In principle, in the measurement of enzyme activity, either the rate of disappearance of substrate or the rate of appearance of product can be measured. In general, it is easier to measure small increases in product than to measure small decreases in a relatively high concentration of substrate often needed to achieve saturation. As discussed previously, to measure enzyme activity in a sample, it is most common to use substrates at saturating concentrations where zero-order kinetics with respect to $[S]$ occur. Under these conditions, the reaction rate is directly proportional to the total amount of enzyme present.

Equation 20-11 states that, at saturation, the rate of product formation with time is constant. This implies that the concentration of product increases linearly with time. Experimentally, P is determined at different time points, and a least-squares best-fit line through the points is determined. If the correlation coefficient is high, $[P]$ increases linearly with t , confirming saturation of the enzyme by substrate. The slope of this line is V_{\max} , which may be reported directly as activity or divided by k_2 to give enzyme concentration.

The most common cause of a *nonlinear* relationship between P and t is the presence of an inhibitor that will be discussed later. In cases such as these, dilution of the serum or other body fluid sample is warranted because this will dilute the concentration of the inhibitor, although it will also dilute the total enzyme concentration. However, as long as $[S]$ is present at saturating conditions, and $[P]$ can be measured, valid total enzyme concentrations or activities can be measured.

Typically, in enzyme assays, a lag phase follows mixture of the specimen and reagents, when preliminary reactions and mixing of sample occur. The initial absorbance of the sample is based on the absorbance due to the reagents and the sample, and is considered to be zero in terms of making an interpretation of enzyme activity. Once the reaction begins, the graph will follow a straight line for a period of time; at this point, the reaction is zero-order and enzyme activity can be determined. If the reaction is allowed to proceed, substrate is consumed and $[S]$ falls toward K_M . If $[S]$ falls substantially below K_M , the reaction will then be first-order, and v_0 will be affected both by the amount of substrate (which is not a constant) and by the enzyme activity.

Spectrophotometric Assays

In most cases, enzyme activity is measured spectrophotometrically. In addition, other detection methods are used as appropriate, depending on the product being measured. For example, lipase acts on emulsions of lipid; these are often turbid, so that measurement of the rate of clearance of turbidity could be used to determine lipase activity. Glucose oxidase, widely used to measure glucose concentration, is a flavoprotein that uses oxygen as an electron acceptor. The change in potential due to alteration in charge on the acceptor can be measured to determine the reaction rate. Urease is widely used to measure urea concentration; urease splits urea into bicarbonate and ammonium ions. The change in conductance of the specimen due to the appearance of the ions in the sample can be used to determine the rate of reaction.

Because assay methods based on spectrophotometry are the most common, we will focus on these in describing how enzyme assays are performed. In the simplest case, the substrate does not absorb light at a particular wavelength at which the product absorbs strongly. An excellent example of this is LD, which catalyzes reversibly the oxidation of lactate to pyruvate. Because lactate is a unique substrate for LD, it is preferred. Pyruvate can be used as the substrate, except that it is also the substrate for several other enzymes such as pyruvate dehydrogenase and ALT, among others.

When lactate is oxidized to pyruvate, the cofactor, NAD^+ , becomes reduced to NADH. For each mole of lactate oxidized to pyruvate, 1 mole of NADH forms. NADH absorbs strongly at 340 nm, and NAD^+ does not absorb light at this wavelength. Therefore, the addition of saturating concentrations of both lactate and NAD^+ to a patient's serum will result in a linear increase in absorbance at 340 nm over a given period, from which total enzyme activity is directly determined as described earlier. In this case, the increase in concentration of NADH, ΔP , over the time period, Δt , is proportional to the increase in absorbance, ΔA , at 340 nm, by Beer's Law, as described in Chapter 4, that is,

$$\Delta P/\Delta t = \epsilon \times (\Delta A/\Delta t) \times L \quad (20-13)$$

L in Equation 20-13 is the pathlength of the reaction vessel or cuvette, almost always equal to 1 cm. ϵ is a proportionality constant (most often, the molar extinction coefficient) in Beer's Law, which is $6.22 \times 10^3 \text{ L mol}^{-1} \text{ cm}^{-1}$ for NADH at 340 nm. On most current chemistry analyzers, a volume of a patient's serum sample is added to the reaction cuvette containing the reaction components (lactate and NAD^+), and ΔA is observed. This results in dilution of the volume (V_p) of the patient's serum to the total volume of the reaction mixture (V_0), so that

$$\text{Enzyme activity} = \Delta P/\Delta t = \epsilon \cdot (\Delta A/\Delta t) \cdot L \cdot (V_0/V_p) \quad (20-14)$$

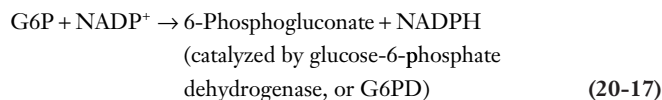

One caveat in the previous assay is that LD also catalyzes the reverse reaction (i.e., pyruvate to lactate). Therefore, as pyruvate forms, it can serve as an end-product competitive inhibitor (see Enzyme Inhibition section later) and can drive the reaction back to lactate.

Therefore, it is important to be able to take the measurements in Equation 20-14 over a short time before pyruvate builds up to significant levels.

Coupled Enzymatic Reactions

In many instances, however, neither the product nor the substrate of a chemical reaction can be measured conveniently. In such instances, the enzymatic reaction can be "coupled" to another reaction that uses the product of the enzyme-catalyzed reaction to produce an indicator substance. An example of a typical coupled enzymatic reaction is the Oliver-Rosalki method for measurement of CK activity, illustrated in Equations 20-15 through 20-17, later. The reverse reaction of CK is used, producing adenosine triphosphate (ATP), which is used in a second reaction to produce glucose-6-phosphate (G6P) from glucose + ATP. The third reaction in the sequence results in the reduction of nicotinamide adenine dinucleotide phosphate, or $NADP^+$, to NADPH, the indicator of the reaction. In these coupled reactions, it is critical that the rate-limiting step in the overall reaction is the CK-mediated step that generates ATP. This can be achieved by using high concentrations of the indicator enzymes to ensure rapid conversion of the substrates of the subsequent reactions.

One potential problem with CK measurements when this reaction scheme is used is the presence of other enzymes that can generate ATP. Adenylate kinase, an enzyme found in red blood cells and liver, converts adenosine diphosphate (ADP) to ATP (see Equation 20-34); specimens with high adenylate kinase activity will have falsely elevated values for CK activity.

Complication:

The absorbance increase at 340 nm due to NADPH is proportional to the $[\text{ATP}]$ generated as the end-product of the CK reaction, as expressed in Equation 20-15.

In assays of enzyme activity, some methods use **endpoint** measurements, determining the concentration of substrate or product at a specific time after addition of the sample. Endpoint methods are typically used in simple methods, such as bedside glucose testing or dipstick reactions, as for glucose or leukocyte esterase in urine. Endpoint methods may give erroneously low results in situations where enzyme activity is very high. Most enzymatic assays use **kinetic** methods of measurement (as discussed earlier), whereby the rate of change in concentration of substrate or product is determined. (For the sake of simplicity, throughout the rest of this section, only measurement systems that detect appearance of product will be described; the same principles, however, would apply to situations where rate of disappearance of substrate is being monitored.) Kinetic methods are more accurate and make it easier to detect changes in reaction conditions and samples requiring dilution. In a time-course study, the rate of reaction can be expressed as $\Delta P/\Delta t$, the change in amount of product per unit time. Because the IU and the katal represent the amount of enzyme producing a specific amount of product in a given time period, this approach allows direct reporting of enzyme activity in either IU or katal, as desired.

Enzyme Assays Under Nonsaturating Conditions: First-Order Rate Processes

As discussed later, there are circumstances under which it may not be possible to perform an enzyme assay under saturating conditions where Equation 20-11 applies. In these circumstances, assay conditions may be used in which $S < K_M$. The Michaelis-Menten equation (20-10) then becomes

$$v_0 = d[P]/dt = k_2 E_T \cdot [S]/K_M \quad (20-19)$$

Because E_T is constant, the initial rate of the reaction depends only on the concentration of S . When S decreases, ES and P increase so that $-d[S]/dt$

$= d[ES]/dt + d[P]/dt$. But, under the reaction condition that $[S] \gg [E]$, the steady-state assumption, $d[ES]/dt = 0$, is valid. Therefore, the rate of product formation equals the rate of substrate depletion, that is,

$$v_0 = d[P]/dt = -d[S]/dt = k_2 E_T \cdot [S]/K_M \quad (20-20)$$

This is the equation for a first-order process, that is, the rate depends only on the concentration of a single species, in this case the substrate. Because the rate also formally depends on E_T , it is properly called a second-order reaction, but in this case, E_T is constant and does not change during the reaction. It is therefore referred to as a *pseudo-first-order* reaction. E_T can be determined from determination of the initial rate of the reaction where the initial substrate concentration, S_0 , is known. Because K_M and k_2 are known,

$$E_T = (v_0/[S_0]) \times (K_M/k_2) \quad (20-21)$$

If only total enzyme activity is to be reported, then v_0/S_0 , which is equal to $(k_2/K_M)[E_T]$, is reported because this quantity is directly proportional to E_T . Note though that these are not the same activity units as are used under saturating conditions because the total enzyme concentration in that case is multiplied only by k_2 , and in the current circumstance, it is multiplied by k_2/K_M because of the fact that saturation has not occurred.

Another approach to determination of E_T under nonsaturating conditions is to integrate Equation 20-20 for S in terms of t . This results in the following relationship:

$$\ln([S]/[S_0]) = 2.303 \log([S]/[S_0]) = -(k_2 E_T / K_M) \cdot t \quad (20-22)$$

where \ln is the natural logarithm to the base e and $[S_0]$ is the initial substrate concentration. If the substrate concentration is determined at specific times, a plot of the $\log([S]/[S_0])$ versus time should give a straight line whose slope is $-(k_2 E_T / K_M) / 2.303$. Because both k_2 and K_M are known, E_T can be directly evaluated. This method eliminates the need to measure initial velocities involving small changes in $[S]$. This method is advantageous when the substrate solubility does not permit saturating substrate concentrations to be reached.

The above first-order rate equation is the general equation for all first-order rate processes that abound in biology. Many reactions in the body occur either by first-order processes or by pseudo-first-order processes in which the rate depends only on the concentration of one species. As is discussed in Chapter 23, when drugs are administered to the body, they decay very often by a first-order process, where the rate of disappearance of the drug depends only on the concentration of the drug. One important feature of this process is the so-called **half-time**. Note, from Equation 20-22, that the half-time, or the time required for half of S_0 to be consumed, that is, when $[S] = [S_0]/2$, is a constant that depends only on the rate constant in the equation. The nondependence of $t_{1/2}$ on concentration is a cardinal feature of first-order rate processes.

Because $\log(2) = 0.3$, the above equation reduces to

$$t_{1/2} = 0.69/k \quad (20-23)$$

where, in this case, $k = K_M/k_2 E_T$ and $t_{1/2}$ is the half-time, that is, the time required for half of the substrate to be consumed. Thus, if the half-time for substrate consumption is known, E_T can also be directly computed from Equation 20-23, provided that K_M and k_2 are known.

OTHER FACTORS AFFECTING ENZYME ACTIVITY

Temperature

Enzyme-catalyzed reaction rates are extremely sensitive to temperature changes; to ensure accuracy, the temperature of the reaction mixture must not deviate by more than $\pm 0.1^\circ \text{C}$ from the assigned temperature. In general, every 10°C increase in the temperature leads to an approximate doubling of enzyme activity, although this varies slightly from one enzyme to another. The use of higher temperatures gives faster reaction rates and improves sensitivity—an advantage when enzyme activities are low. Lower temperatures increase the linear limit of an assay, requiring fewer dilutions. The choice of temperature with most modern instruments is governed by the capabilities of the instrument. There is a limit to the amount of temperature increase that can be used; most enzymes start to denature and become inactive as the temperature is increased. For example, CK starts to denature at 37°C , and amylase begins to denature at 45°C . On the other hand, some enzymes remain stable at extremely high temperatures. As an extreme case, the Taq polymerase used in the polymerase chain

reaction is stable at 95°C . Taq polymerase and the polymerase chain reaction are discussed in Chapter 66.

pH

Enzymes have a pH optimum for maximal activity; usually, the pH of the reaction conditions is chosen to be that at which the enzyme exhibits the greatest activity. Selection of pH is not always critical; some enzymes have a very broad pH maximum, so that small changes in pH do not appreciably change activity. For example, ALP has maximum activity at pH values between 9 and 10. In some cases, particularly for enzymes with multiple isoenzymes, selection of pH represents a compromise, as different isoenzymes may have maximum activity at differing pH values. In this situation, the pH for the reaction is selected to allow measurement of the activities of all isozymes.

Salt and Protein Concentrations

The ionic strength of solutions affects enzyme activity; if ionic strength is too high, enzyme activity drops. The activity of many enzymes is also affected by protein concentration. When enzyme activity is over the linear limits of the assay, dilution of plasma typically requires use of **enzyme diluents** containing plasma proteins. Human plasma contains about 70 g protein/L, but normal urine has almost no protein; use of proteins such as albumin increases the activity of urinary amylase and standardizes its measurement. In protein-free solutions, enzymes lose activity rapidly either by denaturation or by adsorption to the walls of the container.

Inhibitors and Interferences

Typically, enzymes are measured in serum samples. Heparinized plasma is generally considered an equivalent sample to serum for most routine analytes, but this may not be the case for enzymes. Heparin may inhibit the activity of some enzymes, notably amylase and AST (using some, but not all, methods). Citrate, used in evacuated collection tubes for coagulation testing and as a preservative in blood products, complexes divalent cations; citrate-containing specimens may cause falsely low results for enzymes such as CK and ALP. Ethylenediaminetetraacetic acid (EDTA) and fluoride inhibit the activity of many enzymes and should almost never be used for specimens for enzyme analysis. An exception is in measurement of renin, where EDTA inhibits the action of enzymes that convert prorenin to the active enzyme renin and prevents artifactual increase in renin activity.

CAVEATS IN ENZYME ASSAYS

Some of the causes of errors in enzyme assays, such as the presence of inhibitors, have been mentioned previously. Here, we summarize the most common problems that can be encountered.

K_M -Type Mutations

In certain deficiency states, the conditions of the *in vitro* assay may not mirror the *in vivo* conditions that give rise to the deficiency state. In cases where a genetic defect does not alter normal protein levels of enzyme, and the k_{cat} value is unchanged, by applying the principle that the assay should be carried out at saturating substrate concentration, it is possible that a K_M -type mutation may go undetected because the enzyme, inactive at low substrate levels, exhibits full or nearly full activity at the higher $[S]$ used in the assay. For example, a variant erythrocyte hypoxanthine-guanine-phosphoribosyltransferase is inactive in assays at low $[S]$, but full activity is restored by increasing the substrate concentration. To guard against such a false positive, a clinical evaluation should include a determination of the K_M for the mutant enzyme.

One technique that can be employed to detect enzyme mutations that affect activity is the use of monoclonal antibodies directed against the enzyme of interest. Immunoassays for enzymes are discussed later. Correspondence between measurement of enzyme activity and the protein (enzyme) concentration from immunoassays will pertain as long as the enzyme antigen is fully active. Such is not always the case when inherited deficiencies associated with point mutations are involved. In these instances, estimates of enzyme concentration based on immunoassays can exceed those based on measurements of enzyme activity, indicating a defect in the enzyme. If the underlying basis of disease is genetic, it is best to estimate enzyme activity from kinetic measurements and compare these with normal values. Some mutations destabilize protein structure, leading to rapid intracellular proteolysis of the enzyme. In this instance, the result derived from immunologic methods and enzyme activity measurements can concur. The presence of inhibitors in the source biological fluid

may lead to underestimation of the amount of enzyme present based on activity, but not immunologic measurements. Usually, reversible enzyme inhibitors will not interfere with immunologic estimates of enzyme concentration.

Cyclic Enzyme Instability

In some cases, an enzyme defect may go undetected because the clinical evaluation occurs at an inappropriate time. Administration of the antimalarial primaquine to a G6PD-deficient individual carrying the common type A⁻ variant (G6PD A⁻) causes transient hemolytic anemia. Patients can recover completely from the anemia despite continued drug treatment. The type A⁻ variant has normal kinetic parameters but reduced thermal stability. The initial episode clears older erythrocytes that have reduced G6PD activity. The older cells are replaced by new cells that have higher amounts of enzyme. The quantity of G6PD molecules in erythrocytes is a function of erythrocyte age, and the rate of loss of enzyme molecules in type A⁻ variant cells exceeds that in normal cells by a significant margin. Levels of G6PD activity following recovery from anemia will be substantially higher than if assays are performed before or during the hemolytic episode, because hemolysis selectively destroys older cells containing smaller amounts of enzyme. Recovery results in the replacement of these older cells with new cells with higher levels of G6PD A⁻ molecules. During and following recovery, the younger set of cells is able to cope with the primaquine treatment because of the presence of higher levels of enzyme activity.

Presence of Enzyme Inhibitors

As is discussed later, enzyme inhibitors present in biological fluids may permit underestimation of the amount of enzyme present. It is important to note that if the presence of an inhibitor is suspected, the most effective procedure is to dilute the sample, so that the effect of the inhibitor will be minimal. In case of the possibility of end-product inhibition, initial velocity determinations eliminate this effect because, initially, at $t = 0$, $[P] = 0$, where there will be no inhibitory effect. In rare cases, in enzyme-catalyzed reactions in which the product binds to the enzyme with a much higher affinity than the substrate, $\Delta P/\Delta t$ or $-\Delta S/\Delta t$ may be curvilinear, and estimates of the initial velocity are best made from tangents drawn to the substrate or product time-course curves at $t = 0$. These tangents are best determined from continuous traces of substrate disappearance or product formation.

Protease Degradation of Unstable Enzymes

Proteases in plasma may attack the enzyme while the velocity estimate is being made. This is especially true for enzymes that may have reduced thermal stability as discussed earlier. If the enzymes become unfolded, they are subject to attack by serum proteases, including trypsin and chymotrypsin and a number of other proteases. Enzyme damage through proteolysis, and substrate decomposition, may be corrected by the use of suitable blanks and preincubation studies.

Thermal Instability

The stability of the enzyme under evaluation must be known, and sample storage conditions must be determined. For example, LD cannot be stored at temperatures $<0^{\circ}\text{C}$ without significant loss of activity.

Presence of Inhibitory Compounds in Blood Collection Tubes

As discussed previously, in many cases serum or plasma and not whole blood must be used for the determination of enzyme activity in whole blood samples collected in anticoagulant-containing tubes. Polyanionic anticoagulants, such as citrate, heparin, and EDTA, inactivate metal-containing enzymes. For example, EDTA inactivates the zinc-containing enzyme ALP, an enzyme that is commonly assayed.

Competing Reactions in an Enzyme Assay

As noted in the preceding section, substrates used to assay specific enzymes may be subject to attack by other enzymes normally present in biological fluids. Assays for LD using pyruvate as the substrate can be complicated by the presence of other enzymes such as pyruvate dehydrogenase and ALT that react with this substrate. The coupled assay system for CK activity can be complicated by the presence in serum of the enzyme adenylate kinase, which can consume the substrate ADP. (See Equation 20-18.) This problem cannot be corrected by using saturating concentrations of ADP because the product of the adenylate kinase reaction is also ATP, and the

ATP produced in the CK reaction has to be used to determine the amount of G6P produced to determine accurately the CK level.

Time-Dependent Inactivation of Certain Enzymes

Sample age may be important in determining enzyme activity. Enzymes whose activity depends on active-site sulfhydryl groups may suffer slow inactivation through oxidation and/or disulfide exchange reactions. In many instances, these processes are irreversible and lead to underestimation of the enzyme concentration by activity measurements.

ANTIBODY-BASED TECHNIQUES FOR MEASURING ENZYMES

As mentioned earlier, immunoassays can be used to measure the mass of enzyme protein. These assays are described at length in Chapter 23 and in Part 5. Immunoassays are the method of choice when it is desired to quantitate one or more isoenzymes of an enzyme in a sample because specific antibodies raised against each individual isoenzyme will identify and quantitate each of the variants present in the sample.

Immunoassays are, in general, less affected by factors that affect enzyme activity and are often more precise. As with enzyme activity, however, the determination of enzyme mass may vary depending on the reagents used; calibrators often lead to different results for mass activity between different methods. Examples include the MB isoenzyme of CK, the pancreatic isoenzymes of amylase, the prostatic and bone isoenzymes of acid phosphatase (ACP), and the bone isoenzyme of ALP. Antibodies can also be used to selectively inhibit or bind particular enzyme subunits. This approach allows the total and isoenzyme measurements to be expressed in the same units. For example, antibodies to CK-M subunits inhibit half of CK-MB isoenzyme and all of CK-MM isoenzyme. Measurement of CK activity of a sample after incubation with an anti-M antibody can be used to determine the activity of non-M subunits of CK.

Antibodies can also be used as **capture** antibodies to separate a particular isoenzyme from other forms of the same enzyme, followed by measurement of enzymatic activity. Examples of such capture assays include tests for the bone isoenzyme of ALP and the bone and prostate isoenzymes of ACP. Some enzymes circulate bound to antiproteases, such as prostate-specific antigen (PSA) (see Chapter 73) and α -1-antichymotrypsin or trypsin and α -1-antitrypsin. Antibodies may differ in their ability to measure free and bound forms. Some enzymes are also bound to β -2-macroglobulin, such as PSA (Otto, 1998) and ACP (Brehme, 1999); enzyme bound to this antiprotease usually is not enzymatically active and cannot be measured by most immunoassays, because the binding site is hidden from antibody recognition. Finally, in common with other immunoassays, measurement of enzymes by immunoassay can show interferences from substances that bind to reagent antibodies, such as heterophile antibodies (Sosolik, 1997) and rheumatoid factor (Dasgupta, 1999).

INHIBITION OF ENZYMES

The inhibition of enzymes may be reversible or irreversible. In irreversible inhibition, a covalent bond is formed between the inhibitor and the enzyme, and enzyme activity cannot be restored by dissociation of the inhibitor. Examples include the inhibition of acetylcholinesterase (AChE) and pseudocholinesterase (PChE) by chemical warfare agents such as sarin and tabun that irreversibly phosphorylate the side chain **OH** group of the active-site serine residue. The first fluorinated anesthetic, fluroxene ($\text{CF}_3\text{CH}_2\text{OCH}=\text{CH}_2$) proved to be too toxic for use as a general anesthetic because it irreversibly alkylated a heme ring N atom in the cytochrome P450 monooxygenase responsible for its detoxification. This alkylation led to complete loss of enzyme activity.

Reversible inhibition is one of three types: competitive, uncompetitive, and noncompetitive. As noted earlier, if the presence of an inhibitor is suspected in an enzyme assay of a patient's sample, such as by observation of a nonlinear $[P]$ versus time curve, an effective strategy is to dilute the sample, so that the effect of the inhibitor is reduced. Even if this procedure concurrently dilutes the enzyme, the enzyme assay can still be effectively performed, especially if the substrate is present at saturating conditions.

COMPETITIVE INHIBITION

Competitive inhibition occurs when the inhibitor binds at the same site as the substrate. The molecular basis for the binding of competitive inhibitors at the active site is that the substrate and the inhibitor are structurally

Figure 20-6 Schemes for all types of inhibition of enzyme activity. **A**, The scheme for an uninhibited reaction. **B**, The scheme for competitive inhibition, showing that the inhibitor binds competitively to free enzyme, decreasing the binding of the substrate to the free enzyme. This results in a lower apparent affinity of the substrate for the enzyme, making the apparent K_M higher than the true K_M . However, this inhibition does not affect the catalytic rate, V_{max} . K_I is the dissociation constant for the enzyme–inhibitor complex ($[EI]$). **C**, The scheme for uncompetitive inhibition, showing that the inhibitor binds only to the enzyme–substrate complex such that it blocks catalysis but not the binding of the substrate to the enzyme and therefore affects V_{max} but not K_M . K_I in this case is the dissociation constant for the enzyme–substrate–inhibitor ternary complex ($[ESI]$). **D**, The scheme for noncompetitive inhibition, which is of two types: (1) simple and (2) mixed. In both cases, the inhibitor binds both to the free enzyme and to the enzyme–substrate complex, affecting both V_{max} and K_M . In simple noncompetitive inhibition (1), the affinity of the inhibitor both for the free enzyme and for the enzyme–substrate complex is the same, making the two respective dissociation constants, K_I and K_I' , equal. In mixed noncompetitive inhibition (2), K_I and K_I' are not equal.

similar, with the result that the enzyme is “deceived” into recognizing and binding the inhibitor. Examples of competitive inhibition include the inhibition of trypsin by α -1-antitrypsin, chymotrypsin by α -1-antichymotrypsin, dihydrofolate reductase by the chemotherapeutic agent methotrexate, and the Krebs cycle enzyme succinic dehydrogenase by malonate. In some reactions, the product of the reaction, which may be structurally similar to the substrate, may competitively inhibit the reaction, a phenomenon known as **end-product inhibition**. A variation of this phenomenon can occur occasionally in which the buildup of the end-product can reverse the forward reaction, regenerating the substrate. Not infrequently, drugs are used as competitive inhibitors of targeted enzymes. For example, as discussed later, a major target of antihypertensive drugs is angiotensin-converting enzyme (ACE).

HOW COMPETITIVE INHIBITORS AFFECT THE MICHAELIS-MENTEN EQUATION

The kinetic mechanism for **competitive inhibition** is shown in [Figure 20-6, B](#). The inhibitor is assumed to be in rapid equilibrium with free **E** and the **EI** complex. Kinetically, the inhibitor reduces the concentration of free **E** available to combine with **S**. The equation of conservation of enzyme now reads

$$[E_T] = [E] + [EI] + [ES] \quad (20-24)$$

$[EI]$ is defined in terms of the equilibrium constant, K_I , for the dissociation of the inhibitor from the **EI** complex, and

$$[EI] = [E][I]/K_I \quad (20-25)$$

Because the steady-state equation for **ES** ([Equations 20-3, 20-4, and 20-5](#)) remains the same, [Equation 20-24](#) becomes

$$E_T = E + [E][S]/K_M + [E][I]/K_I \quad (20-26)$$

and

$$[E] = \frac{[E_T]}{\left(1 + \frac{[S]}{K_M} + \frac{[I]}{K_I}\right)} \quad (20-27)$$

Because, as in [Equation 20-2](#),

$$d[P]/dt = k_2[ES] = [E][S]/K_M \quad (20-28)$$

$$\frac{dP}{dt} = \frac{k_2[S]}{K_M} \cdot \frac{[E_T]}{\left(1 + \frac{[S]}{K_M} + \frac{[I]}{K_I}\right)} \quad (20-29)$$

and

$$\frac{d[P]}{dt} = k_2[ES] = \frac{k_2[E_T][S]}{K_M \left(1 + \frac{[I]}{K_I}\right) + [S]} \quad (20-30)$$

Note from this equation that the factor $(1 + [I]/K_I)$ multiplies K_M in the denominator. This means that K_M is multiplied by a number ≥ 1 . Thus, if a competitive inhibitor is present at an appreciable concentration so that this factor $\gg 1$, concentrations of **S** that would have saturated the enzyme will now no longer be able to do so. If a competitive inhibitor is present, its effect can be eliminated by increasing the substrate concentration such that $S \gg K_M(1 + [I]/K_I)$.

Reactions Schemes for the Three Types of Inhibition of Enzyme-Catalyzed Reactions

A. Normal (uninhibited)

B. Competitive Inhibition

C. Uncompetitive Inhibition

D. Noncompetitive Inhibition

1. Simple

2. Mixed: Same scheme as above, except:

$$K_I = \frac{[E][I]}{[EI]} \neq K_I' = \frac{[ES][I]}{[ESI]}$$

$$K_I \neq K_I'$$

Figure 20-7 Lineweaver-Burk plots for each type of inhibition shown in Figure 20-6, showing Y- and X-intercepts. To avoid cluttering, the slopes are not shown. The slopes of the lines for uninhibited reaction (blue) and uncompetitive inhibition (green) are K_M/V_{\max} . The slopes of the lines for competitive (red) and noncompetitive (purple) inhibitions are $K_M(1 + I/K_I)$.

Inversion of Equation 20-30 gives the Lineweaver-Burk linear transform as follows:

$$\frac{I}{V_0} = \frac{K_M \left(1 + \frac{[I]}{K_I}\right)}{V_{\max}} \cdot \frac{1}{[S]} + \frac{1}{V_{\max}} \quad (20-31)$$

Plots of $1/v_0$ versus $1/[S]$ at different inhibitor concentrations give linear traces in which the slope, but not the intercept, is altered in the presence of a competitive inhibitor. V_{\max} is unchanged, and only K_M is altered. K_M is modified by the coefficient $(1 + [I]/K_I)$. The X-intercept of this equation (where $1/v_0$ is 0) is $-1/[(1 + I/K_I)K_M]$. The effect of competitive inhibitors on enzyme-catalyzed reactions is summarized in Figure 20-7.

UNCOMPETITIVE INHIBITION

As shown in Figure 20-6, C, uncompetitive inhibition occurs when the inhibitor binds only to the ES complex, and not to free E. Therefore, no EI complex forms. Binding of the substrate causes a conformational change, creating a site for binding of the inhibitor.

EFFECT OF UNCOMPETITIVE INHIBITORS ON THE MICHAELIS-MENTEN EQUATION

In keeping with a similar procedure that was used for deriving Equation 20-30 above, we obtain the following expression:

$$V_0 = \frac{V_{\max} [S]}{K_M + [S] \left(1 + \frac{[I]}{K_I}\right)} \quad (20-32)$$

Note here that the same factor, $(1 + [I]/K_I)$, now multiplies S, rather than K_M , in the denominator of the Michaelis-Menten equation, as in the case of competitive inhibition discussed previously. This has the paradoxical effect of causing saturation to be reached at lower values of S than for the normal, uninhibited case (see Fig. 20-6) because S is multiplied by a factor that is >1 . However, the rate of the uncompetitively inhibited enzyme-catalyzed reaction at saturation is lower than it normally should be; the maximal rate at saturation is $V_{\max}/(1 + I/K_I)$. No matter how high the substrate concentration is in this case, the normal rate at saturation, that is, V_{\max} , cannot be reached, unlike in the case of competitive inhibition discussed in the preceding section.

At low [S] values, v_0 approaches $V_{\max}/K_M[S]$, as for the uninhibited case, and the uncompetitive inhibitor is without effect. This suggests that dilution of the specimen will remove the effect of the inhibitor and will enable the uninhibited rate of the reaction to be determined. Under these

conditions, E_T or activity can be directly computed from the first-order kinetic analysis (Equation 20-19) at low substrate concentration.

The double reciprocal form of Equation 20-32 above is as follows:

$$\frac{1}{V_0} = \frac{K_M}{V_{\max}} \cdot \frac{1}{[S]} + \left(1 + \frac{[I]}{K_I}\right) \cdot \frac{1}{V_{\max}} \quad (20-33)$$

The Lineweaver-Burk plot of this equation has a slope that is the same as for the uninhibited (normal) reaction, but the intercept, $(1/V_{\max})(1 + [I]/K_I)$, will be higher for uncompetitive inhibition than for the normal case, that is, $1/V_{\max}$, as shown in Figure 20-6, C. The X-intercept (where $1/v_0 = 0$) is $-(1 + [I]/K_I)/K_M$. If [I] is known, either intercept can be used to compute K_I . The effect of uncompetitive inhibitors on enzyme-catalyzed reactions is summarized in Figure 20-7.

SIMPLE AND MIXED NONCOMPETITIVE INHIBITION

Noncompetitive inhibition occurs when the inhibitor, similar to the uncompetitive inhibitor, binds at a site distinct from the substrate-binding site. Both the inhibitor and the substrate are capable of binding the enzyme simultaneously. Binding of the inhibitor to this second site may completely abolish enzyme activity or may only partially reduce it. Hence, noncompetitive inhibition may be **full** or **partial**. Unlike uncompetitive inhibitors, noncompetitive inhibitors bind both to free E and to ES. If the binding of the inhibitor and of the substrate occurs independently of each other, **simple noncompetitive inhibition** exists. If bound substrate alters the affinity of the enzyme for the inhibitor, a condition of **mixed competitive inhibition** exists. Binding of the noncompetitive inhibitor alters the conformation of the substrate-binding site. The substrate can still bind; however, the binding affinity and/or the catalytic activity is/are reduced.

EFFECTS OF NONCOMPETITIVE INHIBITORS ON THE MICHAELIS-MENTEN EQUATION

The kinetic scheme for this type of inhibition is shown in Figure 20-6, D. Here, the inhibitor can bind *both* to the free enzyme *and* to the enzyme-substrate complex. If the affinity or dissociation constants for each of these processes are the same, as shown in Figure 20-6, then the pattern appears to be a combination of competitive and uncompetitive inhibition and is termed simple noncompetitive inhibition. Thus, in this case, the term $(1 + [I]/K_I)$ multiplies both terms in the denominator of the Michaelis-Menten equation (see Equation 20-10), or

$$V_0 = \frac{V_{\max} \cdot [S]}{\left(1 + \frac{[I]}{K_I}\right) \cdot K_M + \left(1 + \frac{[I]}{K_I}\right) \cdot [S]} \quad (20-34)$$

If the two K_I constants differ, the inhibition is termed **mixed** noncompetitive inhibition. For this latter case, if K_I is the dissociation constant for the inhibitor when it binds to free enzyme, and if K_I' is the dissociation constant for the inhibitor when it binds to the enzyme-substrate complex, then the Michaelis-Menten rate law for noncompetitive inhibition is

$$V_0 = \frac{V_{\max} \cdot [S]}{\left(1 + \frac{[I]}{K_I}\right) \cdot K_M + \left(1 + \frac{[I]}{K_I'}\right) \cdot [S]} \quad (20-35)$$

The Lineweaver-Burk equation for simple noncompetitive inhibition is

$$\frac{1}{V_0} = \frac{K_M}{V_{\max}} \cdot \left(1 + \frac{[I]}{K_I}\right) \cdot \frac{1}{[S]} + \frac{1}{V_{\max}} \cdot \left(1 + \frac{[I]}{K_I}\right) \quad (20-36)$$

And, for mixed inhibition,

$$\frac{1}{V_0} = \frac{K_M}{V_{\max}} \cdot \left(1 + \frac{[I]}{K_I}\right) \cdot \frac{1}{[S]} + \frac{1}{V_{\max}} + \left(1 + \frac{[I]}{K_I'}\right) \quad (20-37)$$

As can be seen from Equation 20-35, for simple noncompetitive inhibition, in the presence of inhibitor, both the slope and the intercept increase in value by the factor $(1 + [I]/K_I)$. This result is based on the assumption that the substrate does not modify the affinity of the enzyme for the inhibitor, and vice versa. Note that, because the inhibitor binds to the enzyme-substrate complex, thereby inactivating it, the maximal velocity is lowered as was the case for uncompetitive inhibition as discussed earlier. Therefore, the intercept for this condition is $1/V_{\max} (1 + [I]/K_I)$, that is, instead of $1/V_{\max}$ as in the normal case. Likewise, K_M is increased by the same factor.

TABLE 20-5

Slopes and Intercepts From Double Reciprocal Plots and Computed Values of V_{\max} and K_M From These Plots for Various Types of Reversible Inhibitors

Type of inhibition	Slope	Y-intercept	X-intercept	V_{\max} (apparent)*	K_M (apparent)*
None	K_M/V_{\max}	$1/V_{\max}$	$-1/K_M$	V_{\max}	K_M
Competitive	$(K_M/V_{\max})(1 + I/K_i)$	$1/V_{\max}$	$-1/[K_M(1 + I/K_i)]$	V_{\max}	$K_M(1 + I/K_i)$
Uncompetitive	K_M/V_{\max}	$(1/V_{\max}) \cdot (1 + I/K_i)$	$-(1 + I/K_i)/K_M$	$V_{\max}/(1 + I/K_i)$	K_M
Noncompetitive (simple)	$K_M/V_{\max} \cdot (1 + I/K_i)$	$(1/V_{\max}) \cdot (1 + I/K_i)$	$-1/K_M$	$V_{\max}/(1 + I/K_i)$	K_M

*The observed value that equals the derived expression from the double reciprocal plots shown for each condition.

However, as discussed previously, K_M is computed as the **ratio** of the slope of the Lineweaver-Burk plot to the intercept. Because both of these terms contain the factor $(1 + [I]/K_i)$, this factor cancels, and the computation yields the value of the actual K_M . This, of course, does not happen in mixed noncompetitive inhibition where the two constants for inhibitor binding differ from one another. In this case, K_M^{app} is $K_M \cdot (1 + [I]/K_i)/(1 + [I]/K_i')$. The X-intercept for simple noncompetitive inhibition from Equation 20-36 above is $-1/K_M$, and, for mixed noncompetitive inhibition, it is $-(1 + [I]/K_i')/(1 + [I]/K_i)K_M$. The effect of simple noncompetitive inhibitors (that have the same K_i value for free enzyme and enzyme-substrate complex) on enzyme-catalyzed reactions is summarized in Figure 20-7.

Table 20-5 summarizes changes in the apparent values of V_{\max} and K_M derived from the intercepts and slopes of double reciprocal Lineweaver-Burk plots for competitive, uncompetitive, and simple noncompetitive inhibition. Figure 20-7 summarizes the Lineweaver-Burk plots for a normal enzyme-catalyzed reaction and for the three types of inhibition of enzyme-catalyzed reactions and the values of the Y- and X-intercepts in each condition.

CATALYTIC EFFICIENCY: TRANSITION STATE THEORY AND DRUG DESIGN

Equation 20-19 applies to circumstances where the substrate concentration is present at concentrations below the value of K_M for an enzyme. The rate constant for this reaction is k_2/K_M , which is formally a second-order rate constant because this reaction depends on the concentrations of both the substrate and the enzyme. (As noted previously, the reaction is actually pseudo-first-order in that the total enzyme concentration, E_T , is constant, and only the substrate concentration, $[S]$, changes.) Catalytic efficiency is assessed in terms of the rate constants of the catalyzed reaction. The constant k_2/K_M , often written as k_{cat}/K_M , is a reflection of the frequency of productive encounters of enzyme and substrate molecules in solution.

ENZYMES ACHIEVE HIGH RATES OF REACTION THAT GREATLY EXCEED THOSE FOR UNCATALYZED REACTIONS

An upper boundary to the frequency of encounters is determined by the temperature and the diffusion coefficients of the substrate and enzyme. This limiting value is on the order of 10^8 to $10^9 \text{ M}^{-1}\text{sec}^{-1}$, called the diffusion-controlled limit. If the value of k_{cat}/K_M is at the diffusion-controlled limit, every encounter of the enzyme and substrate leads to product formation, and the enzyme has achieved what may be termed **catalytic perfection**. Some enzymes have actually approached this state. These include superoxide dismutase ($k_{\text{cat}}/K_M = 2.8 \times 10^9 \text{ M}^{-1}\text{sec}^{-1}$), AChE ($k_{\text{cat}}/K_M = 1.5 \times 10^8 \text{ M}^{-1}\text{sec}^{-1}$), and catalase ($k_{\text{cat}}/K_M = 4.0 \times 10^8 \text{ M}^{-1}\text{sec}^{-1}$). Most other enzymes do not have constants that are of this magnitude but have values that vastly exceed those for the corresponding uncatalyzed reactions, the second-order rate constants which are termed k_{uncat} (uncatalyzed).

The ratio $k_{\text{cat}}/k_{\text{uncat}}$ gives the rate enhancement, which is often difficult to obtain because most cellular reactions occur very slowly in the absence of enzymes. For enzymes, rates are in the range of 10^8 to 10^{12} , but some are even higher. For example, the rate acceleration for adenosine deaminase, which catalyzes the deamination of adenosine to inosine, is 10^{14} , and the rate acceleration of ALP is 10^{17} . Both adenosine deaminase and ALP have modest k_{cat} values, 10^2 sec^{-1} . Their unusually large rate accelerations stem from the stability of their substrates at pH 7.0 and 25° C. For

example, the half-time for the deamination of adenosine to inosine at 20° C and pH 7.0 is approximately 20,000 years, and k_{uncat} is $10^{-12} \text{ sec}^{-1}$. The nonenzymatic rate constant for the hydrolysis of phosphate esters under neutral, room temperature conditions is estimated to be on the order of $10^{-15} \text{ sec}^{-1}$. The question arises as to how enzymes can induce such large rate enhancements and in some instances attain rates that are the highest that can physically be achieved.

ENZYMES ACHIEVE HIGH RATE ENHANCEMENTS BY BINDING TO THE TRANSITION STATE ON THE REACTION PATHWAY

From Figure 20-3, it can be seen that when the enzyme binds noncovalently to the substrate, if the energy of the resulting enzyme-substrate complex is lowered significantly relative to the energies of the separated species, this would lead to an increased activation energy. However, if the enzyme rather stabilizes the transition state leading to the formation of products, then the activation energy would be greatly lowered, as indicated in Figure 20-3. Considerable accumulating evidence suggests that enzymes have high affinities for **transition states**. Because, in the transition state, the substrate is somewhat distorted from its ground state structure by the incipient breaking and making of covalent bonds, the resulting increase in energy of the substrate is greater than that compensated by favorable interactions of the distorted substrate with the enzyme. It should be realized that transition states in reactions are not stable structures but rather are inferred from knowledge of the reaction path. However, substrate molecules have been designed that have critical features of inferred transition states, and these modified substrates have been found to bind to the enzymes with enhanced affinities (Fersht, 1999).

These considerations have direct clinical applicability in two areas: drug design and the advent of so-called catalytic antibodies, that is, antibodies that have been designed to have strong and specific enzyme activity. We give one example of each of these applications to illustrate the importance of transition state theory to practical clinical problems.

TRANSITION STATE THEORY IN DRUG DESIGN

HIV Protease Inhibitors in Treating HIV-AIDS

A host of new drugs have been developed as protease inhibitors that block the protease enzymes of the human immunodeficiency virus (HIV) involved in viral replication of the acquired immunodeficiency syndrome (AIDS) virus (Vance, 1997). Proteases catalyze hydrolytic reactions in which peptide or amide bonds are cleaved by water into a carboxylic acid and a primary (or, in the case of proline, a secondary) amine. HIV proteases are vital for cleaving large protein precursors into gag and pol proteins that enable viral replication. Absence of this protease activity results in inability of the virus to replicate. Thus this protease has become the target for the design of inhibitory compounds (Vance, 1997).

HIV protease functions as a homodimer, that is, two subunits having the exact same sequence. It catalyzes the hydrolysis of X-Pro (proline) peptide bonds where X is an aromatic amino acid, such as phenylalanine (Phe) or tyrosine (Swain, 1990; Vance, 1997). Two critical aspartic acid residues (25 and 125) are known to be the actual catalytic residues effecting peptide bond cleavage (Swain, 1990). Thus HIV protease, similar to a number of other proteases such as angiotensin-converting enzyme, discussed in the next section, is an aspartic acid peptidase. It has been known for many years that the hydrolysis of peptide (and ester) bonds involves

Figure 20-8 Steps in the hydrolysis of a peptide bond. **A.** A typical peptide bond for two amino acids in a peptide bond link. R is the side chain of the first amino acid. This bond will be cleaved by addition of water to the carbonyl group, as shown by the arrow. **B.** The transition state on the way to the addition of water to the carbonyl group. The carbonyl oxygen takes on a partial negative charge (δ^-). **C.** The tetrahedral intermediate that results from the addition of water. Note that an oxyanion forms on the former carbonyl oxygen. The attacking water molecule has given up a proton that can add to the amino nitrogen of the leaving group, that is, the amino acid on the right of the peptide bond, or to the oxyanion of the former carbonyl group. **D.** The final products, that is, a carboxylate from the left amino acid and an amine (ammonium ion) from the right amino acid.

the formation of a so-called tetrahedral intermediate, as illustrated for a peptide bond in Figure 20-8. This intermediate results from the addition of water to the unsaturated carbonyl carbon on the reaction pathway. The carbonyl carbon and the three atoms to which it is attached all lie in the same plane, the so-called planar configuration. Attack by the oxygen atom of water on the carbonyl carbon results in the addition of a fourth atom attached to the carbonyl carbon, causing replacement of the planar arrangement of the atoms by a tetrahedral arrangement of these atoms. Note that the transition state leading to this intermediate is inferred also to have tetrahedral features and a partially negatively charged oxygen. Thus, substrates have been designed that have, in place of the normally occurring amide bond, a tetrahedral structure with an oxyanion or a hydroxyl group at this position that resembles the transition state.

An example of an inhibitory transition state analog of HIV protease is shown in Figure 20-9. For comparison, a typical substrate of HIV protease is also shown (Matayoshi, 1990). As can be seen in Figure 20-9, in the Phe residue in the transition state analog, the normally occurring planar C=O group in the peptide backbone is replaced with a tetrahedral C(H)-OH group, giving rise to the so-called Phe-Psi residue. This occurs at the normal peptide cleavage site. This analog binds to HIV protease with a K_i (dissociation constant) of 0.24 nM (Swain, 1990). The substrate has a K_M on the order of 103 μ M (Matayoshi, 1990). This K_M is a true dissociation constant in that the k_2 is much lower than the noncovalent dissociation constant. Therefore the ratio of the affinity constant (reciprocal of the dissociation constant) for the transition state analog to that of the substrate

is on the order of 400,000! Thus, the application of transition state theory has resulted in the design of a very potent HIV protease inhibitor. Newer HIV protease transition state inhibitors, such as the modified peptide KNI-272, that have substantially lower K_i values have been designed (Adachia, 2009). The X-ray crystal structures of the transition state analogs bound to HIV protease have been determined (Swain, 1990; Adachia, 2009). The two critical Asp residues interact strongly with the tetrahedral atoms of the modified Phe residue and are clearly involved in stabilization of the tetrahedral transition state (Swain, 1990; Adachia, 2009).

One drawback to the HIV protease inhibitors currently being used clinically in the treatment of AIDS is that viral mutations result in HIV proteases that have lower affinities for these inhibitors. More recently, therefore, new transition state analogs have been designed such that they interact with amino acid residues that surround the active site and actually bind to critical backbone atoms of sections of the polypeptide chain that have well-defined secondary structures (such as α -helices and β -sheets), greatly increasing their affinities (K_i 's in the picomolar range) (Ghosh, 2008). In this case, because mutations of constant structural residues would be expected to decrease the stability of the protease greatly, it is hoped that viral mutations will have much less effect on their efficacies.

Design of New Catalytic Antibodies With Predetermined Enzyme Activity

Antibodies generally bind to antigens with high affinities. If antibodies can be raised to transition state analogs of compounds that undergo specific chemical reactions, by stabilizing the transition state for these specific chemical reactions they might themselves serve as enzymes that catalyze these reactions. Although still in its infancy, this area of enzymology has achieved some notable success, providing, in turn, further support for the transition state theory of enzyme action. As an example, a clinically important finding using this approach is seen in the design of antibodies that induce hydrolysis of cocaine. Hydrolysis of the benzoate and acetyl esters results in effective inactivation of this drug of abuse, as discussed in Chapter 23. The structure of cocaine and a tetrahedral transition state analog are shown in Figure 20-10 (Cashman, 2000). This analog has a tetrahedral structure for the benzoyl moiety in which a nonhydrolyzable phenyl phosphonate ester replaces the normally occurring carbonyl group. Antibodies have been raised to a thiol derivative of cocaine and then assayed for their abilities to bind to the transition state analog. Several antibodies have been isolated that bind strongly to the transition state analog and also catalyze, with large rate enhancements over the uncatalyzed reaction, the hydrolysis of the benzoyl ester of cocaine, resulting in a cocaine derivative of much lower potency. It is of considerable interest that, using another approach, the serum enzyme, butyrylcholinesterase, discussed in the next section, has been modified, based on the X-ray crystal structure of this enzyme bound to inhibitors, using site-specific mutagenesis techniques, so that it is active in the de-benzoylation of cocaine leading to its inactivation. The rates of catalysis of the catalytic antibodies and the engineered butyrylcholinesterase are similar to one another. Both approaches may provide rational treatment modalities for detoxification of harmful substances, in this case, drugs of abuse.

SPECIFIC ENZYMES

Numerous enzymes are clinically useful in recognition and monitoring of particular disease processes. In all but a few circumstances, abnormal conditions in specific tissues are recognized by elevations of one or more enzymatic activities or enzyme concentrations. For example, elevations of the activity of serum CK suggest the presence of muscle disease. The reason for elevation of specific enzymes in blood and other body fluids as the result of disease processes in specific tissues is not completely understood. One explanation for this occurrence is that disease processes that cause cell injury or death result in damage to the cell membrane, leading to the release of specific intracellular enzymes into tissue spaces and the microvasculature, causing increased enzymatic activity in serum or other body fluids. On occasion, mutant forms of enzymes occur, resulting in lowering of their activities, although, generally, not of their concentrations. One prominent example of this phenomenon is butyrylcholinesterase (discussed later).

Several enzymes are distributed predominantly in a single tissue, so that damage to this tissue results in elevations of the enzyme in serum. For example, as discussed in Chapter 21 on liver function, elevation of the level of the enzyme ALT, which is distributed predominantly in the liver, indicates acute hepatic injury, often as a result of hepatitis. Although measured

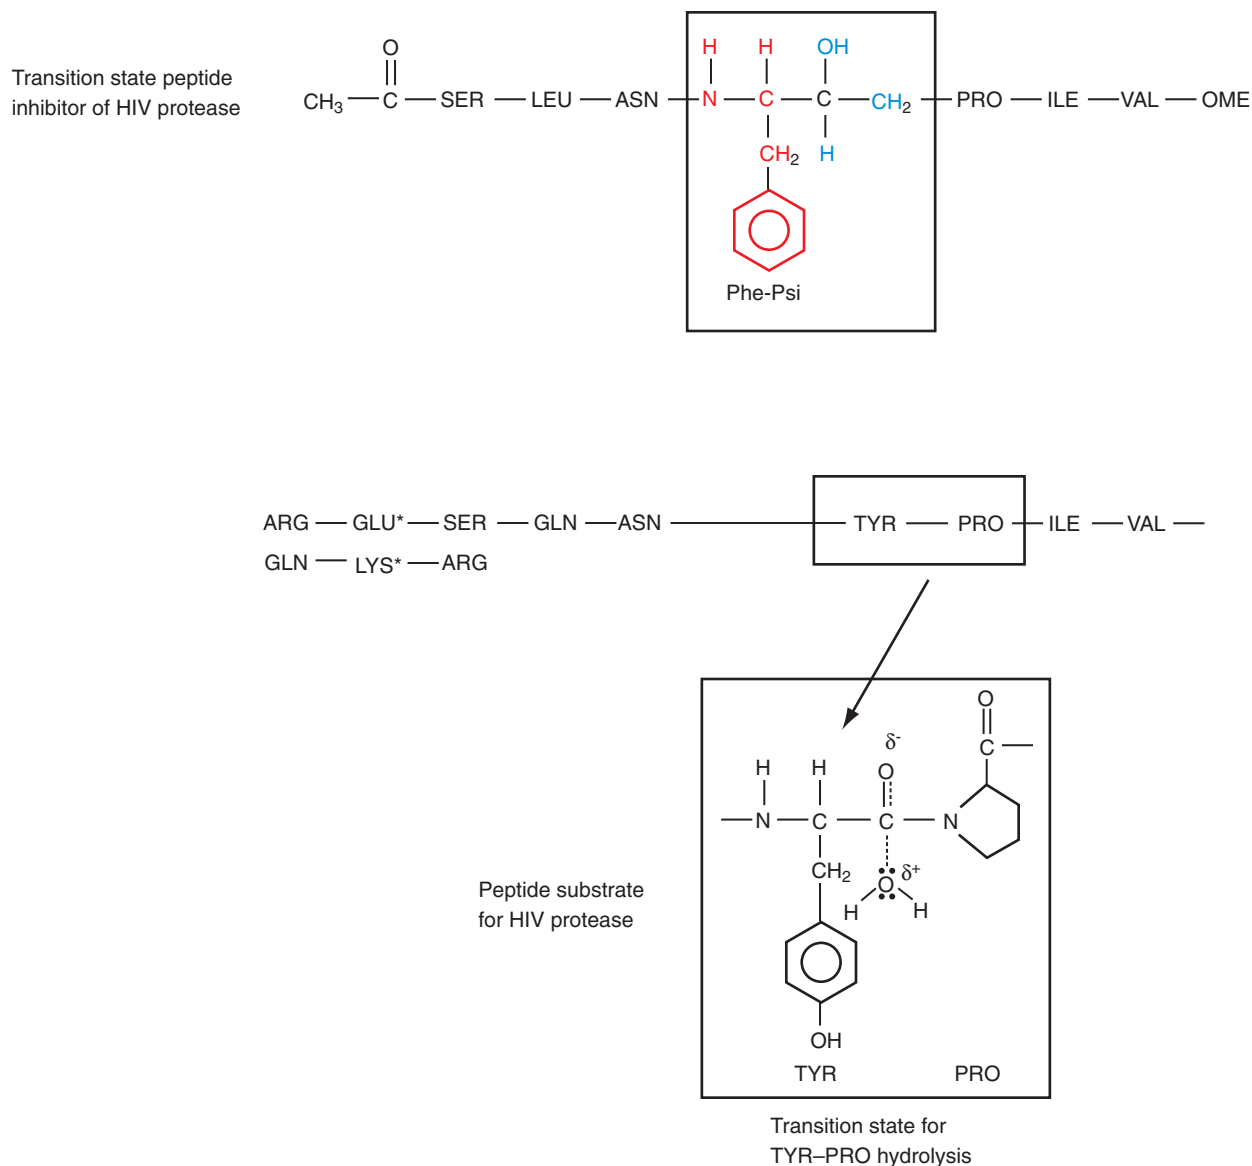

Figure 20-9 Human immunodeficiency virus (HIV) protease transition state analog peptide inhibitor. HIV protease cleaves at X-Pro bonds, where X is an aromatic amino acid like Tyr and Phe. In this case, X is a modified Phe residue, labeled Phe-Psi, most of whose atoms are colored red such that, in place of the normally occurring C=O (carbonyl) group, a tetrahedral carbon is present attached to an OH group. The tetrahedral atoms are shown in blue. This mimics the transition state shown for a substrate of HIV protease whose amino acid sequence is shown below that for the transition state analog. This sequence contains the bond cleavage site, TYR-PRO, as shown in the small box. The tetrahedral transition state for this cleavage is shown in the larger box. The asterisks on the two substrate residues denote that these residues can be attached to fluorescent probes in an enzyme assay for this protease using this substrate. Because the transition state analog resembles the transition state in the hydrolysis of the Tyr-Pro peptide bond, it is a strong and specific inhibitor of the protease.

by immunoassay, PSA is a form of chymotrypsin and occurs almost exclusively in the prostate gland. Serum elevations of PSA, therefore, suggest prostate pathology, often prostate cancer. Other enzymes do not have selective tissue distributions but have isozymes that do have selective distributions, making elevations of these isozymes valuable in diagnosing specific tissue pathology. For example, as discussed in Chapter 18, elevation of serum levels of CK-MB (also, see previous discussion) points to myocardial disease, most often infarction. As discussed later, elevations of specific isozymes of ALP point to specific tissue disease. The biliary tract form is elevated in biliary disease, and the bone form is elevated in diseases of bone.

For enzymes with no tissue-specific isozymes, the relative amounts of different enzymes in plasma provide a clue as to the type of organ injured. For example, LD, AST, and ALT are found in many organs, but the relative amounts in each differ (Table 20-6). If LD is markedly elevated, while AST and ALT are only slightly elevated, this would suggest damage to an organ or tissue (such as red blood cells, white blood cells, or tumors) with a high LD/AST ratio. On the other hand, if AST and ALT are elevated, but LD is only slightly elevated, this suggests damage to liver, which has a low LD/AST ratio.

Many other enzymes, elevations of which denote damage to specific tissues, are discussed in other chapters of this book. Discussion of enzymes

and enzyme inhibitors in serum and urine for recognition of renal disease is found in Chapter 14; enzymes of bone metabolism are presented in Chapter 15; enzymes and other proteins utilized for the diagnosis of myocardial infarction are discussed in Chapter 18; enzymes useful in recognition of liver and biliary tract disease are discussed in Chapter 21; pancreatic enzymes are covered in Chapter 22; and enzyme deficiencies that produce hemolytic anemia are discussed in Part 4.

The remainder of this chapter is concerned with a discussion of enzymes, each of whose isozymes is specific for a different tissue (e.g., acid and alkaline phosphatases, 5'-NT, LD), and two enzymes that are not tissue specific but whose activities have major systemic effects: angiotensin-converting enzyme, vital for control of blood pressure, and AChE, which is critical in neuromuscular transmission.

ACID PHOSPHATASE (EC 3.1.3.2)

Biochemistry and Physiology

ACPs belong to the hydrolase class of enzymes (see Table 20-1) and occur as several isoenzymes with a common enzymatic function (the hydrolytic breakdown of phosphate monoesters). They all show optimal enzyme

Figure 20-10 Hydrolysis of the benzoate ester moiety of cocaine (A) an ecgonine derivative, occurs via a tetrahedral intermediate (B) containing an oxyanion, and presumably, a tetrahedral transition state resulting in the free $-OH$ group of an ecgonine derivative shown in C and benzoic acid. This results in a cocaine derivative that is much less active. D, A nonhydrolyzable benzyl phosphonate ester transition state analogue which has a tetrahedral structure that likewise contains an oxyanion. An antibody that binds with high affinity to this analogue has been found to catalyze the hydrolysis of cocaine with a greatly enhanced rate over that for the noncatalyzed reaction.

TABLE 20-6

Relative Amounts of Enzymes in Various Organs (Relative to Serum)*

Tissue	AST [†]	ALT	LD	CK
Liver	7000	3000	7000	
Kidney	4500	1200	500	10
Brain				1700
Spleen	700	150		
Heart	8000	500	600	5000–8000
Skeletal muscle	5000	300	700	20,000–30,000
Smooth muscle				300–600
Red cells	15	7	500	0

ALT, Alanine aminotransferase; AST, aspartate transaminase; CK, creatine kinase; IU, international unit; LD, lactate dehydrogenase.

*Relative amount is calculated by dividing the activity of enzyme in tissue (in IU/kg of tissue) by the upper reference limit of plasma activity of the enzyme (in IU/L), assuming that 1 L of plasma = 1 kg. Because the data are derived from multiple publications, the relative amounts among enzymes may be approximate, but the relative amount of a single enzyme in each tissue is accurate.

[†]Total amount in cells; varying amounts represent mitochondrial isoenzyme, which reaches serum in only small amounts.

activity below a pH of 7.0. They possess some tissue specificity (greatest concentrations occur in prostate, liver, spleen, erythrocytes, and bone). The major forms are coded for by different genes and possess different molecular weights and structures, as well as differences in sensitivity to tartrate inhibition. Lysosomal, prostatic, erythrocyte, macrophage, and osteoclastic ACPs are five important types found in humans. Normally, concentrations in serum are low (Moss, 1999; Bull, 2002). The activity of erythrocyte ACP can be distinguished from that of the other ACP isoenzymes in that it is inhibited by 2% formaldehyde solution and 1 mM cupric sulfate solution. This is in contrast to the other isoenzymes, which are not inhibited by these agents. In addition, erythrocyte ACP is not inhibited by 20 mM tartrate solution, which does inhibit the other isoenzymes. It is important to note that tartrate-resistant acid phosphatase (TRAP) is present in certain chronic leukemias and some lymphomas, most notably in hairy cell leukemia, as described in the section on leukocytic disorders. In addition, a particular isoform of TRAP, called TRAP-5b, occurs predominantly in osteoclasts in bone marrow and is used as a marker for bone

remodeling (Lu, 2006); it has also been proposed as a marker for metastatic cancer (e.g., breast cancer) in bone marrow (Chao, 2005).

Reference Ranges and Preanalytic Variation

Reference values depend on age, gender, and hormonal status (in women). Total and tartrate-resistant ACP values are high in children, rising through the first decade to peak at three to four times adult levels in adolescence, paralleling changes in ALP (Chen, 1979). In the late teen years, levels decline to adult values that are constant to approximately 80 years in both genders. Normal men and women up to about age 55 have the same reference ranges for ACP. In women, total and tartrate-resistant ACPs increase after menopause (Schiele, 1988) and increase with the use of depot medroxyprogesterone acetate in premenopausal women (Mukherjee, 1981).

The enzymatic activity of ACP is unstable at normal plasma pH; specimens must be acidified to prevent loss of ACP activity (Theodorsen, 1985). The effect of specimen pH is not as consistently seen with immunoassays for prostatic ACP; some studies have recommended routine use of acidification for all ACP specimens, but it is not clear that this is essential (Panteghini, 1992).

The half-life of prostatic ACP is about 1 to 3 hours (Wadstrom, 1985). Day-to-day variation in ACP is relatively high; average variation of the prostatic isoenzyme is 30% (Maatman, 1993), although it may be as high as 100% in patients with prostatic carcinoma (Brenckman, 1981), and bone isoenzyme variation averages about 35% (Panteghini, 1995).

Measurement

Assays for all phosphatases utilize the strategy that phosphate esters, which have no visible light absorbance, are hydrolyzed to inorganic phosphate and a strongly visible light-absorbing alcohol or alcohol anion. Total ACP is typically measured by its ability to cleave phosphate groups at an acid pH. Usually the test is utilized for the measurement of prostatic serum ACP in the diagnosis or monitoring of prostatic adenocarcinoma. A variety of substrates and conditions have been used to measure enzymatic activity with increased specificity; these include thymolphthalein monophosphate and α -naphthyl phosphate, both of which give rise to strongly absorbing products, α -naphthol and thymolphthalein. *High bilirubin causes falsely low values for TRAP activity*, but not for total ACP (Alvarez, 1999).

Isozymes of ACP can be separated by electrophoresis (Moss, 1986); however, there is usually little interest in isoenzymes other than prostatic and bone. Immunoassays (Bull, 2002) for both prostatic and bone isoenzymes of ACP have been developed; the former are widely available.

TABLE 20-7

Relative Levels of Enzymes, by Gender, Relative to Young Adult Males (1.0)*

Enzyme	Gender	AGE, YEARS							
		8	12	16	22	30	40	50	60
Aspartate aminotransferase	Male	0.75	0.86	0.82	1.00	1.16	1.26	1.21	1.11
	Female	0.73	0.80	0.69	0.89	0.89	1.01	0.77	0.96
Alanine aminotransferase	Male	1.14	1.09	0.89	1.00	1.03	1.11	1.06	0.83
	Female	0.11	0.89	0.83	0.75	0.75	0.75	0.72	0.83
Alkaline phosphatase	Male	3.61	4.76	4.48	1.52	1.00	1.00	0.95	0.95
	Female	0.14	4.10	2.52	0.81	0.86	0.76	1.00	1.38
γ -glutamyl transferase	Male	0.25	0.29	0.37	0.62	1.00	1.07	1.16	0.99
	Female	0.24	0.28	0.33	0.38	0.52	0.58	0.9	1.09

Data from Siest G, Henry J, Schiele F, Young DS. Interpretation of clinical laboratory tests: reference values and their biological variation. Foster City, Calif.: Biomedical Publications; 1985.

*Results expressed as upper reference limits as a fraction of the upper reference limits for healthy young males.

Causes of Abnormal Results

The main cause of increased ACP is prostate disease; with development of PSA as the major serum test for prostate (see Chapter 73), ACP has become less popular for use in prostate cancer, although, with the availability of newer immunochemical methods, its use in the diagnosis of prostate cancer is being reevaluated (Pontes, 2006). In early prostate cancer, the sensitivity of ACP is inferior to that of PSA (Burnett, 1992), although ACP, similar to PSA, is elevated in a significant percentage of patients with benign prostatic hyperplasia (Salo, 1990) or prostatic infarction, making ACP of little use for prostate cancer screening (Kaplan, 1985). Almost all patients with prostate cancer and elevated ACP have extracapsular extension or metastases (Salo, 1990; Burnett 1992), so that an elevated ACP may provide useful information in staging of patients. Occasionally, elevated prostatic ACP may be due to other causes. Urinary tract obstruction and acute urinary retention may cause elevated ACP (Collier, 1986). Extensive prostatic massage, prostatic inflammation, infarction/ischemia, and prostatic manipulations such as needle biopsy and cystoscopy may also cause a transient increase in serum ACP; testing should be done before any procedures are performed.

After surgical treatment of prostate cancer, ACP falls faster than PSA (Price, 1991), and levels should become undetectable after complete tumor resection. Because PSA is an androgen-dependent protein, androgen deprivation therapy decreases PSA production but has no effect on ACP (Price, 1991; Narayan, 1995), suggesting that ACP may be of use in monitoring patients treated in this fashion.

ACP has been used for many years in cases of suspected rape. Fluid collected from the vagina on a cotton swab will give a positive test for ACP if semen is present, provided a stabilizing fluid with an acidic pH is used (Ricci, 1982). Peak values are generally present in the first 12 hours, and values remain elevated for up to 4 days.

ALKALINE PHOSPHATASE (EC 3.1.3.1)

Biochemistry and Physiology

Similar to ACP, ALPs are a type of hydrolase (see Table 20-1). Discussion of ALP in the canalicular (biliary) system can be found in Chapter 21 on liver function. Alkaline phosphatases represent a family of enzymes coded for by different genes. Their physiologic role is not completely understood. The most abundant plasma ALP isoforms are coded for by a single gene on chromosome 1, producing the tissue-nonspecific isozyme found in kidney, liver, and bone. However, in different tissues, this **parent** isozyme is subjected to different posttranslational modifications, resulting in differences in their carbohydrate side chains. Two other genes on chromosome 2 code for ALP of placental and intestinal origin; another gene on chromosome 2 codes for the so-called germ cell or placental-like isoenzyme, which has some antigenic and physical similarities to the placental isozyme.

In cells, ALP is primarily bound to cell membranes, where it appears to be involved in cleavage of phosphate-containing compounds and may facilitate movement of substances across cell membranes. Hepatocytes produce ALP in the liver, where it is found attached to the canalicular surface of the cells (see Chapter 21). Osteoblasts produce bone ALP, which

appears to be involved in cleavage of pyrophosphate, an inhibitor of bone mineralization. Intestinal epithelial cells produce intestinal ALP, which is released into the intestine following ingestion of fatty foods.

There appear to be different mechanisms for release of ALP from cells, leading to varying forms of ALP in plasma. With liver injury, ALP synthesis increases, but bile acids dissolve fragments of canalicular cell membranes with attached enzymes (including ALP, GGT, leucine aminopeptidase, and 5'-NT [Moss, 1997]). In normal serum, a single form (of liver or bone origin) of ALP is typically seen; however, with hepatobiliary disease, both the normal product and the membrane-attachment form (high molecular weight) bound to lipoproteins can be seen (Wolf, 1994). The intestinal isoenzyme of ALP is released in large amounts into duodenal fluid (Deng, 1992), and large amounts enter lymphatic fluid, draining the intestinal tract following a meal (Reynoso, 1971). However, much of the isoenzyme apparently becomes bound to red blood cell (RBC) ABO antigens (Bayer, 1980), so that only small amounts reach the plasma, except in individuals who possess both the secretor gene and a large amount of H substance (group O or B), where ALP may increase by up to 30 IU/L following a meal (Domar, 1993). ALP is also higher in individuals of group O or B than in A and AB individuals (Agbedana, 1996) because of differences in intestinal ALP levels (Domar, 1993). It is curious that placental ALP is also lower in pregnant women of groups A and AB (Ind, 1994).

The half-lives of isoenzymes of ALP differ significantly, so it is necessary to know the isoenzyme that is elevated before rate of clearance can be evaluated: intestine, minutes; bone, 1 day; liver, 3 days; and placenta, 7 days. Day-to-day variation in total ALP is 5% to 10%, although the bone isozyme shows 20% day-to-day variability.

Reference Ranges and Preanalytic Variation

Reference ranges for ALP are highly dependent on age and gender (Table 20-7). During childhood, levels gradually rise throughout the first decade, reaching peak values three to four times normal adult levels, and are higher in boys than in girls. The higher values in children are due to the bone isoenzyme. After a peak in the early teens, values gradually decrease to adult levels by the early 20s, and are similar in men and women until age 50. After menopause, the bone isoenzyme increases slightly in women, causing a rise in reference limits after age 50. Reference limits are 15% higher in African American men and 10% higher in African American women (Manolio, 1992). Pregnancy causes a two- to threefold increase in ALP, mainly due to the placental isoenzyme, but also because of an increase in bone isoenzyme (Valenzuela, 1987).

A number of other factors affect ALP levels as well. High body mass index is associated with a 10% average increase in ALP (Salvaggio, 1991). Oral contraceptives decrease ALP by an average of 20% (Schiele, 1988; Dufour, 1998a); fibric acid derivatives decrease total ALP by 25% and the liver isoenzyme by 40% (Day, 1993). Antiepileptic agents commonly cause increased total ALP, mainly because of increases in the liver isoenzyme; however, in some cases, the bone isozyme may also be elevated (Nijhawan, 1990). Smoking causes an average 10% increase in total ALP as the result of pulmonary production of placental-like ALP (Kallioniemi, 1987). Blood transfusion and cardiopulmonary bypass decrease alkaline phosphatase, often causing low levels (Kyd, 1998); this may be due to chelation of necessary cations by citrate.

Measurement

Although numerous methods are known, ALP activity is usually measured using *p*-nitrophenyl phosphate as the substrate at alkaline pH. Hydrolysis of this phosphate ester yields inorganic phosphate plus the highly colored (and, therefore, easily measured) *para*-nitrophenoxide anion. A variety of buffers are used to bind phosphate groups; this increases activity, because inorganic phosphate (as well as some other anions) inhibits ALP (competitive end-product inhibition). Zinc is a component of the enzyme, and magnesium and other cations activate the enzyme. Chelators present in collection tubes (such as EDTA, citrate, and oxalate) falsely lower ALP activity; in the case of EDTA, activity is often too low to measure. The activity of the enzyme increases slowly on storage because of loss of inhibitors, but specimens are relatively stable at 4° C for up to 1 week.

Isoforms

High-performance liquid chromatography (see Chapter 23) using weak anion-exchange columns has been able to separate at least six different isoforms of ALP in the sera of healthy individuals (Haarhaus, 2009). These are bone/intestinal (B/I), two bone isoforms, called B1 and B2, and three liver isoforms termed L1, L2, and L3. Recently, another bone isoform was isolated, termed B1x, that appears in the serum of dialysis patients (Swolin-Eide, 2006). These bone isoforms have been used to study low bone mineral disease (BMD) in patients with chronic kidney disease and have been found to rise in BMD of the hip, which is predominantly made up of trabecular bone. It is interesting to note that acid phosphatase TRAP-5b, discussed in the preceding section, was also found to be a marker for this condition (Haarhaus, 2009).

In addition, several other methods have been used to separate ALP isoenzymes. Inhibition by phenylalanine reduces reactivity of intestinal and placental isoenzymes, and levamisole inhibits bone and liver isoenzymes; inhibition assays are poorly reproducible and are seldom used. Heat fractionation has been used for many years to determine the source of an elevated total ALP. The most heat-stable isoenzyme is placental (and germ cell) ALP; the liver isoenzyme is moderately stable, and the bone isoenzyme is the most heat-labile. To achieve reliable results, use of standards of known composition and careful control of both temperature and time are essential. For these reasons, electrophoretic separation has been used for a number of years. Standard cellulose acetate and agarose gel electrophoresis cannot completely resolve bone and liver isoenzymes, making them unsuitable for other than qualitative studies. Because the difference between these isoenzymes is seen in their carbohydrate side chains, use of neuraminidase (to remove sialic acid) and wheat germ lectin (to bind to other isoenzymes) improves separation of bone and liver forms, allowing their quantitation. High-resolution electrophoresis using polyacrylamide gel and isoelectric focusing are capable of resolving multiple bands of ALP. Immunoassays for bone and placental isoenzymes of ALP are available commercially. Bone isoenzyme assays typically show some degree of cross-reactivity with the liver isoenzyme, and placental isoenzyme assays have varying cross-reactivity with the germ cell isoenzyme.

Causes of Abnormal Results

The most common causes of increased ALP are liver and bone disease. Hepatic causes of elevated ALP are discussed in greater detail in Chapter 21; disorders causing cholestasis more frequently cause elevation of ALP than do hepatocellular disorders. Increased osteoblastic activity in Paget's disease, osteosarcoma, tumor metastatic to bone, and metabolic bone disease are the most common causes of elevated bone isoenzyme. It appears that acid phosphatase TRAP-5b is associated with bone resorption conditions, and that the three major isoforms of bone ALP (B/I, B1, and B2) are associated with conditions involving bone deposition. Occasionally, patients will have elevations of both bone and liver isoenzymes, especially in metastatic carcinoma. Rarely, marked transient elevations of ALP occur, usually in children and often following trivial illness; these may reach several thousand IU/L and may persist for weeks to months before resolving (Steinherz, 1984).

Increases in intestinal ALP may occur in patients with intestinal infarction, inflammation, and ulceration. Increases in placenta-like isoenzymes, such as Regan and Nagao, are commonly found in patients with malignancies (ovary, cervix, lung, breast, colon, pancreas) and are due to ectopic production by the neoplasm.

As mentioned before, low ALP may occur transiently after blood transfusion or cardiopulmonary bypass. Prolonged, severely low levels of ALP occur in hypophosphatasia, a rare inherited disorder of bone metabolism (Whyte, 1996) as the result of missense mutations of tissue-nonspecific

ALP (Haarhaus, 2009). Decreased ALP can also occur in zinc deficiency because zinc is a necessary cofactor for ALP activity, as well as other conditions.

Placental alkaline phosphatase (PLAP) is a useful tumor marker in serum and cerebrospinal fluid (CSF) for most germ cell tumors. In the latter case, CSF levels of PLAP are of diagnostic value in discerning whether a tumor in the pineal body is a pinealoma or a germ cell tumor. Because most germ cell tumors are radiosensitive, elevated CSF levels of PLAP suggest radiation treatment for this condition, allowing circumvention of surgical removal.

ANGIOTENSIN-CONVERTING ENZYME (EC 3.4.15.1)

Biochemistry and Physiology

ACE, also known as kininase II and peptidyl-dipeptidase A, belongs to the hydrolase class of enzymes (see Table 20-1) and is usually involved in the hydrolysis of peptide bonds at a free C-terminus, releasing the dipeptide His-Leu in the reaction. However, it may also act as an endopeptidase or an aminopeptidase. Its chief function is to cleave the His-Leu sequence from a decapeptide called angiotensin 1, whose sequence is Asp-Arg-Val-Tyr-Ile-His-Pro-Phe-His-Leu. This peptide, in turn, is cleaved from an α 2-macroglobulin called angiotensinogen, produced predominantly in the liver. Angiotensin I travels to the lungs, where ACE cleaves its carboxyl-terminal His-Leu peptide to produce angiotensin 2. The latter peptide has two major activities: It is a potent vasoconstrictor in arterioles, and it induces the secretion of aldosterone from the zona glomerulosa of the adrenals. As discussed in both Chapters 8 and 24, aldosterone induces sodium retention in the collecting ducts in the kidneys, resulting in conservation of water. This action results in an increase in vascular volume. Therefore, by increasing arteriolar resistance via vasoconstriction and by increasing vascular volume, thereby increasing flow, angiotensin 2 induces higher arteriolar pressures. The renin-angiotensin system is summarized below:

It is interesting to note that ACE also inactivates bradykinin (in the kallikrein-kinin system) by cleaving a dipeptide from its carboxyl terminus. Although the catalytic action of ACE is somewhat nonspecific in vitro, only angiotensin 1, bradykinin, and the hemoregulatory peptide Ac-DSKP are definite in vivo substrates (Macours, 2004). Because angiotensin 2 induces increased blood pressure, and because it is produced uniquely by the activity of ACE, the latter enzyme is a major target of competitively inhibiting drugs in the treatment of hypertension.

ACE consists of a single polypeptide chain, with two homologous, zinc-binding catalytic sites (ACE is a zinc-metalloprotease). Enzyme activity is lost if zinc is bound to a chelating agent, such as EDTA, or is replaced by a different cation. It is important to note that ACE, similar to HIV protease as discussed earlier, is an aspartic acid protease, that is, two Asp residues are involved in catalysis at each active site. In cells, ACE is a transmembrane protein with a large amino-terminal extracellular domain, a very short hydrophobic transmembrane domain, and a small intracellular carboxyl-terminal domain; the cell-bound molecule is referred to as tissue ACE. The two catalytic sites are present in the extracellular domain: one near the amino terminus and one nearer the carboxyl terminus. The carboxyl-terminal active site is thought to harbor the predominant angiotensin 1 hydrolytic activity, and the amino-terminal active site has activity against bradykinin. Proteolytic cleavage releases the functional enzyme from the cell membrane into the extracellular environment, producing circulating ACE.

The majority of ACE is tissue bound (>90%), with much lower levels circulating in plasma. ACE is found predominantly in endothelial cell membranes throughout the body. The lungs and the testes are particularly rich in ACE. Information on the molecular biology and structure of ACE is available (Dzau, 2002; Macours, 2004). There appear to be two distinct forms of ACE: a somatic form (sACE) and a smaller isoform found in testes (tACE). A single gene encodes both forms by utilizing alternative promoters. sACE is found in many tissues and contains two active sites

(as described previously); ACE contains only the C-terminal active site and is exclusively found in testes. Although both active sites of sACE require zinc ion, their biochemical properties are not identical (Dzau, 2002; Macours, 2004).

The Design of ACE Inhibitors

As mentioned earlier, ACE is a critical target for inhibitory drugs designed to lower blood pressure. Because ACE and HIV protease are Asp proteases, many of the considerations used for the design of these inhibitors were subsequently used in the design of HIV protease inhibitors, as discussed earlier. It was known that the nonapeptide teprotide, from the snake *Bothrops jararaca* whose sequence is Glu-Trp-Pro-Arg-Pro-Gln-Ile-Pro-Pro, was a potent antihypertensive that acted by competitively inhibiting ACE (Crantz, 1980). This was the first effective therapeutic ACE inhibitor, but it could not be given orally because of its hydrolysis in the stomach and the gut. Because it was known that there was a critical positively charged Arg residue in the active site, in addition to the positively charged Zn ion, and that the enzyme had a high affinity for Phe and Pro residues, the inhibitor succinyl proline was developed. The affinity of this inhibitor was greatly enhanced if the carboxylate of the succinic acid moiety was replaced with a thiol that had a high affinity for the bound Zn ions. This resulted in the synthesis of 3-mercapto-2-methylpropanoyl-L-proline, also called captopril, a highly effective agent that, however, had several undesirable side effects such as skin rash and loss of taste (Cushman, 1991). In addition, Phe-containing tripeptides that contained carboxylate groups were synthesized, allowing for tight binding to the active site and to Zn concurrently (i.e., enalapril and lisinopril—both effective agents). In addition, transition state analog inhibitors, such as the ones discussed for HIV protease, have been developed (Dive, 2004; Gerogiadis, 2004; Redelinghuys, 2006). Several contain modified Phe as seen in the HIV protease inhibitors, except that they also contain nonhydrolyzable tetrahedral phosphinic acid in place of the normally occurring backbone carbonyl group. Several of these inhibitors inhibit the carboxyl-terminal active site preferentially, making them good antihypertensive agents, because it is this active site that predominantly hydrolyzes angiotensin 1. At the same time, considerable bradykinin hydrolytic activity still occurs in the amino-terminal active site; this is considered desirable in that bradykinin itself induces vasodilatation and angioedema and can compound the lowering of blood pressure so as to induce hypotension, an undesirable side effect.

Reference Ranges and Preanalytic Variation

ACE activity is higher in children than in adults; during adolescence, values are higher in boys than in girls (Beneteau-Burnat, 1990), gradually falling to adult levels by 18 years. Men and women have the same values, although not all studies show this pattern. ACE appears to be cleared by the liver; the half-life in plasma is roughly 48 hours. Average day-to-day variation is less than 10%, with no diurnal variation (Thompson, 1986).

A number of other factors affect ACE levels. Smokers have ACE activities about 30% lower than in nonsmokers or former smokers who have stopped smoking for at least 10 years (Ninomiya, 1987). Thyroid hormone stimulates ACE synthesis. Postmenopausal estrogen replacement causes a 20% fall in ACE activity in serum (Prouder, 1995). Rare families lack an endogenous inhibitor of ACE activity and, consequently, have markedly elevated serum ACE levels (Luisetti, 1990).

Measurement

ACE is typically measured by its ability to cleave synthetic peptides, releasing hippuric acid (Hip) or other indicator molecules as in the following reaction:

Hip is then extracted, and its absorption is measured at 228 nm. A modification of the assay is required in CSF samples because of their much lower ACE activity (Oksanen, 1985).

Causes of Abnormal Results

The most common reason for ordering ACE levels involves the diagnosis and monitoring of sarcoidosis. In general, ACE levels are directly related to the number of organs affected (Muthuswamy, 1987) and the activity of granulomas; mature granulomas tend to produce less ACE than developing ones (Mimori, 1998). In sarcoidosis, a general correlation has been noted between disease activity and ACE levels (Gupta, 1992); as disease progresses to fibrosis, ACE levels decline. ACE is more likely to be elevated

with pulmonary involvement than with purely hilar adenopathy. ACE is also increased in many other granulomatous diseases, although not as frequently as in sarcoidosis. Although most individuals with sarcoidosis have elevated ACE, the frequency of elevation of other granulomatous disorders is 10% (Studdy, 1978). For this reason, ACE is not usually considered a diagnostic test, although it may be helpful in patients with primarily ocular involvement, in whom biopsy cannot be readily performed (Power, 1995).

ACE is frequently elevated in a number of other disorders, including multiple sclerosis (Constantinescu, 1997), Addison's disease (Falezza, 1985), hyperthyroidism (Reiners, 1988), diabetes mellitus (Scherthaner, 1984), alcoholic hepatitis (Borowsky, 1982), peptic ulcer (D'Onofrio, 1984), and nephrotic syndrome (Huski, 1996), and at various stages in patients with bacterial (Kerttula, 1986) or *Pneumocystis* pneumonitis (Singer, 1989). Other pulmonary disorders with a significantly increased ACE are emphysema, asthma, small cell carcinoma, and squamous cell carcinoma (Ucar, 1997). In chronic renal failure, it is increased only in those on hemodialysis and rises during the course of a dialysis procedure (Docci, 1988); it is decreased in those with chronic renal failure who are not on dialysis (Le Treut, 1983). In HIV infection, the frequency and degree of elevation correlate with stage of disease (Ouellette, 1992). Decreased ACE levels are seen in various malignancies (Romer, 1980; Schweisfurth 1985), in chronic liver disease (Sakata, 1991), in anorexia nervosa (Matsubayashi, 1988), and in hypothyroidism (Reiners, 1988).

Use of CSF ACE levels for diagnosis and monitoring of neurosarcoidosis has been criticized (Dale, 1999). A number of other diseases cause elevated CSF ACE, among them viral encephalitis, multiple sclerosis, and central nervous system (CNS) syphilis (Schweisfurth, 1987).

In all cases of assays for ACE, attention should be paid to the possible use of ACE inhibitors in hypertensive patients. Because virtually all ACE inhibitors are competitive inhibitors, if competitive inhibition is suspected, use of higher concentrations of Hip-His-Leu substrate in the ACE assay can be used to overcome the inhibition. Alternatively, the sample can be diluted to remove the effect of the inhibitor. Assays for the levels of ACE inhibitors such as captopril have been developed (Prior, 2007).

ACETYLCHOLINESTERASE (EC 3.1.1.7) AND BUTYRYLCHOLINESTERASE (EC 3.1.1.8)

Biochemistry and Physiology

AChE (true cholinesterase or choline esterase I) and PChE (or choline esterase II) are carboxylic ester hydrolases (class 3; see Table 20-1) that have different specificities (Abdallah, 2007). AChE catalyzes the following reaction:

PChE catalyzes this reaction:

AChE and PChE are two different enzymes produced by different tissues that are able to cleave acetylcholine, one of the body's major neurotransmitters. True cholinesterase has acetylcholine (ACh) as its primary natural substrate and is also inhibited by it at approximately 10^{-2} mole/L; it is found in high activity in the CNS, RBCs, lung, and spleen. ACh is a primary neurotransmitter at various sites in the CNS, and AChE rapidly hydrolyzes ACh, producing rapid termination of neurotransmission. AChE is not normally found in amniotic fluid.

The normal function of the enzyme found in serum, PChE (also called acetylcholine acylhydrolase), is not known, but it is important in the cleavage of acetylcholine antagonists such as succinylcholine and mivacurium, muscle relaxants used during surgery. Serum PChE is not subject to substrate inhibition by high levels of ACh. PChE production occurs primarily in the liver, although other tissues, such as myocardium and pancreas, can also produce it. Although both enzymes hydrolyze acetylcholine, AChE, but not PChE, hydrolyzes acetyl- β -methylcholine; conversely, PChE, but not AChE, hydrolyzes butyryl- and benzoylcholine.

A number of genetic variants of PChE have reduced affinity (higher K_M) for acetylcholine, as well as for competitive inhibitors such as dibucaine and fluoride, when compared with the common U (usual) form; these are termed A (for atypical), F (for fluoride resistant), and S (for silent). The S variant actually represents a number of mutations that may cause absence of enzymatic activity or absence of PChE synthesis. Heterozygous deficiency is found in about 4% of the population, and homozygous deficiency

affects 0.3% to 0.5% of individuals. These variants cause decreased (or, in the case of the *S* variant, absent) PChE activity when present in homozygous or mixed heterozygous forms (AA, AF, AS, FF, FS, SS). Because of the broad range of normal values, reduced PChE activity is not usually found in U form heterozygotes.

Another way to detect such variants is to measure the percent of enzyme activity remaining after *in vitro* incubation of serum enzyme with dibucaine or fluoride (termed dibucaine number, or DN, and fluoride number, respectively). As mentioned previously, increased K_M of variants produces less effective catalysis than normal; decreased affinity thus exists for dibucaine and fluoride, making these variants more resistant to inhibition than normal. In general, dibucaine inhibits U plasma cholinesterase activity by approximately 70% to 90%. Variant cholinesterase activity is more resistant to inhibition, such that heterozygote activity is inhibited by approximately 50% to 70%, and homozygous variant activity is inhibited by approximately 10% to 30%. The DN will then reflect percentage inhibition of enzyme activity and will give a rough measure of the enzyme's activity; this in turn will indicate the presence or the absence of a variant form of the enzyme. The DN is calculated using the formula in Equation 20-42. For example, the UU form may show 85% inhibition, or 15% remaining activity, and may yield a DN of 85.

Dibucaine (fluoride) number = 100X

$$(1 - \text{Enzyme activity with inhibitor} / \text{Enzyme activity without inhibitor}) \quad (20-42)$$

Newer molecular biology techniques, such as the use of polymerase chain amplification with separation of the reaction products by gel electrophoresis (Cerf, 2002), allow much more accurate identification of variants, as compared with traditional biochemical analysis.

Pseudocholinesterase as an Antixenobiotic Enzyme

In addition to its involvement in the metabolism of anticholinergic drugs, PChE has been found to catalyze the debenzoylation of cocaine (Duysen, 2008; Yang, 2009) and the hydrolysis of procaine (Duysen, 2008). Although catalysis by PChE of debenzoylation of cocaine is inefficient, absence of this enzyme or mutations that reduce its activity, discussed in the preceding section, can prolong and exacerbate the negative effects of cocaine such as its cardiotoxicity (Duyson, 2008). It is interesting to note that recently, based on transition state theory analysis and molecular modeling of this enzyme bound to cocaine, site-specific mutagenesis of the gene encoding this enzyme has resulted in a form of PChE that efficiently debenzoylates cocaine (Yang, 2009). Humanized forms of this engineered enzyme may prove to have significant therapeutic value.

Reference Ranges and Preanalytic Variation

PChE values are low in infants and gradually rise to adult levels by 4 months of age (Karlsen, 1981). Values in men do not change after this point until age 45; in women, they fall by about 10% at menarche and increase by 15% after menopause. A recent study (Abou-Hatab, 2001) found no significant correlation between older patient age and changes in plasma enzyme activities of AChE and PChE; healthy young and older individuals (study age range, 18–85 years) showed similar enzyme activities. Values in men are about 15% to 20% higher than in women until age 45, when values in women become equal. Oral contraceptives cause a decrease of about 15% in PChE activity (Lepage, 1985). About a fourfold range of values is seen in normal individuals. Increased body mass index is associated with an increase in PChE, and low protein intake leads to decreased PChE.

The half-life of PChE has been estimated at between 2 and 10 days. Average day-to-day variation is about 7% (Moses, 1986)—much smaller than that for most other enzymes.

Measurement

Enzyme activity is typically measured using an acylthiocholine ester as a substrate; released thiocholine reacts with Ellman's reagent (dithiobisnitrobenzoic acid), releasing 5-mercapto-2-nitrobenzoic acid, which is measured spectrophotometrically. Pseudocholinesterase activity is measured in serum, and AChE activity is measured in a hemolysate of washed RBCs. AChE may also be determined in amniotic fluid by gel electrophoresis. To measure dibucaine or fluoride numbers, serum is incubated with dibucaine (30 $\mu\text{mol/L}$) or fluoride (4 mmol/L) in the assay reaction mixture.

Causes of Abnormal Results

The main reasons for measuring PChE are (1) to monitor exposure to cholinesterase inhibitors, (2) for use as a liver function test, or (3) for

diagnosis of genetic variants. Organophosphate insecticides are irreversible inhibitors of both AChE and PChE, although typically PChE plasma activity falls before AChE activity in RBCs with poisoning (Areekul, 1981). Because of small individual variation and large interindividual variation in PChE values, it is advisable to obtain baseline values for PChE before individuals are exposed to organophosphates (Trundle, 1988). A decrease of 40% from baseline is needed before symptoms develop, and severe symptoms typically occur with falls in values greater than 80%; thus, symptoms often occur with PChE values within the reference range. If no baseline values are present, serial determinations are helpful. In one study, 90% of symptomatic organophosphate poisonings were associated with PChE values within the reference range, and postexposure levels showed a rise, confirming toxicity (Coye, 1987). Although PChE reflects acute toxicity, AChE (RBCs) better reflects chronic exposure.

In contrast to other hepatocyte enzymes, PChE production by the liver appears to reflect synthetic function rather than hepatocyte injury. Levels of PChE are decreased in acute hepatitis, cirrhosis, and carcinoma metastatic to liver. PChE is decreased in malnutrition but is normal or increased in nephrotic syndrome. As is the case when monitoring organophosphate exposure, changes in values compared with baseline are more useful than single values, limiting the diagnostic usefulness of PChE as a nutritional or liver injury monitor.

The other common use of PChE measurements is in recognizing the presence of genetic variants. Most commonly, such testing involves family members of individuals who have prolonged apnea after use of succinylcholine or mivacurium (neuromuscular blocking agents/muscle relaxants) during anesthesia. Testing typically involves both total PChE and determination of fluoride and dibucaine numbers to recognize homozygous or compound heterozygous variants that put an individual at risk from exposure to cholinesterase inhibitors. Patients at risk (with variant cholinesterase forms) may more slowly hydrolyze the neuromuscular blocking agent, unexpectedly increasing the duration of respiratory muscle relaxation and prolonging apnea. This is in contrast to the usual rapid drug hydrolysis seen with the U forms, leading to rapid recovery of the patient.

As mentioned previously, measurement of RBC AChE is useful in organophosphate exposure and poisoning. In addition, qualitative analysis of AChE in amniotic fluid may be useful in the diagnosis of neural tube defects, especially in high-risk groups (Muller, 2003). AChE can be identified in amniotic fluid from pregnancies with neural tube defects, as well as some other types of birth defects. AChE is absent in amniotic fluid from normal pregnancies.

LACTATE DEHYDROGENASE (EC 1.1.1.27)

Biochemistry and Physiology

LD is a class 1 enzyme (oxidoreductase; see Table 20-1) that acts on a CH–OH group of donors with NAD^+ as acceptor and catalyzes the transfer of hydrogen in the form of a hydride ion:

The enzyme is also capable of oxidizing other (L)-2-hydroxymonocarboxylic acids.

LD is a zinc-containing enzyme that is part of the glycolytic pathway; it is found in the cytoplasm of all cells and tissues in the body. LD is a tetramer of two active subunits: H and M with a molecular weight of 134 kDa. Combinations of subunits produce five isoenzymes ranging from LD₁ (HHHH) to LD₅ (MMMM); the intermediate isoenzymes contain differing combinations of H and M subunits (LD₂, HHHM; LD₃, HHMM; LD₄, HMMM). Inherited forms of deficiency of H (Joukyuu, 1989) and M (Kanno, 1980), subunits of LD, are associated with low LD levels in plasma and only one isoenzyme on electrophoresis. Another form of LD composed of four C subunits is found in spermatozoa and in semen but has never been detected in serum, even in individuals with seminoma (Vogelzang, 1982). Rarely, another band detected in electrophoresis and termed LD₆ can be seen; this probably represents alcohol dehydrogenase, which can also metabolize lactate (Kato, 1984). LD₁ and LD₂ have lower K_{MS} (higher affinities) for lactate than for pyruvate, and the reverse is true for LD₄ and LD₅.

