antibodies for matching organs and bone marrow in allogeneic transplants
- Identity testing
- HLA genotyping (high resolution)
- HLA typing for disease association (HLA-B27)

Autoimmune Diseases

- Systemic rheumatic diseases: Antinuclear antibodies; anti-dsDNA, anti-Sm, anti-RNP, anti-SSA, anti-SSB, anti-Scl70, anticardiolipin, anti-CCP
- Organ-specific diseases: Antithyroid, anti-parietal cell, antiendomysial, antiadrenal, antiskin, antimitochondria, anti-smooth muscle
- Vasculitis: Cryoglobulins (RF), c-ANCA, p-ANCA

Allergy/Hypersensitivity/Asthma

- Total IgE
- Allergen-specific IgE: Foods, pollens, animals, insects, mold
- Skin tests for allergy

c-ANCA, Classical antineutrophil cytoplasmic antibodies; HIV, human immunodeficiency virus; NK, natural killer; p-ANCA, protoplasmic-staining antineutrophil cytoplasmic antibodies; RF, rheumatoid factor.

groups. Common immunizations result in the presence of detectable antibodies against the protein antigens of diphtheria and the tetanus toxoid, and against the carbohydrate antigens of *Pneumococcus* and *Haemophilus*. Measurements of antibodies against these antigens are standard procedures for evaluation of immunodeficiencies; if they are lacking, reimmunization can be done to elicit evidence of an immune response.

The **complement system** is most frequently examined by measurement of C3 and C4 components to look for depressions that suggest consumption through activation. Although circulating immune complexes (CICs) are the presumptive cause of decreased C3 and C4 concentrations, CICs are rarely measured directly; however, deposition of CICs in tissues can be detected by immunofluorescent staining for immunoglobulin and C3 or C4d. Hereditary deficiencies of individual complement components are screened for by the CH50 test, which traditionally has used antibody-coated horse erythrocytes in a hemolysis assay (now often replaced by an equivalent assay using liposomes in place of erythrocytes), and then are confirmed with specific immunoassays for deficiencies of individual complement proteins.

Determinations of **cytokine** concentrations are usually considered investigational procedures without definitive application, despite the understanding we have of the roles they play in pathophysiology. Some of the potential candidates for future monitoring are the interleukins IL-1 β , IL-2, IL-2 receptor, IL-4, IL-5, IL-6, IL-8, IL-10, IL-12, and IL-13. These factors can be elaborated as locally acting messengers in many different inflammatory processes, and so lack specificity for distinguishing different etiologies such as infection versus autoimmune. They act at sites of tissue injury or inflammation and so do not reach easily measured concentrations in blood. Perhaps by looking at concentrations of multiple factors simultaneously both in blood and at the tissue level, interpretation will be feasible using patterns related to specific stimuli and physiologic insults. Other substances that fall into this category of immunomodulating agents include TNF- α and IFN- α , - β , and - γ . A recent clinical application utilizes the quantitation of IFN- γ released by lymphocytes in a peripheral blood specimen after *in vitro* stimulation with mycobacterial antigens to determine previous exposure status of a patient to that organism.

HLA testing and crossmatching between donors and recipients form the basis of solid organ and bone marrow transplantation. Traditional serologic testing for antigens and antibodies has now been expanded with high resolution HLA genotyping. HLA typing has also been used for matching platelet transfusions in select refractory patients. HLA typing has been used for identity testing, and some antigenic types (e.g., HLA-B27) are recognized to be associated with specific autoimmune disorders.

Applications of testing to **autoimmune diseases** are multiple. Systemic rheumatic diseases such as lupus erythematosus, rheumatoid arthritis, and scleroderma are commonly diagnosed with a battery of autoantibody assays, including the antinuclear antibody plus individual antibodies such as anti-DNA, anti-Sm, anti-RNP, anti-SS-A, anti-SS-B, Scl-70,

anticardiolipin, rheumatoid factor, and anti-cyclic citrullinated peptide. Organ-specific autoimmune diseases are characterized by tissue or organ-elle reactive autoantibodies such as antithyroid, anti-parietal cell, antiskin, antiendomysial (antitissue transglutaminase), antimitochondrial, anti-smooth muscle, antiadrenal, and so forth. Antibodies important in vasculitis include cryoglobulins and classical antineutrophil cytoplasmic antibodies/protoplasmic-staining antineutrophil cytoplasmic antibodies. Although some autoantibodies are etiologic and serial measurements of their titers are important for monitoring disease progress, other antibodies are nonetiologic and so are most useful for diagnosis alone.

Allergies, hypersensitivities, and asthma have common pathways in which allergens are recognized by specific IgE that is bound to the surfaces of basophils and mast cells, thereby liberating histamine and creating allergic symptoms. Diagnostic evaluation of allergies includes measurements of total IgE plus allergen-specific IgE to determine which allergens are significant for particular patients. Typical allergens for this testing include foods, pollens, molds, animal dander, and insects. Skin testing *in vivo* with these allergens is complementary because a positive response depends on the presence of reactive IgE plus competent T cells with CD4.

THERAPEUTICS IN IMMUNOLOGY

Therapeutic targets in the immune system are important to consider because of the need to measure the effects of such treatments to make adjustments and guide clinical management (Table 43-2). Of course, one of the most common abnormalities of cellular immunity today is HIV infection, for which antiretroviral drugs are essential with monitoring that includes viral load measurements as well as genotyping to predict response to specific drugs.

Cellular immunity is the target of several different drugs that act against T cells and so are often used to suppress immune responses against allogeneic solid organ transplants, as well as graft-versus-host disease (GVHD) from allogeneic bone marrow transplants. These drugs include the cyclophilin binding drugs cyclosporine and tacrolimus, which inhibit calcineurin, and the immunosuppressants sirolimus and mycophenolate, both of which block activation of T cells and B cells. Therapeutic drug monitoring of blood concentrations of these immunosuppressants is useful to achieve therapeutic effect (usually as a synergistic action of agents from different drug classes) while avoiding drug toxicities. Polyclonal antilymphocyte globulin is used to reduce the circulating numbers of T cells in an effort to block transplant rejection. Also used is monoclonal anti-CD3 antibody, which binds to that molecule on T cells to reduce their numbers. Experimental anti-IL-2 receptor (CD25) antibody has also been used to block organ transplant rejection. Extracorporeal photopheresis has been successfully applied in the treatment of GVHD, and even for cellular rejection of transplanted solid organs, beyond its well-established role in controlling cutaneous T cell lymphoma.

TABLE 43-2

Therapeutic Targets in the Immune System

Cellular Immunity

- Glucocorticoids
- Anti-T cell drugs (e.g., calcineurin inhibitors)
- Anti-CD20 (e.g., rituximab)
- Antilymphocyte globulin
- Photopheresis
- Interleukin-2
- Antiretroviral drugs

Humoral Immunity

- Intravenous immunoglobulins (pooled)
- Plasma exchange (remove harmful antibodies, cryoglobulins)
- Humanized monoclonal/chimeric antibodies for target antigen neutralization (e.g., anti-CD20)

Complement

- Plasmapheresis to remove complement-activating immune complexes

Cytokines

- Interferons
- Anti-tumor necrosis factor- α
- Granulocyte-colony stimulating factor (G-CSF)

Human Leukocyte Antigens

- Organ transplant rejection: plasmapheresis
- Graft-versus-host disease: photopheresis

Autoimmune Diseases

Suppression of cellular or humoral immunity by

- Glucocorticoids
- Alkylating agents (e.g., cyclophosphamide)
- Antimetabolites (e.g., methotrexate, azathioprine)
- Nonsteroidal antiinflammatory drugs
- Anti-T cell drugs

Allergy/Hypersensitivity/Asthma

- Antihistamines
- Glucocorticoids
- Allergen desensitization injections
- Leukotriene antagonists
- β -Adrenergic agonists

Humoral immunity can be enhanced by passive intravenous infusion of immunoglobulin (IVIG) fractions pooled from multiple individuals who can be expected to contain antibodies against a multitude of infectious agents; high titer immunoglobulins against specific microorganisms are also available (e.g., against hepatitis B virus). IVIG is also used to modulate some autoimmune disorders such as myasthenia gravis, possibly by interfering with the attachment of harmful autoantibodies to tissue sites. Alternatively, harmful antibodies can be removed by plasma exchange using apheresis, in which plasma proteins are replaced by another protein solution such as 5% albumin.

Monoclonal antibodies designed to interact with very specific antigens on cell surfaces or in the blood are now in use for several clinical applications (Griggs, 2009). Because of the potential side effects of stimulating immune or even allergic responses, these large molecule drugs have been reconfigured to appear as naturally occurring proteins by humanizing them with constant regions derived from human immunoglobulin genes. An example of such a chimeric antibody is anti-CD20, which has application in treating B cell lymphomas, as well as in modulating the synthesis of some autoantibodies.

Complement consumption through CICs can be addressed therapeutically by plasmapheresis to remove those CICs (usually in the form of cryoglobulins) and thus lower the burden of harmful deposition in tissues such as the glomeruli or other vasculitides.

Cytokines in regular clinical use include IFN- α for combating infection with hepatitis B virus or hepatitis C virus, and IFN- γ for stimulating immune responsiveness. TNF- α can be neutralized in the circulation by specific therapeutic antibodies or a modified receptor molecule to decrease undesired inflammatory responses in conditions such as rheumatoid arthritis and Crohn's disease. Granulocyte-colony stimulating factor is used regularly in clinical practice to rescue patients who have developed

leukopenia after chemotherapy, and to mobilize hematopoietic stem cells for collection from the peripheral blood to prepare for transplantation. Administration of IL-2 does succeed in raising CD4 counts, but this approach has not yet been found to improve outcome in HIV infection (INSIGHT-ESPRIT, 2009). It is likely that other stimulators or inhibitors of cytokines will come into clinical practice in the future.

HLA mismatches in allogeneic transplanted organs are typically dealt with by administration of immunosuppressant drugs but can also be treated with extracorporeal photopheresis to diminish cellular immune rejection, as well as with plasmapheresis to remove HLA antibodies that the host might have previously formed or later formed in response to the transplanted organ.

Autoimmune diseases have been treated with different groups of drugs to reduce the inflammatory response, such as corticosteroids, alkylating agents (e.g., cyclophosphamide), antimetabolites (e.g., methotrexate, azathioprine), nonsteroidal antiinflammatory drugs, and even some of the immunosuppressants normally used to reduce T cell activity in preventing organ transplant rejection. A new medication under trial for systemic lupus erythematosus is a monoclonal antibody against B lymphocyte stimulator, which is a member of the TNF family that acts to stimulate B cell proliferation and immunoglobulin secretion (Cancro, 2009). Other future therapies of autoimmune disorders will likely involve stimulation or suppression of specific sites in the immune response by specific monoclonal antibodies; bone marrow transplantation has also been successful in some cases.

Allergies and hypersensitivities are often treated long term by desensitization methods in which allergens are used to stimulate IgG that competes with IgE to neutralize those allergens that are known to cause problems in individual patients. Medications that are commonly used to control symptoms acutely and chronically are antihistamines, corticosteroids, leukotriene antagonists, and adrenergic agonists.

IMMUNOASSAYS AND IMMUNOCHEMISTRY

GENERAL CHARACTERISTICS OF ANTIGEN–ANTIBODY REACTION

Biological ligands based on the affinity between molecules, such as enzyme and substrate, hormone and receptor, antigen and antibody, play an

important role in living organisms. Specific recognition characteristics of immunoassays (antigen–antibody [Ag–Ab] reactions) have become widely used as analytic tools, adding to the wide range of methods available in clinical laboratory testing.

Immunoassays can be used for the detection of antigens or antibodies. For antigen detection, the corresponding specific antibody should be prepared as one of the reagents. The reverse is true for antibody detection. The sensitivity of immunoassays has been enhanced through the development of new types of signal detection systems and solid-phase technology. Immunoassays have been optimized to detect less than 0.1 pg/mL of

[†]Deceased

antigen present in blood. They can be applied to the detection of haptens as small molecules; proteins and protein complexes as macromolecules; and any antibody to allergens, infectious agents, and autologous antigens.

CHARACTERISTICS OF ANTIGENS

An antigen can be defined as any substance that can represent antigenic sites (epitopes) to produce corresponding antibodies, from small molecules such as haptens and hormones to macromolecules such as proteins, glycoproteins, glycolipids, and other natural products. Artificial chemical compounds can also be antigens acting as haptens. Antigens should have at least one epitope. Epitopes that can be recognized by antibodies include amino acid sequences of peptides in proteins and high-dimensional protein structures such as neoantigenic sites.

CHARACTERISTICS OF ANTIBODIES

Immunoglobulin, an important plasma protein, refers to antibodies in the context of the biological functions of immunoglobulin specific to antigens. Antibodies, therefore, are produced in response to antigenic stimulation. Antibodies are formed of both functional and heterogeneous molecules that bind antigens via the antigen-combining site. Five classes (isotypes) of immunoglobulin have been identified: IgG, IgM, IgA, IgD, and IgE. IgG is further divided into four subclasses, and both IgA and IgM have two subgroups. All known antibody molecules have a heavy chain with a κ or a λ light chain. The molecular structure of antibodies is composed of variable regions and constant regions. The hypervariable domain (epitope-binding spot) can be assembled to interact with a wide variety of epitopes (antigen determinants). In laboratory medicine, two categories of antibodies can be distinguished: antibodies as reactants and antibodies as analytes. Antibodies as analytes are often classified by IgG, IgM, and IgA subtypes. Antibodies as reactants are prepared from antiserum obtained through animal immunization with purified antigen.

Polyclonal Antibodies

A polyclonal antibody can be obtained through immunization with an antigen, which presents various epitopes. In other words, the antibody generated is specific against each epitope. The avidity of a polyclonal antibody to a complex antigen is usually stronger than a single monoclonal antibody. Carrier proteins may be needed for the immunization of smaller molecules, such as haptens or hormones.

Monoclonal Antibodies

Monoclonal antibodies (Koehler and Milstein, 1975) have been developed using the following biotechnologies: somatic cell fusion, selection of the resulting hybridoma, and limiting dilution to ensure the clone is derived from a single cell. They are defined as uniform homogeneous antibodies directed to specific epitopes. An established cell line allows the secretion of all reactive immunoglobulin specific to single epitopes. Monoclonal antibodies have made it possible to analyze molecules on an epitope-to-epitope basis because of their narrow specificity. Yet monoclonal antibodies, in contrast to polyclonal antibodies, do not have the ability to recognize the entire molecule. For monoclonal antibodies, different antigens with a common epitope appear to be the same antigen. CA 19-9 antibody (Magnani, 1983) as a tumor marker can detect different sizes and shapes of molecules that have common carbohydrate epitopes. Monoclonal antibodies enable identification of isoenzymes, subtypes, and isotypes of protein, and conformational changes in molecules because they can discern the slightest differences in molecules.

Monoclonal antibodies may be cross-reactive with different antigens. This cross-reactivity can be explained by the probable existence of the same amino acid sequences, carbohydrates, or lipids on different molecules. Monoclonal antibody technology has allowed the development of extremely useful and nearly ideal immunoassay systems for clinical laboratory testing.

The production methods and applications of monoclonal antibodies have been extensively reviewed (Nakamura, 1983; Zola, 1987). Advantages of monoclonal antibodies are as follows:

- Monoclonal antibodies provide a well-defined reagent.
- Monoclonal antibody production can yield an unlimited quantity of homogeneous reagent with highly consistent affinity and specificity.

- Monoclonal antibodies can be prepared through immunization with a nonpurified antigen.
- Monoclonal antibodies have certain limitations in their use, as follows:
 - Insufficient reactivity is seen in precipitation or agglutination because network formation in the immunocomplex is weak or does not occur when single monoclonal antibodies are used.
 - Antigens with multiple heterogeneous epitopes are more difficult to characterize immunochemically with a single monoclonal antibody.

Antibody Production by Recombinant Technology

Skerra and Pluckthun (1988) have developed an expression system for the Fv fragment of variable domains of an antibody specific to phosphoryl choline using recombinant technology in *Escherichia coli*. This technology makes it possible to produce chimeric antibody fused to an enzyme.

A new technology called phage display has emerged for the production of antibodies (Winter, 1994). In this method, antibody fragments of predetermined binding specificity are constructed from a repertoire of antibody variable (*V*) genes, thereby eliminating the need for immunization and hybridoma technology. The *V* genes can be assembled in vitro. The phage selected from the repertoire by binding to antigen and antibody fragments is expressed in infected bacteria. Furthermore, the binding affinity of the antibodies is improved through mutation. In the near future, this technology will allow the use of specific antibodies with high avidity.