The tissue distribution of LD varies primarily in its isoenzyme composition, not in its content of LD (see Table 20-6). It is important to note that LD₁ and LD₂ are expressed at high levels in myocardial tissue and in erythrocytes and at much lower levels in tissues such as liver and muscle; the reverse is true for LD₄ and LD₅. In myocardial damage, the predominant isozymes that become elevated in serum are LD₁ and LD₂; in liver

TABLE 20-8
Relative Percentage of LD Isoenzymes in Various Tissues

Tissue	LD ₁	LD ₂	LD ₃	LD ₄	LD ₅
Serum	25	35	20	15	5
Heart	45	40	10	5	0
Red cells	40	35	15	10	0
Renal cortex	35	30	25	20	0
Lung	10	15	40	30	5
Skeletal muscle	0	0	10	30	60

LD, Lactate dehydrogenase.

or skeletal muscle disease, the LD₄ and LD₅ isozymes become elevated predominantly in serum. In contrast to enzymes such as AST, ALT, and CK, which show marked variation in enzyme activity between tissues, the range in values for LD is only about 1.5-fold between those with the highest amounts (such as liver) and those with lower amounts (such as kidney); most tissues have LD activities that are 500 to 1000 times greater in tissue than those found in normal serum (see Table 20-6). Thus, significant elevation of plasma levels occurs with a small amount of tissue damage/breakdown. The tissue distribution of LD isoenzymes is shown in Table 20-8. The specific composition of elevated isoenzyme levels found in plasma will reflect tissue origin. In plasma, the majority of LD comes from breakdown of erythrocytes and platelets, with varying contributions from other organs. LD is apparently eliminated in bile, as injection of radiolabeled LD results in radioactivity in the gallbladder and small intestine (Smith, 1988).

Reference Ranges and Preanalytic Variation

LD values are highest in newborns and infants; values do not change with age in adults, and there is no gender difference. Persons over age 65 tend to have slightly higher values. Exercise causes, at most, slight increases in total LD; even strenuous exercise causes only a 25% rise in average values (Tanada, 1993). Even trace to slight hemolysis invalidates LD and LD isoenzyme analyses. Contact with the clot increases LD, and physical agitation of specimens, as occurs in most pneumatic tube systems, tends to cause some hemolysis and increased LD. Hemolysis affects both total LD and the LD₁/LD₂ ratio. Exercise has little effect on LD or its isoenzymes. Extreme exercise can cause LD₁ to become greater than LD₂. Total LD increases transiently after blood transfusion but returns to baseline within 24 hours (Wiesen, 1998). Delayed separation of red cells from serum does not affect LD values for 1 to 2 days. Few drugs directly affect LD activity, but granulocyte-macrophage colony-stimulating factor appears to increase LD in parallel to the increase in white blood cell (WBC) count (Sarris, 1995).

The half-life of LD isoenzymes varies greatly, from approximately 4 to 4 ½ days for LD₁ to 4 to 6 hours for LD₅. Day-to-day variation of LD is only 5% to 10%.

Measurement

LD activity can be measured using either the forward (lactate-to-pyruvate) or the reverse (pyruvate-to-lactate) direction of the reaction. A vast majority of laboratories use the forward reaction; the reverse reaction, predominantly used in the dry slide method for LD, produces activities that have good correlation with the forward reaction but at measured activities approximately threefold higher. This underscores the point made earlier—if total activity units are reported, it is vital to list the substrate and to provide the reference range for that substrate.

The reverse (pyruvate-to-lactate) reaction is used in a few laboratories currently because of faster reaction kinetics, the less costly cofactor (NADH) needed, and the smaller specimen volume requirement. Disadvantages of the pyruvate-to-lactate reaction include early loss of linearity of reaction kinetics, the effect of potent LD inhibitors in some NADH preparations, and use of suboptimal concentrations of pyruvate because of substrate inhibition. Also, lactate is a more specific substrate for this enzyme; pyruvate is less specific and serves as a substrate for such enzymes as pyruvate dehydrogenase.

Electrophoretic separation of LD isoenzymes is typically used when quantitation of different isoenzymes is required; agarose gel is most commonly used. Quantitation usually uses the forward reaction,

allowing detection of fluorescent NADH or a reduced formazan dye in a colorimetric development step. The electrophoretic support and developing agent affect the results, and the reference ranges for the different methods are not the same. Inhibition methods for LD₁ are also available but allow quantitation only of this isoenzyme; results are often expressed as the ratio of LD₁ to total LD. Hydroxybutyrate is preferentially cleaved by the LD₁ isoenzyme; until the early 1970s, measurement of **hydroxybutyrate dehydrogenase** was used as a diagnostic test for myocardial infarction.

Serum LD is, on average, 30 IU/L higher than plasma LD, owing to release of LD from platelets. With prolonged incubation of plasma containing platelets (separated at <1200 g centrifugation), LD can leak from damaged platelets, increasing plasma LD as well (Hollaar, 1979). LD is not stable on storage at 4° C because of cold lability of LD₅. Specimens can be stored for up to 24 hours at room temperature with little change. Three days of storage at room temperature decreases total LD by about 20%, increases apparent LD₁ by 20%, and decreases apparent LD₅ by 18%. If specimens are frozen, LD₅ decreases significantly and the isoenzyme pattern shifts with an artifactual increase in LD₁ and decrease in LD₅. Serum should not be frozen for assay of LD or for its isoenzymes.

Causes of Abnormal Results

LD is a highly nonspecific test; an abnormal value is not specific for damage to any particular organ. Relative amounts of LD, AST, and ALT (along with CK) may provide clues to the source of LD elevation. If LD is markedly elevated, but AST, ALT, and CK are normal or minimally increased, this suggests damage to cells such as red or white blood cells, kidney, lung, lymph nodes, or tumors. Increases in both CK and LD, with greater increases in AST than ALT, occur with cardiac or skeletal muscle injury. Increases in LD occur in liver disease, and LD can be elevated in hepatitis, although these increases by themselves are not specific to liver injury (Cassidy, 1994). Recently, it was found that in fulminant hepatic failure (see Chapters 8 and 21), the serum levels of ALT and LD both increase such that LD increases more rapidly initially. An ALT-LD index has been computed in these patients and was found to be a reliable predictor of survival in patients with this condition (Kotoh, 2008). As discussed in Chapters 8 and 21, serum elevations of LD and ALP frequently occur in space-occupying lesions of the liver; most cases are identified as metastatic carcinoma or primary hepatocellular carcinoma.

In many conditions, such as shock and metastatic carcinoma, LD is increased because of damage to multiple organs, so that mixed patterns can be seen. Marked elevations of LD (>5 to 10 times normal) are seen in megaloblastic anemia, hemolytic anemias, advanced malignancies (particularly lymphoma and leukemia), sepsis or other causes of shock, and cardiopulmonary arrest. LD is often moderately elevated in *Pneumocystis carinii* pneumonia (Smith, 1988) but is often normal in most other forms of pneumonia (Rotenberg, 1988). Although LD is highly sensitive (so that normal values make the diagnosis unlikely) (Quist, 1995), the predictive value of LD is not adequate to establish a diagnosis in an HIV patient (Grover, 1992). In patients with biliary pancreatitis (inflammation due to gallstones impacted in the bile duct), the LD/AST ratio is elevated, which appears to indicate the presence of pancreatic necrosis (Isogai, 1998). Note that 10% to 20% of patients with biliary pancreatitis may present with normal liver function tests (Dholakia, 2004).

In cases where the cause of elevated LD cannot be determined by other means, LD isoenzymes may be useful in determining the source of injury. In normal serum, the LD isoenzymes, in decreasing order of activity, are 2 > 1 > 3 > 4 > 5. In germ cell tumors (particularly seminoma and dysgerminoma), LD₁ is increased and can serve as a tumor marker (von Eyben, 2000, 2001).

As noted in Chapter 18 on cardiac function, LD increases in serum over about a 36-hour period, during which time the LD₁/LD₂ ratio, which is normally less than 1, increases to values of 1 or above, the so-called flipped ratio. This confirmed the diagnosis of myocardial infarction (MI) but could not be used to make acute diagnoses of MI because of the prolonged time (36 hours) required for the flipped ratio to develop. As discussed in Chapter 18, better biomarkers, specifically the inhibitory subunit of troponin, are available for the acute diagnosis of MI and for confirmation of the diagnosis (serum troponin levels remain elevated for longer than 1 week after the acute event). Also, hemolytic anemia, megaloblastic anemia, and renal cortical diseases such as renal infarcts and renal cell carcinoma cause increases in LD₁ and, often, a flipped LD₁/LD₂ ratio. In tumors of WBCs (leukemia, lymphoma, multiple myeloma) LD₃ and often LD₄ are typically increased, whereas the relative amounts of LD₁ and LD₂

are decreased (Ricerca, 1988; Copur, 1989; Pandit 1990). Pulmonary disease can produce a similar pattern. Increases in LD₅ and sometimes LD₄ are typically seen with skeletal muscle injury or with ischemic or toxic hepatic injury. The presence of LD₆ is associated with a poor prognosis (Ketchum, 1984). An isomorphic pattern, in which total LD is increased but isoenzymes are present in normal proportions, and a **tombstone** pattern, seen when the relative amount of each isoenzyme is roughly the same, are typically noted in persons with diffuse tissue damage, often accompanied by shock or hypoxemia.

5'-NUCLEOTIDASE (EC 3.1.3.5)

Biochemistry and Physiology

5'-NT is a phosphoric monoester hydrolase (class 3 enzyme; see Table 20-1), also known as 5'-ribonucleotide phosphohydrolase, which catalyzes the following reaction:

It is a cytoplasmic membrane-bound phosphatase with a wide specificity for 5'-ribonucleotides and a molecular weight of about 70 kDa. It acts only on nucleotides (such as adenosine 5'-monophosphate and guanosine 5'-monophosphate) and is believed to function in extracellular adenosine production, nutrient absorption, and cell proliferation. 5'-NT is a metalloprotein, and zinc is believed to be an integral part of the enzyme. It is widely distributed in the body, predominantly attached to cell membranes (similar to ALP and GGT). Plasma 5'-NT is derived predominantly from the liver. A detailed review of 5'-NT is available (Sunderman, 1990).

Reference Ranges and Preanalytic Variation

5'-NT is normally present at low activities in children, rises in adolescence, and plateaus until age 40, when levels increase significantly (Moses, 1986); reference values are independent of gender and race. A slight increase in 5'-NT is seen during the second and third trimesters of pregnancy (Bacq, 1996). Similar to ALP and GGT, antiepileptic drugs can increase 5'-NT activity; however, values are usually less than twice the reference limits, and less than 25% of those taking such agents show elevated 5'-NT activity (Fortman, 1985).

Measurement

Measurement of 5'-NT is difficult because other phosphatases, notably ALP, are capable of cleaving the substrate used to measure the lower activity of 5'-NT present in the sample. Approaches usually utilize large quantities of other, nonnucleoside substrates to "competitively inhibit" ALP (although they are actually undergoing reactions catalyzed by ALP, they prevent ALP from acting on nucleotide phosphates). Although it would be simplest to measure generated phosphate, this cannot be done because cleavage of other phosphates by ALP would produce incorrect results. Therefore, measurement of the nucleoside released by the action of 5'-NT is required. Most chelating agents such as EDTA inhibit enzyme activity, presumably by making zinc unavailable.

Causes of Abnormal Results

Similar to GGT, 5'-NT is most commonly used to determine whether the source of an elevated ALP is liver or bone. Although 5'-NT is more commonly elevated in cholestatic disorders, acute hepatitis causes an increase in 5'-NT synthesis by the liver and a slight elevation in 5'-NT in plasma (Fukano, 1990). 5'-NT is increased in ovarian carcinoma (Chatterjee, 1981) and in rheumatoid arthritis, where levels correlate with extent of inflammation as reflected by erythrocyte sedimentation rate (Johnson, 1999). Sapey et al (2000) prospectively studied ALP, GGT, and 5'-NT in 80 cholestatic patients, correlating intrahepatic (i.e., secondary to intrahepatic parenchymal disease) and extrahepatic (i.e., secondary to biliary tree obstruction) causes with enzyme changes. They found markedly increased levels with extrahepatic causes (compared with intrahepatic disease) and noted that elevations in GGT and 5'-NT levels were independently linked to cause. The GGT/5'-NT ratio differed significantly between the two groups, with a ratio <1.9 highly suggestive of (but insensitive to) intrahepatic disease (Sapey, 2000).

SKELETAL MUSCLE INJURY: CREATINE PHOSPHOKINASE

The basic assay for this enzyme was discussed earlier (see [Equations 20-15 to 20-17](#)). This enzyme has two major isoenzymes, M and B, each of which has the same activity. CK is composed of three types of dimers: MM (mainly in skeletal muscle), MB (found mainly in cardiac tissue), and BB (found predominantly in brain and intestine). As discussed at length in Chapter 18, because CK-MB is found mainly in myocardial tissue, CK-MB is used as a serodiagnostic test for MI. In this section, CK is discussed as a biomarker for skeletal muscle injury.

Skeletal muscle injury can occur from a variety of sources. Direct trauma, as occurs with physical injury (including contact sports), surgery, strenuous exercise, and intramuscular injection, are common causes of mild elevations of CK (up to about five to six times reference limits). In these situations, CK typically increases rapidly and then falls quickly, returning to baseline with a half-life of approximately 24 hours. An important clinical disorder associated with acute muscle injury is neuroleptic malignant syndrome, a rare complication of treatment with phenothiazines or other psychotropic agents. Typically, affected individuals present with muscle rigidity, fever, and elevated WBC counts; CK is considered a diagnostic test for this disorder. Prompt recognition and treatment are necessary to prevent death from this syndrome; discontinuation of medications and use of the muscle-stabilizing agent dantrolene are the cornerstones of treatment (Pelonero, 1998).

Chronic damage to muscle causes more persistent elevation of CK, which may be mild or more extensive. The broad range of normal values and the preanalytic variation seen in total CK values can hamper recognition of mild, ongoing muscle injury. Generally, persistent elevation above the reference limits for an appropriate comparison group despite cessation of any other factors known to affect CK is needed to diagnose muscle injury in asymptomatic individuals. Common causes of chronic muscle injury include medications (particularly 3-hydroxy-3-methylglutaryl-coenzyme A reductase inhibitors and glucocorticoids), congenital myopathies (such as Duchenne's muscular dystrophy), inflammatory disorders (such as polymyositis and dermatomyositis), hypothyroidism, and alcohol abuse. In chronic myopathies, CK-MB is often increased, reflecting its production by regenerating muscle.

With severe acute damage to muscle, a clinical picture termed rhabdomyolysis may develop. In such situations, CK-MB/total CK may be elevated above normal, in the absence of myocardial infarction (cardiac troponin levels are normal); this is commonly seen in patients with inflammatory muscle disease (Kiely, 2000). In addition to normal cardiac troponin levels with elevated CK levels, two distinct isoforms (representing fast or slow skeletal fiber types) of serum skeletal troponin I may be identified (Simpson, 2002).

No specific criteria are known for differentiating rhabdomyolysis from lesser degrees of muscle injury; among the more important features are the higher total CK (one suggested diagnostic level is CK >20 times upper reference limits), the rapid rise and fall of CK, and the appearance of myoglobinuria. Many assays for myoglobin (found in skeletal, smooth, and cardiac muscle) are relatively insensitive, and myoglobin has a short half-life; thus, CK is a more reliable test for establishing the diagnosis. As a form of **cell lysis syndrome**, rhabdomyolysis is associated with the release of other cell contents, such as potassium, phosphate, and nucleotides that can be converted to uric acid. Qualitative testing for myoglobin in the urine is important because myoglobin is potentially toxic to the kidneys, and the patient is at risk for acute renal failure. Myoglobinuria may lead to the development of acute tubular necrosis, with the appearance of pigmented casts in the urine sediment. If renal failure develops, hyperkalemia, hyperphosphatemia, and hyperuricemia typically also will be present. No direct relationship has been discerned between the degree of elevation of CK and the likelihood of development of renal failure (Gabow, 1982; Ward, 1988). Common causes of rhabdomyolysis include drugs (particularly ethanol and cocaine), viral infection, extreme exertion, hyperthermia, trauma including crush injuries, ischemia of the lower extremities, and inflammatory myopathy. In addition, strenuous exercise in individuals with sickle trait can result in massive rhabdomyolysis, leading to myoglobin-induced renal failure and the other sequelae discussed previously (Mitchell, 2007; Ouyang, 2008).

KEY POINTS

- The liver is composed of three systems: the hepatocyte, concerned with metabolic reactions, macromolecular (especially protein) synthesis, and degradation and metabolism of xenobiotics (e.g., drugs); the biliary system, involved with the metabolism of bilirubin and bile salts; and the reticuloendothelial system, concerned with the immune system and the production of heme and globin metabolites (e.g., bilirubin).
- The function of each of these systems can be measured conveniently and virtually noninvasively by determining the serum levels of specific analytes, in the so-called **liver function test profile**.
- One of the most common causes of acute liver injury is viral hepatitis, mainly hepatitis A, B, and C, all of which induce acute elevations of serum alanine and aspartate aminotransferase.
- Diagnosis of viral hepatitis can be made by screening for viral antigens, especially in hepatitis B, and for immunoglobulin M and G directed against specific viral antigens. Confirmation of the diagnosis of a particular form of viral hepatitis is carried out using suitable molecular diagnostic techniques such as real-time PCR using primers encoding specific viral gene sequences.
- The diagnosis of specific liver diseases, including hepatitis, cirrhosis, chronic passive congestion, acute biliary obstruction, space-occupying lesions, autoimmune diseases, and fulminant hepatic failure, can be made from specific patterns of serum liver function tests and from the presence of specific antibodies in serum.

NORMAL LIVER FUNCTION

The liver is the largest and most complex organ of the gastrointestinal tract. Overall, it comprises three systems: first, the biochemical hepatocytic system, which is responsible for the vast majority of all metabolic activities in the body, including protein synthesis; aerobic and anaerobic metabolism of glucose and other sugars; glycogen synthesis and breakdown; amino acid

and nucleic acid metabolism; amino acid and dicarboxylic acid interconversions via transaminases (aminotransferases); lipoprotein synthesis and metabolism; xenobiotic metabolism (e.g., drug metabolism), usually involving the cytochrome P450 oxidation system; storage of iron and vitamins such as A, D, and B₁₂; and synthesis of hormones such as angiotensinogen, insulin-like growth factor I, and triiodothyronine. It is also the site of clearance of many other hormones such as insulin, parathyroid hormone, estrogens, and cortisol. Uniquely, the liver is the site of metabolism of ammonia to urea.

Albumin in the body is synthesized in the liver, as are all coagulation factor proteins, with the exception of von Willebrand factor, which is synthesized in endothelial cells and megakaryocytes. Patients with liver disease may have signs or symptoms related to disturbance of any of the above functions.

The second major hepatic system is the hepatobiliary system, which is concerned with the metabolism of bilirubin, a process that involves transport of bilirubin into the hepatocyte and its conjugation to glucuronic acid and its secretion into bile canaliculi and the enterohepatic system. Last is the reticuloendothelial system, that is, Kupffer cells. These are a form of macrophage involved (a) with the immune system, including being a major site of defense against intestinal bacteria and the primary location for removal of antigen-antibody complexes from the circulation, and (b) with the breakdown of hemoglobin from dead erythrocytes, giving rise to bilirubin, which, together with bilirubin from the spleen, enters the hepatocyte.

Because clinical symptoms in liver disease often lag behind the progression of disease, it is important to detect the presence and even the onset of these conditions. Fortunately, evaluation of liver function can often be achieved by determination of serum analytes in a test profile known as **liver function tests**, many of whose components are not unique to liver but, when evaluated together, allow for accurate diagnosis of abnormalities of liver function. An outline of liver function tests and their interpretation has been presented in Chapter 8.

This chapter reviews the most common laboratory tests for evaluation of liver function and injury, methods used for their measurement, testing for causes of liver injury, and patterns of laboratory abnormalities seen in specific liver diseases.

Figure 21-1 Structures of critical molecules in the metabolism of bilirubin to its diglucuronide. Bilirubin is transported into the hepatocyte, where it is converted into the diglucuronide form and secreted into canaliculi. (From Crawford JM, Hauser SC, Gollan JL. Formation, hepatic metabolism, and transport of bile pigments: a status report. *Semin Liver Dis* 1988b;8:105–18.)

METABOLIC FUNCTIONS

Bilirubin

Normal Bilirubin Metabolism

Bilirubin is the major metabolite of heme, the iron-binding tetrapyrrole ring found in hemoglobin, myoglobin, and cytochromes. Approximately 250–350 mg of bilirubin is produced daily in healthy adults, about 85% of which is derived from turnover of senescent red blood cells (Berlin, 1981; Chowdhury, 1988; Berk, 1994a). In macrophages mainly in the spleen, methemoglobin from red cells is split to give free globin chains and heme. The porphyrin ring of heme is oxidized by microsomal heme oxygenase, producing the straight-chain compound biliverdin and releasing iron. In this ring-opening reaction, 1 mole of carbon monoxide is released, which is transported ultimately as carboxyhemoglobin, whose serum levels can be useful in the diagnosis of hemolytic anemia, as discussed in Chapter 8. Biliverdin is then reduced to bilirubin (Fig. 21-1) by the nicotinamide adenine dinucleotide phosphate (NADPH)-dependent enzyme, biliverdin reductase. Bilirubin, bound mainly to albumin, is then transported mainly in the portal system to the liver, where it enters the hepatocyte through its membrane surface in contact with the sinusoids, as shown in Figure 21-2.

As free bilirubin enters hepatocytes, additional bilirubin dissociates from albumin. This process is highly efficient; clearance of unconjugated bilirubin at normal values is about 5 mg/kg/day or, for a 75-kg individual, about 400 mg/day (Berk, 1994b). The half-life of unconjugated bilirubin is short; 60% of labeled bilirubin appears within hepatocytes within 5 minutes of injection (Bloomer, 1973). Clearance rate increases with an increasing concentration of unconjugated bilirubin up to at least 4 mg/dL (Berk, 1994b).

In its most common isomeric (*trans*-) form, bilirubin is highly insoluble in water, and most of it is transported bound to albumin, with only a small fraction of free bilirubin. Light can cause photoisomerization of bilirubin, from a *trans*- form to a more compact *cis*- form, making it much more water soluble and allowing it to be excreted in urine (Onishi, 1986); this forms the basis for phototherapy in the treatment of neonatal (unconjugated) hyperbilirubinemia. The pathway for clearance of bilirubin by the liver is illustrated in Figure 21-2. Note that unconjugated bilirubin enters the hepatocyte at the membrane surface adjacent to the sinusoids, opposite the face that is in contact with bile canaliculi.

Bilirubin enters hepatocytes by two mechanisms: one is passive diffusion, and the other is receptor-mediated endocytosis. As summarized in Figure 21-2, once in the hepatocyte, bilirubin is “handed-off” from one protein complex to another in a chain. First, it complexes with the so-called **Y and Z proteins**, and then it binds sequentially to a protein complex called **ligandin**. From this complex, it is transported to the smooth endoplasmic reticulum (SER). In the SER, bilirubin becomes the substrate of the enzyme, glucuronyl transferase, which catalyzes the esterification of the propionic acid side chains of bilirubin with glucuronic acid (present as uridine diphosphoglucuronic acid) to form mainly the diglucuronide conjugate shown in Figure 21-1 (Chowdhury, 1988). Some monoglucuronide and a small amount of triglucuronide also form. The ratio of monoconjugate to diconjugated pigment in bile is 1:4, whereas the ratio is nearly 1:1 in plasma, suggesting that monoconjugates reflux into plasma more readily.

As schematized in Figure 21-2, conjugated bilirubin is then transported to the canalicular face of the hepatocyte at which it is directly secreted, by an energy-dependent mechanism, into the canaliculi; only conjugated bilirubin can be directly excreted into the canaliculi, and unconjugated bilirubin cannot traverse this membrane.

Once bilirubin is excreted into the canaliculi and ultimately into the intestinal tract, it is further metabolized by intestinal bacteria, which affect its deconjugation and oxidation or reduction with the formation of compounds collectively called **urobilinogen** and **urobilin**, which can then be reabsorbed from the gut. Most urobilinogen absorbed is reexcreted by the liver. A minor fraction may be excreted in the urine. Larger quantities are found in the urine in conditions leading to hyperbilirubinemia, or in conditions in which the liver cannot readily secrete urobilinogen absorbed from the gut. Ultimately, intestinal urobilinogen is converted to stool pigments such as stercobilin; their absence leads to clay-colored stools, often an early sign of impaired bilirubin metabolism.

When conjugated bilirubin is present in serum, it can become covalently bound to albumin, producing biliprotein or delta-bilirubin (Lauff, 1982; McDonagh, 1984). Although conjugated bilirubin has a half-life of less than 24 hours, delta-bilirubin has a half-life similar to that for albumin at 17 days (Fevery, 1986), causing prolonged jaundice during recovery from hepatocellular injury (Van Hootegeem, 1985) or biliary obstruction (Kozaki, 1998). Conjugated bilirubin, being water soluble, can be filtered by the glomerulus and can appear in urine, where it may be detected by dipstick examination; urobilinogen measurement adds little to standard tests of liver function or injury, however (Binder, 1989). Urinary bilirubin is elevated in most patients with increased serum conjugated bilirubin (Binder, 1989).

Derangements of Bilirubin Metabolism

As shown in Figure 21-2, in each step in the processing of bilirubin a possible lesion leads to elevated serum levels of unconjugated or conjugated bilirubin. Each of these is discussed in turn.

Causes of Elevated Serum Levels of Unconjugated Bilirubin

Hemolysis. As discussed in Chapter 8, in hemolytic anemias unconjugated bilirubin rises as a result of abnormally high levels of hemoglobin released from erythrocytes. If the rate of bilirubin formation exceeds the rate of liver clearance (i.e., a state of overproduction of bilirubin) there will be a rise in the bilirubin level in serum. Virtually all of this bilirubin will be unconjugated bilirubin. This is particularly likely to occur in neonates, whose glucuronyl transferase activity is low. Thus, one manner of confirming a diagnosis of hemolytic anemia is the finding, in adults, of elevated indirect bilirubin levels in serum. Usually, these levels are not dramatically elevated and are generally in the 1.5–3.0 mg/dL range.

Gilbert's Syndrome and the Crigler-Najjar Syndrome Are Caused by Gene Mutations and Deletions. In Gilbert's syndrome, characterized by a mild unconjugated hyperbilirubinemia, the most common genetic lesion appears to be the insertion of two bases into the promoter region of the *UGT1A1* gene, resulting in lower transcriptional rates (Kraemer, 2002; Maruo, 2004) and overall lower enzymatic activity (reduced to about 30% of normal). In the more serious Crigler-Najjar syndrome, frequently characterized by high serum levels of unconjugated bilirubin, multiple mutations are found to occur in this gene, including shifts in the reading frames, stop codons, and critical amino acid substitutions, all of which give rise to a spectrum of dysfunctional proteins from mildly dysfunctional to completely nonfunctional proteins (Kraemer, 2002).

In Gilbert's syndrome, which occurs in a significant fraction (3%–5%) of the population, the genetic defect may be necessary but not sufficient because, in an earlier study (Persico, 1999), a significant percentage of

Figure 21-2 Schematic summary of the pathway of bilirubin (*Bili*, in brown circles) transport and metabolism. Bilirubin is produced from metabolism of heme, primarily in the spleen, and is transported to the liver bound to albumin. It enters the hepatocyte by binding to a transporter protein (red crescents) and crosses the cell membrane (circled 1), thus entering the cell. It binds to Y and Z proteins (not shown) and then to ligandin for transport to the smooth endoplasmic reticulum (SER). In the SER, bilirubin is conjugated to glucuronic acid by UDP-glucuronyl transferase 1 (circled 2 and labeled GT), producing monoglucuronides and diglucuronides of bilirubin—Bili-Gu and Bili-(Gu)₂. Conjugated bilirubin is then secreted into the canaliculi (circled 3) by the adenosine triphosphate-binding cassette transporter protein MRP2/cMOAT/ABCC2 (shown as blue crescents). In overproduction disease (A), such as hemolytic anemia, unconjugated bilirubin is produced at rates that exceed the ability of the liver to clear it, leading to a usually transient increase in unconjugated bilirubin in serum. In both Gilbert's and Crigler-Najjar syndromes, mutations in the gene encoding UDP glucuronyl transferase (*UDPGT1A1*), shown at C in the figure, result in buildup of unconjugated bilirubin in hepatocytes and ultimately in serum. In Gilbert's syndrome, there may also be a defect in the bilirubin transporter protein, shown at B in the figure. Mutations in the *MRP2/cMOAT/ABCC2* gene result in defective secretory proteins, causing buildup of conjugated bilirubin in hepatocytes and, ultimately, in serum, resulting in the Dubin-Johnson syndrome (D), an autosomal recessive disease. Conjugated hyperbilirubinemia is also found in the Rotor syndrome, possibly virus induced. In adults, blockade of any of the major bile ducts, especially the common bile duct, by stones or space-occupying lesions such as tumors (E), is the most common cause of conjugated hyperbilirubinemia. *Hb*, Hemoglobin; *RBC*, red blood cell.

males with this defect were found to have hyperbilirubinemia, but no females with this enzyme deficit were found to have elevated serum bilirubin levels (Bosma, 1995). In some patients with Gilbert's syndrome, the rate of organic anion uptake has been found to correlate negatively with serum bilirubin (Persico, 1999), suggesting that an additional defect may be present to cause hyperbilirubinemia that may be related to a transport deficit in the sinusoidal membrane of the hepatocyte. In this condition, total bilirubin, virtually all of which is unconjugated, is typically elevated to 2–3 mg/dL; levels can increase further with fasting but seldom exceed 5 mg/dL. Because passive diffusion of bilirubin into hepatocytes occurs, this condition is rarely serious and may result in mild elevations of bilirubin such as those seen in hemolytic anemia as described previously.

Gilbert's syndrome has perhaps been overdiagnosed; it is most frequently diagnosed in young adults ranging in age from 20–30 years. However, normal bilirubin ranges are age dependent and actually reach their highest levels in adolescents and young adults (Rosenthal, 1984), as discussed further later.

In the more serious or type I form of the Crigler-Najjar syndrome (i.e., homozygously nonfunctioning proteins), the unconjugated hyperbilirubinemia becomes marked, almost always exceeding 5 mg/dL and causing jaundice, and sometimes exceeding 20 mg/dL. Affected infants develop severe unconjugated hyperbilirubinemia, which typically leads to kernicterus, deposition of bilirubin in the brain, particularly affecting the basal ganglia, mainly the lenticular nucleus, causing severe motor dysfunction and retardation. In the less severe type II form, enzyme activity is approximately 10% of normal, and survival to adulthood is possible (Berk, 1994c). The danger of kernicterus is a certainty at levels exceeding 20 mg/dL. It is vital to treat these infants with phototherapy, as discussed earlier, to cause excretion of the unconjugated bilirubin.

Causes of Elevated Serum Levels of Conjugated Bilirubin

Excretion Deficits: Dubin-Johnson Syndrome. In another inborn error of metabolism, called the **Dubin-Johnson syndrome**, there is a blockade of the excretion of bilirubin into the canaliculi, caused by defects in the adenosine triphosphate (ATP)-binding cassette (ABC) canalicular multi-specific organic anion transporter, *MRP2/cMOAT/ABCC2* (Paulusma, 1997; Tsujii, 1999; Gottesman, 2001). This protein is a member of a family of approximately 100 different transporter proteins that share homology

within the ABC region and contain transmembrane domains involved in recognition of substrates, which are transported across, into, and out of cell membranes and include proteins involved in multiple drug resistance to chemotherapeutic agents in cancer treatment. Some protein members utilize ABCs to regulate ion channels. Several genetic diseases result from transporter mutations, including the Dubin-Johnson syndrome, cystic fibrosis, age-related macular degeneration, Tangier disease, and progressive familial intrahepatic cholestasis (Gottesman, 2001).

Dubin-Johnson syndrome is associated with increased plasma conjugated bilirubin, typically with mild jaundice (total bilirubin, 2–5 mg/dL), and intense dark pigmentation of the liver due to accumulation of lipofuscin pigment. Thus conjugated bilirubin accumulates within the hepatocyte and eventually back-diffuses into the circulation, where it is detected in serum. This inborn error can sometimes be confused with the Rotor syndrome, possibly of viral origin, where there is also a block in the excretion of conjugated bilirubin but without liver pigmentation (Berk, 1994d). In these cases, liver biopsy often will reveal cytosolic inclusion bodies within hepatocytes.

Biliary Obstruction. In adults, cholelithiasis is the most common cause of hyperbilirubinemia. This condition results from the presence of bile stones (that are composed of bilirubin or cholesterol) most commonly in the common bile duct (choledocholithiasis). Most frequently, patients presenting with this condition are parous white females in early middle age (giving rise to the semi-mnemonic, “fair, fecund, fortyish female”). Biliary obstruction due to cholelithiasis results in elevation of total bilirubin, with >90% being direct bilirubin. In more than 90% of such patients, a concomitant rise in alkaline phosphatase occurs. The levels of this enzyme are variable but are frequently above 300 international units (IU)/L.

Inflammatory conditions of the biliary tract, such as ascending cholangitis, also give rise to elevated serum levels of direct bilirubin and alkaline phosphatase, as discussed later in this chapter. The rise in direct bilirubin often exceeds 5 mg/dL. In gram-negative sepsis, there can be what appears to be a mild inflammation of the biliary tract, resulting in mild elevation of direct bilirubin to levels of 2–3 mg/dL. A concomitant elevation of alkaline phosphatase to levels of 200–300 IU/L is also observed.

In hepatitis, in which toxic destruction of hepatocytes is due to viral, chemical, or traumatic causes, focal necrosis and/or cellular injury results both in blocking conjugation of bilirubin and in excretion of conjugated

bilirubin. Thus elevation of both direct and indirect bilirubin occurs. Serum levels of bilirubin are variable, depending on the severity of infection and the extent of disease. In viral hepatitis, such as hepatitis B, as discussed subsequently, serum bilirubin levels often reach levels of 5–10 mg/dL or greater.

Aside from liver disease, elevations of conjugated bilirubin may occur with a few other disorders. Septicemia (as noted previously), total parenteral nutrition, and certain drugs such as androgens commonly cause increased conjugated bilirubin, but the mechanism is not understood (Zimmerman, 1979). Fasting causes increases in unconjugated bilirubin in normal individuals, but to a lesser degree than is seen in Gilbert's syndrome.

Laboratory Tests for Bilirubin

Bilirubin is typically measured using diazotized sulfanilic acid, which forms a conjugated azo compound with the porphyrin rings of bilirubin, resulting in reaction products that absorb strongly at 540 nm. Because unconjugated bilirubin reacts slowly, accelerants such as caffeine or methanol are used to measure total bilirubin. Deletion of these accelerants allows determination of direct-reacting, or direct, bilirubin.

Until the early 1980s, it was accepted that direct bilirubin was equal to conjugated bilirubin. The introduction of dry slide technology, using differential spectrophotometry to measure conjugated and unconjugated bilirubin separately, led to the observation that the sum of these two entities did not equal total bilirubin and to the characterization of delta-bilirubin. Approximately 70%–80% of conjugated bilirubin and delta-bilirubin and a small percentage of unconjugated bilirubin are measured in the direct bilirubin assay (Lo, 1983; Doumas, 1991). Although good data support the measurement of conjugated bilirubin instead of estimating it from direct bilirubin (Arvan, 1985; Doumas, 1987), the direct bilirubin assay is still widely used. The accuracy of direct bilirubin assays is dependent on sample handling and reagent composition. Prolonged exposure to light causes photoisomerization, increasing direct-reacting bilirubin (Ihara, 1997). Use of wetting agents or incorrect pH buffers increases the amount of unconjugated bilirubin measured as direct bilirubin (Doumas, 1991). Typically, direct bilirubin should measure 0–0.1 mg/dL in normal individuals, with rare values of 0.2 mg/dL in the absence of liver or biliary tract disease.

Reference values for total bilirubin are both age and gender dependent. Bilirubin levels typically reach peak values at around ages 14–18, falling to stable adult levels by age 25 (Rosenthal, 1984; Notter, 1985; Zucker, 2004). Values are higher in males than in females at all ages (Rosenthal, 1983; Carmel, 1985; Notter, 1985; Dufour, 1998a; Zucker, 2004). Strenuous exercise causes a significant increase in bilirubin values compared with those seen in sedentary individuals or those with chronic exercise (Dufour, 1998b). African Americans have bilirubin levels significantly lower than those of other ethnic groups.

Other Metabolic Tests

Ammonia

This critical and toxic compound is metabolized exclusively in the liver. Ammonia is derived mainly from amino acid and nucleic acid metabolism. Some ammonia is also produced from metabolic reactions such as the action of the enzyme glutaminase on glutamine, resulting in the production of glutamic acid and ammonia. As it happens, ammonia can be metabolized only in the liver because the liver uniquely contains the critical enzymes for the Krebs-Henseleit or urea cycle, in which ammonia, a toxic substance, is ultimately converted into urea, a nontoxic compound that is readily excreted. In this cycle, ammonia, with the enzyme carbamoyl phosphate synthetase, is condensed with carbon dioxide (CO_2) and ATP to form carbamoyl phosphate that then, in the rate-determining step, carboxamidates the delta-amino group of ornithine to form citrulline using the enzyme ornithine carbamoyltransferase (OCT), an enzyme that is unique to the liver. Congenital deficiency of this or other urea cycle enzymes leads to increased levels of ammonia in serum and in cerebrospinal fluid (Batshaw, 1994).

A unique feature of liver tissue is its ability to regenerate. To abolish liver tissue function, more than 80% of the liver must be destroyed. If most of the liver is destroyed as a result of such conditions as cirrhosis (Stahl, 1963) or, less commonly, acute fulminant hepatic failure, including Reye's syndrome (Heubi, 1984; Sunheimer, 1994), urea cycle enzymes are no longer present, resulting in the toxic buildup of ammonia and some of the amino acid intermediates in the urea cycle, such as arginine, which has known neurotoxic effects. The result is an increase in ammonia and these amino acid intermediates in the circulation and in the central nervous

system (CNS), giving rise to hepatic encephalopathy. In addition, in most cirrhotics, intrahepatic portal-systemic shunting occurs, thereby causing ammonia to bypass the liver and resulting in elevated serum ammonia concentrations. Elevated serum levels of ammonia therefore often indicate some form of liver failure, although other conditions can also induce increases in serum ammonia levels.

In patients with cirrhosis or fulminant hepatic failure, there has been some dispute as to whether ammonia itself is the cause of the observed metabolic encephalopathy; possibly other toxins that accumulate as a result of absent hepatic detoxification are the cause. One of the arguments often used is that there is no clear correlation between the severity of the encephalopathy and serum ammonia concentrations (Lewis, 2003). Countering this argument is the finding that, although venous ammonia levels do not correlate with degree of encephalopathy (Stahl, 1963), arterial levels of ammonia do generally correlate with degree of encephalopathy. Furthermore, in patients with cirrhosis or fulminant hepatic failure, lowering the serum ammonia invariably diminishes the severity of the encephalopathy (Pincus, 1991). Furthermore, idiopathic hyperammonemia, not related to liver disease, also induces lethal encephalopathy (Shepard, 1987; Davies, 1996). An important mechanism by which ammonia can cause toxicity to the CNS is its ability to lower the concentration of γ -aminobutyric acid (GABA), a critically important neurotransmitter in the central nervous system, by reacting with glutamic acid to form glutamine via reversal of the glutaminase-catalyzed reaction (Butterworth, 1987). This depletes glutamic acid in the CNS. However, GABA is formed directly from the decarboxylation of glutamic acid, so that GABA levels consequently decrease, with potentially serious effects on neurotransmission (see Chapter 23). Because ammonia causes accumulation of glutamine in the CNS, there is the suggestion that, at least in valproic acid–induced hyperammonemia, cerebrospinal fluid levels of glutamine can be used in the diagnosis and management of hepatic encephalopathy (Vossler, 2002). More recently, besides evidence that ammonia in the CNS is directly toxic to astrocytes, other evidence indicates that ammonia induces neutrophil dysfunction that results in the generation of reactive oxygen species contributing to oxidative stress and inflammation, with lowered ability of the CNS to block infectious agents (Shawcross, 2010). One major new finding put forth by these studies is that treatment of hepatic encephalopathy with suitable antiinflammatory agents may be effective.

At present, most commonly, elevated serum ammonia concentrations in hepatic encephalopathy are reduced by the agent lactulose, which is metabolized by specific gut bacteria to lactic acid. The acid so produced in the intestinal lumen traps ammonia as ammonium ion, which can no longer diffuse across the intestinal membrane and is thus excreted. Ammonia-producing bacteria in the intestine are removed by treatment with antibiotics such as neomycin.

Assays for Ammonia. Ammonia is typically measured by enzymatic assays using glutamate dehydrogenase, which catalyzes the reaction of α -ketoglutarate and ammonia to form glutamate, with oxidation of NADPH to NADP as the indicator (decrease in absorbance at 340 nm, as described in Chapter 20). Ammonia is also measured via a dry slide method (e.g., on the Johnson and Johnson Vitros systems) using alkaline pH buffers to convert all ammonium ions to ammonia gas, with bromphenol blue as the indicator (Huizenga, 1994). Because ammonia is a product of cellular metabolism, methods used in specimen collection and transportation are critical in preventing artifactually increased levels. Arterial blood is the preferred specimen for measurement of ammonia. Although venous blood is not recommended, if used, tourniquets should be used minimally, and fist clenching and relaxing avoided during collection. Specimens should be kept in ice water until separation of cells from plasma occurs (Howanitz, 1984; da Fonseca-Wollheim, 1990).

Lipids

Cholesterol and Other Lipids

(See Chapter 17.)

Because the liver is vital in lipoprotein synthesis and interconversions, hepatic disorders often cause derangements in lipoprotein metabolism. Although none of these abnormalities is used to diagnose liver pathology, it is important to recognize that they may result from liver disease. In severe liver injury, including cirrhosis, these abnormalities include a decrease in high-density lipoprotein (HDL), particularly the HDL₂ (but often not the HDL₃) subfraction, and in other altered lipoprotein distributions, caused in part by deficiencies of lecithin/cholesterol acyltransferase (the enzyme that esterifies cholesterol) and lipoprotein lipases, resulting

in hypertriglyceridemia (triglyceride levels ranging from 250–500 mg/dL). In addition, decreased synthesis of LCAT and lipoprotein lipases causes increases in blood and in the HDL fraction of unesterified cholesterol, as well as increased levels of phospholipids, including lecithins, in blood and in the very-low-density lipoprotein fraction, along with increased serum triglycerides. Overall, the resulting lipoprotein pattern is that of the so-called **abnormally migrating β -lipoprotein**, typical of type III hyperlipoproteinemia (see Chapter 17). However, in cirrhotics with poor nutrition, despite critical enzyme deficiencies, low levels of cholesterol (<100 mg/dL) may be found.

In contrast, in alcohol-induced liver injury, alcohol induces increased expression of apolipoprotein (apo)A-I protein. Thus, HDL, especially HDL₃, may be elevated if alcohol ingestion continues. Because, in cirrhosis, apoA-I protein decreases, serum levels of this protein have been used to diagnose this disease using the so-called **PGA index** (Teare, 1993)—a combination of prothrombin time (PT), which increases, with γ -glutamyl transferase activity (discussed later), which also increases, and apoA-I protein. This index differs for alcoholic hepatitis, enabling the distinction to be made between these two conditions without the necessity of liver biopsy (Mun, 2003).

In cholestasis, regurgitation of biliary contents into the bloodstream results in the buildup of lipoprotein X (LpX) (discussed in Chapter 17) and elevation of biliary lipids. Because LpX carries high levels of unesterified cholesterol, cholesterol levels in serum can become markedly elevated (Turchin, 2005).

Bile Salts

Bile salts, which are products of cholesterol metabolism, facilitate absorption of fat from the intestine. They are stored in the gallbladder and released to the intestine after meals through gallbladder contraction mediated by cholecystokinin. They are not usually used in the diagnosis of abnormal liver function but are important in that they constitute a substantial amount of bile in bilirubin excretion and can therefore be of use in diagnosing cholestasis. Also, in severe biliary obstruction, the buildup of bile salts in serum causes symptomatic illness in the form of intractable itching, although this has been disputed (Jones, 1999). The primary bile salts, cholate and chenodeoxycholate, are produced in the liver; they are excreted into the biliary and enterohepatic systems, and, in the intestinal tract, they are metabolized by bacteria, producing secondary bile salts (i.e., lithocholate, deoxycholate, and ursodeoxycholate) (Carey, 1988) by bacterial 7- α -dehydroxylation in the intestinal lumen. Ursodeoxycholate, an end-product of bile salt metabolism in man, is produced by isomerization of secondary bile salts and has been found to be therapeutic in cholestatic diseases (Rost, 2004). These bile salts are conjugated, in the microsomal system discussed later, to glycine and taurine and are also sulfated and glucuronidated. Conjugation of bile salts to taurine and sulfates increases with the severity of cholestasis in conditions causing obstruction to bile outflow. Recirculation of bile salts to the liver occurs by reabsorption from the terminal ileum, where deoxycholate is almost completely reabsorbed, and chenodeoxycholate is about 75% reabsorbed. In cirrhosis, a disproportionate decrease in cholic acid is seen, along with a reduced ratio of primary to secondary bile salts. With cholestasis, secondary bile salts are not formed; thus, the ratio of primary to secondary bile salts is markedly increased.

Renal clearance of bile salts is negligible in normal patients, but in cholestasis, renal excretion of bile salts, mainly in the form of sulfates and glucuronides, is enhanced. Fasting bile salts, when normal, can exclude the presence of parenchymal liver disease in patients with Gilbert's syndrome (Vierling, 1982), as discussed previously. It should also be recognized that defective production of bile salts, which helps solubilize the contents of bile, in the liver may predispose to the formation of bilirubinate or cholesterol stones and posthepatic biliary obstruction.

Analysis of bile salts must be performed on serum taken from patients who are in the fasting state, or on serum taken at a specified time after meals, because food ingestion causes a significant increase in bile acid levels. Bile salts can be measured by many techniques, but chromatographic methods, particularly high-performance liquid chromatography, as discussed in Chapter 23, are most widely used and allow separation of different bile salts.

Drug Metabolism

Many xenobiotics, such as drugs, are metabolized in the liver, mainly in the microsomes of hepatocytes. Complex series of reactions occur, many of which are dependent on cytochrome P450, which is involved in the oxidation of these compounds. Whether or not specific exogenous

compounds are converted to metabolites depends on the isoforms of cytochrome P450, such as CYP1A and CYP2B (cytochrome P450 1A and 2B, respectively). Often, the conversion of xenobiotics into metabolites using this system involves two phases: phase I reactions involve oxidations/hydroxylations, and phase II reactions conjugate the metabolite (or parent compound) to polar compounds, such as glucuronic acid, glycine, taurine, and sulfate. In more severe liver disease, which involves microsomal damage, this ability to metabolize xenobiotics is compromised. Thus the ability of hepatocytes to metabolize drugs can be used to measure liver damage.

This is generally accomplished by administering a known dose of radio-labeled (usually ^{13}C -labeled) drug and measuring the $^{13}\text{CO}_2$ exhaled over time in a patient's breath. Two categories of breath tests have been developed based on the rate-limiting step in metabolism. The first group includes drugs such as aminopyrine, caffeine, and diazepam, which are metabolized at rates that are independent of hepatic blood flow to the liver and depend only on the enzymatic activity of different cytochromes P450 (e.g., CYP1A). The second group is composed of drugs such as methacetin, phenacetin, and erythromycin, whose rates of metabolism depend on the rate of blood flow (i.e., their rates of metabolism are fast compared with their rates of delivery to the liver). These types of dynamic tests appear not to be so useful in the initial diagnosis of hepatic disease; rather, they are more useful in estimating the extent of liver damage in known liver disease (Nista, 2004).

Some interferences that complicate interpretation of the results of these tests include dependence of the demethylation of aminopyrine (the methyl group is oxidized to CO_2) on vitamin B₁₂; in cases of vitamin B₁₂ deficiency, less than normal amounts of $^{13}\text{CO}_2$ will be exhaled because of low B₁₂ levels, not necessarily because of liver damage. Rates of caffeine metabolism generally decrease with increasing age but are increased by smoking; these findings can complicate interpretation of test results.

SYNTHETIC FUNCTIONS

Protein Synthesis

The liver is the site of synthesis for most plasma proteins. Major exceptions include immunoglobulins (Igs) and von Willebrand factor. Synthesis of more than 90% of all protein and 100% of albumin occurs in the liver. Thus extensive destruction of liver tissue will result in **low serum levels** of total protein and albumin. In cirrhosis, besides hepatocyte destruction, another cause of diminished protein production is portal hypertension, which decreases delivery of amino acids to the liver. Two vital measurements of liver function, therefore, are total protein and albumin levels in serum. However, it should always be kept in mind that other major causes of low serum total protein and albumin have been identified; these include renal disease, malnutrition, protein-losing enteropathy, and, less commonly, chronic inflammatory disease. These alternative causes must always be considered when liver function status is evaluated.

In liver disease with widespread injury or necrosis, such as fulminant hepatic failure and cirrhosis, plasma levels of liver-synthesized proteins fall, such that proteins with longer half-lives tend to decrease more slowly. Albumin has a half-life of about 20 days, so that decreases in its serum levels occur more slowly than those of proteins with shorter half-lives. Among the liver-produced proteins with short half-lives are factor VII (4–6 hours), transthyretin (1–2 days), and transferrin (6 days).

Determination of Serum Protein Levels

This is based usually on the Biuret method. This method reflects the ability of the peptide backbone C=O groups of proteins to form color complexes with copper that absorb strongly at 540 nm. Some methods utilize a dye-binding method in which the proteins form a complex with the dye Coomassie blue. Albumin forms a unique color complex with the dyes bromocresol green and bromocresol purple, such that they absorb maximally at slightly different wavelengths, thus allowing direct spectrophotometric quantitation (Ihara, 1991). Bromocresol purple tends to react more exclusively with albumin than does bromocresol green (which reacts to a minor extent with some globulins), so that serum albumin levels may be slightly lower when determined with bromocresol purple. The reference range for total serum protein levels is generally in the 6–7.8 g/dL range. At least 60% of this should be albumin, the normal range for which is about 3.5–5 g/dL.

Serum protein electrophoresis and quantitative Igs may reveal characteristic changes in liver disease, as discussed in Chapter 19. Typically, in cirrhosis, albumin is significantly decreased, as are the α -1, α -2, and β

(principally transferrin) bands. However, a polyclonal increase in Igs, which is seen frequently, produces the characteristic β - γ **bridging** pattern, as discussed in Chapter 19. In autoimmune hepatitis, albumin is typically decreased; this is accompanied by a marked polyclonal increase in IgG. Primary biliary cirrhosis is accompanied by a polyclonal increase in IgM.

Albumin

Albumin is the major protein produced by the liver; liver synthesis is increased by low plasma oncotic pressure and is decreased by cytokines, particularly interleukin-6. Although normal albumin synthesis occurs at about 120 mg/kg/day, the rate of synthesis can approximately double with low oncotic pressure. A decrease in albumin is one of the major prognostic features in patients with cirrhosis. Albumin measurements were discussed previously and more fully in Chapter 19.

Albumin is a transport protein for many substances, both endogenous (e.g., bilirubin, thyroid hormone) and exogenous (e.g., drugs). Low serum albumin levels due to liver disease are almost always caused by massive destruction of liver tissue and are seen primarily in cirrhosis, most often secondary to alcoholism. The diminution in albumin is paralleled by a fall in total serum protein. Because albumin is the osmotically active intravascular colloid, hypoalbuminemia often results in edema. In cirrhosis, where increased resistance to blood flow in the sinusoids causes portal hypertension, the combined effect of elevated hydrostatic pressure in the portal system and low colloid osmotic pressure results in ascites, a frequent finding in cirrhosis. These same changes may also be seen acutely in fulminant hepatic failure (Sunheimer, 1994).

Other Serum Proteins

Although most of the proteins discussed in Chapter 19 are produced by the liver, two bear special importance in the detection of congenital liver disorders.

α -1-Antitrypsin. α -1-antitrypsin (AAT), the most abundant α -1-globulin, is the most important protease inhibitor in plasma. Although its name indicates that it inhibits trypsin, it also is an inhibitor of other serine proteases, such as elastin. AAT is coded for by the *PI* gene on chromosome 14; several genetic variants are due to point mutations, leading to single amino acid substitutions (Chappell, 2004). The most common variant, M, is associated with normal serum AAT levels. The mutations present in the S and Z variants prevent normal protein glycation, leading to accumulation of AAT within hepatocytes and reduced plasma AAT levels (Propst, 1994). In the United States, the overwhelming genotype is PiMM, where Pi is the protease inhibitor. The other genotypes—PiZZ, PiSS, PiSZ, PiMZ, and PiMS—all contain measurable activity of antiprotease, except a rare null genotype Pi⁻. If the antiprotease activity of the MM phenotype is used as the reference, then the activity in phenotype ZZ is 15%, SS is 60%, MZ is 57.5%, and MS is 80%. Adults with PiZZ are most prone to develop emphysema relatively early in life as a result of uninhibited trypsin activity on alveolar wall elastin. Patients with PiZZ tend to accumulate the Z protein in periportal hepatocytes, where it forms discrete cytoplasmic bodies and may also develop neonatal hepatitis. Curiously, although infants may die of hepatic injury, it resolves in most infants and progresses to cirrhosis in only about 3% (Sveger, 1988). In adults, the likelihood of liver injury is increased in patients heterozygous or homozygous for the Z variant of AAT; this may be due to accumulation of AAT in the endoplasmic reticulum that induces autophagy and apoptosis of hepatocytes (Teckman, 2004). AAT phenotyping can be performed using isoelectric focusing (Propst, 1994). Because AAT is an acute phase reactant, its serum levels can be normal in MZ heterozygotes.

Ceruloplasmin. The major copper-containing protein in serum, ceruloplasmin, is also the enzyme present in highest circulating concentration. Ceruloplasmin is a ferroxidase, essential for converting iron to the ferric state to allow binding to transferrin. Low levels of ceruloplasmin are found in Wilson's disease, a rare congenital disorder (1 in 30,000 individuals) associated with one of many mutations in the gene on chromosome 13 coding for a cellular adenosine triphosphatase (ATPase), ATP7B, a new member of the cation-transporting p-type ATPase family (Bull, 1993). This protein is principally expressed in the liver and promotes copper secretion into plasma, coupled with ceruloplasmin synthesis, and into the biliary tract. More than 200 mutations of this Wilson's disease gene have been detected, resulting in impairment of ATP7B function and intracellular copper accumulation (Langner, 2004). Excess intracellular copper is deposited in lysosomes in hepatocytes; it induces free-radical reactions such as lipid peroxidation and membrane instability. Resultant liver damage

can lead to chronic active hepatitis, cirrhosis, or, uncommonly, fulminant hepatic failure. In addition, steatosis and inflammation can result in this condition. Copper becomes deposited in the CNS, especially in the lenticular nucleus of the basal ganglia, causing neuropsychiatric disease; it can also be deposited at the edge of the iris, forming the observed Keyser-Fleischer rings.

The diagnosis of Wilson's disease is made on the basis of typical clinical and laboratory findings, including low serum ceruloplasmin, which can be measured by immunoassay or by enzymatic assay, increased urinary copper excretion, and increased hepatic copper content. Although ceruloplasmin is characteristically low in Wilson's disease, factors that increase ceruloplasmin synthesis (e.g., cytokines, pregnancy, estrogens) may cause normal ceruloplasmin levels in up to 15% of patients overall, and in as many as 35% with hepatic manifestations of Wilson's disease (Dufour, 1997), particularly acute Wilsonian hepatitis (Berman, 1991). Genetic testing is the most reliable means to establish the diagnosis, but it is difficult because more than 200 mutations have been shown to cause disease.

Clotting Factors

As mentioned earlier, except for the von Willebrand factor, which is made by endothelial cells and megakaryocytes, coagulation proteins are synthesized in the liver. In addition, inhibitors of coagulation, such as antithrombin III, α -2-macroglobulin, α -1-antitrypsin, C1 esterase inhibitor, and protein C, are synthesized in the liver. In addition, fibrin degradation products are catabolized in the liver. Low levels of antithrombin III in patients with cirrhosis and hepatitis may be caused by decreased synthesis, increased consumption, or alteration in the transcapillary flux ratio (Kelly, 1987). The most common coagulopathy seen in liver failure (i.e., cirrhosis and acute fulminant hepatic failure) is disseminated intravascular coagulopathy (DIC), as discussed in Chapter 8 and extensively throughout Part 5 of this book. This condition is characterized by increased consumption of clotting factors and platelets, causing thrombocytopenia and elevations of both prothrombin (PT) and partial thromboplastin (PTT) times. The mechanism has been postulated to be decreased synthesis of clotting inhibitory factors, decreased clearance of activated clotting factors, or release of tissue thromboplastin from hepatocytes (Kelly, 1986). D-Dimer and fibrin split products, detected in DIC, have been found in up to 80% of patients with liver disease without evidence of fibrinolysis (Van de Water, 1986). It is important that the diagnosis of DIC be made certain by determination of elevated blood D-dimer levels, as described in Part 5 on hemostasis and thrombosis. In some cases of liver failure, platelet counts are decreased because of sequestration in an enlarged spleen due to hepatosplenomegaly. This condition combined with elevated levels of PT and PTT caused by low levels of synthesis of coagulation factors can masquerade as DIC. In these cases, D-dimer levels are not elevated, excluding this diagnosis.

Perhaps the most frequently ordered laboratory test for detecting liver-associated coagulation abnormalities is PT and its associated measurement, the international sensitivity ratio, as described in Part 5. The PT measures the efficacy of the extrinsic clotting system in which factor VII is activated by tissue factor, as discussed in Part 5; because factor VII is uniquely synthesized in the liver, its measurement can be used to evaluate liver function status. Often, PT is computed as the international normalized ratio (INR), which attempts to standardize all PT measurements relative to a "gold standard" PT-measuring method, using the international sensitivity index (ISI), as described in Part 5.

Some Caveats in Using PT and INR to Evaluate Liver Function.

Because PT and PTT measure the status of the coagulation cascades (extrinsic and intrinsic, respectively), any coagulation disorder will give rise to abnormal PT and/or PTT, independent of liver function. In addition, in patients with cholestasis (i.e., disease of the biliary tract) with no hepatocytic dysfunction (e.g., cirrhosis, fulminant hepatic failure), absorption of fat-soluble vitamin K from the gut may be impaired because of low levels of bile salts that allow membrane transport of this vitamin. Because factors II, VII, IX, and X depend on vitamin K for biosynthesis via carboxylation, coagulation abnormalities often result. Therefore, in patients with cholestasis, normal serum levels of inactive precursor forms of these four coagulation factors can be detected, as discussed later. Correction of prothrombin time by the administration of vitamin K is usually possible when factor V is normal in patients with cholestatic liver disease.

Also, use of the INR in evaluating liver function can provide misleading results. As discussed in Part 5, the INR is based on PT values for patients treated with Coumadin (warfarin, which blocks mainly the extrinsic system). Thus its appropriateness for evaluating non-Coumadin-induced

coagulopathies has been questioned, especially in view of the finding that PT increases much less with lower ISI in patients with liver disease than in patients being treated with Coumadin (Kovacs, 1994; Ts'ao, 1994; Johnston, 1996; Robert, 1996).

Prothrombin Times Are Used to Compute the MELD Score. The PT is an integral part of the model for end-stage liver disease (MELD) score in evaluating priority for liver transplantation in liver disease (Trotter, 2004). This score is a computed number based on the values of bilirubin, creatinine, and INR and is applied in categories of 10 (i.e., scores of 40 or higher predict 100% mortality [30–39, 83%; 20–29, 76%; 10–19, 27%; <10, 4%]). Although this score appears to predict accurately the 3-month mortality for cirrhotic patients awaiting liver transplantation (Farnsworth, 2004), it must be used with caution both because reference ranges of these analytes differ among different laboratories, making standardization difficult, and because caveats are associated with using INR values, as described earlier.

Des- γ -Carboxy Prothrombin

The vitamin K–dependent coagulation factors (II, VII, IX, X) are synthesized in the liver and require a vitamin K–mediated posttranslational modification (γ -carboxylation of a number of terminal glutamic acid residues to γ -carboxyglutamic acid) to occur before secretion into the blood, which is necessary for functional activity of these factors in the coagulation cascade. The unmodified precursor of prothrombin, des- γ -carboxy prothrombin (DCP), has been found to be elevated in the sera of patients with hepatocellular carcinoma. DCP is measured using two monoclonal antibodies, 19B7 and MU-3. Recently, a new rapid immunoassay for DCP has been developed (Yamaguchi, 2008). Increases of DCP in patients with hepatocellular carcinoma predict decreased survival times (Nagaoka, 2003). However, assays for DCP do not have the same general use as α -fetoprotein, discussed later, for diagnosing and following this disease, although both analytes are sometimes assayed together in screening for and following this disease.

TESTS OF LIVER INJURY

PLASMA ENZYME LEVELS

As metabolically complex cells, hepatocytes contain high levels of a number of enzymes. With liver injury, these enzymes may leak into plasma and can be useful for diagnosis and monitoring of liver injury. Although enzymes were discussed in Chapter 20, an understanding of the cellular locations of enzymes and patterns of enzyme change is critical in understanding the findings in various types of liver disease.

Cellular Locations of Enzymes

Within the hepatocyte, the commonly measured enzymes are found in specific locations; the type of liver injury will determine the pattern of enzyme change. Figure 21-3 illustrates the locations of the most important hepatocytic enzymes. Cytoplasmic enzymes include lactate dehydrogenase (LD), aspartate aminotransferase (AST), and alanine aminotransferase (ALT). Mitochondrial enzymes, such as the mitochondrial isoenzyme of AST, are released with mitochondrial damage. Canalicular enzymes, such as alkaline phosphatase and γ -glutamyl transferase (GGT), are increased by obstructive processes.

Mechanisms of Enzyme Release

Enzymes are released from hepatocytes as a result of injury to the cell membrane that directly causes extrusion of the cytosolic contents. In addition, agents like ethanol cause release of mitochondrial AST from hepatocytes and its expression on cell surfaces (Zhou, 1998a). Accumulation of bile salts with canalicular obstruction causes release of membrane fragments with attached canalicular enzymes (Schlaeger, 1982; Moss, 1997). Increased synthesis of GGT, and to a lesser extent alkaline phosphatase, can occur with medications that induce microsomal enzyme synthesis, notably ethanol, phenytoin, and carbamazepine (Aldenhovel, 1988).

Aminotransferases (Transaminases)

Two diagnostically very useful enzymes in this category are AST, also known as serum glutamate oxaloacetate transaminase, and ALT, formerly called **serum glutamate pyruvate transaminase**. These enzymes catalyze reversibly the transfer of an amino group of AST or ALT to α -ketoglutarate to yield glutamate plus the corresponding ketoacid of the starting amino acid (i.e., oxaloacetate or pyruvate, respectively). Both enzymes require

Figure 21-3 Location of hepatocellular enzymes. The major diagnostic hepatocellular enzymes are located at various sites in the hepatocyte, giving rise to different patterns of enzyme release with different causes of injury. Alanine aminotransferase (ALT) and the cytoplasmic isoenzyme of aspartate aminotransferase (ASTc) are found primarily in the cytosol. With membrane injury as in viral or chemically induced hepatitis, these enzymes are released and enter the sinusoids, raising plasma AST and ALT activities. Mitochondrial aspartate aminotransferase (ASTm) is released primarily with mitochondrial injury, as caused by ethanol as in alcoholic hepatitis. Alkaline phosphatase (ALP) and γ -glutamyl transferase (GGT) are found primarily on the canalicular surface of the hepatocyte. Bile acids accumulate in cholestasis and dissolve membrane fragments, releasing bound enzymes into plasma. GGT is also found in the microsomes, represented as pink rings in the figure; microsomal enzyme-inducing drugs, such as phenobarbital and Dilantin, can also increase GGT synthesis and raise plasma GGT activity.

pyridoxal phosphate (vitamin B₆) as a cofactor. Using ALT as an example, alanine reacts with pyridoxal phosphate to yield pyruvate plus pyridoxine. Pyridoxine then reacts with α -ketoglutarate to yield glutamate plus regenerated pyridoxal phosphate.

At the core of these reactions is the cofactor, pyridoxal phosphate (vitamin B₆). In many of the serum assays for ALT and AST, it is assumed that the patient's serum provides a sufficient complement of pyridoxal phosphate, a circumstance that does not always apply. In a most poignant case illustrating this point, a patient, a known alcoholic, was admitted to a hospital with a presumptive diagnosis of alcoholic hepatitis, a condition described at length later. His admission clinical chemistry profile showed normal to low serum levels of ALT and AST. This finding is unusual in alcoholic hepatitis because, as we discuss later, both enzymes become significantly elevated such that AST levels are higher than those for ALT. During the course of the next 24 hours, he was treated for his condition, with apparent clinical improvement. However, a repeat liver function profile showed marked elevations of both enzymes to levels greater than 200 IU/L. This presented a diagnostic dilemma, which was resolved when it was realized that, as part of the protocol for treatment of alcoholic hepatitis, the patient had received vitamin supplements, including vitamins B₆ and B₁₂. Because the serum assays for both ALT and AST required vitamin B₆ supplied by the patient's serum, and the patient, an alcoholic, was vitamin B₆ deficient (common in alcoholics), the assays for both enzymes showed normal to low levels caused by the absence of vitamin B₆. Upon therapeutic intervention, when vitamins were administered, sufficient serum levels of vitamin B₆ were present to allow full enzyme activities. This clinical history illustrates the central role of pyridoxal phosphate in enzyme catalysis by AST and ALT, and the importance of understanding the chemical basis for enzyme assays.

AST and ALT have respective blood half-lives of 17 and 47 hours, respectively, and have upper reference range limits of around 40 IU/L. (See Chapter 20 for the definition of international units, or IU.) AST is both intramitochondrial and extramitochondrial, but ALT is completely extramitochondrial. Mitochondrial AST isoenzyme has a half-life of 87 hours (Panteghini, 1990). AST is ubiquitously distributed in the body tissues, including the heart and muscle, whereas ALT is found primarily in the liver, although significant amounts are also present in the kidney.

Total cytoplasmic AST is present in highest activity in hepatocytes, with cell AST level approximately 7000 times that in plasma. ALT is also present in highest activity in hepatocytes, with cell ALT level approximately 3000 times that in plasma. With pyridoxine deficiency, hepatic synthesis of ALT is impaired; a similar phenomenon occurs in hepatic fibrosis and cirrhosis. The enzyme changes seen in hepatic injury can be readily explained by differing hepatic activity levels and half-lives of enzymes. With most forms of acute hepatocellular injury, such as hepatitis, AST will be higher than ALT initially because of the higher activity of AST in hepatocytes. Within 24–48 hours, particularly if ongoing damage occurs, ALT will become higher than AST, based on its longer half-life.

An exception to these observations is seen in acute alcohol-induced hepatocyte injury, as in alcoholic hepatitis. Studies suggest that alcohol induces mitochondrial damage, resulting in the release of mitochondrial AST, which, besides being the predominant form of AST in hepatocytes, has a significantly longer half-life than do extramitochondrial AST and ALT. This frequently results in the disproportionate elevation of AST over ALT, yielding an AST/ALT quotient, also called the **DeRitis ratio**, of 3–4:1 in alcohol-induced liver disease. Whether cessation of alcohol consumption reduces this ratio is a topic of disagreement. In one early study, serum mitochondrial AST was measured in cirrhotic and noncirrhotic patients who abused alcohol (Nalpas, 1986). Patients with chronic alcohol abuse, regardless of the extent of their underlying liver disease, had more consistent mitochondrial AST elevations than other patients; values dropped by more than 50% with abstinence for longer than 1 week. On the other hand, in more recent studies, involving more than 300 patients, it was found that high AST/ALT ratios suggest advanced alcoholic liver disease (Nyblom, 2004). It should also be noted that many alcoholics are vitamin B₆ deficient, causing lower rates of synthesis of ALT and suppression of existing ALT activity.

In chronic hepatocyte injury, mainly in cirrhosis, ALT is more commonly elevated than AST; however, as fibrosis progresses, ALT activities typically decline, and the ratio of AST to ALT gradually increases, so that by the time cirrhosis is present, AST is often higher than ALT (Williams, 1988; Sheth, 1998). However, in end-stage cirrhosis, the levels of both enzymes generally are not elevated and may be low as the result of massive tissue destruction. In acute fulminant hepatic failure, as discussed later and in Chapter 8, the serum levels of both aminotransferases are markedly increased and are such that the AST/ALT ratio is often significantly greater than 1 (Sunheimer, 1994).

Overall, ALT activity is more specific for detecting liver disease in nonalcoholic, asymptomatic patients. Mild elevations are often seen in hepatitis C infection. AST is used for monitoring therapy with potentially hepatotoxic drugs; a result more than three times the upper border of normal should signal stopping of therapy. Chronic elevation of aminotransferase activities in asymptomatic patients may have several causes, including alcohol or medication use, chronic viral hepatitis, or nonalcoholic fatty liver disease. Weight reduction may lower ALT in overweight patients whose ALT is elevated (Palmer, 1990). Ursodeoxycholic acid lowers ALT as well as GGT (see later) when these are found to be elevated in blood donors (Bellentani, 1989).

Assays for AST and ALT

Several variants of assays can be used with these enzymes. In one, alanine for ALT or aspartate for AST is added to force the reaction to the right, yielding glutamate. Production of the latter is then coupled to the enzyme glutamate dehydrogenase, in the so-called **indicator reaction**, yielding α -ketoglutarate. In this reaction, nicotinamide adenine dinucleotide (NAD) is converted to NADH (reducing agent derived from NAD), which can be measured as an increase in absorbance at 340 nm. These reactions must be evaluated over short periods because one of the substrates for these enzymes, α -ketoglutarate, is regenerated by the indicator reaction. Another variant for AST involves coupling the oxaloacetate (OAA) that is formed from aspartate in the reaction to malate dehydrogenase, which converts OAA to malate, and in which NADH is converted to NAD that is measured by a decrease in absorbance at 340 nm. For ALT, conversion of alanine to pyruvate allows coupling to the pyruvate dehydrogenase complex in which pyruvate is converted to acetyl coenzyme A, and in which NAD is converted to NADH that can be directly measured by an increase in absorbance at 340 nm. As noted earlier, it is vital that pyridoxal phosphate be present in sufficient quantity to allow these reactions to proceed.

Lactate Dehydrogenase

As described in Chapter 20, this cytosolic glycolytic enzyme catalyzes the reversible oxidation of lactate to pyruvate. As discussed in Chapter 18, five

major LD isozymes exist, consisting of tetramers of two forms, H and M, the former having high affinity for lactate, the latter for pyruvate. Progressing from HHHH to MMMM, the five possible isozymes are labeled LD₁–LD₅. LD₁ and LD₂ predominate in cardiac muscle, kidney, and erythrocytes. LD₄ and LD₅ are the major isoenzymes in liver and skeletal muscle. The upper reference range limit for total LD activity in serum is around 150 IU/L (see Chapter 20 for the definition of international units, or IU). Serum LD levels become elevated in hepatitis; often, these increases are transient and return to normal by the time of clinical presentation (Dufour, 1988c; Singer, 1995; Fuchs, 1998) because LD isozymes originating in liver (LD₄ and LD₅) have relatively low activity in hepatocytes relative to plasma (about 500 times) and a half-life of approximately 4–6 hours.

More important is the large increase in total LD to levels of 500 IU/L or more, combined with a significant increase in alkaline phosphatase (ALP), discussed later and in Chapter 20, to levels >250 IU/L, in the absence of other dramatic abnormalities in liver function enzyme levels, especially AST and ALT. These selective increases often accompany space-occupying lesions of the liver, such as metastatic carcinoma and primary hepatocellular carcinoma or, rarely, benign lesions, such as hemangiomas and adenomas. The source of the LD, most often the LD₅ isozyme, is not clear because it can originate from hepatocytes, from the tumor, or from both. The rise in ALP is due to blockage of local canaliculi and ductules by the masses in the liver, as discussed later. Assays for LD are described in Chapter 20.

Enzymes Primarily Reflecting Canalicular Injury

As shown in Figure 21-3, these enzymes are located predominantly on the canalicular membrane of the hepatocyte and include alkaline phosphatase, γ -glutamyl transferase, and 5'-nucleotidase. In contrast to cytoplasmic enzyme activities, canalicular enzyme activities within hepatocytes are typically quite low; focal hepatocyte injury seldom causes significant increases in canalicular enzyme levels.

Alkaline Phosphatase

As discussed at length in Chapter 20, ALP is present in a number of tissues, including liver, bone, kidney, intestine, and placenta, each of which contains distinct isozymes that can be separated from one another by electrophoresis. Total ALP in serum is mainly present in the unbound form and, to a lesser extent, is complexed with lipoproteins or rarely with Igs.

ALP in the liver, which has a half-life of about 3 days, is a hepatocytic enzyme that is found on the canalicular surface and is therefore a marker for biliary dysfunction. The bone isozyme is particularly heat labile, allowing it to be distinguished from the other major forms. In addition, small intestinal and placental ALP is antigenically distinct from liver, bone, and kidney ALP. The bulk of ALP in the serum of normal patients is made up of liver and bone ALP.

In obstruction of the biliary tract by stones in the ducts or ductules, or by infectious processes resulting in ascending cholangitis, or by space-occupying lesions, biliary tract ALP rises rapidly to values sometimes in excess of 10 times the upper limit of normal. The reasons for this increase probably include a combination of increased synthesis and decreased excretion of ALP. In obstructive cholestasis, ALP most commonly rises to twice the upper limit of normal or greater, roughly paralleling the rate of rise in serum bilirubin. If obstruction is partial, ALP usually increases as much as with complete obstruction, often out of proportion to the increase in conjugated bilirubin (dissociated jaundice). Passive congestion of the liver can occasionally result in moderate ALP elevations, more so than abnormal bilirubin levels. ALP is also moderately elevated in most instances of jaundice resulting from hepatic injury. When the resulting cholestasis is relieved, serum ALP levels fall to normal more slowly than bilirubin.

A high molecular weight ALP appears in serum in cholestasis. This ALP is attached to fragments of canalicular membrane. Bile salts solubilize the enzymes from the sinusoidal and canalicular membranes. In serum, the membrane-bound enzymes aggregate with lipids and lipoproteins. This may explain the relationship that has been observed, for instance, with LpX (see Chapter 17). Another form of high molecular weight ALP, which migrates differently on electrophoresis from the isozyme just described, has been found in malignant disease involving the liver (Viot, 1983).

Intestinal ALP is increased in a variety of disorders of the intestinal tract and in cirrhosis. Serum intestinal ALP is detected in more than 80% of cirrhotic patients as compared with 10% of normal controls. Measurement of this enzyme activity was suggested as one method of discriminating intrahepatic from extrahepatic jaundice, because intestinal

ALP may be absent in extrahepatic obstruction, but it lacks adequate sensitivity and specificity (Collins, 1987). Assays for ALP are described in Chapter 20.

γ -Glutamyl Transferase

This enzyme regulates the transport of amino acids across cell membranes by catalyzing the transfer of a glutamyl group from glutathione to a free amino acid. Its major use is to discriminate the source of elevated ALP (i.e., if ALP is elevated and GGT is correspondingly elevated, then the source of the elevated ALP is most likely the biliary tract). The highest values, often greater than 10 times the upper limit of normal, may be found in chronic cholestasis due to primary biliary cirrhosis or sclerosing cholangitis. This enzyme is also elevated in about 60%–70% of those who chronically abuse alcohol, with a rough correlation between amount of alcohol intake and GGT activity (Whitehead, 1978). Levels often decline slowly with abstinence from alcohol and remain elevated for at least 1 month after abstinence begins (Belfrage, 1977; Moussavian, 1985). GGT has a half-life of 10 days, but, in recovery from alcohol abuse, the half-life may be as long as 28 days. It tends to be higher in obstructive disorders and with space-occupying lesions in the liver than with hepatocyte injury (Kim, 1977).

The gene for human GGT has been cloned and the nucleotide sequence identified (Rajpert-De Meyts, 1988). GGT can be detected in three major forms in serum (Wenham, 1985), but such determinations are not readily available. A high molecular mass form is present in normal serum, as well as in biliary obstruction, and more frequently in malignant infiltration of the liver. An intermediate molecular mass form consists of two fractions—the major one detected in liver disease and the other one found in biliary obstruction. Determination of these fractions lacks sufficient sensitivity and specificity to be worthwhile (Collins, 1987). The third form is a low molecular mass compound of uncertain importance.

Serum levels of GGT differ from those of ALP during pregnancy, in which GGT remains normal even during cholestasis in pregnancy. GGT is often increased in alcoholics even without liver disease; in some obese people; and in the presence of high concentrations of therapeutic drugs, such as acetaminophen and phenytoin and carbamazepine (increased up to five times the reference limits), even in the absence of any apparent liver injury. Possibly, increases in GGT occur to restore glutathione used in the metabolism of these drugs, which may account for the elevated GGT activities assayed. Glutathione is conjugated to these drugs via the glutathione S-transferase system, and the complex is then excreted.

Most assays for GGT utilize the substrate γ -glutamyl-p-nitroanilide. In the reaction catalyzed by GGT, p-nitroaniline is liberated and is chromogenic, enabling this colored product to be measured spectrophotometrically.

Other Enzymes

5'-Nucleotidase activity is increased in cholestatic disorders with virtually no increase in activity in patients with bone disease. This enzyme is discussed further in Chapter 20. Measurement of 5'-nucleotidase can corroborate the elevation of ALP from a hepatic source. Other enzymes, such as **leucine aminopeptidase (LAP)**, can be used for the same purpose but virtually never are. **Isocitrate dehydrogenase** and **OCT** (the latter unique to the liver) activities are elevated in hepatocellular injury and parallel ALT and AST. Again, as with LAP, they are virtually never used in routine laboratory assays.

α -FETOPROTEIN

α -Fetoprotein (AFP) is synthesized by embryonic hepatocytes and fetal yolk sac cells and peaks in the second trimester of pregnancy, reaching levels that constitute up to one third of fetal serum protein. The function of AFP is not known. It may be immunosuppressive, preventing fetal destruction by circulating maternal antibodies.

As discussed in Chapter 25, AFP becomes elevated to abnormal levels in fetal neural tube deficits. The reasons for this correlation are unclear. It is important to note that normal AFP levels vary considerably with gestational age. Therefore, the decision that the serum level of this protein is abnormally high will depend on the reference interval for the gestational age of the patient. Shortly after birth, AFP levels fall, reaching the adult normal range at around 1 year of age. After acute hepatic injury, a rise in AFP (typically 100–200 ng/dL) from regenerating hepatocytes usually occurs. Often, however, these typical elevations after acute hepatic insults do not occur after surgical resection of the liver. Regeneration is therefore not a sufficient impetus for the occurrence of elevated AFP levels.

As discussed in Chapter 73, AFP has been found to be an important marker for hepatocellular carcinoma (HCC) (Zhou, 2006). Elevated levels occur in more than 90% of patients with this disease. As noted previously, elevated levels can also occur after acute liver disease and fibrosis, making this marker somewhat nonspecific. However, at levels >400 ng/dL, there is a high probability of HCC, but at these levels of AFP the tumor is widespread, so its use as an early detector of HCC is limited. Recent studies have shown that serial measurements of AFP in those with HCC receiving chemotherapy may serve as a good prognostic tool (Chan, 2009). Serum levels of AFP in HCC are also dependent on the extent and degree of differentiation of the tumor and the age of the patient. In addition, α -fetoprotein has been used as a marker for rare germ cell tumors, especially yolk sac (endodermal sinus) tumors of infants, and other even rarer tumors such as Sertoli–Leydig cell tumors (Watanabe, 2008).

AUTOIMMUNE MARKERS

Antimitochondrial Antibody Is a Marker for Primary Biliary Cirrhosis

Occasionally, autoimmune disease may be the primary cause of liver injury. The most common autoimmune liver disease is primary biliary cirrhosis (PBC), which occurs primarily in women, usually in the fifth decade, often accompanied by other autoimmune diseases (especially Sjögren's syndrome). There is a strong association of occurrence of this disease among siblings. This condition, which is discussed at length in Chapter 53, causes fibrosis of the bile canaliculi in the portal triads. Bile eventually seeps into hepatocytes, causing necrosis. Granulation tissue replaces hepatocytes, so that fibrosis eventually spreads into the liver parenchyma, giving rise to the pattern of fibrosis and regenerating nodules. A similar course occurs in secondary biliary cirrhosis as a result of other underlying conditions such as choledocholithiasis, carcinoma of the head of the pancreas, and, occasionally, hepatitis and sepsis.

A vital difference between primary and secondary biliary cirrhosis is that the former uniquely appears to be part of a generalized autoimmune condition. More than 90% of patients with primary biliary cirrhosis are found by immunofluorescence to have serum antibodies that react with liver, kidney, stomach, and thyroid tissue. These circulating antibodies, which can be detected in serum using an enzyme-linked immunosorbent assay, are directed against mitochondrial antigens (anti-mitochondrial antigen [AMA]) from the inner mitochondrial membrane, called **M2**, which has been found to be dihydrolipoamide acetyltransferase, a component of the pyruvate dehydrogenase multienzyme complex (Kaplan, 1984; Coppel, 1988; Krams, 1989). Antimitochondrial antibodies have been found in a variety of disease states, but two anti-M2 antibodies in primary biliary cirrhosis uniquely react either with a protein of molecular mass 62 kilodalton (kDa)—the E2 subunit of pyruvate dehydrogenase (Manns, 1987; Fussey, 1988), the predominant autoantibody—or with a 48-kDa E2 subunit of branched-chain oxo-keto-acid dehydrogenase. In other disorders, AMA against M1 antigen has been found in syphilis, anti-M5 in collagen vascular disease, anti-M6 in iproniazid-induced hepatitis, and anti-M7 in cardiomyopathy (Berg, 1986). AMA with anti-M2 specificity is 100% specific for primary biliary cirrhosis.

In a recent human genome-wide study (see Chapter 77), DNA samples from more than 500 patients with this condition and a control group were genotyped for more than 300,000 single-nucleotide polymorphisms (SNPs). This analysis revealed that PBC has a strong association with two SNPs in the HLA-2 region, particularly in the gene encoding interleukin (IL)-12, and a more modest but significant association with SNPs at the signal transducer and activator of transcription 4 (STAT4) locus and the CTLA4 locus, encoding cytotoxic T lymphocyte-associated protein 4. These results now implicate IL-12 signaling and CD4-positive helper T cells in the pathogenesis of this condition (Hirschfield, 2009).

ANCA Is a Marker for Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is an autoimmune disease associated with destruction of extrahepatic and intrahepatic bile ducts. More than 80% of patients with this disease have circulating perinuclear antineutrophil cytoplasmic antibodies (p-ANCA) (Chapman, 2005) with specificities against antigens such as bactericidal/permeability-increasing protein, cathepsin G, and/or lactoferrin (Mulder, 1993; Roozendaal, 1998). Up to

75% also have other autoantibodies such as antinuclear antibodies (ANAs) or anti-smooth muscle antibodies (ASMAs) (Chapman, 1986). There is some question as to whether pANCA, which is a reliable indicator of large cholangiole disease, can likewise serve as a reliable biomarker for PSC involving small cholangioles (Tervaert, 2009). Unlike primary biliary cirrhosis, PSC occurs primarily in young to middle-aged men and is often associated with inflammatory bowel disease, particularly ulcerative colitis.

Serum Markers for Autoimmune Hepatitis

Autoimmune hepatitis is responsible for as much as 3%–5% of chronic hepatitis and occasionally may present as acute hepatitis. Several variants of autoimmune hepatitis are associated with various markers (Czaja, 1995a,b). In the United States, the most common variant, type 1, is associated with ANAs most commonly, and also with antibodies to actin (often detected as ASMAs). Titers of AMAs and/or ASMAs greater than 1:80 support the diagnosis in patients with hepatitis (Johnson, 1993). Type 2 autoimmune hepatitis typically affects children and is much more common in Europe than in the United States, where it is rarely encountered. ANAs and ASMAs are often negative in type 2, and antibodies to liver-kidney microsomal antigens are positive in most cases. Lower-level titers of ANAs or ASMAs are commonly seen in other forms of liver disease, particularly hepatitis C, in which they may be found in up to 40% of cases (Czaja, 1995a,b). Both types of autoimmune hepatitis affect females predominantly.

TESTING FOR VIRAL-INDUCED HEPATITIS

Numerous viruses cause liver damage. Some, such as hepatitis A, B, and C viruses and the arboviruses, are hepatotoxic, but others, such as Epstein-Barr virus, cytomegalovirus, varicella zoster virus, herpes simplex virus, human herpesvirus 6, human immunodeficiency virus (HIV), adenovirus, and echovirus, induce transient to moderately aggressive hepatitis. Even newly identified hepatitis G causes only a self-limited form of hepatitis. In actuality, viruses are the cause of 80%–90% of acute and chronic hepatitis. Although a variety of such viruses can affect the liver, most viral-induced liver pathology is caused by five viruses that are known to cause hepatocyte injury and are termed **hepatitis viruses**, namely, hepatitis A, B, C, D, and E.

Hepatitis A

Hepatitis A virus (HAV) is a member of the picornavirus family of RNA viruses. It is transmitted by the fecal–oral route and typically has an incubation period of 15–50 days with a mean time of about a month, dependent upon the inoculum (Brown, 2003). Epidemics or clusters of HAV infection often occur with conditions of poor sanitation, in day care centers, with military actions, and from contaminated food. Epidemics of HAV occur generally in crowded urban areas, especially where there is a preponderance of uncooked food. Infection with HAV is almost always self-limiting, although in 5%–10% of cases a secondary rise in enzymes occurs. The time course of markers of HAV infection is shown in Figure 21-4.

During the incubation period, HAV RNA is present in stool and in plasma and remains detectable for an average of 18 days after clinical onset of hepatitis (Fujiwara, 1997). The initial immune response to the virus is IgM anti-HAV, which typically develops about 2–3 weeks after infection; increasing AST and ALT develop after antibody development. IgM antibodies typically persist for 3–6 months after infection. The presence of elevated titers of IgM anti-HAV is considered to be diagnostic of acute infection, although some apparently false-positive results have been found (Funk, 2005), resulting in the recommendation that only symptomatic individuals be screened for acute infection using IgM titers. IgG antibodies develop within 1–2 weeks of IgM antibodies and typically remain positive for life (Skinhoj, 1977).

“Total” anti-HAV assays detect both IgM and IgG antibodies. The prevalence of total anti-HAV varies, ranging from 5%–10% in children younger than 5 years to 75% in those older than 50 years of age (Koff, 1995). Following HAV immunization, using attenuated hepatitis A virus, detectable antibody develops in 2–4 weeks and persists to 5 years in 99% of responders (Totos, 1997). Similar protection from the use of Igs in passive immunization seems to occur, although this conclusion is tentative (Liu, 2009). If necessary for epidemiologic purposes, polymerase chain reaction (PCR) assays are available to identify HAV RNA in plasma and stool. There is no need, however, to incorporate the use of PCR for routine diagnostic purposes.

Figure 21-4 Typical time course for appearance of viral antigens and antiviral antibodies in hepatitis A viral (HAV) infection. The appearance of the hepatitis A antigen, HAAg, occurs early on; it is no longer present during the acute phase, during which time jaundice may develop. During the incubation period (which averages 2–3 weeks), HAV RNA is replicating, and viral particles can be detected in stool by immune electron microscopy. Viral RNA is also detectable during this time by real-time polymerase chain reaction (PCR). The most effective diagnostic determination of hepatitis A acute infection is the detection of anti-HAV immunoglobulin (IgM). Also shown in this figure is the rise of the aminotransferases, aspartate aminotransferase (AST) and alanine aminotransferase (ALT), which occurs at the beginning of the early acute phase and lasts for several weeks to 1–2 months. The patient ceases to be infectious after anti-HAV IgM falls to undetectable levels in 3–6 months post early phase. Permanent anti-HAV IgG rises over several months and lasts for many years, conferring immunity on the exposed or infected individual. (Adapted from Abbott Laboratories Diagnostic Educational Services. Hepatitis A diagnostic profile. North Chicago, Ill.: Abbott Labs; 1994, with permission.)

Hepatitis B

Hepatitis B virus (HBV) is a member of the hepadnavirus (i.e., hepatodna virus) family, a group of related DNA viruses that cause hepatitis in various animal species. This virus causes infection of the liver with clinical features that are extremely variable, ranging from absent or mild disease to severe liver failure (Horvat, 2003). Viral particles attach to host cells by an unknown receptor, where they enter the cell by receptor-mediated endocytosis and are transferred to the nucleus by so-called **chaperone proteins**.

Once in the nucleus, HBV replicates by an unusual mechanism (Beck, 2007; Kay, 2007). The viral DNA is partially duplex and consists of a shorter plus strand and a longer minus strand. It consists of four known genes: **C**, that encodes the core protein; **X**, whose protein product is unknown; **P**, that encodes DNA polymerase; and **S**, that encodes the surface protein, also called the **surface antigen**. The latter consists of three open reading frames, giving rise to three types of surface proteins—large, middle, and small. During viral replication, the two unequal strands elongate and become circular. Several messenger RNAs (mRNAs) are transcribed, and the longest is longer than the original coding DNA. This mRNA is secreted into the cytosol, where it is involved in the replication of more virions, requiring the use of **reverse transcriptase**, as in retroviruses. Thus HBV replication requires reverse transcriptase, making it susceptible to reverse transcriptase inhibitors. Four serotypes of HBV (adr, adw, ayr, ayw) and eight genotypes, some of which occur in geographically different regions, have different virulences and may respond differently to different treatment modalities (Kramvis, 2007).

Hepatitis B is transmitted primarily by body fluids, especially serum; however, it is also spread effectively by sex and can be transmitted from mother to baby. Hepatitis B produces several protein antigens that can be detected in serum: a core antigen (HBcAg), a surface antigen (HBsAg or HBs), and e antigen (HBeAg), related to the core antigen; commercial assays are available for HBsAg and HBeAg. Antibodies to each of these antigens can also be measured, and commercial assays for each are available. The time course of self-limited infection with HBV is illustrated in

Figure 21-5 Typical time course for appearance of viral antigens and antiviral antibodies in hepatitis B viral (HBV) infection. In the early acute phase, the HBV surface antigen (HBsAg) (red curve) appears and lasts for several months. Detection of this antigen signifies acute HBV infection. Between the time the titer of HBsAg falls and the titer of anti-HBV immunoglobulin (IgG) (dark blue curve), which confers immunity, rises, there is a gap of about 6 months. In this time period, the titers of anti-HBV core antigen (anti-HBc) IgM (purple curve) and IgG (black curve) rise, indicating acute HBV infection. This is the so-called **core window**. IgG anti-HBV e antigen (anti-HBe) (cyan or light blue curve) also rises during this core window period. Permanent immunity is conferred by anti-HBsAg IgG (anti-HBs) (dark blue curve). It is difficult to determine the time at which the patient is no longer infectious. Generally, an individual is considered noninfectious when no HBsAg or HBeAg, and no anti-HBcAg IgM, can be detected, and the anti-HBsAg IgG has plateaued. Also shown in this figure is the pattern of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) elevations. These occur in the early acute phase, slightly after HBsAg rises. AST and ALT levels may remain elevated for several weeks to several months, after which time they decline. In HBV chronic active hepatitis, HBsAg is present continuously. AST and ALT generally remain elevated, although they can oscillate throughout the course of the disease. (Adapted from Abbott Laboratories Diagnostic Educational Services. *Hepatitis B diagnostic profile*. North Chicago, Ill.: Abbott Labs; 1994, with permission.)

Figure 21-5. Different groups of tests are recommended for three different clinical situations as follows:

1. Acute HBV hepatitis: HBsAg, IgM anti-HBc.
2. Chronic HBV hepatitis: HBsAg, IgG anti-HBc, IgG anti-HBs
3. Monitoring chronic HBV infection: HBs, HBeAg, IgG anti-HBs, IgG anti-HBe, and ultrasensitive quantitative PCR.

The initial serologic marker of acute infection is HBsAg, which typically becomes detectable 2–3 months after infection. After another 4–6 weeks, IgM anti-HBc appears, accompanied by increases in AST and ALT. When symptoms of hepatitis appear, most patients still have detectable HBsAg, although a few patients have neither detectable HBs nor anti-HBs, leaving anti-HBc the only marker of infection (**core window**). IgM anti-HBc typically persists for 4–6 months; however, it may be intermittently present in patients with chronic HBV infection (Czaja, 1988).

In most individuals, HBV hepatitis is self-limited, and the patient recovers; about 1%–2% of normal adolescents and adults have persistent viral replication, which causes chronic hepatitis. The frequency of chronic HBV infection is 5%–10% in immunocompromised patients and 80% in neonates, with the likelihood of chronic infection declining gradually during the first decade of life. With recovery from acute infection, HBsAg and HBeAg disappear, and IgG anti-HBs and IgG anti-HBe appear; development of anti-HBs is typically the last marker in recovery and is thought to indicate clearance of virus. Anti-HBs and anti-HBc are believed to persist for life, although in about 5%–10% of cases anti-HBs ultimately disappears (Seeff, 1987). Isolated anti-HBc can also occur during periods of viral clearance in acute and chronic hepatitis, and as a false-positive result. The titer of anti-HBc is important in determining its significance; low titers are typically false-positive results, and high titers almost always (50%–80% of cases) indicate immunity to HBV infection, as demonstrated by an anamnestic response to hepatitis B vaccine (Aoki, 1993).

The newest assay to assess HBV infection is the ultrasensitive quantitative real-time PCR technology, which is discussed extensively in Part 8. This quantitative HBV DNA PCR detects a highly conserved region of the surface gene at a level as low as 200 copies of viral genome per mL

(0.001 pg/mL) with a range up to 2×10^8 copies/mL. Its primary use is to monitor therapeutic responsiveness in clinically infected patients.