KINETICS OF ANTIGEN-ANTIBODY REACTION

Certain aspects of equilibrium or the law of mass action in chemistry can be applied to the Ag-Ab reaction. The kinetics of the reversible Ag-Ab reaction is as follows (Steward, 1986):

where

Ag represents free antigen

Ab represents free antibody sites

AgAb represents the antigen-antibody complex concentration

K_1 and K_2 are the association and disassociation rate constants, respectively.

The rate of formation of the antigen-antibody complex is represented as follows:

$$d[\text{AgAb}]/dt = K_1[\text{Ag}][\text{Ab}] - K_2[\text{AgAb}] \quad (44-2)$$

and at equilibrium, the net rate is zero. Therefore,

$$K_1/K_2 = [\text{AgAb}]/[\text{Ag}][\text{Ab}] = K_a \quad (44-3)$$

(association equilibrium constant or affinity constant).

K_a is the parameter limited to site-to-site reactions, although antigens and antibodies often have multiple binding sites on the molecule. The apparent association constant for multiple antigen and antibody reactions may be referred to as **avidity** instead of affinity. The K_a value may be obtained from the following equations and experimental data:

$$[\text{Ab}] = [\text{Ab}]_t - [\text{AgAb}] \quad (44-4)$$

where $[\text{Ab}]$ is the antibody concentration at equilibrium, and $[\text{Ab}]_t$ represents the total original antibody concentration.

$$K_a = B/([[\text{Ab}]_t] - B)F \quad (44-5)$$

where *F* is free antigen or analyte, and *B* is bound antigen or analyte.

A Scatchard plot is produced when the amount of antigen bound (*B*) is plotted on the *x*-axis and the bound over free (*B/F*) ratio of analytes is plotted on the *y*-axis. The two parameters that can be determined from the Scatchard plot are the dissociation or affinity constant from the slope of the line and the concentration of antibody-binding sites from the *X*-intercept (Scatchard, 1949).

TABLE 44-1

Classification of Various Immunoassays and Their Characteristics

	Labels (reporter groups)	B/F separation*	Signal detection	Sensitivity
Precipitation immunoassays	Not required	Not required	Naked eye, turbidity, nephrometry	≈10 µg/mL ¹
Particle immunoassays	Blood cells, artificial particles (gelatin, particles, latex, etc.)	Not required	Naked eye, pattern analyzer, spectrophotometry, particle counting	≈5 ng/mL ²
Radioimmunoassays	Radioisotopes (¹²⁵ I, ³ H)	Required	Photon counting	≈5 pg/mL
Enzyme immunoassays	Enzymes	Required	Spectrophotometry, fluorometry photon counting (CL-EIA)	≈5 pg/mL ≈0.1 pg/mL ³
Fluorescence immunoassays	Fluorophores	Required	Photon counting	≈5 pg/mL ⁴
Chemiluminescence immunoassays	Chemiluminescent compounds	Required	Photon counting	≈5 pg/mL ⁴

OVERVIEW OF GENERAL PRINCIPLES OF IMMUNOASSAYS

CLASSES OF IMMUNOASSAYS

A brief classification and a list of features of various immunoassays appear in Table 44-1. Precipitation immunoassays provide the simplest method for antigens and antibodies to react with each other without involving the detection of any labels. The resulting Ag–Ab complex in gel or liquid phase may be observed qualitatively as a precipitant by the naked eye and quantitatively with a detector.

The particle agglutination immunoassay (Kasahara, 1992b) uses inert particles as labels, as opposed to direct precipitation of the Ag–Ab complexes. Antigens or antibodies attached to particles such as erythrocytes, latex, or metal sol react with the analyte in the specimen. As a result of this immune reaction, large particles show significant agglutination patterns that may be seen by the naked eye. Yalow (1959) reported on the development of a radioimmunoassay (RIA) using radioisotopes as labels. This breakthrough allowed for the quantitative detection of a trace level of analytes and contributed to the advancement of basic research and clinical medicine. Insulin, for example, was quantified by RIA, which subsequently replaced the insulin bioassay. RIA may be formatted in a solid-phase procedure for easy separation of bound and free labels. Since the development of RIAs, the search for alternative labels to hazardous radioisotopes has intensified, with the aim of developing nonisotopic immunoassays using enzymes, fluorescent labels, and other reporter groups.

The enzyme immunoassay (EIA), using enzymes as labels, was developed in the early 1970s (Engvall, 1971; Van Weeman, 1971) and rapidly gained wide popularity. Enzymes can amplify signals depending upon the turnover of enzyme catalytic activity. Efforts to improve substrates and to increase sensitivity have led to the introduction of chromophore, fluorophore, and later chemiluminescent compounds. Depending on the substrate chosen, the assay method can be defined as a fluorescent enzyme immunoassay or as a chemiluminescent enzyme immunoassay (Thorpe, 1984).

Fluorescent immunoassays (FIAs) use fluorophores as labels. Fluorophores require optimal wavelength light energy for their excitation to produce detectable emission light. FIA sensitivity is likely to decrease because of the nonspecific background fluorescence present in biological specimens. Fluorophores that have a delayed fluorescence emission time of 100 ns (nanoseconds) are suitable for application on time-resolved FIA. The introduction of a new class of fluorescent compounds has resulted in improvements in FIA such as the elimination of background noise. Sophisticated instrumentation has been introduced that can detect low concentrations (10^{–15} M) of analytes using FIAs.

Chemiluminescent immunoassays use chemiluminescent compounds as labels. Chemiluminescent compounds include chemically synthesized molecules as well as natural products such as aequorin. Unlike fluorophores, most chemiluminescent compounds require chemical rather than light energy to generate emission light. The reduction–oxidation reaction is a process common to all chemiluminescent assays. Signal amplification is not expected of chemiluminescent labels because chemiluminescent

molecules generate just one photon through molecular decomposition. A series of new and innovative compounds for electrochemiluminescence have proved suitable for application on immunoassays. Metal chelate with tribiphenyls emits light through a continuous reduction–oxidation reaction on the surface of electrodes (Blackburn, 1991).

In the various types of assays mentioned earlier, the main factors affecting assay sensitivity are the association constant (affinity or avidity) of the reactant, the signal intensity of the labels, and the signal/noise ratio of the detection signal reduced by background from the signals themselves or by a nonspecific reaction.

Iodine-125 (¹²⁵I) requires about 7 million molecules to generate 1 photon/second, based on half-life calculations of radioisotopes (Bouaud, 1987). Chemiluminescent substrates to enzymes can increase events by an order of magnitude six times greater than that of iodine-125. This is attributable to the catalytic amplification capacity of enzymes.

CONJUGATION CHEMISTRY

Depending on the assay chosen, the method of conjugation that couples one molecule to others, enzymes (or cofactors) to antigens (or antibodies), or antigens (or antibodies) to solid phase may vary. The coupling reaction applied should be performed under conditions that avoid the reduction of any of the biological activities of the protein. In the glutaraldehyde method (Avrameas, 1978), glutaraldehyde, along with two (or possibly more) aldehyde groups as coupling reagents, has been used for conjugation of protein amino groups. This method is based on mixed reactions, including aldol condensation at high pH (the pKa of the NH residue is 8.6–10.8). With this method, shown in Figure 44-1, the resulting conjugate has different forms because of the existence of multiple active sites for coupling. The periodate oxidation method (Nakane, 1966) for the conjugation of antibodies uses horseradish peroxidase, which contains carbohydrates in its molecules. The methods mentioned earlier are not suitable for regulation of site-specific reactions, such as when configurational stereospecificity of conjugates is required.

As shown in Figure 44-2, new coupling methods (Kato, 1975; Kitagawa, 1978) have been developed using a sophisticated coupling reagent, *m*-maleimidobenzyl-*N*-hydroxysuccinimide ester (MBS). The MBS is a bivalent reagent consisting of an activated ester and maleimide, and can react with an NH₂ group and an SH group, respectively. The carboxy group can also be used as a specific site for conjugating with α- or ε-NH₂ residues of proteins using *N*-hydroxysuccinimide (NHS) as the coupling reagent. The NHS coupling reagent extends to conjugate protein or the carboxyl group introduced on the solid phase.

CHARACTERISTICS OF THE SOLID PHASE

All heterogeneous immunoassays using conjugate with labels, including radioisotopes, require at least one separation step to distinguish the reacted immunocomplex (bound) from unreacted materials (free). Immobilization of antigens or antibodies for solid phase is performed by covalent binding or physical adsorption through noncovalent interactions. Gel particles made of agarose, polyacrylamide, and plastic beads, or titer plates

composed of polystyrene, have been used as the solid phase, as well as particles coated with iron oxide that can be separated by a magnetic field.

The inner wall of a tube or a microtiter well is commonly used as a solid phase. With these relatively large solid phases, shaking of the reaction mixture may be needed to shorten the time required for the immune reaction to take place. The prozone phenomenon or hook effect caused by high concentrations of the analyte is likely to be observed in one-step immunoassay when limited quantities of solid-phase antibody or labeled antibody are employed. Microtiter or strip-type plates may cause an "edge effect." This effect can be explained by the different kinetics of the immune reaction or enzyme activity with variations in temperature. A difference in temperature may be present between the wells located at the edge of the microtiter plate and the center of the plate. A difference of about 2° C may be observed with an infrared thermometer between the edge and the center of wells at ambient temperature. The size and shape of the solid phase are critical factors affecting the immunoreaction kinetics and the capturing capacity of solid-phase antibody or antigen. Small spherical magnetic particles or latex particles with 3000 Å diameters provide a larger total surface area for immunoabsorbency than is usually obtained with other solid phases. The larger total surface area helps shorten the immunologic reaction time (Nishizono, 1991).

The particles used for the particle agglutination assay are listed in Table 44-2. The phenomenon of particle agglutination (direct agglutination)

caused by an immunoreaction was first observed in tests after incubation with infected patient serum. Agglutination of erythrocytes after incubation with serum led to the discovery of ABO blood types. Particle immunoassays are based on the agglutination principle and use the reactant of an antibody or an antigen attached to the inert particle as a label, as opposed to direct precipitation of an Ag-Ab immunocomplex. As a label, the particle can significantly increase the immunoassay sensitivity, regardless of whether the resulting agglutination is detected by the naked eye or with spectrophotometric instruments for quantification.

Erythrocytes, gelatin particles, liposomes, metal sols, and various kinds of latex particles, including latex modified with iron oxide or dyes, are all suitable solid phases. The diameter of these particles used for agglutination reactions varies from 0.01–7 µm. No single theory can explain the kinetics of agglutination (Kasahara, 1992a) because of the wide variety of particle sizes used as labels. Brownian motion is not significant at room temperature for dispersed particles larger than 3–5 µm. However, the theory of potential energy of interaction between particles, or the theory of colloidal coagulation reaction, can apply to small particles such as latex microparticles. The IgM antibody, being multivalent, is estimated to be 750 times more efficient than the bivalent IgG antibody in an agglutination reaction. The distance between particles in flocculation should be less than or equal to 120 Å because of the molecular length of the antibody. In summary, important factors to consider in an immunoreaction are the surface properties of particles, such as charge and hydrophobicity, and the stability of dispersion.

Silicate particle	Passive agglutination: titer plate/CCD camera	<i>T. pallidum</i> antibody
Gold particle	Reverse agglutination enhancement photometry	Total estrogen
Metal sols	Reverse agglutination	hCG, hHb

From Nakamura RM, Kasahara Y. Heterogeneous enzyme immunoassays. In: Nakamura RM, Kasahara Y, Rechnitz GA, editors. Immunochemical assays and biosensor technology for the 1990s. Washington, DC: American Society for Microbiology; 1992. Reproduced with permission.

precipitin techniques have the advantages of sensitivity, specificity, and simplicity. The sensitivity limitation of these assays is a major consideration. Even under the best conditions of enhanced sensitivity afforded by newer light-scattering techniques, the lower limit of sensitivity of immunoprecipitin assays remains in the range of 0.1–0.5 mg/dL. This lower limit of sensitivity appears to be sufficient for the quantification of many major serum proteins. The precipitin reaction forms the basis for many quantitative and qualitative immunochemical techniques now used in the clinical laboratory (Kabat, 1961).

Factors affecting the precipitin reaction were extensively investigated by Heidelberg in 1935, who found that the relative proportions of reactants; conditions of temperature, pH, and ionic strength of the medium; and antibody characteristics of avidity and affinity were all important in the formation of the immune precipitate. On the pattern of precipitin formation, it can be noted that there is a point at which precipitation is maximum or optimal, which is designated as **the point of equivalence**. Continued addition of antigen once the point of equivalence has been reached produces a solubilizing effect on the precipitate. The dynamic range suitable for the determination of analytes should be up to the zone of equivalence. Optimization of the antibody concentration as a reactant is necessary, in addition to optimization of buffer solutions. Typical precipitant reaction methods are as follows:

1. Qualitative Precipitant Assay Methods
 - Single immunodiffusion (Williams, 1970)
 - Double immunodiffusion (Garvey, 1977)
 - Double immunodiffusion in two dimensions (Williams, 1970)
 - Electroimmunodiffusion reaction (Ritzmann, 1975)
 - Immunoelectrophoresis (Rose, 1973)
2. Semiquantitative Precipitant Assay Methods
 - Single radial immunodiffusion (Mancini, 1965, Fahey 1965)
 - Single-dimension electroimmunodiffusion (“rocket” electrophoresis) (Axelsen, 1975)

NEPHELOMETRIC IMMUNOASSAYS

A number of techniques for immunoprecipitin analysis have been developed that use light-scattering devices (Ritchie, 1978). The occurrence of immune complex formation has been related to the amount of such light scattering and has been used as a basis for antigen quantitation. Sophisticated instruments have been designed to rapidly measure light scattering. Measurements of scattered light are generally referred to as **turbidimetry** or **nephelometry**.

PARTICLE IMMUNOASSAY

PRINCIPLE OF PARTICLE AGGLUTINATION

The agglutination reaction may be used to detect antibodies in specimens with specific antigens sensitized to a particle (passive or direct agglutination; Fig. 44-3, B). Reverse agglutination using a corresponding antibody sensitized to particles can be employed to detect soluble antigens in the specimen (Fig. 44-3, A). A hapten unit single-binding site (for drugs, hormones, or small particles) does not form a cross-linking structure and hence cannot become agglutinated unless it is immobilized on the solid phase. As shown in Figure 44-4, A and B, when a particle or carrier immobilized with a hapten is used as a reactant, an agglutination inhibition reaction occurs that allows detection of the hapten. This assay is based on a competitive-type principle in which agglutination of hapten particles with a limited amount of antibody, whether free or sensitized on particles, is inhibited by the hapten present in the specimen. Also, labeled particles can react with reactants fixed on the solid phase of the membrane. After immunoreaction, particles within the immunocomplex can be developed to show color on part of the membrane. This type of assay has been popular as a simple device for the qualitative detection of human chorionic gonadotropin (hCG) and other analytes.

Hemagglutination

Hemagglutination tests (Boyden, 1951) are simple to perform and do not require special equipment. For this reason, both advanced and developing countries have adopted a variety of hemagglutination tests. A popular worldwide hemagglutination test is used for the detection of antibody to *Treponema pallidum*, marketed as Serodia-TP, by Fujirebio, Inc. (Tokyo, Japan). In the United States, the hemagglutination test for *T. pallidum* was approved in 1981 by the Centers for Disease Control and Prevention. It was also recommended by the World Health Organization because of its superiority over other tests in terms of specificity and sensitivity (Kasahara, 1992b).