Also available is the quantitative digene hybrid capture assay, which employs a signal amplification antibody capture microplate test that utilizes chemiluminescent detection. But this quantitative HBV PCR technique utilizes an RNA probe and has detection limits of 5000 copies/mL (0.02 pg/mL), making it less sensitive than the ultraquantitative assay, although branched-DNA assays, discussed in Chapter 66, are also used widely, with detection limits of 2000 copies/mL. Patients who have clinically recovered from HBV infection and are anti-HBs positive have no detectable HBV DNA using most assays.

Using sensitive PCR assays, circulating HBV DNA can be found in a high percentage of anti-HBs-positive patients who have clinically recovered from HBV infection (Cabrerizo, 1997; Yotsuyanagi, 1998), as well as in patients with hepatitis C and isolated anti-HBc (Cacciola, 1999). The significance of finding low levels of HBV DNA is not known, although in patients with concurrent hepatitis C viral infection this finding may be associated with more severe liver damage. The e antigen has historically been used to detect the presence of circulating viral particles; a good correlation has been noted between levels of HBeAg and amount of HBV DNA (Hayashi, 1996). In chronic HBV infection, approximately 1%–1.5% of patients will spontaneously clear HBeAg each year; some will recover, but others enter a nonreplicative phase in which HBV DNA integrates into the cell genome. This transition phase is often associated with a rise in AST and ALT and, occasionally, jaundice. Rarely, HBeAg may again be detectable in plasma in such patients. Patterns of HBV markers and their interpretation are shown in Table 21-1.

Hepatitis C

Hepatitis C (HCV) is an RNA virus of the flavivirus group consisting of an icosahedral viral protein coat, embedded in cellular lipid and surrounding RNA. The viral RNA encodes a single protein with more than 3000 amino acids that is then processed into individual proteins using viral and host cellular proteases. These include two core proteins, E1 and E2, and

a series of proteins labeled as NS1–5. NS2 is a transmembrane protein, NS3 contains protease and RNA helicase activities, and NS4A and B proteins are known cofactors; NS5A is an interferon-resisting protein, and NS5B is RNA polymerase. The virus has a tropism for hepatocytes that it enters via specific receptors, including CD 81 protein. Once inside the hepatocyte, HCV initiates the lytic cycle utilizing the intracellular translational machinery required for its replication (Lindenbach, 2005). Replication using NS5B RNA polymerase produces a negative-strand RNA intermediate, which then serves as a template for the production of new positive-strand viral genomes. Because viral replication does not involve proofreading, the mutation rate for HCV is high. On the basis of sequencing studies, six genotypes, labeled 1–6, that have been further divided into subgroups (e.g., 1a, 1b, 2a, 2b) have been recognized. Genotype 1a predominates in North America, and 1b predominates in Europe. Genotypes 4 and 5 are unique to Africa. It is important to note that genotypes 1 and 4 are more resistant to interferon therapy than are the other genotypes, resulting in longer treatment times (48 vs. 24 weeks). Thus genotyping has therapeutic implications.

HCV, formerly known as non-A, non-B hepatitis, is the primary etiologic agent, transmitted via blood transfusions and transplantation before 1990. At present, 60% of all new cases occur in injection drug users, but other serum modes of transmission are also seen, such as accidental needle punctures in health care workers, dialysis procedures in patients, and, rarely, transmission from mother to infant. Although sexual transmission is thought to be an inefficient means of transmitting infection, it nevertheless accounts for at least 10% of new cases. Monogamous sexual partners of HCV-infected patients rarely become infected, although a history of multiple sexual partners has been recognized as a risk factor. In contrast to HAV and HBV, chronic infection with HCV occurs in about 85% of infected individuals, with an estimated 4 million individuals chronically infected in the United States alone (Alter, 1999). About half of HCV chronically infected individuals with persistent viremia will have elevated ALT levels. Physical symptoms are absent for the first two decades after infection. As the disease progresses, inflammation and liver cell death can lead to fibrosis, and in about 20% of patients, fibrosis will advance to cirrhosis. The risk for HCC in a patient with chronic HCV is about 1%–5% after 20 years. HCC is seen only in patients with cirrhosis (Shuhart, 2003). Laboratory tests for HCV infection and their common uses are summarized in Table 21-2.

HCV has not been grown in culture; however, HCV genomes can be amplified by recombinant technology. A number of structural and non-structural antigens have been identified. An immunoassay for the core antigen of HCV has been developed (Aoyagi, 2001) but has been found to

be less sensitive than HCV RNA assays (Krajden, 2004). The major diagnostic test for HCV infection has been the second-generation anti-HCV, which detects the presence of antibody to one of four different viral antigens at an average of 10–12 weeks after infection (Alter, 1992a). A third-generation anti-HCV assay detects antibody at an average of 7–9 weeks after infection (Barrera, 1995). IgM anti-HCV is present in both acute and chronic HCV infection and is therefore not helpful diagnostically (Brillanti, 1993). Total anti-HCV typically persists for life, although it may disappear with recovery from HCV infection (Seeff, 1994; Beld, 1999).

In high-risk populations, the predictive value of anti-HCV for HCV infection is over 99%, so that further testing is not typically needed to prove viral exposure (Pawlotsky, 1998). In low-risk populations, such as blood donors, the predictive value of positive anti-HCV is only 25%. In low-risk patients, or when needed to confirm HCV exposure, supplemental tests for anti-HCV should be used. The HCV recombinant immunoassay test uses recombinant HCV proteins isolated in a dot or strip blot assay; this is analogous to Western blot tests used to confirm positivity in other types of infectious disease. Using the second-generation RIBA-2 assay, the presence of antibodies to two (of four) or more HCV antigens is considered a positive result, and the absence of antibodies is considered negative; an antibody to one antigen or an antibody to more than one antigen and the nonspecific marker superoxide dismutase are considered indeterminate results. In the third-generation RIBA assay, isolated antibody to the NS5 antigen is virtually never associated with HCV viremia, suggesting that it may indicate a false-positive result (Vernelen, 1994; LaPerche, 1999).

The primary test for confirming persistence of HCV infection is HCV RNA, detected by a variety of amplification techniques. Quantitative assays can typically detect as few as 1000 copies/mL; however, results from different assays are not interchangeable, and detection limits vary between methods (Ravaggi, 1997; Lunel, 1999). Qualitative HCV RNA assays generally have lower limits of detection compared with quantitative methods using the same amplification technique, are less expensive, and are more useful for detecting the presence or absence of infection.

A World Health Organization standard has been developed to improve comparability between methods (Saldanha, 1999) and is based on an international unit or IU/mL of serum or plasma and on recently developed real-time PCR techniques, which have a detection range of 5–200,000,000 IU/mL, thereby eliminating the need to obtain qualitative and quantitative levels. In a recent study (Shiffman, 2003), it was found, using the international standard, that approximately 90% of serum values for HCV RNA were within 1 log unit, irrespective of which virologic assay was used. However, significant differences in results have been found, a few samples giving a maximum of 2 log unit differences (factor of 100). Such discrepant results may have an impact on the management of patients receiving interferon therapy. These findings suggest that it is important to obtain more than one HCV RNA determination before making treatment decisions (Shiffman, 2003).

With acute infection, HCV RNA is typically present within 2 weeks of infection but falls with development of antibody; as many as 15% of those with acute HCV infection have negative HCV RNA (Alter, 1992b; Villano, 1999). Viral RNA may be intermittently present for the first year of infection, but then becomes persistently present (Villano, 1999). In later stages of infection, HCV RNA levels generally fluctuate by no more than 0.5–1.0 log around mean values (Nguyen, 1996). HCV has a high rate of mutation, similar to that of other reverse transcriptase viruses such as HIV. This produces a number of “quasispecies” of HCV that may emerge, often associated with fluctuating ALT levels (Yuki, 1997). Unique species of

HCV are termed genotypes. In the United States, the most common is genotype 1, divided into subtypes 1a and 1b; these together cause about 65% of HCV infections in Caucasians, but 90%–95% of infections in African Americans (McHutchison, 1999; Reddy, 1999). Genotypes 2 and 3 are generally more responsive to treatment (McHutchison, 1998; Poynard, 1998); other strains are responsible for 1%–2% of infections. Detection of the unique nucleic acid sequences of each strain by one of several nucleic acid methods (Lau, 1995), discussed at length in Part 8, is the most reliable means to identify the responsible genotype in an individual.

Hepatitis D

Hepatitis D (delta-agent; HDV) is an RNA virus that can replicate only in the presence of HBsAg; circulating viral particles have viral RNA inside a shell of HBsAg. Although HDV is rare in the United States, occurring primarily in injecting drug users and hemophiliacs, it is endemic in some parts of the world (London, 1996). Overall, about 20 million individuals may be infected with HDV (Taylor, 2006). In patients with HBV infection, HDV may occur in two forms. If infection with both viruses occurs at about the same time (coinfection), the course of infection is more severe, often follows an atypical course, is a cause of acute fulminant hepatic failure (Sunheimer, 1994), and has a higher fatality rate than HBV infection alone. If HDV infection occurs in the presence of persistent HBV infection (superinfection), progression of disease may be faster. The major diagnostic test is the presence of anti-HDV; both total and IgM antibody tests are available. Both antibodies may eventually disappear following convalescence. The simultaneous assessment of anti-HBc IgM will help differentiate coinfections (present) from superinfections (absent).

Hepatitis E

Hepatitis E (HEV), an RNA virus, now classified as a Hepevirus, with a clinical course similar to that of HAV infection, is common in parts of Asia, Africa, and Mexico, but is rarely seen in the United States, except in individuals who have traveled to endemic areas (Erker, 1999). Similar to HAV, it is spread by the fecal–oral route. Person-to-person transmission of HEV appears to be uncommon. For travelers to endemic areas, the usual food and water hygiene precautions are recommended. Evidence suggests that humans can contract this virus from animal reservoirs (e.g., from uncooked boar and deer meat), but this route of transmission has not been fully verified (Kuniholm, 2008). When infection occurs in pregnancy, there is an increased fatality rate of about 20%, although in general the fatality rate is between 0.5% and 4%. HEV infections range from inapparent illness to severe acute hepatitis, sometimes leading to fulminant hepatitis and death. The signs and symptoms cannot be distinguished from those associated with cases of acute hepatitis caused by other hepatotropic viruses (Schlauder, 2003).

The viral genome encodes at least six proteins, including a capsid protein, whose X-ray structure has recently been determined (Guu, 2009). There are presumed to be five genotypes: 1 and 2 are from humans, 3 and 4 from humans and swine, and a fifth genotype is an avian HEV found in chickens that represents a branch distinct from human and swine HEVs. Genotypes 1 and 2 occur in younger populations, whereas genotypes 3 and 4 occur in older age groups that may be immunocompromised. Antibody tests for HEV are available but appear to have frequent false-positive results, depending on the antigens used to detect reactivity (Mast, 1998). Two serologic tests are available: anti-HEV IgM, which detects recent or current infection, and anti-HEV IgG, which detects current or past infection. Because of the current questionable specificity of serologic assays, a confirmatory test is required. A PCR amplification of an HEV RNA-specific product using serum, plasma, bile, or feces becomes the definitive indicator of acute infection. However, the PCR test window of detection is from 2–7 weeks after infection.

Hepatitis G

Two other viruses have been suspected, but have not been proven, to cause posttransfusion hepatitis: hepatitis G virus (HGV, sometimes called **G-B**) (Laskus, 1997), and transfusion-transmitted virus (Matsumoto, 1999). Although both viruses can be isolated from a high percentage of persons with posttransfusion hepatitis, and viremia is found in at least 1% of blood donors, they do not seem to cause liver disease in these cases. To date, no serologic or PCR assays that can detect these agents are commercially available. Although acute and chronic HGV can be detected at some research centers with a qualitative PCR assay for HGV RNA, no routine testing is recommended because the clinical significance of HGV remains unknown (Shuhart, 2003). Several other viruses, including herpes viruses,

can cause hepatitis, but they typically affect other organs as well. These viruses are discussed in Chapter 55.

DIAGNOSIS OF LIVER DISEASES

In Chapter 8, the fundamental patterns of laboratory findings in liver function abnormalities are summarized and are encapsulated in Table 8-5. In this section, the major hepatic disorders are discussed with emphasis on laboratory evaluations that enable diagnoses to be made, often without the need to perform invasive procedures such as liver biopsies.

It is important to remember that in acute hepatitis, the principal changes include significant elevations of aminotransferases; in cirrhosis, these tend to remain normal or become slightly elevated while total protein and albumin are depressed, and ammonia concentrations in serum are elevated. In posthepatic biliary obstruction, bilirubin and alkaline phosphatase become elevated; in space-occupying diseases of the liver, alkaline phosphatase and lactate dehydrogenase are elevated. In fulminant hepatic failure, the aminotransferases and ammonia are elevated, but total protein and albumin are depressed.

HEPATITIS

Hepatitis usually first manifests clinically with the symptoms of fatigue and anorexia. Microscopically, cell injury and generally minimal necrosis are caused both by direct virus (or toxic agent)–induced cell damage and by the immune response to the virus. Jaundice may be present. By far, the most common cause (>90% of cases) of hepatitis is viral, with about 50% of cases due to hepatitis B, 25% to hepatitis A, and 20% to hepatitis C. Jaundice is often initially seen as scleral icterus when the patient has total serum bilirubin concentrations above 2 mg/dL. The cause of *acute* hepatitis is likewise almost always (>90% of cases) viral, although chemical exposure such as to carbon tetrachloride or chloroform or to drugs such as acetaminophen, especially in children, should be considered. A special category of toxin-induced hepatitis is that induced by alcohol, discussed later.

The cardinal finding in hepatitis is a rise in the aminotransferases to values greater than 200 IU/L and often to 500 or even 1000 IU/L. An exception to this finding is seen in hepatitis C, in which only modest elevations of ALT (but not AST) can occur. The AST/ALT ratio generally favors ALT. The bilirubin is frequently elevated and is composed of both direct and indirect types. Frank jaundice occurs in about 70% of cases of acute hepatitis A (Lednar, 1985), 33% of cases of hepatitis B (McMahon, 1985), and about 20% of acute hepatitis C cases (Hoofnagle, 1997). Elevations of indirect bilirubin are due to the inability of injured hepatocytes to conjugate bilirubin, and the rise in direct bilirubin is due to the blockage of compromised canaliculi secondary to the inflammatory process that occurs in the acute phase. Because of hepatocyte damage, LD levels are mildly elevated to values typically around 300–500 IU/L. Because of inflammation and/or necrosis or apoptosis of canalicular and ductular lining cells, the alkaline phosphatase may also be elevated typically to values of 200–350 IU/L. Unless the hepatitis is severe and involves the whole liver, progressing to fulminant hepatic failure, total protein and albumin are within their normal ranges. The γ -globulin fractions may be elevated as a result of infection (Lotfy, 2006).

Given the pattern of the analytes suggestive of hepatitis as previously discussed, screens for specific causes should be made (i.e., determination of serologic markers for hepatitis A, B, and C). Screening for anti-hepatitis A IgM and for HBsAg can be performed within 1 day. If either of these is positive, the diagnosis is established. If negative, further screening for hepatitis B should be undertaken (i.e., determination of serum titers of anti-HBcAg IgM and IgG [core window] and anti-HBsAg IgG, as already described). If only the latter is positive, it may be difficult to establish whether hepatitis B is the cause of the infection, or whether the patient has had past exposure to the virus. Unless the patient has chronic active or persistent hepatitis, in which case HBsAg is continuously present, elevated titers of anti-HBsAg IgG occur long after the aminotransferases return to normal levels. Screens for hepatitis C should also be performed. If these are negative, other viral causes should be sought (e.g., cytomegalovirus, Epstein-Barr virus). Especially in the event that a viral hepatitis screen is negative, nonviral causes, such as chemical toxins, should be considered. In addition, less common causes of hepatitis such as Wilson's disease (see earlier), in which decreased serum ceruloplasmin and increased urinary copper are found, and autoimmune hepatitis should be considered. Both conditions can present as acute or chronic disease; in chronic forms, both can give rise to chronic active hepatitis and, less commonly, cirrhosis. In the chronic form of autoimmune hepatitis (often accompanied by

elevations in ANA titers), polyclonal increases in the γ -globulins can usually be detected.

Alcoholic Hepatitis

In alcoholic hepatitis, the previously described pattern of abnormal analyte concentrations holds, except that AST, much of it mitochondrial AST, often becomes disproportionately elevated over ALT. In addition, marked elevations of the enzyme GGT are often out of proportion to elevations in alkaline phosphatase. Unless malnutrition exists in the alcoholic patient, total protein and albumin are found to be within their reference ranges.

Chronic Hepatitis

In chronic hepatitis, hepatocyte damage is ongoing, and chronic inflammation is seen in hepatocytes on biopsy. This condition is caused mainly by chronic hepatitis B or C infection, detected by persisting HBsAg or real-time PCR for hepatitis C sequences, respectively, and is a major predisposing factor for cirrhosis and hepatocellular carcinoma, the two leading causes of death from liver disease. Chronic hepatitis may be asymptomatic or mildly symptomatic. A mild elevation of AST and ALT is seen, and, more commonly in hepatitis C, a mild elevation of only ALT may be noted.

CHRONIC PASSIVE CONGESTION

In chronic passive congestion of the liver, most often secondary to congestive heart failure, back pressure from the right heart is transmitted to the hepatic sinusoids from the inferior vena cava and the hepatic veins. Increased pressure causes sinusoidal dilation, which may cause physical damage to hepatocytes. The result is a mild increase in aminotransferases and occasionally mild hyperbilirubinemia. Other analytes that measure liver function are usually within their reference ranges.

CIRRHOSIS

Cirrhosis of the liver is a condition that results in parenchymal fibrosis and hepatocytic nodular regeneration and can be caused by alcoholism (macronodular or Laennec's cirrhosis), panhepatic hepatitis, chronic active hepatitis, toxins and drugs, and diseases of the biliary tract, such as primary and secondary biliary cirrhosis as discussed previously.

In addition, systemic disease can predispose to cirrhosis. In hemochromatosis, for example, excess iron becomes deposited in a variety of tissues, including liver, and becomes toxic to hepatocytes, predisposing to cirrhosis. As discussed in Chapter 23, this disease is caused by single amino acid substitutions, most commonly tyrosine for cysteine 282 (C282Y), in the protein product of the *HFE* gene on chromosome 6 (Feder, 1996; Crawford, 1998a). This protein is thought to be involved in the interaction of transferrin with the transferrin receptor (Zhou, 1998b), and in amino acid substitutions such as C282Y, which induce protein malfunction, resulting in abnormal iron deposition in tissues, including liver. More recent work suggests that the HFE protein can regulate intracellular iron storage independently of its interaction with transferrin receptor-1 (Carlson, 2005).

Testing for this condition involves determination of the serum iron-binding saturation, discussed in Chapter 23, which is greater than or equal to 45%. This test has high sensitivity but low specificity, diminishing its screening value. Other tests for this condition include determination of iron content of liver biopsy samples and genetic analysis.

As discussed previously, in Wilson's disease, copper deposits in liver are also toxic and can likewise lead to a form of chronic active hepatitis and cirrhosis. In α -1-antitrypsin deficiency, because of continuing proteolysis in hepatocytes, patients have a significantly increased propensity to develop cirrhosis. Chronic hepatitis due to persistent circulating hepatitis B or C virus and autoimmune disease with elevated ANA or ASMA also predispose to cirrhosis.

In general, irrespective of the cause, cirrhosis is a chronic but gradually worsening condition that can occasionally progress to fulminant hepatic failure, as discussed later (Sunheimer, 1994). At its inception, it is often focal and may not be evident clinically.

Diagnosing and Following Cirrhosis, Fibrosis, and Necroinflammation of the Liver Noninvasively Using Serum Analytes

The definitive diagnosis of fibrosis and/or necrosis and inflammation of the liver is attained by liver biopsy. Because this invasive procedure carries

with it morbidity such as bleeding and pneumothorax, and because the liver biopsy itself has the confounding problem of sampling errors, a search is under way to devise methods to diagnose and follow these disease processes noninvasively using the levels of serum analytes that measure liver function. The first of these was the **PGA index** (Poynard, 1991), computed from the PT and from serum levels of γ -glutamyl transferase and apolipoprotein A-I. Ranges of values for each of these analytes are divided into four categories, numbered 0–4, in increasing order of severity. For example, GGT values between 20 and 49 are scored as 1, values between 50 and 99 are scored 2, etc. For apoA-I, increasing severity of disease correlates with decreasing concentration of this protein in serum. The prothrombin time increases with severity of disease because the liver is the sole site for synthesis of coagulation factors. These scores are then summed to give the PGA index. Higher PGA scores have been found to correlate with the degree of hepatic fibrosis and with the severity of cirrhosis as judged both by clinical grading and from liver biopsies (Teare, 1993). This index also has a good correlation with the level of procollagen type III propeptide in serum, also used to follow active cirrhosis.

More recently, other indices have been developed that appear to be more effective. These include the Fibrotest and the Actitest index (Poynard, 2004), which utilize the measurement of six analyte levels (i.e., apolipoprotein A1, GGT [these two analytes also being in the PGA index], haptoglobin, total bilirubin, α -2-macroglobulin, and ALT) and also include the patient's age and gender. Correlations with liver biopsy results are then performed based on an artificial intelligence algorithm, resulting in an equation that computes the score on a scale of 0 to 1.0. These scores correspond to the scores of one or more histopathologic staging systems, the most commonly used one of which is called **METAVIR** (METAVIR Cooperative Group, 1994; Bedossa, 1996), as follows: F0, no fibrosis; F1, portal fibrosis; F2, bridging fibrosis with few septa; F3, bridging fibrosis with many septa; and F4, frank cirrhosis. Actitest scores are computed likewise on a scale of 0–1.0, using the same parameters, except that they are correlated with necroinflammatory activity using a METAVIR grading system (Bedossa, 1996) as follows: A0, no activity; A1, minimal activity; A2, moderate activity; and A3, severe activity. These indices are widely used in Europe but thus far not in the United States. Some disagreement has been seen as to the efficacy of these indices in diagnosing and following liver fibrosis and necrosis/inflammatory activity. For example, in one study (Rossi, 2003) on 125 patients with hepatitis C, serum samples were obtained and assayed for the six analytes in the Fibrotest and the Actitest. Using cutoffs of <0.1 to signify minimal fibrosis and >0.6 to indicate severe fibrosis, of 33 patients with a score of <0.1, 6 (18%) were found to have significant fibrosis, and of 24 patients with scores >0.6, 5 (21%) were found to have mild fibrosis on biopsy. On the other hand, in another similar study of more than 300 patients with hepatitis C, for whom analyses were performed before and after a treatment regimen using antiviral agents, high values (almost 0.8) for the areas under the receiver-operator curves (see Chapter 7) were found at pretreatment and posttreatment. The overall sensitivity (see Chapter 7) of the method was 90%, and the positive predictive value was 88%. These values indicate that the index is of value in detecting fibrosis.

It has been pointed out that false-positive results may occur as the result of treatment for hepatitis C with ribavirin because this drug can induce hemolysis, thereby reducing haptoglobin and increasing unconjugated bilirubin, both of which will change the index in a manner unrelated to increasing liver fibrosis (Halfon, 2008). Other conditions that are unrelated to liver fibrosis and can change the index are acute hepatitis, extrahepatic cholestasis (as from choledocholithiasis), Gilbert's disease, acute inflammatory conditions, and severe hemolysis (Halfon, 2008) as mentioned previously. With these caveats, Poynard has estimated that 18% of discordances between liver biopsy and Fibrotest and Actitest results are due to sampling errors on liver biopsy, a known problem with this procedure, especially for small biopsy sample sizes of <15 mm, and that 2% were due to the test (Poynard, 2004). For biopsy sizes of >15 mm, correlation of Fibrotest scores with biopsies resulted in an area of 0.88 under the receiver-operator curve (see Chapter 7). Other investigators have concluded from studies that there is a need for standardization of methods, so that all testing laboratories obtain similar values for individual test results (Rosenthal-Allieri, 2005), as well as a need for large prospective studies (Afdhal, 2004). More recently, it has been found that, overall, Fibrotest, which is now commercially available from the Laboratory Corporation of America (LabCorp, Philadelphia) under the title "Fibrosure," has a similar prognostic value to that obtained from liver biopsy and appears to be the most accurate of the noninvasive biomarker indices (Naveau, 2009).

These other indices (reviewed and evaluated in Parkes, 2006) include the FIBROSpect II index based on tissue inhibitors of metalloproteinases, α -2-macroglobulin, and hyaluronic acid, the latter appearing to give better correlations with liver fibrosis than procollagen type III peptide, as mentioned earlier; the INR; platelet count; ratio of AST to ALT; AST/platelet ratio index, and the Forns index, which correlates age, platelet count, GGT, and cholesterol with extent of liver fibrosis (Forns, 2002). These appear to have similar although somewhat lower sensitivities and/or specificities than the Fibrotest and the Actitest (Thabut, 2003; Naveau, 2009).

Biochemical and Clinical Correlations of Cirrhosis

As cirrhosis progresses to involve most (>80%) of the liver parenchyma, liver function becomes compromised. Total protein synthesis drops to low levels, as does synthesis of albumin. Portal hypertension, together with the drop in colloid osmotic pressure, results in ascites and even anasarca. Compression of the intrahepatic bile ductules and cholangioles results in diminished excretion of bilirubin and bile salts, causing hyperbilirubinemia and a rise in alkaline phosphatase, GGT, and 5'-nucleotidase. The serum concentrations of hepatocyte enzymes such as AST, ALT, and LD may be normal or diminished. If injury to viable hepatocytes is ongoing, the levels of these enzymes in serum may become mildly elevated. In more advanced stages of cirrhosis, serum ammonia levels become significantly elevated and correlate roughly with the degree of encephalopathy.

Four clinically graded levels of hepatic encephalopathy have been identified: motor tremors detected as asterixis, in which the hands of the patient, when pressed back and are then released, move back and forth in a flapping motion; a lethargic, stuporous state; severe obtundation; and frank coma. Lowering ammonia levels reduces the degree of encephalopathy. More recently, earlier signs of encephalopathy have been observed, including sleep disturbance and abnormal results on neuropsychiatric tests.

Because the liver is the site of synthesis of all of the coagulation factors except von Willebrand factor, and because synthesis of these factors is markedly diminished in cirrhosis, coagulation disorders may result, as discussed previously. Accelerated partial thromboplastin and prothrombin times become prolonged, often accompanied by diminished platelet counts. The latter may be caused by splenic sequestration due to splenomegaly caused by portal hypertension. However, disseminated intravascular coagulopathy may occur in cirrhosis, as evidenced by high levels of D-dimer and fibrin split products in serum, and may be the cause of the diminished platelet count. Because of derangements in lipid metabolism in the liver, fats enter the circulation and become deposited in erythrocyte membranes, causing these cells to appear as target cells.

Loss of vascular volume from ascites and anasarca can cause low tissue perfusion and lactic acidosis. Volume receptors, sensitive to volume loss, stimulate the secretion of antidiuretic hormone. The retained water causes serodilution, leading to hyponatremia.

Cirrhosis of the liver is often associated with renal failure as a result of the hepatorenal syndrome. In this condition, which is not well understood, renal tubular function is compromised. Serum blood urea nitrogen and creatinine rise to markedly elevated levels, indicating renal failure. Low tissue perfusion may also cause acute tubular necrosis. In hepatorenal syndrome, restoration of liver function generally reverses the renal failure.

Primary and secondary types of biliary cirrhosis have been discussed previously in this chapter. The diagnosis of these conditions is made difficult by the changing pattern of serum analyte concentrations used to evaluate liver status. Usually beginning as an obstructive pattern, in which alkaline phosphatase and sometimes bilirubin are elevated, the pattern progresses to one that resembles hepatitis because of the toxic effects of bile salts on hepatocytic function. With time, this pattern gives way to a cirrhotic pattern in which the aminotransferases decrease, total protein and albumin decrease, and ammonia rises. In patients with a persistent obstructive pattern indicated by laboratory results, with no evidence of mass lesions or stones causing blockage of bile flow, the presence of anti-M2 antimitochondrial antibody should be ascertained. Increased titers of this antibody are virtually 100% diagnostic of primary biliary cirrhosis. In addition, assays for serum p-ANCA antibodies should be performed to detect secondary biliary cirrhosis, which can also produce a cholestatic pattern.

Survival for patients with primary biliary cirrhosis may be computed using an empirical formula, analogous to the MELD score discussed earlier, that utilizes the age of the patient, the serum albumin and bilirubin, the prothrombin time (as in the MELD score), and the extent of edema

(Dickson, 1989). This formula gives an estimate of the time within which the patient may undergo liver transplantation.

POSTHEPATIC BILIARY OBSTRUCTION

Posthepatic biliary obstruction refers to blockage of the intrahepatic and extrahepatic ducts and/or to blockage of bilirubin excretion from the hepatocyte into the canaliculi, leading to backflow of bile into the hepatocyte and ultimately into the circulation. The most common cause of this condition is cholelithiasis. Other causes include primary biliary cirrhosis and primary sclerosing cholangitis, as discussed earlier, and inflammation of the biliary tract, as occurs in ascending cholangitis and in gram-negative sepsis. Drugs such as the neuroleptics, like chlorpromazine, can cause cholestatic jaundice. Mass lesions such as carcinoma of the head of the pancreas or lymphoma can also cause posthepatic biliary obstruction by blocking the common bile duct at the porta hepatis. These conditions cause elevated bilirubin (most of it direct), ALP, and GGT. Often, however, especially in inflammatory conditions in the biliary tract, obstruction to bile flow is incomplete, resulting in partial flow of bile. Under these conditions, bilirubin remains normal or is only mildly increased. However, alkaline phosphatase, GGT, and 5'-nucleotidase become significantly elevated.

Occasionally, hyperbilirubinemia may be observed in patients who are otherwise normal. The bilirubin is of the indirect type and most often results from hemolysis, usually in hemolytic anemia. Hemolytic anemias may be triggered by hepatic disease. For example, viral hepatitis may precipitate hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency. In Zieve's syndrome, hemolysis occurs in conjunction with alcoholic hepatitis and hyperlipidemia. Wilson's disease is sometimes associated with acute hemolysis. Patients with chronic hepatitis secondary to autoimmune disease may develop severe hemolytic disease, sometimes requiring splenectomy.

SPACE-OCCUPYING LESIONS

In space-occupying lesions of the liver, a high percentage of which are due to metastatic cancer; a smaller percentage to lymphoma, primary hepatocellular carcinoma, and angiosarcoma of the liver; and a small percentage to benign lesions such as hemangioma of the liver, the cardinal finding is isolated increases in the two enzymes LD and alkaline phosphatase. Increases in the latter are caused by encroachments of the mass(es) on canaliculi and cholangioles and even on the main bile ducts. The reasons for increases in LD are not clear. Most commonly, it is the LD₅ fraction that is responsible for the increase. This fraction may be produced by the liver but also may be produced by tumors. Typically, the values for LD are 500–1000 IU/L or more, and for alkaline phosphatase, >500 IU/L. If a malignant tumor spreads widely through the liver, mild elevation in the aminotransferases may be seen, along with hyperbilirubinemia due to bile duct obstruction, and low protein and albumin. The latter findings may not be caused as much by liver dysfunction as by generalized cachexia associated with tumor spread. A number of cancers that originate in the liver can be identified using serodiagnostic tests. For example, as discussed earlier in this chapter, serum levels of AFP are elevated in hepatocellular carcinoma. As discussed in Part 9 of this book, angiosarcomas can be diagnosed using specific antibodies to mutated ras-p21 protein.

FULMINANT HEPATIC FAILURE

In acute fulminant hepatic failure, an uncommon but highly fatal condition, massive destruction of liver tissue results in complete liver failure. Depending on the nature and extent of the destruction, ultimate liver regeneration frequently does not occur, although if cell death is limited, and if hepatocytes can recover from the acute injury, normal liver function may return. The causes of this condition are largely unknown. Reye's syndrome is an example of this condition, in which a child has an acute viral infection with fever and is treated with aspirin. Within 1–2 weeks after the infection and fever have dissipated, the child suddenly becomes encephalopathic secondary to hyperammonemia caused by acute hepatic failure. An adult form of Reye's syndrome has also been described. Other possible causes of fulminant hepatic failure include acute hepatitis B with hepatitis D superinfection, Budd-Chiari syndrome and other hepatic vein thrombotic conditions, vascular hypoperfusion of the liver, ileojejunal bypass for obesity, Tylenol intoxication, alcoholism, and cirrhosis. Another significant predisposing condition is the fatty liver of pregnancy (Sunheimer, 1994).

Two histopathologic forms of fulminant hepatic failure are known: panhepatic necrosis, in which all hepatocytes have become necrotic, and microvesicular steatosis, in which sinusoidal enlargement and cholestasis are present. The latter is most commonly observed in Reye's syndrome and the fatty liver of pregnancy. It is important to note that, because the microvesicular steatosis pattern often shows only minimal changes histologically, liver biopsy is unrevealing. It is necessary to rely on laboratory analysis of liver function for a definitive diagnosis, as described later.

Many of the pathophysiologic sequelae of cirrhosis also occur in fulminant hepatic failure (Sunheimer, 1994). Patients develop ascites and become encephalopathic as the result of hyperammonemia. Total serum protein and serum albumin are depressed. Virtually all patients with fulminant hepatic failure exhibit severe coagulopathy, particularly disseminated intravascular coagulopathy, and virtually all are anemic. All develop renal failure as a result of the hepatorenal syndrome and acute tubular necrosis.

In addition, many patients become hypoglycemic, possibly because of the absence of enzymes involved in glycogenolysis. Lactic acidosis also develops as the result of poor tissue perfusion. It is interesting to note that, unlike in cirrhosis, in which patients become hyponatremic, patients with fulminant hepatic failure may become hypernatremic and hypokalemic. This observation may be explained by the finding that circulating levels of aldosterone in the serum of some of these patients are quite high (Sunheimer, 1994). Perhaps failure of the liver to clear aldosterone from the circulation results in the observed high levels of this hormone.

Diagnostic laboratory findings for fulminant hepatic failure include rapid increases in serum levels of the aminotransferases to markedly elevated levels, such that AST, which can reach levels greater than 20,000 IU/L, may be at least 1.5 times greater in value than ALT because of acute release of mitochondrial AST, as discussed previously. Although these enzymes rise in value, the total protein and albumin become markedly depressed. Overall, this pattern resembles hepatitis and end-stage cirrhosis combined, except that usually in acute hepatitis, save alcoholic hepatitis, AST and ALT rise in a ratio of about 1:1, or in a ratio that favors ALT. Shortly after these patterns occur, serum ammonia increases rapidly, leading to encephalopathy. LD, alkaline phosphatase, and bilirubin all increase markedly. All of the changes described previously occur over a period of about 1 week. After another week, the serum AST and ALT return to low, sometimes undetectable, levels. This finding signifies complete destruction of all viable liver tissue (Sunheimer, 1994).

Patients whose AST and ALT undergo the stereotypic changes described should be observed closely for fulminant hepatic failure, especially if there is any indication of encephalopathy. Although supportive therapy can sometimes result in restoration of normal liver function, for most patients in fulminant hepatic failure the only ultimate cure is liver transplantation. The MELD score, as discussed earlier, has been shown to have prognostic value in patients with hepatic failure, in particular those with alcoholic hepatitis, and serves as a predictor of patient survival among liver transplant candidates (Dunn, 2005; Srikureja, 2005).

KEY POINTS

- Almost all patients with duodenal ulcers and most with chronic gastritis have demonstrable *Helicobacter pylori* infection. *H. pylori* stool antigen assays and urea breath tests are useful in diagnosis and in monitoring for eradication after treatment.
- Acute pancreatitis presents with abdominal pain and elevated levels of serum amylase or lipase. Reversible causes must be excluded in patients with recurrent episodes of acute pancreatitis. Routine laboratory testing is of limited value in diagnosing chronic pancreatitis.
- Sweat chloride determination is the necessary initial test in the workup for cystic fibrosis. Genetic testing can be used to identify the mutations associated with this disease.
- Patients with chronic diarrhea should be evaluated for fecal blood, fat, leukocytes, and stool pathogens (bacterial culture on routine media, ova and parasite examination).
- *Clostridium difficile* should be considered a cause of diarrhea in patients on antibiotic therapy or hospitalized for more than 3 days.
- Diagnostic evaluation of a patient suspected of celiac disease should be initiated with anti-tissue transglutaminase immunoglobulin A and total serum immunoglobulin A before placing the patient on a gluten-free diet.
- Primary lactose intolerance is common in adults, and secondary lactose intolerance may occur in infection and in inflammatory bowel disease.
- Positivity of perinuclear antineutrophil cytoplasmic antibody is most often associated with ulcerative colitis, and that of anti-*Saccharomyces cerevisiae* antibody with Crohn's disease.
- Endoscopy has replaced gastric acid aspiration for diagnosis. Gastric acid output testing is useful when acid levels are very high or very low.
- Gastrin, the most powerful gastric acid stimulator, varies inversely with gastric acid secretion. Serum gastrin levels are elevated in gastric atrophy, and gastric acid levels are reduced.

- Secretin stimulates gastrin production in patients with a gastrinoma but not in patients with other causes of hypergastrinemia.
- Intraoperative gastrin measurements are useful in identifying whether the abnormal tissue is completely removed in patients undergoing surgery for gastrinomas.
- Fecal occult blood test is used to screen for colon cancer.

Diagnosis of gastrointestinal disease is guided by the patient's history and the significant signs and symptoms. Findings with strong negative predictive values exclude some possible causes and focus the differential diagnosis. Initially, noninvasive procedures are preferentially performed. Patient preparation is as important as correct selection of the diagnostic tests or procedures indicated. Endoscopy, when warranted, can provide direct visualization of the entire gastrointestinal lumen and permits biopsy. Imaging-assisted invasive techniques may be required in the critically ill with gastrointestinal bleeding or obstruction. To ensure interpretable endoscopic results, and to avoid false-positive and false-negative results, stringent patient preparation is required. Similarly, testing requires appropriately collected specimens. Emphasis is given in this chapter to frequently used diagnostic tests.

PANCREATIC DISORDERS

MACROAMYLASEMIA

Macroamylasemia is not a disease, but an acquired benign condition that is more frequent in men and is usually discovered incidentally in the fifth through seventh decades (Remaley, 1989). A persistent increase in serum amylase is seen without clinical symptoms. Urine amylase is normal or low.

Threatte to Laboratory diagnosis of gastrointestinal and pancreatic disorders. In: McPherson RA, Pincus MR, editors. *Henry's Clinical Diagnosis and Management by Laboratory Methods*. 21st ed. Philadelphia: WB Saunders; 2007, upon which portions of this chapter are based.

TABLE 22-1

Differential Diagnosis of Hyperamylasemia and Macroamylasemia

Condition	Serum amylase	Serum lipase	Urinary amylase	$C_{am}:C_{cr}$	Serum macroamylase
Pancreatic hyperamylasemia	High	High	High	High	Absent
Salivary hyperamylasemia	High	Normal	Low or normal	Low or normal	Absent
Macroamylasemia	High	Normal	Low	Low	High

Adapted from Kleinman DS, O'Brien JF. Macroamylase. Mayo Clin Proc 1986;61:669-70.

$C_{am}:C_{cr}$ Amylase clearance:creatinine clearance ratio = (urinary amylase/serum amylase) \times (serum creatinine/urinary creatinine).

Macroamylases are heterogeneous complexes of normal amylase (usually salivary isoenzyme) with immunoglobulin (Ig)G, IgA, or polysaccharide (Van Deun, 1989). Because of their large size, macroamylases cannot be filtered through the glomerulus and are retained in the plasma; they are not present in urine. Plasma amylase activity is often increased two- to eightfold. Serum lipase is normal. Macroamylasemia is found in about 1% of randomly selected patients. Renal function is normal, and the amylase/creatinine clearance ratio is low (Table 22-1).

PANCREAS IN SYSTEMIC DISEASE

Cystic Fibrosis

Cystic fibrosis (CF) is the most common genetic disorder in Caucasian North Americans and is often fatal in childhood. Some Native American tribes (Pueblo) have a similar incidence. It is also frequent in Hispanics but is uncommon in Asians and blacks. More than 25,000 Americans have CF, and almost 1000 new cases are diagnosed each year. The incidence is 1 in 1600 Caucasian births and 1 in 17,000 African American births in the United States.

CF of the pancreas is an autosomal recessive disease of ion transport affecting the CF transmembrane conductance regulator (CFTR) gene on chromosome 7 that encodes an epithelial chloride channel protein. Approximately 1 in every 20 Caucasians is a carrier of one of the alleles. More than 1300 nonfunctional mutations of the CFTR gene have been identified. Available probes can be used to test for 70 mutations that account for >90% of cases of CF. Genetic testing can identify the mutations associated with CF (Weiss, 2005).

The degree of the defect depends on the nature of the mutation. Several characterized mutations lead to a milder form of the disease. The classic $\delta F508$ mutation leads to CF when two copies of the gene are inherited. Persons heterozygous for the *R117H* mutation may develop pancreatic insufficiency as the result of plugging of ducts, causing idiopathic chronic pancreatitis (Durie, 2000).

CF is characterized by abnormally viscous mucous secretions from the various exocrine glands of the body, including the pancreas, salivary glands, and peritracheal, peribronchial, and sweat glands. Involvement of the intestinal glands may result in the presence of meconium ileus at birth. Two thirds of cases are diagnosed before 1 year of age. Chronic lung disease and malabsorption resulting from pancreatic insufficiency are the major clinical problems of those who survive beyond infancy, but intelligence and cognitive functions are unaffected and are normal (Cheng, 1990).

Because of multiple alleles at the cystic fibrosis gene, the demonstration of increased chloride in the sweat is a necessary initial test in the workup. More than 99% of children with CF have concentrations of sweat chloride greater than 60 mmol/L. The sweat chloride may not be as dramatically increased in adolescent or adult patients. The test needs to be performed with care (LeGrys, 2007).

In children, chloride concentrations greater than 60 mmol/L in sweat on at least two occasions are diagnostic. Levels of between 50 and 60 mmol/L are suggestive in the absence of adrenal insufficiency. Patients in whom cystic fibrosis is suspected on the basis of indeterminate sweat electrolyte results may undergo confirmatory testing following administration of a mineralocorticoid such as fludrocortisone. In those patients with CF, electrolyte values would remain unchanged, whereas normal controls would show a decrease in sweat electrolytes. Sodium concentrations in sweat tend to be slightly lower than those of chloride in patients with cystic fibrosis, but the reverse is true in normal subjects. Sweat chloride concentrations greater than 60 mmol/L may be found in some patients with malnutrition, hyperhidrotic ectodermal dysplasia, nephrogenic diabetes insipidus, renal insufficiency, glucose-6-phosphatase deficiency, hypothyroidism, mucopolysaccharidosis, and fucosidosis. These disorders usually can be easily differentiated from cystic fibrosis by their clinical symptoms.

False-negative sweat test results have been seen in patients with cystic fibrosis in the presence of hypoproteinemic edema.

Sweat electrolytes in about half of a group of premenopausal adult women were shown to undergo cyclic fluctuation, reaching a peak chloride concentration most commonly 5-10 days before the onset of menses. Peak values were slightly less than 65 mmol/L. Men showed random fluctuations up to 70 mEq/L. For this reason, interpretation of sweat electrolyte values in adults must be approached with caution (Rosenstein, 1998; NCCLS, 2000).

Sweat Chloride

Pilocarpine is introduced into the skin by iontophoresis to stimulate locally increased sweat gland secretion. The resulting sweat is absorbed by filter paper or gauze and is weighed, diluted with water, and analyzed for sodium and chloride concentrations. Total body sweating in patients with cystic fibrosis is hazardous, and a number of deaths from the procedure have been reported.

When performed properly in duplicate, the sweat test has a sensitivity of 90%-99%. High rates of incorrect results have been attributed to problems associated with sweat specimen sample collection and test analysis (NCCLS, 2000; LeGrys, 2007).

Heterozygotes have no recognizable clinical symptoms. Homozygotes fully express the syndrome of recurrent pulmonary infection, pancreatic insufficiency, steatorrhea, and malnutrition. CF is due to defective epithelial chloride transport across membranes, which causes abnormally dehydrated tenacious secretions of all exocrine glands. The viscid inspissated mucous plug ducts cause chronic inflammation with atrophy of acini, fibrosis, dilation, and cystic duct changes.

Pancreatic abnormalities occur in >80%. The clinical manifestations are varied. Islets of Langerhans are usually spared. No cure is available. Median survival has increased, in the past 25 years, from 18 to 36 years of age because of advances in treatment. Ninety percent die from pulmonary complications.

Resultant pancreatic lipase deficiency causes maldigestion of fat and steatorrhea. Pulmonary changes are the most serious in cystic fibrosis. Thick intestinal mucus may cause intestinal obstruction in the neonate as the result of meconium ileus. Most CF men are infertile with azoospermia due to duct obstruction.

Hemochromatosis

Excessive body iron accumulation from any source is directly toxic to cells and causes fibrosis. Symptoms include the triad of bronze coloration of the skin, cirrhosis, and diabetes. Humans have no major iron excretory pathway. The screening test consists of transferrin saturation (TS) = serum iron \div total iron binding capacity \times 100. Results are interpreted as abnormal if >60% in women and >50% in men. Confirm with fasting TS and ferritin levels. Liver biopsy with assay for iron is used to confirm and assess the extent of tissue iron load (Powell, 2002).

Early diagnosis and chelation therapy and/or phlebotomies are effective in preventing tissue damage. In disease, the pancreas is slightly enlarged and deep brown as the result of accumulated hemosiderin, the iron-containing pigment. When untreated, progressive fibrosis of the pancreas with atrophy occurs. Iron is deposited in the acinar and duct cells and in the β cells of the islets. Other cells of the islets appear spared. Similar pigments are noted in the skin. β -cell loss results in **bronze diabetes**. Hypogonadism with pituitary dysfunction is present in half of cases, and cardiomegaly and osteoarthritis are present in most cases. Cirrhosis is seen in 70% of cases. Hepatocellular carcinoma occurs in 30% of cases, and this tumor has become a chief cause of death in hereditary hemochromatosis (HH) (Barton, 1998).

Secondary hemochromatosis is typically seen in anemia caused by multiple blood transfusions, hemolytic anemias, or increased oral iron intake, which result in excess iron storage.

TABLE 22-2

Laboratory Tests in Acute Pancreatitis

Laboratory test	Purpose	Usage and limitations
Amylase	Diagnosis	Accurate over 3× the upper normal limit; decreased specificity in renal failure; normally elevated in macroamylasemia; test interference in hypertriglyceridemia; elevated from other sources such as salivary gland and/or intraabdominal inflammation (not above 3×); can be normal in alcohol-induced pancreatitis
Lipase	Diagnosis	Decreased specificity in renal failure; immune complex creates false positives; elevated from salivary gland and intraabdominal inflammation
Trypsinogen 2	Diagnosis	Limited use; unclear if superior to amylase/lipase
AST/ALT	Etiology	If greater than 3× upper normal limit; gallstones present as cause in 95% of cases; low sensitivity
Lipase/amylase ratio	Etiology	>5 is diagnostic for alcohol-induced acute pancreatitis; low sensitivity
CDT	Etiology	Useful in patients who deny alcohol; remains elevated for weeks after binge drinking
TAP	Severity	>30 mmol/L in 6- to 12-hour urine; 100% negative predictive value
Hematocrit	Severity	>44 on admission, or rising over initial 24 hours; associated with pancreatic necrosis
C-reactive protein	Severity	>200 IU/L associated with pancreatic necrosis; useful after first 36–48 hours

ALT, Alanine aminotransferase; AST, aspartate aminotransferase; CDT, carbohydrate-deficient transferrin; TAP, trypsinogen activation peptide.

Hereditary Hemochromatosis

HH is a human leukocyte antigen (HLA)-linked autosomal recessive defect in duodenal iron absorption regulation. The *HFE* gene is on the short arm of chromosome 6. In this common genetic disease, the homozygosity frequency is 1 in 220. When hereditary hemochromatosis is diagnosed, other family members should be screened; one quarter of siblings will test positive (Powell, 1996; Bulaj, 2000; Beutler, 2002).

INFLAMMATORY DISEASES OF THE PANCREAS

Pancreatitis is an inflammation of the pancreas caused by injury to acinar cells due to activation of digestive enzymes within the pancreatic parenchyma; it is characterized by significant morbidity and mortality. Clinical manifestations of pancreatitis are highly variable.

Acute Pancreatitis

Acute reversible inflammation is due to enzymatic necrosis. Acute pancreatitis occurs at any age—usually 30 to 70 years—but is rare in children. Diagnosis is based on compatible clinical features such as abdominal pain, nausea, and vomiting. Clinical suspicion is supported by findings of elevated serum amylase and/or lipase (Table 22-2). The pancreas contributes 40% of the total serum amylase; the rest comes mostly from the salivary glands (Halangk, 2005).

In 30% of patients, the diagnosis of acute pancreatitis was not suspected and was made only at autopsy (Wilson, 1985). Many causes have been identified. Gallstones continue to be the leading cause (30%–60%), and alcohol is the second most common cause (responsible for 15%–30%). Other causes include duct obstruction due to tumors or parasites, duct anomalies such as pancreas divisum, infections (mumps, coxsackievirus A), blunt trauma or post endoscopic retrograde cholangiopancreatography (ERCP), many drugs (diuretics, sulfonamides), organophosphates, methyl alcohol, nitrosamines, hypertriglyceridemia, and hypercalcemia.

Amylase

Amylase in serum and urine is stable for 1 week at ambient temperature and for at least 6 months under refrigeration in well-sealed containers. Plasma specimens that have been anticoagulated with citrate or oxalate should be avoided for amylase determination because amylase is a calcium-containing enzyme. Heparinized plasma specimens do not interfere with the amylase assay.

Diagnosis is confirmed by detection of elevated serum amylase threefold above normal. It peaks in 20–30 hours, often at 10–20 times the upper reference limit (Papachristou, 2005). Amylase returns to normal in 48–72 hours. Elevated values persisting longer than this suggest continuing necrosis or possible pseudocyst formation. Serum amylase sensitivity is 72%, and specificity is 99% (Treacy, 2001). Serum amylase has poor sensitivity for pancreatitis; it is not increased in about 20% of patients with pancreatitis. Serum amylase increases nonspecifically in many acute abdominal conditions. In hyperlipidemic patients with pancreatitis, normal serum and urine amylase levels are frequently encountered. The spuriously normal levels are believed to be the result of suppression of amylase activity

by triglyceride or by a circulating inhibitor in serum. Serum amylase levels do not correlate with cause or severity of pancreatitis. Amylase is also produced by the salivary glands.

Although a variety of reliable amylase methods are available, care is required in specimen handling. Caution must be exercised to avoid contamination of specimens with saliva, because its amylase content is approximately 700 times that of serum. Red cells contain no amylase, so hemolysis does not affect most methods, except those coupled-enzyme methods in which the released peroxide is determined by a coupled-peroxidase reaction.

The urine amylase activity rises promptly, often within several hours of the rise in serum activity, and may remain elevated after the serum level has returned to the normal range. Values greater than 1000 Somogyi units/hour are seen almost exclusively in patients with acute pancreatitis. In a majority of patients with acute pancreatitis, serum amylase activity is elevated, and a concomitant increase in urine amylase activity occurs. Increased renal clearance of amylase can be used in the diagnosis of acute and relapsing pancreatitis, but the ratio of amylase clearance to creatinine clearance expressed as a percentage adds little to the diagnosis, because elevated ratios may be found in unrelated conditions.

Lower than normal serum amylase activity may be found in patients with chronic pancreatitis and has been seen in such diverse conditions as congestive heart failure, pregnancy (during the second and third trimesters), gastrointestinal (GI) cancer, bone fracture, and pleurisy.

Serum amylase may be elevated in patients with pancreatic carcinoma, but often too late to be diagnostically useful. Serum amylase activity may also be elevated in patients with cholecystitis, peptic ulcer, renal transplant, viral hepatitis, or ruptured ectopic pregnancy, or post gastrectomy.

Increased ascites fluid amylase levels have been seen in patients with pancreatitis, a leaking pancreatic pseudocyst, pancreatic duct rupture, pancreatic cancer, abdominal tumors that secrete amylase, and perforation of a hollow viscus. Fractionation of amylase in serum, urine, and other body fluids can be done by physical means, such as electrophoresis, chromatography, or isoelectric focusing; each isoenzyme is then quantitated by direct densitometry.

Lipase

The pancreas is the major and primary source of serum lipase. Human pancreatic lipase is a glycoprotein with a molecular weight of 45,000 Da. Lipase is not present in the salivary glands. Lipases are defined as enzymes that hydrolyze preferentially glycerol esters of long-chain fatty acids at the carbon 1 and 3 ester bonds, producing 2 moles of fatty acid and 1 mole of β -monoglyceride per mole of triglyceride. After isomerization, the third fatty acid can be split off at a slower rate. Lipolysis increases in proportion to the surface area of the lipid droplets, and the absence of bile salts in duodenal fluid with resultant lack of emulsification renders lipase ineffective.

Serum lipase is more specific for the diagnosis of acute pancreatitis. Serum lipase increases in 4–8 hours and remains elevated for 8–14 days. Increased lipase activity rarely lasts longer than 14 days; prolonged increases suggest a poor prognosis or the presence of a pancreatic cyst. Hyperglycemia and elevated bilirubin concentrations may be present, and leukocytosis is frequently reported.

Pancreatic lipase must be differentiated from lipoprotein lipase, alies-terase, and arylester hydrolase, which are related but different enzymes. The activities of these enzymes may be included in the measurement of lipase activity unless suitable assay conditions for **pancreatic lipase** are adapted. Lipase is also present in liver, stomach, intestine, white blood cells, fat cells, and milk.

Calcium is necessary for maximal lipase activity, but at higher concentrations it has an inhibitory effect. It is speculated that the inhibitory effect is due to its interference with the action of bile salts at the water/substrate interface. Similar to serum albumin, bile salts prevent the denaturation of lipase at the interface. Heavy metals and quinine inhibit lipase activity.

Lipase is filtered by the glomeruli owing to its low molecular weight; it is normally completely reabsorbed by the proximal tubules and is absent from normal urine. In patients with failure of renal tubular reabsorption caused by renal disorders, lipase is found in the urine. Urine lipase activity in the absence of pancreatic disease is inversely related to creatinine clearance.

Serum lipase is stable up to 1 week at room temperature and may be kept stable longer if it is refrigerated or frozen. The optimal reaction temperature is about 40° C. The optimal pH is 8.8, but other values ranging from 7.0–9.0 have been reported. This difference probably is due to the effects of differences in types of substrate, buffer, incubation temperature, and concentrations of reagents used. Serum is the specimen of choice for blood lipase assays. Icterus, lipemia, and hemolysis do not interfere with turbidimetric lipase assays.

Both serum lipase and amylase are useful in ruling out acute pancreatitis. Although determination of serum lipase has diagnostic advantages over serum amylase for acute pancreatitis, this value is not specific for acute pancreatitis. Serum lipase may also be elevated in patients with chronic pancreatitis, obstruction of the pancreatic duct, and nonpancreatic conditions, including renal disease, acute cholecystitis, intestinal obstruction or infarction, duodenal ulcer, and liver disease, as well as alcoholism and diabetic ketoacidosis, and in patients who have undergone ERCP. Patients with trauma to the abdomen uniformly have increases in both serum amylase and lipase. Elevation of serum lipase activity in patients with mumps strongly suggests significant pancreatic involvement by the disease.

Trypsinogen

Trypsin is produced in the exocrine pancreas as two proenzymes, known as trypsinogen 1 and trypsinogen 2. These proenzymes are activated in the duodenum by an enterokinase that yields trypsin 1 and trypsin 2, respectively. Trypsin present within the peripheral circulation is inactivated by complexing with α -2-macroglobulin or α -1-antitrypsin (AAT). Trypsin, unlike amylase, is produced solely by the pancreatic acinar cells, and therefore is a specific indicator of pancreatic damage. Premature activation of the proenzyme to active trypsin within the pancreatic parenchyma is thought to be a key mechanism in the development of acute pancreatitis (Andersen, 2001). Currently, levels of all forms of trypsin are determined by specific immunoassays.

Trypsin assays are currently used to differentiate the cause of an acute episode of pancreatitis. One study demonstrated that trypsinogen 2 and trypsin-2-AAT are increased in all forms of acute pancreatitis but are more elevated in alcohol-associated pancreatitis than in biliary pancreatitis. Trypsinogen 1, amylase, and lipase were found to be more elevated in patients with biliary pancreatitis. Furthermore, the ratio of serum trypsin-2-AAT to trypsinogen 1 was determined to be the best discriminator between biliary and alcoholic pancreatitis (Andersen, 2001). Another study supported the use of trypsin assays for the diagnosis of acute pancreatitis, because the determined time course profile of trypsinogen 2 and trypsin-2-AAT is appropriate for diagnostic purposes. These enzymes are elevated within hours of onset of the acute episode and therefore are already elevated upon admission; this is followed by a rapid rise. Both enzyme levels remain elevated longer than amylase, and the magnitude of elevation corresponds to the severity of pancreatic inflammation, which is extremely useful for diagnosing acute pancreatitis upon admission, for predicting severity of illness, and for monitoring disease progression (Kemppainen, 2000). Elevated trypsin-1-ATT has also been demonstrated in patients with biliary tract cancer (Andersen, 2001).

Serum trypsinogen 2 levels rise rapidly, showing a ten-fold to twenty-fold increase. Urinary concentrations are even more steeply elevated. A urinary strip test is available. The limitation is the frequent false-positive elevations seen in cases of nonpancreatic abdominal pain. However, a negative trypsinogen 2 urinary test strip can exclude acute pancreatitis with a high degree of probability. Irrespective of the cause, all origins allow activation of the inactive proenzyme trypsinogen to trypsin, which then

TABLE 22-3

Laboratory Findings in Acute Pancreatitis

At onset		At 48 hours	
Age	>55	Hematocrit	Fall by $\geq 10\%$
Leukocyte count	>16,000/mm ³	BUN	Increase by ≥ 5 mg/dL (1.8 mmol/L) despite fluids
Blood glucose	>200 mg/dL (11.1 mmol/L)	Serum calcium	<8 mg/dL (2 mmol/L)
LD	350 U/L	pO ₂	<60 mm Hg
AST	>250 U/L	Base deficit	>4 mEq/L
		Fluid sequestration	>6000 mL

AST, Aspartate aminotransferase; BUN, blood urea nitrogen; LD, lactate dehydrogenase; pO₂, partial pressure of oxygen.

activates most of the other digestive enzymes and produces tissue damage and necrosis of the pancreas, surrounding fat, and adjacent structures.

Other enzymes that have been proposed as diagnostic tools include pancreatic isoamylase, phospholipase A, elastase 1, and trypsinogen 2 (Forsmark, 2007). Other tests (aspartate aminotransferase, alanine aminotransferase, C-reactive protein [CRP], hematocrit, carbohydrate-deficient transferrin [CDT], trypsinogen activation peptide [TAP]) have shown low sensitivity for diagnosing acute pancreatitis. CDT is a marker for chronic alcoholism. Urinary TAP is a valuable marker for severity of pancreatitis. Markers of inflammatory response (e.g., CRP) peak, following interleukin (IL)-1 and IL-6 increases, on day 3 after onset of abdominal pain; this is useful in predicting the severity of pancreatitis (Smotkin, 2002).

Computed tomography (CT) scan is the most useful test to establish the diagnosis, with characteristic radiologic findings of enlarged edematous and inflamed pancreas with or without surrounding fluid collection, with or without necrosis. An ultrasonogram may be useful in showing a diffusely enlarged, hypoechoic pancreas, and may show the presence of gallstones in the gallbladder, indicating a possible cause. A CT severity score (the Balthazar score) is based on the degree of necrosis, inflammation, and fluid collection. A 23% mortality rate is associated with any degree of pancreatic necrosis, and a strong association has been noted between necrosis and morbidity and mortality. After initial assessment, a CT scan need not be repeated unless one suspects development of a complication such as pancreatic necrosis. Magnetic resonance imaging (MRI) is being used increasingly to detect pancreatitis, and to characterize the **pancreatic necrosis** seen on CT into peripancreatic necrotic fluid collection, necrotic pancreatic parenchyma, and hemorrhagic foci. MRI can also detect pancreatic duct disruption, seen early in the course of acute pancreatitis.

Serum and urine amylase elevations occur in many conditions other than pancreatitis, such as renal failure, parotitis, and diabetic ketoacidosis. Patients with acidemia may have spurious elevations of serum amylase. This explains why patients with diabetic ketoacidosis may have marked elevations of serum amylase without evidence of acute pancreatitis. No data indicate that measuring both amylase and lipase adds significant diagnostic accuracy. Once the diagnosis is established, daily measurement of amylase or lipase provides little value in gauging the clinical course or the prognosis.

Predictors of severe acute pancreatitis include hematocrit >44% with failure to decrease at 24 hours (this is indicative of pancreatic necrosis and is predictive of organ failure) and C-reactive protein >150 mg/L. Serum creatinine >2.0 mg/dL or marked hyperglycemia (>150 mg/dL) is predictive of mortality (Lankisch, 2001). A strong association has been found between the extent of blood urea nitrogen (BUN) increase and mortality at 24 hours. Each increase in BUN of 5 mg/dL was associated with a corresponding increase in mortality. A reduction in blood urea was associated with significantly improved survival (Wu, 2009) (Table 22-3).

Hemorrhagic pancreatitis, a severe form of acute pancreatitis, results from necrosis within and around the pancreas with hemorrhage that may cause shock and death. Initially, necrosis is coagulative, but necrotic cells rapidly undergo liquefaction. Biliary tract disease with gallstones or inflammation of the gallbladder or bile ducts, or alcoholism, is present in about 80% of patients. The male/female ratio is 1:3 in acute pancreatitis associated with biliary tract disease, and 6:1 in alcoholism. Pancreatic microlithiasis may be responsible for many cases.

The sequence of changes following release of activated intrapancreatic enzymes in acute pancreatitis consists of microvascular leakage causing

edema, necrosis of fats, and acute inflammatory reaction. Proteolytic destruction of pancreatic tissue and blood vessels causes edema and focal dilation of acini with variable amounts of hemorrhage. In fat necrosis, neutral fats are broken down, glycerol is reabsorbed, and fatty acids combine with calcium salts to form soaps (saponification) with a zone of acute inflammation around the foci of necrosis. After a few days, secondary infection with suppuration and abscesses may occur.

In 15%–30% of those with pancreatic necrosis, poorly defined areas of acute fluid collection occur, along with fibrosis. The liquefied areas are walled off, and pseudocysts form. Pseudocysts contain pancreatic fluid enclosed in fibrous tissue with no epithelial lining; they often communicate with a pancreatic duct and continue to increase in mass.

Complications of Acute Pancreatitis

Hypocalcemia and mild jaundice may appear after 24 hours as the result of biliary obstruction. A sepsis-like syndrome due to digestive enzymes in the systemic circulation may cause the release of inflammatory cytokines, a systemic immune response syndrome with severe systemic complications. About 75% of patients with acute pancreatitis have a benign course and recover rapidly. No treatment has proven to interrupt the inflammatory process effectively.

Idiopathic acute pancreatitis occurs in about 10%–20% of patients with pancreatitis. It is believed that many cases are germline mutations of cationic trypsinogen (*PRSS1*) or serine protease inhibitor, kazal type 1 (*SPINK1*). There is high risk for development of endocrine or exocrine insufficiency and pancreatic adenocarcinoma. These mutations can cause an autosomal recessive hereditary acute or chronic pancreatitis with onset in childhood or early adulthood. *PRSS1* abrogates the inactivation of trypsinogen for cleavage of trypsin. *SPINK1* mutation inactivates pancreatic secretory trypsin inhibitor (Howes, 2005; Schneider, 2005).

Patients with these disorders typically have recurrent acute pancreatitis sometime between infancy and the fourth decade. Chronic pancreatitis and pancreatic cancer develop at a relatively young age. No specific treatment is known for the prevention or treatment of hereditary pancreatitis. Clinical testing is available for the disorders described (Ettemad, 2001).

Chronic Pancreatitis

It is the irreversible damage and often progressive inflammation with irregular fibrosis, duct dilation, and loss of pancreatic parenchyma that characterize chronic pancreatitis. This occurs after repeated bouts of acute pancreatitis, obstruction of pancreatic duct by mechanical blockage or congenital defect or by neoplasm, gallstone duct obstruction, or alcoholism. Early in the course, the pancreas becomes enlarged. Some cases develop pseudotumor mass lesions. Subsequently, as the result of scarring, the gland usually shrinks with loss of acini and still later loss of ductules. Preserved or even increased islets are seen in the fibrous scar. Patients seek medical attention for abdominal pain or maldigestion.

Maldigestion/malabsorption and steatorrhea are due to pancreatic insufficiency with loss of enzymes; glucose intolerance or diabetes, and islet damage. A low level of fecal elastase is diagnostic. Clinically, recurrent or chronic pain is reported at a lower incidence than in acute pancreatitis, but this is now increasing in frequency. The incidence is greater in males than in females, and the average age of onset is 40 years. It is more prevalent in tropical countries, and the main form is chronic calcifying pancreatitis with duct calcifications. In temperate areas, chronic alcoholism is reported in more than half of cases. No causative factor is apparent in 40% of cases.

The central enzyme involved in activation of all digestive proenzymes is trypsin, which is synthesized and maintained as inactive trypsinogen in secretory granules in the pancreatic acinar cell. After release into the pancreatic duct, trypsinogen is cleaved by enterokinase on the brush border of the duodenum to active trypsin. Trypsin is stabilized in the pancreatic acini by a serine protease inhibitor, *SPINK1*. Mutations in *SPINK1* increase the risk of chronic pancreatitis almost 12-fold by impairing the ability of acinar cells to counteract and inhibit the damaging effects of intracellular trypsin (Schneider, 2004; DiMagno, 2005). *PRSS1* mutations involving codons 29 and 122 cause autosomal dominant forms of hereditary pancreatitis (Whitcomb, 2000; Cohn, 2005).

GASTROENTEROLOGIC DISORDERS

PEPTIC ULCERATION

Helicobacter pylori has been recognized as the principal cause of duodenitis and duodenal ulcers, and has been strongly associated with chronic antral gastritis, gastric ulcer, nonulcer dyspepsia, gastric carcinoma,

and mucosa-associated lymphatic tissue lymphoma (Peterson, 1991; Veldhuyzen, 1994; Thiede, 1997; Wotherspoon, 1998). The use of nonsteroidal anti-inflammatory drugs (NSAIDs) causes or aggravates peptic and gastric inflammation and ulceration. Hypersecretory states are a much rarer cause of peptic ulcer disease. Data gathered by history and physical examination may initially suggest peptic ulcer disease. Radiologic and/or endoscopic techniques are employed to confirm the diagnoses. Testing for *H. pylori* and hypersecretory states involves laboratory analysis.

Because *H. pylori* has been shown to be the most important cause of peptic ulcer disease and is significantly associated with multiple other types of upper GI pathology, a great deal of research has focused on its detection and treatment, and on confirmation of pathogen eradication. Within the last decade, numerous products used for the detection of this bacterium have become commercially available. A cogent argument has been made that all patients found to harbor this organism should be treated (Graham, 1997). Although the numbers and types of tests will likely continue to grow, tissue sampling, breath tests, and fecal antigen detection are currently the mainstay in the diagnostic armamentarium.

Testing for *H. pylori* often utilizes the organism's ability to produce urease. Radioactive and nonradioactive hydrogen breath tests are examples of noninvasive means for detecting active *H. pylori* infection. Each is sensitive and specific before therapy. The incidental use of proton pump inhibitors (PPIs), antibiotics, or bismuth-containing antacids may lead to false-negative tests. Treatment of *H. pylori* may not lead to complete eradication of the organism. Hydrogen breath tests may be falsely negative if they are performed too soon after treatment, before the bacterial load is great enough to be detected (Atherton, 1994).

Serum antibodies directed against *H. pylori* can be used to detect exposure to *H. pylori*. Enzyme immunoassay (EIA) tests are available and reliable (Feldman, 1995; Feldman & Evans, 1995; van de Wouw, 1996). Although quantitative levels of these antibodies are not currently routinely utilized in the clinical setting to determine whether there is current or past infection, they have been reported to be highly accurate (Lerang, 1998). At present, serology is generally used to screen for *H. pylori*, and breath tests are used to confirm eradication after treatment. Alternatively, endoscopy allows collection of tissue for rapid urease testing or histologic examination (Megraud, 1997).

Urease-based chemical tests are used routinely to detect *H. pylori* in biopsy specimens obtained via endoscopy. Fresh biopsy specimens obtained via endoscopy are placed into fluids or gels containing urea. The bacterial urease splits the urea, producing ammonia. The change in pH affects a color indicator, thus providing the basis for detection. Bacterial load will determine the amount of urease present and can affect the rapidity of the response. If the load is too low, the test can be falsely negative (Xia, 1994).

Office-based serologic quick-test kits are available. The accuracy of these kits has been shown to be dependent on the antibody preparations used. IgG preparations perform most consistently. Other test qualities such as reproducibility, cost, and ease of utilization are factors to be considered when reviewing each of the many available brands marketed today (Laheij, 1998). Histologic review of biopsy specimens stained with Warthin-Starry or Giemsa stain remains one of the most frequently employed techniques to detect active infection. Culture of the organism may be inconsistent and usually is not done in routine clinical settings. If endoscopy must be performed for other reasons, a rapid urease test is the least expensive means of documenting the presence of *H. pylori*.

Hypersecretory states are suggested by extensive peptic ulcer disease, especially in the absence of *H. pylori*, and by the use of NSAIDs. Failure to respond to the usual doses of histamine-2 (H_2)-receptor blocking agents and PPIs also suggests oversecretion of hydrochloric acid. Although gastric analysis remains the "gold standard" with regard to the amount of acid secreted, it is invasive and is used much less frequently. Care must be taken to avoid the use of antisecretory medications for the appropriate time intervals before such testing. H_2 -receptor blockers should be held for 48 hours, and PPIs should be avoided for 7 days. H_2 -receptor blockers are available without a prescription, so patient education is important, and clinicians must remember to review all of the medications utilized by their patients.

ZOLLINGER-ELLISON SYNDROME

This syndrome is defined by the triad of peptic ulceration, hyperchlorhydria, and non- β islet cell tumors (gastrinomas). Duodenal ulcers do not occur in achlorhydric individuals but are present in those with extreme hyperchlorhydria. Gastrinomas may occur in the body or tail of the pancreas or in the upper duodenum; they may be multiple and malignant.

About 25% of Zollinger-Ellison (ZE) patients have multiple endocrine neoplasia (MEN) 1 with hyperparathyroidism (Hung, 2003).

Gastrin levels, with and without secretin stimulation, can be used to diagnose ZE syndrome. Serum gastrin levels greater than 150 ng/L (reference, <100 ng/L), especially with simultaneous gastric pH values of <3, are highly suggestive of a gastrinoma. For equivocal results, secretin (2 U/kg in 10 mL 0.9% sodium chloride) can be given intravenously in 30 seconds, and serial gastrin levels can be drawn at 0, 2, 5, 10, 15, 20, and 30 minutes. An increase in gastrin of ≥ 200 ng/L within 15 minutes of injection is considered a positive test result. Octreotide, a synthetic form of somatostatin, has been used for localization of tumors. Radiolabeled octreotide binds to somatostatin receptors and can be subsequently localized by scintigraphy (Zimmer, 1995). If such tumors are surgically removed, gastrin levels can be used to assess potential success or future recurrence (see Gastrinoma in the Neuroendocrine Tumors section).

Gastrin is a primary GI hormone that is produced mainly by the antral G cells; it regulates gastric acid secretion and stimulates growth of the gastric mucosa, among other functions. To a lesser extent, gastrin is produced by G cells of the proximal small intestine and δ cells of the pancreas. Gastrin acts on the parietal cells located in the fundus of the stomach, stimulating the secretion of gastric acid. Gastrin also increases blood flow to the stomach and is responsible for increased gastric and intestinal motility. Other functions include stimulation of gastric pepsinogens and intrinsic factor secretion, release of secretin from the small intestine, and secretion of pancreatic enzymes as well as bicarbonate (Hill, 2006). This hormone is secreted from antral distention mainly after the detection of digested protein products. Maximal stimulation of gastrin secretion occurs within a pH range of 5–7. An acid environment serves as a negative feedback mechanism for the release of gastrin, with 80% reduction in secretion at a pH of 2.5 (Hill, 2006). This serves to protect the stomach from over-acidification caused by excess stimulation of gastrin. For this reason, individuals on acid suppression therapy for peptic ulcer disease may have elevated gastrin levels.

Three main forms of gastrin are found in human blood and tissues: G34, G17, and G14, known as big gastrin, little gastrin, and mini gastrin, respectively. There are different assay sensitivities to these forms. All gastrins originate from a single precursor, progastrin, which is cleaved by the action of trypsin. It is interesting to note that in pathologic cases of increased gastrin production, as with achlorhydric gastritis or gastrinomas, larger molecular forms of gastrin and incompletely processed precursors are present and are beyond the scope of detection by conventional assays. In such cases, only little gastrin would be detectable in serum (Goetze, 2003).

Laboratory determination of gastrin levels with radioimmunoassay (RIA) or EIA is indicated for the confirmation of suspected gastrin-secreting tumors, namely, gastrinomas or ZE syndrome. The antibodies present in these assays are specific for the biologically active C-terminal of the gastrin molecule, and they have minimal cross-reactivity with cholecystokinin (CCK) peptides. Before determination of gastrin levels, a patient must be fasting for 12 hours because the concentration of G34 doubles and the concentration of G17 quadruples following a meal, altering the results of the assay. Specimens must be frozen immediately because gastrin is unstable in serum. Because of the action of proteolytic enzymes, 50% of the specimen's immunoreactivity may be lost within 48 hours at a temperature of 4° C. It is recommended that specimens should be kept in a freezer at a temperature of –70° C without a self-defrosting cycle, if long-term storage is required. Specimens must be analyzed immediately after thawing, while avoiding refreezing and thawing.

Fasting serum gastrin levels are increased with increasing age, especially in patients older than 60 years, in part because of gastric mucosal atrophy. Approximately 15% of individuals older than 60 years may have gastrin levels between 100 and 800 ng/L (Hill, 2006). Reference intervals for infants and children differ from those for adults; interpretation should use age-specific reference ranges. Gastrin concentration greater than 1000 ng/L with gastric acid hypersecretion (basal acid secretion >15 mmol/hour) is diagnostic of gastrinoma. The secretin stimulation test is a provocative biochemical test that can help confirm the diagnosis of ZE in questionable cases. Infused secretin should cause a drop in gastrin levels in normal individuals. However, in patients with ZE, a dramatic increase in gastrin level is seen after secretin infusion. The mechanism by which secretin stimulates an increase in gastrin levels in these patients is poorly understood; however, it is thought to be due to a direct local effect on blood flow to the tumor (Ashley, 1999). Limitations include altered results from conditions that may lead to elevated gastrin levels such as gastric ulcer disease, chronic renal failure, hyperparathyroidism, pyloric obstruction, vagotomy, retained gastric antrum, short bowel syndrome, and

pernicious anemia. Certain medications, such as antacids, H₂-blocking agents, and proton pump inhibitors, can also increase gastrin measurements; all of these agents are commonly used in the treatment of patients with peptic ulcer disease. However, the elevations are moderate and certainly are not as high as in a patient with a gastrin-secreting tumor.

Intraoperative testing for gastrin is of potential use because gastrinomas can be multiple and are often difficult to locate, because they can be distributed widely in the stomach, pancreas, and duodenum or periaortic lymph nodes. Intraoperative gastrin measurement is of potential use because gastrin has a short half-life of approximately 10 minutes. The catabolic breakdown of most peptide hormones follows first-order exponential decay. Therefore, if the entire hormone-secreting tissue is surgically resected, only approximately 12.5% of the baseline concentration would be present in serum after three half-lives. When patients with ZE or gastrinoma were evaluated with intraoperative gastrin assays, a drop in gastrin levels to within reference values within 20 minutes of resection was indicative of cure (Sokoll, 2004).

Pepsin and Pepsinogen

Pepsinogens are the biologically inactive proenzymes of pepsins that are produced by chief cells and other cells in the gastric mucosa and are found in two distinct types: pepsinogen I (PGI), also known as pepsinogen A, and pepsinogen II (PGII), also known as pepsinogen C. Pepsinogen secretion is stimulated by the vagus nerve, gastrin, secretin, and CCK, and is inhibited by gastric inhibitory peptide (GIP), anticholinergics, histamine H₂-receptor antagonists, and vagotomy (Hill, 2006). PGI is produced in the chief cells and mucous cells of oxyntic glands; PGII is produced in mucous cells in oxyntic and pyloric regions and in the duodenum. The ratio of concentration of PGI to PGII in the serum or plasma of healthy individuals is approximately 4:1 (Samloff, 1982). Pepsinogen is converted to the active form, pepsin, by gastric acid that can activate additional pepsinogen autocatalytically. Both groups of pepsinogens are activated at an acid pH below 5 and are destroyed by alkaline pH. Both types can be detected in blood. Only type I pepsinogens are present in the urine. Pepsins are responsible for the hydrolysis of proteins to polypeptides. The pepsinogen released from the gastric mucosa constitutes a major component of gastric fluid. Only approximately 1% gets into the peripheral blood. Active pepsin is rapidly inactivated in the bloodstream, whereas pepsinogen is stable in the blood. Pepsinogen is then filtered by the kidneys and is excreted in the urine, where the slightly acidic pH converts the pepsinogen, now called **uropepsinogen**, to uropepsin (Hill, 2006). Immunoassay is the method used to detect serum pepsinogen. However, the PGI isoform is commonly analyzed in the clinical laboratory because it is the isoform commonly associated with disease.

Serum levels of pepsinogen I provide an accurate estimate of parietal cell mass and correlate with the acid-secretory capacity of the stomach. Increased pepsinogen levels and associated activity are observed in patients with disease states that lead to increased gastric output or with increased parietal cell mass, namely, gastrinoma, ZE syndrome, duodenal ulcer disease, and acute and chronic gastritis. Decreased levels of pepsinogen are associated with decreased parietal cell mass, atrophic gastritis, and gastric carcinoma, as well as with myxedema, Addison's disease, and hypopituitarism (Hill, 2006). The PGI/PGII ratio decreases linearly with worsening atrophic gastritis. Absence of pepsinogen is noted in patients with achlorhydria. PGI levels measured by immunoassay usually range from 20–107 μ g/L, and PGII levels usually range from 3–19 μ g/L.

Pepsinogen assays are being explored for their utility in the noninvasive identification of patients with chronic atrophic gastritis and to obtain an estimate of the extent of atrophic gastritis, a known precursor of gastric carcinoma. Severe atrophic body gastritis causes a four- to fivefold increase in the risk of gastric carcinoma compared with healthy individuals (Miki, 2003). It is hoped that this finding will help to identify a subgroup of individuals with chronic atrophic gastritis who would benefit from endoscopic evaluation for detection of early-stage gastric tumor. These assays are currently utilized in Japan, an area marked by high prevalence of gastric cancer, as a potential method for widespread screening of high-risk individuals (Miki, 2003). These authors recommended that criteria for diagnosing chronic atrophic gastritis should include persons with PGI <70 μ g/L and a PGI/PGII ratio <3.0. In Japan, the pepsinogen serum screening test has been demonstrated to detect a higher percentage of early cancers compared with conventional methods, and a considerable number of patients have subsequently been candidates for treatments with endoscopic surgery (Miki, 2003). The most sensitive test for fundic atrophic gastritis is considered to be the PGI/II serum ratio, with 99% sensitivity and 94% specificity (Hill, 2006). Furthermore, PGII levels may be a useful marker

of prognosis, serving as an independent predictor of tumor biology and survival in patients with gastric carcinoma. The absence of PGII production has been associated with aggressive tumor behavior and shorter overall survival in gastric cancer patients (Fernandez, 2000). Pepsinogen assays therefore may prove useful as a serum screening method for detection of gastric carcinoma among high-risk individuals.

DIARRHEA AND MALABSORPTION

Diarrhea

About 8–10 L of fluid enters the duodenum every 24 hours. Much of this fluid is absorbed in the small intestine, and about 1.5 L enters the large intestine, but only 100–150 mL is voided in stools. Increased fluid secretion or decreased fluid absorption in the small or large intestine may result in diarrhea. One of the most important parameters defining diarrhea in an individual patient is a change in the usual bowel habit to more frequent looser stools. Diarrhea is the passage of three or more loose or liquid stools per day, or more frequently than is normal for the individual (WHO, 2009). A decrease in fecal consistency (i.e., increased fluidity) is difficult to measure, thus increased stool weight, frequency, and duration are used in defining diarrhea.

The diagnosis of diarrhea starts with a thorough history to characterize the condition: Is the diarrhea bland or bloody (dysentery); are there constitutional symptoms; what is the duration of the illness? Self-limited, acute diarrhea (<2 weeks in duration) without bleeding or constitutional symptoms rarely requires diagnostic testing. Chronic diarrhea, the passage of blood, and constitutional symptoms all suggest the need for a specific diagnosis. History is the key to developing the differential diagnosis and guiding the laboratory evaluation (Table 22-4). The physical examination, although usually less helpful than the history, must be comprehensive.

Acute diarrheas of <4 weeks generally have an infectious origin. Those with a course of >4 weeks are considered chronic diarrheas (Fine, 1999) and are categorized as osmotic, secretory, or inflammatory. Hypermotility or shortened gut may reduce the transit time and absorptive surface, resulting in diarrhea and/or some degree of malabsorption.

Osmotic diarrhea results from unabsorbable or poorly absorbed solutes. These include polyethylene glycol in colon-cleansing solutions, magnesium salts (magnesium citrate in cathartics, magnesium hydroxide in some antacids), sorbitol in chewing gum, lactulose in the treatment of hepatic encephalopathy, and lactose in lactase-deficient individuals. These osmotically active substances in the lumen alter the osmotic gradient that normally favors Na^+ absorption, drawing fluid into the lumen.

Fasting or cessation of consumption of the suspected solute stops osmotic diarrhea. Stool pH values of <5.6 are consistent with carbohydrate malabsorption (Fine, 1999). Sodium and potassium concentrations in stool water are measured to calculate the fecal osmotic gap, which estimates the contributions of electrolytes and nonelectrolytes to water retention in the gut lumen. Osmotic gap is useful in differentiating osmotic from secretory diarrhea; it is best calculated as $290 - 2 \times ([\text{Na}^+] + [\text{K}^+])$, where 290 represents the stool osmolality that approximates plasma osmolality, and a factor of 2 is used to account for associated anions. Osmotic gaps of >125 mOsm/kg characterize osmotic diarrhea, and those of <50 mOsm/kg are seen in secretory diarrhea (Fine, 1999).

Stool osmolality must be measured on a freshly collected specimen. Because of continued degradation of stool carbohydrates, osmolality of the specimen increases over hours. Continued diarrhea during a 48-hour fast is suggestive of a secretory process, although fecal weight may decrease because of increasing dehydration (Fordtran, 1967; Fine, 1999).

Disaccharidase Deficiency

Many of the previously listed conditions causing malabsorption may also be associated with intolerance to disaccharides. Disaccharide absorption may be diminished from primary disaccharidase deficiencies such as sucrase-isomaltase deficiency, lactase deficiency, primary alactasia, or primary trehalase deficiency; or from secondary disaccharidase deficiencies due to celiac disease, tropical sprue, acute viral gastroenteritis, or drugs such as orally administered neomycin, kanamycin, and methotrexate. These secondary disaccharidase deficiencies are usually transient and involve more than one enzyme. Although the incidence of lactose intolerance due to congenital lactase deficiency is low, the prevalence of lactose intolerance in adults is quite high. About 10% of Caucasians, 70% to 80% of African Americans, and an even greater percentage of Asians manifest some degree of lactose intolerance, even though they were able to digest lactose well as infants. In these disorders, intestinal bacteria ferment unhydrolyzed and unabsorbed carbohydrates, producing gas, lactic acid, or

other organic acids. Normally, absorption of digested carbohydrates is rapid and fairly complete in the proximal small intestine. Unhydrolyzed disaccharides or monosaccharides unabsorbed because of deficiencies in transport are osmotically active and hence cause secretion of water and electrolytes into the small and large intestines. This can result in protracted diarrhea, as well as complaints of bloating and flatulence.

Screening tests for disaccharidase deficiencies include oral challenge of suspected disaccharides to reproduce the abdominal symptoms, followed by stool analysis. The stools are usually watery, acidic, explosive, and fermentative. Stool pH of less than 5.5 is suggestive, but the measurement of pH is not valid if the patient is taking oral antibiotics. High pH does not exclude the diagnosis. Normal infants between 3 and 7 days of age commonly have high stool pH. Stools can be analyzed for sugars by chromatography or by one of the semiquantitative nonspecific tests for urinary sugar adapted for stool analysis. The Clinitest tablet (Bayer Diagnostics, Australia) is suitable for this purpose. The presence of 0.25 g/dL reducing substances is considered normal; from 0.25–0.5 g/dL is regarded as suspicious; and more than 0.5 g/dL is considered abnormal. In patients with intolerance to sugar, the amount of total reducing substance in the stool usually exceeds 0.25 g/dL feces.

An oral tolerance test using a specific sugar such as lactose or sucrose can be used to establish a specific carbohydrate intolerance. Although the oral tolerance test is fairly specific and sensitive, in some instances 23%–30% false-positive results were noted following administration of lactose, that is, a flat tolerance curve and less than 20 mg/dL (1.1 mmol/L) increase in blood sugar (Krasilnikoff, 1975). Delayed gastric emptying appears to be the cause of the false-positive result because duodenal instillation of lactose eliminates the flat tolerance curve.

Definitive diagnosis of disaccharidase deficiency depends on the demonstration of low specific enzyme activity in the mucosa of small intestinal biopsy material. An assay for disaccharidase has been published (Dahlqvist, 1968).

Lactose Tolerance Test

A lactose tolerance test provides a presumptive diagnosis of lactase deficiency. In patients with alactasia or hypolactasia, whether primary or secondary to mucosal disease, oral lactose results in an insignificant rise in blood glucose. Following an overnight fast, a blood sample is drawn, and 50 g of lactose dissolved in 400 mL of water is orally administered. A 100 g lactose dose has been reported to yield more definitive results. Blood samples are collected at 30, 60, and 120 minutes after lactose ingestion. An optional 5-hour stool specimen can be collected, and its appearance, consistency, and pH noted.

Patients with lactase deficiency exhibit a peak rise of <20 mg/dL of reducing substances, expressed as glucose. In individuals with flat tolerance curves, the test should be repeated in 2 days and the less abnormal of the two curves used for interpretation. In patients with lactase deficiency, the nonabsorbed lactose, upon reaching the colon, is degraded to gas and lactic acid, which inhibits salt and water absorption, resulting in abdominal discomfort and diarrhea. In children, the oral dose of lactose or other sugars is 2 g/kg body weight. Lactase can also be detected in a mucosal biopsy specimen.

Secretory diarrhea is evoked by a variety of exogenous and endogenous secretagogues. The hypersecretion of isotonic fluid exceeds the absorptive capacity of the colon. Cholera toxin activates mucosal cyclic adenosine monophosphate (cAMP) that results in outpouring of vast quantities of salt and water in jejunum with normal structure. In Verner-Morrison syndrome (pancreatic cholera), vasoactive intestinal peptide also activates cAMP. Thus, secretory diarrhea remains unrelieved despite fasting.

Diarrhea also occurs in hypergastrinemic states (e.g., ZE syndrome). Sustained hypersecretion of acid lowers intestinal pH, denatures pancreatic enzymes (causing steatorrhea), and precipitates bile salts (causing bile salt malabsorption); the latter induces water secretion in the colon. In patients with mastocytosis, excessive histamine release stimulates acid hypersecretion, but plasma gastrin concentrations remain low or normal. Gastrointestinal dysfunction caused by release of mast cell mediators can be observed in both cutaneous and systemic mastocytosis (Liu, 2010). Signs and symptoms include abdominal pain, diarrhea, nausea, vomiting, peptic ulcer disease, and GI bleeding. Diarrhea can result from increased motility induced by prostaglandin D_2 secretion or from decreased rectal compliance and overactive rectal contractility (Jensen, 2000).

Drug-Induced Diarrhea

Prokinetic agents (metoclopramide, domperidone, cisapride), proton pump inhibitors, and antibiotics (erythromycin and other macrolides)

TABLE 22-4

Laboratory Tests in the Differential Diagnosis of Diarrhea

Test	Method	Use
Initial Screening Tests		
Fecal leukocytes	Wright's stain or methylene blue	Identify inflammatory diarrhea
Fecal occult blood test	Peroxidase reaction for hemoglobin	Identify hemorrhagic diarrhea
Fecal osmotic gap	$290 - 2 \times (\text{fecal Na}^+ + \text{K}^+)$	Distinguish secretory vs. osmotic diarrhea
Stool alkalization	Color change after adding NaOH to stool/urine	Phenolphthalein laxative ingestion
Infectious Causes		
Stool bacterial culture	Routine culture and sensitivity	Identify <i>Shigella</i> , <i>Salmonella</i>
Stool special culture	Specialized culture and serotyping	Identify <i>Escherichia coli</i> 0157:H7, <i>Yersinia</i> , <i>Campylobacter</i>
Stool <i>Clostridium difficile</i> toxin assay	EIA for toxins A and B	Pseudomembranous colitis
HIV serology	EIA, Western blot	HIV enteritis
Stool rotavirus screen	EIA for antigen	Rotavirus enteritis
Stool ova and parasites	Concentration and stains	Enteric parasitic infection
Stool mycobacteria	Acid-fast stain and culture, PCR	<i>M. tuberculosis</i> , MAI complex
Stool <i>Entamoeba histolytica</i> antigen (Ag)	EIA for antigen	<i>E. histolytica</i>
Stool <i>Giardia</i> Ag	EIA for antigen	<i>Giardia lamblia</i>
Stool <i>Cryptosporidium</i> Ag	EIA for antigen	<i>Cryptosporidium parvum</i>
Endocrine Causes		
Urine 5-HIAA or blood serotonin	HPLC	Carcinoid syndrome
Serum VIP	RIA	VIPoma
Serum TSH, free thyroxine (T_4)	Immunoassay	Hyperthyroidism
Serum gastrin	RIA	Zollinger-Ellison syndrome
Serum calcitonin	RIA	Hypocalcemia-related diarrhea
Serum somatostatin	RIA	Somatostatinoma
Malabsorption		
Lactose tolerance test	See text	Lactase deficiency
Stool-reducing sugars	Clinitest tablets	Carbohydrate intolerance
Sweat chloride	See text	Cystic fibrosis
D-Xylose absorption test	See text	Evaluate jejunal function
Fecal fat stain	Sudan stain for globules	Lipid malabsorption
Serum carotene	Spectrophotometry	Lipid malabsorption
^{14}C -glyceryl trioleate test malabsorption	See text	Lipid malabsorption
Serum IgA	Nephelometry	Rule out IgA deficiency
Anti-tissue transglutaminase antibody	EIA	Celiac disease
Hydrogen breath test	Gas chromatography	Carbohydrate malabsorption
Bacterial colony count	Small bowel aspirate and quantitative culture	Bacterial overgrowth
Other		
Serum ionized calcium	Ion-specific electrode	Hypocalcemia-related diarrhea
Serum protein and albumin	Nephelometry, turbidimetry	IBD, protein-losing enteropathy
Stool α -1-antitrypsin	See text	Protein-losing enteropathy
Quantitative immunoglobulins	Nephelometry	Agammaglobulinemia
7- α -hydroxy-4-cholestin-3-one	HPLC	Bile salt malabsorption
Fecal elastase or pancreolauryl test	EIA	Pancreatic insufficiency
Intestinal biopsy	Endoscopic or open biopsy	Whipple's disease, MAI, abetalipoproteinemia, neoplasia, lymphoma, amyloidosis, eosinophilic gastroenteritis, agammaglobulinemia, intestinal lymphangiectasia, Crohn's disease, tuberculosis, graft-versus-host disease, <i>Giardia</i> , other parasitic infections, collagenous colitis, microscopic colitis
Extraintestinal causes	See text	Hyperthyroidism, diabetes, hypoparathyroidism, adrenal cortical insufficiency, hormone-secreting tumors

5-HIAA, 5-hydroxyindoleacetic acid; Ab, antibody; Ag, antigen; EIA, enzyme immunoassay; HIV, human immunodeficiency virus; HPLC, high-performance liquid chromatography; IBD, inflammatory bowel disease; Ig, immunoglobulin; MAI, *Mycobacterium avium-intracellulare*; PCR, polymerase chain reaction; RIA, radioimmunoassay; TSH, thyroid-stimulating hormone; VIP, vasoactive intestinal polypeptide.

produce loose stools or diarrhea. Erythromycin binds motilin receptors on the GI smooth muscle membranes (motilin agonist). When used as a prokinetic agent, intravenous administration is more effective than oral dosage, and long-term use downregulates motilin receptors.

Other Causes of Diarrhea

Diarrhea may occur in patients with hypothyroidism and hyperthyroidism, diabetes and adrenal insufficiency, tumors (villous adenoma, small bowel carcinoid), and infiltrative disorders (scleroderma, reactive amyloidosis,

gut lymphoma). Ethanol abuse, ischemic bowel disease, and radiation enteritis also produce diarrhea. Heat-labile enterotoxin of *Escherichia coli* and toxins of *Staphylococcus aureus* and *Clostridium perfringens* activate biochemical events that induce a secretory response.

Gut Peptides in Diarrhea

In acute infectious diarrheas, the plasma concentrations of glucagon, PYY, and motilin may be increased, contributing most likely to altered gut motility and promoting mucosal repair. Patients with Crohn's disease have

an elevated pancreatic polypeptide, GIP, motilin, and glucagon, and in ulcerative colitis, a modest elevation is observed in pancreatic polypeptide, GIP, motilin, and gastrin, the last in response to the associated hypochlorhydria. No demonstrable abnormalities in gut peptides account for disordered motility in the irritable bowel syndrome.