In the *T. pallidum* agglutination test, the reagent consists of sensitized and unsensitized sheep red cells, as well as a serum diluent solution for the reconstitution of lyophilized sensitized cells as a positive control. Both qualitative and semiquantitative tests can be carried out using the following serum dilution protocol and a titer plate as a reaction container as follows: Using a 25 μ L pipette dropper, place 4 drops 100 μ L of serum diluent in well 1 (Fig. 44-5) and one drop in wells 2–4 for the qualitative assay (wells

Figure 44-3 Principles of passive particle agglutination immunoassay for detection of antigen with multiple **A**, epitopes or **B**, antibodies. 2–8 are used for the quantitative assay). The resulting agglutination patterns are shown in Figure 44-6. Negative patterns, indicating that immunoreaction has not taken place, show condensed flocculation particles with a cross-packing structure at the bottom of the microtiter well. On the other hand, positive patterns, indicating that immunoreaction has occurred, show an expanded agglutination pattern of particles. Agglutinated particles cannot be sedimented any further to obtain condensation as negative patterns, because their global shape is lost on account of the agglutination of particles. In the first and second rows, serum and unsensitized cells (negative control) were used, respectively. Specimens 1 and 2 show negative results. Specimens 3–8 show negative or positive results, depending on the

specimen dilution. A positive result is observed for both specimens 7 and 8 up to 1:2560 (rows 3–8).

Hemagglutination kits are now available for the detection of antibodies to hepatitis type B virus (HBV), hepatitis type C (HCV), human immunodeficiency virus (HIV1/2), thyroglobulin, thyroid microsome, and other substances. Reverse hemagglutination tests are used for the detection of HBV surface antigen, α -fetoprotein (AFP), human hemoglobin in stool specimens, and so forth. The sensitivity of hemagglutination tests is approximately 50 ng/mL for antigen (analyte) detection. Kemp (1988) developed a hemagglutination assay that uses a mouse monoclonal antibody specific to the surface antigen of human erythrocytes. The antibody

can recognize an epitope common to different types of red cells or to abnormal cells, such as those found in sickle cell anemia. As shown schematically in Figure 44-7, blood cells in the specimens are used as solid-phase particles, and the resulting agglutination can be observed by the naked eye. Bivalent antibodies are conjugated chemically, so that one antibody specifically reacts with the surface epitopes of the blood cell, and the other is specific to the target antigen or analyte. The assay is applied for the detection of antibody to HIV, as well as for the detection of various antigens. Unlike conventional agglutination formats, the separation of plasma or serum is not required. This assay is simple, saves time, and offers safety advantages because it eliminates the need for serum separation for hazardous HIV- or HBV-positive specimens.

Gelatin Particle Agglutination

The development of a special gelatin particle with a highly hydrophilic surface that is able to prevent nonspecific binding of materials present in a specimen has provided an alternative to erythrocytes (Ikeda, 1984). This particle is made by phase separation and three-dimensional cross-linkage at 40° C and optimum pH. The resulting particle is fixed with formaldehyde or glutaraldehyde, and its diameter is about 3 µm. The physical properties of gelatin particles in comparison with those of erythrocytes are shown in Figure 44-8. A gelatin particle has no antigenicity and is therefore free from problems associated with heterophilic antibodies when

erythrocytes are used as particles. This type of artificial particle requires much less serum dilution to avoid nonspecific binding and guarantees a more sensitive detection than with blood cells. Other synthetic particles (Hirayama, 1991) made from block copolymer composed of L-glutamic acid and derivatives have been developed by Hirayama (1991) as alternatives to gelatin particles. These synthetic particles can be stained with dye of any color because the particles themselves are colorless, as are gelatin particles. The gelatin particle agglutination test was initially applied to the detection of antibodies to human T cell lymphotropic virus, which was first discovered as a retrovirus in humans. This agglutination test (Ikeda, 1984) soon became very popular for blood screening for HIV, HBV, and HCV because of its high sensitivity and specificity and its simplicity, and the fact that strict temperature control is not required to perform the tests. Gelatin particle agglutination can replace any assay based on hemagglutination, with the exception of assays that use red blood cells in specimens as particles.

Latex Agglutination

Latex agglutination (Galvin, 1984), using latex as particles, has been employed for the detection of various analytes, such as hCG for qualitative pregnancy tests, and for the quantitative detection of other plasma proteins with or without instrumentation. The format of this qualitative assay is simple. For example, one might have to mix only a couple of drops of latex sensitized with reactant and specimen using a stick on a black slide. Two to three minutes later, phase inversion agglutination resulting from the immunoreaction can be observed by the naked eye. Latex agglutination was adapted for quantitative assays using light detection methods based on turbidimetry (light absorption) or nephelometry (light scattering). With these techniques, latex agglutination achieves an enhanced sensitivity of subnanograms per milliliter, while the sensitivity of the assay measuring intact precipitation of the Ag-Ab complex remains below 0.5 µg/mL.

Latex Turbidimetric Assay

Light adsorption (light loss by scattering on the surface of a particle) is proportional to the diameter of the particle and depends on the wavelength of light used. Most latex reagents commercially available use latex with a diameter of less than 1 µm and are applied in automated chemistry analyzers using photometric measuring principles. To further improve sensitivity, efforts were made to upgrade reagents and instrumentation, and to optimize particle size, selection of appropriate wavelength, and improvements in computer software for integration of data. Automated systems now use latex particles that can perform about 200 tests per hour at a subnanogram-per-milliliter sensitivity.

Particle-Counting Immunoassay

The particle-counting immunoassay (PACIA) (Masson, 1986) uses optical cell counting to assess the decrease in the number of unagglutinated particles after an immunoreaction. In the PACIA format, the rate assay, that is, the rate of decrease in the number of unagglutinated particles, or the endpoint of the assay reaction can be measured. The endpoint assay can be used to obtain a sensitivity at the nanogram-per-milliliter level; however, a longer incubation time is required for an endpoint immunologic reaction.

Other Particle Immunoassays

Quasielastic scattering immunoassays were developed using a measurement of the change in response to particle size distribution (Yarmush, 1987). This technique uses a laser light beam to measure the reduction in the mean diffusion coefficient of particles as a result of immunoreaction. Other methods measure the change in angular anisotropy of scattered light with the increasing average size of the particle. Particles with diameters about equal to the size of a wavelength achieve a size-dependent angular variation of scattered light.

SUMMARY

Indirect hemagglutination and gelatin particle agglutination tests using microtiter plates are popular procedures for qualitative and semiquantitative determination of various analytes. These tests do not require additional instrumentation or strict temperature control. Most important, they guarantee a sensitivity equal to or greater than conventional enzyme immunoassays when applied to antibody detection of infectious agents. Latex as a solid phase provides great kinetic advantages, such as a shorter immunoreaction time. For this reason, it was possible to adapt latex

cyclosporine determination. As described earlier in Kinetics of Antigen-Antibody Reaction, from the following equation:

$$B/F = K_a ([Ab]_t - B) \quad (44-6)$$

the y -axis is the B/F ratio that is proportional to free $[Ab]$ from $[Ab]_t - B$, equal to free $[Ag]$. Therefore, K_a represents the slope of the plot. In Figure 44-9, the affinity constant K_a is 8.1×10^9 L/M for the antibody specific to cyclosporine. Radioactive emissions, such as γ -rays of iodine-125 labels, can be measured in terms of counts per minute (CPM) using a γ -scintillation counter. Typical radioisotopes used as labels and their properties are shown in Table 44-3. The choice of label affects the assay protocol considerably. For example, the most popular label, iodine-125, requires a rather short time for signal counting but has a limited shelf life because of its short half-life. On the other hand, the tritium (^3H) label requires a longer time for counting, thereby increasing the total assay time. Most RIAs now use iodine-125 as labels to expedite the conjugation process and to retain the biological activity of the reactants. A commonly used method for conjugation of iodine-125 with proteins is the chloramine-T method (Hunter, 1962). Tyrosine, in particular, has greater reactivity with iodate because of its hydroxy group at the para-position on the aromatic ring. The signal can be measured in terms of CPM as γ -ray emissions. Unlike enzymes, isotopes as labels with a small Stokes radius are not likely to disrupt antigenic activity because of the lack of steric hindrance when isotopes are conjugated with small antigens (haptens).

ASSAY PRINCIPLES AND METHODS

Various methods (antigen excess) based on the competitive binding reaction (Elkins, 1960) to antibodies between labeled antigens and nonlabeled antigens (analytes present in the specimen) have been developed for a wide variety of analytes. A conventional competitive method is shown in Figure 44-10. At first, known amounts of labeled antigen and antigen in the specimen are mixed and reacted competitively with a constant amount of antibody coated on a solid phase, such as sepharose beads or the inner wall of plastic tubes. After the immune reaction reaches its equilibrium, the mixture is washed to remove unreacted conjugates and antigens, and the immune complex trapped on the solid phase is separated. The washing step is referred to as B/F separation. Applying the competitive principle, the plot of antigen-bound percentage against logarithmic concentration of analyte provides the standard curve shown in Figure 44-10. The CPM plot on the standard curve gives the concentration of analytes.