Vasoactive Intestinal Peptide

VIPomas are rare tumors that secrete vasoactive intestinal polypeptide (VIP). VIP suppresses gastric acid secretion, resulting in secretory diarrhea with stool volume exceeding 700 mL/day in all patients (even during fasting) and 3 L/day in approximately 70%. The stools are tea-colored and odorless, with features of a secretory diarrhea such as persistence with fasting, high sodium concentration, and a low stool osmotic gap. Most patients with VIPoma have the watery diarrhea-hypokalemia-hypochlorhydria (WDHA) syndrome. The diagnosis of VIPoma is established by the presence of an otherwise unexplained high-volume secretory diarrhea and a serum VIP concentration in excess of 75 pg/mL. It is important to replace fluid losses in these patients, and octreotide may be used to control diarrhea.

Patients usually present between 30 and 50 years of age; 90% of cases are primary pancreatic tumors, most commonly arising in the body or tail. Metastatic spread has already occurred in 60%–70% at presentation. Long-acting somatostatin analogs control symptoms in >90% (Kapoor, 2009).

Vasoactive intestinal peptide, released in response to gut distention, is a potent vasodilator and is responsible for the relaxation of vascular and nonvascular smooth muscle of the intestinal tract. It is also a potent stimulator of water and electrolyte secretion, acting through stimulation of cAMP. Similar to glucagons, VIP stimulates breakdown of glycogen and lipid stores and inhibits histamine-stimulated acid secretion in the stomach, resulting in hypochlorhydria or achlorhydria.

Laboratory evaluations for determination of VIP levels are clinically relevant for diagnosis of VIPomas. These VIP-secreting tumors, most commonly of pancreatic origin, account for 10% of neuroendocrine tumors of the gastrointestinal tract. Approximately 60% of VIPomas are malignant, and 6% are associated with MEN type 1. This syndrome was first described in 1958 by Verner and Morrison, and is characterized by WDHA.

VIPomas produce a severe, secretory diarrhea that has been termed pancreatic cholera. Diarrhea may be present for several years before the diagnosis of VIPoma. Patients typically produce more than 3 L of watery stools per day, although volume can be as high as 30 L/day. Diarrhea is not controlled with fasting, and an average secretion of 300 mmol of potassium per 24 hours occurs (Vinik, 2004). Stool volume of less than 700 mL/day excludes the diagnosis of VIPoma. If the diagnosis is missed or delayed, as is often the case, chronic diarrhea results in severe fluid and electrolyte imbalances that produce a myriad of clinical symptoms, the most severe of which is sudden death from cardiac arrhythmias resulting from electrolyte disturbances with potassium depletion and acidosis. The typical metabolic profile seen in these patients is hypokalemia with hyperchloremic metabolic acidosis. The diagnosis of VIPoma is made with confirmation of raised fasting VIP levels in association with secretory diarrhea and the presence of a lesion, most commonly located in the pancreas and associated with VIP production.

The biochemical assay of VIP is sensitive and specific. The normal value for circulating VIP levels is <170 pg/mL. For patients with functional VIP-secreting tumors, values range from 675–965 pg/mL (Thomas, 2003). Appropriate handling of the serum sample is critical for the accuracy of the VIP assay because VIP has a half-life of 1 minute. The serum must be added immediately to aprotinin, a protease inhibitor that prevents breakdown of VIP. The sample must be separated within 10 minutes and frozen to –20° C. Some of the non-VIP products of the precursor molecule are secreted at higher levels than VIP; however, commercially available assays are not available, and clinical utility has not been established. False-positive elevations of VIP can be observed in patients with small bowel ischemia or severe low-flow states resulting from diarrhea and subsequent dehydration not associated with VIP-producing lesions. In addition, serum pancreatic polypeptide level should be determined at the time of the VIP assay; this value will be elevated if the VIPoma is located within the pancreas.

CT scan, MRI, and abdominal ultrasound are useful imaging modalities for VIPoma tumor localization. Angiography can be used to localize smaller tumors. Various nuclear scans have been utilized for localization of VIPomas, including ¹²³I VIP receptor scintigraphy, which is currently under investigation.

Antibiotic-Associated Diarrhea

This term is typically reserved for *Clostridium difficile*, a gram-positive, spore-forming anaerobic bacillus that is the most important cause of nosocomial diarrhea in adults; more than 300,000 cases are reported per year in the United States. It is thought to be associated with approximately 25% of all antibiotic-associated cases of diarrhea and 50%–75% of cases involving antibiotic-associated colitis (Malnick, 2000). It may present clinically, from a mild watery diarrhea to life-threatening pseudomembranous colitis and toxic megacolon. This can lead to colonic perforation and peritonitis, with a mortality rate as high as 38% (Poutanen, 2004). Patients can present with watery diarrhea, lower abdominal pain/cramping, or systemic symptoms such as fever and malaise, or can have occult gastrointestinal bleeding. The pathogenesis of this disease entity usually involves disruption of the normal colonic flora, typically following a course of antibiotic therapy in hospitalized patients, followed by exposure to a toxigenic strain of *C. difficile*. Broad-spectrum antibiotics such as penicillin, clindamycin, and cephalosporins have been particularly implicated; however, any antibiotic can lead to development of *C. difficile* colitis (Malnick, 2000). Clinical suspicion of the disease is confirmed with detection of *C. difficile* toxin A or B virulence factors in stool samples. Toxins A and B lead to increased vascular permeability and have the potential to cause hemorrhage. They induce the production of tumor necrosis factor- α and inflammatory interleukins that are responsible for the inflammatory response and pseudo-membrane formation (Poutanen, 2004).

Endoscopic visualization of the colonic mucosa is required for diagnosis of pseudomembranous colitis associated with *C. difficile*. However, endoscopy should be avoided in cases of suspected fulminant colitis because of the risk of perforation. Laboratory methods are available for confirmation of *C. difficile* infection. Tissue culture cytotoxicity assays, which take at least 48 hours to complete, are considered the “gold standard” for the detection of *C. difficile* cytotoxin B in stool specimens, with a sensitivity ranging between 94% and 100% and a specificity of approximately 99%. This tissue culture assay can detect as little as 10 pg of toxin in stool specimens. Rapid EIAs, which can be completed within several hours, have been developed for the detection of toxin A or B from stool specimens. However, the sensitivity and specificity of these immunoassays are 65%–85% and 95%–100%, respectively, compared with cytotoxic assays. The EIA can detect 100–1000 pg of toxin in stool specimens. In hospitalized patients with more than six stools per day, EIA is the optimal diagnostic test (Malnick, 2000). Stool cultures can also be performed but require up to 96 hours for completion. Polymerase chain reaction (PCR) methods for detection of *C. difficile* toxin A or B are currently being developed with similar sensitivity and specificity profiles compared with cytotoxic assays (Poutanen, 2004). However, PCR is unable to distinguish between asymptomatic carriage and symptomatic infection. It is currently recommended that these tests be performed on diarrheal stools; in most cases, one stool sample is sufficient for the diagnosis of *C. difficile* infection (Poutanen, 2004). However, multiple samples may be required for confirmation, and empirical treatment with oral antibiotics may be indicated in patients with clinical evidence of *C. difficile* infection. Diarrheic stools can also be screened by an immunoassay for glutamate dehydrogenase antigen, a *C. difficile*-specific antigen, and those positive should be tested for toxins A and B (Fenner, 2008). Refer to Table 22-5 for laboratory tests available for the diagnosis of *C. difficile*-associated diarrhea.

HIV-Related Diarrhea

Diarrheal disease in human immunodeficiency virus (HIV)-infected individuals is frequently caused by infectious agents but may also be due to infiltrative diseases, such as lymphoma or Kaposi's sarcoma. Common enteric pathogens with sufficient virulence that cause disease in healthy hosts can also cause diarrheal disease in HIV-infected individuals with intact or compromised immunologic function. Less virulent pathogens such as *Cryptosporidium parvum*, which appear to require some immune compromise to establish disease, are more common in patients with more advanced HIV infection or acquired immunodeficiency syndrome (AIDS).

Mycobacterium avium-intracellulare complex (MAC) is predominantly associated with lung infection in immunocompetent patients. MAC may also produce disseminated disease with bowel infiltration and malabsorption in patients with severe immune compromise and should be considered in the differential diagnosis. In these cases, blood should also be obtained in fungal isolator tubes for culture.

In patients with HIV, it is important to ascertain the nature and chronicity of symptoms and the CD4 cell count. Patients with CD4 cell counts <100 cells per microliter are at risk for opportunistic infections that are

TABLE 22-5

Laboratory Tests for the Diagnosis of *Clostridium difficile*-Associated Diarrhea

Test	Advantages	Disadvantages
<i>Clostridium difficile</i> cytotoxin assay	Excellent specificity (99%–100%)	Decreased diagnostic sensitivity (80%–90%); test results not available until after 48 hours; requires tissue culture facility; detects toxin B only
Immunoassay for glutamate dehydrogenase antigen (GDA) of <i>C. difficile</i>	High negative predictive value without additional tests	Toxin assay required because GDA does not distinguish toxigenic and nontoxigenic strains
Immunoassay for detection of toxin A or toxins A and B	Good specificity (95%–100%); test results available within 4 hours; technically simple	Reduced sensitivity as compared with cytotoxin assay
Stool culture to isolate <i>C. difficile</i> with subsequent cytotoxin assay of isolate	Excellent sensitivity (>90%) and specificity (>98%); enables typing of strain for outbreak investigation	Results not available for at least 72–96 hours; labor intensive; requires tissue culture facility

Adapted from Poutanen SM, Simor AE. *Clostridium difficile*-associated diarrhea in adults. Can Med Assoc J 2004;171:51–8; Fenner L, et al. Rapid and reliable diagnostic algorithm for detection of *Clostridium difficile*. J Clin Microbiol 2008;46:328–30.

typically chronic, such as *C. parvum*, MAC, cytomegalovirus, *Isospora belli*, or microsporidia.

An epidemiologic history with focus on travel history (*Entamoeba histolytica*, *Giardia lamblia*), sexual exposure (history of unprotected anal intercourse suggesting transmission of herpes simplex virus, *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, or, occasionally, *E. histolytica*), and food associations (lactose intolerance) should be sought. In patients who are taking highly active antiretroviral therapy, medication-induced diarrhea (nelfinavir, ritonavir) should be considered, particularly when diarrhea is the sole presenting symptom. *Clostridium difficile* should be considered because most patients with HIV are given antibiotics for the treatment of various infection (Sanchez, 2005).

Malabsorption Syndromes

Malabsorption is the pathologic state of impaired nutrient absorption in the gastrointestinal tract. Normal nutrient absorption occurs in three steps: luminal and brush border processing, absorption into the intestinal mucosa, and transport into the circulation. Disruption in any one or a combination of these steps can result in inadequate mucosal absorption of carbohydrates, proteins, fats, vitamins, or minerals. Malabsorption can also result from the presence of substances in the bowel that cannot be absorbed (e.g., lactulose, sorbitol). Maldigestion results from an intraluminal defect that leads to the incomplete breakdown of nutrients into their absorbable substrates. This can occur with pancreatic insufficiency and loss of exocrine function, resulting in increased osmotic load of the colon and diarrhea. In addition, patients can have selective malabsorption/maldigestion of specific nutrients, resulting in associated clinical sequelae. Irrespective of the cause, diarrhea, especially steatorrhea, is the most common feature of malabsorption.

Hepatic maldigestion results from interference or obstruction of bile flow. Loss of bile salts interferes with fat emulsification, diminishing the surface area available for lipolytic action. In addition, bile salt activation of lipase activity is lost. Patients are usually jaundiced, pass dark urine, and have other signs of liver disease. Hepatic steatorrhea may coexist with pancreatic steatorrhea, as in patients with a neoplasm obstructing the ampulla of Vater. The inability to assimilate fats and proteins due to maldigestion also occurs in patients with vasculitis, diabetes mellitus, carcinoid syndrome, hypogammaglobulinemia, and relative vitamin B₆ or B₁₂ deficiency.

Enteric malabsorption comprises a variety of conditions that have in common normal digestion but inadequate net assimilation of nutrients. This may result from competition by bacteria or altered bacterial flora, as in the blind loop syndrome or diverticulosis of the small bowel, or from obstruction to the flow of lymph. It may also result from diseases affecting the small bowel mucosa, such as amyloidosis, inflammation following irradiation (radiation enteritis), diminished mucosal surface area as in gastroileostomy (gastric bypass), or small bowel resection. Depending on the location within the intestinal tract of such pathology, preferential loss of specific substrates may occur. One of the most common clinical scenarios encountered is regional enteritis localized to the distal ileum, the site of vitamin B₁₂ and bile salt absorption, which will result in vitamin B₁₂ deficiency, as well as a decreased pool of circulating bile salts for metabolism.

Steatorrhea is a hallmark finding in patients with malabsorption, resulting in fluid, semifluid, or soft and pasty, pale, bulky, and foul-smelling stools. These stools may be foamy because of the high fat content and may

float on water. However, the latter may occur with stools from healthy individuals and therefore is a nonspecific sign of malabsorption.

In patients with steatorrhea, unabsorbed fecal dietary fat is passed in stools above and beyond the normal 1%–9%, along with as much as 40% of ingested fat. The quantity of fecal fat depends on the dietary fat intake. Thus, dietary fat intake must be known for proper interpretation of fecal fat, which is expressed as percentage of dietary fat, allowing assessment of variation in an individual patient. Normally, >93% of dietary fat is absorbed, but diarrhea of any cause may lead to a slight increase in fecal fat content.

Another clinical presentation of malabsorption is the development of fat-soluble vitamin (A, D, E, and K) deficiencies. Primary and secondary alterations of the bowel mucosa may also result in deficiencies of water-soluble vitamins. Other evidence of nutritional deficiencies, such as hypoprothrombinemia, glossitis, anemia, edema, ascites, and osteomalacia, may be evident in these individuals. These patients may experience significant weight loss due to diarrhea, leading to cachexia in severe cases.

Quantitative fecal fat measurement has many limitations and should be abandoned (Holmes, 1988; Hill, 2001). Sample collection is known to be incomplete (Ditchburn, 1971; West, 1981). Also, there is poor precision in the analytic performance, making interpretation uncertain (Duncan, 1998). Newer tests provide improved sensitivity and specificity for the diagnosis of malabsorption (Hill, 2001): ¹⁴C-glycerol trioleate breath test (Turner, 1987) and mixed-chain triglyceride breath test are widely available (Vantrappen, 1989; Amarri, 1997). However, these tests have limited reliability in diabetes, obesity, hyperthyroidism and hypothyroidism, and chronic respiratory insufficiency, and should not be performed in pregnancy.

The test is based on the measurement of ¹⁴CO₂ in expired air following the ingestion of various ¹⁴C-labeled triglycerides (triolein, tripalmitin, and triotanooin). Steatorrhea from pancreatic insufficiency or other causes results in decreased absorption of triglycerides. This in turn results in a decrease in expired carbon dioxide (CO₂) derived through the metabolism of triglyceride fatty acids.

After an overnight fast, the patient consumes ¹⁴C-labeled triglyceride. Periodically, breath CO₂ is collected in a trapping solution containing an indicator that changes color when a predetermined amount of CO₂ is in solution. The radioactivity of the ¹⁴CO₂ is then measured in a liquid scintillation counter, and the results are reported as a percentage of the dose of ¹⁴CO₂ excreted per hour.

To distinguish pancreatic insufficiency from other causes of steatorrhea, some investigators have developed a two-stage breath test (Goff, 1982). In the first stage of the test, the patient consumes a ¹⁴C-labeled triglyceride, and ¹⁴CO₂ is measured as previously described. The second stage of the test is performed 5–7 days later and is the same as the first stage, except that the patient is given an oral dose of pancreatic enzymes along with the dose of ¹⁴C-labeled triglyceride. In patients with steatorrhea due to pancreatic insufficiency, the amount of ¹⁴CO₂ expired should increase relative to the amount of ¹⁴CO₂ expired in the first stage of the test. Patients with steatorrhea from other causes should show no significant change in the amount of ¹⁴CO₂ expired following the oral administration of pancreatic enzymes.

Agammaglobulinemia

X-linked agammaglobulinemia is a primary humoral immunodeficiency characterized by recurrent bacterial infection of the respiratory tract and

increased susceptibility to enteroviral infection. Absence of humoral immunity makes the patient susceptible to bacterial gastroenteritis.

Abetalipoproteinemia

Abetalipoproteinemia is a rare autosomal recessive disorder that is characterized by defective assembly and secretion of apolipoprotein B (apoB) and apoB-containing lipoproteins, resulting from mutations in the gene encoding the microsomal triglyceride transfer protein; the serum β lipoprotein is absent. Abetalipoproteinemia causes defective absorption of lipids. Patients may have neurologic manifestations, acanthocytes, fat malabsorption, steatorrhea, and associated fat-soluble vitamin deficiencies (Gregg, 1994).

Tests for Steatorrhea

Screening tests for detection of steatorrhea include microscopic examination of feces for fat globules and determination of serum carotenoid. Carotenoids are a group of compounds that are the major precursors of vitamin A in humans. Absorption of carotenoids in the intestines depends on the presence of dietary fat. Because carotenoids are not stored in the body to any appreciable degree, lack of carotenoids in the diet or disturbances in absorption of lipids from the intestine can result in decreasing levels of serum carotenoid. This is a simple and useful screening test for steatorrhea. In addition to steatorrhea and poor dietary intake, liver disease and high fever may cause a low level of serum carotenoid. Elevated serum carotenoid levels are seen in patients with hypothyroidism, diabetes, hyperlipidemia, and excessive intake of carotene.

Tests for Malabsorption

When a diagnosis of malabsorption is being entertained, it is important to distinguish pancreatic maldigestion from enteric malabsorption. In children, the main cause of pancreatic malabsorption is CF, and the sweat chloride determination should be used when clinical evidence warrants it. Screening tests based on absent stool trypsin have also been used. One of the most valuable differential diagnostic tests, especially in adults, is the D-xylose absorption test.

The cellobiose-mannitol sugar permeability test and the lactulose-mannitol test have been used in the diagnosis of celiac disease. Modern evaluation of this disorder has been described earlier. Isotopic techniques and the starch tolerance test have been used as alternatives to the D-xylose test. Quantitative specific fecal trypsin and chymotrypsin assays may be helpful, as may the Schilling test for vitamin B₁₂ absorption, which tends to be abnormal in patients with enteric steatorrhea in whom the abnormality is not correctable with intrinsic factor. Endoscopy, radiologic studies, and biopsy have replaced these methods in many cases.

Fecal Elastase. Elastase-1 is a proteolytic enzyme produced by the pancreas. Pancreatic elastase survives intestinal transit intact and is five- to sixfold concentrated in the feces (Lankisch, 2004). Reduced pancreatic elastase-1 in feces indicates pancreatic insufficiency in infants older than 2 weeks of age with CF and in older children with the disorder (Phillips, 1999; Cade, 2000; Leus, 2000).

This EIA is unaffected by pancreatic enzyme replacement therapy. Although sensitive for detection of severe pancreatic insufficiency, it lacks sensitivity for detection of milder forms. Fecal elastase is better than fecal chymotrypsin, para-aminobenzoic acid, bentiromide, and pancreolauryl tests (Lankisch, 2004). Single analysis of a 100 mg stool sample is adequate for determination of fecal elastase levels. If borderline values are detected, a repeat sample may be useful. This test should be performed only on formed stool. With a cutoff of 200 μ g/g stool, the positive predictive value of fecal elastase determination is estimated to be approximately 50% (Lüth, 2001).

Xylose Absorption Test. The D-xylose absorption test is a valuable test for the differential diagnosis of malabsorption. In this procedure, a 25-g dose of pentose sugar in water is administered orally, and the amount excreted in urine over a 5-hour period is determined. If the amount excreted is less than 3 g, the diagnosis is most likely enterogenous malabsorption, because pancreatic enzymes are not required for absorption of D-xylose. D-Xylose is passively absorbed in the small intestine and is not metabolized by the liver, although a portion of an orally or intravenously administered dose is destroyed. The accuracy of the method depends not only on the rate of absorption of D-xylose but also on the rate of renal excretion. Therefore, in patients with renal disease, xylose should be quantified in blood 2 hours after its oral administration because urine values are difficult to interpret in the absence of reference values.

Isotopic techniques and the starch tolerance test have been used as alternatives to the D-xylose test. Quantitative specific fecal trypsin and chymotrypsin assays may be helpful, as may the Schilling test, which is used to assess the function of the terminal ileum. An oral dose of radioactive vitamin B₁₂ is followed by an intramuscular large dose of nonradioactive vitamin B₁₂, and radioactivity in urine is measured. Urinary radioactivity reflects the absorbed amount of vitamin B₁₂. A repeat test to diagnose pernicious anemia or gastric pathology in a patient with steatorrhea involves coadministration of intrinsic factor and vitamin B₁₂. An abnormal result indicates ileal disease.

Laxative Abuse

Surreptitious laxative abuse is a frequently overlooked cause of chronic diarrhea and is the final diagnosis for chronic diarrhea in 15%–26% of patients at referral centers (Bytzer, 1989; Duncan, 1992). In Munchausen's syndrome by proxy, adults administered laxatives surreptitiously to young children (Duncan, 2000). The main prerequisite for making the diagnosis of surreptitious laxative abuse is clinical suspicion. Analysis of urine and fecal samples taken during diarrhea is necessary. Phenolphthalein is less frequently found since over-the-counter sales were banned. Senna, aloin, and cascara are colonic stimulants that are abused and can be detected by thin-layer chromatography.

Celiac Disease

Celiac disease (gluten-sensitive enteropathy) is a disorder precipitated, in genetically predisposed individuals, by the ingestion of gluten, the major storage protein of wheat and similar grains, characterized by intestinal malabsorption of nutrients due to sensitivity to the alcohol-soluble portion of gluten known as gliadin. Wheat, rye, and barley contain this protein and can induce mucosal damage in the gut, causing nonspecific villous atrophy of the small intestinal mucosa. Celiac disease does not develop unless a person has alleles that encode for HLA-DQ2 or HLA-DQ8 proteins, products of two of the human leukocyte antigen genes. This genetic predisposition is most common in Caucasians of Northern European descent. The prevalence is not clear but is estimated to be as high as 1% in some countries, and the condition is being increasingly recognized (Green, 2007; Sabatino, 2009).

Some patients remain asymptomatic, but an astute clinician may suspect this disorder when patients present with thin stature, iron deficiency anemia, weight loss, chronic bloating, and/or diarrhea. In severe cases, one may see malabsorption, steatorrhea, and wasting. Associations have been noted between celiac disease and type 1 diabetes mellitus, Down syndrome, dermatitis herpetiformis, IgA deficiency, autoimmune thyroid disease, and other disorders (Barr, 1998). Because of enteropathy associated with the disorder, multiple hematologic and biochemical abnormalities may be found in persons with untreated celiac disease, including deficiencies of iron, folate, or vitamin D. The peripheral blood film may reveal nonspecific target cells, siderocytes, crenated red cells, Howell-Jolly bodies, and Heinz bodies. Similarly, small bowel absorptive testing will be abnormal, including oral D-xylose testing and fecal fat evaluation.

The gold standard for diagnosis remains histologic examination of multiple biopsies of the affected small bowel mucosa for the identification of villous atrophy and crypt hyperplasia. The lesions may be patchy, and sampling errors can occur (Green, 2007; Ensari, 2010). Biopsy is reserved for patients in whom the diagnosis is suspected on the basis of signs or symptoms of the disease, especially in higher-risk populations with supporting serologic findings. These patients must be maintained on a gluten-free diet for the rest of their lives to control symptoms and mitigate cancer risk.

In current clinical practice, four serologic studies are used to assist in the diagnosis of celiac disease. These include testing for antibodies to gliadin (AGA-IgA and AGA-IgG), endomysium (EMA-IgA), reticulin (ARA-IgA), and transglutaminase (tTG-IgA), all of which are commercially available. Results of serologic testing for celiac disease must be analyzed with caution because this disease is associated with selective IgA deficiency that will give rise to false-negative serum IgA antibody tests (Thomas, 2003). Transient IgA deficiency may be seen in patients on phenytoin, penicillamine, or sulfasalazine. Therefore, total IgA levels should be checked or specific IgG serology performed if there is a high clinical suspicion of celiac disease. The sensitivity and specificity of these tests are extremely high when compared with a gold standard of flattened small bowel villi responding to dietary changes (Farrell, 2001). Endomysial antibodies have the best sensitivity and specificity, but they are currently detected via immunofluorescence of sections of monkey esophagus or

human umbilical cord and are costly, cumbersome, and subject to inter-observer interpretive variability.

Wheat storage protein, gliadin, is available to be used as an antigen in an EIA. Although serum IgA and IgG AGA levels are frequently elevated in untreated celiac disease, these tests are of only moderate sensitivity and specificity. IgG AGA testing is particularly useful in the 2% of patients with celiac disease who appear to be IgA deficient. However, these tests have largely been replaced by EMA. EMA binds to connective tissue surrounding smooth muscle cells. Most laboratories use sections of human umbilical cord. Serum IgA EMA binds to the endomysium to produce a characteristic staining pattern seen on indirect immunofluorescence. The antibody is highly sensitive and specific. However, after treatment, the titers fall quickly to undetectable levels (Volta, 1995). The epitope against which EMA is directed has been shown to be tissue transglutaminase. Use of IgA anti-tTG assays has been shown to be highly sensitive and specific for the diagnosis of celiac disease (Dieterich, 1998). An EIA for IgA anti-tTG is widely available, less costly, and easier to perform than the older immunofluorescence assays for IgA EMA.

Antigliadin antibody serology is best avoided in the diagnosis of celiac disease because of frequent false positives. A second generation of antigliadin antibody test based on the potentiation of toxic gliadin peptides by tTG enzymatic activity is used to monitor dietary compliance. These IgA and IgG deamidated gliadin peptide (DGP) assays appear similar to tTG IgA or IgG in diagnostic accuracy, leading to the belief that strongly positive tTG IgA in conjunction with positive DGP serology may be used as confirmation of celiac disease without the need for biopsy histology.

Although IgG endomysium and IgG tTG antibodies may be suitable for serologic diagnosis of celiac disease, they cannot be used to monitor the response to dietary modification. Endomysium IgA antibodies disappear following treatment of celiac sprue with a gluten-free diet.

The HLA-DQ2 allele is identified in 90%–95% of patients with celiac disease, and HLA-DQ8 in most of the remaining patients. These alleles occur in 30%–40% of the general population, and the absence of these alleles is important for its high negative predictive value. Thus, the presence of HLA-DQ2 and HLA-DQ8 is important for determining which family members should be screened with serologic testing (Kaukinen, 2002).

Uncontrolled celiac disease appears to predispose patients to intestinal carcinomas and lymphomas (Nehra, 1998).

Whipple's Disease

It is a rare multisystem disease that often presents with arthralgias, diarrhea, malabsorption, and weight loss. It is predominantly found in males, and about 15% of patients do not present with classical signs and symptoms of this disease (Fenollar, 2007). It is caused by *Tropheryma whipplei*, a bacillus that does not stain well with Gram stain, although it is classified with gram-positive bacteria based on 16S rRNA sequencing (Marth, 2003). This disorder can affect the central nervous system and cause endocarditis. Demonstration of periodic acid-Schiff (PAS)-positive material in the lamina propria and villous atrophy of the small intestine is diagnostic. A prothrombin time should be checked before biopsy because of the frequent occurrence of vitamin K malabsorption.

T. whipplei has been cultured from the stools of a patient with Whipple's disease using a specific axenic medium and specific techniques (Raoult, 2006). PCR testing of infected tissue or cerebrospinal fluid has been used to confirm the diagnosis and monitor treatment (von Herbay, 1997). Biopsy of the duodenum with PAS staining had been considered pathognomonic for Whipple's disease. It is now recognized that PAS-positive macrophages may be seen in AIDS patients with *Mycobacterium avium-intracellulare* complex. Thus, PCR has gained even more importance in the management of this entity. Long-term antibiotic therapy with central nervous system penetration is used to treat patients with Whipple's disease (Ramzan, 1997; Singer, 1998).

Inflammatory Bowel Disease

Immunologic mechanisms within the colon are involved in the pathogenesis of inflammatory bowel disease. The underlying antigenic challenge to the immunologic response is not clearly understood. Over the past decade, two antibody tests have become available that assist in the laboratory evaluation of patients with inflammatory bowel disease (Rutgeerts, 2000). The combination of clinical findings, endoscopy, radiologic imaging, and blood work may help differentiate the subtypes of inflammatory bowel disease. Perinuclear-antineutrophil cytoplasmic antibody (p-ANCA) and anti-*Saccharomyces cerevisiae* antibody (ASCA) can be used to help distinguish abdominal pain seen in irritable bowel syndrome from inflammatory bowel disease, and can help distinguish ulcerative colitis from Crohn's disease

TABLE 22-6

Markers for Inflammatory Bowel Disease

	FREQUENCY, %	
	p-ANCA	ASCA
Irritable bowel syndrome (normal patients)	<5	<5
Ulcerative colitis	70	15
Crohn's disease	20	65

ASCA, Anti-*Saccharomyces cerevisiae* antibody; p-ANCA, perinuclear antineutrophil cytoplasmic antibody.

(Sendid, 1998; Shanahan, 1994) (Table 22-6). These tests have limitations, and interpretation requires careful understanding of the tests. Whereas few normal persons with irritable bowel syndrome will have ANCA, 70% of persons with ulcerative colitis and 20% of persons with Crohn's disease will have significant titers. Among patients with inflammatory bowel disease, 65% of those with Crohn's disease will have ASCA, whereas only 20% of patients with ulcerative colitis will have significant titers. Given their low sensitivity and specificity, use of these tests should be dependent upon the clinical circumstance. For example, a person with diarrhea and equivocal biopsy findings found to have a positive ANCA is more likely to have inflammatory bowel disease than irritable bowel syndrome. Likewise, if a person with what appears to be ulcerative colitis is found to have a positive ASCA, Crohn's colitis may be present.

GASTROINTESTINAL TUMORS

Pancreatic Adenocarcinoma

Ductal adenocarcinomas of the exocrine pancreas are malignant epithelial tumors composed of mucin-producing glandular structures. They constitute 85% of all pancreatic tumors and are the fourth most frequent cause of death from cancer. They originate in small ducts and progress from noninvasive pancreatic intraepithelial lesions to invasive cancers. Little change in their incidence or survival rate has been seen in the past 20 years; 5-year survival is <5%. A slight male predominance has been noted, especially in younger age groups. This is a disease mostly of late life; 80% of patients are 60–80 years of age, although cases in the third decade are not uncommon. This cancer is more common in African Americans and Native Americans. A two- to threefold greater risk has been reported among cigarette smokers. Patients with chronic pancreatitis and diabetes mellitus are at increased risk. High intake of meat and fat appears to be a risk factor, as well as intake of nitrosamines and polycyclic hydrocarbons. The neoplastic mechanism remains obscure.

Clinical presentation depends largely on the location of the tumor: 60% arise in the head, often with painless jaundice; 10% in the body and 10% in the tail are often silent until quite large or widely disseminated; 20% are diffuse at presentation. Familial clusters have been reported, but no distinct genetic abnormality has been described.

The ampullary region is invaded by carcinomas of the head of the pancreas, causing bile duct obstruction. Acute painless dilation of the gallbladder (Courvoisier's sign) and jaundice occur as the result of common bile duct obstruction by tumor in most cases. Carcinomas of the body and tail do not impinge on the biliary tract. Migratory thrombophlebitis (Trousseau's sign) develops in 10% of patients with pancreatic cancer, especially those with tumors of the body and tail, probably because of platelet-aggregating factors and procoagulants from the tumor. Anorexia, conspicuous weight loss, and gnawing epigastric pain that radiates to the back are frequent clinical features.

Early diagnosis of pancreatic carcinoma is unusual. These tumors are typically silent until they impinge on a vital structure or on the posterior wall of the abdomen and then cause severe pain. Pain is usually the first symptom. Less than 20% of the tumors are resectable at the time of presentation.

No morphologic difference is known between carcinomas of the head of the pancreas and those of the body and tail. These tumors are usually moderately or poorly differentiated mucin-producing adenocarcinomas. They have abortive tubular structures and dense stromal fibrosis and aggressive infiltrative growth, often with perineural invasion. Tumor cells are cuboidal or columnar and are usually poorly differentiated. The adjacent pancreatic parenchyma often demonstrates foci of ductal dysplasia and intraductal tumor growth.

TABLE 22-7

Pancreatic Cancer–Associated Genetic Syndromes

Genetic syndrome	Gene(s)	Pancreatic cancer risk increase	Histopathologic features
Hereditary breast and ovarian cancer syndrome	<i>BRCA2</i> <i>BRCA1</i>	3.5- to 10-fold 2-fold	Ductal adenocarcinoma
Peutz-Jeghers syndrome	<i>STK11/LKB1</i>	132-fold	Intraductal papillary mucinous neoplasm
Familial adenomatous polyposis	<i>APC</i>	Up to 4-fold	Ductal adenocarcinoma, intraductal papillary neoplasm, pancreatoblastoma
Familial atypical multiple melanoma	<i>CDKN2A</i>	13- to 22-fold	Ductal adenocarcinoma
Hereditary nonpolyposis colorectal cancer syndrome	Mismatch repair genes	Increased	Medullary carcinoma
Hereditary pancreatitis	<i>PRSS1</i> <i>SPINK1</i>	53-fold	Ductal adenocarcinoma
Familial pancreatic cancer	Unknown	9- to 32-fold	

Adapted from Shi C, Hruban RH, Klein AP. Familial pancreatic cancer. Arch Pathol Lab Med 2009;133:365–74.

Point mutations in *KRAS* and in *p16* are found in >90% of cases, and mutations in *p53* cause inactivation in 50%–70% of cases. Both carcino-embryonic antigen (CEA) and CA 19-9 (tumor marker for pancreatic cancer) are elevated in some pancreatic adenocarcinomas. The serum markers *KRAS*, CEA, and CA19-9 have not been useful in case finding for early diagnosis. However, their increases can be used to monitor for recurrence (Table 22-7).

Neuroendocrine Tumors

Gastroenteropathic neuroendocrine tumors (GEP-NET) are relatively rare neoplasms with varied clinical manifestations. Abdominal pain and diarrhea are two of the more common clinical symptoms. Carcinoid tumor was the term chosen, more than 100 years ago, to distinguish these tumors from carcinomas of the GI tract. Because these tumors are rare, they were lumped together. Recently, with greater knowledge of their development and biological behavior, the World Health Organization classification of GEP-NET was published in 2000. Specific markers of normal and neoplastic neuroendocrine cells are the hormones that occur in the GEP system. The organ in which a certain hormone-producing tumor develops appears to make a difference (e.g., the differing malignant potential of duodenal compared with pancreatic gastrinoma) (Klöppel, 2004). These tumors exhibit amine precursor uptake and decarboxylation (APUD) and are therefore known as APUDomas. Cells of the GEP-NET belong to the system of disseminated neuroendocrine cells called **APUD cells**. These cells are scattered throughout the mucosa of the GI tract and the islets of the pancreas. Insulinomas and gastrinomas are the most common pancreatic endocrine tumors. Glucagonomas are rare and make up 2%–5% of series. Other even rarer types, such as somatostatinomas and VIPomas, have been identified (Perry, 1996). Chemical measurement of the secretagogues of these tumors generally suggests the diagnosis in the right clinical setting.

Localizing these tumors can be challenging. Ultrasonography, CT scanning, MRI, endoscopy, angiography, and octreotide scanning all have significant technical limitations. With the exception of ultrasonography and MRI, potential morbidity can result from the testing as well. Although it was initially hoped that octreotide scanning would replace other modes of localization, recent data suggest that it is useful in determining the extent of carcinoids and gastrinomas, although of little use in finding insulinomas or nonfunctional tumors (Kisker, 1997). These tumors are often small, frequently are multifocal, and can be located in a variety of organs. They can be malignant or benign. They are similar on histologic examination, so histologic staining is used to distinguish the types (Perry, 1996). As with all neoplastic lesions, biopsy is essential to confirm the diagnosis.

GEP-NET make up about 10% of pancreatic neoplasms and are classified as functioning or nonfunctioning tumors. These tumors are single or multiple, and benign or malignant. They are often solitary, circumscribed lesions, amenable to surgical resection. Immunohistochemistry is needed for demonstration of endocrine activity. Hormone assays are useful for the diagnosis of pancreatic endocrine tumors (Modlin, 1997; Eriksson, 2000; Barakat, 2004).

Cytologic criteria are unreliable in diagnosis. The diagnosis of malignancy requires demonstration of metastases and vascular or tissue invasion. These tumors are often slow growing. Functioning tumors cause

recognizable clinical syndromes due to excess peptide hormone secretion. Nonfunctioning tumors have a worse prognosis and typically present with metastases or local symptoms.

GI endocrine tumors may be part of the syndrome of MEN 1 with parathyroid disease and pituitary and pancreatic tumors. Islet cell tumors may secrete various normal hormones that are not ordinarily produced in the pancreas, including adrenocorticotrophic hormone (ACTH), parathyroid hormone, calcitonin, and vasopressin.

Insulinoma

Insulinomas are derived from β cells and produce insulin that induces clinically significant hypoglycemia. Factitious disease due to exogenous insulin is part of the differential diagnosis. Insulinomas are usually found in the pancreas and are typically small and solitary and often contain amyloid; 10% are malignant. Diagnosis is made by demonstrating elevated plasma insulin associated with hypoglycemia and measurement of C-peptide. C-peptide is equimolar to insulin and is needed to exclude increases in insulin from exogenous sources.

Gastrinoma

Gastrinomas are gastrin-secreting non- β cell pancreatic tumors that cause a syndrome of intractable peptic ulcer disease and gastric acid hypersecretion. Gastrin binds cholecystokinin-B receptors on parietal cells of the stomach to stimulate acid secretion and also has a trophic effect on gastric mucosal parietal and enterochromaffin-like cells, causing mucosal hypertrophy (McIntyre, 2002). The mean age of onset is 50 years, with male preponderance. At the time of diagnosis, 70%–90% of the tumors are malignant with metastases or local invasion. Up to 60% of gastrinomas are associated with MEN 1, and about one half of MEN 1 patients develop gastrinomas. Most gastrinomas arise in the gastrinoma triangle: duodenum, pancreatic head, hepatoduodenal ligament.

Gastrin is not usually detected in the adult pancreas, but is present in the fetal pancreas. Gastrinomas induce peptic ulcer disease refractory to treatment, esophagitis, and diarrhea. High levels of plasma gastrin are noted with high basal gastric acid secretion. Increased gastrin levels are also caused by gastric atrophy and by acid antisecretory drugs such as H_2 blockers. Some gastrinoma patients are hypercalcemic because of PTH-related protein production, or because patients with MEN 1 may develop hyperparathyroidism. About 50% of patients with gastrinomas have metastases, mainly to the liver and nodes. The 5-year survival is 20% with liver metastases, and without metastases, 80% will survive for 5 years.

Gastrinomas can cause high-volume diarrhea through an increased rate of gastric acid secretion, resulting in a volume that cannot be fully reabsorbed. The acid exceeds the neutralizing capacity of the pancreatic bicarbonate and inactivates the pancreatic digestive enzymes; this interferes with the emulsification of fat by bile salts, resulting in steatorrhea. A secretory component to the diarrhea has also been observed. Diagnosis is established by measuring serum gastrin levels; a level greater than 1000 pg/mL is virtually diagnostic. The secretin stimulation test can differentiate patients with gastrinomas from those with the many other causes of hypergastrinemia; this test should be performed in every patient suspected to have the ZE syndrome who has a nondiagnostic fasting serum gastrin concentration (Berna, 2006).

Glucagonoma

This is a rare tumor, mostly of pancreatic origin, that secretes glucagon (α cells), which induces glycogenolysis and gluconeogenesis in the liver and raises blood glucose levels. It causes a syndrome of mild diabetes, necrotizing migratory erythematous rash, anemia, and venous thrombosis, and is associated with severe infection. Onset occurs at 40–70 years of age, with slight female predominance (Bloom, 1987). These are large, locally invasive tumors that histologically resemble trabecular and solid patterns of insulinomas; two thirds are malignant. Plasma glucagon levels are elevated up to 30 times above normal.

Somatostatinoma

These usually solitary tumors are derived from δ cells that produce somatostatin, which inhibits pituitary release of growth hormone and secretion by α , β , and δ cells. This peptide also regulates glucose homeostasis and causes a syndrome of mild diabetes, gallstones, steatorrhea, and hypochlorhydria, due to the inhibitory effect of somatostatin on the other islet and gastrointestinal neuroendocrine cells (Krejs, 1979). Somatostatin measurement in a fasting serum specimen may aid diagnosis; patients with somatostatinomas may have 1000-fold elevated concentrations. These tumors may also secrete calcitonin or ACTH, and most are malignant with metastases at diagnosis.

VIPoma

These tumors are presented in the previous section on diarrhea and malabsorption.

Carcinoid Syndrome

Pancreatic carcinoids are rare malignant neoplasms resembling intestinal carcinoids. They synthesize serotonin and motilin. When confined to the pancreas, these tumors may induce an atypical carcinoid syndrome that consists of facial flush, hypotension, periorbital edema, and lacrimation. Cases with liver metastases cause a classical carcinoid syndrome. Diagnosis is aided by demonstration of increased 5-hydroxyindoleacetic acid (5-HIAA) levels in 24-hour urine specimens.

Amyloidosis

GI amyloidosis is mainly of the reactive type (secondary or amyloid-associated [AA] amyloidosis) and results from mucosal or neuromuscular infiltration. It may result in GI bleeding from vascular friability. The patient may also have diarrhea from a combination of altered intestinal motility, bacterial overgrowth, and protein-losing enteropathy. Liver involvement can be seen in primary (amyloid light chain) or AA amyloidosis. Common symptoms include involuntary weight loss, fatigue, and abdominal pain. Common physical findings consist of hepatomegaly, ascites, purpura, and splenomegaly. The most common laboratory abnormality is an elevated alkaline phosphatase. The diagnosis of multiple myeloma should be confirmed by tissue biopsy of duodenal or colorectal mucosa. Although GI complications can result in significant morbidity, they usually are not the cause of death, which is most often caused by renal failure, restrictive cardiomyopathy, or ischemic heart disease (Ebert, 2008).

GASTROINTESTINAL BLEEDING

Throughout most of the GI tract, the lumen of the gut is separated from the capillary blood supply by only a single layer of epithelial cells. Thus even minor injury to the epithelial lining may result in GI bleeding. Occult GI bleeding is bleeding unknown to the patient. Iron deficiency anemia should be considered to be the result of GI bleeding until excluded (Rockey, 2010).

Hemoglobin and hematocrit are usually low, and their levels may have some relation to blood loss. A low mean cell volume (MCV) may indicate that the patient is iron deficient, and that chronic blood loss has occurred. An elevated MCV may indicate a folate or vitamin B₁₂ deficiency with macrocytosis and raises the possibility of ethanol abuse, chronic liver disease, gastric cancer in association with pernicious anemia, or regional enteritis involving the terminal ileum.

If a clotting defect exists, prompt correction of the deficiency is crucial. Extensive transfusion dilutes platelets and clotting factors, particularly factors V and VII. Also, a high proportion of patients who bleed while taking therapeutic anticoagulants do so from a clinically significant lesion. It is important to evaluate these patients for a GI pathologic condition and to correct their clotting status. Leukocytosis may accompany acute

GI bleeding, but it is usually not in excess of 15,000 white blood cells/mm³. Leukocytosis should not be attributed to acute blood loss without completion of a search for sources of infection.

Elevated BUN in a patient whose BUN was recently normal, or whose serum creatinine concentration is normal, suggests an upper GI bleed. The BUN rise may be due to the hypovolemia of acute blood loss, but digestion of blood proteins in the small intestine and absorption of nitrogenous products may be the cause.

Fecal Occult Blood Testing

The fecal occult blood test (FOBT) depends on the peroxidase activity of hemoglobin. Reagents used include guaiac (Hemoccult), benzidine (marketing restricted by federal regulation because of its carcinogenicity), orthotoluidine (Hematest), and ortho-dianisidine. The reagents differ in sensitivity, although all are associated with frequent false-positive and false-negative results, mostly due to the specimen tested. Specimens collected by digital rectal examination have a high frequency of false positives caused by injury to the rectal mucosa.

The normal person loses 0.5–1.5 mL of blood into the GI tract daily in association with the normal shedding of epithelial cells. Commercial tests are designed to turn positive with blood loss greater than 5–10 mL per day. This corresponds to 5–10 mg of hemoglobin/gram of feces, assuming a blood hemoglobin of 15 g/dL and an average daily 150-g stool.

In addition to sample handling and testing, diet is very important in compromising these tests. The high rate of false positives is due to the lack of specificity of the reagents and the presence of peroxidase activity in other fecal constituents, as well as the sensitivity of the different chromogens to peroxidase activity. The myoglobin and hemoglobin of ingested meat and fish have peroxidase activity that may falsely indicate the presence of occult blood. Bacteria in the bowel, as well as ingested vegetables and fruits, such as horseradish, turnips, bananas, black grapes, pears, and plums, have peroxidase and can falsely elevate fecal peroxidase activity. False-negative tests occur in the presence of large amounts of vitamin C and other antioxidants.

Patient preparation and specimen collection are important in ensuring valid test results. For 72 hours prior, patients should be on a diet free of exogenous peroxide activity (meat, fish, turnips, horseradish), GI irritants (aspirin, nonsteroidal antiinflammatory drugs), and vitamin C. Variations in testing technique produce errors due to stool consistency, the application of large aliquots of stool, and, particularly, inaccurate timing of the reaction.

Immunochemical tests for hemoglobin are more sensitive and specific and yield fewer false negatives. They are not affected by diet, animal hemoglobin, or human myoglobin. Dietary peroxidases do not affect immunochemical test results. They are useful only for screening blood of the lower intestinal tract and are insensitive to upper GI bleeding because globin is destroyed in the small intestine. Immunochemical tests are expensive and are not done at the point-of-care.

Fecal immunochemical testing for human hemoglobin, such as HemeSelect or InSure, has been developed to improve the sensitivity and specificity of guaiac testing to detect colonic neoplasia. HemeSelect testing is based on an antigen–antibody reaction involving fixed chicken red blood cells coated with anti-human hemoglobin antibody (Allison, 1996). Samples demonstrating agglutination are interpreted as positive for occult human blood. InSure is a test that uses monoclonal mouse anti-human hemoglobin antibody with subsequent colorimetric detection; it is sensitive enough to detect 50 μ g hemoglobin/g feces (Quest Diagnostics). These tests do not react with nonhuman hemoglobin or peroxidase, so food restrictions are not necessary. Immunochemical InSure tests target the globin portion of hemoglobin, which does not survive passage through the upper GI tract. Therefore, these tests are more specific for lower gastrointestinal colonic bleeding (Quest Diagnostics).

Colon cancer is a leading cause of cancer-related deaths in the United States, accounting for approximately 55,000 deaths annually. According to recent cancer statistics, approximately 150,000 new colon cancer cases were diagnosed in 2003. Evidence has demonstrated the clinical usefulness of FOBT to detect these cancers at an earlier stage, potentially resulting in decreased mortality. Because of the generally favorable clinical biology of these tumors when detected earlier (with an 80%–90% survival rate with local confined disease) (Helm, 2003) and the relatively inexpensive, noninvasive nature of FOBT, this may serve as a useful screening technique. Several professional organizations recommend annual or biennial FOBT, but universally accepted screening protocols have not been established. The American Cancer Society guidelines for colorectal cancer screening, the most widely utilized, recommend annual FOBT and flexible

sigmoidoscopy every 3–5 years, beginning at age 50, in asymptomatic, average-risk individuals (Marshall, 1996). Limitations of this testing include the high numbers of false-positive and false-negative results. The sensitivity of FOBT has been estimated at between 30% and 50%. The true sensitivity of FOBT is difficult to determine because individuals who test negative do not undergo further colonoscopic evaluation to determine whether the FOBT is a true negative. Only approximately 5%–10% of positive reactions prove to be caused by an occult malignancy (Simon, 1998). However, following a stepwise approach to colon cancer screening should minimize the clinical effects of limited sensitivity and specificity and offer valuable information nonetheless.

Occult blood can be detected by chemical (guaiac), hemoporphyrin, or immunologic methods. Occult blood may arise anywhere along the intestinal tract and is often the first warning sign of GI malignancy. Other potential sources of occult blood may arise from bleeding esophageal varices, polyps, esophageal or gastric inflammation, hemorrhoids or fissures, inflammatory bowel disease, peptic ulcer disease, or angiodysplasias of the colon. Laboratory diagnosis of the presence of fecal occult blood generally involves a guaiac-smear test (Hemocult, Seracult, Coloscreen), the most commonly used method at present. Guaiac is a naturally occurring phenolic compound that is oxidized to quinone by hydrogen peroxidase, resulting in a detectable color change. These tests detect the pseudoperoxidase activity of heme as intact hemoglobin or as free heme (Allison, 1996). These tests are not specific for human hemoglobin, and hemoglobin from red meat, peroxidase from fruits and vegetables, and certain medications can lead to false-positive results. The presence of more than 5–10 mL/day of blood in the stool results in a positive guaiac smear. Stool specimens should be received from three consecutive stools. Two slides should be prepared for each stool sample. Slides should not be rehydrated and should be developed within 7 days of collection. To ensure quality testing, some medical institutions now require that stool samples be sent to the laboratory for guaiac testing, rather than having residents or nurses perform tests on the ward. In addition, the test must be performed under appropriate conditions that serve to limit its sensitivity. Factors that can cause inaccuracies in the results include the presence of bleeding gums, for example, or ingestion of large amounts of red meat before testing. In addition, patients may be using certain medications that will influence the results of FOBT. For example, drugs that can cause GI irritation and subsequent bleeding, such as anticoagulants, aspirin, NSAIDs, or colchicines, may lead to false-positive results. Other drugs that have been implicated include reserpine and oxidizing drugs such as iodine. Ingestion of large amounts of vitamin C can cause false-negative results. Patients should avoid such medications or food products before FOBT. A positive FOBT prompts further evaluation for a GI lesion. Additional evaluations usually include sigmoidoscopy with barium enema or full colonoscopy, the latter being the preferred modality. A negative FOBT, however, cannot definitely rule out the presence of colonic neoplasia. If a patient is presenting with signs and symptoms suggestive of colon cancer, further evaluation is warranted, even in the presence of negative FOBT.

Fecal DNA testing is a promising technique for colorectal cancer screening. This test involves the collection of a single stool specimen, which is then screened for DNA markers. PCR is used to amplify the fecal DNA. These tests are useful because DNA is shed continuously and remains stable in stool, and minute amounts are detectable. Clinical studies have shown that fecal DNA testing has high specificity and sensitivity for cancer detection, considerably more than chemical guaiac testing. Several markers have been investigated; however, further evaluation and improved specificity and sensitivity are needed for their widespread use (Itzkowitz, 2008; Mandel, 2008; Lieberman, 2009).

Blood in Newborn Feces (Apt Test for Swallowed Blood)

When blood is found in the GI tract or stool of neonates, usually on the second or third day of life, a determination must be made of whether it is swallowed blood of maternal origin or is secondary to disease in the newborn (Guritzky, 1996). The Apt test is a qualitative test that is used to make this determination in grossly bloody stools or vomitus (hematemesis) from a newborn. Infants may ingest maternal blood during birth, or from a fissured or bleeding nipple. The sample first is mixed with water and then is centrifuged. The supernatant, which should be pink, is then mixed with 1% sodium hydroxide in a 5:1 ratio. If the blood is of maternal origin, the mixture turns yellow-brown after several minutes. Fetal blood remains pink because fetal hemoglobin is more resistant to alkali denaturation than

adult hemoglobin. The test has relatively low sensitivity, and the result must be interpreted with caution (McRury, 1994).

MARKERS FOR GASTROINTESTINAL AND PANCREATIC TUMORS

Tumor markers are substances produced by tumor cells or other body cells in response to neoplastic or certain nonneoplastic conditions; they are found in tissues or body fluids. Different tumor markers are found in different types of cancers, and the same tumor marker may be found in more than one type of cancer. Tumor markers are not expressed in all people with cancer, and some are expressed in patients with benign conditions. Identification or measurement of tumor markers is used in detection, diagnosis, or management of some types of cancer. Although an abnormal tumor marker level may suggest cancer or limited efficacy of therapy, this alone is not enough to establish diagnosis and is usually combined with other tests such as biopsy (Bigbee, 2003; Chan, 2006; Locker, 2006).

Enzymes

Enzymes were one of the first groups of tumor markers identified, and their elevated levels were linked with cancer. Most changes in enzyme levels are not specific or sensitive enough to be used to identify the cancer type or the specific organ involved. Lactate dehydrogenase, a glycolytic pathway enzyme, is released as a result of cell damage, and its elevation in malignancy is nonspecific (Schwartz, 1982). Neuron-specific enolase (NSE) is found in neural tissue and in cells of the diffuse neuroendocrine system. NSE is found in association with tumors of neuroendocrine origin, and its serum levels are of prognostic significance (Zeltzer, 1986). Urokinase-plasminogen activator, a serine protease system, is a prognostic marker in colorectal cancer (Duffy, 1999). Tumor-associated trypsin inhibitor (TATI) is identical to pancreatic secretory trypsin inhibitor, also known as the kazal inhibitor. It is strongly expressed in pancreatic cells and in low concentrations in normal GI and urogenital tissues. TATI is a useful marker for GI, urologic, and pancreatic cancers (Stenman, 2002).

Hormones

Hormones are normally produced in endocrine organs but may also be produced in nonendocrine tissue. They are assayed by EIA using monoclonal antibodies, or by RIA. Multiple endocrine neoplasia (MEN 2A and MEN 2B) syndromes synthesize several polypeptide hormones such as ACTH, calcitonin, gastrin, glucagon, and insulin. Vasoactive intestinal peptide is produced by some endocrine tumors (Perry, 1996).

ACTH may be the result of pituitary or ectopic production. Elevated ACTH levels have been reported from pancreatic, gastric, and colonic carcinomas. Patients with serotonin-producing carcinoid tumors often have marked ten-fold increases in urinary 5-HIAA excretion. Ingestion of serotonin-rich foods, such as bananas, chocolate, plums, or walnuts, or medications containing guaifenesin may produce false-positive elevations (Kema, 1992).

Other Protein Markers

Oncofetal antigens are proteins produced in fetal life that decrease to low levels or disappear after birth but reappear in cancer patients. The discoveries of α -fetoprotein (AFP) and carcinoembryonic antigen (CEA) in the 1960s had a profound effect on the use of tumor markers. AFP is a marker for hepatocellular and germ cell (nonseminomatous) carcinomas. CEA, a glycoprotein, is a marker for colorectal, GI, lung, and breast carcinomas. CEA testing may be useful as an adjunct to clinical staging (Sikorska, 1992). Amplification of Her2/neu, a tyrosine kinase receptor of the epidermal growth factor family, is seen in GI, breast, and ovarian tumors. bcl-2, a protein known to inhibit apoptosis, appears early in colorectal cancer. C-peptide is a marker for insulin production.

Blood Group Antigens

Some of the blood group carbohydrates are tumor markers with elevated levels in specific types of cancer. CA19-9, a sialylated Lewis antigen, is elevated in patients with colorectal and pancreatic carcinomas (Lamerz, 1992). Its levels are elevated in benign conditions such as Mirizzi's syndrome (Robertson, 2007). It is absent in individuals with pancreatic tumors who are Lewis negative. Another related Lewis antigen, C50, is used as a pancreatic tumor marker but is considered less sensitive than CA19-9. CA 242 and CA 72-4 are markers for GI and pancreatic tumors, but CA 72-4 is considered of greater prognostic value in pancreatic cancer (Louhimo, 2004).

Genetic Markers

Two classes of genes are implicated in cancer: cell activator genes and cell suppressor genes. Most oncogenes code for proteins that activate cell proliferation. Mutated *K-ras* is present in 95% of pancreatic cancers, in 40% of colon cancers, and in lower percentages of other tumors (Chan, 2006). Mutations of *ras* oncogenes have been detected in the stools of 9 of 15 patients with curable colorectal tumors (Sidransky, 1992).

Any genetic testing requires that the physician clearly understand how to interpret the results and how the results may affect patient management; patients and their family members must be counseled appropriately (Grody, 2001; LeGrys, 2007).

Tumor Suppressor Genes

Oncogenicity derives from loss of the gene, rather than its activation, as with the *p53* gene. Three fourths of colon carcinomas show deletion in one *p53* allele and a point mutation in the other allele.

STOOL COLLECTION AND EXAMINATION

COLLECTION

Uninstructed patients sometimes exhibit considerable ingenuity in collecting stool specimens, but a few simple instructions are likely to produce more satisfactory specimens. A scoured, well-rinsed bedpan is a convenient collection container. If the patient does not own one, a carefully cleaned, rinsed, and boiled glass jar of suitable size is a satisfactory alternative. Patients should be warned against passing urine at the same time into the bedpan or container because, among other things, urine has a harmful effect on protozoa. Tongue depressors or pieces of cardboard are reasonably convenient instruments for transferring the stool from bedpan to transport vessel, for which plastic, cardboard, and glass containers are available. We prefer to use two 2-oz ointment jars with screw caps for small stool samples because they are odor free, leakproof, and easy to transport. Patients should be instructed not to contaminate the outside of the container and not to overfill the container. Gas, which frequently accumulates, should be released gradually by carefully loosening the cap. Failure to observe this simple precaution, especially in the case of an overfilled container, can result in an explosive release of contents. Fecal specimen collection at home is by no means simple and easy unless the patient has been instructed properly.

MACROSCOPIC EXAMINATION

The quantity, form, consistency, and color of the stool should be noted. Normally, 100–200 g of stool is passed per day. Diarrheic stool is watery. Passage of large amounts of mushy, foul-smelling, gray stool that floats on the water is characteristic of steatorrhea. Constipation may be associated with passage of small, firm, spherical masses of stool (scybalae). Clay color suggests diminution or absence of bile or the presence of barium sulfate. Blood, especially blood originating from the lower gut, may cause the stool to be red; beets in the diet may mimic this. Bleeding from the upper GI tract is more likely to cause the stool to be black and have a tarry consistency. Bismuth, iron, and charcoal may also cause a black color. Stool that is allowed to stand in the air for a time may darken on the surface.

Mucus

The presence of recognizable mucus in a stool specimen is abnormal and should be reported. Translucent gelatinous mucus clinging to the surface of the formed stool suggests spastic constipation or mucous colitis. It is seen in stools of emotionally disturbed patients and may result from excessive straining. Bloody mucus clinging to the fecal mass suggests neoplasm or inflammatory processes of the rectal canal. Mucus associated with pus and blood is found in stools of patients with ulcerative colitis, bacillary

dysentery, ulcerating diverticulitis, and intestinal tuberculosis. Patients with villous adenoma of the colon may pass copious quantities of mucus, amounting to 3–4 L in 24 hours. They frequently develop severe dehydration and electrolyte disturbances, especially hypokalemia.

Pus

Patients with chronic ulcerative colitis and chronic bacillary dysentery frequently pass large quantities of pus with the stool, the recognition of which requires microscopic examination. This also occurs in patients with localized abscesses or fistulas communicating with the sigmoid colon, rectum, or anus. Large amounts of pus seldom accompany the stools of patients with amebic colitis, and its presence is evidence against this diagnosis. No inflammatory exudate is seen in the watery stools of patients with viral gastroenteritis.

MICROSCOPIC EXAMINATION

Fat

The simplest technique is microscopic examination using one of the Sudan stains. This procedure has been widely employed for screening because of its simplicity. In our experience, results have correlated well with quantitative measurements when aliquots of the same homogenized stool have been analyzed. For this purpose, a small aliquot of stool suspension is placed on a slide and is mixed with two drops of 95% ethanol; then two drops of saturated ethanolic solution of Sudan III are added, with further mixing. A coverslip is applied. Under these conditions, fatty acids are present as lightly stained flakes or as needle-like crystals that do not stain and therefore may be missed. Soaps also do not stain but appear as well-defined amorphous flakes or as rounded masses or coarse crystals. Neutral fats, however, appear as large orange or red droplets. When 60 or more stained droplets of neutral fats per high-power field are seen, one may be reasonably certain that the patient has steatorrhea. Caution is advisable in interpretation, however, because mineral oil or castor oil may mimic neutral fat. The procedure is then repeated by adding several drops of 36% (v/v) acetic acid to the stool mixture and warming the slide several times over a flame until slight boiling occurs. This converts neutral fats and soaps to fatty acids and melts the fatty acids, causing them to form droplets that stain strongly with Sudan III. The slide is then examined while warm. After this procedure has been performed, the presence of up to 100 stained droplets per high-power field is considered normal. Patients with steatorrhea of pancreatic origin are likely to have greater increases in fatty acids and soaps.

Meat Fiber

The technique for sampling is identical to that used for Sudan preparations for detection of fecal fat. The stool is mixed thoroughly on a slide with a solution of eosin in 10% ethanol; it is then allowed to stain for 3 minutes and is examined for muscle fibers. The entire area under the coverslip is examined, and only rectangular fibers with clearly evident cross-striations are counted. More than 10 fibers/high-power field suggests maldigestion and/or hypermotility. It appears that examination for meat fibers correlates well with chemical determination of fat excretion (Moore, 1971).

Leukocytes

A small fleck of mucus or a drop of liquid stool is placed on a glass microscopic slide with a wooden applicator stick. Two drops of methylene blue are added and mixed thoroughly and carefully. A coverslip is placed on the mixture, which is allowed to stand for 2–3 minutes for good nuclear staining. Using low-power scanning, rough quantitative counts are made by approximating the average numbers of leukocytes and erythrocytes. All differential counts should be made under high power, counting 200 cells when possible. Only those cells clearly identified as either mononuclear or polymorphonuclear are included in the differential count. Macrophages and epithelial cells that cannot be clearly identified are ignored. The initial cell counts should be performed at the time of presentation of the specimen.

KEY POINTS

- Testing for the presence of drugs in the blood and other body fluids of patients has undergone a vast increase over the past 20 years.
- Testing for the presence of drugs of abuse and/or poisons in patients has become mandatory both in the emergency room and in employment screening.
- Most drugs for which monitoring is standard can be assayed using homogeneous immunologic techniques.
- Gas chromatography–mass spectroscopy, which involves separation and identification of compounds in the gas phase from their mass/charge ratios and fragmentation patterns, is the “gold standard” for detection and quantitation of drugs in body fluids.

- The mechanisms of action of many therapeutic drugs have been at least partially elucidated. Many of these, such as the antiinflammatory, antiasthmatic, and immunosuppressive drugs, block specific points in signal transduction pathways.
- Ingestion of poisons causes life-threatening illness; poisons include cyanide, carbon monoxide, and a number of metals, such as lead, mercury, iron, and arsenic. If detected, the effects of these poisons can often be reversed.

Toxicology is the study of substances introduced exogenously into the body. Elsewhere in this textbook, the analytic methods presented are concerned with determining the presence and levels of natural substances involved in normal body function. In this chapter, we discuss the biological effects and methods for detection of exogenous chemical compounds that profoundly influence bodily functions, often in a deleterious way but also for therapeutic benefit.

Toxicology has become divided into four areas. The first two areas are the detection of drugs of abuse and the determination of levels of therapeutic drugs being administered to patients. Also, it has been recognized that certain environmental compounds that are mutagens and carcinogens such as benzpyrene and acetylaminofluorene cause mutations in critical sequences of human DNA, leading to the frank development of cancer. In the ongoing revolution in molecular biology, this field has now expanded into the detection of certain markers such as abnormal DNA sequences or the presence of mutated proteins or the presence of carcinogens bound to DNA. This rapidly expanding field is the subject of discussion in Parts 8 and 9, especially in the chapters concerning serum and solid tissue diagnostic markers for cancer and pharmacogenomics. Finally, there are numerous toxins to which individuals become exposed, such as carbon monoxide, cyanide, metals, and so forth, for which detection is vital if physicians are to be able to reverse the adverse acute physiologic effects. In this chapter, we discuss each of these divisions of toxicology with special reference to the detection of drugs and toxins in body fluids.

BASIC TECHNIQUES FOR DETECTING DRUGS IN SERUM AND URINE

The techniques involved in detecting the presence and/or the level of particular drugs, whether they are drugs of abuse or therapeutic drugs, are of two basic types: immunochemical and chromatographic.

IMMUNOCHEMICAL METHODS

Much drug testing today is performed using the so-called **homogeneous immunoassay**. The term homogeneous refers to the fact that these assays are all performed in solution, without any requirement for a phase separation that is traditionally used to separate bound from free ligand. This technology has revolutionized toxicology because it allows performance of rapid, stat analyses of blood and urine constituents. The technique is shown schematically in Figure 23-1. Here we show examples of two types of assays. In the first, the enzyme-mediated (or multiplied) immunologic technique (EMIT), the drug itself is covalently attached to an enzyme such as glucose-6-phosphate dehydrogenase (Fig. 23-1, *A-1*). When the drug-enzyme complex is incubated with an antibody to the drug, enzyme activity is markedly decreased as a result of blocking of the active site of the enzyme by the antibody. When, as in Figure 23-1, *A-2*, exogenous drug (such as in serum) is added to the immune complex, this exogenous drug competes with the drug-enzyme complex for the antibody. Liberated drug-enzyme results in increased enzymatic activity. Increasing concentrations of drug in serum result in increased observed enzymatic activity. This method was pioneered largely by the Syva Corporation (now part of Siemens, Palo Alto, CA) and has been applied both to therapeutic drug monitoring and to detection of drugs of abuse.

Fluorescence polarization immunoassay (FPIA) is the second type of homogeneous drug assay, as shown in Figure 23-1, *B*. Rather than being linked to an enzyme, as in Figure 23-1, *A*, the drug is covalently attached to a fluorescent probe molecule. If a fluorescent molecule is excited with polarized light and is stationary (i.e., it does not “tumble” in solution), it will emit polarized light as a fluorophore. This emitted light has the same polarization as the exciting light. So, for example, if the exciting light is polarized to the left, the emitted light will also be polarized to the left. If a fluorophore tumbles freely in solution, however, the polarization is lost; that is, the emitted light is now polarized equally to the left and right. However, if the fluorophore is bound to a macromolecule such as an antibody, the polarization is strong, because attached to the nontumbling antibody it remains relatively stationary. In these assays, the probe-labeled drug is incubated with the antibody. The fluorescence polarization of the probe-labeled drug is, of course, high because the fluorescence probe is relatively immobilized when bound to the antibody directed against it (Fig. 23-1, *B-1*). Addition of exogenous drug, as in serum, to the incubated mixture results in displacement, by the exogenous drug, of some of the fluorescent probe-labeled drug molecules, as shown in Figure 23-1, *B-2*. These displaced molecules can now tumble freely in solution. The result

is a decrease in fluorescence polarization. This decrease is directly related to the concentration of drug in serum.

This assay can detect drug levels in the nanomolar range and is both highly sensitive and specific. Both Abbott Laboratories (Chicago), on the TDX, IMX, and AXSYM analyzers, and Roche Diagnostic Laboratories (Nutley, N.J.), on the COBAS and INTEGRA analyzers, have pioneered this effective technique in monitoring a wide variety of therapeutic drugs and drugs of abuse.

DRUG BINDING TO ANTIBODIES

In both of the homogeneous methods discussed previously, a nonlinear relationship exists between the concentration of drug in serum and the response of the system—that is, the color that results from the enzymatic reaction (see Fig. 23-1, *A*) or the decrease in fluorescence polarization (see Fig. 23-1, *B*). This nonlinearity in response is due to the phenomenon of binding (i.e., the drug must bind to antibody before it is detected). This phenomenon may be expressed by the following equilibrium:

where D is the drug concentration in serum, D^* is the “marker” drug (i.e., drug labeled with an enzyme or a fluorescent probe), and Ab is the antibody. The concentration of free D^* is a measure of $D - Ab$, because both are equimolar. The concentration of $D - Ab$ is, in turn, related to D ; the more D is present, the more $D - Ab$ is formed. However, because the concentration of Ab is fixed in a given experiment, at sufficiently high concentrations of D , all of the Ab will be saturated, so that at higher concentrations of D , no further $D - Ab$ can form. The relationship between D and $D - Ab$ is given by the Langmuir expression:

$$r = (D - Ab) / (Ab_0) = nkD / (kD + 1) \quad (23-2)$$

where (Ab_0) is the total concentration of antibody, k is the equilibrium constant for formation of the $D - Ab$ complex, n is the number of antibody-binding sites per molecule of antibody, and D is free drug concentration as defined above. Equation 23-2 is very similar to the Michaelis-Menten equation discussed in Chapter 20 (Equation 20-10), except that there is no catalytic step here. This equation shows that the concentration of $D - Ab$ is nonlinear in D , except where $Kd \ll 1$. Where $kD \gg 1$, saturation is achieved. This equation can be linearized in the form used for a Scatchard plot, that is,

$$r/D = kn - kr \quad (23-3)$$

where r/D is plotted versus r . Given the results for a set of experiments, a least-squares-best-fit line is drawn through the points. The slope of the line is $-k$, and the intercept is nk , so that n (the number of sites on the antibody) is equal to the intercept/slope. Thus the values of n and k are readily determined. Once values for n and k are known, the value of D for any measured value of r can be directly computed from Equation 23-3.

Two problems that arise in using Equation 23-3 are that often the antibodies are nonhomogeneous, so that the Scatchard plot is nonlinear, and possible blockage of free antibody sites by drug molecules is seen in solid-phase immunoassays. The first problem was solved by Rodbard (1971), wherein the analysis mentioned previously was applied to multiple-binding equilibria. This analysis is used commonly in microprocessors that analyze the calibration curves in immunoassays. The second problem has been analyzed using a different theoretical approach (Pincus, 1981). Equation 23-3 illustrates the basic principle of how the results of the drug immunoassay on serum are converted into drug concentrations in serum.

CHROMATOGRAPHIC TECHNIQUES

Chromatographic procedures (see Engelhardt, 2004, for an excellent brief history of liquid chromatography) have been applied mainly to the qualitative detection of drugs of abuse and toxins, and less to the determination of levels of therapeutic drugs. The three major methods are thin-layer chromatography (TLC), high-performance liquid chromatography (HPLC), and gas chromatography-mass spectroscopy (GC-MS). Although GC-MS is considered the “gold standard” for detection and quantitation of volatile drugs and poisons, newer analytic techniques such as capillary electrophoresis (CE) and liquid chromatography-mass spectroscopy (LC-MS) are available. These techniques are all discussed in turn.

Thin-Layer Chromatography

Many compounds can be separated from one another with this method, based on their relative affinities for a polar solid stationary phase (usually

EMIT Scheme

A

FPIA Scheme

B

Figure 23-1 Homogeneous methods for detecting qualitatively or quantitatively the levels of drugs in body fluids. **A**, In the enzyme-mediated immunologic technique (EMIT), a drug-enzyme complex is used as the marker. When bound to the antidrug antibody, the active site of the enzyme (linked to the drug) is blocked. Therefore, when substrate is added, no reaction will occur, as is shown in Part 1. However, if free drug (as in serum) is present, some or most of the enzyme-drug complex is displaced from the antidrug antibody. Now the active sites of the liberated enzyme-drug complexes are free, and the substrate undergoes reactions as indicated in Part 2. **B**, In the fluorescence polarization immunoassay (FPIA), the same general approach is used as in **A**, except that, in this method, the drug is attached to a fluorescent label or fluorophore. As shown in the upper scheme, Part 1, when the drug-label complex is bound to the antidrug antibody, it becomes immobilized ("rigid probe"). When excited with polarized light (shown as polarized to the left or "L"), the fluorophore emits light, which is likewise polarized to the left (also seen as "L" in the figure). As shown in the lower scheme, Part 2, when displaced by free drug, as in serum or urine, the drug-probe complex is displaced from the antidrug antibody. It is no longer immobilized and therefore tumbles freely in solution. This results in loss of polarization of the emitted light ("L" and "R," for left and right polarization), that is, in diminished fluorescence polarization.

Figure 23-2 Illustration of the principle of thin-layer chromatography (TLC). Two solutes, **A** and **B**, are applied to the polar silicate strip. **A** is more polar than **B** and has a higher affinity, therefore, for the polar stationary phase than for the nonpolar mobile phase (usually methanol in chloroform). Moreover, this relative affinity of **A** is higher than the affinity of **B** for the polar phase. Therefore, **A** separates out first on the strip, and **B** migrates further on the strip.

a hydrated silicate) and a mobile liquid phase that is nonpolar (such as 10% methanol in chloroform). Depending on these affinities, different compounds adsorb to the hydrated silicate at different positions as the nonpolar solvent migrates up the stationary hydrated silicate. The principle is illustrated in Figure 23-2. For a given solvent system, the ratio of the distance traversed by the compound to the distance traversed by the solvent front is a constant for the compound and can be used to identify the compound in a mixture. This ratio is called the R_f . This technique is central to identifying different drugs of abuse, many of which can be separated from one another using TLC. The method has been packaged in the form of Toxi-Lab (Irvine, Calif.) kits in which the user is supplied with discrete strips of silicate, extraction solvents, and color-developing solutions.

Toxi-Lab Procedures

The best specimen for drug detection, by chromatography, is urine because large quantities can be collected noninvasively. Once a urine specimen is collected, it is subjected to concentration and extraction procedures. In extraction procedures, acidic drugs are separated from basic ones. Almost all drugs of abuse are basic drugs, all of which are amine derivatives. The important **acid drugs** comprise almost exclusively the barbiturates. In aqueous solution, the basic drugs are charged because of the equilibrium in Equation 23-4, *A*:

in which a primary amine (secondary and tertiary amines exhibit the same equilibrium) is represented by RNH_2 . The ammonium ion form (right side of Equation 23-4A) is soluble in water but not in nonpolar organic solvents. However, the amine-free base (left side of Equation 23-4A) is soluble in nonpolar organic solvents. Extraction procedures to isolate the basic drugs are aimed at treating the urine with base, so that significant amounts of the basic drugs will be uncharged as the amine-free base (Equation 23-4B). This form can then be extracted into a nonpolar organic phase and applied to the silicate strip. The reverse process is carried out for acidic drugs (i.e., these are treated with acid and are extracted into nonpolar solvents). In practice, a small paper disk is added to the organic extraction mixture, and the solvent is then evaporated so that all basic drugs adsorb onto the paper disk. This disk is then applied to one end of the silicate strip, and the strip is placed in the migrating nonpolar solvent. A separate strip is used for each extraction; the A strip is used for basic drugs, and the B strip for acidic drugs. The chief utility of the B strip is in identifying the barbiturates, as is discussed subsequently.

Identification of Specific Drugs

After separation of the drugs on the plate, it is necessary to identify them. This objective is achieved by subjecting the drugs to standard color reactions for each separate compound. In this procedure for basic drugs, the strip is simply dipped successively in three different solvents, which results in characteristic color patterns for each drug. The strip is also subjected to ultraviolet (UV) light, which excites fluorescence in selected compounds. Similar procedures are used for the acidic drugs extracted onto the B strip. As shown in Figure 23-3, which is from the Toxi-Lab reference pattern book, each drug can be identified not only by its R_f but also by its color and characteristic color change in different reagents. These patterns are reinforced by the fluorescence characteristics. As an example, notice in Figure 23-3, *A*, on the Toxi-Lab A worksheet that morphine, the main metabolite of heroin, has a characteristic R_f of 0.14 and a characteristic dark red or purple color in the first solvent that diminishes in intensity and changes color in the second solvent, water. It is nonfluorescent. If one or more of these characteristics differ(s) from this pattern, strong doubt about identification of the spot as morphine would exist. If all criteria are met, the sensitivity and specificity of the method are increased.

Reliability of the Method

Because the identification of each drug depends on the use of qualitative color changes and/or the presence of fluorescence, the sensitivity of the method is limited by the ability of the naked eye to detect these changes. Practically, the level of detection is on the order of 1 $\mu\text{g/mL}$ of compound present on the strip. The chief value of the chromatographic method is confirmatory (i.e., confirmation of a positive immunoassay test result). The two methods are often performed together on a single specimen.

The major problems that occur with this method are that extraction procedures are occasionally inefficient, so that insufficient amounts of drug are absorbed onto the disk. Also, the extraction and evaporation procedures are somewhat time consuming, requiring approximately a half-hour for full processing. Furthermore, cocaine has a number of metabolites that are polar (e.g., ecgonine), and that barely migrate from the origin, so that it is sometimes difficult to detect the presence of this drug of abuse because it has been converted completely to the polar metabolites before excretion. Some difficulty may also be encountered in distinguishing among various opiates, such as between morphine and other opiates, because the R_f values of these drugs can be close to one another (see Fig. 23-3 Toxi-Lab A worksheet). However, experienced personnel can make this distinction in most cases. Also, some nontoxic drugs may give characteristic color changes, and R_f values that are similar to those for the drug of abuse. A case in point is that certain antihistamines appear on the A strip to be very similar to amphetamines.

High-Performance Liquid Chromatography

TLC allows direct qualitative detection of drugs in a panoramic way. HPLC allows quantitative detection of drugs and allows sharper separation of these same drugs. In HPLC, the stationary phase, which can be either polar (silicic acid) or nonpolar (such as the C-18 columns), in reverse-phase chromatography is composed of uniform, ultrafine particles that vastly increase its adsorptive surface area. This stationary phase is packed into a column. The resistance to flow in this column is high, so that large pressures are required to deliver constant reasonable flow rates. In the Waters HPLC instrument (Waters Corporation, Milford, Mass.), a constant pressure head is delivered to the column by the use of two pumps that operate so that as one withdraws, the other pushes forward (i.e., the two operate 180 degrees out of phase). The eluate from the column is monitored by a variety of detectors ranging from UV multiwavelength detectors to redox potential electrode detectors. It is the usual practice in performance of quantitative HPLC to use an internal standard—that is, a compound similar in structure to the drug(s) of interest, which is added to the specimen to be analyzed in a known concentration. By knowing how much of this marker compound or internal standard is placed on the column and how much is recovered from the column in the eluate, the percentage recovery from the column can be calculated for this compound and, by extrapolation, for all of the drugs of interest for which concentrations are being quantitated. Thus, losses due to the column (in addition to losses in extraction procedures) can be corrected for using this technique. Generally, HPLC has been used for the quantitation of specific therapeutic drugs but has found use in detection of cocaine and heroin in urine. The sensitivity of the method is in the nanomolar to micromolar range.

One of the greatest uses of HPLC is in the separation and quantitation of the tricyclic antidepressants and their metabolites. These are among the most commonly prescribed drugs and are also used in excess as drugs of

Toxi-lab A Worksheet

Toxi-lab B Worksheet

Figure 23-3 A set of typical separations of the major drugs of abuse (and some therapeutic drugs) on Toxi-Lab thin-layer chromatography. Toxi-Lab **A** worksheet: Typical separation of basic drugs on the **A** strip, together with characteristic color changes. The third Toxi-Lab **A** strip shows characteristic fluorescence of different drugs. Note that amphetamine and methamphetamine on the lower left are both fluorescent. Toxi-Lab **B** worksheet: *Left*: Typical separation of the more acidic drugs on the **B** strip with characteristic color changes. The major use of the **B** strip is to identify the presence of the barbiturates. *Right*: Fluorescence patterns of drugs on the **B** strip.

Figure 23-4 Sketch of a typical separation of the major tricyclic antidepressants on high-performance liquid chromatography. A complete separation can be effected in 12 minutes. The concentration of each drug is on the order of 100 mcg/mL.

abuse in suicide attempts. It is often necessary to determine the levels not only of the parent tricyclic antidepressant but also of its active and inactive metabolites reviewed subsequently. Figure 23-4 shows a typical separation on a silicate column. Protriptyline, a less inactive tricyclic compound, is the internal standard. It is clear that the separation among the metabolites and parent compounds is quite sharp. This separation is completely reproducible.

A recent variant of TLC that includes the advantages of HPLC is CE (Tagliaro, 1998; Shihabi, 1993). In this method, a capillary tube, lined with silicate, 10–100 μm in internal diameter and 100–1000 mm in length, is used as the solid support in an electrophoresis apparatus. Here, the driving force for separation is the voltage (on the order of 25 kV) rather than pressure, as in HPLC. Because of the vast surface area, separations are quite sharp. The system is highly versatile and can be used to separate serum proteins and small molecules. CE possesses a wide analytic spectrum (including biopolymers, pesticides, aromatic compounds, drugs, inorganic ions, etc.) because of high versatility in terms of separation modes. Different analyte selectivity is based on different physicochemical principles of separation without changes in instrumental hardware—a distinct advantage of this technique. Capillary zone electrophoresis, micellar electrokinetic capillary chromatography (MECK), capillary isotachopheresis, capillary isoelectric focusing, capillary electrochromatography, and capillary gel electrophoresis are different separation modes utilized in CE separations. For example, by adding a detergent to the buffer system, as with MECK, micelles will form. A neutral compound (such as a pesticide) will partition into the detergent, forming micelles, and the complex will separate out based on the mobility/charge of the micelle. In addition, new platforms such as chip-based CE and immunoaffinity CE are currently being developed. CE has not yet enjoyed as widespread use as the immunoassay techniques (discussed previously) in clinical toxicology but is commonly utilized in analytic forensic toxicologic studies, as well as in molecular diagnostic studies, and can easily be extended to other uses in clinical laboratory medicine (Boone, 2003; Petersen, 2003).

GAS CHROMATOGRAPHY–MASS SPECTROSCOPY

Testing for drugs of abuse has become one of the most rapidly developing areas in the clinical laboratory in view of the widespread and ever-expanding use of these drugs among large segments of the working population. In view of the increasing requirements for routine drug screening, it is necessary to have “gold standard” techniques to confirm the results obtained using screening methods such as EMIT and TLC.

GC-MS has proved to be such a gold standard because of its great sensitivity and its reliability. This method, as its name implies, involves two techniques: gas–liquid chromatography and mass spectroscopy. In the former, compounds are directly heated into the gas phase or are derivatized to make them labile to facilitate heating them into the gas phase. They are

then passed over a column containing the stationary phase, which often consists of a liquid, usually a hydrocarbon or silicone oil, that coats a solid support in the column and offers a large surface area for adsorption. Separation is based, much as in TLC, on the ability of each compound to adsorb to the stationary phase, which partially depends on the relative solubilities of the compound in the gas versus the liquid phase. Normally, the compounds eluting from the column could be detected by conventional techniques, as discussed previously, except that once the compounds are in the gas phase, where they are heated, advantage can be taken of another feature of the system—the ability of compounds that are heated to high temperatures to lose or gain electrons.

At high temperatures, the highest energy electrons of a compound (i.e., the ones of lowest ionization potential) can be excited, such that the molecule can lose electrons and become charged. This process may be aided by such techniques as electron bombardment in a specially designed chamber that directly creates molecule-ions. Most of these resulting molecule-ions are single cations. Different molecule-ions in general have different sizes and different molecular weights. These molecule-ions decompose into characteristic fragments whose ratios with respect to one another and whose positions of migration relative to one another are also constant. The molecule-ions are then passed through an electric field generated by four rods that are subjected to rapidly alternating currents, the so-called **quadrupole detector**. Depending on the frequency of the alternating current, certain molecule-ions with specific mass/charge ratios can pass through the field to a detector. Thus, the molecule-ions can be separated on the basis of molecular weight or, more exactly, on their mass/charge ratios. The overall design of GC-MS is shown in Figure 23-5.

The presence of the molecule-ion on the plate is detected by a charge multiplier detector system. The technique of GC-MS has become highly refined. Each molecule-ion created in the gas phase can undergo further changes, such as elimination reactions and rearrangements, and further degradation to small fragments that, in turn, ionize and give characteristic decomposition patterns. The patterns of thousands of compounds have now been determined. The position of the parent molecule-ion of the compound and the decomposition fragments give rise to a **fingerprint pattern** unique to the compound. These patterns are stored in a computer so that when a pattern for an unknown compound or group of compounds is obtained, the pattern is compared with the stored patterns to identify the compound(s) of interest. The entire method has been highly successful in detecting even low levels of cocaine and/or its metabolites in body fluids. A typical cocaine pattern is shown in Figure 23-6. Because single molecule-ion species give rise to significant currents in the detector, it is possible to detect very low levels of drugs, making this technique the ultimate reference method and the best confirmatory testing procedure available at present.

LIQUID CHROMATOGRAPHY–MASS SPECTROSCOPY

(Davis, 1989; Maurer, 1998; Marquet, 2002; Niessen, 1995, 2003).

As discussed previously, GC-MS is the gold standard for the identification of volatile compounds. Nonvolatile compounds, however, can be detected utilizing LC-MS. Unlike GC-MS, however, the coupling of LC with MS requires sophisticated interfaces between the LC and MS components. The interface must volatilize nonvolatile compounds that have been separated on the LC; must remove the liquid solvent from the LC; and must correct flow-rate incompatibility between the LC and MS. Two interface methods, electrospray (ES) and atmospheric pressure chemical ionization (APCI), appear to have become the gold standards for LC-MS. Both interface methods are utilized with atmospheric pressure ionization devices to facilitate removal of the mobile phase. They differ primarily in the range of analytes that can be accommodated and in how the solvent phase is nebulized.

Ionizable analytes of high molecular weight and/or high polarity can be accommodated with ES, and APCI can be used for analytes of less polarity and lower molecular weight. At present, ES appears to have more clinical and forensic applications than APCI in toxicology. LC-MS can be used to confirm positive test results from a screening assay and has been used for confirmation of drugs-of-abuse assays, poisoning detection in acute or chronic intoxication, therapeutic drug identification and quantitation, and pharmacokinetic and drug metabolism studies. Although LC-MS has limitations when compared with GC-MS, it has become a powerful “mature and validated” (Marquet, 2002) technique in analytic toxicology and a complementary method to GC-MS.

Figure 23-5 A schematic view of the components of gas chromatography–mass spectrometry instrumentation. On the left of the figure is the gas chromatographic system, where a volatilized compound is moved by an inert gas over a column consisting of rings coated with a liquid. Compounds C, B, and A separate on this column and are maintained in the gas phase by the oven that surrounds the column. The separated compounds then enter the mass spectrometer on the right side of the figure, where they are subjected to bombardment by electrons, resulting in molecule ion species. These ionic species then are accelerated in a field and are passed through an electric quadrupole field. Only those ions with a narrow range of mass/charge ratios (m/e ratios) will pass through the tuned field so that they strike the detector. The electric currents that result are digitalized and stored in a computer that analyzes the data (Davis, 1989).

Figure 23-6 Fragmentogram for cocaine using gas chromatography–mass spectrometry. The specimen is urine. This figure shows the characteristic peaks for cocaine metabolites. m/e is the mass to charge ratio, which for most ions is a measure of the molecular mass. (Courtesy of Dr. Chip Walls, Onondaga County, N.Y., Medical Examiners Office.)

GAS CHROMATOGRAPHY COUPLED WITH INFRARED SPECTROSCOPY

Infrared (IR), or Fourier-transformed infrared, spectroscopy (FTIR) utilizes light of high wavelength (low frequency), which excites vibronic states of molecules involved in bond stretching and bond angle bending. Every compound has a characteristic IR “fingerprint,” that is, IR absorption pattern, so that even closely related compounds can be distinguished readily from one another by gas phase IR. Thus the fractions of patients’ samples that elute from a GC or liquid chromatography column can be analyzed using this technique. As with mass spectrometry, the FTIR spectra for different compounds can be stored in a computer attached to the GC-FTIR system; the spectra obtained from the eluates from the column are then analyzed for the presence of specific drugs of abuse. This method is particularly well suited for the detection of amphetamines (Belal, 2009).

SCREENING FOR DRUGS OF ABUSE

In most states of the United States, two levels of testing for drugs of abuse have become recognized: emergency room testing and employment screening/forensic testing. The former involves rapid, stat screening methods, in particular, EMIT (or FPIA) and TLC. The purpose of this type of screening test is to detect the presence of a drug or several drugs of abuse in the patient’s urine. Rarely are the more sophisticated chromatographic procedures such as HPLC and GC-MS used for this purpose. Forensic testing, on the other hand, requires not only a screen but also an independent confirmatory method, which is almost always chosen to be GC-MS or, less commonly, HPLC. It should be noted that, strictly by law, any confirmatory method is valid, provided it is a completely different method from the primary one. Thus, TLC can confirm EMIT, whereas FPIA cannot confirm it because both EMIT and FPIA are

immunochemical methods. Another important legalistic consideration in forensic testing is the so-called **chain of custody** (DeCresce, 1989; Poklis, 2001). This process is used in the collection of urine from the individual from whom the specimen is taken. It may begin by observation of specimen collection by one person. Then, that person or another specifically designated individual, usually a police officer (in the case of prisoners or suspects) or some other designated official, accompanies the messenger, who brings the specimen from the individual to the laboratory. This individual is a witness to the testing (and must sign a legal document to this effect) of the specific urine sample collected. More than one designated individual may be involved as the witness in this chain.

THE DRUGS OF ABUSE

GENERAL ASPECTS OF THE MECHANISMS OF ACTION

The major drugs of abuse (Flomenbaum, 2006; Sweetman, 2002) are shown in Figure 23-7 (O'Neil, 2001; Haroz, 2006). As may be seen in this figure, these drugs, with the exception of the barbiturates and the cannabinoids, are all basic amino group-containing compounds, most of which also contain benzene rings. The steric relationship of the amino group with respect to the aromatic benzene rings is rather similar, especially in

1. Opiates

2. Tranquilizers

3. Barbituates; Sedative - Hypnotics

Figure 23-7 Chemical structures for the major drugs of abuse. All of the opiates are seen to be basic compounds that are tertiary amines and that contain benzene rings. Notice that, in the barbiturate series, barbituric acid may be considered as a condensation product of urea and malonic acid.

4. Dopaminergic Pathway Stimulants

4A. "Designer" Amphetamines/Phenylethylamines

5. Hallucinogens

6. Tryptamines

7. Piperazines

Figure 23-7, cont'd Chemical structures for the major drugs of abuse. All of the opiates are seen to be basic compounds that are tertiary amines and that contain benzene rings. Notice that, in the barbiturate series, barbituric acid may be considered as a condensation product of urea and malonic acid.

Figure 23-8 Illustration of the possible mechanisms of action of drugs of abuse and some therapeutic drugs on sympathomimetic amine (dopamine and norepinephrine) pathways. *A*, Normal neural transmission. A nerve impulse is conducted down the axon to the terminal boutons at the nerve ending. Vesicles, represented by the round gray structure, release their contents of neurotransmitter, here dopamine, represented by small white circles. Dopamine molecules traverse the synaptic cleft and bind to dendritic receptors, initiating action potentials (at right under "dendrite") in the dendrites. Notice the arrows showing that dopamine is both released and taken up by the vesicles. *B*, In the presence of cocaine and amphetamines, enhanced release of neurotransmitter (red circles) from vesicles occurs, increasing the rate of firing in the dendrites. *C*, Tricyclic antidepressants block (arrow with "X" in yellow box) reuptake of the neurotransmitter (purple circles), in this case norepinephrine and, less specifically, dopamine, causing more neurotransmitter to "recycle" to the dendritic receptors, resulting in increased firing. *D*, Some of the neuroleptics act by blocking (gray wedge) postsynaptic dendritic receptors for dopamine (blue circles), causing decreased firing.

cocaine, the opiates, and methadone. As might be expected, these compounds can cross-react with each other's target receptors. The primary physiologic mechanisms of action of these drugs are not well understood, but some rudimentary knowledge has been gained as to some of the main targets of these drugs. Many of these drugs act directly on dopaminergic and norepinephrinergic neurotransmitter systems, especially the limbic system (sometimes referred to as the **smell brain**). This system is a

more primitive one associated with pleasure seeking and is discussed further later.

In Figure 23-8, possible effects of several of the most important drugs on this system are shown. It appears that the amphetamines, closely related structurally to dopamine and the catecholamines, and cocaine cause release of dopamine from the vesicles at the axonal side of the synapse, which may partially be responsible for their producing a pleasant sensation (so-called

high) in many individuals (Hurd, 1988). The tricyclic antidepressants stimulate pathways that utilize norepinephrine as the neurotransmitter. These pathways, like the dopaminergic pathways, are involved in arousal and pleasure seeking. In this case, the tricyclic antidepressants, rather than promoting release of the neurotransmitters, block the reuptake of norepinephrine into the vesicles on the axonal side of the synapse. They also may exert nonspecific reuptake blockade of dopamine in the dopaminergic pathways (Baldessarini, 2006a). It is of great interest that, paradoxically, the tricyclic antidepressants such as imipramine (Tofranil) have been used successfully to treat the effects of cocaine, although, as described later, benzodiazepine tranquilizers are now preferred. The major tranquilizers such as haloperidol (Haldol) and chlorpromazine, used to treat psychotic states such as schizophrenia, appear to block attachment of dopamine to the dendritic receptors in the synapse, thereby blocking the stimulatory effects of dopamine. Associated with many dopaminergic neurons are inhibitory neurons that use γ -aminobutyric acid (GABA) as their neurotransmitter. It appears that many benzodiazepine receptors exist on these neurons, causing potentiation of GABA at the synapses in this system, reducing the dopaminergic effects of the stimulatory pathways on the limbic system. Thus, some of the tranquilizing effects of diazepam (Valium) and other benzodiazepines can be explained.

Widely distributed throughout the central nervous system and periphery are a variety of opioid receptors classified mainly as μ -, δ -, κ - (the three classic opioid receptor types), and ϵ - (not well characterized; see Tseng, 2001; Snyder, 2003) receptors. The μ -receptors appear to be highly specific for morphine and heroin, both of which produce a general analgesic state. At the moment, there appears to be no direct relationship between these receptors and the dopaminergic pathways.

It is interesting to note that the naturally produced opiate peptide, met-enkephalin, whose amino acid sequence is Tyr-Gly-Gly-Phe-Met, cross-reacts significantly with μ -receptors, although its primary "target" is ϵ -receptors. It has been shown that the benzodiazepines may be structurally related to enkephalin, which, in turn, may be structurally related to morphine (Pincus, 1987; Murphy, 1992). It is therefore possible that these compounds have similar effects, at least indirectly, on the dopaminergic pathways.

Many of the drugs of abuse also act on two other major pathways in the brain: those using serotonin (serotonergic) and those utilizing *N*-methyl-D-aspartate (NMDA) as their neurotransmitter. Neurotransmission by serotonin occurs by its binding to the 5-hydroxytryptamine (5-HT) receptor on the dendritic side of the synapse. There is a rather wide range of 5-HT receptors, not all of which produce the same physiologic effects. The major ones appear to be 5-HT₁ and 5-HT₂ receptors. The serotonin pathways encompass a rather wide swath of the brain and even the spinal cord. This neurotransmitter is the principal one for the limbic system and, in addition, the basal ganglia, especially the amygdala that is involved in aggressive behavior. As mentioned earlier, the limbic system is involved in pleasure seeking and pleasure reinforcement. Serotonergic pathways also extend to the hippocampus and are involved in memory. As a neurotransmitter in the spinal cord, serotonin induces muscle contraction. NMDA pathways are more involved in nociceptive (pain) pathways and are involved in memory and neuronal plasticity (Zhuo, 2009). They have been found to be involved in chronic pain reinforcement. Blockade of NMDA pathways by drugs of abuse can therefore remove this perceived undesirable effect.

COCAINE

Cocaine is derived from the coca plant and has enjoyed much popularity as an additive to certain foods. At the beginning of the 20th century, it was used in Coca-Cola, but owing to its addictive effects, this practice was discontinued. Cocaine is a derivative of the alkaloid ecgonine (i.e., the methyl ester of benzoyllecgonine), as shown in Figure 23-7 (Group 4 drugs). The normal route of administration of cocaine is nasal (i.e., inhalation, called **snorting**), such that the drug passes through the nasal membranes. A particularly potent form of cocaine, called **crack**, is the free-base form that passes rapidly across the nasal membranes such that, for a given dose, most or all of it enters the bloodstream rapidly. The half-life of cocaine is 1–2 hours, and the parent compound and its metabolites are usually cleared from the body within 2 days.

It is estimated that as many as 25 million people in the United States have used cocaine at least once (Jones, 2006). As of 2008, it was estimated that 5.3 million Americans 12 years of age and older actually abused this drug (National Institute of Drug Abuse, 2009). Fatalities from cocaine abuse are of two types: direct toxicity of the drug (Johanson, 1989), and

crime related to the illicit acquisition of the drug. Up to 25% of myocardial infarctions in patients between the ages of 18 and 45 have been attributed to cocaine abuse (Jones, 2006).

Cocaine is used medically to induce local anesthesia during nasopharyngeal surgery. However, in large doses, it induces a euphoric state (the "high" experienced by the user) and may also induce hallucinatory states. It can also promote violent behavior (Flomenbaum, 2006; Hoffman, 2006). Many of these results can be explained by cocaine's dopaminergic effects. One study (Azmitia, 1990) suggests that cocaine induces increased calcium ion influx in dopaminergic neurons. The increased intracellular calcium activates phospholipases that possibly act as second messengers in causing ultimate release of dopamine in synapses. Prolonged action of phospholipases, however, ultimately causes cell death. In the previously mentioned study, in fact, cocaine was found to be neurotoxic. It also has a general cytotoxic effect from formation of an *N*-oxide free-radical produced in the metabolism of this compound in the liver. It appears then that, over time, cocaine induces neuronal loss. In addition, binding of cocaine to cell receptors in the limbic system induces synthesis of cyclic adenosine monophosphate (cAMP) that appears to be critical in activating cell processes involved in dopamine release (Cami, 2003). Cocaine may also block the reuptake of dopamine at the axonal side of the synapse. As if becoming toxic from cocaine abuse was not sufficient, many cocaine abusers consume this drug together with alcohol. Ethanol becomes esterified to cocaine in the liver to form cocaethylene, which blocks reuptake of dopamine in dopaminergic pathways more effectively than does cocaine and causes pronounced vasoconstriction of the coronary arteries and induces increased myocardial oxygen demand. This cocaine derivative is deadlier than either cocaine or ethanol alone (Jones, 2006).

Studies (Lange, 1989, 2001; Frishman, 2003; Jones, 2006) further indicate that prolonged use of cocaine results in cardiotoxicity—that is, cocaine can cause progressive atherosclerosis and causes constriction of the coronary arteries that can, in turn, induce myocardial ischemia and sometimes frank infarction. Cocaine has been found to induce sympathomimetic effects on the myocardium by increasing heart rate. At the same time, it induces increased vasoconstriction. The net effect is increased chronotropy and afterload, resulting in increased oxygen demand by the myocardium. At the same time, cocaine induces platelet aggregation and stimulates production of plasminogen activator inhibitor (Jones, 2006). These events all predispose to development of myocardial infarction.

One highly disturbing aspect of cocaine abuse is the fact that cocaine passes readily across the placenta and also into the lactating mammary gland and is readily passed from mothers to nursing infants. Often in the hospital setting, mothers receive the drug from dealers and breastfeed their newborn babies, who are therefore maintained on this drug. Cocaine causes mental retardation, delayed development, and strong drug dependence in newborns. It can also produce malformations in utero.

Cocaine has not been considered classically to be an addictive drug, as it does not cause the true physical dependence typical of abusers of barbiturates and opiates. However, the high produced by the drug is extraordinarily reinforcing, so that the drug-seeking behavior of the cocaine and opiate abuser is similar. Evidence in experimental animals suggests that cocaine can induce the release of β -endorphins that bind to μ -receptors in the limbic system (Gianoulakis, 2004). This induces a pleasant and positive feeling of reinforcement. Clinically, patients who are overdosed with cocaine may become violent and irrational, requiring sedation. The treatment of choice for patients in hyperexcitable states with cardiac symptoms such as palpitations is one of the benzodiazepines. Thus, it is not uncommon to find cocaine and Valium in the urine of cocaine addicts. Occasionally, overdosed patients will become obtunded or comatose. The treatment for these patients is usually supportive. As noted in the previous section, antidepressants, including the tricyclics, and selective serotonin reuptake inhibitors (SSRIs), like fluoxetine (Prozac), have been found to inhibit some of the undesirable effects of cocaine and have been used in the treatment of cocaine abuse.

Metabolism

The half-life of cocaine, as stated previously, is approximately 1–2 hours. It is metabolized to more polar compounds that have significantly less potency than the parent compound. These metabolites have longer half-lives and, with techniques such as GC-MS, can be detected up to 48 hours after administration of the drug. The immunoassay methods can detect the drug for about 24–36 hours after administration. If a patient has inhaled cocaine free-base ("crack"), it is possible to detect the parent

compound, cocaine, by TLC up to several hours after administration, owing to the high doses of drug present.

THE OPIATES (HEROIN, MORPHINE, CODEINE, FENTANYL)

The structures for these drugs are shown in Figure 23-7. As can be seen in this figure, the first three drugs of abuse—morphine, codeine, and heroin—have quite similar structures. In fact morphine is a metabolite of heroin. Morphine itself is used as a powerful analgesic and acts by binding to μ -receptors in the limbic system (central nervous system [CNS]), mainly in the nucleus accumbens and the ventral tegmental area, resulting in an analgesic state. Binding of each agent to the μ -receptor inhibits the release of GABA from the nerve terminal, reducing the inhibitory effect of GABA on dopaminergic neurons. The resulting increased activation of dopaminergic neurons results in sustained activation of the postsynaptic membrane, causing a sense of euphoria. On the molecular level, binding of morphine to these receptors activates a cell signaling cascade via G-protein activation that results in elevated expression of many transcriptionally active proteins such as ERK, jun, and fos, and superactivation of adenylyl cyclase resulting in high intracellular levels of cAMP (Tso, 2003). Besides being used as a major analgesic, morphine (Dilaudid) is important in treating acute congestive heart failure by lowering venous return to the heart (i.e., it is a powerful preload reducer by causing increased splanchnic pooling of blood). Codeine is used as a mild analgesic and as an antitussive. The codeine analog dextromethorphan (D-3-methoxy-N-methylmorphine), is an antitussive agent that is a component of cough suppressive medications.

Heroin induces a pleasant, euphoric state and is highly addictive both physically and psychologically. As can be seen in Figure 23-7, heroin is a diacetyl form of morphine. This characteristic facilitates heroin's crossing the blood-brain barrier, allowing it to reach higher concentrations in the CNS. Withdrawal from this drug is exceedingly difficult, with a myriad of symptoms such as hypothermia, palpitations, cold sweats, and nightmares. This is a true physical dependence, the molecular basis for which is not fully understood. It appears that the dependence is strongly linked to the number of cell surface μ -receptors (Tso, 2003).

This class of compounds exhibits certain important paradoxical effects on the parasympathetic nervous system. These drugs exert a procholinergic effect on the eyes and on blood vessels in the periphery (i.e., they cause constriction of pupils [**pin-point pupils**] and peripheral vasodilation). In contrast, in the gut they lower gastrointestinal (GI) motility (i.e., they exhibit anticholinergic effects in the GI tract). This fact enables rapid diagnosis of heroin or, in general, opiate abuse in a patient brought to the emergency room in an obtunded or comatose state. These patients typically have severe miosis (pupillary constriction). Although the sign is not useful in acute diagnosis, constipation commonly occurs.

Administration of heroin occurs via the intravenous route. Addicts are readily recognized by the presence of needle tracks on their arms and hands and by extensive thrombosis of their peripheral veins. The half-life of heroin via the intravenous route is about 3 minutes, and the effects of the drug last approximately 3 hours. The major metabolites are N-acetylmorphine and morphine. The half-life of morphine is about 3 hours. Overdoses of heroin are extremely dangerous and can cause severe obtundation, coma, respiratory arrest, hypotension (secondary to histamine release), and cardiac arrhythmias. One of the most common therapeutic modalities for heroin overdose is intravenous treatment with naloxone (Narcan) (see Fig. 23-7), a strong competitive antagonist to the action of heroin. Heroin addiction, as a chronic problem, is treated pharmacologically with a partial agonist of heroin—methadone, which is discussed later.

Codeine and Analogs

The structure of codeine is similar to that of morphine and heroin (Group 1 structures in Fig. 23-7). Codeine, like morphine, has a strong analgesic effect, is a potent antitussive agent, and acts in a manner similar to that of morphine. Dextromethorphan (D-3-methoxy-N-methylmorphine), an analog of codeine, is the active component of cough syrups because of its antitussive effects. Recently, there has been a “run” on cough medicines by addicts, who can obtain them legally and then consume quantities sufficient to reach their desired euphoric state. Unlike codeine, dextromethorphan is believed generally not to be addictive, although cases of drug dependency have been documented. For therapeutic use, the recommended dose of dextromethorphan is 15–30 mg given three to four times

per day. **Light intoxication** is achieved at about 100–200 mg, and **heavy intoxication** is reached at around 1500 mg (Haroz, 2006). It is surprising to note that dextromethorphan does not have analgesic properties because of its lack of affinity for μ -, κ -, and δ -receptors. It has been found to induce the release and to block the reuptake of serotonin. Similar to the action of phencyclidine (PCP), discussed later, dextromethorphan has also been found to block NMDA receptors that are critical for neuronal plasticity and memory and are involved in central pain pathways in the brain, as discussed earlier (Zhuo, 2009). Dextromethorphan is readily absorbed from the GI tract and, in about 85% of individuals, is rapidly metabolized to dextrophan, an active metabolite, and D-hydroxymorphinan via the 2D6 cytochrome P450 isozyme (Haroz, 2006). It is dextrophan that has a high affinity for NMDA receptors, so that most individuals experience PCP-like effects (i.e., euphoria; tactile, auditory, and visual hallucinations; paranoia, altered time perception; and general disorientation). For the 15% of individuals who are slow metabolizers of dextromethorphan, these effects are much less pronounced and are replaced by sedation and dysphoria (Haroz, 2006). Overdoses of dextromethorphan can result in mainly neurologic effects, such as lethargy, or, conversely, hyperexcitability; ataxia; slurred speech; tremors and fasciculations; hypertonia and hyperreflexia; and nystagmus, as well as either pupillodilation or pupilloconstriction. Diaphoresis may also occur. In addition, cardiovascular sequelae include tachycardia and hypertension. Unfortunately, a number of antitussives contain, in addition to dextromethorphan, anticholinergic agents such as chlorpheniramine. Thus, abuse of antitussive medication can give rise to such symptoms as tachycardia, mydriasis, flushed skin, urinary retention, and constipation.

Fentanyl

This opiate analgesic (Group 1 drugs in Fig. 23-7), is about 80 times more potent than morphine in blocking pain. It can be taken orally as so-called **fentanyl lollipops**, smoked, inhaled, or administered by transdermal fentanyl patches (Haroz, 2006). Overdose effects of this drug are the usual ones seen for opiate abuse and include respiratory depression and miosis. Treatment may involve irrigation of the bowel, and antiopiates such as naloxone may be administered. Hypotension is less common than with other opiates like morphine, because of the lack of histamine release.

METHADONE

This interesting compound, whose structure is shown in the Group 1 drugs in Figure 23-7, is a nonbicyclic drug that binds competitively with morphine to μ -receptors in the brain. However, although it can become addictive, the addictive effects are less than those of equivalent concentrations of heroin, possibly because its binding affinity is lower, so that it induces less of an effect than heroin. Thus, administration of methadone to heroin addicts allows them to experience the effects of heroin but in a modulated manner. By gradually lowering the methadone dose, physical dependence becomes reduced, and it appears that a trough serum methadone level greater than 100 ng/mL is adequate for effective methadone maintenance (Bell, 1988). However, it should be noted that addiction to methadone can also occur. In toxicology laboratories, the most common request received for methadone screens comes from methadone clinics to test whether a patient is administering methadone or has relapsed into taking heroin. As can be seen in Figure 23-3, it is a simple matter to distinguish methadone from the opiates by TLC. Similarly, EMIT or FPIA detects each drug with high specificity.

AMPHETAMINES

These compounds, as can be seen in Figure 23-7 (Group 4 drugs), bear a close resemblance to the adrenergic amines such as epinephrine and norepinephrine and may be expected to exert sympathomimetic effects. They also resemble dopamine and may be expected to have effects on dopaminergic pathways. The amphetamines cause euphoria and increased mental alertness that may be attributed to their effects on these pathways. This group of drugs, however, also exerts pronounced stimulatory effects on γ - and β -receptors in the cardiovascular system and in the kidney to cause pronounced adrenergic effects such as increased heart rate, increased blood pressure, palpitations, bronchodilation, anxiety, pallor, and tremulousness. Studies indicate that amphetamines are also competitive inhibitors of the enzyme monoamine oxidase, which inactivates adrenergic neurotransmitters by oxidatively removing their amino groups. Blockage of this enzyme prolongs the effects of epinephrine and norepinephrine, with the attendant neurologic and cardiovascular sequelae. One particular amphetamine,

3,4-methylenedioxymethamphetamine (MDMA or **ecstasy**), a derivative of methamphetamine (see Group 4A drugs in Fig. 23-7), has become popular as a recreational drug of abuse because it has euphoric and psychedelic effects but minimal hallucinogenic effects (Gill, 2002; Haroz, 2006).

Clinical Symptoms

The pharmacologic action of amphetamines includes CNS and respiratory stimulation and sympathomimetic activity (e.g., bronchodilation, pressor response, mydriasis). Loss of weight may also occur as the result of an anorectic effect. Psychic stimulation and excitability, leading to a temporary increase in mental and physical activity, can occur; anxiety and nervousness can also be produced.

Acute Toxicity

Initial manifestations of an overdose may be cardiovascular in nature; symptoms may include flushing or pallor, tachypnea, palpitation, tremor, labile pulse rate and blood pressure (hypertension and hypotension), cardiac arrhythmia, heart block, circulatory collapse, and angina. Mental disturbances such as delirium, confusion, delusions, disorientation, and hallucinations may occur. Acute psychotic syndromes may be characterized by vivid auditory and visual hallucinations, restlessness, homicidal or suicidal tendencies, panic state, paranoid ideation, loosening of associations, combativeness, and changes in affect. A frequent and potential sign of acute intoxication is hyperpyrexia; rhabdomyolysis has also been associated with acute amphetamine overdose. Cardiovascular collapse is the usual cause of death.

Chronic Usage

Tolerance may be produced within a few weeks, and physical or psychic dependence may occur with prolonged usage. Symptoms of chronic abuse include emotional lability, somnolence, loss of appetite, occupational deterioration, mental impairment, and social withdrawal. Trauma and ulcer of the tongue and lip may occur as a result of continuing chewing or teeth-grinding movements. A syndrome with the characteristics of paranoid schizophrenia can occur with prolonged high-dosage use. Aplastic anemia and fatal pancytopenia are rare complications.

Treatment

No specific antidote for amphetamine overdose is known, and treatment of overdose is symptomatic with general physiologic supportive measures immediately implemented. When cardiovascular symptoms are noted, propranolol (Inderal), discussed subsequently under therapeutic drugs, can be used as an antidote.

Detection

Both Toxi-Lab (Irvine, Calif.) and EMIT (Syva, San Jose, Calif.) procedures are effective in detecting these drugs of abuse. Occasionally, on the Toxi-Lab A strip, amphetamines may be confused with antihistamines like diphenhydramine.

“Designer” Amphetamines and Related Drugs of Abuse

The quest for euphoria-producing drugs has resulted in the advent of synthetic phenylethylamines, so-called **designer drugs**, like MDMA, several further examples of which are shown in category 4A of Figure 23-7. With all of these drugs, the price for the sought-after effects of euphoria and hallucinations consists of headaches, nausea, vomiting, anxiety, agitation, violent behavior, tachycardia, hypertension, respiratory depression, and seizures, as discussed previously in the case of **standard** amphetamines.

Other phenylethylamine derivatives shown in Figure 23-7, especially 2C-T-7 and 2CB, bind to 5-HT₂ receptors and induce hallucinogenic effects (Haroz, 2006). These drugs have been taken orally or have been insufflated, smoked, administered intravenously, and even taken rectally. Death from overdose of these designer drugs has been reported but is uncommon. Unfortunately thus far, no specific assays are available for most of these drugs in urine. Their presence must be ascertained by history and/or symptoms reported in the absence of positive urine tests for standard amphetamines. On occasion, GC-MS is used to detect their presence.

TRYPTAMINES

These drugs are derivatives of serotonin whose structure is shown in Figure 23-7—Group 6 drugs. These tryptamines, some of which occur in

plants, are relatively simple to obtain and were not proscribed until relatively recently. An example is *N,N*-dimethyltryptamine (DMT), which has strong hallucinogenic properties. Smoking DMT results in the rapid onset of hallucinogenic effects that are short-lived, giving rise to the term, **businessman’s lunch**. Other tryptamines contain modifications of the indole ring, as shown in the Group 6 drugs in Figure 23-7. These also allow them to interact with 5-HT receptors (Haroz, 2006), and this interaction is thought to result in their hallucinogenic effects. However, the mechanism of action of this class of drugs is not well understood. Psilocin shown in this figure is a component of the so-called **Psilocybe**, called **magic mushrooms** because of their hallucinogenic effects. The hallucinogenic effects of these drugs are enhanced by the presence of monoamine oxidase inhibitors such as β -carbolines (Haroz, 2006). The mixture of these two compounds is present in a South American tea called **ayahuasca**, which combines two plants—one containing DMT and the other carbolines, which themselves can induce nausea and vomiting. Like the amphetamines and other phenylethylamine derivatives, the tryptamines cause, in addition to the “desired” effects of euphoria and empathy, auditory and visual hallucinations, nausea, vomiting, diarrhea, and emotional distress. Symptoms further include agitation, tachycardia, hypertension, diaphoresis, salivation, dystonia, mydriasis, tremors, confusion, seizures, and, in a few cases, rhabdomyolysis and paralysis. Currently, no routine assays are available for these compounds. As with the amphetamines, many of the psychogenic and physiologic effects of the tryptamines can be countered with supportive therapy and the administration of benzodiazepines.

PIPERAZINES

The structure of the parent compound, piperazine, is shown in Group 7 of Figure 23-7. Several of the derivatives of piperazine are also shown in this figure. Many of these piperazines were used as anthelmintics during the 1950s but were subsequently discontinued. However, their euphoria-producing effects were discovered, leading to a “legal” way of obtaining drugs of abuse. Two classes of piperazine derivatives have been identified: *N*-benzylpiperazines, the parent compound of which is *N*-benzylpiperazine (BZP), and phenylpiperazines. The former group includes 1-(3,4-methylenedioxybenzyl)piperazine, and the latter group includes 1-(3-chlorophenyl)piperazine, 1-(4-methoxyphenyl)piperazine, and 1-(3-trifluoromethylphenyl)piperazine (TFMPP). BZP (known as **A2**) and TFMPP (known as **Molly**) are among the most popular piperazines. Studies have shown that these piperazines produced effects that were similar to those of the amphetamines, suggesting that the target receptors of these drugs are the same. Both classes of piperazines have been found to increase dopamine and serotonin levels. TFMPP has been found to act as a partial agonist at 5-HT_{2A} receptors and is a full agonist at other 5-HT receptors. Although TFMPP is three times less potent than MDMA, it produces a full MDMA effect when combined with BZP, with which it is synergistic (Haroz, 2006). The TFMPP-BZP combination at low doses induces euphoria with decreased motor action, making the euphoric “experience” more pleasurable. The acute undesirable effects of piperazines are similar to those of the amphetamines and MDMA (i.e., hallucinations, psychomotor agitation, increased heart rate and blood pressure, and increased body temperature). Two deaths from BZP have been reported when combined with another drug like MDMA (Haroz, 2006). Both TFMPP and BZP have skin-irritant properties, causing sore nasal passages and throats. As with the tryptamines and designer amphetamines, currently no standard assay method detects these drugs in urine; treatment is supportive, as described in the preceding section.

BENZODIAZEPINES

Among this group of drugs, shown in Figure 23-7 (Group 2), the most prominent is Valium; they are used therapeutically, as so-called **minor tranquilizers**. Their mechanisms of action appear to be potentiation of GABA, a neurotransmitter that *inhibits* conduction in dopaminergic neurons, and facilitation of its binding to GABA receptors (Campo-Soria, 2006). Benzodiazepines bind to the α subunit of the so-called **GABA_A receptor** at a site that is distinct from that for GABA itself and cause an increase in the frequency of chloride ion channel opening at the GABA_A receptor. Usually used as a therapeutic drug to produce calming effects at doses between 2.5 and 10 mg and to produce muscle-relaxing effects at higher doses, Valium has been used by drug addicts in high dosage to counter the excitatory effects of other drugs of abuse or as a means of inducing tranquil states. Among some drug abusers, benzodiazepines are

used to potentiate the effects of heroin (Fraser, 1998). A number of drug abusers have become addicted to Valium when using high doses several times each day. Acutely, benzodiazepine overdose may produce somnolence, confusion, seizures, and coma. Rarely, hypotension, respiratory depression, and cardiac arrest may occur. Chronically, physical and psychological dependence occur. Sudden discontinuance of the drug may lead to anxiety, sweating, irritability, hallucinations, diarrhea, and seizures. Treatment is supportive. Gradual diminution of the benzodiazepine removes physical dependence. The half-life for Valium is 20–70 hours, but the half-life of one of its active metabolites is 50–100 hours.

PHENCYCLIDINE

This interesting tricyclic compound, shown in Figure 23-7 (Group 5), has numerous effects on a variety of different neural pathways. Used almost exclusively as a drug of abuse, this drug is traded on the streets under the name of **angel dust** or **angel hair**. It is peculiar that the use of this drug appears to be periodic. The physiologic effects of PCP appear to be analgesic and anesthetic and, paradoxically, stimulatory. This drug has been found to interact with cholinergic, adrenergic, GABA-secreting, serotonergic, and opiate neuronal receptors. It has also been found to block NMDA receptors (Hevers, 2008). Thus, a wide variety of bizarre and apparently paradoxical symptoms can be seen in the same patient. This drug has been shown to bind to specific regions of the inner chloride channels of neurons, apparently profoundly affecting chloride transport. It has also been found to bind strongly to a class of neural receptors called **sigma-receptors** (Schuster, 1994). This receptor binds strongly to the neuroleptic, antipsychotic drug haloperidol (Haldol)—a finding that may implicate the sigma-receptor in some of the clinical findings of severe psychosis in patients suffering from overdose with PCP.

Because of its varied actions, clinically acute manifestations vary from depression to euphoria and can involve catatonia, violence, rage, and auditory and visual hallucinations. Vomiting, hyperventilation, tachycardia, shivering, seizures, coma, and death are among the common occurrences that result from abuse of this drug. Most fatalities occur from the hypertensive effects of the drug, especially on the large cerebral arteries (Bayorh, 1984). As can be inferred from this spectrum of possible symptoms, diagnosis based on clinical findings is impossible. Only the results of a drug screen can be diagnostic. Treatment of drug abuse with PCP is supportive, with the patient kept in isolation in a darkened, quiet room. Acidification of the urine increases the rate of PCP excretion. As might be expected from findings regarding the sigma-receptor, treatment with Haldol results in sedation of the violent, hallucinating patient.

BARBITURATES: SEDATIVE-HYPNOTICS

An almost bewildering variety of these major sedative drugs is available. However, all are derivatives of barbituric acid, which may be regarded as the condensation product of urea and malonic acid, as indicated in Figure 23-7 (Group 3 drugs). Depending on the substituents of the $-\text{CH}_2$ group of the malonic acid portion, the particular drug may be long acting, as is phenobarbital, with a benzene ring and ethyl group substituents on this carbon; short acting, as is pentobarbital, with neopentyl and ethyl groups at this position; or ultra-short acting, as is the case with thiopental. The long-acting barbiturate phenobarbital is a therapeutic drug that is used as an anticonvulsant, unlike the short- and ultra-short-acting drugs, and is discussed subsequently under therapeutic drugs. All of the barbiturates are fat soluble and therefore pass easily across the blood-brain barrier. All of them seem to stabilize membranes such that depolarization of the membranes becomes more difficult.

As with the benzodiazepines, the barbiturates are known to interact with GABA receptors. In particular, they bind to the α subunit of the GABA_A receptor at a site that is distinct both from the GABA binding site and from the benzodiazepine binding site. Their effect is to increase the *duration* of chloride ion channel opening at the GABA_A receptor, potentiating the GABA effect (i.e., inhibition of dopamine-dependent nerve conduction). It is thought that this action of chloride channel opening, called **direct gating** of the chloride channel, is the basis for barbiturate toxicity, which is greater than for the benzodiazepines, which do not increase the *duration* of chloride channel opening but rather increase the **frequency** of channel opening, as discussed previously in the benzodiazepine section. In addition, at higher doses, barbiturates have been found to inhibit a subtype of glutamate receptors, called **AMPA receptors**. Glutamate is a major excitatory neurotransmitter. More

generally, barbiturates have been found to block calcium ion-induced release of neurotransmitters.

For unknown reasons, the short-acting and ultra-short-acting barbiturates seem to inhibit selectively the reticular activating system, involved with arousal—hence their sedative and hypnotic effects. The ultra-short-acting barbiturates rapidly diffuse out of the CNS, accounting for their rapid action. Phenobarbital, however, selectively reduces the excitability of rapidly firing neurons and is therefore a highly effective anticonvulsant. It may be more than coincidental that phenobarbital and the equally effective anticonvulsant phenytoin (Dilantin) bear structural resemblance to one another and may exert similar effects on rapidly firing neurons. The mechanism of action of phenytoin is discussed subsequently.

Clinically, at low doses, the short-acting and ultra-short-acting barbiturates produce sedation, drowsiness, and sleep. They also impair judgment. At higher doses, anesthesia is produced. At very high dose, these drugs can cause stupor, coma, and death. The toxic manifestations of these drugs are depression, Cheyne-Stokes respiration, cyanosis, hypothermia, hypotension, tachycardia, areflexia, and pupillary constriction. Treatment of drug overdose is supportive and includes the standard treatment for shock. When administered within 30 minutes of drug ingestion, activated charcoal is an effective barbiturate chemoabsorbent.

Diagnosis of drug abuse with short- and ultra-short-acting barbiturates is done by immunoassay and TLC screening procedures. HPLC has found some use in this regard but is not a standard method. The barbiturates are weak acids, the N-H protons being somewhat acidic, so they are acid extracted and placed on the B strip in Toxi-Lab (Irvine, Calif.) procedures. Their presence is easily detected by Toxi-Lab TLC, as shown in Figure 23-3, Worksheet B. Immunoassays for these drugs are also excellent, the one caveat being that high levels of phenobarbital in urine cross-react with antibodies against the short-acting barbiturates. Thus, it is important that TLC confirms a positive immunoassay result for sedative-hypnotic barbiturates.

PROPOXYPHENE (DARVON)

This analgesic drug, whose structure is shown in the Group 1 drugs in Figure 23-7, has pharmacologic properties very similar to those of the opiates, like morphine. As can be seen in Figure 23-1 (drug Group 1), the structure of propoxyphene is quite similar to that of methadone. This drug can be taken orally, so that the sedated, good feelings induced by opiates can be induced without the need to have recourse to the intravenous apparatus needed for infusion of heroin. A major cause of drug-related death is propoxyphene overdose alone or in combination with CNS depressants like barbiturates and alcohol. Toxic symptoms are similar to those seen with overdoses of opiates (namely, respiratory depression, cardiac arrhythmias, seizures, pulmonary edema, and coma). Nephrogenic diabetes insipidus may also occur. In addition, propoxyphene has been found to cause cardiac arrhythmias (Barkin, 2006). Treatment for propoxyphene overdose is mainly supportive. Administration of naloxone (Narcan) reverses the toxic effect of the drug.

METHAQUALONE (QUAALUDE)

Methaqualone is a 2,3-disubstituted quinazoline (Group 5 drugs in Fig. 23-7). Although not structurally similar to the barbiturates, it has many of the same sedative-hypnotic properties as the barbiturates. This compound also possesses anticonvulsant, antispasmodic, local anesthetic, antitussive, and weak antihistamine actions. Oral administration leads to rapid and complete absorption of the drug, with approximately 80% bound to plasma protein. Peak plasma concentrations are reached in approximately 2–3 hours, and almost all of the drug appears to be metabolized by the hepatic cytochrome P450 microsomal enzyme system, with only a small percentage (<5%) excreted unchanged in the urine. The serum half-life ranges from 20–60 hours. The dosages used for its hypnotic-sedative actions range from 150–300 mg daily. Toxic serum concentrations are generally reached at 10 $\mu\text{g/mL}$. Tolerance to some of its actions, as well as dependence, occurs, such that abusive dosages can be up to six to seven times greater than those employed therapeutically. Symptoms of overdose can be similar to barbiturate toxicity and produce CNS depression with lethargy, respiratory depression, coma, and death. However, unlike barbiturate overdose, muscle spasms, convulsions, and pyramidal signs (hypertonicity, hyperreflexia, and myoclonus) can result from severe methaqualone intoxication. Treatment for overdose includes supportive therapy, as well as delaying absorption of remaining drug with activated charcoal and drug removal by gastric lavage.

MARIJUANA (CANNABIS)

This is one of the oldest and most widely used of the mind-altering drugs. Marijuana is a mixture of cut, dried, and ground portions of the hemp plant *Cannabis sativa*. Hashish refers to a more potent product produced by extraction of the resin from the plant. The principal psychoactive agent in marijuana is considered to be δ -9-tetrahydrocannabinol (δ -9-THC) (Group 5 drugs in Fig. 23-7), a lipid-soluble compound that readily enters the brain and may act by producing cell membrane changes. δ -9-THC binds to the presynaptic neural cannabinoid receptor CB1, which releases the inhibitory neurotransmitter GABA in the hippocampus, amygdala, and cerebral cortex (Iversen, 2003). Different forms of THC have been found to cause distinctly different physiologic effects (Fusar-Poli, 2009). δ -9-THC induces an increase in anxiogenic effects, and cannabidiol produces a diminution in anxiety. The latter derivative was found to attenuate blood oxygenation levels in the amygdala and the anterior and posterior cingulate cortex; δ -9-THC was found to modulate activation in frontal and parietal regions of the brain.

Marijuana may be introduced through the lungs by smoking or through the gastrointestinal tract by oral ingestion in food. Once THC enters the body, it is readily stored in body fat and has a half-life of approximately 1 week. Biotransformation is complex and extensive, and less than 1% of a dose is excreted unchanged. About one third is excreted in the urine as, primarily, δ -9-carboxy-THC and 11-hydroxy- δ -9-THC. These metabolites may be detected in the urine from 1–4 weeks after the last ingestion, depending on both dosage and frequency of ingestion.

Marijuana does not appear, in general, to cause physiologic dependence, but tolerance (Martin, 2004) and psychological dependence do seem to occur, although a proportion of chronic users of this drug can develop physiologic dependence on it (Iversen, 2003). Two major physiologic effects of marijuana are reddening of the conjunctivae and increased pulse rate. Muscle weakness and deterioration in motor coordination can also occur. The preponderant changes seen with cannabis intoxication are perceptual and psychic changes. These range from euphoria, relaxation, passiveness, and altered time perception, seen at low doses, to adverse reactions such as paranoia, delusions, and disorientation, which can be seen at high doses in psychologically susceptible individuals.

The dosage, the route of administration, the individual's psychological makeup, and the setting are important determinants in each individual's reaction to cannabis intoxication. Thus, high doses in an individual unprepared or unaware of drug consumption may produce a disturbing experience. More commonly, experienced users report mild euphoria, enhancement or alteration of the physical senses, introspection with altered emphasis or importance of ideas, and heightening of subjective experiences. Heavy chronic use may produce bronchopulmonary disorders; although the relative safety of chronic use is controversial, acute panic reactions, delirium, and psychoses occur rarely (Bryson, 1989). Few users seek treatment, and when this occurs in a distressed patient, medical intervention is generally conservative. However, following an acute episode, psychological evaluation may be necessary in an individual with an underlying psychiatric disturbance. Rarely, marijuana may be ingested by intravenous infusion of a boiled concentrate. Severe multisystem toxicity may be produced by this route of administration. Symptoms may include acute renal failure, gastroenteritis, hepatitis, anemia, and thrombocytopenia.

LYSERGIC ACID DIETHYLAMIDE (LYSERGIDE)

Lysergic acid diethylamide (LSD) (Group 5; see Fig. 23-7) is a semisynthetic indolalkylamine and a hallucinogen. It is one of the most potent pharmacologic materials known, producing effects at doses as low as 20 mcg, and is equally effective by injection or oral administration. Comparison of the structure of LSD with that of 5-hydroxytryptamine (serotonin), as shown in the Group 6 drugs in Figure 23-7, reveals that LSD has a tryptamine-like nucleus, but it lacks the 5-hydroxyl group of serotonin. LSD has multiple complex effects in the CNS. In the locus coeruleus and the median raphe of the midbrain, which utilize serotonergic pathways, it has the paradoxical effect of **inhibiting** both the firing of neurons in these structures and the release of serotonin at the axonal sides of synapses (Passie, 2008). This process, in turn, may produce a state of CNS hyperarousal. On the other hand, it actually acts as a serotonin **agonist** on postsynaptic HT_{1A} receptors. It is a pure agonist on 5-HT₂ receptors in other serotonergic pathways. Recently, it has been found that the hallucinogenic effect of LSD is due to its agonistic effect on 5-HT₂

receptors, and that it behaves very much like the tryptamines (Group 6 drugs; see Fig. 23-7) and phenylethylamines (Groups 4 and 4A drugs; see Fig. 23-7), discussed previously, in producing this effect. In addition, it has been found to have both agonistic *and* antagonistic effects on dopaminergic pathways. Thus it acts at multiple sites in the CNS in complex ways. LSD further affects both the sympathetic and parasympathetic nervous systems. However, the sympathetic effect appears to be greater, and initial symptoms include hypertension, tachycardia, mydriasis, and piloerection.

The usual dosage of LSD is 1–2 mcg/kg; LSD produces an experience that begins within an hour of ingestion, usually peaks at 2–3 hours, and generally lasts 8–12 hours, after ingestion. Metabolism occurs in the liver, whereas excretion occurs mainly in the bile.

LSD is the most commonly abused drug in its class and is believed by its users to provide insights and new ways of solving problems. The psychic effects are usually intense and vary, depending on the user's personality, expectations, and circumstances. LSD acts on all body senses, but visual effects are most intense. Common perceptual abnormalities include changes in the sense of time, organized visual illusions or hallucinations, blurred or **undulating** vision, and synesthesias. Mood may become very labile, and dissolution and detachment of ego may occur. LSD toxicity levels are low, and deaths are generally due to trauma secondary to errors in the user's judgment. Panic reactions—a **bad trip**—are the most common adverse reactions. These may occur in any user and cannot be reliably predicted or prevented. Borderline psychotic and depressed individuals are at risk for the precipitation of suicide or a prolonged psychotic episode by the usage of LSD. Flashbacks, which are poorly understood, occur days to months after ingestion. This occurs when the user experiences recurrences of a previous hallucinogenic experience in the absence of drug ingestion.

Acute panic reactions may be treated by frequent reassurance and a quiet and calm environment; diazepam may also be effective. However, except for treating specific complications, LSD abuse has no systematic program of treatment.

THERAPEUTIC DRUG MONITORING

It has now become recognized that serum levels of many of the therapeutic drugs administered to patients must be frequently determined, both because of the possible toxic side effects of many of these medications and because, often, lack of patient compliance results in subtherapeutic levels of the drug, requiring intervention. Furthermore, it is important for the physician, when initiating drug therapy, to ascertain when the serum levels of the drug have achieved a stable therapeutic level. It becomes important, therefore, to understand the principles, called **pharmacokinetics**, on which drug therapy is based. Some of the basic principles of pharmacokinetics and then the physiologic effects of specific classes of therapeutic drugs are presented in this section. The ones discussed are those whose specific levels are most commonly followed by clinicians and are most commonly assayed for in clinical laboratories. It should be noted that virtually all therapeutic drugs are assayed from specimens of serum, not urine, most commonly using immunoassay techniques such as FPIA.

PHARMACOKINETICS

Figure 23-9 summarizes the two ways in which a therapeutic drug is administered to a patient: discontinuously or continuously (Gerson, 1987a,b). The former method is the most common. Most patients are treated with medications taken orally at fixed periods. For example, to achieve antiinflammatory effects, two aspirin tablets of 350 mg each are taken every 4–6 hours. In this case, the aspirin is taken at discrete times, between which a certain amount will be metabolized and/or excreted before the next dose is given. Sometimes, a patient will be infused with a drug intravenously such as with lidocaine (Xylocaine) in the intensive care unit for a cardiac arrhythmia, or with heparin to prevent thromboembolic events. In this case, while the drug is metabolized, a constant amount of the drug is being infused continuously. Eventually, with continuous infusion of a drug, a steady-state concentration of the drug is reached once the amount of drug infused in a unit of time equals the amount of drug eliminated in the same unit of time. A steady-state concentration of a drug that is discontinuously infused is also reached. However, repeated dosing (equal doses spaced equally apart) produces peak and trough serum concentrations that vary around a steady-state or average concentration.

For both discontinuous and continuous infusions, the ultimate drug level is determined by a battle between the amount infused and the amount

Figure 23-9 Illustration of the time course of drug levels as a function of method of administration. In the discontinuous method, represented by the curve showing peaks and troughs, a constant dose of a drug is administered at regular intervals. After each drug dose, the drug level increases to a peak value, followed by a fall that continues to a trough level, at which time the next regular drug dose is given, resulting in another peak level. After approximately 4 half-times ($4 t_{1/2}$), the drug levels achieve the steady state, as labeled in the figure, when constant peak and trough levels occur. Note that, if a loading dose can be given to the patient, equal to the peak steady-state value, the entire left portion (pre-steady-state) of the curve is eliminated. After the loading dose, the steady state is maintained by giving periodic maintenance doses. The black smooth curve shows a typical time course for drugs that are administered continuously, mainly by the intravenous route. The steady state is achieved as a continuing constant value rather than as peaks and troughs, as in the discontinuous method.

excreted. All drugs are eventually excreted. They can be excreted unchanged in urine, or may be excreted in urine as metabolites of the parent drug. These metabolic conversions occur predominantly in the liver. Occasionally, some drugs enter the enterohepatic circulation and are excreted in stool. Regardless of their mode of excretion, many but not all drugs have a half-life that is more or less independent of their concentrations. The half-life of a drug is the time taken for half the drug that was initially present in serum to be excreted. The reason that the half-life of a drug is independent of its concentration is that many drugs are excreted according to so-called **first-order kinetics**, as discussed in Chapter 20 (Equations 20-22 and 20-23). This process may be summarized as follows:

where D is the drug concentration, and E is the excreted and/or inactivated form of the drug. The constant, k , is the rate constant for the disappearance of D . The half-life, called $t_{1/2}$, is related to the rate constant, k , by the following relationship:

$$t_{1/2} = 0.693/k \quad (23-6)$$

As can be seen from this equation, $t_{1/2}$ is a constant and does not depend on drug concentration. Thus, the half-life of the drug determines the time to reach the steady-state or average concentration.

The object of all drug therapy is to achieve a constant serum level of the drug that will be therapeutic. If the half-life for a drug is known, it is possible to compute the divided dose of the drug that should be given and the time interval between doses so that this level will be achieved. As can be seen in Figure 23-9, at the beginning of drug administration, wide fluctuations in the drug level occur until, after a given period, the fluctuations give the same maxima (peaks) and the same minima (troughs), and the mean level of the drug becomes constant. The problem in dosing is to ensure that the maximum level of the drug will be in the therapeutic range and will not reach toxic levels and, at the same time, to ensure that the minimum level of the drug will remain in the therapeutic range and will not be subtherapeutic.

In general, for discontinuous doses, the drug level at the end of the n th dosing period can be expressed as the sum of a geometric series:

$$D = (D_0 r^N - D_0)/(r - 1) \quad (23-7)$$

where D_0 is the constant dose given at each regular time period; r is the fraction of drug remaining after the constant time interval between doses; and n is the number of the dose (e.g., the second dose, the third dose).

Note that, because r is a fraction less than 1, as N becomes large, the first term in Equation 23-7, $D_0 r^N$, becomes small, so that

$$D = D_0/(1 - r) \quad (23-8)$$

For example, if the time interval between doses is chosen as the $t_{1/2}$, then $r = 1/2$. If the time interval is chosen to be that for $3/4$ of the drug to remain, then $r = 3/4$. (This time can be calculated directly from the $t_{1/2}$ as $1/2 \times t_{1/2}$.) Suppose we take $r = 1/2$. Then after four timed doses, the first term in the numerator of Equation 23-7 is $D_0 \times (1/2)^4 = D_0/16$ or approximately $0.06 \times D_0$, which is small compared with D_0 , and, in effect,

$$D = 2D_0 \quad (23-9)$$

This level is the maximum (peak) level shown in Figure 23-9. It is the level achieved just after the dose, D_0 , is given. Note that, at the end of the dosing period, just before the next dose, D_0 , is given, the drug level decreases to $r \times (2D_0)$. If $r = 1/2$, then this level becomes D_0 . The problem then in pharmacokinetics is to determine what dose, D_0 , and what period, r , to choose, such that the peak and trough values lie within the therapeutic range for the drug. Frequently it is found that, to achieve the right peak and trough levels, the time required to achieve the steady state is too long, especially where the need for drug therapy is urgent. In these cases, a **loading dose** can be administered. Here, the peak level is administered; for the above example, this level would be $2D_0$. Then, after the usual time period, defined by r , elapses, a **maintenance dose**, D_0 , is given. This process is repeated every r -defined time period so that the peaks and troughs are maintained. This process obviates the entire dosing schedule shown in Figure 23-9 (i.e., the entire left side of the curve is eliminated, leaving only the steady-state portion). The reason that this process is not performed uniformly is that not all patients can tolerate large initial doses of specific drugs. Therefore, giving loading doses may not always be possible.

For continuous infusions (Fig. 23-9), for the simplest case where drug distribution is instantaneous, the rate of drug infusion is constant, and the drug is excreted in a first-order manner, the rate law is

$$dD/dt = k_1 - k_2 D \quad (23-10)$$

where D is the drug concentration, k_1 is the constant rate of infusion, and k_2 is the first-order rate constant for excretion/inactivation of D . This equation can be solved for D :

$$D = (k_1/k_2)(1 - e^{-k_2 t}) \quad (23-11)$$

From Equation 23-11, if t is large, the term $e^{-k_2 t}$ becomes small, and D approaches its steady state value, k_1/k_2 . This value is approached when the rate of drug infusion equals the rate of drug disappearance. Another way to obtain this value is to note that, at steady state, as in the formation and disappearance of the enzyme-substrate complex in Michaelis-Menten kinetics (see Chapter 20, Equation 20-4), dD/dt must = 0. Then, from Equation 23-10,

$$dD/dt = k_1 - k_2 D = 0 \quad (23-12)$$

so that

$$D_{\text{steady state}} = k_1/k_2 \quad (23-13)$$

As in the case of periodic drug administration at constant intervals, 4 half-lives are sufficient to reach the steady-state condition. Because, as shown previously in Equation 23-6, $k_2 = 0.693/(t_{1/2})$, after 4 half-lives when $t = 4t_{1/2}$,

$$D = (k_1/k_2) \cdot (1 - e^{-2.772}) \quad (23-14)$$

where, in effect, D is close to k_1/k_2 . Thus, for continuous infusions, the ratio of k_1 (the rate of drug infused per unit of time) to k_2 (the rate constant for the first-order disappearance of the drug) is the desired steady-state level of the drug (i.e., where the amount of drug delivered equals the amount of drug eliminated over the same unit of time). Unlike the situation with discontinuous infusion, the only parameter that is needed to achieve the steady-state level in a given time is k_1 , which includes drug concentration and infusion rates, whereas with discontinuous administration of the drug, both D_0 and r are needed.

There are two major points from this presentation. First, it is a good rule of thumb to wait for 4 or more half-lives to achieve the steady-state level of a drug. Second, results of an assay for a drug level in the time period during which this steady state is being achieved should be interpreted with extreme caution—a rule often forgotten in clinical practice. Notice from Figure 23-9 that if assays are performed in the pre-steady-state period (before achievement of 4 or more half-lives), erratic

results are obtained owing to fluctuations in drug concentrations for the discontinuous case, and rising but persistently low values for the continuous case.

Volume of Distribution

When one is administering drugs, it is of vital importance to know whether the drug is stored in fat or other tissue, or whether it is all present in serum. Because a given dose of a drug is known and the concentration of the drug in serum can be determined, one can measure the total volume of body fluid in which the drug is dissolved by the following relation:

$$D = D_0/V_d, \text{ or } V_d = D_0/D \quad (23-15)$$

where D is the concentration of drug in serum, D_0 is the amount of drug administered, and V_d is the volume in which D_0 must be dissolved to give the concentration D . This volume, V_d , is referred to as the volume of distribution. If all of the drug is present in serum, V_d is the blood volume that can be determined from conversion tables relating body weight to blood volume. If, however, some of the drug is stored in body tissue, a smaller amount is present in serum, so that the denominator in Equation 23-15 ($V_d = D_0/D$) is reduced and V_d will be larger than the expected blood volume, indicating that some drug is being stored in tissue. If this result occurs, it means that the drug will very likely be released continuously from storage depots (i.e., tissues), which can raise anomalously the level of drug in serum, potentially to toxic levels. Thus, before any drug is administered, the volume of distribution should be known.

Metabolism in the Liver

Many drugs are converted to metabolites, some of which are pharmacologically active and some inactive. Much of this conversion occurs in the extramitochondrial, microsomal system present in hepatocytes. This metabolic system is mainly an oxidative one that utilizes a series of oxidative enzymes that, in turn, utilize a special cytochrome system: cytochrome P450 (Gonzalez, 2006). This extremely critical cytochrome system has now been strongly implicated as predisposing particular individuals to develop cancer by metabolizing certain environmental compounds, such as benzopyrene, into frank carcinogens (see later). In addition, genetic polymorphism of the cytochrome P450 enzymes affects an individual's particular response to a drug, including toxicity and an adverse drug reaction (Ingelman-Sundberg, 2004). As is described in Chapter 72, it is now possible to test individuals for their abilities to metabolize specific drugs by amplification of their genes encoding cytochrome P450. Certain amino acid substitutions in this protein cause it to be very active in drug metabolism (i.e., rapid inactivation of the drug). This implies that the patient may need substantially higher doses to achieve a therapeutic level, or that it may be necessary to use another less rapidly metabolized drug.

Because the excretion of many drugs depends on the integrity of the liver and the cytochrome P450 system, in patients with liver failure due to passive congestion, hepatitis, cirrhosis, and the like, the effective half-life of the drug is increased, making it necessary to lower the divided dose of the drug. Conversely, some drugs induce the intracellular synthesis of the microsomal enzymes, leading to diminished half-life values, so that it may be necessary to raise the divided dose.

One example of drug induction of microsomal enzymes is phenobarbital. (Dilantin is another example of this phenomenon.) This drug induces its own metabolism (so that its concentration levels do not obey first-order kinetics). In instances in which the levels of a drug metabolized in the liver are higher than the highest therapeutic value, reductions in the levels may be induced by administering low levels of phenobarbital to induce the microsomal system.

This summary of some of the general principles of drug administration should be helpful in the interpretation of values clinically and should permit a better understanding of the subsequent discussion of specific therapeutic drugs, most commonly measured or determined in the laboratory. Tables 23-1 to 23-7 summarize the critical pharmacologic data for a number of commonly assayed drugs.

In the following presentation, seven classes of the drugs most commonly assayed for are discussed: cardiotropic, anticonvulsant, antiasthmatic, anti-inflammatory, immunosuppressive, psychotropic, and chemotherapeutic. (Antibiotics are discussed in Part 7.) The emphasis in this discussion is on the mechanisms of action of these drugs. Common to most of these drugs is the fact that they interfere with specific steps in signal transduction pathways in cells, which are often remarkably similar to one another. Despite these similarities, specific drugs block signal transduction pathway steps that affect only specific cells and seem not to affect signal transduction in other cells.

Cardiotropic Drug Actions

Figure 23-10 Overview of the effects of different antiarrhythmic agents on the myocardial conduction system. The normal action potential is shown as the black line that first spikes to a high voltage, mainly because of a rapid sodium influx into cells in the conduction system. This component of the action potential, caused by sodium ion influx, is shown enclosed in the red area. The actual action potential is prolonged by a succeeding influx of calcium ions shown enclosed under the blue area that overlaps somewhat with the red (sodium influx) area. Termination of the calcium ion influx and efflux of potassium ions results in repolarization, shown by the curve bordered by the blue area. Class I channel blockers, as listed in the figure, block sodium influx, thereby diminishing the rate of depolarization. Class II blockers, like propranolol, block β -adrenergic (epinephrine and norepinephrine) stimuli, diminishing the rate of diastolic depolarization. Class III blockers, like amiodarone, block potassium channels, resulting in reduction in potassium efflux and slowing down repolarization. This results in prolongation of the action potential, as shown by continuation of the voltage curve over the yellow area. Class IV blockers, like verapamil, block calcium channels, again prolonging the action potential (blue), although this prolongation is not explicitly shown. By prolonging the action potential, Class III and IV agents slow down nodal conduction through prolonged refractoriness of the affected cells. Various ion currents induce the action potentials. (Redrawn from Opie LH, Gersh BJ. *Drugs for the heart*. 5th ed. Philadelphia: WB Saunders; 2001.)

CARDIOTROPICS

(Opie and Gersh, 2001; Roden, 2006).

These drugs are the ones most commonly used to treat congestive heart failure and cardiac arrhythmias. Despite differences in the structures and properties of the drugs and their specific uses, all of them act on one or another phase of the action potentials in cells that are in the conduction system and in myocytes. Their net effect is to slow down electrical conduction. In addition, it is important to remember that the conduction tissue is innervated by both sympathetic and parasympathetic (mainly vagal) nervous systems. The former increases the conduction rate, and the latter tends to slow conduction. The actions of each of the cardiotropic drugs are summarized in Figure 23-10. As shown in this figure, several major ion currents control the action potentials of the cells making up the pacemaker tissue of the atrioventricular (AV) node and the ventricular conduction bands (composed of Purkinje cells): first, rapid sodium influx current, and then decreased flux (shutoff of sodium conductance channels), as outlined in the red area in Figure 23-10; second, a calcium ion influx that prolongs the action potential and then calcium channel shutoff, as outlined in the blue area in Figure 23-10; and third, potassium ion efflux that promotes

repolarization of the cell. As shown in Figure 23-10, there are four classes of drugs that act on one or more of these phases of the action potential, resulting in its prolongation. Class I drugs block sodium influx in phase I and include quinidine, procainamide, and lidocaine. These agents, especially lidocaine, act by blocking the rapid sodium influx of phase I, decreasing the rate of ventricular diastolic depolarization. Class II drugs include the β -receptor blockers, like propranolol (Inderal), that inhibit the chronotropic effects of adrenergic neurotransmitters like epinephrine and norepinephrine. Class III drugs, like amiodarone, block repolarizing potassium currents, increasing the length of the action potential, as represented by the black curve over the yellow area in Figure 23-10, and increase the length of the refractory period. Class IV drugs, of which verapamil is an important member, slow calcium ion influx, resulting in action potential prolongation. In addition to these classes of drugs, digitalis cardiac glycosides have parasympathetic-like effects on the cells of the AV node, resulting in slowing of conduction. Both digitalis and amiodarone also have marked inotropic effects on the myocardium. Thus both are used in the treatment of congestive heart failure. In damaged myocardium, digitalis blocks sodium-potassium adenosine triphosphatase (ATPase), resulting in transient increases in sodium ion around the sarcolemma, which leads to the release of cytosolic calcium ion to the T-system. This allows increased myocardial contractility. We now discuss the key properties and actions of these cardiotropic drugs.

Cardiac Glycosides (Digitalis and Its Derivatives)

Digoxin

Because they slow conduction in the AV node, digoxin and the other cardiac glycosides are used to treat atrial arrhythmias, in particular atrial flutter and atrial fibrillation. Their main antiarrhythmic effect is to block rapid atrial conduction signals to the ventricles, thereby slowing ventricular response. This is due to their parasympathetic effects, which include enhancement of blockade of depolarizing calcium currents and increased hyperpolarizing potassium currents in the AV node. These effects result in shortening action potential duration and increasing AV nodal refractoriness (Roden, 2006).

Their direct positive inotropic effect increases cardiac output in cardiac failure. This effect has been found to be due to increased intrasarcolemmal concentration of calcium, allowing it to activate proteins such as troponin C that are important in the contractile apparatus (Rocco, 2006). This increase in calcium concentration is due to the binding of digoxin to the α subunit of sodium-potassium-activated ATPase, causing its inhibition and the consequent reduction of sodium efflux and diminution of the trans-membrane potential; as this potential increases, more calcium efflux occurs, resulting in less activation of muscle contraction. Blockade of sodium efflux therefore allows accumulation of intrasarcolemmal calcium and increased activation of contractile proteins (Rocco, 2006).

Digoxin (Table 23-1) has a rapid onset of action (within 1–2 hours when given orally) and a relatively short half-life (35–40 hours). Most patients will excrete approximately 50%–75% of a dose unchanged in the urine. The general range of therapeutic serum levels is from 0.5–2 ng/mL. High concentrations of the drug are found in skeletal and cardiac muscle, as well as in liver, brain, and kidneys.

Digoxin

In contrast, digitoxin has a longer half-life (4–6 days) with a relatively slower onset of action (within 1–4 hours when given orally, with maximal effect in 8 hours); 90%–100% of a dose is absorbed, with approximately 95% bound to plasma protein. The general range of therapeutic serum levels is from 9–25 ng/mL. The drug is extensively metabolized in the liver (90%), with digoxin being the active metabolite.

Toxic side effects of the digitalis glycosides include gastric disturbances, nausea, vomiting, and atrial and ventricular arrhythmias. It is crucial that levels of digoxin (or digitoxin) be monitored closely and accurately while the patient is initially being given this drug. As mentioned previously, the therapeutic range for digoxin is from 0.5–2 ng/mL (i.e., the range is narrow). Toxic levels exceed 2 ng/mL, so the difference between therapeutic and toxic doses is small. This difference necessitates careful digoxin assay.

Digoxin toxicity is often treated with Digibind (GlaxoSmithKline, Research Triangle Park, N.C.), consisting of ovine Fab fragments. This antidote can interfere with determination of digoxin serum levels (Valdes, 1998). Some assays have been reported to determine only the “free” digoxin level (i.e., that not bound to Digibind Fab), which inactivates digoxin. For other assays that determine total digoxin (i.e., free plus

TABLE 23-1

Digoxin

Purpose	Treatment of congestive heart failure and atrial fibrillation-flutter
General adult dose	Oral: 0.75–1.5 mg for digitalization, 0.125–0.5 mg/day for maintenance
Usual bioavailability	Approximately 60%–85% for tablet or elixir; 90%–100% for liquid-filled capsules
Half-life	Approximately 35–40 hours; however, prolonged in patients with decreased renal function
General therapeutic range	0.5–2 ng/mL
General toxic level	>2 ng/mL, but somewhat variable
Transport	Approximately 20%–25% plasma protein bound
Metabolism	Generally, only small amounts are metabolized (liver, lumen of large intestine)
Elimination	Approximately 50%–75% unchanged in urine
Steady state	Approximately 7 days in undigitalized patients with normal renal function
Mechanism of action	Causes release of calcium ions in T-system of myocardium; slows AV node conduction
Toxic effects	Gastric disturbances, nausea, vomiting, atrial and ventricular arrhythmias; irregular pulse

AV, Atrioventricular.

TABLE 23-2

Procainamide

Purpose	Treatment of supraventricular or ventricular arrhythmias
General adult dose	Oral: 4 g/day, in divided doses, for maintenance therapy
Usual bioavailability	75%–95%
Half-life	Approximately 3.5 hours in patients with normal renal function
General therapeutic range	4–10 mcg/mL
General toxic level	>12 mcg/mL
Transport	Approximately 15% plasma protein bound
Metabolism	Hepatic: <i>N</i> -acetylprocainamide (active), with $t_{1/2}$ approximately 7 hours in patients with normal renal function
Elimination	Approximately 50%–60% unchanged in urine
Steady state	Minimum of 12 hours
Mechanism of action	Prolongation of atrial refractory period and decreased myocardial excitability
Toxic effects	Reversible lupus erythematosus-like syndrome, irregular pulse, hypotension, rash, agranulocytosis

Fab-bound digoxin), it is recommended that an ultrafiltrate of serum be employed to determine the level of free or active digoxin. Alternatively, given that Digibind can cause spurious and erroneous results, it has been recommended that, because the half-life of Digibind is 15–20 hours, therapeutic levels of digoxin should be determined 2–4 days after the last Digibind dose.

Procainamide (Pronestyl)

Procainamide (Table 23-2) is a class I antiarrhythmic drug that is useful in treating supraventricular or ventricular arrhythmias. One of its major effects includes increased refractoriness of the atrium and decreased myocardial excitability by blocking open sodium channels and outward potassium currents, both of which prolong action potentials and increase refractoriness (Roden, 2006). Because there is an effect on potassium currents, some of its effects resemble those of the Class III potassium current blockers. The bioavailability of procainamide is 75%–95%. Approximately 15% is bound to plasma protein, and approximately 50% is excreted by the kidneys. The half-life is approximately 3.5 hours, with a general range

of therapeutic serum level of 4–10 µg/mL. *N*-acetylation to the major active metabolite *N*-acetylprocainamide (NAPA) is the major metabolic pathway of biotransformation. NAPA, however, does not block open sodium channels but effectively prolongs action potentials (Roden, 2006). Both drugs prolong the QRS and Q-T intervals on electrocardiography over time.

Toxic side effects include a reversible lupus-like syndrome with elevated antinuclear antibody titers, urticaria, rash, agranulocytosis, and nephrotic syndrome. The lupus-like syndrome may be initiated by leukocyte metabolism of procainamide to a chemically reactive metabolite that could then covalently bind to monocyte/macrophage membrane proteins to stimulate production of autoantibodies. In addition, the tertiary amino moiety of the covalently bound procainamide metabolite might mimic a portion of histone protein, resulting in the production of antihistone antinuclear antibody (Utrecht, 1988).

Quinidine

Quinidine, also a class I antiarrhythmic, like procainamide, is used to treat supraventricular and ventricular arrhythmias and tachyarrhythmias. The prevention of ventricular tachycardia or frequent premature ventricular contractions and the maintenance of sinus rhythm after the conversion of atrial flutter or atrial fibrillation are its two major uses (Valdes, 1998). Like procainamide, quinidine blocks sodium channels and outward potassium currents, especially the I_{K_r} rectifier current, resulting in prolongation of action potentials and increased refractoriness, leading to prolongation of both the QRS complex and the Q-T interval (Roden, 2006).

The bioavailability of quinidine is 90%–100%, with approximately 85% of the drug bound to plasma protein. Quinidine is 60%–85% metabolized in the liver via hydroxylation reactions, with some metabolites being active. Urinary excretion is approximately 20%. The half-life of quinidine is 5–12 hours, and the general therapeutic range is 2.3–5 mcg/mL. Maximal serum levels are reached in 1–3 hours. Toxic side effects of quinidine include cinchonism (vertigo, tinnitus, headache, visual disturbances, and disorientation), fever, hepatitis, and blood dyscrasia. Ventricular arrhythmias, AV block, and ventricular fibrillation leading to syncope and sudden death can occur.

Lidocaine

Lidocaine (Xylocaine), another class I antiarrhythmic, can also be used as a local anesthetic. Its major use as an antiarrhythmic is in the acute control and prevention of ventricular arrhythmias after acute myocardial infarction. Its effect is to block sodium channels mainly in ventricular but not atrial tissue. Unlike procainamide and quinidine, lidocaine does not cause QRS and Q-T prolongation (Roden, 2006). A loading intravenous dose of 50–100 mg is given over 2–3 minutes to treat ventricular arrhythmias in adults. These dosages may be repeated in 5- to 10-minute intervals of 25–50 mg, up to a maximum of 300 mg in a 1-hour period. Following loading, infusion is then continued at a rate of 1.4–3.5 mg/min for a 70-kg man. In children, 0.5–1 mg/kg can be given every 5 minutes for a maximum of three doses. Unfortunately, lidocaine can cause heart block and congestive heart failure, limiting its use in critical care patients (Roden, 2006).

Lidocaine is neither highly protein bound nor appreciably stored in body tissues; it has a half-life of approximately 2 hours and a therapeutic serum range of 1.2–5.5 mcg/mL. The time to reach a maximum serum level is generally 5–8 hours. Ninety percent of a dose of lidocaine is metabolized in the liver via *N*-dealkylation. Urinary excretion is 10%. Toxic side effects include convulsions, coma, and respiratory depression (CNS effects), as well as bradycardia and hypotension.

Propranolol

Propranolol, a class II antiarrhythmic β receptor–blocking drug that antagonizes the effects of epinephrine on the heart, on the arteries and arterioles of skeletal muscles, and on the bronchus, exerts its effects largely on the AV node and is used to treat sinus tachycardia, atrial tachycardia, and ventricular arrhythmias. Overall, blockade of β -1-receptors increases AV conduction time and reduces heart rate, myocardial contractility and output, and cardiac automaticity. Because it is a vasodilator, it is also used in the treatment of angina pectoris; hypertension; and symptomatic coronary artery disease, particularly after an acute myocardial infarction. Oral dosages vary from 40–320 mg daily in adults for antiarrhythmic activity, to as high as 480 mg daily in the control of hypertension. Both supine and standing blood pressures are also reduced. Bioavailability of propranolol is approximately 30%. The half-life of propranolol is 3 hours, with a therapeutic serum range of 50–100 ng/mL, and with maximum serum levels reached in approximately 6 hours. Approximately 93% is protein

bound. Propranolol is metabolized in the liver, with 0.5% excreted in the urine unchanged. Toxic effects include bradycardia, arterial insufficiency (Raynaud's type), hypotension, AV block, nausea, vomiting, pharyngitis, bronchospasm, and thrombotic thrombocytopenic purpura. Marrow suppression occurs rarely.

Amiodarone

Amiodarone, a structural analog of thyroid hormone, is chiefly a class III antiarrhythmic drug, which markedly prolongs the action potential mainly by blocking potassium channels in cardiac muscle (see Fig. 23-10). Its activity is complex in that it significantly blocks inactivated sodium channels by a poorly understood mechanism, thus exhibiting class I action, and also exhibits weak adrenergic- and calcium channel–blocking effects (Roden, 2006). All of these actions prolong the effective refractory period along the conduction bands. Its indication for use is with life-threatening ventricular arrhythmias. The oral loading dose is 1200–1600 mg/day with a maintenance dose of 200–400 mg/day. Bioavailability is \approx 35%–65%. Amiodarone has two components in its half-life: a rapid component of 3–10 days (involving \approx 50% of the drug) and a slow component of 25–110 days. The general therapeutic range is 1–2.5 mcg/mL, although this is not well defined, and the toxic level is $>$ 2.5 mcg/mL, again not well defined. Approximately 96% is plasma protein bound; the drug undergoes liver metabolism and shows extensive body distribution because of its hydrophobic (lipid soluble) structure. Excretion is very slow by skin, biliary tract, and lacrimal glands. Toxic effects can be profound and include symptomatic bradycardia, heart block, fatal pulmonary fibrosis, hepatitis, visual field disturbances, photodermatitis, and mainly hypothyroidism but sometimes hyperthyroidism.

Verapamil

Verapamil is a class IV antiarrhythmic drug that blocks activated and inactivated calcium channels that are especially prominent in nodal tissue (particularly the AV node). Indications include angina, hypertension, and supraventricular arrhythmias. Unlike β -adrenergic receptor blockers, calcium channel blockers have not been found to reduce mortality after a myocardial infarction (Roden, 2006). The oral dose is 120–480 mg/day in three to four divided doses. Bioavailability is \approx 10%–20%. The half-life is 2–8 hours but increases to 4.5–12 hours after repeated oral doses. The general therapeutic range is 80–400 ng/mL, although this is not well defined. Approximately 90% is plasma protein bound, and the drug undergoes extensive metabolism in the liver, where norverapamil, an active metabolite, is produced. Approximately 75% of the active components are eliminated by the kidney and \approx 25% through the GI tract. Toxic effects include hypotension, ventricular fibrillation, constipation, and peripheral edema.

ANTICONVULSANTS

Anticonvulsants are used in the treatment of seizure disorders, in particular grand mal, petit mal, and psychomotor seizures and other specialized seizure disorders such as tic douloureux (trigeminal neuralgia). Although the mechanisms of action of these drugs are incompletely understood, it appears that all of these agents, with the possible exception of phenobarbital, block sodium influx into neurons that have damaged membranes, as schematized in Figure 23-11. In addition, several of these agents, especially phenytoin, block secondary calcium influxes into such cells, which also seems to inhibit the rapid firing of these cells. Another effect of phenobarbital, and possibly also of phenytoin, is membrane stabilization through intercalation, as is shown in Figure 23-11. Many of the anticonvulsants are effective against grand mal seizures but have no effects or adverse ones on petit mal seizures. Only drugs like ethosuximide (Zarontin) and valproic acid (Depakote) are effective against this condition. Thus, although the mechanism of action of these drugs appears to be similar, they differ in specificities.

Phenobarbital

Phenobarbital (Table 23-3), a long-acting barbiturate, is used in the treatment of generalized grand mal tonic-clonic seizures and simple partial seizures with motor or somatosensory symptoms, as well as for anxiety and insomnia. It is not used in the treatment of absence seizure (i.e., petit mal), which may be exacerbated by phenobarbital, nor for complex partial seizures, which do not respond well. As discussed previously in the barbiturates section under The Drugs of Abuse, phenobarbital increases the duration of chloride ion channel opening at the GABA_A receptor, thereby potentiating the GABA effect and raising the threshold for neuronal

Figure 23-11 Effects of anticonvulsants on neurons. *Top:* Damaged neuronal membranes, as shown in the section in the upper right of the figure, result in sodium (yellow circles) and calcium (red circles) influxes via their respective channels that cause repeated firing, as shown in the voltage–time curve to the right of the figure. *Bottom:* Anti-convulsants like phenytoin (Dilantin), carbamazepine (Tegretol), and valproic acid (Depakote; represented by small blue circles) block sodium and calcium channels, resulting in a substantially diminished rate of firing, as shown in the voltage–time curve to the right of the figure. Both phenytoin and phenobarbital, shown as blue cylinders, are also thought to stabilize the damaged neuronal membrane, as shown in the membrane section schematized in the upper right drawing.

membrane depolarization, resulting in the diminished frequency of firing of action potentials. In addition, it can stabilize damaged neuronal membranes (see Fig. 23-11).

Phenobarbital is also given for withdrawal symptoms in infants born to opiate- or barbiturate-addicted mothers. Because phenobarbital enhances the metabolism of bilirubin by induction of cytochrome P450-dependent enzymes in the hepatic microsomal system, it has been used to treat patients with congenital hyperbilirubinemia (familial nonhemolytic, nonobstructive jaundice). The oral dose of phenobarbital for anxiety in adults is 30–120 mg daily in divided doses; for sleep induction in adults, 100–320 mg daily is generally used. For seizure control, divided doses of 100–200 mg/day in adults or 30–100 mg/day in children are generally used.

Phenobarbital has a long half-life of 4–6 days. Oral doses are almost completely absorbed (90%–100% bioavailability), and the optimal serum concentration for seizure control is generally 15–30 µg/mL; 40%–60% is

metabolized in the liver, whereas 10%–40% may be eliminated unchanged in the urine. Approximately 40%–60% is plasma protein bound, and the main site of storage is the brain. A steady state is reached in 14–21 days. Toxic side effects include nystagmus, ataxia, stupor, respiratory depression, coma, and hypotension. Barbiturates are contraindicated in patients with acute intermittent porphyria (i.e., partial porphobilinogen deaminase deficiency), because barbiturates enhance the synthesis of δ -aminolevulinic acid synthetase and thus the synthesis of heme pathway intermediates in the liver.

Phenytoin (Dilantin)

Phenytoin is used to treat generalized tonic-clonic, simple partial, and complex partial seizures (Table 23-4). It is ineffective in treating myoclonus, absence (petit mal), and atonic seizures. It is usually given intravenously in addition to intravenous diazepam to terminate status epilepticus.

TABLE 23-3
Phenobarbital

Purpose	Treatment of generalized tonic-clonic seizures, simple partial seizures, anxiety, insomnia
General adult dose	Oral: 100–200 mg/day for seizure control; 30–120 mg/day for anxiety; 100–320 mg for sleep induction
Usual bioavailability	Approximately 90%–100%
Half-life	Approximately 5–6 days in adults; approximately 3–4 days in children
General therapeutic range	15–30 mcg/mL for epilepsy control
General toxic level	>40 mcg/mL, although tolerance may develop
Transport	Approximately 40%–60% plasma protein bound
Metabolism	Approximately 75% hepatic: <i>p</i> -hydroxyphenobarbital, inactive
Elimination	Approximately 25% unchanged in urine
Steady state	Approximately 14–21 days
Mechanism of action	Stabilizes damaged membranes and raises threshold for neuronal membrane depolarization
Toxic effects	Drowsiness, depression, respiratory depression, coma, sedation, hypotension. Respiratory depression may be caused by rapid intravenous administration.

TABLE 23-4
Phenytoin (Dilantin)

Purpose	Treatment of generalized tonic-clonic seizures, simple partial seizures, complex partial seizures
General adult dose	Oral: 300–400 mg/day maintenance dose
Usual bioavailability	Variable: 30%–95%
Half-life	24 ± 12 hours, and dose dependent
General therapeutic range	10–20 µmcg/mL
General toxic level	>20 µmcg/mL
Transport	Approximately 90%–95% plasma protein bound
Metabolism	Hepatic: 5-(<i>p</i> -hydroxyphenyl)5-phenylhydantoin, inactive
Elimination	Approximately 5% unchanged in urine
Steady state	Approximately 7–8 days
Mechanism of action	Appears to block sodium and calcium ion influxes into repeatedly depolarizing CNS neurons
Toxic effects	Nystagmus, ataxia, diplopia, drowsiness, coma; rapid intravenous administration may produce cardiovascular collapse and/or CNS depression

CNS, Central nervous system.

Remarkably, phenytoin has no apparent effects on resting neurons or on normally firing neurons. It is thus specific for epileptogenic foci in the CNS (Yaari, 1986). It is interesting to note that carbamazepine (Tegretol) exerts similar effects, as discussed later. Data on the mechanism of action of this drug strongly suggest that phenytoin blocks sodium and calcium influxes into repeatedly depolarizing neurons in the CNS and also into neurons that are partially depolarized. Reducing sodium and calcium influx into these cells reduces their excitability and prolongs their refractory period (Yaari, 1986). In fact, phenytoin appears to bind selectively to fast-firing sodium channels in their refractory states, thereby prolonging their refractory periods (Bazil, 1998) (i.e., it slows the rate of recovery of inactivated sodium channels) (McNamara, 2006). This finding helps explain the ability of phenytoin to block only neurons that are firing rapidly and repetitively.

Although the average daily maintenance dose in adults is 300–400 mg, dosage must be tailored to the patient's response and serum drug concentrations. The usual therapeutic serum concentration is 10–20 µg/mL, with a steady state reached in 5–10 days (for plateau; see Figure 23-9). The serum half-life is generally 24 hours, but it is dose dependent. Thus, its excretion is not a first-order process. Phenytoin is stored in the brain, is

metabolized in the liver (95%), and is approximately 90%–95% bound to plasma protein. Both aspirin and phenylbutazone can displace phenytoin from serum albumin and can significantly increase the serum concentration of phenytoin. Because phenytoin, like phenobarbital, is a relatively potent hepatic microsomal enzyme inducer, certain antibiotics, oral anti-coagulants, quinidine, and oral contraceptives may be more rapidly metabolized, thus decreasing their effectiveness.

Because the relationship between serum concentrations and daily dosage is not linear, small increases in dosage can greatly increase therapeutic serum concentrations. Symptoms of toxicity generally occur at serum concentrations greater than 20 µg/mL. Toxic side effects include nystagmus, ataxia, stupor, and coma. Arrhythmias can be produced by rapid intravenous administration.

Fosphenytoin is a water-soluble parenteral formulation of phenytoin that is rapidly converted (half-life of 8–15 minutes) *in vivo* to phenytoin. The half-life is independent of plasma concentration, and it has identical pharmacodynamic, pharmacokinetic, and clinical properties to phenytoin. This prodrug offers improved flexibility and tolerability for the patient, as compared with intravenous phenytoin, and is indicated for the treatment of partial and generalized seizures in adults in whom intravenous administration is indicated (Bazil, 1998).

Primidone (Mysoline)

Primidone is used to treat generalized tonic-clonic, simple partial, and complex partial seizures. Its chemical structure is closely related to the basic structure of the barbiturates, and it is metabolized in the liver into two active metabolites: phenobarbital and phenylethylmalonamide. Thus some of its anticonvulsant effects are due to phenobarbital activity. Unlike phenobarbital, however, primidone may increase the threshold of membrane depolarization within the CNS.

Oral doses range from 250 mg daily to 2 g/day in divided doses. Absorption is rapid and complete (100%), with a usual therapeutic serum concentration of 5–21 µg/mL. A steady state is reached in 4–7 days, and the half-life is approximately 12 hours. Plasma protein binding is relatively low (20%), with most of the drug remaining free in the serum, and with little drug being stored in body tissues.

Sedation is a common toxic side effect. Dizziness, ataxia, and skin rashes have also been observed. Primidone, like phenobarbital, is contraindicated in patients with acute intermittent porphyria.

Ethosuximide (Zarontin)

Ethosuximide is the drug of choice for absence (petit mal) seizures unaccompanied by other types of seizures. It is preferred over valproic acid (see later), at least initially, because hepatotoxicity is a rare but serious side effect of valproic acid. Ethosuximide may depress the motor cortex and may reduce the frequency of neuronal firing. It also inhibits T-current spikes on the electroencephalogram that underlie bursts of action potentials in the thalamus but does not affect normal electrical conduction (McNamara, 2006). The basis for its specificity, however, is not well understood.

The oral dosage in adults is generally 500–1000 mg daily. Absorption is fairly rapid and complete (100%), with peak serum concentrations occurring in 1–4 hours. A steady state is reached in 8–10 days. The usual therapeutic serum concentration is 40–100 µg/mL, but it can be as high as 170–190 µg/mL in children. The serum half-life is generally 60 hours in adults and 30 hours in children. Ethosuximide is essentially free in serum and not protein bound. It is mainly metabolized in the liver (60%–90%) to desmethyldesmethylmethsuximide. Gastrointestinal disturbances are among the most common toxic effects and include nausea, vomiting, and gastric distress. Other effects include drowsiness and ataxia. Rare serious side effects, such as systemic lupus erythematosus, aplastic anemia, and pancytopenia have been reported.

Carbamazepine (Tegretol)

Carbamazepine (Table 23-5) is a primary antiepileptic drug that is used in the treatment of generalized tonic-clonic seizures and simple partial and complex partial seizures, as well as in combinations of these seizure types. Absence (petit mal), myoclonic, and atonic seizures may be exacerbated by this drug. This drug is also used to treat tic douloureux (trigeminal neuralgia) and glossopharyngeal neuralgia, and is, in fact, the drug of choice in the treatment of these neuralgias.

Carbamazepine is a tricyclic compound (i.e., iminostilbene) that is chemically related to imipramine, a tricyclic antidepressant. It is believed that a reduction in excitatory synaptic transmission in the spinal trigeminal nucleus is the basis for this drug's antineuralgic action. Its antiepileptic

TABLE 23-5

Carbamazepine (Tegretol)

Purpose	Treatment of generalized tonic-clonic seizures, simple partial seizures, complex partial seizures; trigeminal neuralgia and glossopharyngeal neuralgia
General adult dose	Oral: 0.8–1.2 g/day maintenance for seizure control; 0.2–1.2 g/day for neuralgia
Usual bioavailability	70%
Half-life	Initially approximately 35 hours; approximately 8–20 hours after 3–4 weeks of administration
General therapeutic range	4–12 mcg/mL
General toxic level	>12 mcg/mL
Transport	60%–70% plasma protein bound
Metabolism	Hepatic: carbamazepine-10,11-epoxide (active); carbamazepine-10,11-transdihydrodiol (inactive)
Elimination	1%–2% unchanged in urine
Steady state	3–7 days
Mechanism of action	Decreases sodium and calcium ion influx into repeatedly depolarizing CNS neurons; reduces excitatory synaptic transmission in the spinal trigeminal nucleus
Toxic effects	Drowsiness, ataxia, dizziness, nausea, vomiting, involuntary movements, abnormal reflexes, irregular pulse

CNS, Central nervous system.

action is quite similar to that of phenytoin, that is, it decreases sodium and calcium influx into hyperexcitable neurons (Yaari, 1986; Bazil, 1998). Like phenytoin, carbamazepine slows the rate of recovery of voltage-activated sodium channels from inactivation (McNamara, 2006).

Oral doses of carbamazepine are completely absorbed, and the usual adult maintenance dose is 0.8–1.2 g/day. Ninety-eight percent is biotransformed in the liver into two active metabolites: a 10,11-epoxide form, which is active (McNamara, 2006), and a 10,11-dihydroxy form of carbamazepine. The usual therapeutic serum concentration is 4–12 µg/mL, and steady state is reached in 3–4 days. The serum half-life of Tegretol is 8–20 hours (after 3–4 weeks of administration), and 60%–70% is plasma protein bound. The more common toxic reactions seen with this drug include drowsiness, ataxia, dizziness, nausea and vomiting, and light-headedness. Rare hematologic reactions may occur and can be quite serious; they include aplastic anemia, thrombocytopenia, and agranulocytosis.

Valproic Acid (Depakene)

Valproic acid is commonly used in the treatment of generalized tonic-clonic seizures, absence seizures, myoclonic seizures, and atonic seizures. It is not effective for the treatment of infantile spasms. Although the mechanism of action is not definitely known, valproic acid is thought to enhance the activity of the GABA-mediated inhibitory system. In addition, its action is similar to that of phenytoin and carbamazepine in that it inhibits sustained, repetitive firing of depolarized neurons by prolongation of the refractory state of sodium channels (Hardman, 2001; McNamara, 2006). Like ethosuximide, it decreases T-current-induced action potentials (McNamara, 2006). Absorption of valproic acid is rapid and complete. The average daily maintenance dose of valproic acid in adults is 15–30 mg/kg, when utilized alone, and 30–45 mg/kg in combination with other antiepileptic drugs. The usual therapeutic serum concentration is 50–100 µg/mL, and a steady state is reached in 1–4 days. Most (90%–100%) of the drug is metabolized in the liver, and a high percentage (90%) is plasma protein bound. The serum half-life is 8–15 hours.

Valproic acid has been shown to produce teratogenic effects in experimental animals; these included developmental abnormalities and skeletal defects. Thus, valproic acid should be used with caution in pregnant women. Toxic side effects include sedation, gastric disturbances, hematologic reactions, ataxia, somnolence, and coma. Rare fatal hepatotoxicity has occurred, and severe or fatal pancreatitis has been reported (Sztajnkrycer, 2002).

Newer Anticonvulsants

Topiramate, lamotrigine (Lamictal), gabapentin (Neurontin), and felbamate are four anticonvulsant agents that have been approved recently for

use in this country for patients whose response to the more established anticonvulsants is less than optimal. Therapeutic ranges and toxic concentrations for these drugs have not been determined. Topiramate and lamotrigine are utilized as adjunctive treatment for partial seizures in adults. Topiramate is a substituted sulfamate monosaccharide that induces hyperpolarizing potassium currents and enhances GABA_A receptor currents at synapses (McNamara, 2006). Lamotrigine is a triazine derivative that acts much in the same manner as phenytoin and carbamazepine. However, because it has broader antiseizure activity than either of these other two anticonvulsants, other mechanisms may be involved, one of which appears to be blockade of glutamate release at synapses using this amino acid as a neurotransmitter (McNamara, 2006).

Topiramate has a half-life of approximately 21 hours, with approximately 15% of the drug bound to protein. Lamotrigine has a variable half-life, depending on whether the drug is used as monotherapy or with an inducer. Approximately 55% of lamotrigine is protein bound.

Gabapentin is also utilized as adjunctive treatment for partial seizures and for migraines, chronic pain, and bipolar disorder (McNamara, 2006). As its name suggests, it was designed to act as a GABA-like drug, but it has been found that it does not have this effect but rather seems to induce cortical release of GABA from synaptic vesicles by a poorly understood mechanism (McNamara, 2006). It has a half-life of 5–7 hours with less than 3% protein binding.

Felbamate is a phenyl-substituted dicarbamate that not only inhibits NMDA-evoked responses but also enhances GABA-evoked responses (McNamara, 2006).

Common side effects of topiramate include fatigue, psychomotor slowing, somnolence, and difficulty with concentration and speech. Acute-angle glaucoma can also occur (Asconape, 2002). Common side effects of lamotrigine include ataxia, CNS depression, diplopia, dizziness, abnormal thinking, nausea, nervousness, rash, and somnolence. An additional major toxic effect reported for lamotrigine is Stevens-Johnson syndrome (Brodtkorb, 1998; Warner, 1998). Common side effects of gabapentin include ataxia, dizziness, fatigue, and somnolence. Felbamate has been found to produce a relatively high incidence of aplastic anemia and hepatic failure (Asconape, 2002). Thus, the drug is utilized in patients failing other treatments only when the potential clinical benefits outweigh the potential clinical risks (Bazil, 1998; Brodtkorb, 1998; Asconape, 2002; McNamara, 2006).

ANTIASTHMATICS

Asthma is a form of chronic obstructive pulmonary disease that has a variety of causes, some of them allergenic in nature. As indicated in Figure 23-12, at the heart of asthma is bronchoconstriction due to contraction of smooth muscle fibers in bronchioles. This may be induced by allergenic causes that trigger inflammatory processes that, in turn, result in the release of histamine from mast cells. Histamine, when it binds to H₁-receptors in smooth muscle cells, induces second messengers such as inositol triphosphate and diacylglycerol that ultimately stimulate muscle contraction (see Fig. 23-12). Opposing this process is the binding of epinephrine to β-2-receptors, resulting in stimulation of adenylate cyclase that induces synthesis of cAMP, a second messenger molecule that induces blockade of muscle contraction. As part of a regulatory process, phosphodiesterase induces hydrolysis of cAMP and thus helps to remove inhibition of smooth muscle contraction.

As indicated in Figure 23-12, there are at least three different therapeutic strategies for blocking bronchiolar smooth muscle contraction. The first is blockade of release of histamine from mast cells by drugs such as cromolyn. This is not the only inflammatory process that can induce the bronchoconstriction of asthma. Other components of the inflammatory process may also be active in provoking bronchoconstriction. These are summarized in Figure 23-13, which shows that, among the agents promoting bronchoconstriction, the leukotrienes and the prostaglandins are quite prominent. To counter these effects, oral anti-inflammatory agents, such as the leukotriene inhibitors zileuton and zafirlukast, have been found to be effective in asthma because they interrupt the leukotriene/arachidonic acid pathways involved in inflammation and bronchial reactivity. It is important to note that steroids have been found to be highly effective in blocking inflammation-induced bronchospasm. As indicated in Figure 23-13, these agents potently inhibit leukotriene, prostaglandin, and platelet-activating factor production (not shown in Fig. 23-13) by inhibiting phospholipase A2 and the inducible cyclo-oxygenase-2 isoform. Lipid-soluble steroids, especially in aerosolized form, avoiding adverse systemic effects, have been found to be among the most effective agents against

Mechanism for Anti-Asthmatic Agents

Figure 23-12 Summary of the mechanisms of action of antiasthmatic agents. Three basic mechanisms are shown. Note that all three mechanisms result in promotion of smooth muscle relaxation in the small airways (i.e., fewer actin-myosin cross-bridges) (arrows show loss of cross-bridges), as shown at the bottom of the figure. On the left, release of histamine from mast cells in response to allergenic stimulation results in histamine- H_1 -receptor complexes that promote a signal transduction pathway in which inositol triphosphate (IP_3) and diacylglycerol (DAG), both second messengers, are induced and promote smooth muscle contraction. Histamine release is blocked (minus sign in circle, next to green arrow) by the drug, cromolyn. In the middle of the figure, epinephrine and albuterol are shown to form complexes with β -receptors; these complexes induce adenyl cyclase activity such that cyclic adenosine monophosphate (cAMP) is synthesized; this second messenger blocks smooth muscle contraction. On the right, xanthines, such as theophylline, are shown to block the enzyme phosphodiesterase, resulting in prolonged lifetimes of cAMP, allowing it to function for prolonged periods in blocking smooth muscle contraction.

asthma. These agents include beclomethasone, flunisolide, and triamcinolone. Longer-acting lipid-soluble β -2-agonists, such as formoterol and salmeterol, are also available and appear to be long acting because of their ability to dissolve into the bronchial smooth muscle membrane.

Second, for severe asthmatic attacks, subcutaneous injection of epinephrine is effective in relieving bronchoconstriction on an acute basis via the mechanism shown in Figure 23-12. For more long-term treatment, β -2-receptor-binding agonist drugs, including albuterol (Proventil, Ventolin) and terbutaline (Brethine), are effective in reversing this process by the same mechanism. Both of these agents stimulate production of cAMP, as shown in the central pathway of Figure 23-12. Third, as shown in Figure 23-12, blockade of phosphodiesterase by such drugs as theophylline and the xanthines prevents hydrolysis of cAMP, allowing for continuous inhibition of bronchoconstriction.

Although still a commonly prescribed antiasthmatic drug, theophylline is being replaced with other antiasthmatics such as steroid and β -adrenergic bronchial inhalers, used mainly for acute and subacute asthmatic attacks in adults. These latter agents have fewer toxic side effects (Pesce, 1998). However, laboratory assays for therapeutic levels of antiasthmatics have been performed only for theophylline, predominantly because its therapeutic range is narrow, and potential side effects are serious, as is now discussed.

Theophylline

Theophylline (Table 23-6) is used as a bronchodilator for the treatment of moderate or severe asthma, both for the prevention of attacks and for the treatment of symptomatic exacerbations. Besides its main effect of inhibiting a variety of phosphodiesterases, theophylline also inhibits the bronchoconstrictive action of adenosine and activates histone deacetylases. The latter action may result in decreases in the transcription of

TABLE 23-6

Theophylline

Purpose	Treatment and prevention of moderate to severe asthma
General adult dose	Depends on body weight, route of administration, and age and condition of patient
Usual bioavailability	Varies according to form, with about 100% for oral liquids and uncoated tablets
Half-life	Varies: 8–9 hours in nonsmoking adults, 5–6 hours in adults who smoke, and 3–4 hours in children, but may vary widely
General therapeutic range	10–20 mcg/mL
General toxic level	>20 mcg/mL
Transport	60% plasma protein bound
Metabolism	Hepatic: caffeine; 1,3-dimethyluric acid; 1-methyluric acid; 3-methylxanthine
Elimination	10% unchanged in urine
Steady state	5 half-lives; 90% of steady state reached in 3 half-lives
Mechanism of action	Increases intracellular cAMP by inhibiting phosphodiesterase; this causes the smooth muscle of the bronchial airways and pulmonary blood vessels to relax
Toxic effects	Hypotension, syncope, tachycardia, arrhythmias, seizures, gastrointestinal bleeding

cAMP, Cyclic adenosine monophosphate.

proinflammatory genes. It also inhibits the release of proinflammatory agents, like histamine, from a variety of inflammatory cells (Undem, 2006).

Theophylline exerts additional actions such as vasodilation, diuresis, positive cardiac inotropic effects, and stimulation of diaphragmatic contraction. Owing to the latter stimulating effect, theophylline may be of benefit to some patients with emphysema. Theophylline has also been effective in the treatment of primary apnea of prematurity, in which the absence of respiratory effort lasts longer than 20 seconds in newborn infants. This latter effect is thought to be due to medullary stimulation by the drug. It has been found that caffeine is more effective for this purpose because it has diminished toxicity (Pesce, 1998).

In the treatment of asthma, dosage is calculated on the basis of body weight and depends on the route of administration and the age of the patient. Because the therapeutic index (i.e., the closeness of toxic levels to therapeutic levels) of theophylline is low, cautious dosage determination is essential. Careful monitoring of patient response and serum theophylline levels is required because theophylline is metabolized at different rates for each patient. Theophylline levels can be estimated 1 hour after intravenous administration, 1–2 hours after oral administration, or generally 3–8 hours after extended-release administration from appropriately drawn blood samples.

The therapeutic serum level is 10–20 mcg/mL, and the mean half-life is approximately 8.7 hours in nonsmoking adults (5.5 hours in smoking adults). However, the half-life may vary widely among individuals, again indicating the need for close supervision of the patient and appropriate monitoring of serum concentrations in each patient. Approximately 60% of the drug is protein bound, and about 90% is metabolized in the liver, with caffeine being one of the metabolites produced. Theophylline crosses the placenta and may be teratogenic in pregnant females. Other common side effects include tachycardia, arrhythmias, seizures, and gastrointestinal bleeding.

ANTIINFLAMMATORY AND ANALGESIC DRUGS

As noted in the preceding section, and as shown in Figure 23-13, membrane damage, resulting from immune complexes, trauma, or other stress, induces, among other events, the release of phospholipids. These, in turn, become substrates for phospholipase A_2 , which results in the production of arachidonic acid. This centrally important compound may be converted into leukotrienes via lipoxygenase, or thromboxanes and prostaglandins via cyclooxygenase (COX). All of these agents provoke chemotaxis of neutrophils, resulting in their activation and, ultimately, in inflammation.

Figure 23-13 Mechanisms of action of anti-inflammatory drugs. The figure shows that the fundamental event in inflammation-induced cell death is membrane damage in cells that results in activation of phospholipase A₂. This enzyme promotes the synthesis of arachidonic acid. This is a substrate for two critical enzymes: lipoxygenase, which promotes synthesis of leukotrienes, and cyclooxygenase (COX), which promotes synthesis of thromboxanes and prostaglandins. Both classes of compounds promote neutrophil chemotaxis (lower right) with resulting phagocytosis of damaged cells and a further destructive inflammatory response. Leukotrienes themselves promote increased vascular permeability, causing increased migration of neutrophils to damaged cells, and smooth muscle contraction (lower left). In this figure, corticosteroids such as prednisone and cortisone are shown to block (black minus signs in circles, next to arrows) two key enzymes in this signal transduction inflammatory cascade: phospholipase A₂ and cyclooxygenase. Corticosteroids are also thought to stabilize damaged membranes. Nonsteroidal anti-inflammatory drugs (NSAIDs) block predominantly cyclooxygenase; acetaminophen (Tylenol) blocks mainly COX in the central nervous system and only weakly blocks peripheral COX and is therefore more of an antipyretic than an anti-inflammatory drug.

In addition, they increase vascular permeability (inducing more influx of neutrophils) and smooth muscle contraction. As noted in the preceding section, and as shown in Figure 23-13, corticosteroids are powerful anti-inflammatory agents that work through the blockade of cyclooxygenase, in addition to their blocking the formation of arachidonic acid.