A second antibody method is shown in Figure 44-11. The first antibody specific to a particular antigen (analyte) reacts competitively with both the conjugate and the antigen. Then, the immune complex is captured by the second antibody specific to the first antibody, on the solid phase. When the second antibody is coated on a fine solid phase, the immune complex on the second reaction can be separated as a precipitant from the unreacted molecules. For antibody determination, labeled antibody and antibody in the specimen react competitively with the antigen (analyte) fixed on the solid phase. The steeper slope of the standard curve provides more precise data. Competitive methods require lesser amounts of antibody or antigen (analyte) than the sandwich-type assays described later. Noncompetitive assays, originally demonstrated by Miles (1968), have recently gained greater popularity.

Immunoradiometric assays and sandwich assays (Fig. 44-12) have alternative relationships between analyte and antibody. The classical competitive assay achieves an immunologic response with a minimum amount of antibody; the sandwich assay uses a large amount of antibody on the solid phase. Monoclonal antibody technology has made it possible to manufacture large quantities of specific antibodies at moderate costs, thereby

for use in existing or sophisticated instruments by applying different principles, resulting in an assay sensitivity of about three orders of magnitude greater than standard immunoprecipitation assays. Latex is susceptible to interferences from unknown factors present in specimens. To eliminate this problem, various absorbents have to be used in both the reagent and the incubation medium. The great advantage of particle immunoassay is its simplicity, because it does not require separation of bound and free reactants.

RADIOIMMUNOASSAY

BACKGROUND

Since RIA technology using radioisotopes as labels was first developed by Yallow and Berson (1959), it has been improved dramatically in sensitivity and precision. Numerous variations in the method have been introduced into the clinical laboratory. Two main RIA techniques, competitive and noncompetitive heterogeneous formats, require washing steps to separate bound and free labels (conjugates). The competitive assay follows the law of mass action, which specifies the reaction between analytes and binding proteins, receptors, and antibody. The key factor in assay optimization is the binding affinity of the antibody. The Scatchard plot of the ratio of bound to free antibody to analyte concentration is commonly used to evaluate antibody performance. Figure 44-9 shows the Scatchard plot for

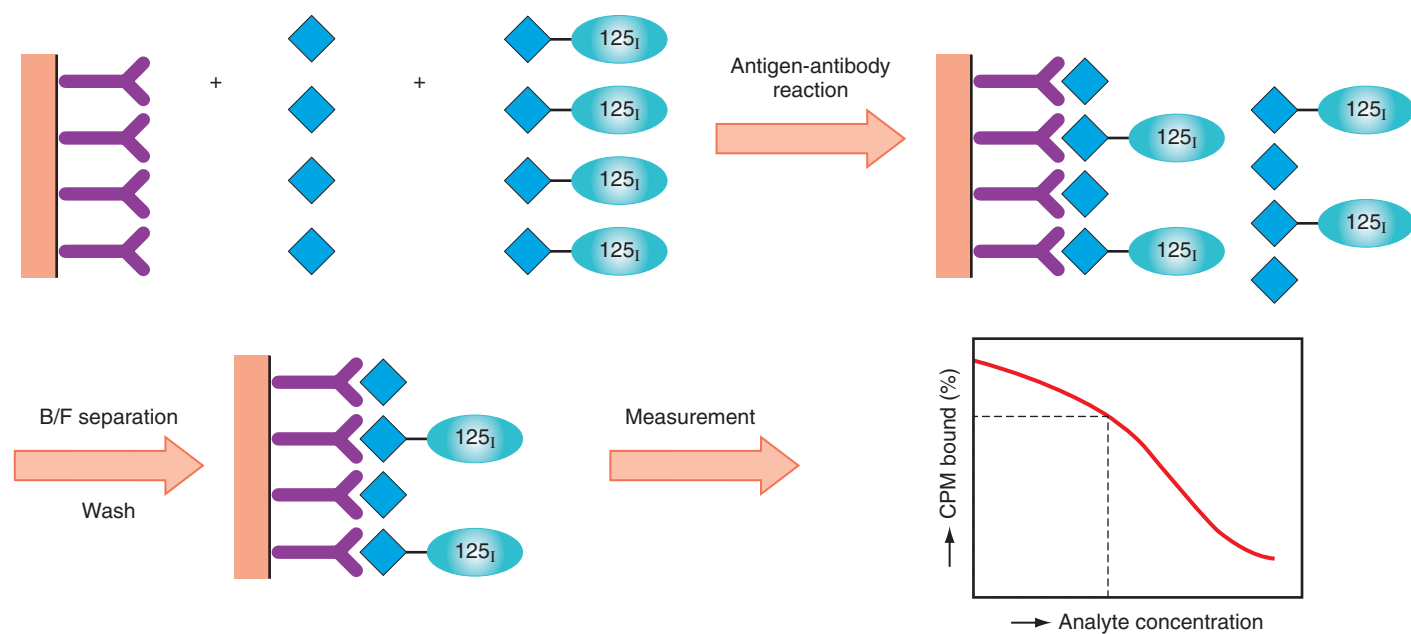

Figure 44-10 Assay principle of competitive radioimmunoassay (RIA) using first antibody as solid phase.

Ab, Antibody.

allowing the sandwich assay to be exploited. The sandwich assay, which uses excess antibody, is more sensitive than the competitive assay. When background noise is completely omitted, the ultimate theoretical sensitivity of the sandwich assay is one molecule of analyte, which is possible when the amount of antibody used in the assay system approaches infinity. As shown in Figure 44-12, the antibody on the solid phase first captures the antigen (analyte) in the specimen. Following B/F separation, the conjugate reacts with the antigen (analyte) fixed on the solid phase; the signal can then be counted after the elimination of free conjugates through a washing step. This assay requires antigens with more than two antigenic sites. When two different antibodies (i.e., a solid-phase antibody specific to one antigenic site and a conjugate antibody specific to another antigenic site) are used, the assay protocol can be simplified by performing a one-step sandwich. Thus, the solid phase can mix together with the antigen in the specimen and the conjugate simultaneously. Interference does not occur because the antibodies on both the solid phase and the conjugate are capable of recognizing different antigenic sites. In this assay, the signal generated is proportional to the analyte concentration present in the specimen, as in the two-step sandwich assay. This assay method can be applied to antibody detection with an assay format using antigen as the solid phase or labeled antigen. For a two-step format, antigen as the solid phase or labeled antibody specific to the target antibody can be used. Using the sandwich format, assay sensitivity (Rodriguez-Espinosa, 1987) is high. An example is seen when an immunoradiometric assay is used for determination of the peptide hormone thyroid-stimulating hormone (TSH); the level of assay sensitivity is below $0.07 \mu\text{U/mL}$ of TSH, as compared with about $0.7 \mu\text{U/mL}$ with conventional competitive antigen-labeled assay.

SUMMARY

Compared with other immunoassays, RIAs are advantageous for a number of reasons: (1) precision and high sensitivity, (2) ease of isotope

conjugation, (3) signal detection without optimization, and (4) stability against interference from the assay environment, among others. Disadvantages of RIAs are the short shelf-life of the reagents and the need to protect against hazardous radioactivity. Furthermore, as discussed later, RIAs may not be applied to homogeneous immunoassays because signals from isotopes cannot modulate Ag–Ab reactions.

ENZYME IMMUNOASSAY

BACKGROUND AND CLASSIFICATION

Quantitative immunoassays using enzymes as labels were developed as alternatives to radioisotopes (Avrameas, 1971; Engvall, 1971; Van Weeman, 1971). The most widely used are the enzyme-linked immunosorbent assay (ELISA), the EIA, and the enzyme-multiplied immunoassay technique (EMIT), which is a registered trade name of SYVA Co. (Dade Behring Inc., Cupertino, Calif.) (Rubenstein, 1972). Essentially, heterogeneous EIAs are similar to RIAs, except that they use enzymes as labels. Enzymes make it possible to develop homogeneous EIAs, eliminating the otherwise necessary washing steps for B/F separation. Table 44-4 compares the features of heterogeneous and homogeneous EIAs versus RIAs. Improvements in EIAs have provided many innovative formats with different degrees of speed, sensitivity, simplicity, and precision. Advantages and disadvantages of EIAs are listed in Table 44-5 (Nakamura, 1992a).