Although steroids are highly effective anti-inflammatory agents, they provoke a number of undesirable side effects, including fluid retention, weight gain, osteoporosis, gastrointestinal bleeding, and mental changes. Other nonsteroidal drugs, including **nonsteroidal anti-inflammatory drugs**, have been found to be effective in blocking inflammation by similar mechanisms, as shown in Figure 23-13, without the undesirable side effects of the corticosteroids. These agents, most of which block COX specifically, include such drugs as naproxen (Naprosyn), ibuprofen (Advil, Motrin), and piroxicam (Feldene). These agents inhibit two forms of COX: COX-1 and COX-2. The former is involved in maintaining membrane integrity of mucosal cells in the gastrointestinal tract, and the latter is involved in the inflammatory process. Because all of these agents inhibit both forms of COX, they have the undesirable side effect of gastrointestinal tract toxicity and induce GI bleeding. Newer agents that more selectively inhibit COX-2 have recently become available, including celecoxib (Celebrex) and rofecoxib (Vioxx). Because some patients treated with Vioxx have been diagnosed with myocardial infarction, this drug was withdrawn.

Aspirin, a potent cyclooxygenase inhibitor, is an effective anti-inflammatory agent and has, in addition, antipyretic and analgesic effects, which also result from cyclooxygenase inhibition. The latter two effects are thought possibly to be due to inhibition of COX in the CNS (so-called **COX-3**), mainly in the hypothalamus, although this is not certain (Burke, 2006).

Acetaminophen (Tylenol) inhibits COX-3 but exerts little effect on COX-1 and COX-2. Thus it is non-anti-inflammatory, does not result in gastrointestinal tract bleeding, and is an effective analgesic and antipyretic.

Of all of these drugs, therapeutic drug monitoring is performed only with aspirin and Tylenol. We therefore discuss these two drugs further.

Aspirin

Acetylsalicylic acid (aspirin) is a nonsteroidal anti-inflammatory compound that is used as an analgesic, an antipyretic, and, in larger doses, an anti-inflammatory agent. In lower doses, it exhibits its anticoagulant activity due to its antiplatelet activity through inhibition of COX in platelets, resulting in blockade of platelet plug formation. It can be effective in the treatment of fever, neuralgia, headache, myalgia, and arthralgia, and in the management of some rheumatic diseases.

Oral dosages of aspirin that are generally used for analgesia and antipyresis in adults range from 500 mg as necessary, to a maximum of 4 g/day. Increased dosages (3.5–5.5 g/day) are used for rheumatoid arthritis and osteoarthritis in adults, and for juvenile arthritis (up to 3.5 g/day) in children.

The small intestine is the primary site of aspirin absorption, and absorption usually occurs rapidly following oral administration, with peak plasma levels established within 1–2 hours. Before entering the systemic circulation, aspirin is rapidly hydrolyzed to acetic acid and salicylic acid. Hydrolysis occurs partially by plasma esterase and partially by the liver. Both aspirin and salicylic acid enter the CNS.

Approximately 70%–90% of salicylic acid is plasma protein bound. The serum half-life is dose dependent and increases with the dose—from approximately 3 hours with 500 mg to approximately 15 hours with 4 g. Salicylic acid is cleared not only by metabolism but also by urinary excretion, and, as the half-life increases, the rate of urinary excretion decreases. This can produce toxic effects if the dosage interval is not increased appropriately. However, the rate of elimination can vary widely with the patient, necessitating individualization of dosage for large amounts of drug. Tinnitus, muffled hearing, and a sensation of fullness in the ears are the most common signs of chronic aspirin toxicity. In infants, young children, and

Figure 23-14 Aspirin toxicity levels in children as a function of time. (Howanitz, 1984; modified with permission from Done AK. *Pediatrics* 1960;26:800.)

patients with preexisting hearing loss, otic symptoms will not occur, and hyperventilation is the most common sign of overdose.

As discussed in Chapter 14, overdoses of aspirin can cause metabolic acidosis. Because salicylate itself stimulates central respiratory centers, overdose causes an increased breathing rate, leading to a respiratory alkalosis that can predominate, so that the patient exhibits respiratory alkalosis subsequent to initial metabolic acidosis. Acute aspirin intoxication is a common cause of fatal drug poisoning in children. Toxic doses produce acid-base disturbances, direct CNS stimulation of respiration, hyperpyrexia and hypoglycemia, gastrointestinal bleeding, and nausea and vomiting. Acute renal failure, CNS dysfunction with stupor and coma, and pulmonary edema may develop. Figure 23-14 summarizes the toxic levels of aspirin in children as a function of time after the toxic dose was taken.

A serious toxic effect of aspirin, mainly in children but also recognized in adults, is hepatotoxicity leading to fulminant hepatic failure (i.e., Reye's syndrome). This occurs when a patient is treated with aspirin for fever during a viral illness. After apparent recovery, the patient becomes seriously ill from hepatic failure with signs and symptoms, including hepatic encephalopathy, described in Chapters 8 and 21. Although once almost always fatal, newer supportive measures have resulted in a significant increase in survival from this life-threatening condition, the basic cause of which is as yet undetermined.

Acetaminophen

Acetaminophen (Tylenol), or *N*-acetyl-*p*-aminophenol, is used as an analgesic and antipyretic to treat fever, headache, and mild to moderate myalgia and arthralgia. Acetaminophen is as effective as aspirin in its analgesic and antipyretic actions and is preferred over aspirin in patients

with a bleeding/coagulation disorder or in children requiring only antipyretics or analgesics, because no association between acetaminophen and Reye's syndrome has been demonstrated. Furthermore, an accidental overdose in children may be less toxic than with aspirin; hepatotoxicity is rarely associated with acetaminophen overdose in children younger than 6 years of age.

Oral doses of acetaminophen are rapidly and essentially completely absorbed from the GI tract. Generally, 325–650 mg at 4-hour intervals is prescribed for adults and children over the age of 12, with a maximum of 4 g daily. The plasma half-life is approximately 2 hours, with peak plasma levels of 5–20 µg/mL occurring in 30–60 minutes. Plasma protein binding is about 20% with therapeutic doses. The major metabolites of acetaminophen produced by the liver are glucuronide and sulfate conjugates, with minor metabolites being deacetylated and hydroxylated derivatives. The latter metabolite is thought to produce hepatotoxicity with overdose.

At therapeutic levels, about 90% of acetaminophen is conjugated as glucuronides or sulfates in the liver. About 5% is converted to a toxic metabolite, *N*-acetyl-*p*-aminobenzoquinoneimine (NAPQI), which is hepatotoxic at high concentrations (Rowden, 2006). It is this metabolite that causes toxic liver effects at high doses of acetaminophen in the liver by the cytochrome P450 mixed oxidase system. This metabolite is normally cleared by conjugation to glutathione (GSH) by glutathione-S-transferase (GST) in the liver. In cases of toxic levels of NAPQI, where the NAPQI levels overwhelm the GST system, acetylcysteine is administered. This compound conjugates to NAPQI, detoxifying it.

Toxic doses of acetaminophen occur at acute ingestion levels of 140 mg/kg (White, 1998). Acute manifestations of toxic doses generally occur within 2–3 hours after ingestion and include nausea, vomiting, and

abdominal pain. A characteristic sign of toxicity is cyanosis of the skin, mucosa, and fingernails due to methemoglobinemia. However, this is seen more frequently with phenacetin poisoning. CNS stimulation followed by CNS depression may occur in severe poisoning, with vascular collapse, shock, and total seizures. Coma usually precedes death. At very high doses (as with suicide attempts), fulminant hepatic failure may occur, with maximum liver damage not becoming apparent until 2–4 days after drug ingestion (Sunheimer, 1994). Chronic acetaminophen abuse may produce chronic toxicity and death. Anemia, renal damage, and gastrointestinal disturbances are usually associated with chronic toxicity. Toxic effects can be treated effectively with NAC (Rowden, 2006).

IMMUNOSUPPRESSIVES

(Dunn, 2001; Dancey, 2002; Drosos, 2002; Scott, 2003; Mueller, 2004).

Although intact humoral and cell-mediated immunity is essential in preventing infection, it becomes vital to suppress functioning of these systems in some circumstances. These include aberrations of the immune system such as autoimmune disease (e.g., lupus erythematosus, Sjögren's syndrome) and normal functioning of the immune system (e.g., in tissue transplantation). In the latter circumstance, the most important component of the immune system is cell-mediated immunity. As shown in Figure 23-15, in host-versus-graft or in graft-versus-host disease, CD4⁺ T cells become activated when a foreign antigen binds to the major histocompatibility class (II) Ia protein on the surface of macrophages (antigen-presenting cells). Specific T cell clones bind to the antigen using their T cell receptors (CD3), which recognize the antigen–Ia complex. Activation of the T cell receptor results in a signal transduction cascade that ultimately ends in engulfment via receptor-mediated endocytosis of the antigen by the macrophage and destruction in lysosomes. In this cascade, calcium ions are mobilized, resulting in the activation of calcineurin, a phosphatase that forms a complex with calmodulin. Activated calcineurin dephosphorylates cytosolic nuclear factor of activated T cells (NF-AT)^C resulting in its activation, whereupon it translocates to the nucleus and binds to NF-AT from the nucleus (NF-AT)^N. This transcriptionally active complex results in the synthesis of interleukin (IL)-2, which becomes secreted as an extracellular mitogen (i.e., an autocrine factor). It binds to the IL-2 receptor of the T cell, activating it toward the binding of a protein, called **target of rapamycin (TOR)**, which serves to activate cyclin kinases that promote progression of the cell cycle from G1 to S and stimulate nucleotide synthesis. This ends in differentiation and proliferation of the T cell and ultimate antigen destruction.

As shown in Figure 23-15, there are specific agents (Hess, 1988; Kahan, 1989; Isoniemi, 1997; Braun, 1998; McEvoy, 2004; Krensky, 2006) that block one or more of these steps and, by so doing, inhibit antigen destruction. The drugs cyclosporine and tacrolimus are cyclic polypeptides that bind to intracellular proteins called **immunophilins**. Cyclosporine (CsA) binds to the immunophilin cyclophilin, while tacrolimus binds to the immunophilin called **FKBP12**. These complexes then block calcineurin-induced activation of NF-AT, and therefore block interleukin-2 synthesis, so that antigen destruction cannot occur. On the other hand, another immunosuppressive agent, rapamycin (Sirolimus), has no such effect on T cells, but rather binds to the critical TOR protein, disabling activation of cyclin kinases so that T cell activation cannot proceed. Finally, mycophenolate mofetil, an antibiotic, is hydrolyzed to free mycophenolic acid in the cell. This agent is a powerful inhibitor of inosine monophosphate dehydrogenase and guanosine monophosphate synthetase, disabling deoxypurine nucleotide synthesis, which, in turn, disables DNA synthesis uniquely in lymphocytes. Other cells have rescue pathways that circumvent this blockade, making the effects of this drug selective for lymphocytes (Krensky, 2006). In the same vein, some alkylating agents that are generally used as chemotherapeutic agents, such as cyclophosphamide (Cytosan), can be used to suppress DNA synthesis in T cells, but these are not selective for lymphocytes.

It should be noted that the corticosteroids also have immunosuppressive effects on cell-mediated immunity but are much less specific and, as noted in the previous section, have multiple undesirable side effects. They are, therefore, not the drugs of choice for use in transplantation. In the following section, we discuss the properties of the more specific immunosuppressive drugs, most of which require monitoring of serum (plasma) levels.

Cyclosporine

CsA is a cyclic polypeptide containing 11 amino acids, five of which are methylated. Maximum suppression with CsA occurs during the first

Figure 23-15 Mechanisms and sites of action of immunosuppressive drugs. This figure shows two linked, centrally important signal transduction pathways induced by antigen, in this case foreign transplanted cells, for activation of cell-mediated immunity. In the first pathway, antigen is “presented” to antigen-specific (clonal) T cells by attachment of the antigen to the Ia molecule (major histocompatibility class [MHC] II—or DR in humans—protein). The formation of a ternary complex of antigen (red box), Ia (green receptor on the antigen presenting cell; i.e., macrophage), and the T cell receptor (purple receptor, upper left) results in a signal transduction cascade that causes the synthesis of IL-2, shown as a space-filling model in the lower left part of the figure. Critical to this pathway is activation, by calcium-activated calmodulin, of the phosphatase, calcineurin, which dephosphorylates cytosolic nuclear factor of activated T cells (NF-AT)^C resulting in its activation; whereupon it translocates to the nucleus and binds to NF-AT from the nucleus (NF-AT)^N, which directly promotes transcription of interleukin (IL)-2. In the second, linked, signal transduction pathway (right side), newly synthesized IL-2 is then secreted by the T cell and acts as an autocrine factor in binding to the extracellular domain of the IL-2 receptor of the T cell to form a complex as shown in the upper right part of the figure. This complex induces activation of a second signal transduction cascade in which target of rapamycin (TOR) protein is stimulated and, in turn, activates cyclin kinases that promote activation of cyclins, which, in turn, promote progression of the cell cycle from G1 to S necessary for blast transformation of clonal T cells that, with macrophages, engulf and destroy the antigen. All elements of the normal signal transduction pathways are shown as pink boxes. The immunosuppressive drugs and their target proteins block different parts of these two pathways and are shown as yellow ellipses. Cyclosporine (CsA) and tacrolimus (FKBP12), respectively, with cyclophilin and FKBP12 to form inhibitory complexes that block calcineurin in the first pathway. On the other hand, rapamycin blocks TOR, thereby blocking IL-2-induced blast transformation in the second pathway; mycophenolate mofetil (MMF) blocks nucleotide synthesis, thereby blocking G1-S progression in the second pathway.

24 hours of antigen stimulation by the allograft. Thus, CsA must be administered in the early phase of the immune response for optimal suppression of T cell function and increased success of transplantation (McEvoy, 2004).

CsA is indicated to prevent organ rejection in kidney, heart, and liver allogeneic transplants and is the drug of choice for maintenance of kidney,

liver, heart, and heart–lung allografts. CsA may also be utilized as a first- or second-line drug in the treatment of acute graft-versus-host disease following bone marrow transplantation, in the active stage of severe rheumatoid arthritis, and for severe, recalcitrant plaque psoriasis. It may also be used in the treatment of other autoimmune diseases and in organ transplantation.

Because CsA is variably absorbed from the GI tract, the optimal dose must be carefully determined for each patient individually, and blood levels should be monitored frequently. It has been occasionally found that, although serum levels of the parent drug are low, the metabolites, some of which are active, maintain a therapeutic drug level. Therefore, in patients with apparently low levels of the parent drug, it is necessary to determine the levels of metabolites. Peak blood concentrations occur at approximately 3.5 hours after administration. About 20%–40% of a given dose of CsA is absorbed, and it is metabolized on the first pass through the liver. Human cytochrome P450 III A3 (CYP3A) of the P450 III gene family appears to be the primary enzyme responsible for CsA metabolism. Because a number of drugs may induce or may be metabolized by this cytochrome P450 isoenzyme, coadministration of these drugs may be responsible for alterations in CsA levels that can complicate CsA therapy (Kronbach, 1988). Agents that inhibit the CYP3A system include calcium channel blockers (e.g., verapamil, discussed earlier), antimicrobials, and HIV protease inhibitors. Grapefruit and grapefruit juice are also known to exert inhibitory effects on this system (Krensky, 2006). Trough whole blood or plasma concentrations, at 24 hours, of 250–800 ng/mL or 50–300 ng/mL, respectively (as determined by immunoassay), are believed to minimize graft rejection and, concurrently, toxic effects.

Adverse effects of CsA may occur in all organ systems of the body. Trough serum levels greater than 500 ng/mL are associated with CsA-induced nephrotoxicity, which is the most frequent toxic reaction seen with CsA. CsA-induced nephrotoxicity is accompanied by hyperkalemia and hyperuricemia, hypertension, and gingival hyperplasia.

Other toxic effects include neurologic effects (tremors, seizures, headache, paresthesia, flushing, confusion), dermatologic effects (hirsutism, hypertrichosis, rash), hepatotoxicity, GI effects (diarrhea, nausea, vomiting, anorexia, abdominal discomfort), infectious complications, hematologic effects (leukopenia, anemia, thrombocytopenia), and sensitivity reactions, including anaphylaxis (Philip, 1998). It is important to note that the risk of immunosuppressed states is increased, and the occurrence of lymphoma, especially CNS lymphoma, may be associated with immunosuppression by CsA. It has also been found that CsA induces immune system–independent increased invasiveness of adenocarcinoma cells in culture, apparently by activating transforming growth factor- β (TGF- β) (Hojo, 1999). This behavior is blocked by monoclonal antibodies to TGF- β .

Both oral and intravenous preparations of CsA are available. Interpatient and inpatient absorption of the oral preparation is variable, and absorption can be affected by many factors. It is generally recommended that whole blood be used for drug level monitoring, and that an assay method with high specificity for unchanged drug (vs. metabolites) be used. Thus, the optimal dose must be carefully determined for each patient individually, and blood levels should be monitored frequently, with CsA blood concentrations qualified by biological fluid (whole blood vs. plasma vs. serum) and assay method (immunoassay vs. HPLC) used. At present, any currently available immunoassay (FPIA, EMIT) is acceptable for routine monitoring, although it is important that consistent laboratories and methods be used (McEvoy, 2004).

Neoral is a microemulsion formulation of CsA that is miscible in water; it increases the solubility of CsA in the small bowel (Miller, 1998). This preparation has shown superior pharmacokinetics with improved bioavailability and equivalent safety with no apparent increase in toxicity. It appears to offer advantages over oral solutions of CsA, by decreasing inpatient and outpatient blood level variability. Intravenous CsA is reserved for patients unable to tolerate oral administration; this route of administration carries a low but definite (0.1%) risk of anaphylaxis, which does not occur following oral administration of the drug.

Tacrolimus (FK-506)

Tacrolimus is a macrolide lactone antibiotic with a mechanism of action similar to that of cyclosporine; it is more potent than CsA in its inhibitory effect (McEvoy, 2004). It is currently being utilized in transplant surgery to prevent organ rejection. As is the case with CsA, higher trough concentrations of tacrolimus appear to increase the relative risk of toxicity, and therapeutic drug monitoring is recommended. The same monoclonal antibody is used in the two methods available for monitoring. One method is

a microparticle enzyme immunoassay, and the other method is an enzyme-linked immunosorbent assay. Whole blood is the specimen of choice. The toxic potential appears to be similar to the toxic effects of CsA. The most common include nephrotoxicity, neurotoxicity (such as tremor and headache), gastrointestinal effects such as diarrhea and nausea, hypertension, alterations in glucose metabolism (diabetes mellitus), hyperkalemia, and infectious complications. However, unlike with CsA, gingival hyperplasia and hirsutism do not occur. Anaphylaxis may occur with intravenous administration, and oral therapy is recommended whenever possible. Tacrolimus appears to be best suited for use in combination with other new immunosuppressive agents.

Rapamycin (Sirolimus)

Rapamycin is an antibiotic similar to tacrolimus. Peak concentrations are reached after about 1 hour after a single oral dose or after about 2 hours after multiple doses for patients who have undergone renal transplant (Krensky, 2006). The parent drug is the major active form, although several metabolites also have activity. About 40% of the drug is bound to serum proteins, especially albumin; it is metabolized predominantly in the liver by the CYP3A4 system (Krensky, 2006). Major side effects include GI symptoms, abnormalities in lipid levels, anemia, leukopenia, and thrombocytopenia. It can also cause delayed wound healing; however, it does not appear to be nephrotoxic. If used in combination with cyclosporine, because sirolimus aggravates CsA-induced renal dysfunction, administration of these two drugs must be separated in time (Krensky, 2006).

Mycophenolate Mofetil

Mycophenolate mofetil is a derivative of mycophenolate acid, a fungal antibiotic. The parent drug is metabolized to mycophenolic acid (MPA) within minutes of administration. The half-life of MPA is about 16 hours. Virtually all MPA is excreted in the urine as the glucuronide. This drug is used for prophylaxis of renal allograft rejection, usually in combination with a steroid or a calcineurin inhibitor (Krensky, 2006). Although this drug appears to decrease the rate of renal allograft rejection, differences in patient and allograft survival have not been demonstrated (Isoniemi, 1997). It may be of use in patients who do not tolerate CsA or tacrolimus (FK-506) well. Major side effects include GI symptoms such as diarrhea, nausea, and myelosuppression. Neither nephrotoxicity nor neurotoxicity has been demonstrated.

Leflunomide

Leflunomide (LFM), which inhibits lymphocyte proliferation by inhibiting dihydroorotic acid synthetase (Krensky, 2006), critical to deoxy pyrimidine nucleotide synthesis, is an isoxazole derivative. It is presently used in the treatment of rheumatoid arthritis, the only condition for which it has been approved for treatment, although it is being used increasingly for treatment of polyoma virus nephropathy seen in immunosuppressed renal transplant recipients (Krensky, 2006). LFM has not been demonstrated to cause nephrotoxicity or myelosuppression in humans.

DRUGS USED IN THE TREATMENT OF MANIA AND DEPRESSION

Both lithium and the antidepressants are used in the treatment of psychiatric affective disorders.

Lithium

Lithium is a monovalent cation, a member of the group of alkali metals, and is available commercially as citrate and carbonate salts. Lithium salts are considered to be antimanic agents and are used for the prophylaxis and treatment of bipolar disorder (manic–depressive psychosis) and as an adjunct to antidepressant therapy in melancholic depression (Baldessarini, 2006a). In addition, lithium is considered by some investigators to be the drug of choice for the prevention of chronic cluster headache, and it may be effective in episodic or periodic forms of cluster headache. Initial oral dosages of lithium for acute mania range from 0.6–1.8 g daily (maximum, 2.4 g) and produce a therapeutic serum level of 0.75–1.5 mEq/L. Once the attack subsides, the dose is reduced rapidly to produce a serum concentration of 0.4–1.0 mEq/L. Oral adult dosages for cluster headaches generally range from 0.6–1.2 g daily in divided doses. In cases of acute mania, especially in agitated, uncooperative patients, because of the relatively slow onset of action of lithium, a benzodiazepine sedative (e.g., lorazepam, clonazepam) or the anticonvulsant valproate (Depakote; see

previous section) is administered until some stabilization of the agitated state is achieved. Then lithium is administered to achieve long-term stabilization. Alternatively, continuation of both drugs may be continued, or, in some cases, the patient can be maintained on Depakote alone (Baldessarini, 2006b).

In general, serum levels of and patient response to lithium are used to individualize dosage and must be monitored carefully. Complete absorption of lithium occurs 6–8 hours after oral administration. Plasma half-life varies from 17–36 hours, and onset of action is slow (5–10 days). Elimination occurs almost entirely by the kidneys, and about 80% of filtered lithium is reabsorbed. Lithium is not protein bound and is distributed in total body water, but it shows delayed and varied tissue distribution. Thus, symptoms of acute intoxication may not correlate well with serum levels, because the distribution of the drug into different organs may be slow and/or varied.

The exact mechanism of action of lithium is unknown, but lithium, as a monovalent cation, competes with other monovalent and divalent cations (such as sodium, potassium, calcium, and magnesium) at ion channels in cell membranes and at protein-binding sites such as membrane receptors and protein/peptide transport molecules and enzymes that are critical to the synthesis, storage, release, and uptake of central neurotransmitters. Lithium also has a marked inhibitory effect on inositol monophosphatase and on the synthesis of phosphatidylinositides, which are second messengers involved in neurotransmission, and on the synthesis of cAMP, also involved in neurotransmission (Phiel, 2001; Baldessarini, 2006a,b). These effects are exerted on the postsynaptic side of dopamine- and norepinephrine-utilizing tracts in the mesolimbic and mesocortical pathways that inhibit the mobilization of calcium ions required for postsynaptic depolarization. The effect, then, is to inhibit neurotransmission. In addition, lithium blocks release of dopamine from presynaptic vesicles, also resulting in diminished neurotransmission.

Toxicity may occur acutely, as the result of a single toxic dose, or chronically, from high and/or prolonged dosages or changes in lithium pharmacokinetics. Water loss (resulting from fever, decreased intake, abnormal gastrointestinal conditions such as diarrhea or vomiting, diuretics, or pyelonephritis) is the main contributing factor underlying chronic intoxication. Renal toxicity and hypothyroidism are also known possible side effects of lithium. Thus it is advisable to monitor creatinine and thyroid-stimulating hormone periodically in patients who are under continuing treatment with this drug. Severity of intoxication is not clearly related to serum lithium levels. However, an imprecise prediction of severity of intoxication may be attempted from serum lithium levels obtained 12 hours after the last dose: Slight to moderate intoxication with 1.5–2.5 mEq/L, severe intoxication with 2.5–3.5 mEq/L, and potentially lethal intoxication if greater than 3.5 mEq/L. Severity of lithium intoxication also depends on the length of time that the serum concentration remains toxic.

The most common symptoms of mild to moderate intoxication include nausea, malaise, diarrhea, and fine hand tremor. In addition, thirst, polydipsia, and polyuria, as well as drowsiness, muscle weakness, ataxia, and slurred speech, may occur. Symptoms of moderate to severe toxicity include hyperactive deep tendon reflexes, choreoathetoid movements, persistent nausea and vomiting, fasciculations, generalized seizures, and clonic movements of whole limbs. These may progress rapidly to generalized seizures, oliguria, circulatory failure, and death with serum levels greater than 3.5 mEq/L.

Antidepressants

Three classes of drugs are currently used in the treatment of clinical depression: classical tricyclic antidepressants (TCAs), SSRIs, and monoamine oxidase inhibitors (MAOIs) (Baldessarini, 2006a). The rationale for use of the first class of drugs is their ability to block the uptake of norepinephrine at the axonal side of synapses in neural tracts from the brainstem to the forebrain that utilize this neurotransmitter, as indicated in Figure 23-8. This blockade allows longer stimulation times and higher concentrations of norepinephrine at the dendritic side of the synapse, allowing them to bind to α -1-receptors in these tracts for prolonged times, resulting in prolonged and enhanced stimulation. Drugs in the second class produce the same effect in parallel neural pathways that utilize serotonin as the stimulatory neurotransmitter (see earlier in the The Drugs of Abuse, General Aspects of the Mechanisms of Action section). Finally, MAOIs block the inactivating metabolism of both norepinephrine and serotonin neurotransmitters by inhibiting their oxidation by the enzyme monoamine oxidase, present in the mitochondria of the presynaptic (axonal) terminal, wherein their amino groups are oxidized to the

corresponding aldehydes. This inhibition results in increased concentrations of these neurotransmitters.

Tricyclic Antidepressants

The structures of these related compounds are shown in Figure 23-16. Also shown are two other effective antidepressant drugs: doxepin and Desyrel (trazodone), a second-generation, so-called **atypical antidepressant**, which does not contain the three fused ring system of the TCAs. Besides blocking reuptake of norepinephrine at the axonal side of synapses, the TCAs have been found to *bind directly* to two classes of norepinephrine receptors: α -1, which occur on the postsynaptic side of the synapse, and α -2, so-called **autoreceptors**, which occur on the presynaptic side of the synapse. The postsynaptic α -1-receptors are involved in postsynaptic membrane depolarization involving calcium ion fluxes resulting in nerve conduction. The presynaptic α -2-receptors, when bound to norepinephrine, induce its downregulation by causing decreased synthesis of tyrosine hydroxylase, the critical enzyme that catalyzes the rate-limiting step in norepinephrine biosynthesis (Baldessarini, 2006a). This results in decreased levels of norepinephrine and in decreased secretion of this neurotransmitter into the synaptic cleft.

When the TCAs bind to α -1-receptors, they cause temporary blockade of these receptors. This effect is thought to cause the **observed side effect of initial hypotensive episodes** in patients who are treated with these drugs. Over time, the binding of TCAs to these postsynaptic receptors apparently causes **increased sensitization** of the α -1-receptors to norepinephrine, overcoming the initial inhibition, while the presynaptic reuptake blockade of norepinephrine continues unimpeded. Concurrently, binding of the TCAs to presynaptic α -2-receptors has the opposite effect from their binding to the postsynaptic α -1-receptors, that is, desensitization with resulting loss of inhibition of epinephrine biosynthesis. Thus the TCAs enhance norepinephrine-induced neurotransmission in the limbic system by blocking norepinephrine reuptake, sensitizing postsynaptic α -1-receptors, and desensitizing inhibitory presynaptic α -2-receptors. In addition, TCAs appear to block, in a nonspecific manner, the reuptake of dopamine in the dopaminergic pathways in the limbic system (Baldessarini, 2006a).

Besides stimulating dopaminergic pathways, the tricyclics, especially amitriptyline, have anticholinergic effects (Baldessarini, 2006a). The pharmacologic side effects of the tricyclic antidepressants, in fact, reflect their anticholinergic activities. These include dry mouth, constipation, blurred vision, hyperthermia, adynamic ileus, urinary retention, and delayed micturition. Other CNS effects include drowsiness, weakness, fatigue, and lethargy, which are most common, as well as agitation, restlessness, insomnia, and confusion. Seizures and coma can also occur. Extrapyramidal symptoms may occur and include a persistent fine tremor, rigidity, dystonia, and opisthotonos. It is important to note that TCAs unfortunately have been used in suicide attempts by some depressed individuals who are being treated with them. The cardinal signs of tricyclic antidepressant overdose are anticholinergic symptoms, such as dilated pupils and dry skin.

Toxicity. Overdose produces symptoms that are primarily extensions of common adverse reactions with excess CNS stimulation and anticholinergic activity. These include seizures, coma, hypotension, respiratory depression, areflexia, shock, and cardiorespiratory arrest. Agitation, confusion, hypertension, and the parkinsonian syndrome may also occur, as well as hallucinations and delirium. Occasional manifestations include ataxia, renal failure, dysarthria, and vomiting.

Treatment. Symptomatic and supportive care is the general mode of treatment. Gastric lavage, accompanied by instillation of activated charcoal, is usually recommended for removal of the tricyclic from the GI tract. Seizures are generally treated with intravenous diazepam. For overdoses with amitriptyline (see Fig. 23-16), use of cholinesterase inhibitors such as neostigmine has proved to be effective in reversing anticholinergic symptoms.

Selective Serotonin Reuptake Inhibitors

These are nontricyclic drugs with strong antidepressant activity that have been developed more recently. The most prominent of these is fluoxetine (Prozac), whose structure is shown in Figure 23-16. These drugs block the reuptake of serotonin in central serotonergic pathways as noted previously. Their effects on serotonin receptors parallel those of the TCAs on norepinephrine receptors, including ultimate downregulation of presynaptic autoreceptors. It is interesting to note that if the trifluoromethyl group of fluoxetine is placed at the ortho rather than the para position, the

Tricyclic and Atypical Antidepressants

Selective Serotonin Reuptake Inhibitors

Monoamine Oxidase Inhibitors

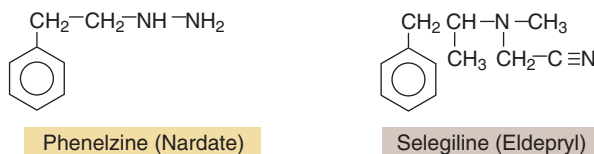

Figure 23-16 Structures of the most commonly used drugs in the three classes of antidepressants: tricyclic and atypical antidepressants, selective serotonin reuptake inhibitors, and monoamine oxidase inhibitors.

resulting drug behaves as a tricyclic antidepressant (Baldessarini, 2006a). It is an important note that Prozac and SSRIs in general do not appear to cause some of the side effects, such as the anticholinergic effects, associated with TCAs. For this reason, they have become the drugs of choice for treating clinical depression, although reports have described attempted suicide with some patients, especially adolescents, who are being treated with SSRIs. In addition, SSRIs have been reported to cause nausea and decreased libido and sexual function.

MAO Inhibitors

MAO is a flavin-containing oxidative enzyme that is encoded by two distinct genes. The two resulting enzymes, called **MAO-A** and **MAO-B**, have about 70% sequence identity. Each enzyme is found on the mitochondrial membrane. MAO-A deaminates epinephrine, norepinephrine,

and serotonin, and MAO-B deaminates phenylethylamine. Both enzymes deaminate dopamine. Several MAOIs have been synthesized that inhibit either enzyme selectively. Thus, for example, MAO-A is inhibited selectively by corgyline, and MAO-B is inhibited by selegiline (see Fig. 23-16).

MAOIs are not used as the “first line” of treatment for depression because of their potential toxic effects and unfavorable interactions with TCAs and SSRIs. Toxic effects from overdoses include hypertension and/or hypotension, agitation, hallucinations, hyperreflexia, fever, and seizures (Baldessarini, 2006a). The combination of an MAOI with an SSRI can lead to the so-called **serotonin syndrome**, which includes akathisia, myoclonus, hyperreflexia, diaphoresis, and shivering progressing to seizures and coma. In addition, MAOIs potentiate the action of over-the-counter anti-cold sympathomimetic amines such that they can cause hypertensive crises and intracerebral bleeding. Therefore, it is imperative to avoid use of these

anticoagulant medications in individuals treated with an MAOI. Their use is mostly for patients who do not respond to either SSRI or TCA therapy and who refuse electroconvulsant shock therapy.

Therapeutic Levels and Metabolism of Antidepressants

It is difficult to obtain reference ranges for the antidepressants because of their large numbers of metabolites, some of which may be active and others of which may be inactive, and which vary significantly in concentration from individual to individual—a problem that also exists for the neuroleptics discussed later. In addition, the volumes of distribution of these drugs are quite high because most are lipophilic and thus are stored in tissue and slowly released. For the TCAs, serum levels from 100–250 ng/mL generally are considered therapeutic; toxic effects may result at levels above 500 ng/mL and lethal doses above 1 µg/mL. Assays for the TCAs are performed by immunoassay (see Immunochemical Methods section earlier and Fig. 23-1) or by HPLC (see High-Performance Liquid Chromatography section earlier and Fig. 23-4).

Virtually all of these drugs are metabolized in the liver using the cytochrome P450-dependent oxidase system (Baldessarini, 2006a). Different antidepressants require different isoforms of cytochrome P450. These isoforms include CYP2D6, CYP2C19, CYP3A3/4, and CYP1A2. In general, for both TCAs and SSRIs, oxidation, a modification that often includes glucuronidation and elimination of these drugs, occurs over several days. Most tricyclics are completely eliminated within 10 days. Secondary amine TCAs and *N*-demethylated derivatives of SSRIs have about twice the half-lives of their parent compounds. The **atypical TCA**, trazodone, is metabolized to mCPP, a piperazine that is discussed earlier under the drugs of abuse section. MAOIs have much shorter half-lives than TCAs and SSRIs, requiring frequent dosing to maintain therapeutic levels.

THE NEUROLEPTICS, ANTIPSYCHOTIC MAJOR TRANQUILIZERS

These drugs are used mainly in the treatment of acute schizophrenia and result in suppression of the agitated state. All neuroleptics appear to block the actions of dopamine and serotonin postsynaptically in the limbic system and motor cortex (see Fig. 23-8). Specific dopaminergic pathways, called the **mesolimbic-mesocortical pathways**, connect the substantia nigra of the midbrain to the limbic system and motor cortex (Baldessarini, 2006b). In addition, the substantia nigra connects to the basal ganglia via the nigrostriatal pathway; depletion of dopamine in this pathway results in Parkinson's disease. Thus it may be expected that dopamine antagonists would affect the latter pathway, in addition to the mesolimbic-mesocortical pathways. Indeed many of the neuroleptics have, as side effects, dystonias, tardive dyskinesias, and frank parkinsonism, the latter fortunately being much less common. Originally, two classes of neuroleptics, the phenothiazines, typified by chlorpromazine, and the butyrophenones, typified by haloperidol (Haldol), were the drugs of choice. Besides postsynaptic blockade of dopamine, Haldol is known to bind with high affinity to sigma-receptors in the CNS, and this action may stimulate inhibitory pathways that modulate the activity of the dopaminergic pathways. All compounds in both classes have the undesired extrapyramidal side effects mentioned previously. In addition, the neuroleptics inhibit dopamine in the hypothalamic-pituitary tract, which inhibits release of prolactin by the pituitary. The effect of the neuroleptics therefore is to increase prolactin secretion by the pituitary, resulting in hyperprolactinemia. Treatment of patients with breast cancer with any neuroleptic that causes this effect is contraindicated (Baldessarini, 2006b).

Newer neuroleptics have been developed that affect the nigrostriatal pathway to a lesser extent but are potent postsynaptic dopamine blockers in the mesolimbic-mesocortical pathways and therefore are effective, with fewer of the extrapyramidal side effects of the older drugs. These newer drugs (Burns, 2001) include risperidone (Risperdal) (which does have some documented extrapyramidal side effects), olanzapine (Zyprexa), quetiapine (Seroquel), and aripiprazole (Abilify).

It has been difficult to monitor the levels of any of these drugs in serum because of the large number of metabolites for each drug resulting from extensive metabolism in the liver. Chlorpromazine, for example, has approximately 150 metabolites. The therapeutic efficacy of most of these metabolites is unknown. Reference ranges for serum levels therefore have not been established. Similar to the antidepressants, the neuroleptics,

being lipophilic, have high volumes of distribution and are stored in tissues from which they are released over time.

Methods for assay include FPIA (see Immunochemical Methods section earlier and Fig. 23-1) and by HPLC (see High-Performance Liquid Chromatography section earlier and Fig. 23-4). It is not clear in FPIA which, if any, metabolites cross-react with the antibody. For chlorpromazine, the estimated therapeutic range is wide—between 50 and 300 ng/mL. The half-life of the drug is 16–30 hours, and its bioavailability is 25%–35%. Normal doses for chlorpromazine are 200–600 mg/day in divided doses. Other drugs in the phenothiazine series include thioridazine and fluphenazine (Prolixin).

Besides the extrapyramidal side effects, the phenothiazines can cause orthostatic hypotension, cholestasis, and, rarely, aplastic anemia. Occasionally, contact dermatitis has been reported to occur with phenothiazines. Of great importance is the subset of patients who have been chronically treated with these drugs and develop tardive dyskinesia. In most of these patients, the motor disturbances are irreversible.

Neuroleptics can cause a rare but important adverse reaction termed the neuroleptic malignant syndrome. This can occur in patients who are extremely sensitive to the extrapyramidal effects of these drugs, and it may be fatal. Marked muscle rigidity, the first symptom to occur, may be followed by high fever, altered pulse and blood pressure, and leukocytosis. An excessively rapid inhibition of postsynaptic dopamine receptors is believed to be responsible for this syndrome. Treatment is cessation of the drug.

CHEMOTHERAPEUTIC AGENTS: METHOTREXATE AND BUSULFAN

Serum levels of both of these agents are monitored to assess whether therapeutic serum levels are present. Both agents are used in the treatment of different forms of cancer.

Methotrexate

Methotrexate, an antimetabolite consisting of a mixture containing no less than 85% 4-amino-10-methylfolic acid and related compounds, is a folic acid antagonist (Table 23-7). It inhibits the enzyme dihydrofolate reductase (Chabner, 2006). This results in blockade of the synthesis of tetrahydrofolic acid, which is needed for the formation of *N*-5,10-methylene-tetrahydrofolic acid, an intermediate in the transfer of a methyl group to deoxyuridylylate to form thymidylate, needed in DNA synthesis. It has also been suggested that methotrexate may cause a rise in the intracellular levels of adenosine triphosphate (ATP), which blocks ribonucleotide reduction, also resulting in blocking of DNA synthesis. Methotrexate appears to inhibit polynucleotide ligase involved in DNA synthesis and repair. Furthermore, methotrexate and its analogs, like pemetrexed, a pyrrolo-pyrimidine folate analog, accumulate in cells and are stored as polyglutamates, which allows them to inhibit other enzymes in DNA synthesis, including thymidylate synthase. Methotrexate polyglutamates also inhibit enzymes involved in purine nucleotide biosynthesis such as glycylamide

TABLE 23-7
Methotrexate

Condition	Usual dose	Serum level
Psoriasis	IM or IV: 7.5–50 mg/week Oral: 7.5–30 mg/week	<10 nM (Roenigk, 1998)
Refractory rheumatoid arthritis	IM: 5–25 mg/week Oral: 7.5–15 mg/week	(Tugwell, 1987a and b)*
Malignant neoplastic diseases†	IM or IV: 25 mg/m ² , 1–2 times/week Oral: 2.5–5 mg/day High-dose IV: 1.5 g/m ² with rescue every 3 weeks (different regimens are available)	Approximately 50 nM

IM, Intramuscular; IV, intravenous.

*Baseline monitoring of patient parameters (hemoglobin; white blood cell count; mean corpuscular volume; platelet count; urinalysis; blood urea nitrogen; and serum creatinine, transaminase, and alkaline phosphatase levels) is advocated.

†With high-dose therapy, methotrexate levels are followed, and leucovorin doses are adjusted until serum methotrexate levels are less than 50 nM (Grem, 1995).

ribonucleotide transformylase, and aminoimidazole carboxamide transformylase in the synthesis of inosine monophosphate.

Methotrexate is used in the treatment of childhood acute lymphatic leukemia and a number of other hematologic malignancies, such as Hodgkin's lymphoma, usually in combination with other antineoplastic agents. It has also been used successfully in the treatment of choriocarcinoma (Chabner, 2006). Pemetrexed is used to treat mesothelioma and refractory non-small cell carcinoma of the lung.

Methotrexate is also an important immunosuppressive agent. Indications are severe, recalcitrant psoriasis and severe, active rheumatoid arthritis; in the latter, it may be used in combination with cyclosporine (Tugwell, 1995). Depending on the specific disease entity being treated, dosages given will vary, as will the therapeutic level of the drug. In Table 23-7, the doses and therapeutic drug levels for several different conditions are noted. The serum levels were determined by FPIA.

The kinetics of steady-state levels of this drug is triphasic: a rapid distribution phase followed first by a renal clearance phase with $t_{1/2}$ of 2–3 hours, and then by a slow phase with $t_{1/2}$ of 8–10 hours, in which methotrexate and its metabolites are filtered through the glomerulus and secreted in the renal tubules. If renal blood flow is compromised, the third phase is slowed, allowing toxic effects of the drug to occur. Excretion of the drug is biphasic: 92% is excreted within 24 hours, and the remainder over a period of days. Approximately 50% of the drug in blood is bound to serum proteins. Based on these considerations, it is important, when treating with methotrexate, not to administer drugs that compromise renal blood flow and not to modify the drug regimen to account for reduced renal blood flow. The same considerations apply to patients with renal insufficiency. In both circumstances, it is important to monitor blood levels of methotrexate. Treatment with high-dose methotrexate and leucovorin (see later) can itself be nephrotoxic because of the tendency of methotrexate to precipitate in acidic urine. Therefore, it is important to maintain high levels of hydration and to ensure alkalinization of the urine (Chabner, 2006).

As with most antineoplastic agents, methotrexate does not discriminate between transformed and normal cells. The rationale for using this drug is that it will kill rapidly dividing cancer cells that require rapid DNA synthesis but will not immediately affect normal cells, many of which are not dividing. Normal cells can be “rescued” from the effects of methotrexate and its analogs by treatment with *N*-5-formyltetrahydrofolate (called **leucovorin** or **citrovorum**), the product of dihydrofolate reductase. Leucovorin rescue is critical in cases where it is necessary to administer high doses of methotrexate to individuals with tumors that do not respond to normal doses of this drug. In such cases, leucovorin is given 18–36 hours after the initial methotrexate dose, while serum levels of methotrexate are monitored. In addition, leucovorin should immediately be administered to a patient receiving low-dose methotrexate when methotrexate overdose is suspected (Roeningk, 1998). Serum methotrexate levels should be monitored during this time (Grem, 1995; Chabner, 2006).

The methotrexate/leucovorin strategy is compromised by the existence of many fast-growing normal cells in bone marrow, the gastrointestinal tract, the skin, and other epithelial lining cells. These cells are as susceptible to the cell-killing effects of methotrexate as neoplastic cells. Thus, the toxic effects of methotrexate include hematologic effects (e.g., leukopenia, thrombocytopenia) from bone marrow suppression, gastrointestinal effects (e.g., ulceration, glossitis, stomatitis, nausea, vomiting), and dermatologic effects (e.g., urticaria, vasculitis). They further include hepatic lesions such as cirrhosis; pulmonary lesions such as pulmonary fibrosis; and CNS effects from intrathecal methotrexate, including arachnoiditis, leukoencephalopathy, and increased cerebrospinal fluid pressure.

Toxicity of methotrexate can be treated using continuous flow hemodialysis. Alternatively, intravenous infusion of carboxypeptidase G2, a methotrexate-cleaving enzyme, results in rapid clearing of the drug (Chabner, 2006).

Busulfan

Busulfan is an alkylating agent used to treat a variety of leukemias and lymphomas before bone marrow transplantation. It is cytotoxic to marrow cells and is used in combination with cyclophosphamide, which is cytotoxic to mature lymphocytes that may be involved in a graft-versus-host reaction (Slattery, 1998). The therapeutic index of the drug is narrow. High plasma levels increase the possibility of development of hepatic venoocclusive disease (VOD), a potentially fatal complication. Therefore, therapeutic monitoring of busulfan levels, using HPLC or GC-MS, with measurement of the dose interval of this drug, is now routinely performed at bone marrow transplant centers. This decreases the incidence of VOD in patients whose initial serum levels of busulfan are too high and allows

increasing doses for patients with too low an initial level of busulfan, thus optimizing therapeutic levels for each patient.

TOXINS AND ACUTE POISONING

In this section, agents that cause chronic or acute injury to the patient are discussed. This injury can be direct, as with poisons such as cyanide and carbon monoxide, or indirect, as with carcinogens that induce mutations in genes that encode proteins that are critical in controlling the cell cycle.

ENVIRONMENTAL CARCINOGENS

Over the past decade or so, attention has been focused on the effects of chemical agents in the environment—carcinogens, which predispose individuals exposed to them to develop tumors in various tissues where these agents accumulate. Many of the individuals who are exposed to these agents work in industries where these agents are produced. Benzpyrene, an aromatic compound produced in cigarettes and in the exhaust of engines, is a known potent carcinogen and has been implicated in causing lung cancer. Nitrites, used as preservatives in red meats, have been associated with colon cancer. Aflatoxin, produced by the fungus *Aspergillus*, has been implicated in causing hepatocellular carcinoma. Aromatic hydrocarbons such as benzene and ionizing radiation have been implicated in causing acute leukemias. Vinyl chloride and the formerly used dye Thorotrast have been linked to angiosarcoma. Benzidine dyes, β -naphthylamine, dimethylbenzanthracene, and other aromatic compounds have been linked to multiple malignancies occurring in humans. Exposure to asbestos has been strongly implicated as a carcinogen in lung cancer and mesothelioma. In animal studies, polychlorinated biphenyls (PCBs) and dioxin, the former produced in fires, have been strongly implicated as causing a variety of cancers.

A number of carcinogens, like benzpyrene, are inactive in their native forms but are transformed into carcinogens through oxidative reactions catalyzed by cytochrome P450-dependent systems. Thus, to be an active carcinogen, benzpyrene must be converted into benzpyrene diol epoxide. Because only particular isoforms of cytochrome P450 react with particular carcinogens, only those individuals carrying the genes that encode these forms are susceptible (Caraco, 1998). A major effort is now being devoted to identifying those individuals with phenotypes who would be at risk (Peto, 2001).

Much interest has been focused on workers in occupations where carcinogens are present in significant amounts. Steel foundries, shipbuilding and rubber plants, and other industrial plants may produce such carcinogens in significant amounts. In some of these industries, certain cancers occur at rates higher than in the general population (Brandt-Rauf, 1998; Pincus, 2003). Thus, in these exposed populations, it has become desirable to determine the levels of exposure to certain known carcinogens.

Carcinogens are thought to bind to DNA, leading ultimately to mutations in the genetic code, often resulting in synthesis of mutated proteins involved in control of the cell cycle (Brandt-Rauf, 1998; Pincus, 2003). These proteins are called **oncogene-encoded proteins** or **oncoproteins**. Mutagenesis, oncogenes, and oncoproteins are discussed in Chapter 74.

In populations with histories of exposure to carcinogens, assays have been developed to detect the presence of these carcinogens or of their DNA adducts. For detection of most unmodified carcinogens, the method of choice is currently GC-MS. For certain carcinogenic compounds like PCBs, the method of electron capture is used. Halogenated compounds like PCBs are separated on a GC column using an ionized gas as the carrier. Halogenated compounds “capture” electrons conducted through the carrier gas and thus are detected by the reduced currents.

Often, the presence of carcinogens in blood or urine is hard to detect directly. The carcinogens, however, may be bound to proteins or to DNA intracellularly. These adducts can be detected using Western blotting, which takes advantage of the existence of monoclonal antibodies to carcinogen–DNA adducts (Santella, 1987; Perera, 1988). This technique is sensitive to nanogram quantities of the nucleic acid adduct, which can be conveniently harvested from peripheral lymphocytes. It is also very useful in detecting oncoproteins in the body fluids of patients who have been exposed to carcinogens (De Vivo, 1994), as described in Chapter 74.

CYANIDE

The cyanide anion binds avidly to iron in the ferric or trivalent state. Because cyanide forms a relatively stable cyanoferric complex, it is able to inactivate iron-containing enzymes that cycle between the ferrous and

ferric states in oxidation–reduction reactions. Cyanide produces tissue and cellular hypoxia primarily by reversibly binding to cytochrome A3 and by inhibiting its reoxidation. This inhibits the electron transport system and prevents cellular respiration and ATP (high-energy phosphate) formation. This blockade prevents the utilization of oxygen and aerobic metabolism, producing severe metabolic (lactic) acidosis. Although cyanide binds preferentially to the ferric form of iron, it can also bind to the ferrous iron of hemoglobin, producing cyanohemoglobin, which cannot transport oxygen. Cyanide will form complexes with other iron-containing enzymes, but its acute poisonous effect is attributable to the inhibition of electron transport and cell death, predominantly in the CNS.

The principal symptoms of cyanide overdose are tachypnea (initially), followed by respiratory depression and cyanosis, hypotension, convulsions, and coma. Death may occur in a matter of minutes because cyanide is a fast-acting toxin. Diagnosis may be difficult, and a high index of suspicion is needed to make the correct diagnosis. Clues include the odor of bitter almonds, the occurrence of an altered mental status and tachypnea in the absence of cyanosis, and an unexplained metabolic acidosis (with an increased anion gap).

Antidotal therapy has been based on a two-step strategy: First, to pull the CN^- ions away from cytochrome A3, hemoglobin is converted to methemoglobin (Fe^{3+} state) by using specific oxidants (i.e., amyl nitrite and sodium nitrite). The former is given first because it can be inhaled. Methemoglobin directly competes with ferricytochrome A3 to form a methemoglobin- CN^- complex. This cyanomethemoglobin complex is relatively nontoxic. In a second step, sodium thiosulfate is given intravenously. This reagent reacts with cyanomethemoglobin to form thiocyanate, which is harmless and is excreted in urine. The first step is necessary simply to remove CN^- from the respiratory chain. Approximately 25%–40% of the patient's total hemoglobin is converted to methemoglobin in this step; this methemoglobin is rapidly reconverted to oxyhemoglobin by red cell enzymes. The antidotes that are involved in each step are sold commercially as a cyanide antidote package by Eli Lilly and Company (Indianapolis). Cyanide also binds tightly to cobalt ions, and hydroxocobalamin (a form of vitamin B_{12}) has recently been U.S. Federal Drug Administration approved as a cyanide antidote (Cyanokit, King Pharmaceuticals, Bristol, Tenn). It has the advantages of rapid onset of action and low toxicity at antidotal doses, making it suitable for prehospital administration to firefighters and others (Hall, 2009). Unfortunately, hydroxocobalamin has a different type of side effect that laboratorians need to be aware of, namely, that its deep red color can interfere in certain assays (Beckerman, 2009).

CARBON MONOXIDE

Carbon monoxide (CO) intoxication produces tissue hypoxia as a result of decreased oxygen transport. CO disrupts oxygen transport by binding to hemoglobin to form a reversible complex, carboxyhemoglobin (CO-Hb). It produces toxicity by decreasing or inhibiting oxyhemoglobin saturation by inducing a leftward shift of the oxyhemoglobin dissociation curve, causing a decrease in oxygen delivery to tissues, and by binding to other heme-containing proteins such as myoglobin and cytochrome A3 (Kao, 2006). Binding to cytochrome A3 inhibits cellular respiration and electron transport, as occurs with cyanide poisoning (see earlier), and binding to hemoglobin decreases the oxygen reserve available to cardiac and skeletal muscle, with cardiac muscle being more severely affected.

However, binding of CO to hemoglobin cannot explain all of its toxic effects. Exchange transfusion into dogs of compatible blood that contained 57%–64% CO-Hb—levels that are fatal—failed to induce any effect on the recipients (Goldbaum, 1975; Kao, 2006). The role of CO in inducing toxicity is therefore more complicated. In fact, numerous studies suggest that CO, in addition to its binding to hemoglobin and cytochrome A3, is involved in multiple other toxicity-inducing pathways. These include direct cellular toxicity caused by its binding to myoglobin, resulting in direct damage to skeletal and cardiac muscle. Further, it has been found that CO activates guanylyl cyclase in the CNS; this results in increased cyclic guanosine monophosphate that induces cerebral vasodilation and can cause loss of consciousness. CO also induces the synthesis of nitric oxide (NO), a potent vasodilator that causes large decreases in systemic blood pressure. CO-induced damage to CNS structures such as the basal ganglia, white matter, and hippocampus correlates with the degree of systemic hypotension that it induces. Abnormally elevated levels of NO appear also to cause oxidative damage to the brain, resulting in delayed neurologic sequelae (DNS). This effect may be due to the ability of NO to enhance the ability of neutrophils to adhere to the endothelium via

specific adherence molecules, such as β -2-integrin, which results in free-radical formation via activation of such enzymes as xanthine oxidase (Kao, 2006). These free-radicals are thought to cause the oxidation of brain lipids that may serve as a basis for the observed DNS (Kao, 2006). Animal studies have further revealed that cerebrovascular vasodilation is inhibited by NO inhibitors. In addition, in several animal studies, it has been found that CO induces changes in myelin basic protein (MBP) that may cause an immunologic reaction. This effect is obviated in rats that have been made immunologically tolerant to MBP before exposure to CO (Kao, 2006).

Because the brain and the heart are most susceptible to carbon monoxide poisoning, CO intoxication is commonly manifested through respiratory, neurologic, and cardiac symptoms, with dyspnea being a principal symptom. Others include headache, visual disturbances, tachycardia, syncope, tachypnea, coma, convulsions, and death. However, diagnosis is difficult because no pathognomonic sign occurs, except for a cherry red color of the face that is a strong clue to acute CO poisoning. However, this sign is not common in CO poisoning (Kao, 2006). Another problem is delayed neurologic symptoms that develop from days to months after apparent recovery. These include mental deterioration, mutism, memory impairment, gait disturbance, and urinary and fecal incontinence, which may be caused by NO-induced damage to CNS membrane lipids and cerebral vasodilation as discussed previously (Kao, 2006).

CO poisoning should enter into the differential diagnosis of an acute encephalopathic state in the appropriate circumstances or setting. Car exhaust fumes cause more than 70% of known CO poisoning, including attempted suicides and chronic incidental exposure (e.g., auto repair). In addition, exposure to house fires, indoor heaters, and stoves predisposes to CO toxicity.

A cooximeter is utilized to make the definitive diagnosis by measuring the concentration of blood CO-Hb. This instrument is a dedicated spectrophotometer that measures total hemoglobin and the percentages of CO-Hb, oxyhemoglobin, and methemoglobin by screening at four different wavelengths simultaneously. This accurate and rapid analysis is mandatory to establish the diagnosis and should be performed with minimal delay after CO exposure. CO may also be quantitated by gas chromatography or GC-MS. Treatment is mainly with 100% oxygen, in some cases under hyperbaric conditions, with additional supportive treatment given as necessary.

ALCOHOLS AND GLYCOLS

Ethanol

Ethanol (Table 23-8) is probably the most common drug of abuse and is frequently responsible for the presentation of patients with altered mental

TABLE 23-8

Influence of Acute Ethanol Ingestion on Ethanol Levels and Behavior

Ounces	Blood concentration	Influence
1–2	10–50 mg/dL (2.2–10.9 mmol/L)	None to mild euphoria
3–4	50–100 mg/dL (10.9–21.7 mmol/L or greater)	Mild influence on stereoscopic vision and dark adaptation
4–6	100 mg/dL (21.7 mmol/L)	Legally intoxicated
	100–150 mg/dL (21.7–32.6 mmol/L)	Euphoria; disappearance of inhibition; prolonged reaction time
6–7	150–200 mg/dL (32.6–43.4 mmol/L)	Moderately severe poisoning; reaction time greatly prolonged; loss of inhibition and slight disturbances in equilibrium and coordination
8–9	200–250 mg/dL (43.4–54.3 mmol/L)	Severe degree of poisoning; disturbances of equilibrium and coordination; retardation of the thought processes and clouding of consciousness
10–15	250–400 mg/dL (54.3–86.8 mmol/L)	Deep, possibly fatal, coma

status to hospitals and emergency rooms. Ethanol is rapidly absorbed from the gastrointestinal tract, has a volume of distribution approximately equal to that of total body water, and diffuses freely in body tissues. It is predominantly metabolized by hepatic alcohol dehydrogenase to acetaldehyde and acetic acid/acetyl coenzyme A and then, by way of the Krebs cycle, to carbon dioxide and water. The fatal dose is generally 300–400 mL of pure ethanol (600–800 mL of 100 proof whiskey) consumed in less than 1 hour. Peak plasma concentrations are usually reached within 1 hour after ingestion. Table 23-8 summarizes the effects of different levels of ethanol in serum on human function.

Ethanol acts as a sedative-hypnotic and depresses the CNS irregularly in descending order from cortex to medulla. Acute intoxication may be manifested by decreased inhibitions, incoordination, blurred vision, slurred speech, stupor, coma, seizures, and death. Most fatal intoxications occur at blood concentrations greater than 400 mg/dL. Capillary and arterial blood samples most accurately reflect brain ethanol concentrations. Serum ethanol concentrations are usually determined by enzymatic, gas chromatographic, or electrochemical oxidation techniques. In the most accurate assays for ethanol, serum is incubated with alcohol dehydrogenase, which oxidizes ethanol to acetaldehyde, and nicotinamide adenine dinucleotide (NAD) is converted to NADH (reduced form of NAD). Thus, simple monitoring of the absorbance of the incubated serum at 340 nm gives a direct determination of alcohol present. Acute poisoning is generally treated by supportive therapy, gastric lavage with tap water, or hemodialysis, if indicated (>500 mg/dL). Symptoms of chronic intoxication, such as acute alcoholic mania, may be treated with diazepam. Phenytoin may be utilized in patients with a history of seizures.

Methanol

Methanol (wood alcohol) poisoning occurs in patients who ingest methylated spirits or methanol-containing antifreeze. It is rapidly absorbed from the gastrointestinal tract and is metabolized and excreted at approximately 20% of the rate of ethanol. The toxic range is thought to be 60–250 mL, although as little as 15 mL has caused death. Alcohol dehydrogenase metabolizes methanol to formaldehyde and formic acid, which is responsible for ocular toxicity (diminished light sensation or frank blindness), and anion gap metabolic acidosis; these are the principal symptoms of intoxication. Other symptoms include nausea, vomiting, headache, seizures, and coma. GC-MS is used to measure blood methanol levels, with a peak level greater than 50 mg/dL considered toxic. In addition, serum osmolality levels are increased to levels greater than 300 mOsm. Methanol (or ethylene glycol) poisoning should be considered in acutely ill patients with hyperosmolality, metabolic acidosis, and increased anion gap.

Osmolal Gap

For methanol, ethylene glycol, and isopropyl alcohol poisoning, because the molecular masses of these simple compounds are low, relatively small quantities in serum give rise to high serum osmolalities. As discussed in Chapter 8, serum osmolality can be estimated as $\text{NaX}2 + \text{glucose}/18 + \text{blood urea nitrogen}/2.8$. This value should be close to the serum osmolality measured by freezing-point depression. If, however, any of these three compounds (or ethanol) is present in serum, the computed osmolality will be significantly less than the measured value (i.e., a so-called **osmolal gap** will exist), suggesting that a toxin is present. This is an effective screening method as a first step in detecting the presence of toxic compounds.

Ethylene Glycol

Ethylene glycol (1,2-ethanediol) is used in car radiator antifreeze. It has a half-life of around 3 hours and is metabolized to three major toxic compounds: glycolaldehyde, glycolic acid, and glyoxylic acid. The oxidation of ethylene glycol to glycolaldehyde is catalyzed by liver alcohol dehydrogenase. Both oxalic acid and formic acid are formed in smaller amounts. Oxalic acid itself is a highly toxic compound, which can rapidly precipitate as calcium oxalate crystals in various tissues as well as in urine. The formation of these crystals in urine, although not a constant finding, is an important diagnostic clue to ethylene glycol poisoning. The metabolite that accumulates in the highest concentrations in the blood is glycolic acid, and its concentration in blood and urine appears to correlate directly with symptoms and mortality. It is the major contributor to the high anion gap seen in metabolic acidosis. The fatal dose of ethylene glycol is around 100 g, and anuria and necrosis are the principal symptoms of acute poisoning. Other symptoms include nausea and vomiting, myoclonus, seizures, convulsions, depressed reflexes, and coma. Definitive diagnosis of ethylene glycol intoxication can be made by measuring serum ethylene glycol and glycolic acid by HPLC.

Treatment of ethylene glycol and methanol toxicity is similar and is based on symptoms and serum level. The mainstay of treatment is inhibition of the alcohol dehydrogenase enzyme, to minimize the formation of toxic metabolites, while the relatively nontoxic parent alcohol is eliminated renally. Although ethanol was originally used as a competitive inhibitor of alcohol dehydrogenase, the nonintoxicating agent fomepizole (4-methylpyrazole, Antizol, Paladin Labs, Montreal, Canada) is now generally preferred (Brent, 2009). Dialysis, either hemodialysis or peritoneal dialysis, is utilized to remove either parent compound and its corresponding toxic metabolic products.

Isopropyl alcohol has a half-life of approximately 3 hours and a volume of distribution similar to that of ethanol. It is readily absorbed through the GI tract and is metabolized at approximately 50% of the rate of ethanol. The metabolism of isopropanol occurs mainly by alcohol dehydrogenase to produce acetone, carbon dioxide, and water. The fatal dose of ingestion is 250 mL. Both isopropyl alcohol and its major metabolite, acetone, are CNS depressants.

CNS depression is the principal symptom of acute isopropanol intoxication. In addition, it produces significant GI irritation, which may be manifested by nausea and vomiting, including hematemesis and melena, abdominal pain, and gastritis. Other symptoms include confusion, coma, hypertension, respiratory failure, and death.

The diagnosis of isopropanol intoxication is difficult to make. Clues to the diagnosis include acetonuria, acetonemia and hyperosmolality without glycosuria, hyperglycemia, or acidosis. Gas chromatography is generally considered to be the best technique to determine isopropanol blood concentrations. Treatment includes supportive care, activated charcoal with gastric lavage, and hemodialysis in severe poisoning.

ARSENIC

Arsenic is used in ant poisons, rodenticides, herbicides and weed killers, insecticides, paints, wood preservatives, and ceramics, in the production of various metal alloys and livestock feed, as a tanning agent, and in medicines. Inorganic arsenicals, including sodium arsenate and lead or copper arsenite; organic arsenicals, such as carbarsone and tryparsamide; and arsine gas are the major toxicologic forms of arsenic. Arsine gas poisoning generally occurs in the industrial setting, where its production arises from the action of acid or water on arsenic-bearing metals. Arsenic compounds occur in three oxidation states: elemental, trivalent arsenite, and pentavalent arsenate.

Arsenic is readily absorbed through the GI tract and lungs, whereas absorption through the skin occurs more slowly. Twenty-four hours after ingestion, arsenic is distributed to all body tissues. The major route of excretion is through the kidneys. Arsenic can cross the placenta. The major concern with arsenic ingestion is systemic poisoning, presumably through its reversible interaction with multiple enzyme sulfhydryl groups. This, in turn, leads to the disruption of multiple metabolic systems. This phenomenon suggests that effective treatment of arsenic poisoning would be provided through administration of sulphydryl-containing compounds that would compete with those of proteins for binding to the different forms of arsenic, as discussed later.

Arsine gas, the most dangerous of the three forms of arsenic, may irreversibly attach to sulphydryl groups of hemoglobin, causing intravascular hemolysis, hemoglobinemia, and consequent acute renal failure, as well as direct nephrotoxicity. The acute fatal dosage of arsenic trioxide is approximately 120 mg, whereas less than 30 parts per million (ppm) of arsenic gas can produce poisoning. Organic arsenicals release arsenic slowly and have a fatal dose of approximately 0.1–0.5 g/kg.

Acute toxicity is usually manifested within the first hour of ingestion and generally reflects multiorgan involvement. Gastrointestinal symptoms are the most common presentation, with burning and dryness of the mouth and throat, difficulty in swallowing, vomiting, and watery or bloody diarrhea containing shreds of intestinal lining or mucus. The odor of garlic may be on the breath, and a metallic taste in the patient's mouth. Cyanosis, hypotension, tachycardia, and ventricular arrhythmias may develop. Neuropathy usually occurs late (approximately 1–2 weeks) after ingestion, or may become most intense during this time period. Severe volume depletion with resulting hypovolemic shock and acute renal tubular necrosis may occur, with death resulting from circulatory failure. Cutaneous manifestations of arsenic poisoning include hyperpigmentation of the skin and keratosis. The nail beds can show transverse white striations, called **Mees lines**, although this is not specific for arsenic poisoning (Ibrahim, 2006). Symptoms of poisoning with arsine gas usually manifest approximately 2–24 hours after exposure and may initially include nausea and vomiting,

headache, anorexia, and paresthesias. Hematemesis and abdominal pain are also common, and acute renal failure, cardiac damage, anemia and hemolysis, or pulmonary edema may occur. The diagnosis of chronic intoxication is usually difficult and should be considered in patients with a combination of GI symptoms, neuropathy, and cutaneous, cardiovascular, and renal disturbances.

Analysis of urine, hair, and nails, using ion emission spectroscopy, is important for the diagnosis of chronic arsenic poisoning.

Treatment of acute poisoning includes removal of residual arsenic by gastric lavage or emesis, and treatment with dimercaprol, or British anti-lewisite (BAL), which combines with arsenic through its sulfhydryl groups to produce cyclic water-soluble complexes. However, the inherent toxicity of this compound limits its therapeutic usefulness. Less toxic derivatives of BAL are available, such as 2,3-dithioerythritol, which is less toxic in cell culture but shows greater efficacy than BAL at rescuing arsenic-poisoned cells in culture (Boyd, 1989). In severe poisoning, hemodialysis can be used to remove the arsenic-dimercaprol complexes.

MERCURY

Mercury compounds exist in four different forms with different toxicologic potential: elemental or metallic (Hg^0); mercurous (Hg^+); mercuric (Hg^{2+}); and alkyl mercury (i.e., organomercurials). Elemental mercury is poorly absorbed from the GI tract if mucosal integrity is preserved and shows no toxic effect unless it is converted to the divalent form. This may occur slowly by oxidation-reduction with water and chloride ion if a GI site for mercury stasis exists, but this is uncommon. Significant poisoning occurs with elemental mercury when it is inhaled or absorbed through the skin. It can pass through the blood-brain barrier and can accumulate in the CNS, where oxidation produces mercuric ion; thus, primarily pulmonary and CNS toxicities are produced.

Of the two inorganic salts of mercury, mercurous (Hg^+) salts are poorly soluble and thus poorly absorbed. However, the mercuric (Hg^{2+}) salt is readily soluble and is readily absorbed after oral ingestion or inhalation. Severe inflammation of the mouth and other GI symptoms can result. The kidney is a preferred site of accumulation of inorganic mercuric compounds, where acute renal tubular and glomerular damage can ensue. Both elemental mercury and the inorganic mercury compounds are excreted mainly in urine.

In contrast to elemental and inorganic mercury, organic mercury compounds, containing alkyl, aryl, and alkoxyalkyl moieties, are environmental pollutants. These compounds contain at least one covalent mercury-carbon bond. Both the alkoxyalkyl and aryl mercurial compounds undergo metabolic breakdown and biotransformation to produce inorganic mercury, which toxicologically acts and manifests intoxication as would the previously mentioned inorganic mercury compounds. In contrast, the mercury-carbon bonds that occur within the methyl and ethyl forms are extremely stable and produce greater toxicity than the aryl and alkoxyalkyl forms. The alkyl forms are more lipid soluble, pass readily through biological membranes, and, on ingestion, show generally greater absorption into the body. Their major chemical effect is on the CNS, and they show a biological half-life of 70–90 days. A devastating effect of methylmercury, known as congenital Minamata disease, has been described in Japan in the children of mothers who were exposed to methylmercury who were born with many of the stigmata of cerebral palsy (Ibrahim, 2006).

Because bile is the major route of excretion, methylmercury can be reabsorbed into the blood, via the enterohepatic system, accounting, in part, for its extended half-life. The major mechanism of action of mercury poisoning is through covalent bonding with protein sulfhydryl groups, producing widespread and nonspecific enzyme dysfunction, inactivation, and denaturation. Mercury inhibits the enzyme catecholamine-O-methyltransferase, a major enzyme in the metabolism of catecholamines, especially epinephrine and norepinephrine (see Chapter 24), resulting in hypertension, tachycardia, and sweating (Ibrahim, 2006). Thus mercury poisoning can masquerade as a pheochromocytoma, which should be ruled out by performing 24-hour urine catecholamine determination (see Chapter 24). At the same time, blood mercury levels should be determined (reference range $<10 \mu\text{g/L}$). Unfortunately, the usefulness of this testing is limited by the short half-life of mercury in the blood.

Mercury, depending on its form, may cause systemic toxicity or local skin and mucous membrane lesions. Both organic and elemental mercury can cause CNS effects, whereas GI symptoms primarily occur with inorganic salts. Elemental mercury may produce severe pulmonary reactions. Chronic exposure to elemental mercury can give rise to two syndromes: acrodynia and erethism (Ibrahim, 2006). Acrodynia, also called **pink**

disease, **Feer-Swift disease**, and **Feer syndrome**, occurs mainly in children but can also occur in adults, and involves a complex of symptoms that include a desquamating, erythematous rash of the palms and soles, sweating, hypertension, tachycardia, pruritus, poor muscle tone, and weakness of the proximal pelvic girdle. Erithism is a complex of neurologic symptoms that include, most prominently, personality changes involving memory loss, drowsiness, withdrawal, depression, and irritability. A fine motor intention tremor of the hands also occurs. Inorganic mercury can induce severe renal tubular damage, especially in the proximal tubule; chronic exposure can cause membranous glomerulonephritis and nephrotic syndrome (Ibrahim, 2006).

In general, acute toxicity, with elemental, inorganic, or most organic forms, can be diagnosed from 24-hour urine levels. Blood levels may rise rapidly after acute exposure, but fall rapidly and may not reflect total body burden. In contrast, because the short-chain alkyl organic mercuric compounds are mainly excreted in the bile, blood levels are better indicators of tissue levels and significant acute exposure. Hair analysis for mercury may help identify chronic mercury exposure, especially with organic mercury.

Treatment includes gastric lavage or emesis to remove the ingested poison, as well as the use of dimercaprol and succimer. However, in methylmercury and alkylmercury poisoning, dimercaprol is contraindicated because it has been found to increase the concentrations of these compounds in the brain (Bryson, 1989). In these cases, treatment is symptomatic, although new agents are being evaluated clinically.

IRON

Acute iron poisoning is common in young children and is usually the result of ingestion of iron-containing products. Generally, iron overload that causes increased deposition of iron in tissues is termed hemosiderosis; if the excess iron induces tissue damage, the condition is termed hemochromatosis. Hemochromatosis can be inherited or acquired. Acquired hemochromatosis is caused by overingestion of iron or by leakage of iron from red blood cells, as may occur in a hemolytic crisis. Although ferric ions from food are usually reduced to ferrous ions and absorbed in the stomach, the large and small bowel can rapidly absorb toxic amounts ($>30 \text{ mg/kg}$) of elemental iron. Once absorbed into the body, iron removal is difficult. Large doses of iron are thought to cause acute mucosal cell damage, and significant absorption of iron occurs once the binding capacity of transferrin is exceeded. Unbound iron in serum causes toxicity by hepatic cell damage, shock, and production of lactic acidosis. The hepatotoxicity seems to be dose related, occurs within 1–2 days of ingestion, and has been associated with levels equal to or greater than $1700 \mu\text{g/dL}$ (Tenenbein, 2001).

Iron absorption is tightly regulated by the HFE gene-encoded protein that is expressed mainly on hepatocytes and on epithelial cells in the gastrointestinal tract. This protein interacts with another protein synthesized in the liver called **hepcidin**. In addition, HFE protein interacts with transferrin receptors. In inherited or primary hemochromatosis, sometimes associated with other diseases such as type 2 diabetes (Davis, 2008), mutations in the *HFE* gene that result in single amino acid substitutions at critical positions in the amino acid sequence, such as cysteine-to-tyrosine 282 (C282Y) and histidine-to-aspartic acid 63 (H63D), cause this protein to fail to regulate iron absorption in the gut, resulting in iron overload. The occurrence of hereditary hemochromatosis is on the order of 1 per 200–300 individuals, making this condition important as a cause of iron overload. Recent studies have further determined that patients who have received more than 10 transfusions with packed red blood cells are at risk for developing acquired hemochromatosis (Takatoku, 2007).

Assays for Serum Iron

Iron can be determined by specialized techniques for trace elements such as atomic absorption spectrophotometry, but in the modern clinical laboratory setting, it is almost always measured using a colorimetric indicator such as ferrozine. The Fe^{2+} -ferrozine complex has an intense purple color (absorption maximum, 562 nm), and other metal ions generally do not interfere, with the possible exception of copper, whose effects can be minimized through addition of thiourea. It is necessary to use a reagent such as acid or detergent to release the serum iron from transferrin, and another reagent such as ascorbate to reduce iron to the ferrous state.

Iron-Binding Capacity

Normally all iron present in serum is bound to the iron-transporting protein, transferrin, which contains two iron-binding sites per transferrin molecule. In evaluating iron poisoning, it is important to measure

iron-binding capacity, because toxicity will drastically increase as that capacity is exceeded. To obtain the total iron-binding capacity (TIBC), saturating concentrations of iron are added to a serum sample, excess iron is removed, for example, by adsorption with MgCO_3 , and iron is remeasured. Alternatively, the amount of excess iron can be measured, and subtraction from the concentration of iron added gives the unsaturated iron-binding capacity.

Signs of Iron Intoxication

Vomiting appears to be an early manifestation of iron intoxication, along with severe gastroenteritis, melena, abdominal pain, and hematemesis. This occurs up to 6 hours after ingestion. For up to the next 10 hours, the patient may appear to improve. This is deceptive because manifestations of systemic toxicity (cyanosis, convulsions, shock, coagulopathy, renal and hepatic failure) may occur, producing death. Patients who develop severe systemic symptoms and those who do not may develop late complications, including GI obstruction or stricture.

Definitive diagnosis is made with measurements of serum iron concentration and TIBC. In addition to supportive treatment, emesis or gastric lavage is used to prevent iron absorption. Chelation therapy with deferoxamine is also utilized if the acute intoxication is severe.

LEAD

Both organic and inorganic compounds of lead may be highly toxic, with their most serious effects occurring in the central and peripheral nervous systems. Absorption may occur by inhalation or ingestion. If more than 0.5 mg of lead is absorbed per day, lead accumulation and toxicity are believed to occur, whereas 0.5 g of absorbed lead is considered a fatal dose. However, acute toxicity is uncommon and is generally observed in patients who have been exposed to high concentrations of lead dusts. Lead poisoning is seen in children in large cities who consume lead in the form of paint (pica). Acute manifestations are primarily CNS symptoms (encephalopathy, convulsions, stupor) and GI symptoms such as colic. Chronic toxicity with lead accumulating in blood, soft tissues, and bone is more common. The largest body compartment of lead is bone, which contains approximately 96% of the total body burden. The half-life of lead in bone is 32 years, and bone may act as a reservoir for endogenous intoxication. Chronic toxicity may be manifested by a wide range of systemic effects, including general malaise, weight loss, anorexia, and constipation; lead encephalopathy exhibited by malaise with apathy, drowsiness, stupor, and seizures; peripheral neuropathy with wrist drop or foot drop; and lead nephrosis with albuminuria, hematuria, and pyuria and anemia (hypochromic, microcytic, or normocytic) with basophilic stippling—the latter finding often a strong clue.

In addition, lead-induced pathologic changes may occur at even low levels of lead exposure. Needleman and Gatsonis (1990) reviewed 24 studies of childhood lead exposure to provide statistical evidence that low doses of lead may produce an intellectual deficit in children. However, the association of increased lead levels with decreased IQ has been called into question by the presence of confounding factors (Ibrahim, 2006). Schwartz and colleagues (1990) examined lead-induced anemia in children 1–5 years of age, using a cross-sectional epidemiologic study. They found a relationship between age, blood lead level, and hematocrit such that younger children had an increased risk of anemia at lower blood levels than children only a few years older. It thus appears that lead may produce deleterious effects, especially in children, at low levels of exposure. Generally, blood lead levels greater than or equal to 10 $\mu\text{g}/\text{dL}$ indicate excessive lead absorption in children, and concentrations greater than 25 $\mu\text{g}/\text{dL}$ indicate consideration of chelation therapy in the child. Several more recent studies suggest that no neurologic benefit is derived from chelation therapy among children with blood lead levels between 20 and 44 $\mu\text{g}/\text{dL}$ (Ibrahim, 2006). The Centers for Disease Control and Prevention recommends universal screening of children, beginning at 6 months of age (Klaassen, 2001; Bernard, 2003).

Organolead compounds such as tetraethyl and tetramethyl lead are lipid soluble and, similar to the organomercurials discussed previously, produce their major toxic effects on the CNS. Lead encephalopathy may occur early in the onset of intoxication and does not correlate well with blood lead concentrations. Hyperactive deep tendon reflexes, intention tremor, abnormal jaw jerk, and abnormalities of stance and gait are the most consistently observed neurologic manifestations of organolead toxicity.

Lead appears to interact with thiol, carboxylic, and phosphate groups to form stable complexes with enzymes and proteins (Bryson, 1989). This

is particularly well known for heme synthesis, in which lead blocks the action of δ -aminolevulinic acid (ALA) synthetase, δ -ALA dehydratase (ALAD), coproporphyrinogen decarboxylase, and ferrochelatase, producing anemia. In addition, lead blocks two other enzymes—pyrimidine-5'-nucleotidase and Na-K-dependent ATPase, resulting in diminished energy supply for red blood cells, leading to decreased cell membrane integrity. Because pyrimidine-5'-nucleotidase is required for removal of clumped intracellular RNA, lead inhibition of this enzyme results in clumping of RNA complexes, giving rise to the observed basophilic stippling of red blood cells (Ibrahim, 2006). Lead-induced disruptions in heme synthesis allow for objective testing for inorganic lead exposure. Increased amounts of ALA in urine, decreased ALAD activity in red blood cells, increased amounts of free erythrocyte protoporphyrin, and elevated amounts of zinc protoporphyrin are found with inorganic lead poisoning. The assay for zinc protoporphyrin is a particularly simple fluorometric one that is widely used and is an excellent screening test for frank lead toxicity, but the test is not sensitive to the low blood lead levels now regarded as harmful. The most sensitive screening test for organolead poisoning is decreased ALAD activity in urine because changes in the activities of other enzymes and in the levels of the products of heme synthesis are not consistent. Although whole blood lead concentrations are a reliable indicator of recent lead exposure, the short half-life of circulating lead in blood makes estimates of total body burden unreliable. However, use of *in vivo* X-ray fluorescence of bone allows determination of cumulative lead burden (Kosnett, 1994). Treatment of poisoning includes supportive therapy as well as removal of soluble lead compounds by gastric lavage. Dilute magnesium sulfate or sodium sulfate solutions are commonly used. In addition, chelating agents such as dimercaprol, calcium disodium edetate, and succimer may be utilized, if necessary.

Quantitation of Lead in Blood

Unlike many other toxins, lead is generally measured in whole blood rather than in serum or plasma, because most of the circulating lead is bound within the blood cells. Lead levels may be determined directly using atomic absorption spectroscopy, inductively coupled plasma/mass spectrometry (ICP/MS), or anode stripping voltammetry (ASV). In ICP/MS, a very hot source (the “inductively coupled plasma”) atomizes the blood sample so that individual elements can be injected into and quantified by the mass spectrometer. In ASV, a voltaic cell is set up such that the anode consists of a mercury-coated graphite rod. When a negative potential is applied to this anode, cationic metals, such as lead, “plate out” in their metallic forms on the anode. The applied voltage is then stopped. Because an excess of electrons is present on the anode, current will flow to the cathode. Each of the metals plated on the anode therefore will become oxidized back to their respective ionic forms (i.e., be stripped from the anode). The metals with lowest oxidation potentials will strip first. Each metal will strip from the anode in the order of oxidation potential, recorded as the half-wave potential, which is a constant for a given metal. The total current associated with the stripping of each metal is proportional to the concentration of that metal.

ORGANOPHOSPHATES AND CARBAMATES

Pesticides generally contain organophosphates, which are esters of phosphoric acid or thiophosphoric acid, or carbamates, which are synthetic derivatives of carbamic acid. Although these are two distinctly different types of compounds, they both unfortunately interfere with neurotransmission. Both compounds inhibit the enzyme acetylcholinesterase (AChE), which normally hydrolyzes the neurotransmitter acetylcholine (ACh) after ACh has effected an action potential and has been released from its receptor site (see Chapter 20). Both compounds produce inhibition by reacting with the active site of AChE. This occurs by phosphorylation with the organophosphates to produce a relatively stable phosphate ester bond, and by carbamoylation with the carbamates to form a more labile, and hence more easily reversible, carbamate ester bond. Both compounds thus cause accumulation of ACh at neuronal synapses and myoneural junctions to produce toxicity.

ACh is an important neurotransmitter in both the peripheral and central nervous systems. It is located at a number of different synapses in the CNS, at ganglionic synapses between the sympathetic and parasympathetic preganglionic and postganglionic fibers, at junctions between parasympathetic postganglionic fibers and effector organs, and at junctions between somatic motor neurons and skeletal muscle cells. Thus, signs and symptoms of organophosphate poisoning include parasympathetic manifestations such as salivation, lacrimation, urination, and defecation;

pupillary constriction; bradycardia; and bronchoconstriction, which may predominate at low-dose poisoning. Autonomic ganglionic and somatic motor manifestations (such as muscular weakness, twitching, areflexia, tachycardia, and hypertension) and CNS manifestations (such as confusion, slurred speech, ataxia, convulsions, and respiratory and/or cardiovascular center depression) may predominate in severe intoxication. Death usually results from respiratory failure as the result of a combination of central depression, bronchospasm, excessive bronchial secretions, and respiratory muscle paralysis.

Morbidity and mortality due to carbamate poisoning are less severe because carbamates do not penetrate the CNS as effectively as organophosphates, and central cholinergic effects are thus minimal. In addition, the much greater lability of the carbamate ester bond allows spontaneous reactivation of AChE. This, in turn, decreases the slope of the toxicity dose-response curve, as compared with that of the curve for organophosphates, such that small increments in carbamate dose are less likely to produce severe increases in toxicity.

In addition to acute poisoning, organophosphates may produce an intermediate syndrome occurring 1–4 days after poisoning, and/or delayed neurotoxicity usually occurring 2–5 weeks after acute exposure. The former syndrome develops after acute cholinergic crisis and appears to involve cranial nerve palsies, proximal limb weakness, and respiratory paralysis, with the patient requiring ventilatory support (Senanayake, 1987, 1998). In contrast, delayed neurotoxicity, which is not seen with all organophosphate compounds, appears to be due to neurotoxic esterase inhibition and usually produces a distal and symmetric sensorimotor polyneuropathy of the extremities (Davies, 1987; Tafuri, 1987).

Diagnosis of organophosphate poisoning depends on a history of exposure shortly before the onset of illness, signs and symptoms of diffuse parasympathetic stimulation, and laboratory confirmation of exposure by measurement of erythrocyte acetylcholinesterase and plasma

pseudocholinesterase activities (see Chapter 20). Whereas AChE is found primarily in nervous tissue and erythrocytes, pseudocholinesterase is found in plasma. The latter enzyme is much more nonspecific in its action than AChE, in that, in addition to hydrolysis of ACh, pseudocholinesterase can hydrolyze many other natural and synthetic esters, as described in Chapter 20. Both activities may be decreased, and both activities can be measured in the laboratory. However, only inhibition of AChE is considered specific for organophosphate poisoning because a number of conditions may produce a low plasma pseudocholinesterase level (Tafuri, 1987). Thus, the latter measurement is more sensitive but less specific than the red blood cell cholinesterase level for organophosphate poisoning. Generally, levels 30%–50% of normal indicate exposure, and toxic manifestations occur with greater than 50% inhibition; however, symptoms may not appear until levels are 20% or less of normal. In actuality, confirmation of poisoning, rather than diagnosis, occurs by laboratory determinations. Because baseline values of cholinesterase levels before exposure are unlikely to be available, sequential postexposure cholinesterase determinations appear to be the best way to confirm organophosphate poisoning (Coye, 1987).

Treatment of acute poisoning includes respiratory support and, if necessary, decontamination of the patient and gastric lavage or emesis. Administration of activated charcoal appears not to be effective in removing the toxic agent (Eddleston, 2008). In the presence of symptoms, atropine is given to ameliorate excessive parasympathetic stimulation by competitively blocking the action of ACh at muscarinic receptors. Pralidoxime is also given as a specific antidote for organophosphate poisoning. If pralidoxime is given within 24–48 hours of exposure, it may reactivate phosphorylated cholinesterase by removing the covalently bound phosphate group from the enzyme's active site. However, this time period is variable, and utilization of pralidoxime after 48 hours may be indicated (Clark, 2006; Howland, 2002). Chronic poisoning is usually treated by avoidance of further exposure until cholinesterase levels become normal.

SELECTED REFERENCES, 401**KEY POINTS**

- The endocrine system is a finely integrated system whereby the hypothalamus, the pituitary, and target glands continually communicate through feedback inhibition and stimulation to control all aspects of metabolism, growth, and reproduction. By understanding this interplay, and carefully manipulating these systems via provocative and suppressive stimuli, it is possible to characterize an underlying abnormality and provide directed treatment.
- Prolactin levels can be elevated as the result of a variety of pharmacologic and physiologic stimuli; however, values greater than 200 ng/mL are almost always associated with the presence of a pituitary tumor.
- The initial screen for someone suspected of having acromegaly should be a serum insulin-like growth factor-I.
- It is often unnecessary to perform provocative stimulation tests to document growth hormone deficiency in patients with a known history of pituitary disease or in those with evidence of three or more pituitary hormone deficiencies.
- Provided the hypothalamic-pituitary-thyroid axis is intact, the ultrasensitive thyroid-stimulating hormone test is the best method for detecting clinically significant thyroid dysfunction.
- When measuring thyroglobulin as a tumor marker for thyroid cancer, always check a simultaneous sample for thyroglobulin antibodies.
- The chromatographic measurement of plasma free metanephrines and normetanephrines is the best screening test for pheochromocytoma. The patient should avoid caffeine, alcohol and acetaminophen, monoamine oxidase inhibitors, and tricyclic antidepressants for at least 5 days before testing.

- It is frequently unnecessary to perform an adrenocorticotrophic hormone stimulation test in critically ill patients. A random cortisol of greater than 25 µg/dL (700 nmol/L) during stress makes it highly unlikely that the patient is adrenally insufficient.
- The measurement of day 2–3 follicle-stimulating hormone is a good indicator of follicular reserve; a day 21–22 progesterone is used to assess whether cycles are ovulatory.

PITUITARY

The endocrine system is a finely tuned servo-system in which the hypothalamus, the pituitary, and various endocrine glands communicate through an intricate scheme of feedback inhibition and stimulation. In the classic sense, a hormone is defined as a substance that acts at a site distant from its place of origin. Under the rubric of hormones, we now include moieties that act in an autocrine (act directly upon themselves), paracrine (act adjacent to the cells of origin), or intracrine (act within the cells of origin without ever exiting the cells) fashion. It is through this intimate interplay of signals that the endocrine system serves to control metabolism, growth, fertility, and responses to stress.

The pituitary gland, also known as the hypophysis, is located within the confines of the sella turcica; it is connected by the infundibular stalk to the median eminence of the hypothalamus. It is divided into an anterior lobe (adenohypophysis) and a posterior lobe (neurohypophysis). It weighs about 0.6 g and measures about 12 mm in transverse and 8 mm in antero-posterior diameter. The anterior pituitary possesses five distinct hormone-synthesizing and -secreting populations of cells. These cell groups include somatotrophs, which secrete growth hormone (GH); lactotrophs, which secrete prolactin (PRL); thyrotrophs, which secrete thyroid-stimulating hormone (TSH); gonadotrophs, which secrete the α and β subunits of

follicle-stimulating hormone (FSH) and luteinizing hormone (LH); and corticotrophs, which secrete proopiomelanocortin (POMC). POMC is cleaved within the pituitary to form adrenocorticotropin (ACTH), β -endorphin, and β -lipotropin (β -LPH). The hypothalamus communicates with the anterior pituitary by secreting its own set of trophic hormones that are specific for each of the cell populations. (Fig. 24-1). These trophic hormones travel along the infundibular stalk to the adenohypophysis through a system of portal vessels.

In contrast to the anterior pituitary, the posterior pituitary (neurohypophysis) does not synthesize hormones. The hormones that it does secrete, arginine vasopressin (AVP; also known as antidiuretic hormone [ADH]) and oxytocin, are synthesized in the magnocellular neurons of the paraventricular and supraoptic nuclei of the hypothalamus, transported along the axons, and stored in the nerve terminals that end in the neurohypophysis. A summary of the different hormones secreted by the pituitary can be found in Table 24-1.

Abnormalities of pituitary function fall within two broad categories: hormonal excess and hormonal deficiency. Hormonal excess usually occurs as the result of clonal expansion of a distinct population of cells; however, it can result from an increase in trophic hormones from the hypothalamus or ectopic sites. The causes of hormonal deficiency are more varied (Table 24-2) and can result in the deficiency of one or more hormones, often with continued and progressive loss of other hormones over time.

PITUITARY TUMORS

Pituitary tumors may be classified as microadenomas (<1 cm in greatest diameter and confined to the sella) or macroadenomas (\geq 1 cm in greatest

diameter). They are further subcategorized into secretory and nonsecretory varieties (Table 24-3). All tumors have the potential to grow; in doing so, they can compress the optic chiasm, resulting in visual field defects, of which bitemporal hemianopia is the most frequent presentation. Invasion into the cavernous sinus can lead to compression of cranial nerves III, IV, VI, V1, and V2 and the intracavernous portion of the internal carotid artery. It can also lead to hydrocephalus caused by obstruction of the third ventricle. Aside from oversecretion of a particular hormone and extension

into surrounding regions, these tumors can also cause hormonal deficiency due to compression of other cell lineages within the pituitary.

PROLACTIN

PRL is a polypeptide produced by the lactotrophs of the pituitary; it is responsible for the initiation and maintenance of lactation. Its secretion is normally kept at low levels by the inhibitory actions of dopamine produced by the hypothalamus. Similar to several pituitary hormones, PRL is secreted in a circadian fashion, with the highest levels attained during sleep and a nadir occurring between 10 AM and noon (Sassin, 1972). PRL is secreted in a pulsatile fashion, the amplitude and frequency of which not only vary throughout the day but are influenced by a variety of physiologic stimuli (e.g., stress, postprandially, exercise). Because of these factors and a serum half-life of 26–47 minutes, it is recommended that when a patient is screened for hyperprolactinemia, three specimens should be obtained at 20- to 30-minute intervals. These samples can be analyzed separately and their results averaged, or, alternatively, an equal aliquot from each sample can be pooled into one final sample that is then analyzed. PRL is measured by immunometric assay.

The major circulating form of PRL is the nonglycosylated monomer. A number of other forms can occur, including “big” PRL and macroprolactin (“big, big” PRL), which is considered to be PRL coupled with immunoglobulin (Yazigi, 1997; Conner, 1998). Because these forms all react with the immunoassays, they can produce falsely high PRL results in patients in whom pathologic elevation of PRL is not supported by computed tomography (CT) or magnetic resonance imaging (MRI). Various analytic methods have been developed to eliminate this confusion, including the performance of immunoassay following polyethylene glycol

extraction and centrifugal ultrafiltration (Diver, 2001; Amadori, 2003; Fahie-Wilson, 2003; Prazeres, 2003; Suliman, 2003; Toldy, 2003).

In some instances of prolactinoma, the values of PRL may be falsely low or minimally elevated considering the size of the tumor. Usually only a single dilution is performed when assaying for PRL, and extremely high concentrations can saturate the antibody binding sites, resulting in a falsely low result (Barkan, 1998; Petakov, 1998). This “hook” effect may result in misdiagnosis of the patient as having a nonfunctioning chromophobe adenoma. If the pretest probability of the patient having a macroprolactinoma is high, it is recommended that the serum sample be subjected to at least a 1:100 dilution.

PRL acts on breast tissue, where, in the setting of estrogen priming, it stimulates lactation. PRL also acts at the hypothalamus to inhibit the secretion of gonadotropin-releasing hormone (GnRH). Inhibition of GnRH results in a decrease in the release of LH and FSH from the anterior pituitary. In females, this leads to a decrease in estrogen and progesterone synthesis and secretion by the ovaries and failure of ovarian follicular maturation (ovulation). In males, a deficiency of FSH and LH causes a decrease in testicular production and synthesis of testosterone and a halt in spermatogenesis. In addition, it has been suggested that hyperprolactinemia may stimulate adrenal androgen production and may have an effect on immune responsiveness (Lobo, 1980; Walker, 1993).