HETEROGENEOUS ENZYME IMMUNOASSAYS

The assay principle of heterogeneous EIAs is similar to that of RIAs, except that enzyme activity, not radioactivity, is measured. EIAs require a secondary process to obtain signals through the catalytic reaction of enzymes. Microtiter plate wells, plastic beads, plastic tubes, magnetic particles, and latex with filters, among others, can be used as the solid phase for the

separation of bound and free conjugates. The use of small magnetic particles and latex allows shortening of the immunoreaction time, thereby reducing the total assay time. The development of substrates to be cleaved by enzymes was marked by the introduction of colorimetric and fluorometric substrates, and later chemiluminescent substrates, which increased the signal sensitivity. The enzymes commonly used in various heterogeneous EIAs are horseradish peroxidase, alkaline phosphatase, β -galactosidase, glucose oxidase, urease, and catalase. The most widely used enzymes and their characteristics are listed in Table 44-6. Assay sensitivity using enzymes may be determined by the turnover rate of each enzyme and by selection of signal measurement in which chemiluminometry is the most sensitive method.

The assay format of heterogeneous EIAs, similar to RIAs, can be divided into competitive and noncompetitive assays (Fig. 44-13). Competitive assays (analyte excess) use antigen–enzyme conjugates (Fig. 44-13, A), and noncompetitive assays (reactant excess) include two-site immunometric sandwich assays (Fig. 44-13, B1) and indirect assays to measure antibodies (Fig. 44-13, B2). Immunometric sandwich assays have gained much popularity for the determination of antigens such as tumor markers, plasma proteins, and infectious agents. Indirect assays for antibody measurement (Figs. 44-13, B2) have been adopted for the detection of antibodies to infectious agents (e.g., HIV, HBV, HCV) and to autoantibodies.

Heterogeneous EIA (see Fig. 44-13) consists of the following steps:

1. The solid phase with the attached reactants is mixed with analyte, regardless of whether the assay is based on the competitive or the noncompetitive format.
2. Following the addition of conjugate and incubation, washing steps are performed with a buffer solution containing a detergent, one or

two steps after the immunoreaction. The immunoreaction should reach certain yields to obtain a stable and precise assay.

3. The solid phase, with the immunocomplex containing enzyme-labeled antigen or antibody, is incubated at constant temperature with the enzyme–substrate solution.
4. The enzyme reaction is stopped (stopping is not needed in rate assay), and the substrate reaction product is measured with various detectors, depending on the substrate used.

Colorimetric Enzyme Immunoassay

In this assay, enzyme reaction is performed by using chromogenic substrates to develop a color by prime catalytic reaction, for example, horseradish peroxidase, catalyzing ABTS (diammonium salt of 2,2'-azino-di[[3-ethyl-benzothiazoline-6-sulfonate]]) with H_2O_2 to form a green color, and alkaline phosphatase specific to the *p*-nitrophenylphosphate, to form a yellow color. Both enzymes are the most commonly used types of colorimetric enzyme immunoassays. A spectrophotometer is used to measure the optical density of the resulting chromogen. Many instruments are available for the measurement of optical density in tubes or microtiter plates, ranging from a fully automated system that performs sample pipetting and data printout to simpler manual devices. When the EIA reaction is performed on nitrocellulose membrane (Western blotting method) or other membranes, substrates that generate insoluble dyes are utilized. An hCG pregnancy test with an immunoassay format that is sold as an over-the-counter test commonly uses benzidine derivatives to react with peroxidase, or indoxyl phosphate derivatives to react with alkaline phosphatase, to generate insoluble dyes. The dye accumulating on the solid phase through enzyme reaction can be read by the naked eye. Theoretically, the measurement of optical density is limited to a range of 0–2.0. Therefore, the determination of optical density for analytes that require determination of a wide dynamic range can be problematic, even when an excess amount of conjugate and a solid phase with sufficient capturing capacity are used with a sandwich-type assay.

Efforts to improve EIAs, the milestone of nonisotopic immunoassays, have brought to light several disadvantages of RIAs, such as hazardous isotopic waste, radiolysis of labeled analytes, and the short half-life of iodine-125. Ishikawa (1989) developed an ultrasensitive EIA capable of detecting 3 fmoles of specific IgG antibody. But to achieve this level of sensitivity, several tedious steps are required, such as immunocomplex transfer from a first solid phase to another solid phase to reduce background signals.

Fluorescent Enzyme Immunoassay

Fluorescent EIAs are identical to other EIAs, except that they use fluorescent substrates. In the fluorescent EIA, a fluorophore is generated by an enzyme reaction. Following excitation of the fluorophore at its optimal light excitation wavelength, light at a characteristic wavelength is emitted. Instruments such as a fluorometer require both a supplier of the excitation light source and a photomultiplier tube as a detector of the emission fluorescence. Substances that emit fluorescent light may be present in the specimen. These substances may increase the background signal, which may interfere with the assay's sensitivity. Thus, close attention should be paid to the selection of substrates for EIAs to avoid interfering factors. Compared with colorimetric EIAs, fluorescent assays generate a signal intensity that is at least one order of magnitude greater.

TABLE 44-5

Advantages and Disadvantages of Enzyme Immunoassay

A. Advantages

1. Sensitive assays can be developed by the amplification effect of enzymes.
2. Reagents are relatively cheap and can have a long shelf life.
3. Multiple simultaneous assays can be developed.
4. A wide variety of assay configurations can be developed.
5. Equipment can be inexpensive and is widely available.
6. No radiation hazards occur during labeling or disposal of wastes.

B. Disadvantages

1. Measurement of enzyme activity can be more complex than measurement of the activity of some types of radioisotopes.
2. Enzyme activity may be affected by plasma constituents.
3. Homogeneous assays at the present time have the sensitivity of 10^{-9} M and are not as sensitive as radioimmunoassays.
4. Homogeneous EIAs for large protein molecules have been developed but require complex immunochemical reagents.

Chemiluminescent Enzyme Immunoassay

Chemiluminescent enzyme immunoassays (CL-EIAs) use chemiluminescent substrates that react with various enzymes employed as labels. The chemiluminescent enzymatic reaction generates light, similar to bioluminescence, which involves the use of natural substrates such as luciferin-adenosine triphosphate. Over the past 20 years, much attention has been paid to the application of chemiluminescence in immunoassays, and a variety of systems consisting of substrates and enzymes have been developed. Current systems using luminol derivatives to peroxidase with an enhancer or dioxetane derivatives to alkaline phosphatase achieve highly sensitive immunoassays. These assays are effective tools in practical diagnosis. The enzymatic oxidation reaction of luminol analogs has long been

used for CL-EIA. Use of peroxidase with H_2O_2 is a common method that is interchangeable with an alternative coupling enzyme producing H_2O_2 , such as glucose oxidase or uricase. The discovery of enhancers by Thorpe (1985) for luminol-based chemiluminescence remarkably improved the assay's sensitivity. Enhancers include phenol derivatives and aromatic compounds. For example, luminol-peroxidase with *p*-iodophenol as an enhancer achieves a light emission increase of up to 2800-fold in the optimized reaction mixture. This assay is able to detect TSH at $0.04 \mu\text{U/mL}$ when serum is used as the specimen. However, oxidative reactions, such as those for luminol, are likely to be interfered with by multiple factors that cause increased nonspecific background signals (noise).

Bronstein (1989a) developed a chemiluminescent substrate for alkaline phosphatase that differs considerably from other compounds. This new substrate is known as AMPPD (disodium 3-(4-methylspiro [1,2-dioxetane-3,2'-tricyclo-[3.3.1.1]decan]-4-yl) phenyl phosphate), an adamantyl dioxetane derivative. It requires no additional molecules for the emission of chemiluminescent light, unlike luminol, which needs oxidative compounds from outside the luminol molecules. AMPPD is a novel molecule that is a complete substrate because it is composed of the adamantyl group as a stabilizer of the entire molecule, the dioxetane bond as an energy source, and phosphoryl ester as a cleavage site of the enzyme, along with a phenyl group for chemiluminescence—all assembled within one molecule. The structure of the molecule and the reaction process for light generation are shown in Figure 44-14. Cleavage of the phosphoester bond of AMPPD by alkaline phosphatase triggers chemically initiated electron exchange luminescence by releasing electron-rich dioxetane. A chemiluminescent signal with maximum wavelength of 477 nm can be detected within a couple of minutes to a few hours, depending on substrate concentration. The alkaline phosphatase with AMPPD assay system has a sensitivity of less than 10^{-20} mol (Bronstein 1989b, 1991; Kricka, 1991).