The reference value for serum PRL is 1–25 ng/mL (1–25 μ g/L) for women and 1–20 ng/mL (1–20 μ g/L) for men. The higher PRL levels seen in females begin postpuberty and are presumably due to the stimulatory effect of estrogen (Eastman, 1996). During pregnancy, a progressive rise in serum PRL is observed, with levels reportedly reaching as high as 500 ng/mL by the third trimester (Rigg, 1977). This is largely due to an increase in the number of PRL-secreting cells and can be associated with a doubling or even greater increase in pituitary gland size (Scheithauer, 1990). PRL levels fall back to baseline about 3 weeks postpartum in women who are not breastfeeding. In nursing mothers, basal PRL levels remain moderately elevated, with episodic bursts in secretion in response to suckling.

PRL levels are increased by many physiologic and pathologic factors, as well as by a wide variety of medications (Table 24-4). Elevations in PRL resulting from physiologic and pharmacologic stimuli rarely exceed 200 ng/mL.

PRL deficiency can be seen with pituitary necrosis or infarction and in some cases of pseudohypoparathyroidism. In women with complete PRL

deficiency, menstrual disorders and infertility have been found (Kauppila, 1997). It is PRL excess that is associated with clinical pathology. Hyperprolactinemia leads to inhibition of GnRH secretion, which typically manifests as sexual dysfunction and infertility in both men and women. Women may present with luteal phase abnormalities, oligomenorrhea, or frank amenorrhea, with or without galactorrhea. Men will present with hypoandrogenemia, decreased libido, and impotence. Pituitary adenomas are an important cause of hyperprolactinemia; however, any sellar or parasellar process that compresses the pituitary stalk and interrupts the tonic delivery of dopamine can lead to disinhibition of PRL secretion. Usually, the height of elevation of serum PRL levels correlates with the likelihood of the presence of a pituitary tumor, and levels of PRL in excess of 200 ng/mL almost always signify the presence of a prolactinoma (Kleinberg, 1977; Frantz, 1998; Freda, 1999). Unlike other functioning pituitary tumors, the degree of elevation of PRL correlates fairly well with the size of the tumor.

Hyperprolactinemia exists in 20%–40% of patients with acromegaly; this may be due to the presence of a mixed tumor (containing both lactotrophs and somatotrophs) or to interference with the normally active, PRL-inhibitory mechanisms (e.g., interruption of dopamine delivery owing to stalk compression by a tumor, resulting in disinhibition of prolactin secretion). Another important cause of hyperprolactinemia is hypothyroidism. Thyrotropin-releasing hormone (TRH) not only stimulates TSH secretion, but it also stimulates PRL secretion, thus explaining the mild hyperprolactinemia seen in both primary (thyroid) and secondary (pituitary) hypothyroidism. Therefore, thyroid function tests (free thyroxine [FT₄] and TSH) are always indicated to rule out hypothyroidism when a patient with hyperprolactinemia is evaluated. Thyroid hormone replacement therapy will usually return the PRL to normal.

It is important to evaluate all patients discovered to have an abnormally elevated PRL. Since hyperprolactinemia can be found in upward of 40% of cases of acromegaly, it is appropriate to measure insulin-like growth factor (IGF)-I. Other hormones that may be assayed include FSH, LH, free testosterone, estradiol, and, if clinically indicated, tests of adrenal axis function. Rarely, hyperprolactinemia may be caused by ectopic hormone production. All patients should undergo CT or MRI of the sella, performed with and without contrast. MRI provides better contrast and anatomic detail and is better for visualizing microadenomas. A formal visual field examination is also a key monitoring tool in managing patients with pituitary tumors and should be done at least yearly in patients with stable disease.

GROWTH HORMONE

GH is a single-chain polypeptide of 191 amino acids synthesized, stored, and secreted by the somatotrophs of the pituitary in response to the secretion of growth hormone–releasing hormone (GHRH) by the hypothalamus. Somatostatin, also produced by the hypothalamus, inhibits GH release. Although evidence exists for the direct action of GH on long bone growth in children, most of its anabolic and metabolic actions are mediated indirectly through an intermediary, IGF-I (also called **somatomedin C**). IGF-I is synthesized in the liver and in certain target tissues, in response to stimulation by GH. IGF-I circulates in the blood complexed to IGF-binding proteins (IGF-BPs); IGF-BP3 is the predominant circulating species. As with all hormones, it is the free, unbound form that is biologically active. Like somatostatin, IGF-I negatively feeds back on the pituitary to inhibit GH secretion.

GH is secreted in a pulsatile fashion; the frequency and amplitude of the peaks are greatest during puberty, exhibiting a steady decline with increasing age (Casanueva, 1992). As up to 70% of GH secretion occurs during stage 4 (slow wave) sleep, it has been suggested that the age-related decline in stage 4 sleep may account for the decline in GH seen with aging (Van Cauter, 1998, 2000). In addition to GHRH and somatostatin, several other factors regularly mediate GH secretion (Fig. 24-2). Major stress (e.g., surgery, sepsis), fasting, sex steroids, chronic malnutrition, apomorphine, levodopa, and high-protein meals all stimulate GH secretion. Women tend to have higher GH levels than men, perhaps because of estrogen sensitization of the hypothalamus to other GH stimuli (Eastman, 1996).

Serum GH is undetectable for most of the day in healthy, nonstressed individuals. This fact along with the episodic nature of GH secretion makes a single sampling difficult to interpret. As a result, the diagnosis of GH deficiency is made using GH measurements following pharmacologic stimulation, and GH excess is confirmed by failure of GH suppression following an oral glucose load. GH is commonly measured by chemiluminescent immunoassay.

Somatostatin is synthesized in the paraventricular and arcuate nuclei of the hypothalamus. It inhibits GH and TSH secretion. It also inhibits

the secretion of insulin and several gut hormones (e.g., motilin, secretin, gastrin). Ghrelin, a 28 amino acid peptide produced by the gastric neuroendocrine cells and the hypothalamus, binds to the GH secretagogue receptor to stimulate the secretion of GHRH and GH.

Growth Hormone Deficiency

Idiopathic growth hormone deficiency is the most common cause of GH deficiency (GHD) in children, whereas a pituitary adenoma is the most common etiology in adult-onset GHD. No simple, reproducible method for determining abnormal GH secretory patterns exists. In healthy normal individuals, 70%–80% of GH results are below 1 ng/mL (<1 µg/L), and secretory peaks typically reach 20–40 ng/mL (20–40 g/L) (Baumann, 1987). Thus, in a child with decreased growth velocity, a low or nondetectable GH does not necessarily indicate GHD. Similar to GH, IGF-I declines with age. IGF-I is more diagnostically useful in patients younger than age 40; however, it is still not sensitive enough to be used as a stand-alone test to make the diagnosis of GHD (Almeretti, 2003). Manipulation of the endocrine system through stimulation and suppression of the various axes is often required for diagnosing conditions of hormonal deficiency and surfeit. In this vein, GHD is diagnosed by showing failure of GH to increase adequately in response to pharmacologic stimulation. Several endocrine organizations have published guidelines on GH deficiency, which patients to test, which test to utilize, and what cutoffs to apply (Ho, 2007; Casanueva, 2009). The insulin tolerance test (ITT) has long been considered the “gold standard” for diagnosing GHD; however, it is most unpleasant for the patient, requires the attendance of a physician throughout the testing period, and is contraindicated in those with a history of seizures or cardiac or cerebrovascular disease. Failure of GH to rise above 5 ng/mL in adults and above 10 ng/mL in children is considered to be abnormal. In patients unable to undergo an ITT and in those needing a second confirmatory test, arginine stimulation alone or in combination with GHRH is usually the next step. Combination testing with GHRH plus arginine is preferred, as many normal adults will fail stimulation with arginine alone (Biller, 2002). Failure of GH to rise above 4.1 carries a sensitivity of 95% and a specificity of 91% in diagnosing GH deficiency (Biller, 2002). Because body mass index (BMI) affects the GH response to stimulation with GHRH plus arginine, newer guidelines recommend the use of GH cutoffs based on BMI for interpretation of results (Cook, 2009). Other methods to assess for GHD include 24-hour or nighttime monitoring of GH and provocative tests using clonidine, L-dopa, or glucagon (following priming with propranolol). All of these tests carry significant individual variability and have not been systematically studied; they are used mainly in the pediatric population (Rose, 1988). The same normal ranges hold for these tests as described for the ITT. There are two settings in which an argument can be made against the need to test for GHD. The first is in patients with known pituitary disease who have a low IGF-I level. The other scenario is in patients with evidence of three or more pituitary hormone deficiencies; studies have shown these patients to have a >96% chance of being GHD (Hartman, 2002).

For children, it is common to use exercise testing in screening for GHD. Further testing is not indicated if the results are normal; however, if GH fails to increase adequately, pharmacologic testing is warranted (Eddy, 1974). Healthy children may not respond to any single GH provocative test; therefore, GHD in childhood is defined by failure of serum GH to reach defined levels when at least two different pharmacologic stimuli are used. IGF-I measurements have been used to screen for GHD in children; however, since a variety of factors can decrease IGF-I, it is not used to confirm the diagnosis of GHD. IGF-I levels decline in malnutrition, hypothyroidism, hepatic disease, uncontrolled diabetes mellitus, and with age. Levels of IGF-BP3 usually parallel those of IGF-I and are often low in GHD; however, results falling within the reference range do not exclude the diagnosis if GHD. Up to 18% of subjects with GHD may have normal IGF-I levels. Care should be taken when interpreting values for IGF-I, IGF-BP3, and GH because the assays themselves and the cutoffs used to define normal differ greatly between laboratories. To address these issues there is a move to have labs utilize a World Health Organization international standard for GH and IGF-I, and to create a normative range from a statistically valid control group (Giustina, 2010).

It is important to understand the difference in the physiology behind testing with GHRH as opposed to the other secretagogues. ITT and arginine stimulate the production of GHRH; clonidine inhibits somatostatin. For these stimuli to elicit a rise in GH, the hypothalamus must be intact. When GHRH is used, the hypothalamus is bypassed and the pituitary is directly stimulated. Therefore, it is possible to miss up to 50% of patients who have tertiary (hypothalamic) GHD. Individuals with

Figure 24-2 Hypothalamic-pituitary-growth hormone axis. Feedback loop influencing GH-IGF-I secretion and action. (From Melmed S, Kleinberg D. Anterior pituitary. In: Larsen PR, Kronenberg HM, Melmed S, Polonsky KS, editors. *Williams textbook of endocrinology*. 10th ed. Philadelphia: WB Saunders; 2003, p. 221, with permission.) FFA, Free fatty acid; GH, growth hormone; GHBP, growth hormone-binding protein; GH-IGF, growth hormone-insulin-like growth factor; GHR, growth hormone receptor; GHRH, growth hormone-releasing hormone; IGF-I, insulin-like growth factor I; IGF-BP, IGF-binding proteins.

childhood-onset idiopathic GHD are less likely to have permanent GHD. It is recommended that they be taken off GH replacement and retested when they reach early adulthood, unless they have a known genetic mutation, embryopathic lesion, or irreversible lesion/damage to the pituitary/hypothalamus (Molitch, 2006).

Growth Hormone Excess

Growth hormone overproduction can result in the condition called **acromegaly**. If the condition develops before closure of the epiphyses, these individuals may be exceedingly tall (**gigantism**). More commonly, it presents during adulthood, causing diffuse enlargement of soft tissues and organs throughout the body; characteristic features include prognathism, frontal bossing, and spade-like hands. The screening test for clinically suspected acromegaly is a randomly collected IGF-I. If the level of IGF-I is elevated with respect to the appropriate age- and gender-related reference range, then it is necessary to confirm the diagnosis using an oral glucose tolerance test (OGTT). The OGTT is performed by orally administering 75 g of glucose and obtaining blood samples at baseline and every 30 minutes over the next 2 hours for glucose and GH. A normal response is suppression of GH to <1 ng/mL ($1 \mu\text{g/L}$) at any time during the test. If GH fails to drop to below 1 ng/mL ($1 \mu\text{g/L}$), the patient is diagnosed as having acromegaly (American Association of Clinical Endocrinologists, 2004). The difficulty comes in diagnosing mild disease. Freda had studied 60 postoperative patients with acromegaly, 22 patients with active disease (elevated IGF-I), 38 patients in remission (normal IGF-I),

and 25 healthy controls. The highest nadir GH was $0.13 \mu\text{g/L}$ in the controls and $0.3 \mu\text{g/L}$ in those with active disease. Fifty percent of those with active disease had GH values $<1 \mu\text{g/L}$, leading to misclassification of these individuals as being normal when the above stated criteria were applied (Freda 1998, Trainer 2002). In a more recent study of 16 patients with mild disease (the majority have microadenomas), Dimaraki (2002) found that 50% of patients with acromegaly were able to suppress their GH levels to $<1 \mu\text{g/L}$ following an OGTT. A proposed reason for these patients with active disease showing normal suppression is that they may have subtle changes in GH secretion that are not elicitable with this short suppression test. To address this issue, the following suggestion has been proffered (Trainer, 2002). If an initial random IGF-I is normal and GH is $<0.3 \mu\text{g/L}$, then acromegaly is excluded. If either test is abnormal, repeat the IGF-I and proceed to an OGTT. Failure of GH to be suppressed below $0.3 \mu\text{g/L}$, accompanied by an elevated IGF-I, is diagnostic of acromegaly. Suppression of GH below $0.3 \mu\text{g/L}$ with normal IGF-I excludes acromegaly. For those who adequately suppress their GH but have an elevated IGF-I, close follow-up is recommended (Trainer, 2002). Oral but not transdermal estrogen can reduce IGF-I concentrations (Giustina, 2010), therefore temporarily withholding oral estrogen therapy during testing may be prudent.

Acromegalic patients may show a paradoxical rise, an absent response, or a partial decline in GH in response to an OGTT (Ezzat, 1997). Random GH sampling is not adequate to establish the diagnosis of acromegaly because considerable overlap in GH exists between healthy persons and

patients with the disease. In addition, GH can be increased in patients with a number of disorders, including renal disease, cirrhosis, malnutrition, and in patients under physical or emotional stress. Although larger adenomas are generally associated with higher GH levels, the correlation between GH levels and acromegalic manifestations is poor. In most patients with untreated acromegaly, GH levels remain above basal levels throughout the day, ranging from 10–100 ng/mL (10–100 µg/L). Serum GH levels in excess of 50–100 ng/mL (50–100 µg/L) are virtually never seen in nonacromegalic persons (Barkan, 1989). Other diagnostic maneuvers using TRH, GnRH, and GHRH yield discordant results in about 50% of patients with acromegaly; therefore, their use for diagnostic purposes or for monitoring disease activity is not recommended (American Association of Clinical Endocrinologists, 2004). In patients with documented acromegaly but no evidence of a pituitary tumor, GHRH should be measured to detect a hypothalamic or ectopic source for acromegaly.

Patients treated for acromegaly require lifelong monitoring for disease activity. Patients treated with surgery or radiation can be monitored by the GH response to OGTT and a random IGF-I measurement. The goal of therapy is to normalize IGF-I and suppress the GH response to OGTT to <1 ng/mL (<1 µg/L). Several studies have shown that when these goals are attained, mortality rates become comparable with those of the normal population (Swearingen, 1998; Holdaway, 2004; Rajasooriya, 1994; Orme, 1998). Caution is required in interpreting IGF-I levels in women on oral but not topical estrogen treatment, as oral estrogens lower IGF-I concentration (Giustina, 2010). For patients on somatostatin receptor analogues, monitoring is performed by random IGF-I and GH measurements. Patients on GH receptor blockers are monitored by a random IGF-I alone. In rare instances, acromegaly may be due to ectopic secretion of GHRH (e.g., bronchial carcinoid, pancreatic islet cell tumors, small cell lung cancer), in which case the measurement of GHRH may be useful.

POSTERIOR PITUITARY HORMONES

Oxytocin and vasopressin (see Chapters 8 and 14) are the two major hormones of the posterior pituitary. They each have distinct physiologic roles, with partially overlapping effects in stimulating smooth muscle contraction and in maintaining water homeostasis. They are small oligopeptides, each composed of nine amino acid residues with a total mass of about 1 kDa. They are synthesized in the nerve cell bodies within the hypothalamus and are transported along axons to the nerve terminals within the posterior pituitary, where they are stored in secretory granules. Neuronal action potentials originating in the hypothalamus are conducted along the axons, resulting in degranulation of the vesicles and release of oxytocin and vasopressin into the perivascular space and ultimately into the circulation. Unlike the anterior pituitary, the posterior pituitary is little more than a repository where hormones are held until they are secreted. Accordingly, disruption of the infundibular stalk or destruction or removal of the posterior pituitary does not necessarily result in complete loss of these hormones, as they are produced in the hypothalamus.

Oxytocin

Oxytocin secretion is stimulated by stretching of the cervix and vagina during parturition; this is known as the Ferguson reflex. Oxytocin contributes to uterine contractions late in labor both by direct action on the myometrium and by stimulation of prostaglandin secretion by the decidua (Fuchs, 1982). It also plays a role in hemostasis at the placental site following delivery. Throughout pregnancy, estrogen upregulates the numbers of oxytocin receptors on the uterus and decidua, resulting in increased sensitivity to oxytocin toward the end of term.

Oxytocin stimulates the myoepithelial cells surrounding the mammary glands and lactiferous ducts to contract, resulting in milk ejection. In response to suckling, neurogenic stimuli are transmitted from the nipple to the third, fourth, and fifth thoracic nerves, to the spinal cord, to the midbrain, and on to the hypothalamus, where oxytocin release is triggered. Psychological stimuli can bypass this pathway, with bursts of oxytocin secretion occurring with anticipation of nursing or on hearing a baby cry (Jenkins, 1991; Yokoyama, 1994). Stressful situations can inhibit its secretion, resulting in decreased milk ejection.

Pathologic conditions associated with oxytocin excess or deficiency are rare and are limited to case reports. Its function in males remains unknown. Clinical demand for the measurement of oxytocin levels is extremely rare. Because it has a half-life of 3–5 minutes and is subject to rapid degradation by oxytocinase, individual reference laboratory procedures for its collection must be strictly adhered to if meaningful results are to be obtained.

Arginine Vasopressin/Antidiuretic Hormone

AVP (ADH) is synthesized within the paraventricular and supraoptic nuclei of the hypothalamus. The major function of ADH is to maintain osmotic homeostasis by regulating water balance.

It does this by stimulating the V2 receptors on principal epithelial cells that line the cortical collecting ducts of the kidney. As discussed in Chapter 14, ADH induces an increase in the production of cyclic adenosine monophosphate (cAMP), which, in turn, causes the water channels (aquaporins) to fuse with the apical membrane of the principal cells, increasing water permeability and reabsorption. At much higher blood concentrations, AVP also acts as a potent pressor by causing vasoconstriction (V1 receptor), stimulates ACTH secretion from the anterior pituitary, and stimulates the production of clotting factor VIII.

ADH secretion is modulated by changes in serum osmolality and by alterations in intravascular volume. Changes in plasma osmolality are detected by osmoreceptors located within the anterior hypothalamus. Plasma ADH rises and falls in direct proportion to the serum osmolality. A concordantly linear relationship exists between ADH and the urine osmolality (Uosm). The Uosm is capped at about 1200 mOsm/kg, the maximum Uosm allowed by the renal medullary concentration gradient.

ADH secretion is maximally stimulated at a serum osmolality >295 mOsm/kg and is suppressed when the osmolality falls below 284 mOsm/kg. Thirst can be considered the fail-safe mechanism for fluid and osmotic homeostasis as it is initiated at a greater plasma osmolality (Posm) than is needed to stimulate ADH secretion. The thirst receptors are located within the hypothalamus and are distinct from the osmoreceptors that stimulate ADH secretion.

Changes in intravascular volume are detected by baroreceptors. There are two sets of baroreceptors: low-pressure volume receptors located in the right atrium and pulmonary venous system; and high-pressure arterial baroreceptors, located in the carotid sinus and aortic arch. These receptors are normally under tonic inhibition; a drop in intravascular volume removes the inhibition and results in a rise in ADH, leading to increased water reabsorption. ADH secretion is much more sensitive to changes in osmolality than to changes in intravascular volume. A 1%–2% increase in osmolality will cause a rise in ADH secretion, whereas a much greater stimulus, such as a 5%–10% drop in blood volume or blood pressure, is needed before the baroreceptors trigger the release of ADH.

In addition to changes in osmolality and intravascular volume, other physiologic factors that can stimulate ADH secretion include nausea, cytokine, interleukin (IL)-6, hypoglycemia, hypercarbia, and nicotine (Reihman, 1985; Masrorakos, 1994).

Basal plasma vasopressin normally ranges from 0.5–2 pg/µL. In concert with atrial natriuretic hormone, thirst, and the renin-angiotensin-aldosterone axis, ADH works to maintain blood pressure, volume, and tonicity. Accordingly, when a patient is evaluated for a disorder of water homeostasis, these multiple interactive factors must be taken into consideration. Normal plasma osmolality ranges from 280–295 mOsm/kg, and plasma sodium from 135–145 mmol/L. It can be determined directly by measuring the plasma freezing-point depression or the plasma vapor pressure. It can also be determined indirectly, by measuring the plasma sodium, blood urea nitrogen (BUN), and glucose, and applying the following formula:

$$\text{Plasma osmolality} = \{2 \times [\text{Na}] (\text{mmol/L})\} + \{[\text{Glucose} (\text{mg/dL})/18] + [\text{BUN} (\text{mg/dL})/2.8]\} \quad (24-1)$$

This equation is discussed at length in Chapters 8 and 14.

Because sodium is the major plasma solute, hyponatremia is tantamount to hypoosmolality. There is usually excellent agreement between directly measured and calculated osmolality. However, there are two situations when this does not hold true: in pseudohyponatremia (also termed **fictitious hyponatremia**), and in the presence of high concentrations of other effective solutes. In pseudohyponatremia, the plasma volume is displaced by the presence of high concentrations of lipids or proteins (e.g., hyperglobulinemia), resulting in a low plasma concentration of Na⁺, although the activity of Na⁺ in water is normal. If Na⁺ is directly measured with an ion-specific electrode (ISE) in this case, the activity reading is normal. However, high-throughput analyzers, in order to extend electrode life, generally perform ISE measurements on diluted plasma (so-called indirect ISE measurement), making the reading a plasma concentration measurement vulnerable to pseudohyponatremia. The measured Posm is unaffected by the presence of hyperlipidemia or paraproteinemia, as the concentration of solute particles per volume of fluid is unchanged.

The presence of high concentrations of osmotically active solutes such as glucose, radiographic contrast agents, mannitol, and ethylene glycol

causes a shift of water from the intracellular to the extracellular compartment, leading to dilutional hyponatremia (this situation, though quite different from what was described in the preceding paragraph, is also sometimes referred to as pseudohyponatremia). Similar **translocational hyponatremia** occurs with the absorption of glycine during transurethral prostate resection, as well as in gynecologic and orthopedic procedures (Ayus, 1997; Hahn, 2001). The calculated Posm is unreliable in these situations; Posm must be measured directly instead. A difference between the calculated and measured Posm of >10 mOsm/kg supports the presence of pseudohyponatremia or other osmolar solutes (Kumar, 1998). The most common situation causing a large “osmolar gap” is ethanol intoxication.

In hyperglycemia, the measured Na⁺ should be corrected by the addition of 1.6 mmol/L for each 100-mg/dL increase in serum glucose above normal (100 mg/dL). A more recent analysis suggested that this formula may underestimate the decrease in Na⁺ caused by hyperglycemia, and supported the use of a 2.4-mmol/L correction factor (Hillier, 1999). True hyponatremia is present if, after the correction formula is applied, the serum Na⁺ is still <135 mmol/L.

During pregnancy, there is a resetting of the osmostat with a drop in osmolality of approximately 10 mOsm/kg (Lindheimer, 1995). The precise mechanism for this is not known; however, studies have suggested a role for the hormone relaxin and for the enzyme oxytocinase. During pregnancy, there is a progressive increase in placental production of oxytocinase, which, in addition to breaking down oxytocin, breaks down vasopressin, possibly resulting in a change in the hypothalamic AVP osmolality feedback loop.

Diabetes Insipidus

Diabetes insipidus (DI) is classified as being either central (due to absent or decreased ADH secretion from the hypothalamus or neurohypophysis) or nephrogenic (due to renal resistance to the actions of ADH). Each is further subcategorized as being complete or partial. All variants are characterized by the passage of large volumes of dilute urine (>2.5 L/day) in the face of an inappropriately elevated plasma osmolality. Provided the thirst mechanism is intact and there is free access to water, most individuals can avoid dehydration and maintain normal plasma osmolality (Posm) and serum sodium levels.

The water deprivation test is the preferred diagnostic test for identifying the presence of DI (Table 24-5). Central and nephrogenic DI can be distinguished by the response to either endogenous or exogenous vasopressin (Table 24-6). In neurogenic DI, ADH levels are low and the kidney rapidly acts to conserve water in response to exogenous ADH administration. In contrast, nephrogenic DI is associated with normal or increased levels of ADH, and administration of additional ADH has little or no effect on renal water reabsorption. Differentiating partial nephrogenic DI from primary polydipsia can be more difficult. Unlike DI, where the underlying problem is difficulty in holding on to free water, in primary polydipsia the pathophysiology arises from increased intake of fluids. Primary polydipsia (PP) can be due to either dipsogenic DI or psychogenic polydipsia. In dipsogenic DI, the setpoint for ADH secretion is normal; however, a resetting of the thirst threshold occurs, so that it is now below the threshold for ADH secretion. In psychogenic polydipsia, the osmostat for ADH secretion is normal; however, because of underlying psychiatric illness, the subject has a compulsion to drink excessive volumes of liquid. This intake of copious volumes of fluid as seen in PP leads to a washout in the medullary concentrating gradient within the kidney, resulting in a decreased ability to concentrate the urine in response to dehydration. Differentiating between nephrogenic DI and PP, as well as among those who have an

equivocal response to ADH, is best achieved by plotting the basal and postdehydration Uosm and plasma ADH on nomograms created by Zerbe and Robertson (Figs. 24-3 and 24-4) (Zerbe, 1981, 1987). Direct measurement of plasma ADH may be helpful in confirming the diagnosis of a pathologic ADH deficiency or excess in the presence of a known or

TABLE 24-5

Water Deprivation Test for Diagnosing and Classifying Diabetes Insipidus

Patients with mild polyuria may be instructed to withhold all fluid intake from 10 PM onward. For those with more severe polyuria (8–10 L/day), water deprivation should be started early in the morning under close observation.

1. During testing, the patient is forbidden to take in anything by mouth.
2. Obtain the following baseline parameters: urine volume (Uvol) and urinary osmolality (Uosm), plasma osmolality (Posm), and plasma sodium (PNa). Also record the weight and blood pressure (BP)/pulse (P) seated and standing.
3. Urine and plasma are collected hourly for Uvol, Uosm, and Posm. Weight, BP, and P are also recorded. Record requests for fluid.
4. When the Uosm has plateaued (e.g., hourly increase <30 mOsm/kg for 3 consecutive hours), or when body weight has decreased by 3%–5%, or the patient develops a >20 mm Hg drop in systolic BP, obtain samples for Uvol, Uosm, Posm, PNa, and AVP (plasma).
5. Administer 1 mcg of desmopressin IV or IM, or 5 mcg of AVP SC. Uosm; urine output and Posm are recorded at 30, 60, and 120 minutes after the injection. The highest Uosm value is used to evaluate the patient's response to AVP.

Precautions

When possible, discontinue any medications that can influence ADH secretion. Observe for hypotension and nausea, which may stimulate ADH secretion. The patient should not be permitted to smoke during the test.

Interpretation

Normal	Final Uosm before AVP challenge is higher than Posm. Following AVP challenge, the Uosm is less than 10% higher than the maximal Uosm achieved with water restriction alone
Neurogenic DI	Final Uosm before AVP challenge is less than Posm. Following AVP administration, there is a greater than 50% increase in Uosm.
Nephrogenic DI	Final Uosm before AVP challenge is less than Posm. Following AVP administration, there is a less than 10% increase in Uosm.
Partial central DI	Uosm may be higher than Posm following dehydration; however, there is only a 10%–50% increase in Uosm following administration of AVP.
Partial nephrogenic DI	Uosm may be higher than Posm following dehydration; however, there is a greater than 10% increase in Uosm following administration of AVP.

Plotting basal and postdehydration Uosm and plasma ADH on the nomograms from Zerbe and Robertson will permit further distinction between partial nephrogenic DI, partial central DI, and primary polydipsia (see Figs. 24-3 and 24-4).

ADH, Antidiuretic hormone; AVP, arginine vasopressin; DI, diabetes insipidus; IM, intramuscular; IV, intravenous; SC, subcutaneous.

TABLE 24-6

Tests in the Differential Diagnosis of Disorders of Water Homeostasis

Disorder	BASELINE			AFTER 12-HOUR FLUID RESTRICTION			
	Serum Na ⁺ and osmolality	Urine Na ⁺ and osmolality	Serum ADH	Serum Na ⁺ and osmolality	Urine Na ⁺ and osmolality	Serum ADH	Urine osmolality post-AVP challenge
Normal control	N	N	N	N	High	High	Same
SIADH	Low	N–High	High	Low–N	High	High	—
Neurogenic DI	N–High	Low	Low	High	Low–N	Low	Increased

Psychogenic polydipsia	Low–N	Low	Low	N	N–High	N–High	Same

ADH, Antidiuretic hormone; AVP, arginine vasopressin; DI, diabetes insipidus; N, normal; SIADH, syndrome of inappropriate secretion of ADH.

Figure 24-3 The relationship between urine osmolality (Uosm) and plasma arginine vasopressin (AVP/ADH) in patients with polyuria of diverse causes and severity. Each of the three categories of polyuria is described by its own family of sigmoid curves of differing heights. Differences in height within a family reflect differences in maximum concentrating capacity caused by “washout” of the medullary concentration gradient. They are proportional to the severity of the polyuria (indicated in liters per day at the right end of each plateau). The normal response is depicted in yellow. The three categories of polyuria differ principally in the ascending portion of the dose-response curve. In patients with partial neurogenic diabetes insipidus (DI), the curve lies to the left of normal, reflecting increased sensitivity to the antidiuretic effects of very low concentrations of plasma ADH. In contrast, in patients with partial nephrogenic DI, the curve lies to the right of normal, reflecting decreased sensitivity to ADH. In primary polydipsia, the relationship of Uosm to ADH remains relatively normal. (Redrawn from Bichet DG. *Diabetes insipidus and vasopressin*. In: Moore WT, Eastman RC, editors. *Diagnostic endocrinology*. 2nd ed. St Louis: Mosby; 1996, p. 158, with permission.)

Figure 24-4 Left: Relationship between plasma arginine vasopressin (AVP/ADH) and plasma osmolality during the infusion of hypertonic saline. Patients with primary polydipsia and nephrogenic diabetes insipidus (DI) have values within the normal range (open area), in contrast to patients with neurogenic DI, who show a subnormal plasma ADH response to a rise in osmolality (pink). Right: Relationship between urine osmolality and plasma ADH during dehydration and water loading. Patients with primary polydipsia and neurogenic DI have values within the normal range (open area), in contrast to patients with nephrogenic DI, who have hypotonic urine despite high plasma ADH (green). (Redrawn from Bichet DG. *Diabetes insipidus and vasopressin*. In: Moore TW, Eastman RC, editors. *Diagnostic endocrinology*. 2nd ed. St Louis: Mosby; 1996, p. 168, with permission.)

TABLE 24-7

Causes of Diabetes Insipidus

Central

Primary

Familial
Idiopathic

Acquired

Tumors—craniopharyngioma, pituitary tumors, metastases (i.e., lung, breast), Rathke's cleft cyst, nonlymphocytic leukemia
Granulomatous disorders—sarcoidosis, Langerhans' cell histiocytosis, Wegener's granulomatosis
Traumatic—head trauma, surgery
Infectious—tuberculosis, meningitis, encephalitis
Vascular—cerebral aneurysm, sickle cell, Sheehan's syndrome
Drugs—alcohol, diphenylhydantoin, chlorpromazine, and β -adrenergic agonists
Other—lymphocytic hypophysitis, hypoxic encephalopathy

Nephrogenic

Hereditary

Mutation in the V2 receptor
Mutation in the aquaporin gene

Acquired

Drugs—lithium, phenytoin, demeclocycline, vinblastine, cisplatin, propoxyphene, colchicine, gentamicin, amphotericin, ethanol, atrial natriuretic hormone, norepinephrine, methoxyflurane anesthetics, furosemide
Electrolyte disorders—hypercalcemia, hypokalemia
Systemic illnesses—sickle cell, multiple myeloma, amyloidosis, sarcoidosis, Sjögren's syndrome, polycystic kidney disease
Other—low-protein diet, postobstructive uropathy

suspected disorder of renal function or fluid and electrolyte homeostasis, or when a patient is unable to tolerate physiologic testing. In cases of congenital DI, family members who are heterozygote carriers of ADH gene mutations may be identified by demonstrating decreased ADH levels, which may be the only subclinical manifestation of ADH deficiency.

Nephrogenic DI is either congenital or acquired. An X-linked receptor defect is the most common etiology for congenital nephrogenic DI; medications are the most common cause of acquired nephrogenic DI (Holtzman, 1994). Medications known to be associated with acquired nephrogenic DI include lithium, demeclocycline, and methoxyflurane anesthetics. Other causes of acquired nephrogenic DI include hypercalcemia, hypokalemia, sickle cell disease, and postobstructive uropathy (Table 24-7).

Neurogenic DI may be congenital, the result of an autosomal dominant mutation in the ADH signal peptide or in the exons that code for neurophysins (McLeod, 1993; Yuasa, 1993). More commonly, neurogenic DI is induced by lesions affecting the hypothalamus, (metastatic tumors, trauma, granulomatous disorders) or medications. Drugs that may cause neurogenic DI by suppressing ADH release include phenytoin, chlorpromazine, and α -adrenergic agonists. It has been suspected that autoantibodies directed against the ADH-producing cells of the hypothalamus may be responsible for some cases of idiopathic neurogenic DI (De Bellis, 1994, 1999; Maghnie 2000). These antibodies are detectable by indirect immunofluorescence antibody.

Another common condition in which decreased ADH levels have been found is primary nocturnal enuresis in children. Although these patients have ADH levels only slightly lower than controls (2.9 ng/L vs. 3.6 ng/L), the clinical symptoms are reliably ameliorated by vasopressin therapy (Willie, 1994). The determination of ADH levels in diagnosing this condition is not always helpful because of moderate overlap between enuretic and normal children. Measuring the specific gravity in the first morning urine is more reliable for identifying children who may benefit from ADH supplementation; they will have a urine specific gravity below 1.015 (Mevorach, 1995).

Syndrome of Inappropriate Secretion of ADH

The syndrome of inappropriate secretion of ADH (SIADH) is characterized by a euvoletic hyposmolar hyponatremia, associated with hyperosmolar urine (the result of continued inappropriate natriuresis). By definition, SIADH cannot be diagnosed until nonosmotic stimuli for ADH secretion and other pathologies that interfere with free water clearance have been excluded (Vistorina, 2002). Physiologic triggers of

TABLE 24-8

Water Load Test

1. Baseline: The patient must be euvoletic and have a serum Na⁺ between 125 and 150 mmol/L and Posm >275 mOsm/kg.
2. The patient is given 20 mL of water per kilogram of body weight (max = 1500 mL) to drink over 30 minutes.
3. With the patient maintained in the recumbent position, urine output is collected every hour for the next 5 hours. Record the volume and osmolality of each specimen.

Interpretation

Normals	Excrete 80%–90% of the administered water load within 4 hours, and suppress the U _{osm} to <100 mOsm/kg.
SIADH	Failure to meet these criteria in the absence of medications or other conditions that may impair diuresis is consistent with the diagnosis of SIADH.

SIADH, Syndrome of inappropriate secretion of ADH.

ADH secretion include nausea, pregnancy, hypoglycemia, intracranial hypertension, mechanical ventilation, and hypoxia. Hypothyroidism and glucocorticoid deficiency cause a decrease in free water clearance, leading to a dilutional hyponatremia. Mineralocorticoid deficiency can lead to hyponatremia caused by increased renal sodium loss. It is therefore extremely important to test for deficiencies of these axes and to institute appropriate hormonal replacement therapy before making a diagnosis of SIADH. Other confounding factors that can hamper the diagnosis of SIADH include renal disease, cardiac disease, and medications such as diuretics. In these situations, one can cautiously perform a water load test (Table 24-8). In the absence of medications or other conditions that may impair diuresis, failure to excrete 80%–90% of the administered water load within 4 hours and to suppress the U_{osm} to <100 mOsm/kg is consistent with the diagnosis of SIADH.

In the right clinical setting, the diagnosis of SIADH often can be confidently made on the basis of serum and urine electrolyte determinations alone. A spot urine Na⁺ <30 mmol/L can generally distinguish those with hyponatremia due to volume depletion from those with SIADH, in whom urine Na⁺ >30 mmol/L (Chung, 1987). In contrast, differentiating the patient with euvolemia and SIADH from the one with hypovolemia and concomitant renal salt-wasting (e.g., salt-losing nephropathy, diuretic use) can be much more difficult. In addition to hyponatremia, both have a spot UNa⁺ >30 mmol/L and a fractional excretion of Na⁺ >1. The fractional excretion of sodium (FENa [%]) is calculated as follows:

$$\frac{U_{[Na^+]} \times P_{[Cr]}}{P_{[Na^+]} \times U_{[Cr]}} \times 100 \quad (24-2)$$

where $U_{[Na^+]}$ = urine sodium concentration; $P_{[Na^+]}$ = plasma sodium concentration; $U_{[Cr]}$ = urine creatinine concentration; and $P_{[Cr]}$ = plasma creatinine concentration.

One way to differentiate between the two is to administer 1 L of 0.9% NaCl intravenously over 24 hours for 2 days. A rise in serum Na⁺ by more than 5 mmol/L is suggestive of hypovolemia. In SIADH, no change or an increase of less than 5 mmol/L occurs. Alternatively, fluid restriction to 600–800 mL/day for 2–3 days will lead to improvement in hyponatremia in SIADH but not in renal salt-wasting (see Table 24-6).

The cause of renal salt-wasting in SIADH is twofold. At the onset of the disease, there is volume expansion, which inhibits the renin-aldosterone axis and leads to greater improved delivery of sodium to the distal tubules. Continued sodium loss is due to secretion of atrial natriuretic protein (Kamoi, 1990).

Because of hyperfiltration and the local actions of ADH on the renal V2 receptor, SIADH is one of the two states in which some of the lowest uric acid levels occur; the other is pregnancy. In SIADH, the serum levels of ADH may be variably increased, usually out of proportion to Posm; however, approximately 20% of cases meeting the physiologic diagnosis of SIADH will not have detectable levels of ADH (Zerbe, 1980). This may be due to insensitivity of the assay to low levels of ADH, increased renal sensitivity to ADH, or perhaps the presence of another hormone with antidiuretic activity (Kamoi, 1997).

The diagnosis of SIADH is largely a diagnosis of exclusion, with the clinician having ruled out other causes of hyponatremia (Fig. 24-5). It most often occurs as a manifestation of the paraneoplastic syndrome; however, it may also occur in central nervous system trauma or infection,

in lung disease, or as the result of medications (vinca alkaloids, tricyclic antidepressants, serotonin receptor uptake inhibitors) (Table 24-9).

THYROID

The normal thyroid gland weighs about 15–25 g. It is divided into lobules, each of which is composed of 20–40 follicles separated by highly vascular connective tissue. The follicles are ring-shaped structures, in which a single cell band of follicular cells surrounds a closed cavity containing colloid, thyroid hormone, thyroglobulin (Tg), and a variety of other glycoproteins. The follicular cells rest on a basement membrane that is rich in glycoprotein that separates the cells from surrounding capillaries. The apex of the follicular cells has microvilli that extend into the colloid, where iodination, exocytosis, and the initial phase of hormone secretion occur. The follicles are sites of thyroid hormone synthesis and storage. The thyroid gland also contains parafollicular cells, or C cells, which are responsible for the synthesis and secretion of calcitonin, a hormone important in calcium metabolism.

An intact hypothalamic-pituitary-thyroid (HPT) axis and a ready source of iodide are required for normal thyroid hormone synthesis. The hypothalamus secretes TRH, which, in turn, stimulates the thyrotrophs of the anterior pituitary to secrete TSH (thyrotropin). As implied by the name, TSH stimulates thyroid hormone synthesis and secretion by the thyroid gland. Thyroid hormone exerts negative feedback on both the hypothalamus and the pituitary gland to maintain a TSH concentration within narrow limits; it also acts peripherally to mediate numerous metabolic activities.

Under TSH stimulation, iodine enters the follicular cells as inorganic iodide and is transformed into thyroid hormones, thyroxine (T₄), and 3,5,3′-triiodothyronine (T₃) through a series of metabolic steps. The sequence of events as depicted in Figure 24-6 can be broken down into (1) active transport of iodide into the cell; (2) iodination of the tyrosyl residues on Tg; (3) coupling of iodotyrosine molecules within Tg to form T₄ and T₃; (4) proteolysis of Tg with release of free iodotyrosine, T₄, and T₃, and secretion of iodothyronine into the circulation; (5) deiodination of iodothyronines within the thyroid and reuse of liberated iodide; and (6) deiodination of T₄ to T₃.

One hundred percent of circulating T₄ is of thyroidal origin, whereas only 20% of T₃ is of thyroidal origin; 80% is produced enzymatically in nonthyroidal tissues by 5′-monodeiodination of T₄ (Lum, 1984). Approximately 110 nmol (85 μg) of T₄ and 10 nmol (8.5 μg) of T₃ are produced daily by the thyroid. The thyroid hormones circulate while attached to plasma proteins. About 70% of T₄ is bound to thyroxine-binding globulin (TBG), 20% to transthyretin (formerly called **binding prealbumin**), and 10% to albumin. Although most of the circulating T₃ is bound to TBG; it does so with a 10-fold reduced affinity as compared with that of T₄ (Robbins, 1996; Braverman, 2000). Small percentages of T₄ and T₃ remain unbound to protein—about 0.03% and 0.3%, respectively. As with other hormones, it is the free component that is metabolically active.

Thyroid disease may be classified functionally into hyperthyroidism, hypothyroidism, and euthyroidism. Signs and symptoms of hyperthyroidism include heat intolerance, tachycardia, weight loss, weakness, emotional

lability, and tremor. The most common clinical syndrome associated with hyperthyroidism is Graves' disease, caused by circulating antibodies to the TSH receptor. Other disorders that lead to hyperthyroidism include toxic adenoma and, rarely, TSH-secreting pituitary tumors and thyroid carcinoma.

Hypothyroidism results in hoarseness, cold sensitivity, dry skin, constipation, bradycardia, and muscle weakness. Myxedema coma is an advanced stage of thyroid hormone deficiency characterized by progressive stupor, hypothermia, and hypoventilation. Failure of the thyroid itself to secrete an adequate amount of thyroid hormone is called **primary hypothyroidism** and is most commonly iatrogenic in origin, the result of either ablation with radioactive iodine or surgery to treat hyperthyroidism. Secondary hypothyroidism occurs when TSH secretion is decreased as a result of a pituitary disorder. Tertiary hypothyroidism is the result of hypothalamic dysfunction.

Thyroid diseases such as goiter, thyroid adenoma, and thyroid carcinoma typically occur in individuals who are euthyroid. Accurate TSH assays permit the diagnosis of subclinical hyperthyroidism and hypothyroidism. These patients appear clinically euthyroid; however, their TSH values are respectively suppressed or elevated. A number of clinical situations can lead to difficulties in the interpretation of thyroid function tests: The presence of abnormal protein-binding proteins (congenital or drug induced); alterations in thyroid hormone metabolism as seen in those hospitalized with acute psychiatric illness; alterations in thyroid hormone

metabolism as seen in those on medications that affect thyroid hormone binding or the HPT axis directly. The most important and most common problem with thyroid function tests probably occurs in those patients with various illnesses that do not directly involve the thyroid, so-called **nonthyroidal illness**.

THYROID HORMONE SYNTHESIS AND METABOLISM

Iodine is a major component of thyroid hormone; the main source of iodine is dietary intake. Deiodination of organic iodine-containing moieties within the gland serves as another source. Inorganic iodide is transported into the follicular cell by the sodium-iodide symporter (NIS) located in the basolateral membrane (Chambard, 1983). TSH modulates NIS activity: An increase in TSH secretion augments the uptake of iodide into the follicular cell. Iodide transport into the thyroid gland is also influenced by the serum iodide level; iodide deficiency increases pump activity, and iodide excess inhibits iodide uptake.

Thyroglobulin is a glycoprotein synthesized by the rough endoplasmic reticulum in the basal and perinuclear regions of the follicular cell. It is acted upon by the Golgi apparatus in the apical portion of the follicular cell, where its tyrosyl residues are iodinated, leading to the formation of monoiodotyrosyls and diiodotyrosyls (MITs and DITs). Tg is then

Figure 24-6 Hypothalamic-pituitary-thyroid axis and thyroid hormone synthesis. The steps for thyroid hormone synthesis and release are described in further detail in the text. *TRH*, Thyrotropin-releasing hormone; *TSH*, thyroid-stimulating hormone.

transferred into the colloid for storage (Vassart, 1973a; Roth, 1985). This transformation of thyroglobulin into thyroid hormone requires two separate oxidative reactions, both catalyzed by thyroid peroxidase (TPO): the binding of iodide to Tg tyrosyl residues to form the iodotyrosyls MIT and DIT, and the subsequent coupling of MIT and DIT to produce T_4 and T_3 (Deme, 1976; Bjorkman, 1981). T_4 is formed by the coupling of two molecules of DIT; T_3 results from the union of one MIT and one DIT. T_4 and T_3 are released from Tg via lysosomal degradation. They are then secreted into the circulation at the basal membrane. All of these reactions are under the control of TSH.

About half of all T_4 is monodeiodinated in the 5' position to form T_3 , and about 40% undergoes deiodination of the inner ring of T_4 to form

reverse T_3 (rT_3). The formation of rT_3 , the third major circulating form of thyroid hormone, is catalyzed by the enzyme 5-deiodinase. Reverse T_3 has no biological activity, has a short half-life of 4 hours, and circulates bound to TBG; its formation is considered a disposal pathway in the peripheral metabolism of T_4 (LoPresti, 1989).

The intake of iodide influences the DIT/MIT ratio in Tg. DIT is the preferential iodotyrosine formed; thus, when iodide is abundant, T_4 is the predominant form of hormone synthesized and secreted, but when iodide sources are diminished, MIT is produced in greater quantities, leading to increased T_3 formation and release. In addition, the thyroid gland has a 5'-deiodinase that converts T_4 to T_3 . This process is under the control of TSH, so that T_3 secretion is enhanced during periods of TSH stimulation

T_3 , 3,5,3'-triiodothyronine; T_4 , thyroxine.

*80% of circulating T_3 comes from the peripheral deiodination of T_4 . To convert total T_4 from nmol/L to $\mu\text{g/dL}$, or free T_4 from pmol/L to ng/dL, divide by 12.87.

To convert total T_3 from nmol/L to ng/dL, or free T_3 from pmol/L to pg/dL, multiply by 65.1.

(i.e., primary hypothyroidism and cases with TSH-stimulating immunoglobulin [TSI]) (Ishii, 1983).

The monodeiodination of T_4 to T_3 and rT_3 accounts for 70% of the peripheral metabolism of T_4 (LoPresti, 1989); the remainder of T_4 metabolism occurs by conjugation of T_4 to sulfate, deamination, and decarboxylation to form the acetic acid analog tetrac, and by ether link cleavage (Engler, 1989) (Table 24-10). T_3 but not rT_3 can be conjugated with sulfate to form T_3 -sulfate and can be converted to its acetic acid analog, triac (Engler, 1989). The enzymes responsible for these reactions are the phenolsulfotransferases, which are present in many tissues throughout the body, and the L-aminotransferase, located in the liver, respectively (Engler, 1984). After their formation from T_4 , both T_3 and rT_3 undergo deiodination to form 3,3'-diiodothyronine (T_2).

Protein-bound thyroid hormones do not enter cells, are considered to be biologically inert, and function as storage reservoirs for circulating thyroid hormones. In contrast, the minute levels of free hormone fractions readily enter cells by specific membrane transport mechanisms to exert their biological effects. These effects are mediated by T_3 receptors located in the nucleus of the cell.

Four isoforms of the T_3 receptors have been described: α -1, α -2, β -1, and β -2 (Brent, 1991). α -1 and β -1 receptors are present in most tissues. Binding of T_3 to them promotes thyroid hormone action, presumably by increasing mRNA and protein synthesis. The β -2 receptor is unique to the pituitary and is central in the negative-feedback regulation of TSH by thyroid hormone. The α -2 receptor is inhibitory and acts as a negative regulator of thyroid hormone action.

Mutations in the β -receptors, which diminish the ability of T_3 to bind to the nucleus, have been described in the syndrome of thyroid hormone resistance. Individuals with this syndrome have growth and mental retardation of varying degrees, as well as hypothyroidism (Refetoff, 1991).

HYPOTHALAMIC-PITUITARY-THYROID AXIS

The physiologic regulators responsible for integrating the function of the thyroid gland and the periphery include the hypothalamic hormone, TRH; the pituitary hormone, TSH; and the serum free T_4 and free T_3 concentrations. TRH enhances TSH synthesis, stimulates the secretion of any pre-formed TSH from the thyrotrophs, and modulates the bioactivity of TSH, resulting in the secretion of bioactive TSH (Beck-Peccos, 1985; Shupnik, 1986). TRH itself is under the negative-feedback influence of circulating thyroid hormones (TRH mRNA levels are inversely related to the circulating T_3 values) (Kakucska, 1992). The same feedback inhibition occurs at the level of the thyrotrophs.

Thyrotropin-Releasing Hormone

TRH is a modified tripeptide (pyroglutamyl-histidyl-proline-amide) derived from a large prepro-TRH molecule. The TRH molecule is released from the prepro molecule by a peptidase (Yamada, 1990). TRH is found in the hypothalamus, the brain, the C cells of the thyroid gland, the β cells of the pancreas, the myocardium, and the prostate and testis, as well as in the spinal cord. The neuron bodies producing TRH are

innervated by catecholamine, leptin, and somatostatin-containing axons; all these hormones can influence the rate of its synthesis.

Thyroid hormones regulate their own production by feedback inhibition to synthesis of TRH and TSH in the hypothalamus and pituitary, respectively. TRH acts also on the production of other pituitary hormones, especially prolactin. Leptin plays a significant role in the regulation of the TRH gene (Bjorbeck, 2004), affecting the individual's appetite for food intake. It is difficult to develop a specific antibody for TRH, and assays are not clinically useful.

Thyroid-Stimulating Hormone

TSH is a glycoprotein consisting of two monovalently linked α and β subunits. The α subunit has the same amino acid sequences as LH, FSH, and human chorionic gonadotropin (hCG). It is the β subunit that carries specific information to the binding receptors for expression of hormonal activities.

The radioimmunoassay for measuring TSH was first developed by Odell and colleagues in 1965. This **first-generation assay** did not have sufficient sensitivity to distinguish normal TSH levels from the suppressed levels seen in primary hyperthyroidism. By the mid 1980s, a "sensitive" or second-generation immunometric TSH method using monoclonal or polyclonal antibodies was developed, which had an improved sensitivity to 0.1–0.2 mIU/L. Refinements in the immunometric method led to the third-generation assays now in common use, which allow measurement down to about 0.005 mIU/L. Although a fourth-generation TSH assay has recently been developed with a sensitivity of 0.0004 mIU/L, it is not widely available, and the third-generation assays provide sufficient sensitivity for the vast majority of clinical applications. The American Thyroid Association (ATA) recommendations state that third-generation assays should be able to quantitate TSH in the 0.010–0.020-mIU/L range on an interassay basis with a coefficient of variation of 20% or less. In reporting assay results, the ATA recommends using functional sensitivity, defined as the point at which the interassay precision has a coefficient of variation equal to or less than 20% (Spencer, 1996).

Owing to improvements in the sensitivity of the TSH assay, this test alone can identify virtually all instances of hyperthyroidism and hypothyroidism, except when there is damage to the hypothalamus or pituitary, thyroid hormone resistance, or interference with normal functioning of the HPT axis due to medication. TSH results within the reference interval usually exclude thyroid dysfunction and help distinguish the profound TSH suppression typical of frank Graves' thyrotoxicosis (TSH <0.01 mIU/L) from the modest degrees of TSH suppression (0.01–0.1 mIU/L) observed with mild (subclinical) primary hyperthyroidism and some cases of nonthyroidal illness. Of note, as assay sensitivity has improved, the normal range has not changed, remaining between approximately 0.5 and 5.0 mIU/L in most laboratories. However, the serum TSH concentration detected in patients with severe thyrotoxicosis has been lower with each successive improvement in the TSH assays: Using a fourth-generation assay, the serum TSH is less than 0.004 mIU/L in patients with severe hyperthyroidism. Hyperthyroid patients have suppressed TSH values, with the exception of those few individuals who have hyperthyroidism caused by a TSH-producing tumor or other diseases such as pituitary resistance to thyroid hormone. Subclinical hyperthyroidism is defined by the presence of a low TSH with normal levels of T_4 and T_3 (Table 24-11).

In most individuals with hypothyroidism, serum TSH results are clearly elevated, but results may be inappropriately normal for the levels of T_4 and T_3 in those with pituitary or hypothalamic disorders. The term *subclinical hypothyroidism* is used to describe patients with elevated TSH concentration but with normal levels of T_4 , T_3 , and FT₄. An important cause of both increased and decreased TSH results is nonthyroidal illness (NTI). Patients with NTI tend to have low TSH results during their acute illness, then TSH rises to within or above the reference range with resolution of the underlying illness, ultimately returning to normal once the acute illness has resolved. The situation is complicated because medications, including glucagons, opioids, glucocorticoids, and dopamine, suppress TSH. The sensitive TSH assays are helpful in evaluation of thyroid hormone treatment for both replacement therapy and suppressive therapy.

Despite the clinical sensitivity of TSH, a TSH-centered strategy has two primary limitations. First, it assumes that hypothalamic-pituitary function is intact and normal. Second, it assumes that the patient is stable (i.e., the patient had no recent therapy for hyperthyroidism or hypothyroidism) (Wardle, 2001). If either of these criteria is not met, the serum TSH result can be misleading (see Table 24-11). In these instances, to confirm the

presence of thyroid dysfunction, in addition to measuring TSH, measurement of FT₄ with or without total T₄ may prove helpful. Serum Free T₃ and serum TSH measurements are appropriate in patients suspected of hyperthyroidism, as they may have overproduction of T₃ with a normal to low-normal T₄ (T₃ thyrotoxicosis).

Thyroxine

After release from its thyroid follicles, thyroxine will bind to various proteins in the blood (thyroid-binding globulin, albumin, thyretin). Thyroxine can be measured by immunoassay after the hormone is separated from the carrier protein. The reference range is 5–12.5 µg/dL in adults, with slightly lower results for certain pediatric age groups. Although TSH is the most important test of thyroid function, thyroxine measurements are often used along with TSH and can be important in interpreting TSH results. The combination of a low T₄ and an increased TSH is indicative of primary hypothyroidism, whereas elevated T₄ and T₃ combined with decreased TSH are characteristic of primary hyperthyroidism. Hyperthyroidism, however, has been reported in patients with an elevated serum T₄

but with serum T₃ levels within the reference range or low. This so-called **T₄ thyrotoxicosis** can occur in patients with iodine-induced thyrotoxicosis; in patients on beta-blockers, amiodarone, or large doses of steroids; and in thyrotoxic patients with NTI. A suppressed TSH level associated with a normal to low-normal T₄ and a high T₃ characterizes T₃ thyrotoxicosis. This is more common in a toxic nodule (see Table 24-11).

Severe nonthyroidal illness is associated with low T₄ and low T₃; this so-called **low T₄ and T₃ syndrome** (an adaptive response to reduce metabolic demands and conserve protein stores) (LoPresti, 1995) is associated with a poor prognosis (Chopra, 1997). It is thought to arise from a maladjusted central inhibition of TRH (Van den Berghe, 1998, 2000) (Fig. 24-7).

Euthyroid hyperthyroxinemia is distinguished by the presence of an increased serum T₄ level in association with a normal TSH in an otherwise euthyroid individual. This entity has a variety of causes, including increased binding proteins as may be seen with certain drugs (e.g., estrogen) or medical conditions (e.g., liver disease). It is also seen in patients who are acutely hospitalized for psychiatric illness and in patients with familial

dysalbuminemia. When medications or other factors cause increased protein binding, there is a consequent increase in the serum total T_4 level; conversely, a decrease in binding capacity leads to a decrease in serum total T_4 . These perturbations do not have any physiologic effect, as it is the free hormone, not the protein-bound component, that is bioactive. In these situations, free T_4 correlates better with thyroid functional status than does serum total T_4 .

The so-called **T_3 uptake (T_3 -UP) test** is a classical method of adjusting a total T_4 measurement for alterations in binding protein. A T_3 -UP result is a relative measurement of the unoccupied binding sites of all circulating proteins. It was originally performed by saturating available binding sites with radiolabeled T_3 , then measuring the unbound T_3 by adsorbing it onto a resin (hence the term **T_3 resin uptake**). Methods giving analogous results can still be performed via nonisotopic methods on automated analyzers. The free thyroxine index (FTI) is then calculated as (T_3 -UP of the patient)/(mean T_3 -UP of the reference population) multiplied by the patient's total T_4 . The FTI (reference range, 5.4–9.7) is only a relative estimate of the free T_4 concentration. In general, during thyrotoxicosis, both total T_4 and T_3 -UP are elevated; conversely, in hypothyroidism, both total T_4 and T_3 -UP are decreased, and when there is a binding globulin abnormality, these two values diverge (e.g., total T_4 is elevated and the T_3 -UP is decreased, or the total T_4 is decreased and the T_3 -UP is increased). The FTI has been largely replaced by the direct measurement of free T_4 by immunoassay, dialysis, or ultrafiltration.

Free Thyroxine

FT_4 is the biologically active fraction of thyroxine in circulating blood. In the past 10–15 years, direct measurement of FT_4 has increased in sensitivity and precision. The traditional reference method for FT_4 is equilibrium dialysis, a method that is not affected by changes in binding protein concentration. The sample is dialyzed against a nonprotein buffer, using a membrane impermeable to proteins, so that FT_4 will achieve equal concentrations on both sides of the membrane. Because bound T_4 vastly exceeds FT_4 in the plasma, their ratio is essentially unperturbed by this process. The protein-free solution is then collected and analyzed for T_4 . This is a time-consuming method that cannot meet the high-volume demand of clinical laboratories. Even this laborious method does not give a true measure of FT_4 in all cases, because small molecules that may affect T_4 binding are diluted in the procedure. Theoretically more accurate are ultrafiltration (using pressure to push the plasma sample through a dialysis membrane) and **symmetrical dialysis** (where plasma is dialyzed against itself, using a radioactive tracer added on one side to measure the rate of diffusion of FT_4 , which is proportional to its concentration). Mass spectrometry is well suited to measurement of thyroid hormone (De Brabandere, 1998), and a method using ultrafiltration followed by tandem mass spectrometry to simultaneously measure FT_4 and FT_3 has recently been published (Gu, 2007).

In common practice, FT_4 is usually measured by immunoassay techniques, which have employed different approaches over the years (Spencer, 1986; Hay, 1991). These methods can be performed on automated clinical chemistry platforms and provide appropriate results in most clinical circumstances. However, depending on the exact method, they can be unreliable in various circumstances and must be used with caution. For example, spurious results can occur with abnormal variants of any of the binding proteins (particularly familial dysalbuminemic hyperthyroxinemia, a condition with high T_4 but normal FT_4 , caused by an albumin variant that binds T_4 abnormally) or in the presence of T_4 or T_3 autoantibodies (Langsteger, 1997). Increases or decreases in serum FT_4 without concomitant changes in metabolic state have been reported in pregnancy with NTI, and in patients being treated with certain drugs. For example, prolonged administration of phenytoin or carbamazepine results in a 15%–30% decrease in both serum T_4 and FT_4 . In these circumstances, dialysis or ultrafiltration methods are indicated.

FT_4 can also be determined using mass spectroscopy, after the FT_4 is separated from the protein–hormone complex using ultrafiltration at 37° C and avoiding dilution effects.

Triiodothyronine

T_3 , generally measured by immunoassay, has a reference interval typically in the range of 60–160 $\mu\text{g/dL}$ (0.9–2.46 nmol/L). T_3 is much less bound to serum protein than T_4 ; thus a relatively greater proportion of T_3 than T_4 exists in the free, diffusible state. Serum total T_3 measurement is helpful in confirming the diagnosis of hyperthyroidism, especially in patients with no or minimally elevated T_4 or ambiguous clinical manifestation. In 90%

of patients with hyperthyroidism, T_4 and T_3 values are increased, with the increase in T_3 usually greater than that in T_4 . Serum T_3 levels, however, can be in the reference range or low in patients with hyperthyroidism if there is coexistent NTI, or if patients are on drugs that decrease the conversion of T_4 to T_3 (e.g., propranolol, amiodarone).

Hyperthyroidism with elevated serum T_3 but normal T_4 and free T_4 is termed T_3 thyrotoxicosis (Bitton, 1990). Patients with this syndrome are a heterogeneous group with no distinctive signs or symptoms. Although most patients have Graves' disease, T_3 thyrotoxicosis may occur in patients with other causes of hyperthyroidism such as toxic nodular goiter or toxic adenoma. About 1%–4% of thyrotoxic patients have T_3 thyrotoxicosis, except in regions of iodine deficiency, where it is more common.

Elevated serum T_3 levels with normal T_4 levels may also be seen in patients with hyperthyroidism early in the course of treatment with antithyroid drugs or during relapse after treatment. Elevated TBG will cause elevated T_3 .

Generally, the measurement of serum T_3 is not useful in evaluating patients suspected of having hypothyroidism because serum T_3 levels are within the reference interval in 15%–30% of hypothyroid patients (Surks, 1990). However, decreased T_3 levels are seen in patients who have severe hypothyroidism, that is, those with serum T_4 levels less than about 2 $\mu\text{g/dL}$ (32 nmol/L) (Bigos, 1978). Low serum T_3 may occur in patients with a wide variety of NTI. In patients with acute illness such as myocardial infarction, the decrease in serum T_3 occurs rapidly, declining to about 50% of the reference value within days (Utiger, 1980). Serum T_3 concentrations are also low in cord blood, but increase rapidly during the first few hours of life.

Patients receiving thyroid preparations containing T_3 such as desiccated thyroid and synthetic T_3 and T_4 combinations and those treated with T_3 will have uninterpretable serum T_3 results unless the time of hormone administration is known. Administration of T_3 (Cytomel) results in a rapid rise in T_3 concentration that peaks within 2–4 hours and then begins to drop off. In contrast, the serum T_3 levels do not show a peak in patients treated daily with T_4 (levothyroxine); instead, stable levels of T_3 , which is derived from the peripheral conversion of T_4 , are reached after only a few weeks of therapy. A number of pharmacologic agents are associated with low levels of T_3 and free T_3 , and with normal or even high levels of serum T_4 and FT_4 . These include glucocorticoids, amiodarone, and large dosages of propranolol. These patients usually have normal TSH results; however, amiodarone can induce hyperthyroidism or hypothyroidism, in which case the TSH values will be suppressed or elevated respectively. Total T_3 concentrations are measured by competitive immunoassay methods that are now mostly nonisotopic and use enzymes, fluorescence, or chemiluminescence molecules as signals (Nelson, 1996).

Reverse Triiodothyronine

rT_3 , a major metabolite of thyroxine, is produced by 5-deiodination of T_4 .

In many clinical situations, serum T_3 and serum rT_3 have been found to vary reciprocally, but serum rT_3 measurements have found little clinical usefulness. Serum rT_3 is high in patients with NTI, whose serum total T_3 is decreased. Serum rT_3 is increased in healthy newborns, in patients with hyperthyroidism (including factitious hyperthyroidism), and in patients taking certain drugs, including amiodarone and propranolol.

Thyroglobulin

Tg is synthesized and secreted by the follicles. It is present in the serum of normal individuals in the range of up to about 30 ng/mL (45 pmol/L). The serum Tg concentration reflects thyroid mass, thyroid injury, and TSH receptor stimulation (Spencer, 1995). Tg is increased in a variety of disorders, including Graves' disease, thyroiditis, and nodular goiter. Patients with thyrotoxicosis factitia have undetectable levels of Tg in contrast to a high level found in patients with other causes of thyrotoxicosis. The routine measurement of Tg is never indicated. Its utility resides in the monitoring of recurrence of certain variants of thyroid cancer, in the diagnosis of thyroid dysgenesis in congenital hypothyroidism, and, as noted previously, in helping to distinguish subacute thyroiditis from thyrotoxicosis factitia.

The main value of Tg measurement is to follow patients with thyroid malignancy postoperatively (Ericsson, 1984). It is helpful in patients with well-differentiated thyroid carcinoma, but not in those who have undifferentiated tumors or medullary thyroid cancer. The clinical value of its measurement is limited by a number of technical problems, including the presence of antibodies, which are present in 20% of patients with thyroid carcinoma (Spencer, 1999). These antibodies interfere with Tg

measurement, causing overestimation or underestimation of serum Tg levels. Therefore, whenever Tg level is drawn to monitor recurrence/persistence of thyroid cancer, it is extremely important to obtain a simultaneous sample for Tg antibodies (TgAb). In patients with positive TgAb, polymerase chain reaction (PCR) methods (using serum) used to amplify the Tg mRNA may eliminate this problem.

Recombinant human TSH (rhTSH) is commonly used to test patients with thyroid cancers for the presence of residual/recurrent disease. This is more practical, more convenient, and markedly less unpleasant for the patient than stopping thyroid hormone suppression over the span of several weeks to increase the TSH level; an elevated TSH is required for RAI (radioactive iodine) uptake to occur in any remaining remnant or recurrent tumor. Measurement of Tg 72 hours following the last dose of rhTSH correlates highly with the presence of recurrence, and some authorities support the use of this test alone without a concomitant whole body iodine scan for those with “low-risk” tumors (age <40, no distant metastases, size <1 cm, well differentiated). All other patients with thyroid cancer need to undergo whole body scanning, in addition to measurement of TSH; concomitant use of both equals the sensitivity of scanning performed after thyroid hormone withdrawal, which is about 97%. Any rise in post-rhTSH serum Tg above 2 ng/mL in patients with thyroid cancer who have undergone remnant ablation and are on hormone suppressive therapy is suspicious for recurrence/persistence of disease and needs to be worked up accordingly (i.e., full restaging while hypothyroid off of suppressive therapy).

Well-differentiated tumors typically display about a 10-fold increase in Tg in response to a high TSH (Spencer, 1999). Poorly differentiated tumors that do not concentrate iodide may display a blunted response to TSH stimulation (Schlumberger, 1980). In early weeks postthyroidectomy, serum Tg levels typically fall, with a half-life of 2–4 days. The pattern of change in serum Tg values on T_4 treatment is a better indicator of a change in tumor burden than any single serum Tg value (Spencer, 1995). Because of interassay variability, it is extremely important to use the same laboratory (TSH assay) for monitoring.

Thyroxine-Binding Globulin

TBG is the main serum carrier protein for both T_4 and T_3 . Measurement of TBG may be helpful in patients who have serum T_4 and T_3 levels that do not agree with other laboratory parameters of thyroid function, or that are not compatible with clinical findings. TBG, which is measured by immunoassay, is in the range of 13–39 $\mu\text{g/dL}$ (150–360 nmol/L) in healthy individuals. Inherited abnormalities in TBG include complete and partial deficiency, as well as TBG variants with decreased affinity for T_4 or T_3 , and TBG excess (Langsteger, 1997). Among the acquired causes of abnormalities in the TBG concentration are a variety of medications and medical conditions (Table 24-12). Medications such as salicylates, phenytoin, penicillin, and heparin can displace T_4 from binding to TBG.

Thyroid Autoantibodies

Autoimmune thyroid disease causes cellular damage and alters thyroid gland function. Cellular damage occurs when the autoantibodies or the sensitized T lymphocytes bind to thyroid cell membranes, causing cell lysis and inflammatory reactions. Three thyroid autoantigens are responsible for the autoimmune thyroid disorders: TPO, Tg, and the TSH receptor. TPO antibodies (TPOAb) are involved in the tissue destructive process associated with hypothyroidism in Hashimoto's and atrophic thyroiditis.

Some studies suggest that TPOAb may be cytotoxic to the thyroid (Chiovato, 1993; Guo, 1997). TgAb, if present even in low concentrations in serum, can interfere with the anti-Tg antibody used in the immunoassay for Tg measurement. Thus, the TgAb concentration should be measured in all patients before Tg analysis. In iodide-deficient areas, serum TgAb measurement can be used to detect autoimmune thyroid disease in patients with a goiter and to monitor iodide therapy in endemic areas.

TSH receptor antibodies (TRAbs) were previously known as thyroid-stimulating immunoglobulin or long-acting thyroid stimulators. TRAbs are classified as stimulating or blocking antibodies. Graves' disease (GD) is an autoimmune condition in which goiter and hyperthyroidism are induced by thyroid-stimulating antibodies that mimic the action of TSH. The target of the autoimmune response is the thyrotropin receptor. Although both stimulating and blocking antibodies are present in GD, the latter usually do not cause symptoms; however, in a few cases, they may lead to the development of hypothyroidism. TRAbs are positive in 85% of patients with GD. Measurement of TRAbs has been used to predict the outcome of Graves' patients treated with drug therapy; if the titer of the antibodies is low before therapy, patients have a better chance for remission after 6–12 months of therapy.

Measurement of TRAbs has also been used to predict the risk of thyroid dysfunction in newborns of mothers with GD as a result of transplacental passage of maternal TRAb (Heithorn, 1999; Radetti, 1999). In these patients, assays that distinguish blocking from stimulating antibodies are important clinically (Davies, 1998).

Longitudinal studies suggest that TPOAb may be a risk factor for future thyroid dysfunction, including postpartum thyroiditis and autoimmune complications from treatment with amiodarone, interferon- α , and lithium (Feldt-Rasmussen, 1994; Johnson, 1999; Martino, 2001).

Urinary Iodine Measurement

Iodine is required for normal thyroid hormone production. Iodine measurements are used mainly to assess the dietary iodine intake of certain populations. This is of great importance in that iodine deficiency disorders affect 2.2 billion persons throughout the world, including the United States (Delange, 1995; Dunn, 1998). Because most of the ingested iodine is excreted in the urine, measurement of urinary iodine (UI) excretion provides an accurate estimate of dietary iodine intake (Dunn, 1998). Suggested ranges for UI excretion are shown in Table 24-13.

Screening Programs for Detection of Neonatal Hypothyroidism

The prevalence of hypothyroidism in newborns is estimated from 1 in 3000 to 1 in 5000. It is higher in certain ethnic groups and is increased in iodine-deficient regions worldwide. Early detection of hypothyroidism in the neonatal period is critical to eliminate the severe mental retardation associated with thyroid hormone deficiency. Measurement of T_4 and TSH is used for screening, which is performed using dry blood spots or cord serum. The detection rate depends on the tests used and the timing of specimen collection. Measurement of only T_4 carries a high false-positive rate, necessitating recall of a large number of infants for retesting. Causes of false-positive results include low T_4 levels, which occur in both premature infants and those with congenital absence of TBG. Screening with only T_4 may miss infants with compensated or partial thyroid insufficiency. Because about 15% of infants with primary thyroid disorders have compensated hypothyroidism (normal serum T_4 levels in association with elevated TSH), an elevated TSH is the most sensitive test for the diagnosis of congenital hypothyroidism. However, false-positive results are occasionally seen, for example, in premature or severely stressed infants. In addition, by screening with TSH alone, those infants with hypothalamic

or pituitary disease will be missed. Very-low-birthweight infants should be retested at 2 and 4–6 weeks to detect late-onset transient hypothyroidism (Frank, 1996). For newborns, if the initial TSH value is <10 mIU/L, no further action need be taken; if it lies in the 10–20-mIU/L range, then a repeat test needs to be performed in 2–6 weeks. Finally, if the initial blood spot TSH >20 mIU/L, endocrinologic evaluation is necessary to make the diagnosis of hypothyroidism.

Nonthyroidal Illness

Seriously ill patients can have abnormal thyroid tests even without underlying thyroid pathology (DeGroot, 1992; Kaptein, 1996). A rapid decline in both total and free T_3 typically develops in the setting of severe illness (e.g., myocardial infarction, sepsis) (Piketty, 1996). As the severity of the illness increases, the serum total T_4 falls because of T_4 -binding protein disruption by inhibitors in the circulation (Wartofsky, 1982; Docter, 1993; Wilcox, 1994). Patients with nonthyroidal illness (NTI) whose T_4 levels drop below 2 ng/dL carry an exceptionally poor prognosis. Alterations in thyroid function tests seen during NTI are termed the euthyroid sick syndrome or the low T_4 syndrome. Figure 24-7 shows the spectrum of changes in the thyroid tests as they relate to the severity and the stage of the illness. Patients with NTI tend to have low or low-normal TSH and normal or low-normal T_4 but very low T_3 during their acute illness; then TSH rises to within normal or above normal with resolution of the underlying illness and finally returns to the normal range (Faber, 1987). This situation can be complicated if certain drugs are used for this illness (e.g., glucagon, dopamine, and high doses of corticosteroids suppress TSH and can mask hypothyroid status during their use) (Kaptein, 1980; Skamene, 1984; Brabant, 1989; Samuels, 1990).

In uremia, there is accumulation of indoleacetic acid, which interferes with thyroid hormone binding (Litaka, 1998).

Physiologic Variables

For practical purposes, variables such as age, gender, race, season, phase of menstrual cycle, cigarette smoking, exercise, fasting, and phlebotomy-induced stasis have minor effects on thyroid function tests in ambulatory adults (Hollowell, 2002). Studies have suggested that each individual has a genetically determined FT_4 setpoint (Meikle, 1988; Andersen, 2002); any deviation from this setpoint will be sensed by the pituitary and cause reciprocal change in TSH secretion. In the early stages of developing thyroid dysfunction, a serum TSH abnormality will precede the development of an abnormal FT_4 because TSH responds exponentially to subtle FT_4 changes as shown in Figure 24-8.

Despite the wider serum TSH variability seen in older individuals, there appears to be no justification for using a widened or age-adjusted reference range. This conservative approach is justified by reports that mildly suppressed or elevated TSH is associated with increased cardiovascular morbidity and mortality (Sawin, 1991; Parle, 2001). In children, the hypothalamic-pituitary-thyroid axis undergoes progressive maturation and modulation; there is a continuous decline in the TSH/ FT_4 ratio from the time of midgestation until after puberty (Nilson, 1993; Adams, 1995;

Lu, 1999; Zurakowski, 1999; Fisher, 2000a,b); as a result, higher TSH concentrations are typically seen in children.

During pregnancy, estrogen production increases, progressively elevating the TBG concentration and resulting in an increase in the total T_4 and T_3 reference range to approximately 1.5 times the nonpregnancy upper reference level by 16 weeks' gestation (Weeke, 1982; Pedersen, 1993; Nohr, 2000). Although TBG excess leads to an increase in both T_4 and T_3 concentrations, the serum FT_4 and T_3 concentrations remain unchanged.

Serum hCG, which has structural similarity to TSH, has weak thyroid-stimulating activity (Talbot, 2001). The increase in hCG soon after fertilization results in a small increase in FT_4 and T_3 concentrations, usually within the normal reference range. These changes result in a fall in serum TSH during the first trimester; a subnormal serum TSH may be seen in about 20% of mothers who have normal pregnancies (Glinioer, 1990, 1997; Panesar, 2001). The peak rise in hCG and the nadir of TSH occur together at about 10–12 weeks' gestation. In 2% of pregnancies, the increase in FT_4 reaches supranormal levels and, if prolonged, may lead to a syndrome referred to as gestational transient thyrotoxicosis, which is characterized by more pronounced symptoms and signs of thyrotoxicosis. This condition is frequently associated with first-trimester hyperemesis gravidarum (Goodwin, 1992; Hershman, 1999).

Medications and Thyroid Function Tests

Drugs can cause both in vitro and in vivo effects on thyroid tests. This can lead to the misinterpretation of test results, inaccurate diagnoses, and further unnecessary tests (Surks, 1995; Kailajarvi, 2000). Estrogen-induced TBG elevation causes abnormally high total T_4 and total T_3 , but has no effect on TSH or FT_4 and free T_3 . Glucocorticoids in large doses can suppress TSH and decrease the conversion of T_4 to T_3 (Samuels, 1997; Kaptein, 1980). Dopamine suppresses TSH and can temper the expected rise in TSH in hospitalized patients with primary hypothyroidism (Kaptein, 1980). Propranolol suppresses the conversion of T_4 to T_3 ; (this is one of the reasons it is used in the treatment of thyrotoxicosis).

Iodide, found in iodide-containing contrast media used in CT scans and coronary angiography or in solution to sterilize skin, and radiopaque dyes can cause both hyperthyroidism and hypothyroidism in susceptible patients (Meurisse, 2000). Iodine-containing drugs such as amiodarone (used as an antiarrhythmic agent) have complex effects on thyroid function and can cause hypothyroidism (10% of patients) or hyperthyroidism (1%–2%) in susceptible individuals with positive antibodies (TPOAb) (Martino, 1987, 2001; Caron, 1995; Harjai, 1997; Daniels, 2001).

Lithium inhibits thyroid hormone synthesis and release and can cause hypothyroidism in about 15%–50% of patients, especially those patients with positive TPOAb (Lazarus, 1998; Kusalic, 1999; Oakley, 2000). The mechanism of lithium action is similar to that of iodide. Lithium is concentrated by the thyroid and inhibits thyroidal iodine uptake. It also inhibits iodotyrosine coupling, alters thyroglobulin structure, and inhibits thyroid hormone secretion. The latter effect is critical to the development of hypothyroidism and goiter (Lazarus, 1998).

Drugs such as phenytoin, carbamazepine, salicylate, salsalate, and furosemide competitively inhibit thyroid binding to serum proteins. They therefore can cause total T_4 levels to be depressed (because the FT_4 is maintained at its normal level), and they can cause the FT_4 estimated by FTI or direct assays to be artifactually low. Therapeutic doses of phenytoin can induce acceleration of T_4 disposal and perhaps can directly suppress TSH centrally, all of these mechanisms being responsible for the reduced T_4 (Surks, 1995). Heparin can stimulate in vitro lipoprotein lipase and can liberate free fatty acids, which inhibit T_4 binding to serum proteins and falsely elevate FT_4 (Mendel, 1987).

Medications such as phenobarbital, phenytoin, rifampin, and carbamazepine increase the rate of thyroid hormone clearance by increasing the deiodination of T_4 and T_3 . Hypothyroid patients treated with any of these medications need to have their hormone levels monitored closely, as an increase in levothyroxine ($L-T_4$) dose may be required. In turn, changes in thyroid hormone status affect the clearance of many medications, including those listed previously (e.g., hyperthyroidism can lead to increased clearance of phenobarbital, hypothyroidism to decreased clearance). Owing to these various alterations in thyroid hormone parameters, the best indicator of thyroid status is the measurement of TSH along with the FT_4 . For those with pituitary disease or in those on Dilantin, T_4 by equilibrium dialysis should be used.

Somatostatin or its analog, octreotide, which is used to treat acromegaly (Itoh, 1988), and dopamine (Kaptein, 1980) inhibit TSH synthesis to undetectable levels in patients with severe NTI.

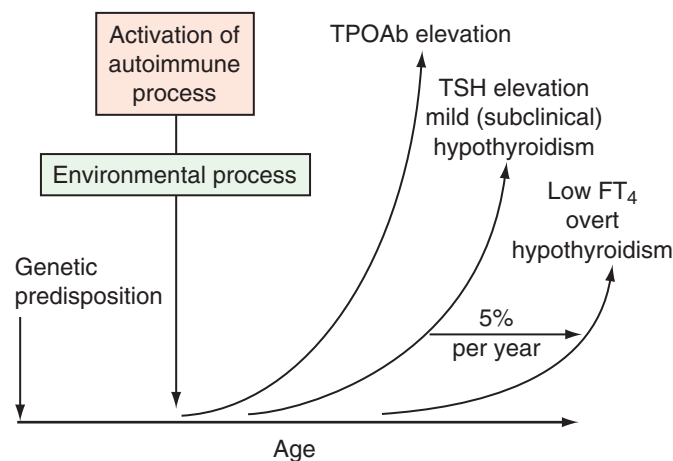

Figure 24-8 Depiction of the evolution of primary hypothyroidism of autoimmune origin. Thyroid Illness

Hyperthyroid patients may present with one or all of the following signs and symptoms: weight loss, sweating, heat intolerance, palpitations, insomnia, increased bowel movement, tremors, infertility, or amenorrhea. They have suppressed TSH values, with the exception of those few individuals who have secondary hyperthyroidism caused by TSH-producing pituitary tumors, or other rare disorders such as pituitary resistance to thyroid hormones. Subclinical hyperthyroidism is defined as low TSH ($<0.1 \mu\text{U/mL}$) with levels of T_4 and T_3 within the reference values with no signs or symptoms of hyperthyroidism (Ross, 1991). Detection of subclinical hyperthyroidism is particularly important in patients who are over 60, as they have increased risk of atrial fibrillation, increased cardiovascular mortality (Sawin, 1994), and osteoporosis. Minimal thyroid hormone excess can cause atrial fibrillation and can stimulate osteoclastic activity in bone, causing osteoporosis.

Patients with primary hypothyroidism can present with one or all of the following signs and symptoms: cold intolerance, constipation, water retention, hypercholesterolemia, depression, pretibial myxedema, periorbital edema, and elevated TSH with low T_4 and T_3 . TSH is low in patients with secondary hypothyroidism caused by pituitary or hypothalamic disorders. Patients with subclinical hypothyroidism have elevated TSH levels ($>4.5 \mu\text{U/mL}$), but both T_4 and T_3 are within the reference range. In 2004, an expert panel recommended TSH reference limits of $0.4\text{--}4.5 \mu\text{U/mL}$, and that patients with TSH in the range of $4.5\text{--}10 \text{ mU/L}$, or $0.1\text{--}0.4$, should not be routinely treated (Surks, 2004). The 2002 AACE guidelines (American Association of Clinical Endocrinologists, 2002) recommend treatment of those with TSH $>10 \mu\text{U/mL}$ or those with goiter and positive TPOAb whose TSH is between 4.5 and $10 \mu\text{U/mL}$. TPOAb measurement is useful for establishing the presence of autoimmunity; those with elevated antibodies have a greater probability of developing overt thyroid failure.

Screening for Thyroid Disease

The ATA guidelines recommend screening at age 35 and every 5 years thereafter (Ladenson, 2000). This appears to be a cost-effective strategy, especially for women (Parle, 2001) and the elderly (Vanderpump, 1995; Ladenson, 2000; Parle, 2001). Hashimoto's thyroiditis is an autoimmune disease of the thyroid caused when sensitized T lymphocytes and/or auto-antibodies bind to cell membrane, causing cell lysis and an inflammatory reaction, resulting in cellular damage. This is associated with high TSH and positive TPOAb and is encountered with increasing prevalence with increasing age (Vanderpump, 1995). The incidence of low TSH is also increased in the elderly (Vanderpump, 1995).

Mounting evidence indicates that a persistent TSH abnormality may lead to major risks if left untreated. One study reported a higher cardiovascular mortality rate in patients with chronically low TSH (Parle, 2001), and numerous reports indicate that mild hypothyroidism in early pregnancy increases fetal loss and impairs the IQ of offspring (Pop, 1995, 1999; Haddow, 1999). It is important to always confirm any TSH abnormality in a fresh specimen drawn 3 weeks later before making the diagnosis of mild abnormalities.

Uses of L-Thyroxine

An average replacement dose is $1.6 \mu\text{g/kg}$ body weight/day for adults, up to $4.0 \mu\text{g/kg}$ body weight/day for children, and lower doses for older individuals ($1.0 \mu\text{g/kg}$ body weight/day) (Sawin, 1983; Davis, 1984). The initial dose and the optimal time needed to establish the full replacement dose are dependent upon the age, weight, and cardiac status of each patient. The requirement might increase during pregnancy and in postmenopausal women starting hormonal replacement (Arafah, 2001). A serum TSH between 0.5 and $2.0 \mu\text{U/mL}$ is the therapeutic goal level for $L\text{-}T_4$ replacement in primary hypothyroidism. A serum FT_4 concentration in the upper third of the reference interval is the therapeutic target in central hypothyroidism.

TSH should be used to monitor patients receiving thyroid hormone replacement therapy, as well as those treated with hormone, to suppress malignant thyroid diseases (Spencer, 1990). Both TSH and FT_4 should be used to monitor hypothyroid patients suspected of intermittent non-compliance. At least 6 weeks is needed before retesting of TSH following a change in the dose of $L\text{-}T_4$. Annual TSH measurement is recommended in patients on a steady dose of T_4 . If FT_4 is being assayed, patients should withhold their levothyroxine dose on the day of the test, as serum FT_4 will be increased (about 13%) above baseline for 9 hours after the last dose is ingested (Ain, 1993); the TSH, however, is unlikely to be affected. Ideally, $L\text{-}T_4$ should be taken before meals, at the same time every day

and at least 4 hours from any other medications or vitamins/dietary supplements.

$L\text{-}T_4$ is used to suppress TSH in patients with well-differentiated thyroid carcinoma, for which thyrotropin is considered a trophic factor (Dulgeroff, 1994). It is recommended to use a TSH target of $0.05\text{--}0.1 \mu\text{U/mL}$ for low-risk patients and a TSH value $<0.1 \mu\text{U/mL}$ for high-risk patients. If the thyroglobulin level is undetectable, and no evidence of recurrence is noted 5–10 years after thyroidectomy, the dose of $L\text{-}T_4$ can be reduced to give low-normal TSH values ($<0.4 \mu\text{U/mL}$).

Calcitonin

Medullary thyroid carcinoma (MTC) originates from the C cells of the thyroid. It accounts for 5%–8% of thyroid cancers and 0.57% of thyroid nodules (Pacini, 1994).

Among cases of MTC, 25% are hereditary (multiple endocrine neoplasia types 2A and 2B) (Dunn, 1994; Brandi, 2001; Cobin, 2001). These are autosomal dominant inherited multiglandular syndromes. An important, recurring MTC genetic mutation was found to be located on the chromosome subband 10q11.2 (Mulligan, 1993; Hofstra, 1994).

The C cell secretes calcitonin. An elevated level of calcitonin in circulating blood indicates the presence of MTC. Mature calcitonin results from posttranslational modification of a larger 141 amino acid precursor (preprocalcitonin) within the parafollicular C cells. Preprocalcitonin undergoes cleavage of a single peptide to form procalcitonin; the latter has 116 amino acid residues. The immature calcitonin peptide consisting of 33 amino acids is located centrally within the procalcitonin molecule. The mature, active, 32 amino acid calcitonin is produced from immature calcitonin by the enzyme peptidylglycine-amidating monooxidase. Measurement of calcitonin is done by two-site immunometric assays using monoclonal antibodies: One recognizes the N-terminal region, and the other the C-terminal region. This method is more sensitive and more specific (Motte, 1988; van Heyningen, 1994; Becker, 1996). The cutoff level in healthy adults is about 10 ng/L .

Serum calcitonin measurements are used as tumor markers for detecting residual thyroid tissue or metastasis in patients with MTC. It should be measured before and 6 months after surgery. The presence of residual tissue or a recurrence of MTC can be ruled out only if both basal and postpentagastrin or calcium-stimulated calcitonin are undetectable. Provocative stimuli, such as calcium and pentagastrin (Pg) or omeprazole, have been used to detect C cell abnormalities, as they increase calcitonin levels at all stages of MTC (Wells, 1978; Barbot, 1994; Gagel, 1996; Erdogan, 1997; Wion-Barbot, 1997; Vieira, 2002; Vitale, 2002).

In the Pg stimulation test for the diagnosis of MTC, an intravenous infusion of Pg ($0.5 \mu\text{g/kg}$ body weight) is given over 5 seconds; blood samples are collected at baseline and 1, 2, 5, and 10 minutes after the start of the infusion. Interpretations of results are summarized in Table 24-14.

In the calcium stimulation test, intravenous injection of 2.5 mg/kg of calcium gluconate is given over 30 seconds; blood samples are then collected at baseline and at 1, 2, and 5 minutes. An increase in the plasma calcitonin level above 100 ng/L is an indication of C cell hyperplasia. The calcium infusion test has been reported to be less sensitive than the Pg test for the diagnosis of MTC, but, if combined with the Pg test, it enhances the sensitivity of the Pg test (Wells, 1978).

Calcitonin may also be elevated in other conditions unrelated to thyroid neoplastic conditions, as summarized in Table 24-15.

TABLE 24-14

Interpretation of the Pentagastrin (Pg) Test

Peak calcitonin (CT) ng/L (pg/mL)	Interpretation
<10	Normal (80% of adults)
>30 but <50	5% of normal adults
>50 but <100	Possible MTC or other thyroid pathology
>100	Probable MTC
Basal or post-Pg CT value $>10 \text{ pg/mL}$	C cell pathology or residual tissue in MEN 2 patients and MTC patients after surgery

ADRENAL

The adrenal glands are pyramidal structures located above each kidney, each weighing approximately 4–6 g. Anatomically, the adrenal is divided into two distinct parts: The medulla (inner layer) and the cortex (outer layer). The medulla, which is of neural crest origin (ectoderm), stores and secretes catecholamines. The cortex is of mesenchymal origin and is further divided into three zones: The outermost zona glomerulosa, which produces mineralocorticoids; the zona fasciculata, which is responsible for glucocorticoid production; and the inner zona reticularis, which synthesizes androgens. The cortex makes up about 80%–90% of the adrenal gland. The glands have a very rich arterial supply that forms a subcapsular plexus and empties into a central vein. By weight, they have the highest perfusion of blood per gram of tissue—a feature that ensures rapid dissemination of hormones throughout the body in response to stress.

HORMONES OF THE ADRENAL MEDULLA

The adrenal medulla is part of the sympathoadrenal axis. Being of neural crest origin, it possesses the capability of synthesizing catecholamines through the process of amine precursor uptake and decarboxylation. The initial and rate-limiting step in catecholamine synthesis is the conversion of tyrosine to 3,4-dihydroxyphenylalanine (dopa) by the enzyme tyrosine hydroxylase. Through a series of steps, L-dopa is subsequently converted to dopamine (D), norepinephrine (NE), and epinephrine (E) (Fig. 24-9). Epinephrine is almost exclusively produced and secreted by the adrenal medulla, where the ratio of NE/E is about 1:4. However, because all three catecholamines are also synthesized within the central and sympathetic nervous systems, the peripheral NE/E ratio is more like 9:1.

The catecholamines are metabolized by either catechol-*O*-methyltransferase (COMT) or monoamine oxidase (MAO). COMT converts D to methoxytyramine, E to metanephrine, and NE to normetanephrine, all of which in turn can be oxidized to vanillylmandelic acid (VMA) by MAO. MAO can also convert E and NE to 3,4-dihydroxymandelic acid, which is acted upon by COMT to form VMA. 3-Methoxy-4-hydroxyphenylacetic acid (homovanillic acid [HVA]) is the final product of dopamine metabolism.

TABLE 24-15

Conditions in Which Calcitonin May Be Elevated Other Than MTC

Neuroendocrine tumors	Small cell lung cancer, intestinal and bronchial carcinoid, all neuroendocrine tumors
Benign C cell hyperplasia (HCC)	Autoimmune thyroid disease, differentiated thyroid cancer
Other diseases	Kidney disease, hypergastrinemia, hypercalcemia

Pheochromocytoma

Pheochromocytomas are rare catecholamine-producing tumors, with an incidence of about 500–1600 per year (Pacak, 2001a). They account for <1% of all secondary causes of hypertension. Although 90% of pheochromocytomas are benign, they are almost invariably lethal if not diagnosed and properly treated (Pacak, 2001a). Approximately 90% of tumors arise within the adrenal medulla, and 10%–15% are of extraadrenal origin (paraganglioma). Most pheochromocytomas are sporadic; however, 10%–20% are familial, occurring as part of the multiple endocrine neoplasia type 2A or 2B (MEN 2A, MEN 2B), von Hippel–Lindau (VHL) disease, neurofibromatosis type 1 (NF-1), or familial paraganglioma (FP). The hereditary forms tend to present at a younger age, and except for FP, the tumors are usually intraadrenal and bilateral.

Sustained or paroxysmal hypertension is the most common manifestation of this disease and is present in about 90% of patients. Remarkably, 10% of patients are normotensive. More than 90% will present with paroxysmal attacks characterized by at least two of the three following symptoms: headache associated with palpitations and diaphoresis (Sheps, 1994). Other symptoms include orthostatic hypotension, labile blood pressure, excessive sweating, anxiety, nervousness, weight loss, fatigue, pallor, and tremor. These symptoms can last from a few seconds to several hours, with the interval between attacks being highly variable—from several times a day to once every few months. Indications for screening for pheochromocytoma are listed in Table 24-16.

There is ongoing debate as to which test is the best for diagnosing pheochromocytoma. With improvement in assay technique, evidence has come to support the measurement of plasma free metanephrine and normetanephrine levels via high-pressure liquid chromatography with tandem mass spectrometry as the initial test. The diagnosis of pheochromocytoma is made if the plasma concentration of either free metanephrine or normetanephrine is about four times the upper reference limit. Further testing is required in patients with high levels that are less than four times

TABLE 24-16

Indications for Screening for Pheochromocytoma

1. Hypertension with episodic features suggestive of pheochromocytoma.
2. Refractory hypertension.
3. Prominent lability of blood pressure.
4. Severe pressor response during anesthesia, parturition, surgery, or angiography.
5. Unexplained hypotension due to anesthesia, surgery, or pregnancy.
6. Family history of pheochromocytoma, MEN 2A or 2B, VHL disease, neurofibromatosis.
7. Incidentally discovered adrenal mass.
8. Idiopathic dilated cardiomyopathy.
9. Spells or attacks occurring during exertion, twisting and turning of the torso, straining, coitus, or micturition.