CL-EIA uses AMPPD as a substrate to react with alkaline phosphatase, which is used as the enzyme label. CL-EIA can be performed on a fully automated instrument. This novel substrate made it possible to develop an extremely sensitive chemiluminescent enzyme immunoassay system. Ferrite particles $0.3 \mu\text{m}$ in diameter as the solid phase shorten immuno-reaction time to within 30 minutes and provide a larger surface area for the immunoabsorbent. The relationship between the chemiluminescent signal and the concentration of analytes is linear up to about seven orders of dynamic range. The sensitivity of CL-EIA (Nishizono, 1991) was 10-fold greater than that of conventional RIAs when AFP was assayed; AFP was detected at a level of 30 pg/mL with an assay time of 30 minutes. Thus, the new chemiluminescent EIA systems are a definite improvement over RIAs in terms of sensitivity, time efficiency, and procedural simplicity, and they are increasing in popularity.

HOMOGENEOUS ENZYME IMMUNOASSAYS

Background

Two options are available to eliminate tedious assay procedures. One is to design fully automated instruments to access heterogeneous types of reagents, and the other is to develop innovative reagents that do not require complicated washing steps, such as those needed for heterogeneous EIAs. Enzymes and their cofactors are advantageous labels in homogeneous EIAs because enzyme activity can be modulated easily by changing factors in the microenvironment of the Ag-Ab reaction. This is not the case when radioisotope decay is used as the signal. At present, homogeneous EIAs are generally less sensitive than their heterogeneous counterparts. Conventional heterogeneous EIAs have equal sensitivity to RIAs in many applications, whereas homogeneous EIAs (Nakamura, 1988) remain one or two orders of magnitude less sensitive than RIAs. Homogeneous EIAs may require complex immunochemical reagents, but the assay systems are rapid and simple and are adaptable to conventional instruments. Various types of homogeneous EIAs are available. In each of these assays, the Ag-Ab interaction modulates the activity of the enzyme or enzyme label in the presence of the substrate. Modulation of the enzyme activity reflects the degree of the immunochemical reaction. Table 44-7 lists the characteristics of typical homogeneous EIAs. Homogeneous EIAs can be classified as competitive and noncompetitive binding assays. Competitive assays usually consist of enzyme-labeled antigens. However, the antigen (analyte) may be conjugated to the substrate or to a prosthetic group of the enzyme in other assay formats. In contrast, noncompetitive binding assays use a conjugate of antibody labeled with enzyme. Among the various methods reported, five homogeneous EIAs deserve our attention.

Figure 44-14 Adamantyl 1,2-dioxetane phenyl phosphate (AMPPD): a chemiluminescent substrate for alkaline phosphatase (ALP) detection. Hydrolytic phosphate cleavage by ALP triggers chemically initiated electron exchange luminescence (CIEEL) decomposition of AMPPD by releasing the electron-rich dioxetane phenolate (AMPD⁻). Charge transfer from the phenolate to the dioxetane ring takes place, forming the charge transfer (CT) intermediate and subsequent breakdown of the cyclic peroxide. Release of energy occurs with light emission.

TABLE 44-7

Classification and Characteristics of Typical Homogeneous Enzyme Immunoassays*

Name and assay type	Conjugate	Manner of modulation
Competitive		
EMIT	Antigen with lysozyme, G6PD*	Steric hindrance
SLFIA	Antigen with substrate	Steric hindrance
ARIS	Antigen with prosthetic group	Steric hindrance
Enzyme-channeling immunoassay	Antigen with G6PDH* and hexokinase*	Enhancement by proximity
Biotin-enzyme avidin immunoassay	Antigen with avidin	Steric hindrance
CEDIA	Antigen with fragments of subunit	Steric hindrance
Noncompetitive		
Hybrid antibody immunoassay	Hybrid antibodies specific to antigen and to inhibitor	Steric hindrance
Proximal linkage immunoassay	Antibody with G6PDH* and hexokinase	Substrate cascade by proximity
EIHA	Antibody with amylase*	Steric hindrance
Enzyme enhancement immunoassay	Antibody with β -galactosidase* and succinyl antibody	Charge effect
AEST	Antibody with peroxidase	Stabilization

*Enzyme discussed in detail in the text.

Enzyme-Multiplied Immunoassay Technique

EMIT, the first homogeneous EIA, was developed by Rubenstein (1972). The EMIT system is illustrated in Figure 44-15. In EMIT, the conjugation of enzymes to haptens does not disrupt enzyme activity; however, the binding of hapten-specific antibodies to haptens results in inhibition of enzyme activity. Free haptens in the standard or sample relieve this inhibition by competing for antibodies. Thus, in the presence of antibodies, enzyme activity is proportional to the concentration of free haptens. As a general rule, the antibody inhibits the enzyme by inducing or preventing conformational changes necessary for enzyme activity (Rowley, 1975). The exception to this inhibition mechanism is the EMIT thyroxine assay, which uses malate dehydrogenase. In this assay, the thyroxine-malate dehydrogenase conjugate is enzymatically inactive, but it becomes activated when it is bound by thyroxine antibody (Ullman, 1979). It is believed that conjugated thyroxine inhibits the enzyme by binding to the active site, thus increasing the "apparent" K_m of the substrate. The antibody reactivates the enzyme by "pulling" the thyroxine out of the active site. In the EMIT assay system, malate dehydrogenase and glucose-6-phosphate dehydrogenase have been found to be most useful because they are less likely to be affected by serum constituents. These assays generally measure drugs at a concentration of milligrams per liter. However, the digoxin assay has a much lower limit of sensitivity in the range of 0.8–2 $\mu\text{g/L}$.

Substrate-Labeled Fluorescent Immunoassay

The substrate-labeled fluorescent immunoassay (SLFIA) (Burd, 1977) uses a characteristic fluorogenic substrate, umbelliferol β -galactoside, attached to the antigen (analyte) as a conjugate. Umbelliferone is the fluorescent

product produced when the substrate is cleaved with the enzyme β -galactosidase, which cannot cleave the substrate–antigen complex when it is reacted with the specific antibody. The free antigen (analyte) in the specimen solution competes with the antigen conjugated with the substrate to form the immunocomplex (Fig. 44-16). The antigen concentration in the sample is proportional to the fluorescent intensity of the cleaved fluorescent product. SLFIA can be used to assay drugs and haptens, as well as protein ligands such as IgG and IgM. A disadvantage of this method is that the amplification properties of the enzyme are not utilized, and thus the assay system has limited sensitivity in the range of 10^{-9} – 10^{-10} molar concentration of the analyte.

Apoenzyme Reactivation Immunoassay

The apoenzyme reactivation immunoassay (ARIS) is a homogeneous assay developed by Morris (1981) using the prosthetic group consisting of flavin adenine dinucleotide (FAD)-conjugated antigen (analyte) and glucose oxidase apoenzyme. As shown in Figure 44-17, the antigen (analyte) and a constant amount of analyte–FAD conjugate compete for a limited amount of specific antibody. At equilibrium, the level of free conjugate is proportional to the amount of antigen (analyte) in the specimen. The apoenzyme combines with the free but not with the antibody-bound form of conjugate to reactivate glucose oxidase activity in proportion to the amount of free conjugate in the mixture. Active enzyme is generated in the procedure, and an amplification mechanism is built into this assay. ARIS has been used to assay for theophylline and IgG (Morris, 1981, 1985). This FAD-labeled conjugate assay is readily adapted to the measurement of high molecular weight proteins (e.g., thyroid binding globulin) (Schroeder, 1985), as well as other haptens such as phenytoin and hormones.

Figure 44-15 Enzyme-multiplied immunoassay technique (EMIT) system diagram: The activity of an enzyme as a label is inhibited by the binding of antibody to antigen (analyte) conjugated with enzyme. The analyte is usually a hapten. Glucose-6-phosphate dehydrogenase (G6PD) and lysozyme are usually used as enzymes. In the assay, enzyme activity is proportional to the concentration of the analyte.