Biosynthetic Pathway for Catecholamines

Figure 24-9 Catecholamines: biosynthetic pathway. The rate-limiting step is the conversion of L-tyrosine to L-3,4-dihydroxyphenylalanine (L-dopa) through the actions of tyrosine hydroxylase. (Redrawn from Dluhy RG, Lawrence JE, Williams GH. Endocrine hypertension. In: Larsen PR, Kronenberg HM, Melmed S, Polonsky KS, editors. Williams textbook of endocrinology. 10th ed. Philadelphia: WB Saunders; 2003, p. 555, with permission.)

the upper reference limit (Sheps, 1994; Eisenhofer, 2004a,b). In centers where this assay is not available, the initial test should be the chromatographic measurement of a 24-hour urine collection for normetanephrine, metanephrine, fractionated free catecholamines (epinephrine, norepinephrine, dopamine), and creatinine (Lenders, 2002; Eisenhofer, 2004a,b). Metanephrine is the most sensitive and specific of these metabolites (Heron, 1996). The diagnosis of pheochromocytoma can also be made by measuring plasma catecholamines; however, given their short half-life and episodic secretion, it is of use only if the sample is collected during a paroxysm. Values from the 24-hour urine collection or plasma catecholamines that are two to three times the upper limit of normal are usually diagnostic of pheochromocytoma.

In cases of **sporadic pheochromocytoma**, the choice and interpretation of diagnostic tests depend on the pretest level of suspicion for disease. In this setting, the 24-hour urinary fractionated metanephrine and fractionated catecholamine measurements provide clinically acceptable sensitivity and significantly better specificity than fractionated plasma free metanephrine values (Sawka, 2003). Given the difficulties in collecting a complete 24-hour urine sample from pediatric patients, fractionated plasma free metanephrines should be considered the biochemical test of choice in that population (Weise, 2002) (Table 24-17).

Several factors can cause false-positive test results, either by stimulating catecholamine secretion and/or by interfering with the assay (Table 24-18). When assaying for plasma free metanephrines, patients should abstain from caffeinated beverages and alcohol for 24 hours before testing. They should also avoid acetaminophen, tricyclic antidepressants,

phenoxybenzamine, α -agonists (e.g., Aldomet), and monoamine oxidase inhibitors for at least 5 days before testing (Lenders, 1995). During testing for catecholamines, in addition to the list of items to avoid when testing for metanephrines, the patient should avoid nicotine, sympathomimetics (theophylline, pseudoephedrine), α -agonists (e.g., albuterol), and levodopa/carbidopa. If antihypertensive medications are needed, angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers, and selective α_1 -adrenoceptor blockers (e.g., prazosin) can be used without fear of causing false-positive results (Eisenhofer, 2003).

Although urinary catecholamine levels may be elevated in renal insufficiency and renal failure, the measurement of plasma free metanephrines can be used to reliably diagnose pheochromocytoma in both conditions (Eisenhofer, 2004b). Stressors such as an acute myocardial infarction, congestive heart failure, surgery, and acute cerebrovascular accident are all associated with elevated levels of catecholamines. In these situations, one can treat empirically and test once the patient has stabilized, or other diagnostic tests, including imaging studies, can be used. Plasma normetanephrine concentrations increase with age; as a result, elderly patients are particularly susceptible to having false-positive tests. The use of fractionated urinary metanephrines and catecholamines may be more suitable for this population (Sawka, 2003).

Plasma levels of normetanephrine less than 112 ng/L (0.61 nmol/L) and of metanephrine less than 61 ng/L (0.31 nmol/L) virtually exclude pheochromocytoma, so that no immediate further testing for the tumor should be necessary. With plasma concentrations of normetanephrine above 400 ng/L (2.19 nmol/L) or of metanephrine above 236 ng/L (1.20 nmol/L), the probability of pheochromocytoma is so high that the immediate task is to locate the tumor (Eisenhofer, 2003). More often than not, test results are returned as equivocal, requiring the need for confirmatory tests such as the clonidine suppression test or the glucagon stimulation test, or the measurement of urinary fractionated catecholamines. Clonidine is a centrally acting α -adrenergic agonist; it suppresses catecholamine release from the nervous system, but has no effect on its release by the tumor (Bravo, 1981). In those with pheochromocytoma, clonidine fails to adequately suppress plasma levels of norepinephrine. The clonidine suppression test is indicated only if the plasma catecholamines are greater than 1000 pg/mL (5.9 nmol/L). It is unreliable in those with normal or mildly elevated plasma catecholamines (Taylor, 1986; Elliott, 1988; Sjöberg, 1992). Eisenhofer (2003) showed that measuring plasma normetanephrines before and after clonidine testing increased the sensitivity and specificity of this test, especially in those who have only modest elevations of norepinephrine. The glucagon stimulation test can lead to dangerous rises in blood pressure and is rarely used. It should be performed only in patients whose blood pressure is well controlled, and a physician must be present throughout the test. A rise in plasma norepinephrine to greater than threefold, or greater than 2000 pg/mL, is diagnostic of pheochromocytoma (Table 24-19). The proposed mechanism of action is stimulation of glucagon-sensitive adenylate cyclase receptors expressed on these tumors.

TABLE 24-17

Sensitivity and Specificity of Hormone Levels for Diagnosing Pheochromocytoma

	SENSITIVITY		SPECIFICITY	
	Hereditary	Sporadic	Hereditary	Sporadic
Plasma				
Free metanephrines	97%	99%	96%	82%
Catecholamines	69%	92%	89%	72%
Urine				
Fractionated metanephrines	96%	97%	82%	45%
Catecholamines	79%	91%	96%	75%
Total metanephrines	60%	88%	97%	89%
Vanillylmandelic acid	46%	77%	99%	86%

Data from Eisenhofer G, Goldstein DS, Walther, et al. Biochemical diagnosis of pheochromocytoma: how to distinguish true from false-positive test results. *J Clin Endocrinol Metab* 2003;88:2656–66.

E, Epinephrine; MN, metanephrines; NE, norepinephrine; NMN, normetanephrine.

*Diuretics, angiotensin-converting enzyme inhibitors, and angiotensin II receptor blockers have little influence on the frequency of false-positive results.

TABLE 24-19

Pharmacologic Tests for Diagnosing Pheochromocytoma

Clonidine Suppression Test

Indications Patients with hypertension and clinical findings or family history that is highly suggestive of pheochromocytoma and the catecholamines are elevated but not to the extent that is diagnostic of pheochromocytoma.

Interpretation Normal: Decrease in NE to below normal or a >50% decline from baseline. A decrease in normetanephrines to below normal or a 40% decline from baseline. Pheochromocytoma: Failure of NE to drop below normal or decrease by more than 50% from baseline. Failure of normetanephrines to drop below normal or decrease by more than 40% from baseline.

Glucagon Stimulation Test

Indications When clinical findings or family history is highly suggestive of pheochromocytoma but blood pressure is normal and catecholamines are only modestly elevated.

Interpretation Pheochromocytoma: A threefold or greater increase in plasma NE, or a rise in the level to >2000 pg/mL.

NE, Norepinephrine.

Unless the history is compelling, or the patient falls into one of the categories of genetically inherited disorders, it is often unnecessary to repeat testing in those with slightly positive results.

Among catecholamine-secreting tumors, 10%–20% are familial. Genetic testing should be considered if the patient is younger than age 50 at presentation, has physical traits suggestive of one of the familial disorders, has multifocal disease, or has a positive family history. Tests include assaying for mutations in the gene for menin in MEN 1, the *RET* oncogene in MEN 2A (Sipple's disease) and MEN 2B, neurofibromin in NF-1, and *VHL* in von Hippel-Lindau syndrome. Familial paragangliomas are associated with various defects in the gene for succinate dehydrogenase. As with all genetic testing, pretest and posttest counseling is mandatory.

Chromogranin A (CgA) is a protein that is stored and secreted along with the catecholamines from the adrenal medulla and sympathetic nervous system. Although it is elevated in more than 80% of pheochromocytomas, it is not specific for this disorder, being secreted by other chromaffin tissues (Hsiao, 1991). CgA was initially thought to be useful in the diagnosis of pheochromocytoma, since medications typically used to treat it had no impact on CgA secretion or measurement. Despite a relatively high sensitivity of 86%, it has poor diagnostic specificity. This is due, in large part, to the fact that the kidneys play a major role in the clearance of CgA from the circulation, so that even mild degrees of renal impairment (e.g., creatinine clearance [CrCl] <80 mg/mL/min) can lead to significant increases in serum concentration of CgA (Bravo, 2003). Among hypertensive patients with CrCl less than 80 mL/min, overall sensitivity, specificity, and accuracy and positive and negative predictive values of serum CgA dropped to 85%, 50%, 59%, 38%, and 90%, respectively. However, when combined with elevated plasma catecholamines in patients with CrCl at least 80 mL/min, the diagnostic specificity and positive predictive values improved to 98% and 97%, respectively (Canale, 1994). Its major use is in postoperative monitoring for recurrence of these tumors.

Testing Procedures

For 24-hour urine collections, creatinine is measured to verify the adequacy of the collection. To preserve the specimen adequately, urine should be collected in a container to which 25 mL of 6 N HCl has been added.

Plasma catecholamines are collected after an overnight fast (water permitted). The patient is placed in a reclining position in a quiet environment, and a heparin lock is inserted intravenously. After 20–30 minutes, blood is collected in a prechilled ethylenediaminetetraacetic acid (EDTA) lavender-top tube. The whole blood sample should be kept in ice water until centrifuged (preferably at 4° C). Separation of plasma should take place within 2 hours of phlebotomy; the sample should then be frozen immediately.

Both urine and plasma specimens should be analyzed using high-performance liquid chromatography with tandem mass spectrometry, as this technique greatly eliminates problems caused by interfering substances (Taylor, 2002). For the urine metabolites, it is important to use age-appropriate reference ranges when interpreting the results. It is also important to be aware that reference ranges can vary widely not only from one laboratory to another, but even within the same laboratory, as newer methods are introduced.

Additional Follow-Up Testing

Once the diagnosis is confirmed biochemically, the tumor should be localized by a CT scan or MRI of the adrenals. If this is negative, imaging studies of the abdomen, chest, and pelvis should be performed. CT has greater sensitivity, and MRI, greater specificity. MRI is superior to CT in detecting extraadrenal lesions and has the advantage of not requiring ionizing radiation or needing ionic contrast. If a tumor cannot be located by CT or MRI, or if metastatic disease is suspected, scanning with ¹³¹I- or ¹²³I-labeled meta-iodobenzylguanidine should be performed. Octreoscaning and positron emission tomography are reserved for when the other techniques have failed.

Following successful tumor resection, the prognosis is generally excellent. Urinary metanephrines should be retested several weeks after surgery to ensure that the resection was complete, and should be measured periodically thereafter as an early marker of disease recurrence (Werbel, 1995).

An algorithm to evaluate pheochromocytoma has been proposed by Eisenhofer (2003) (Fig. 24-10).

Neuroblastoma

Similarly to pheochromocytoma, neuroblastoma is of neural crest origin, arising within the adrenals or the sympathetic chain. It is the second most

common solid malignant tumor in childhood, usually occurring before the age of 3. Symptoms relate primarily to tumor mass rather than to hypertension, which is often mild or absent. At the time of diagnosis, 70% of cases will have distant metastases. About 90% of patients have elevated urinary HVA levels at the time of diagnosis, whereas almost 75% have increased urinary VMA levels (Tuchman, 1985). Both tests should be ordered when screening for the disease. In healthy children, at least up until the age of about 15, urinary VMA and metanephrines tend to be higher (per milligram of creatinine) and more variable than in adults. Urinary metanephrines also can be elevated in neuroblastoma patients, but are not a sensitive measure of residual tumor. Urinary HVA is increased in familial dysautonomia (Riley-Day syndrome) and in some cases of pheochromocytoma.

HORMONES OF THE ADRENAL CORTEX

The adrenal cortex is composed of three distinct zones: The outermost zone, the zona glomerulosa, is followed by the intermediate zona fasciculata, which surrounds the innermost zona reticularis. In the broadest terms, each zone is responsible for the synthesis and secretion of a unique set of hormones: The zona glomerulosa—mineralocorticoids (aldosterone); the zona fasciculata—glucocorticoids (cortisol); and the zona reticularis—sex steroids (dehydroepiandrosterone sulfate and androgens). However, under certain pathologic and physiologic conditions, these distinctions become blurred.

Mineralocorticoid Axis

The chief mineralocorticoid is aldosterone, which promotes the reabsorption of sodium and water by the kidney to help maintain blood pressure and tonicity. Expression of the enzyme CYP11B2 (aldosterone synthetase) within the glomerulosa is site specific; as a result, the synthesis of aldosterone and its intermediary 18-hydroxylated metabolites is restricted to the zona glomerulosa. The precursor molecules to aldosterone, 11-deoxycorticosterone (DOC) and 11-deoxycortisol, similarly possess mineralocorticoid activity. However, unlike aldosterone, they can be synthesized within the zona fasciculata, as well as in the zona glomerulosa, which explains the hypertension and electrolyte disturbances seen in some forms of congenital adrenal hyperplasia. Although aldosterone will respond to acute changes in ACTH, it is mainly under the control of the renin-angiotensin system.

The zona fasciculata makes up 75% of the cortex, and is responsible for the synthesis and secretion of glucocorticoids and to a lesser extent androgens and estrogens. The glucocorticoids are 21-carbon steroid compounds with a hydroxyl group on carbon 17, hence the synonym 17-hydroxycorticosteroids (17-OHCS). Cortisol is the key glucocorticoid, regulating its own secretion through negative feedback on the hypothalamic-pituitary-adrenal (HPA) axis, inhibiting ACTH release from the pituitary and corticotropin-releasing hormone (CRH) from the hypothalamus. Both CRH and AVP (ADH) are produced by the parvocellular neurons of the paraventricular nuclei of the hypothalamus. ACTH secretion is stimulated by CRH and, to a much lesser extent, by AVP. ACTH in turn stimulates cortisol production by the adrenals. Cortisol is needed in times of stress to maintain blood pressure and blood sugar, and to prevent shock. Although cortisol is the most important glucocorticoid, corticosterone, which is a hormone of the mineralocorticoid pathway, also possesses glucocorticoid activity.

Androgens and estrogens are produced by the zona reticularis. The androgens are 18-carbon steroids with saturated A rings, in contrast to the estrogens, which are 17-carbon steroids with unsaturated A rings.

The functions of these hormones are summarized in Table 24-20.

Congenital Disorders of Adrenal Cortical Enzyme Deficiencies

The hormones of the adrenal cortex are steroid derivatives, synthesized from low-density lipoprotein (LDL) cholesterol. LDL is delivered to the adrenals where it is taken up by LDL receptors. Evidence also supports local synthesis of LDL from acetyl coenzyme A. Steroid acute regulatory protein (StAR) shuttles LDL across the mitochondrial membrane, where it begins its journey down the steroidogenic pathway (Fig. 24-11). The enzymes that catalyze these synthetic reactions are of four general types: hydroxylases, dehydrogenases, desmolases, and isomerases. Because most of the inborn errors of metabolism affecting steroid hormone synthesis in the adrenal cortex involve deficiencies of hydroxylases, they constitute the most clinically important group of enzymes.

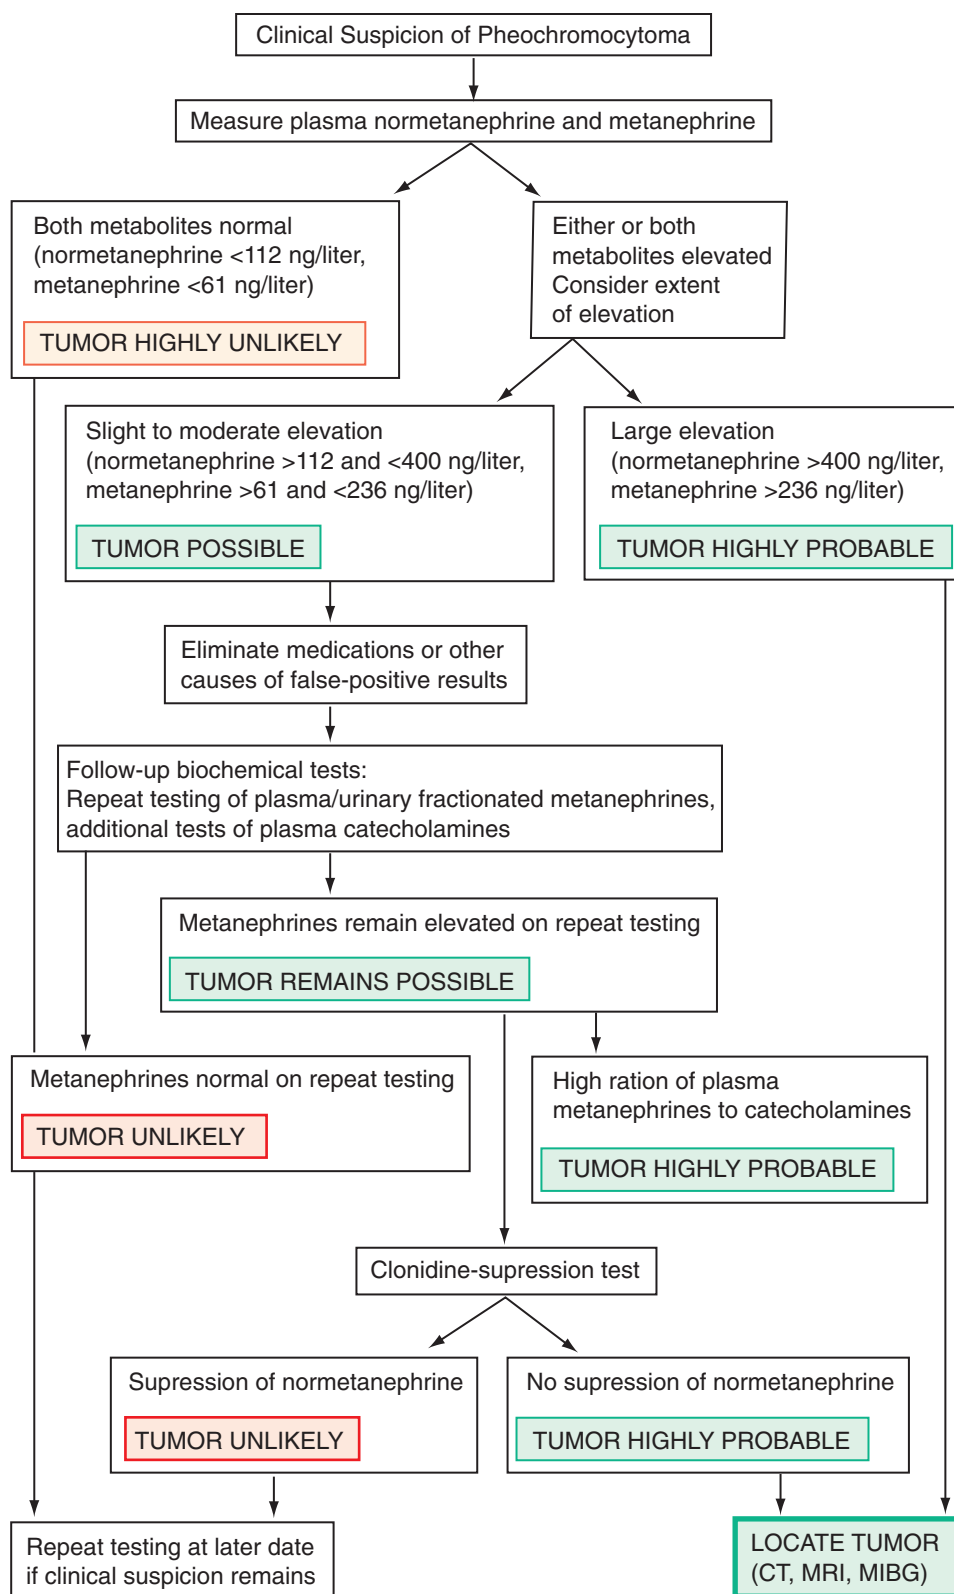

Figure 24-10 Algorithm for the evaluation of pheochromocytoma. (Redrawn from Eisenhofer G, Goldstein DS, Walther MM, et al. Biochemical diagnosis of pheochromocytoma: how to distinguish true- from false-positive test results. *J Clin Endocrinol Metab* 2003;88:2656–66, with permission.) CT, Computed tomography (scan); MIBG, metaiodobenzylguanidine (scan); MRI, magnetic resonance imaging.

At least eight different metabolic defects in the synthesis of cortisol and aldosterone have been described, each characterized by a deficiency of a specific adrenal enzyme. A vast majority of these enzymatic deficiencies are inherited as an autosomal recessive trait with variable degrees of penetrance. Those enzymatic defects that uniquely affect the biosynthesis of cortisol are grouped together under the rubric of congenital adrenal hyperplasia (CAH). These five enzymes are P450_{scc} (defect in StAR), 3- β -hydroxysteroid dehydrogenase, 21-hydroxylase, 11-hydroxylase, and

17-hydroxylase. CRH and ACTH synthesis and secretion are normally under the negative-feedback control of cortisol. In CAH, defects in the enzymes necessary for cortisol production lead to cortisol deficiency; cortisol deficiency results in disinhibition of negative feedback on CRH and ACTH production. As a consequence, CRH and ACTH levels rise, inducing adrenal hyperplasia and a forward push in steroidogenesis, as the body tries to compensate and normalize cortisol production. Not only does this result in a buildup of hormonal precursors directly preceding the

enzymatic defect, it also causes massive shunting of these precursors down the remaining functional pathways. The clinical manifestations of CAH are heterogeneous, depending on the severity and location of the enzymatic defects, which hormones are deficient, and which are produced in excess. Symptoms range from shock, salt-wasting, and anomalous sexual development in infancy, to hirsutism and infertility in the adult.

TABLE 24-20
Physiologic Effects of Steroids

Representative hormone	Biological effects
Cortisol (as a representative glucocorticoid)	Protein nitrogen catabolism increased Gluconeogenesis Increased blood glucose concentration Decreased glucose tolerance Increased liver glycogen Increased liver glycogenolysis Decreased peripheral uptake and utilization of glucose Decreased synthesis of acid-sulfated mucopolysaccharides Fat synthesis and redistribution Cellular or tissue effects Antiinflammatory Dissolution of lymphoid tissue Lymphopenia Eosinopenia Increased erythropoiesis Alteration of cellular permeability, especially decreased membrane permeability to water Increased gastric (HCl and pepsin) secretion
Aldosterone (as a representative mineralocorticoid)	Electrolyte regulation Sodium (Na ⁺) retention Potassium (K ⁺) excretion Retention of water and expansion of extracellular fluid volume Increases in blood pressure
Androgens (as representative sex hormones)	Protein nitrogen anabolism Growth and maturation—osseous and muscular Body hair (pubic and axillary)

Sometimes, as in partial enzymatic deficiencies of cortisol synthesis, near-adequate hormone synthesis is possible if hypersecretion of ACTH is able to stimulate adrenal hyperplasia to compensate for the deficiency. The clinical manifestations of various adrenal cortical enzyme deficiencies and their associated laboratory findings are summarized in Table 24-21.

The diagnosis is made by measuring the various serum hormone levels and assessing which steroids are produced in excess and which are deficient, and by calculating the precursor/product ratio and comparing these results to age- and sex-matched normative data. Levels of hormones distal to the block (product hormones) may be elevated as a result of peripheral conversion of the markedly elevated precursor hormones; the use of precursor/product ratios mitigates the risk of misdiagnosis due to misleading elevations of product hormones (Levine, 2002). If hormone levels return as borderline, but the clinical suspicion for CAH remains high, the steroid levels should be remeasured 60 minutes after intravenous administration of 0.25 mg of ACTH. ACTH drives steroidogenesis forward, accentuating the block. When there is a proband, the diagnosis can be more accurately determined by genotyping.

CAH is categorized according to severity of disease into classic (neonatal, severe) and nonclassic (late-onset, cryptogenic) forms. The classic form is further subdivided into salt-losing and non-salt-losing (simple virilizing) variants.

21-Hydroxylase Deficiency

The enzyme 21-hydroxylase (also referred to as CYP21, CYP21A2, and P450c21) is located within the mitochondrial endoplasmic reticulum. It is the most common cause of CAH, occurring in about 95% of all cases. Screening of newborns using capillary heel blood on paper filter disks has identified this disorder in about 1 in 14,000 persons in North America, and in as many as 1 in 300 Yupik Eskimos of Alaska (Pang, 1988, 1982). The classic form is detected in about 1 in 16,000 live births; the nonclassic form is seen in about 0.2% of the general Caucasian population, and in 1%–2% of those of Eastern European Jewish ancestry (Speiser, 1985; Therrell, 2001).

21-OH catalyzes the conversion of 17-hydroxyprogesterone (17-OHP) to 11-deoxycortisol (compound S), and progesterone to DOC. Thus, 21-OH deficiency leads to elevated levels of the steroid precursors 17-OHP and pregnanetriol in the urine and 17-OHP in the serum. These precursors are shunted toward the pathway, leading to excess androstenedione and testosterone production (Fig. 24-12). Clinical presentation often correlates with the severity of enzymatic dysfunction. The classic variety presents in the newborn period or in early childhood with adrenal insufficiency and virilization, with or without salt-wasting. The nonclassic form presents in late childhood as early adrenarche, or in young adulthood as

hirsutism, amenorrhea, and infertility. The presentation in women is very similar to that of polycystic ovarian disease. Males may develop precocious puberty, adrenal rests within the testes, and infertility.

A close functional relationship exists between the adrenal cortex and the adrenal medulla. Dysplasia of the medulla and catecholamine hyposecretion have been described in classic 21-OH deficiency. In a study of 38 children with classic (CYP21A2) disease, levels of plasma epinephrine and metanephrine and urinary epinephrine were 40%–80% lower in affected individuals than in normal persons (Merke, 2000). In another study, those with CYP21A2 showed a significantly decreased catecholamine response to exercise that was unaffected by the administration of stress doses of glucocorticoids (Weise, 2004). It has been suggested that the degree of medullary impairment may be a biomarker for CAH severity (Merke, 2002).

Diagnosis. Prenatal diagnosis is important because suppressive treatment with steroids can abrogate the development of virilization of the female fetus. Diagnosis is made by measuring the level of 17-OHP in amniotic fluid or by genotyping cells obtained by chorionic villous sampling. The genes responsible for 21-OH deficiency, *CYP21* (CYP21A2) and *CYP21P* (CYP21A), are located on chromosome 6. Of these two homologous genes, only *CYP21* is active; deleterious mutations within *CYP21P* interfere with normal gene expression. These mutations can be identified by PCR and

Southern blotting on chorionic villous samples (White, 1994a; New, 1995). The 2010 consensus statement on the management of CAH due to 21-OH deficiency recommends that prenatal treatment of CAH be regarded as experimental and that the diagnosis should rest on clinical and hormonal data, with genotyping being reserved for equivocal cases and genetic counseling (Speiser, 2010).

Neonatal screening, which is now mandatory in many states, is performed by measuring 17-OHP or by genotyping blood that has been obtained from a heelstick and collected on filter paper. Aside from genotyping being the most definitive test for diagnosing CAH, the fact that the genotype correlates fairly well with disease severity means that it can also be used as a prognostic tool (Nordenstrom, 1999).

In the newborn with salt-wasting, unstimulated 17-OHP levels are typically >8000 ng/dL, rising to 100,000 ng/dL (3000 nmol/L) following administration of ACTH. Levels in the simple virilizing variant range from 10,000–30,000 ng/dL (300–1000 nmol/L). Those with nonclassic disease typically have 17-OHP levels ranging from 1500–10,000 ng/dL (50–300 nmol/L) (New, 1983). It is of note that randomly drawn hormone levels may be normal in those with nonclassic disease; therefore it is important to test during the early morning. If the results are equivocal, the diagnosis can be confirmed by comparing serum 17-OHP levels before and 60 minutes after administration of 0.25 mg ACTH (Cortrosyn). ACTH acts to stimulate steroidogenesis, serving to dramatically increase

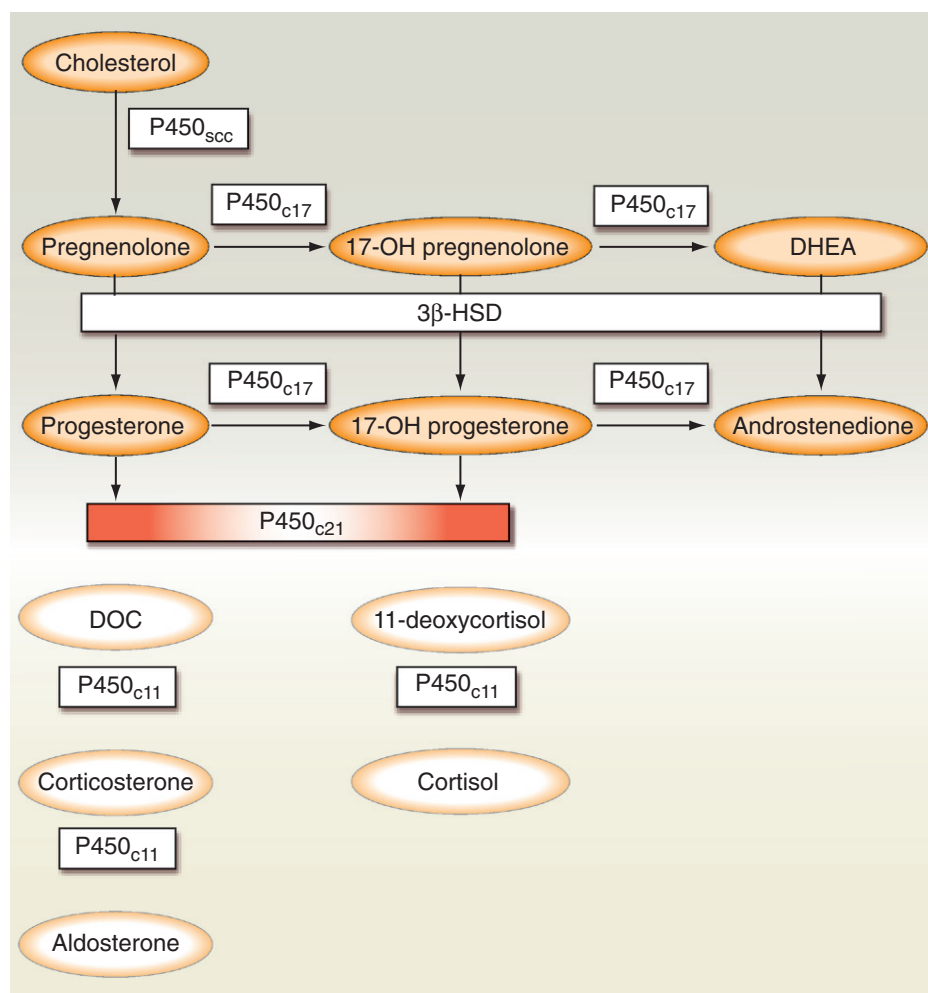

Figure 24-12 Defective steroidogenesis due to 21-hydroxylase deficiency. The relative increase in the hormones proximal to the block is depicted by more intense color. The more severe the enzymatic defect, the greater the concentration of the precursor hormones. DHEA, Dehydroepiandrosterone; DOC, deoxycorticosterone.

the bottleneck at the site of the enzymatic block, resulting in a dramatic increase in precursors, in this case, 17-OHP. Post-ACTH 17-OHP values <330 ng/dL are normal, 330–1000 ng/dL indicates a heterozygote carrier, and levels >2000 ng/dL are diagnostic for nonclassic CAH. If a proband is available, genotyping is superior to these older biochemical tests in identifying heterozygotes (Honour, 1993).

The goals of glucocorticoid and mineralocorticoid replacement therapy in children is the attainment of normal growth, weight, and pubertal development, and optimization of final adult height. On the other hand, major treatment goals in adults include lessening of signs of virilization and resumption of fertility. The objective of mineralocorticoid replacement is to normalize the plasma renin activity. The aim of glucocorticoid replacement is to keep the 17-OHP level partially suppressed to between 100 and 1000 ng/dL (3–30 nmol/L) and the ACTH under 100 ng/L, thereby preventing shunting toward testosterone synthesis, and normalizing levels of androstenedione and testosterone. Normalization of 17-OHP should not be attempted, because this requires supraphysiologic levels of glucocorticoids and may result in Cushing's syndrome (Speiser, 2003).

11-β-Hydroxylase Deficiency

The second most common enzyme deficiency of the adrenal cortex, accounting for about 7% of all cases of CAH, is the 11-β-hydroxylase (11-OH) deficiency. A defect in this enzyme blocks the final conversion of 11-deoxycortisol to cortisol and DOC to corticosterone. As with 21-OH deficiency, a compensatory increase in ACTH secretion leads to adrenal hyperplasia and a mass action shunting of precursor steroids toward testosterone synthesis, resulting in signs of virilization. This block also results in the accumulation of DOC; the mineralocorticoid activity of DOC leads to the development of hypertension and hypokalemia, similar to what is seen with hyperaldosteronism (Fig. 24-13).

11-OH deficiency is an autosomal recessive disorder caused by mutations of the genes *CYP11B1* and *CYP11B2*, located on chromosome 8q21-q22 (White, 1994b). Diagnosis in the neonate is established by the presence of a high basal and a high ACTH-stimulated 11-deoxycortisol. Concentrations of urinary tetrahydro-11-deoxycortisol in the urine are also elevated. During childhood and in young adults, the diagnosis of 11-OH deficiency is made by the presence of elevated early-morning and ACTH-stimulated serum levels of 11-deoxycortisol that are more than three times the upper limit for age-matched normals. Levels of DOC and adrenal androgens (androstenedione, dehydroepiandrosterone, and dehydroepiandrosterone sulfate) are also elevated. Plasma renin activity and aldosterone are often suppressed as a result of salt and water retention induced by elevations of DOC. Unlike the heterozygotes with 21-OH deficiency, those with 11-OH deficiency often fail to show a rise in precursors following ACTH stimulation (Pang, 1980). However, an exuberant response has been seen in those who had hirsutism (Gabrilove, 1965).

Prenatal diagnosis of 11-OH deficiency is made by measuring levels of tetrahydro-11-deoxycortisol (THS) in the maternal urine or amniotic fluid. These levels begin to rise in the first trimester. In addition to THS, elevation of levels of 11-deoxycortisol and of the THS to tetrahydrocortisol plus tetrahydrocortisone ratio is seen (Rosler, 1988).

Treatment consists of the replacement of glucocorticoids, causing normalization of DOC and plasma renin activity.

3-β-Hydroxysteroid Dehydrogenase Deficiency

3-β-hydroxysteroid dehydrogenase (3-β-HSD), which catalyzes the second enzymatic step in steroidogenesis, is coded by two genes, *HSD3B1* and *HSD3B2*. *HSD3B2* is expressed in the adrenals and gonads; *HSD3B1* is expressed in placenta, skin, and other peripheral tissues and usually remains functionally intact at these sites in CAH. A defect in 3-β-HSD leads to a

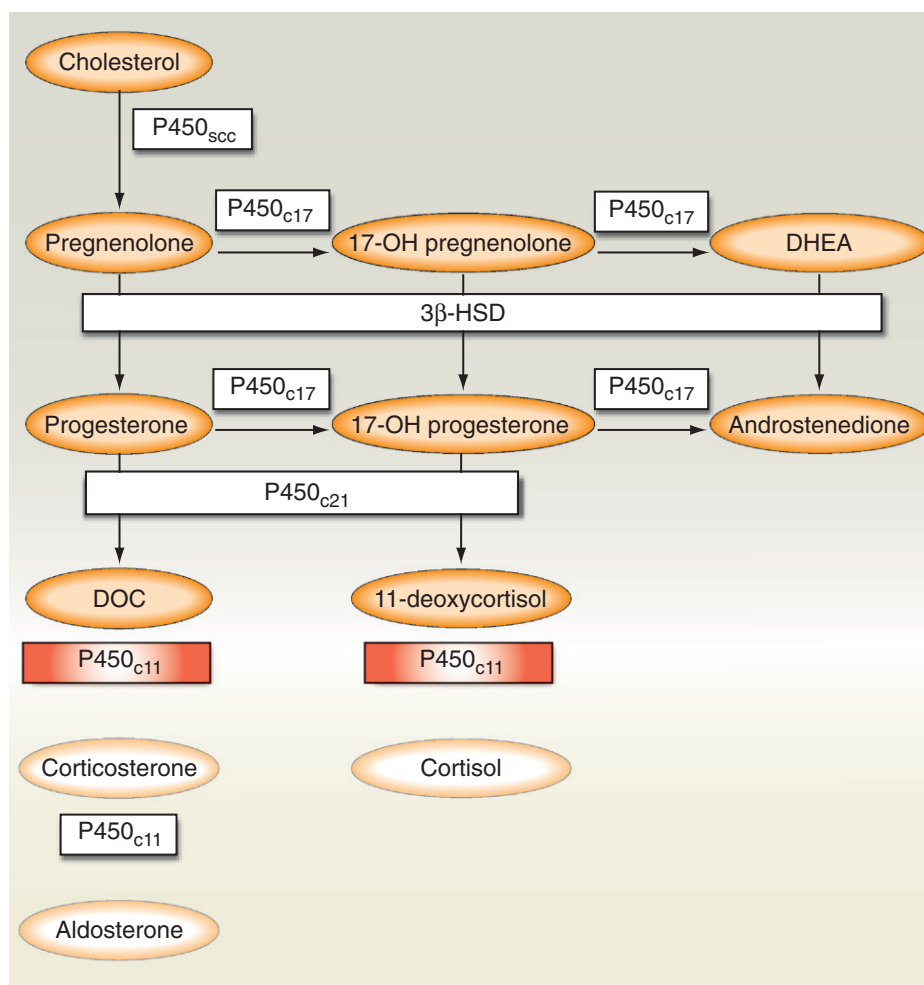

Figure 24-13 Defective steroidogenesis due to 11- β -hydroxylase deficiency. The relative increase in the hormones proximal to the block is depicted by more intense color. The more severe the enzymatic defect, the greater the concentration of the precursor hormones. High levels of 11-deoxycorticosterone (DOC) created by the block produce a state of mineralocorticoid excess. *DHEA*, Dehydroepiandrosterone.

block in the conversion of Δ^5 steroids (pregnenolone, 17-OH pregnenolone, and dihydroepiandrosterone) to Δ^4 steroids (progesterone, 17-OHP, androstenedione), resulting in an increase in circulating levels of Δ^5 steroids (Fig. 24-14). However, because *HSD3B1* is usually intact, levels of the Δ^4 steroids may be normal or even elevated.

Patients with classic disease will have manifestations of glucocorticoid deficiency, with or without the accompaniment of salt-wasting. Affected males have incomplete masculinization, and females may be normal or may have ambiguous genitalia. A late-onset variant has been described that is associated with features typical of polycystic ovary disease, such as hirsutism, oligomenorrhea, and infertility (Pang, 1985).

Previous criteria for the diagnosis of 3- β -HSD deficiency examined the basal and ACTH-stimulated Δ^4/Δ^5 steroid ratios, 17-OH-pregnenolone (17-OHP)/cortisol, and levels of pregnenolone, 17-OH-pregnenolone, and dehydroepiandrosterone in urine and blood. The standard for diagnosing this disorder has been recently revised to correlate more closely with genotypic studies. The ACTH-stimulated Δ^5 -17 P levels and Δ^5 -17 P/cortisol ratios have been shown to be the best indices for definitively diagnosing 3- β -HSD deficiency (Lutfallah, 2002). Applicability of these new criteria to patients with the nonclassic variant is still debatable.

Treatment consists of glucocorticoids and mineralocorticoids, as well as sex steroids, in accordance with normal growth and development.

17-Hydroxylase Deficiency

17-Hydroxylase (CYP17, P450_{c17}) is expressed in the adrenals and the gonads and encodes two enzymes—17- α -hydroxylase and 17,20-lyase. 17- α -hydroxylase catalyzes the conversion of pregnenolone and progesterone to their respective 17-OH derivatives. 17,20-Lyase converts 17-OH pregnenolone to dihydroepiandrosterone, and 17-OH progesterone to androstenedione. CYP17 deficiency blocks the conversion of pregnenolone and progesterone to the 17-hydroxy derivatives, causing shunting

from testosterone and cortisol synthesis to aldosterone (Fig. 24-15). Accordingly, these patients develop hypertension and hypokalemic alkalosis in association with incomplete masculinization (in the male) and decreased testosterone and cortisol levels. 17-OH deficiency is diagnosed by demonstrating high DOC, pregnenolone, and progesterone levels, along with decreased urinary 17-ketosteroids and 17-hydroxycorticosteroids. The gene associated with this condition (*CYP17*) has been located on chromosome 10q, the same gene as 17,20-desmolase (Kater, 1994).

Congenital Lipoid Adrenal Hyperplasia

Congenital lipoid adrenal hyperplasia (lipoid CAH) is the most severe form of CAH, in which the synthesis of all gonadal and adrenal cortical steroids is markedly impaired. Lipoid CAH may be caused by a defect in the StAR or the P450 side chain cleavage (scc) (Fujieda, 2003). StAR, located on chromosome 8p11, controls the rate-limiting step in steroidogenesis. It is responsible for the shuttling of cholesterol from the outer to the inner mitochondrial membrane. 20,22-Desmolase (CYP11A1, P450_{scc}) converts cholesterol to pregnenolone (Fig. 24-16). Pathologically, the adrenal cortex shows marked accumulation of cholesterol and other lipids, which is the primary distinguishing feature from congenital adrenal hypoplasia.

The presentation of this extremely rare disorder is that of severe adrenal insufficiency with hypotension, salt-wasting, and feminization of external genitalia in males. Occasionally, females may not present until the onset of puberty. Diagnosis is made by the presence of extremely low cortisol and aldosterone concentrations and elevated ACTH and plasma renin activity.

Aldosterone Synthetase Deficiency

Aldosterone synthetase (CYP11B2) is the final step in the steroid synthetic pathway leading to the production of aldosterone. It stimulates a multistep

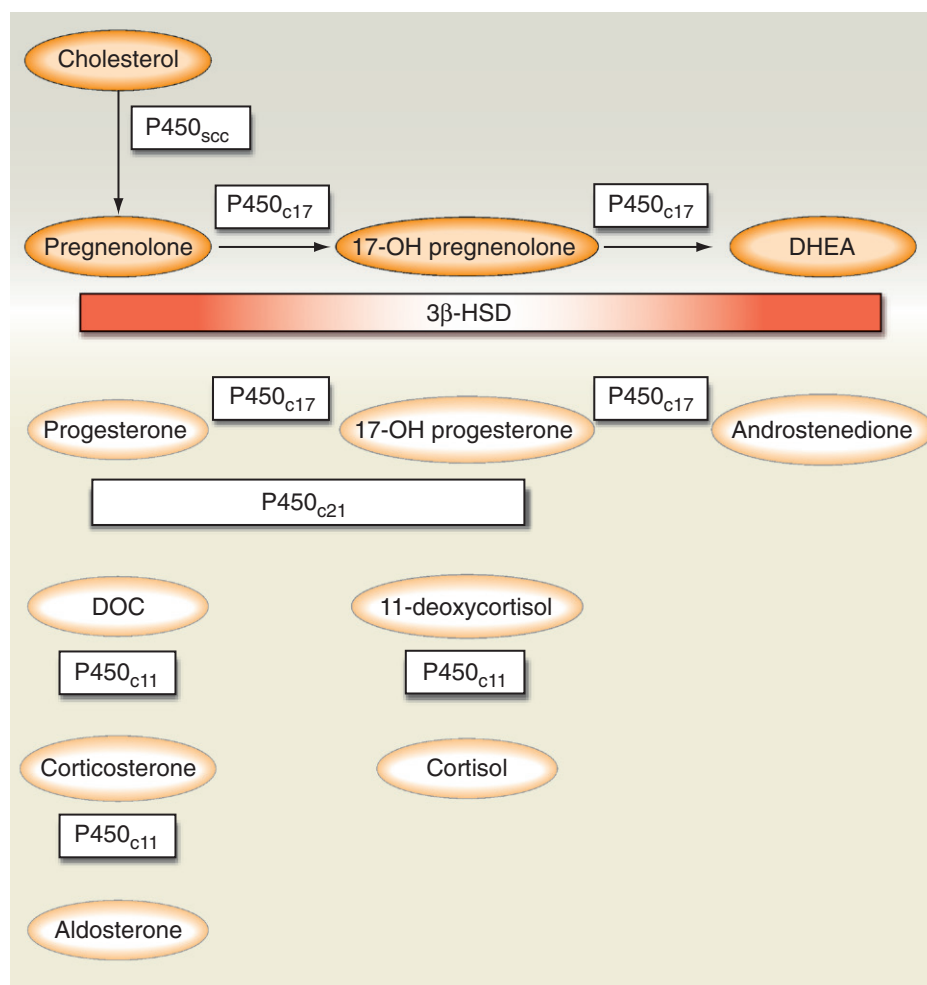

Figure 24-14 Defective steroidogenesis due to 3- β -hydroxysteroid dehydrogenase deficiency. The relative increase in the hormones proximal to the block is depicted by more intense color. process: 11-hydroxylation of DOC to corticosterone, 18-hydroxylation of corticosterone to 18-hydroxycorticosterone, and finally, 18-dehydrogenation to aldosterone. Isolated enzyme deficiency leads to salt-wasting, hyperkalemia, and metabolic acidosis. This condition may be diagnosed by demonstrating the presence of metabolites of corticosterone and 11-deoxycorticosterone in the urine, elevated serum DOC, and deficiency of corticosterone, 18-hydroxycorticosterone, or aldosterone in the serum.

Cortisol and the Glucocorticoids

The adrenal cortex secretes cortisol in response to ACTH, a diurnal rhythm, and stress. ACTH, synthesized in the adenohypophysis, is formed from the cleavage of a much larger precursor molecule: POMC. In addition to ACTH, cleavage of POMC releases β -LPH, which in turn is cleaved to yield γ -LPH and β -endorphin. Within the ACTH sequence are α -MSH and the corticotropin-like intermediate lobe protein. Endorphins, which act on neurons in the brain, constitute a distinct peptidergic system related to pain perception. Although β -endorphin is secreted in parallel with ACTH, the significance of this remains unknown.

ACTH consists of 39 amino acid residues, of which residues 1–24 at the amino terminal possess full hormonal activity. Occasionally, POMC is incompletely processed; this leads to the formation of other forms of ACTH that usually have little biological activity, although they may retain immunoreactivity. These forms may predominate in malignant conditions such as ectopic production by primary or metastatic lung cancer, and in some patients with Nelson's syndrome, a disorder characterized by the occurrence of a pituitary tumor and skin hyperpigmentation following bilateral adrenalectomy. Defects in POMC cleavage enzymes may also be responsible for the formation of rare forms of isolated ACTH deficiency (Nussey, 1993).

ACTH is secreted in response to several factors, of which CRH and AVP are the most important. Among the other moieties reported to stimulate ACTH secretion are atrial natriuretic factor (ANF), angiotensin II, IL-6, IL-1, and tumor necrosis factor- α (Rivier, 1983; Chrousos, 1998).

CRH is synthesized and released from the hypothalamus; it acts to stimulate the synthesis and release of ACTH from the pituitary. CRH is released in a circadian pattern and in response to physiologic stimuli such as stress and hypoglycemia. The HPA axis consists of various feedback loops that control cortisol synthesis and secretion. When plasma cortisol increases, it suppresses the release of ACTH, CRH, and AVP, which, in turn, leads to lowering of the cortisol level. Conversely, when serum cortisol reaches a nadir, the hypothalamus and pituitary respond by increasing CRH and ACTH production, leading to stimulation of cortisol formation and secretion. By this mechanism, ACTH and cortisol control the concentration of each other within a very narrow range, and a small change in one results in a concomitant change in the other. When the adrenal is unable to respond to ACTH because of damage or disease, cortisol levels are low and ACTH levels are high. In those conditions in which the pituitary is destroyed, ACTH is not formed and cortisol levels are consequently low. Damage to the hypothalamus is also associated with low ACTH and cortisol levels; testing with CRH may permit the distinction between these two entities. Synthetic forms of CRH are used in testing the anterior pituitary reserve of ACTH by comparing plasma ACTH and cortisol before and 1 hour after CRH stimulation (Grodum, 1993). This test is useful in distinguishing between lesions affecting the hypothalamus, pituitary, and adrenal glands (Fukata, 1993). If the lesion is in the hypothalamus, after a time delay, ACTH levels rise following CRH administration. If it is in the pituitary, no significant ACTH response occurs. With primary adrenal insufficiency, administration of CRH causes a further rise in an already elevated ACTH level, but little or no rise in the level of cortisol.

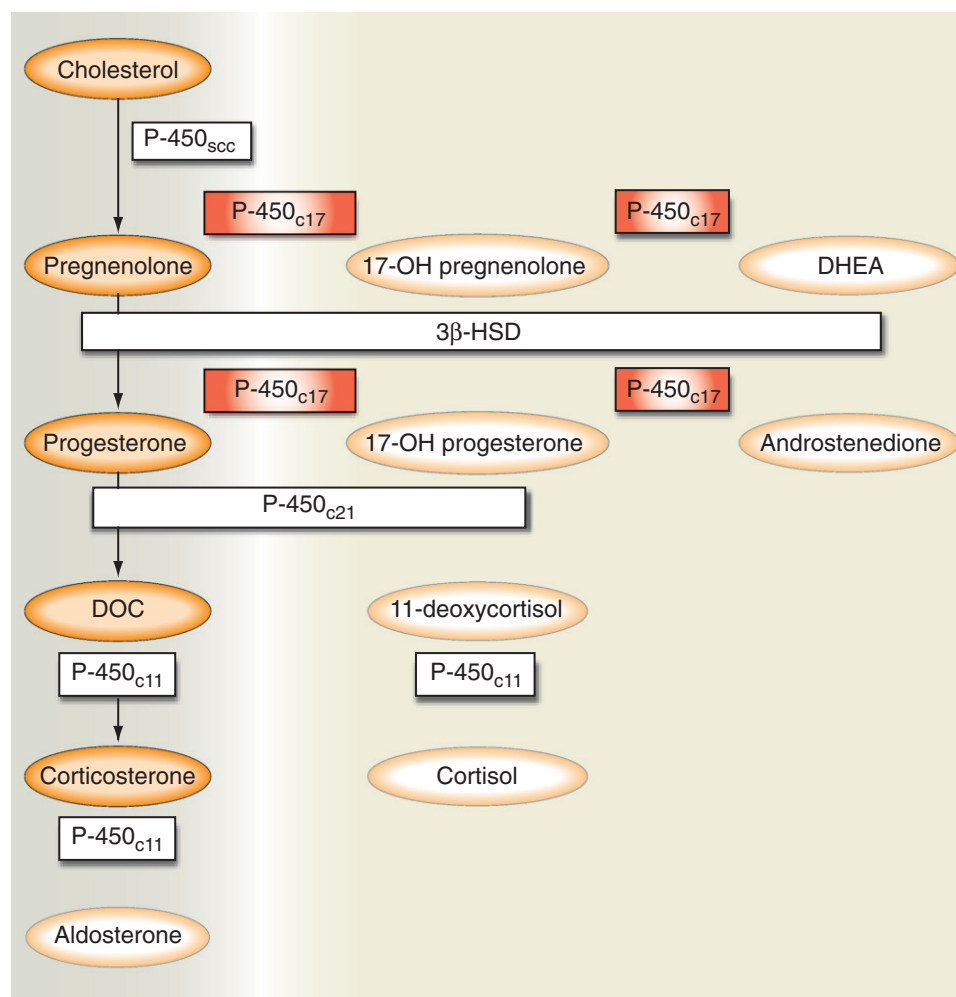

Figure 24-15 Defective steroidogenesis due to 17-hydroxylase deficiency. The relative increase in hormones proximal to the block is depicted by more intense color. The more severe the enzymatic defect, the greater the concentration of the precursor hormones. High levels of 11-deoxycorticosterone (DOC) and corticosterone created by the block produce a state of mineralocorticoid excess. DHEA, Dehydroepiandrosterone.

If the HPA axis is interrupted by the administration of large quantities of exogenous glucocorticoids, they will exert an inhibitory effect on the hypothalamus and pituitary, suppressing CRH and ACTH secretion. If this suppression continues over a period of weeks, it leads to atrophy of the adrenals; as a result, the HPA axis becomes unable to secrete cortisol in times of stress. The HPA axis can fully recover after tapering off of steroids.

The second influence on plasma cortisol levels is the diurnal pattern, which is due to the circadian pattern of ACTH release. Major increases in secretion occur at between 4 AM and 8 AM, followed by a decrease in ACTH during the rest of the day. In subjects with a normal sleep-wake cycle, the lowest ACTH concentrations are found shortly after midnight. Sudden changes in sleep-wake patterns have little effect on the diurnal pattern, but permanent changes in daily sleep habits result in a gradual change in diurnal secretory patterns. Superimposed on the circadian periodicity is an ultradian rhythm of 10–18 secretory bursts per 24 hours (Horrocks, 1990).

The third important influence on cortisol secretion is stress. Stimuli such as surgical trauma, pyrogens, hypoglycemia, and hemorrhage are capable of bringing about an acute increase in ACTH and cortisol secretion. This response to stress may be absent or decreased in magnitude in patients in whom large doses of steroids have been administered for some time. The initiation of any stress response is dependent on an intact nervous system. For example, trauma normally results in the acute release of ACTH and cortisol; however, in patients with spinal cord transections, the normal transmission of neurologic stimuli is interrupted, and as a result, the same trauma applied to an extremity will not elicit any ACTH or cortisol response. Evidence suggests that the stress response of cortisol is mediated through excitatory and inhibitory inputs that integrate at the level of the hypothalamus and modulate CRH secretion. Cortisol levels

also rise after meals, especially those high in protein, and also in depression (Linkowski, 1987).

Most disorders of cortisol secretion can be classified by the patterns of response of the following three hormones to suppression and stimulation: ACTH, plasma cortisol, and urinary free cortisol (Snow, 1992).

Laboratory Measurement of ACTH

Plasma ACTH is measured using a two-site immunoradiometric assay or an immunochemiluminometric assay. To prevent degradation of ACTH, it is best to collect the sample in a prechilled EDTA lavender-top tube. The specimen should be kept in an ice bath and should be processed as soon as possible. Following centrifugation in a refrigerated centrifuge, the specimen should be separated, transferred to a plastic tube, and kept frozen at -20°C until time of analysis. The normal reference range is 2–12 pmol/L (9–52 pg/mL) between 7 AM and 10 AM. Plasma ACTH is a useful tool for distinguishing primary (adrenal) from secondary (pituitary) or tertiary (hypothalamic) adrenal insufficiency. In primary adrenal insufficiency, low cortisol concentrations are found, along with increased ACTH levels. In secondary or tertiary adrenal insufficiency, both ACTH and cortisol are expected to be low. ACTH levels best discriminate between healthy individuals and those with adrenal insufficiency when specimens for ACTH are collected between 8 AM and 10 AM.

ACTH is less useful in diseases of cortisol excess. Up to 50% of patients may have normal ACTH levels in Cushing's disease. Although the values tend to run higher (>20 pmol/L [>90 pg/mL]) in Cushing's syndrome due to ectopic ACTH production, the values overlap with those seen in Cushing's disease in 30% of cases (Findling, 1992). Because of the normal diurnal variation in ACTH and cortisol secretion, measurement of these values during their expected nadir, from 11 PM to 1 AM, is helpful in confirming the diagnosis of ACTH-dependent Cushing's disease. An elevated

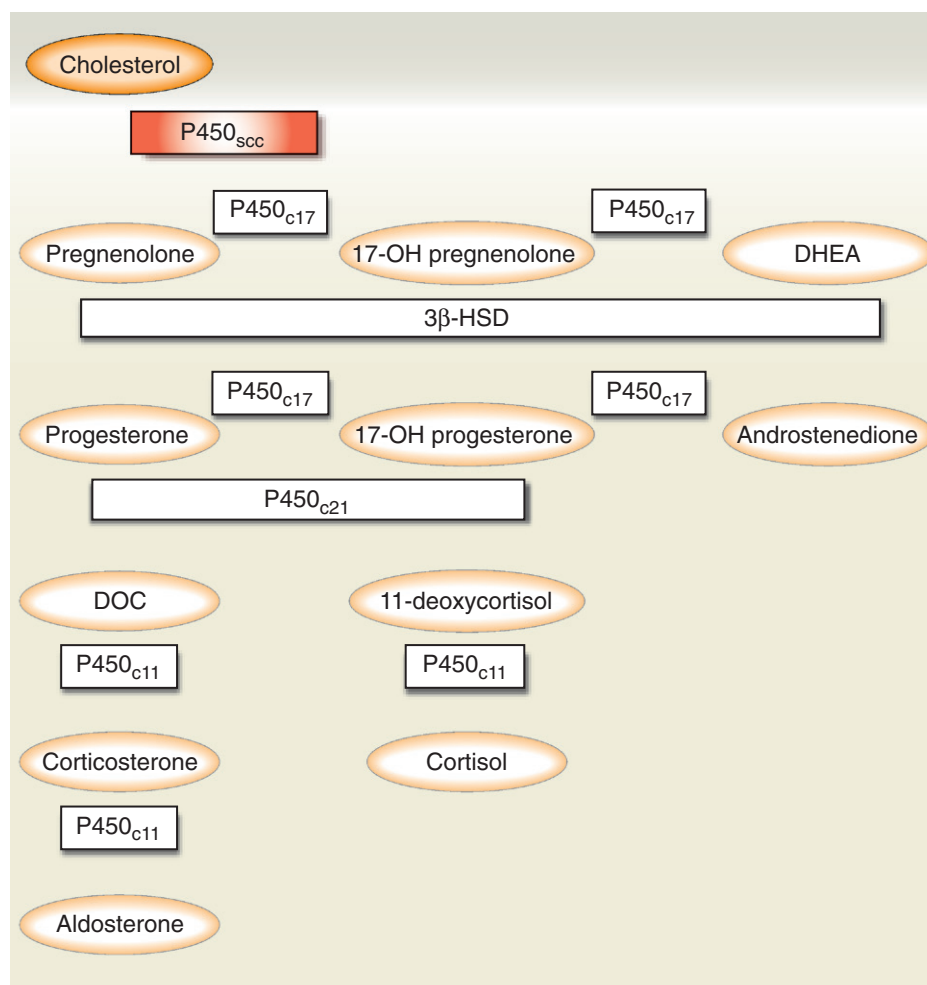

Figure 24-16 Defective steroidogenesis in congenital lipoid adrenal hyperplasia is due to a defect in steroidogenic acute regulatory protein or the side-chain cleavage enzyme (P450_{sc}). The relative increase in hormones proximal to the block is depicted by more intense color. In this disorder, the synthesis of all classes of steroids is defective. DHEA, Dehydroepiandrosterone; DOC, deoxycorticosterone.

midnight ACTH of greater than 5 pmol/L (23 pg/mL) in the face of an elevated serum cortisol confirms the diagnosis of ACTH-dependent Cushing's disease. Those patients with ectopic ACTH-secreting tumors characteristically have markedly elevated plasma ACTH (usually >200 pg/mL) and elevated serum cortisol. Measurement of ACTH by plasma extraction, which detects ACTH precursors and fragments, may be useful in distinguishing patients with cancer-related syndromes or ACTH-secreting tumors from those with Cushing's disease, as the former entities are more likely to produce these other forms of ACTH (White, 1993). ACTH-secreting neoplasms may be occult, creating diagnostic difficulties; in this instance, ACTH measurement using selective venous sampling has proven useful in localization of the lesion.

In patients with increased levels of circulating glucocorticoids due to an adrenal adenoma or carcinoma, and those surreptitiously taking steroids, ACTH secretion is inhibited and levels are low or undetectable. In patients with pituitary-induced adrenal hyperplasia (Cushings' disease), plasma ACTH may be at or above the upper reference interval at 9 AM, and fail to show the expected fall after midnight. Another use of ACTH assays is in the determination of adequacy of cortisol replacement in congenital adrenal hyperplasia. When replacement therapy is optimal, ACTH values are similar to those seen in a reference population.

Plasma Corticotropin-Releasing Hormone

CRH measurements are performed by liquid chromatography and tandem mass spectrometry and remain largely a research tool.

CRH circulates in one of two forms—free or bound to CRH-binding protein. The level of CRH-binding protein increases during pregnancy. CRH is increased in patients with Cushing's syndrome due to ectopic production of CRH. The reference range for plasma CRH in men and nonpregnant women is <34 pg/mL. The normative range varies throughout pregnancy: first trimester <40 pg/mL; second trimester <153 pg/mL; and third trimester <847 pg/mL (Goland, 1986).

Serum Cortisol Measurements

About 90% of circulating cortisol is bound to serum protein, of which 10%–20% is loosely bound to albumin, and the remainder is bound to the glycoprotein transcortin (cortisol-binding globulin [CBG]). The remaining 10% of circulating cortisol is the unbound, free hormone. It is believed that only free cortisol is active, and that the protein-bound fraction is metabolically inert, probably serving as a reservoir for free cortisol. Protein binding also may protect cortisol from deactivation by the liver or filtration by the kidney.

One of the earliest and simplest methods used to determine serum cortisol was a fluorometric assay developed by Nelson and Samuels, which was based on a technique first developed by Porter and Silber (Porter, 1950; Nelson, 1952). A more specific method for cortisol estimation is immunoassay. Advantages include small specimen volume and rapid turnaround time. The problem was that some of the antibodies used showed a large degree of cross-reactivity with other steroid species, resulting in spuriously elevated cortisol concentrations. In chronic renal disease, various steroids and their glucuronides accumulate in the blood, and because these steroids and conjugates may cross-react with antibodies used in the cortisol assay, an interference that can be of the same magnitude as the actual cortisol concentration may result. In CAH, high concentrations of cortisol precursors are seen in the serum because of an enzyme defect. Because these precursors cross-react with assay antibodies, artificial elevations of cortisol are found. The degree of interference varies with the assay used and cannot be easily predicted. Nonisotopic immunoassay methods using organometallic tracers, fluorescence polarization, and enzyme immunoassay techniques have also been developed for cortisol determinations (Bacarese-Hamilton, 1992; Lentjes, 1993; Philomin, 1994). The major disadvantage of all of these cortisol assays continues to be lack of specificity.

The measurement of cortisol by radioimmunoassay (RIA) and chemiluminescent techniques has largely been supplanted by high-performance

liquid chromatography (HPLC) with tandem mass spectrometry, which appears to offer the ultimate in specificity. Most HPLC systems for cortisol measurement use reverse-phase liquid chromatography with ultraviolet detection (Volin, 1992). This method is both highly sensitive and free from many of the sources of interference encountered in immunoassays (Samaan, 1993).

Serum cortisol is collected in a no-additive (red-top) tube. Reference values for serum cortisol for men and women roughly range from 5–25 µg/dL (140–690 nmol/L) at 8 AM to 10 AM, dropping to about 3–12 µg/dL (80–330 nmol/L) by 4 PM. Because of wide swings in basal cortisol levels resulting from its diurnal and ultradian pattern of secretion, serum cortisol assays are most useful when evaluated in the context of dynamic manipulation (i.e., adrenal stimulation or suppression).

Salivary Cortisol

Up to 30% of urinary free cortisol (UFC) and dexamethasone suppression screening tests may return an incorrect result. Recent studies have shown that the use of a midnight salivary cortisol (MSC) is a viable alternative. CBG is not present in saliva; therefore the results may be more useful in situations in which CBG concentration is altered. Salivary cortisol is highly stable and easy to collect, making it a useful tool for screening and for diagnosing instances of increased cortisol secretion. It does not appear to be affected by the rate of saliva production and can reflect a change in serum cortisol in as rapid as a few minutes (Read, 1990). Because of alterations in circadian rhythm, it may not be an appropriate test for shift workers or those with highly variable bed times. One study compared the sensitivity for the detection of Cushing's syndrome by nighttime salivary cortisol levels versus that for simultaneous inpatient serum cortisol levels and urine glucocorticoid excretion. It was found that the salivary cortisol measurements worked as well as plasma measurements and better than urine glucocorticoid excretion. The authors concluded that measurement of bedtime salivary cortisol was a practical and accurate screening test for the diagnosis of Cushing's syndrome (Papanicolaou, 2002). Another study compared the diagnostic performance of MSC measurement versus that of midnight serum cortisol (MNC) and UFC in differentiating 41 patients with Cushing's syndrome from 33 with pseudo-Cushing's states, 199 with simple obesity, and 27 healthy normal weight volunteers. In the whole study population, no statistically significant differences in terms of sensitivity, specificity, diagnostic accuracy, and predictive values were observed among tests. In particular, the overall diagnostic accuracy for MSC was similar to those of UFC and MNC (Putignano, 2003; Elamin, 2008). A recent review of the literature has shown that elevated late-night (11 PM–12 AM) salivary cortisol has greater than 90% sensitivity and specificity for the diagnosis of endogenous Cushing's syndrome (Raff, 2009). It is recommended to have the patient avoid tobacco on the day of specimen collection.

Urinary Free Cortisol Measurements

Only 1% of the total adrenal secretion appears in the urine as cortisol, but it is this fraction that provides valuable aid in the diagnosis of adrenal disease. In the kidney, glomerular filtration of free cortisol (unbound to CBG and albumin) is followed by passive tubular reabsorption without a demonstrable reabsorption maximum. At serum cortisol levels of about 20–25 µg/dL (the upper 8 AM reference value), the binding capacity of transcortin (CBG) is exceeded, leading to a very rapid and disproportionate increase in the unbound fraction compared with the total serum cortisol. Doubling of serum cortisol from 20–40 µg/dL results in at least a fivefold increase in unbound cortisol. At these levels, free cortisol clearance by the kidneys is directly proportional to the unbound serum cortisol concentration, and a steep rise in cortisol clearance is seen. Serum cortisol reflects the sum of free, CBG-bound and albumin-bound cortisol. Only free unbound cortisol is filtered by the kidneys; therefore unlike serum cortisol, UFC is not affected by conditions and medications that alter CBG and albumin concentrations. Thus, when UFC rather than serum cortisol is used, it is easier to differentiate patients with adrenal hyperfunction from a reference population.

UFC is the best specimen to submit because it provides an integrated profile of total cortisol secretion over a 24-hour period, which is most helpful in those with sporadic excess cortisol production. The collection should also be assayed for creatinine to ensure that an adequate specimen has been submitted. The reliability of the test may be further improved by submitting urine collected over 2 or 3 days because day-to-day fluctuations in cortisol excretion are known to occur. Urinary free cortisol levels are unaffected by alterations in hepatic metabolism of cortisol. Although total cortisol production and urinary 17-OHCS may be increased, serum

cortisol and urinary free cortisol remain within the reference interval. Because renal clearance of cortisol is dependent on normal kidney function, it is not surprising that patients with renal disease have low UFC values. UFC is unreliable when CrCl is <20 mL/min, and is of reduced reliability when CrCl is <60 mL/min (Chan, 2004). Increased serum concentration of transcortin during pregnancy and with estrogen therapy results in increased serum cortisol levels. This increase is not reflected by an elevation of cortisol metabolites in urine, but urinary free cortisol may be increased. Conditions in which spuriously elevated levels occur include starvation, use of topical steroids, and perhaps hydration in the form of water loading.

Method. HPLC with mass spectrometry is considered the current reference method for measuring UFC; it has diagnostic sensitivity of 100% and specificity of 98% for distinguishing patients with Cushing's syndrome from normal individuals (Rudd, 1985). Prior assays (like RIA) were less specific with a tendency to overestimate the amount of cortisol present. When measuring free cortisol in the urine by RIA, reference intervals were found to vary with patient gender (men had higher reference intervals than women), use of an extraction procedure, and with the RIA test kit used (Lamb, 1994).

The normal range varies according to the assay technique used; however, values that are four times the upper reference limit are diagnostic for Cushing's syndrome. A low urinary free cortisol value is suggestive of adrenal hypofunction; however, because there is great overlap with the normal reference interval, this test is not used to make the diagnosis of adrenal insufficiency.

Hypercortisolism: Cushing's Syndrome

Cushing's syndrome is a group of clinical and metabolic disorders characterized by adrenocortical hyperfunction; it is associated with excess production of glucocorticoids, or glucocorticoids and androgens. Patients with severe forms of the syndrome are easily recognizable by their florid presentation. In less severely afflicted individuals, the vague signs and symptoms that occur may not be easily recognized as caused by hypercortisolism. Although patients with ectopic ACTH-producing tumors have elevated ACTH and glucocorticoid levels, because of the rapid growth of these tumors, the patients usually die before clinical signs of the syndrome can be manifest.

Laboratory findings in Cushing's syndrome include (1) excessive and persistent production of cortisol measured as elevated serum cortisol, urinary free cortisol, midnight salivary cortisol or 17-OHCS, (2) loss of circadian rhythm of ACTH and cortisol, (3) loss of suppression of cortisol production by administration of the synthetic glucocorticoid dexamethasone, and (4) hyperglycemia. Among the clinical findings in Cushing's syndrome, the most common are central obesity, hypertension, and hirsutism.

Cushing's disease is a state of glucocorticoid excess resulting from an ACTH-secreting pituitary adenoma. Cushing's syndrome is a more global term that encompasses a wide variety of entities associated with hypercortisolemia. Evaluation of a patient suspected of having Cushing's syndrome is best divided into two phases. The first phase is actual documentation of hypercortisolism; the second is identification of the pathophysiologic process behind the hypercortisolism. Cushing's syndrome is most commonly iatrogenic in origin; however, it may also be due to ectopic production of CRH or ACTH by a tumor or due to a primary adrenal malignancy. Adrenal Cushing's syndrome is a disorder of excess autonomous production of cortisol by the adrenals, resulting in suppression of the hypothalamic-pituitary axis. Adrenal Cushing's (adenoma or carcinoma) accounts for less than 20% of cases, whereas pituitary Cushing's accounts for about 68%, and ectopic production of ACTH (outside the pituitary-adrenal axis) is the cause of about 12% of cases (Orth, 1995). Because the treatment and prognosis differ depending on the cause, it is important that a specific diagnosis be reached.

Tests Used for the Diagnosis of Cushing's Syndrome

(Fig. 24-17)

Screening Tests. Three screening tests are used in the evaluation of a patient suspected of having Cushing's syndrome: the 24-hour urinary free cortisol, the overnight dexamethasone suppression test, and the plasma or salivary midnight cortisol level. The 24-hour urinary free cortisol is a reflection of the unbound circulating cortisol that is freely filtered by the glomerulus. Unlike serum cortisol, it is unaffected by the level of circulating CBG. HPLC or gas chromatography coupled with mass spectrometry

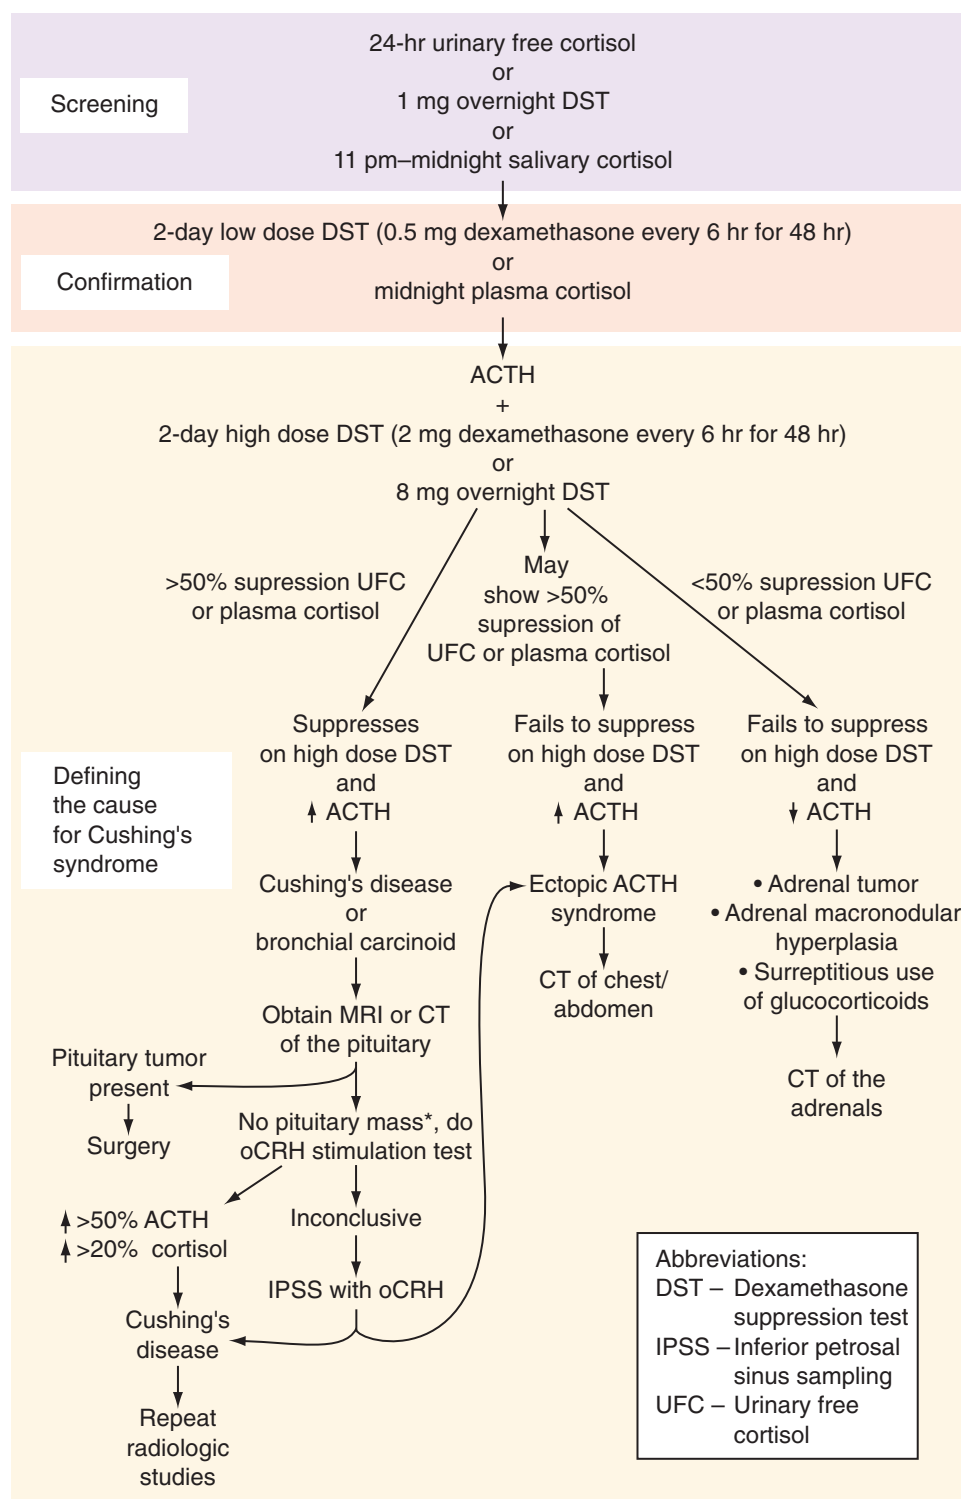

Figure 24-17 Algorithm for the evaluation of Cushing's syndrome. All screening tests must be followed by a confirmatory test. ACTH, Adrenocorticotropin; CT, computed tomography; oCRH, ovine corticotropin-releasing hormone; MRI, magnetic resonance imaging. *If there is no pituitary mass, obtain a chest radiograph and chest CT to rule out bronchial carcinoid before proceeding to IPSS.

provides the best specificity for measuring urinary free cortisol. Unlike RIA or enzyme-linked immunosorbent assay, these techniques are not affected by cross-reactivity with steroid metabolites or synthetic glucocorticoids. The upper range of normal with these methods is 110–138 nmol/24 hours (40–50 µg/hour) (Raff, 2003). The creatinine should be measured in all collections to ensure the adequacy of the specimen. Urinary cortisol excretion is decreased when the glomerular filtration rate is <30 mL/minute, and thus may be normal despite the presence of excessive cortisol production (Arnaldi, 2003). Values greater than four times the upper limit of normal are diagnostic of Cushing's syndrome. However, 10%–15% of

patients with Cushing's syndrome will have at least one in four 24-hour urine collections for free cortisol return as normal (Nieman, 1990). If cortisol excretion is normal but clinical suspicion is high, the study should be repeated or a different screening method should be used. Milder elevations can be seen in pseudo-Cushing's and during normal pregnancy. Pseudo-Cushing's is an entity characterized by HPA axis overactivity but without true Cushing's syndrome. It has been described in depression, anxiety disorders, alcoholism, and morbid obesity. As per the latest guidelines for the diagnosis of Cushing's syndrome, any UFC concentration above the upper limit of normal for that particular assay should be

considered a positive test (Neiman, 2008). Because most pediatric patients being evaluated for Cushing's are of adult weight (>45 kg), adult normal ranges may be used (Neiman, 2008).

The overnight dexamethasone suppression test is a much simpler test to perform. The patient takes 1 mg of dexamethasone orally between the hours of 11 PM and 12 midnight. The plasma cortisol is drawn the following morning between 8 AM and 9 AM. The original criterion for an abnormal response was failure to suppress the morning cortisol level to <5 µg/dL (138 nmol/L); however, this has been revised downward to <1.8 µg/dL (50 nmol/L) (Findling, 1999; Arnaldi, 2003; Neiman, 2008). Failure to suppress could be due to Cushing's syndrome or pseudo-Cushing's, and may even occur in some patients who are normal. The false-positive rate can be as high as 30% for a variety of reasons: Dexamethasone was taken too early; the patient was on phenobarbital, Dilantin, or another medication known to accelerate the metabolism of dexamethasone; malabsorption; alcoholism; or morbid obesity. Pregnancy and drugs such as estrogen, which increase serum transcortin (aka CBG), may also result in elevated cortisol levels. Because of these and possibly other factors, about 1% of healthy individuals, 13% of obese patients, and 25% of hospitalized and chronically ill patients show false-positive overnight dexamethasone suppression tests (DSTs). False-negative results, on the other hand, occur in less than 2% of patients.

The late-night (11 PM) salivary cortisol is a simple test that carries high diagnostic sensitivity and specificity. The patient can collect the sample at home. Two methods can be used to collect the sample: The patient can chew on a cotton pledget for 2–3 minutes and then place the pledget into a plastic tube; alternatively, the patient can passively drool directly into a test tube. The sample is then mailed to the reference laboratory; because salivary cortisol is very stable, there is little concern about degradation during transport. The sample is analyzed by immunoassay or by liquid chromatography-mass spectrometry (LC-MS/MS); normative values vary according to the reference laboratory.

Screening in Special Populations. The preferred screening test during pregnancy is the UFC. UFC levels normally rise during the second and third trimesters, therefore UFC values greater than three times the upper limit of normal are considered consistent with Cushing's syndrome (Neiman, 2008). Because of the decrease in cortisol filtration with declining renal function, the 1-mg DST is the recommended screen in patients with renal failure. For those suspected of having cyclic Cushing's, use of UFC or MSC is suggested. The diagnostic thresholds for MSC during pregnancy and in renal disease remain to be established. In instances of an incidentally discovered adrenal mass, the 1-mg DST or a late-night salivary cortisol are the screening tests of choice (Neiman, 2008).

Confirmatory Tests for the Diagnosis of Cushing's Syndrome.

A positive screen for Cushing's syndrome is followed by confirmatory testing with a midnight plasma cortisol or low-dose DST performed alone or with the administration of CRH.

Midnight plasma cortisol requires hospital admission for at least 48 hours, insertion of a line for IV access before 10 PM, the patient sleeping at the time of the blood draw, and availability of staff to draw the blood at midnight. A midnight plasma cortisol greater than 7.5 µg/dL (207 nmol/L) is diagnostic of Cushing's; this has a 100% specificity for normals and those with pseudo-Cushing's (Papanicolaou, 1998). More recently, several authorities have suggested using 1.8 µg/dL (50 nmol/L) as the cutoff for normal. This value carries a very high degree of sensitivity (Newell-Price, 1995).

The low-dose (2-day 2 mg) dexamethasone suppression test (LDDST) requires the collection of two baseline 24-hour urines for UFC. The patient is then given 0.5 mg dexamethasone orally every 6 hours, starting at 9 AM for 2 days. On day 2 of dexamethasone, another 24-hour urine is collected for UFC. All 24-hour urine collections should include the measurement of creatinine to assay for adequacy of the collection. A normal response is a decrease in UFC to less than 10 µg (27 nmol) per 24 hours on the second day of dexamethasone. This has a sensitivity of 97%–100% for discriminating patients with Cushing's syndrome from normal individuals (Newell-Price, 1998). Instead of measuring UFC, serum cortisol can be measured at baseline (9 AM day 1) and at 48 hours following the first dose of dexamethasone. In this case, a normal response consists of suppression of the plasma cortisol to less than 1.8 µg/dL (50 nmol/L), which has a sensitivity and specificity of more than 95% (Newell-Price, 1998). Performance of the DST with CRH has been purported to better distinguish Cushing's syndrome from pseudo-Cushing's (Yanovski, 1993). For this 1-µg/kg ovine, CRH is administered IV 2 hours after the last dose

TABLE 24-22

Differential Diagnosis of Hormonal Values Seen in Cushing's Syndrome

Cause	Plasma ACTH	Plasma cortisol (PM)	High-dose or overnight dexamethasone suppression
Pituitary-dependent	N–slightly ↑	↑	Yes
Adrenal disease	↓– undetectable	↑	No
Ectopic Cushing's*	↑↑↑	↑↑	Usually no
Pseudo-Cushing's	N–slightly ↑	N–↑	Usually yes

ACTH, Adrenocorticotropin; N, normal.

*ACTH levels may overlap with values seen in pituitary-dependent disease.

of dexamethasone. Cortisol is measured 15 minutes later. A dexamethasone level should be measured at the time of CRH administration to exclude false-positive results. Adherence to the time schedule is important for both LDDST and LDDST with CRH. The normal response for both tests is a serum cortisol <1.8 µg/dL (<50 nmol/L).

Tests for Defining the Cause of Cushing's. Once the diagnosis of Cushing's syndrome is established, the next step is to determine its cause. Cushing's is categorized as being ACTH dependent or ACTH independent; this is accomplished by measuring the plasma ACTH, or by performing a high-dose DST or a CRH stimulation test (Table 24-22).

ACTH-independent Cushing's syndrome results from autonomous production of cortisol, which would feed back on the hypothalamus and pituitary and cause suppression of CRH and ACTH secretion. The technique for measuring plasma ACTH has been described previously. Values below the level of detection or below 10 pg/mL (2 pmol/L) at 9 AM with concomitantly elevated cortisol support an ACTH-independent cause for Cushing's syndrome. Plasma levels greater than 20 pg/mL (4 pmol/L) in the face of hypercortisolism are strongly suggestive of an ACTH-dependent cause. A CRH stimulation test with measurement of ACTH is indicated for values between 10 and 20 pg/mL (2–4 pmol/L) (Orth, 1995). Although patients with ectopic ACTH production tend to have markedly elevated ACTH levels, there is great overlap with the levels seen in Cushing's disease; therefore, it cannot be used to reliably distinguish between these entities.

The high-dose (2-day 8 mg) DST is useful for distinguishing Cushing's disease from adrenal or ectopic Cushing's. It is of note that cortisol levels in neuroendocrine tumors such as bronchial carcinoid may also suppress on high-dose dexamethasone. For the high-dose DST, a baseline 24-hour urine for UFC is collected. Beginning on day 1, the patient receives 2 mg of dexamethasone orally every 6 hours for 48 hours; urine for UFC is collected on day 1 and on day 2. As an alternative to measuring UFC, plasma cortisol can be collected before, during, and after dexamethasone. Suppression of UFC or plasma cortisol by 50% or more from baseline is diagnostic of Cushing's disease. Most patients with adrenal adenomas, carcinomas, or ectopic ACTH syndromes do not show suppression. This test has a sensitivity and specificity of 60%–85%; the greater the degree of suppression, the greater the specificity.

The 8-mg overnight DST has been reported by several authors to share similar sensitivity and specificity to the high-dose DST (Dicheck, 1994). An 8 AM plasma cortisol is obtained, and 8 mg of dexamethasone is administered orally at 11 PM. An 8 AM plasma cortisol is obtained the next morning. Reduction of cortisol to less than 5 µg/dL is strongly supportive of Cushing's disease (see Fig. 24-17).

Most pituitary tumors and a few ectopic ACTH-secreting tumors will respond to CRH stimulation with an increase in plasma ACTH and cortisol, whereas little response is noted in those with adrenal Cushing's. For the CRH stimulation test, two basal plasma cortisol and ACTH levels are collected about 5 minutes apart, then 1 µg/kg of body weight or a single dose of 100 µg of synthetic ovine CRH (oCRH) is injected intravenously. Blood is sampled every 15 minutes for 1–2 hours for cortisol and ACTH. Normal subjects will show a rise in ACTH and cortisol of approximately 15%–20%, while those with Cushing's disease typically show a greater than 50% rise in ACTH and a greater than 20% rise in cortisol above baseline (Kaye, 1990; Newell-Price, 2002; Stewart, 2003). Ovine CRH is

superior to human CRH in distinguishing among the different causes of Cushing's syndrome (Nieman, 1989). Vasopressin stimulates ACTH release through the V3 receptors in the anterior pituitary. Administration of 10 units of vasopressin intramuscularly normally causes doubling of ACTH levels and an increase in serum cortisol of 150 µg/L over baseline. This offers no advantage over testing with CRH. It may prove useful, however, in differentiating Cushing's disease from pseudo-Cushing's syndrome and in the postoperative assessment of Cushing's disease (Newell-Price, 2002).

In rare instances, it may be necessary to use selective sampling of inferior petrosal sinus blood to document that the pituitary is the source of excess ACTH. This invasive, technically difficult procedure carries a relatively high cost and complication rate and should be performed only at a center well experienced with this technique. The ACTH concentration in the petrosal sinus blood should exceed twice that of peripheral venous blood to ensure diagnostic sensitivity and specificity of 100% (Orth, 1995). In those with ectopic production, the ratio is usually less than 1.4:1. Use of CRH during sampling increases the sensitivity and specificity.

Given that the incidence of **incidentaloma** of the adrenals and pituitary has been reported to be as high as 10%, imaging studies should be performed only after the hormonal diagnosis of Cushing's disease or syndrome has been made. In Cushing's disease, visualization of the sella is performed by MRI or CT, with and without contrast. For adrenal Cushing's, the test of choice is a CT of the abdomen; for ectopic disease, CT of the chest may also be needed.

Pseudo-Cushing's Syndrome

Excess activity of the hypothalamic-pituitary axis, similar to that seen in pituitary Cushing's syndrome, has been demonstrated in some patients with alcoholism, major depression, and obesity. Resolution of the underlying problem results in normalization of the HPA axis. These patients may not suppress on a low-dose DST and may have elevated UFC. Depressed patients who fail to suppress cortisol secretion in response to dexamethasone also show an impaired ACTH response to exogenous CRH, but will usually retain a normal cortisol response (Gold, 1986; Thalen, 1993). A single serum cortisol above 7.5 µg/dL at midnight has been shown to discriminate Cushing's syndrome from pseudo-Cushing's with 100% specificity (Papanicolaou, 1998). A more definitive test for distinguishing between these two entities is the combined dexamethasone-oCRH test. oCRH is infused 2 hours after a low-dose dexamethasone test. A plasma cortisol concentration greater than 38 nmol/L measured at 15 minutes following the administration of oCRH correctly identifies all cases of Cushing's syndrome and all cases of pseudo-Cushing's, with specificity, sensitivity, and diagnostic accuracy of 100% (Yanovski, 1993).

Adrenal Insufficiency

Adrenal insufficiency is categorized according to the key site of dysfunction within the HPA axis: primary (adrenal), secondary (pituitary), and tertiary (hypothalamic). A major distinction between primary adrenal insufficiency and either of the central causes is that primary disease is associated with mineralocorticoid deficiency. In the Western world, primary adrenal insufficiency, also known as Addison's disease, is most commonly due to autoimmune adrenalitis (70%–90% of all cases); other causes include tuberculosis (most common cause worldwide), granulomatous disorders, metastatic disease, hemorrhage, human immunodeficiency virus, acquired immunodeficiency syndrome, and infection. The most common cause of central adrenal insufficiency is HPA axis suppression due to prolonged treatment with pharmacologic doses of steroids.

Tests for the Diagnosis of Adrenal Insufficiency

Basal Hormone Measurements. An 8 AM to 9 AM plasma cortisol of <3 µg/dL (83 nmol/L) is indicative of adrenal insufficiency and obviates the need for further testing. Although most patients with hypocortisolism have low serum cortisol levels, a level drawn during a time of stress that falls within the reference range does not exclude the diagnosis. Rather, it may support this diagnosis, as a suboptimal cortisol level may have risen into the reference interval in response to a very high ACTH level induced by stress. A random cortisol of >25 µg/dL (700 nmol/L) during critical illness makes it unlikely that the patient is adrenally insufficient (Burke, 1985), whereas a random cortisol of <10 µg/dL is strongly suggestive of adrenal insufficiency (Fleseriu, 2009).

ACTH Stimulation Test. The most convenient procedure for studying patients suspected of having hypocortisolism is the ACTH stimulation test. This test, which can be performed at any time of day, consists of drawing

a baseline serum cortisol and then administering 250 µg of Cosyntropin (commercially available ACTH analog) intravenously or intramuscularly. Serum for cortisol is again collected at 30 and 60 minutes post Cosyntropin. A normal response is a cortisol level greater than 18–20 µg/dL (500–550 nmol/L) at either time point (Speckart, 1971; Burke, 1985). Drawing an ACTH level at baseline may help in distinguishing primary adrenal insufficiency (associated with an elevated ACTH usually greater than 50–100 pg/mL) from secondary or tertiary forms (which would have a low ACTH level <10 pg/mL) (Oelkers, 1992) (refer to Laboratory Measurement of ACTH). The aldosterone response to ACTH may also help in making this distinction; failure of aldosterone to increase by more than 4 ng/dL over baseline suggests primary adrenal dysfunction.

Steroids should never be withheld from a critically ill patient suspected of having adrenal insufficiency; instead a random sample for cortisol and ACTH should be drawn and treatment initiated with dexamethasone, which does not interfere with the cortisol assay. Formal testing should take place within 72 hours, before HPA axis suppression occurs. About 90% of cortisol circulates bound to CBG and albumin, and approximately 10% circulates freely (unbound). CBG declines during critical illness, resulting in an increase in the fraction of unbound (free) cortisol compared with the bound fraction. Because the serum total cortisol concentration does not accurately reflect this alteration in free/bound cortisol, it is common to overdiagnose adrenal insufficiency in the critical care setting. Since access to laboratories that readily and reliably measure free cortisol is limited, some have advocated use of the free cortisol index (FCI) and calculated free cortisol (CFC) to better delineate those patients in true need of steroid replacement therapy (Hamrahian, 2004; Beishuizen, 2001; Ho, 2006). To obtain the FCI, it is necessary to measure the serum CBG. CFC is the total cortisol (nmol/L)/CBG (mg/L), with normal being a value above 12. Given that for the vast majority of institutions CBG determinations require the sample to be sent to a reference lab, it may be more prudent and certainly more direct to simply send aliquots from t=0, t=+30, and t=+60 minutes post ACTH stimulation for free cortisol and provide steroid coverage pending these results (Fleseriu, 2009). Salivary cortisol, which is unaffected by changes in CBG, may eventually prove useful in this setting (Raff, 2009).

Some have supported the use of a 1-µg dose of ACTH instead of the full 250-µg dose for diagnosing adrenal insufficiency. The premise is that the massively supraphysiologic dose of 250 µg will cause those with partial adrenal insufficiency to mount a normal response, and that these individuals will fail to show an adequate rise in cortisol in response to a 1-µg test dose. This procedure has not gained wide acceptance, nor has the normal range been standardized; more important, the diagnosis of **partial adrenal insufficiency** remains in contention.

The ITT has long been considered the gold standard for assessing the HPA axis. Unlike the ACTH stimulation test, the ITT assesses the integrity of the entire HPA axis. If the HPA axis is intact, insulin-induced hypoglycemia stimulates the hypothalamus and the pituitary to secrete CRH and ACTH, respectively, which, in turn, leads to a rise in cortisol. This test is contraindicated in individuals with ischemic heart disease, in the elderly (>age 70), during pregnancy, and in those with a history of seizures. Patients highly suspected of having central adrenal insufficiency (i.e., prior pituitary surgery or radiation therapy) should receive a lower dose (0.05 U/kg) of insulin, rather than 0.1–0.15 U/kg. Glucose and cortisol are measured at –15 mins, at baseline, and then at 15, 30, 45, 60, 90, and 120 minutes following insulin administration. For the test to be valid, adequate hypoglycemia must be attained (signs and symptoms of hypoglycemia and glucose <40 mg/dL [2.2 mmol/L]). A normal response is a rise in the cortisol level to greater than or equal to 18 µg/L or 20 µg/L at any time during the test (Nelson, 1978; Burke, 1985; Grinspoon, 1994). Preliminary work suggests there was no difference in peak GH or cortisol level attained when analog insulin was substituted for regular insulin for the ITT (Yuen, 2008).

The cortisol response to hypoglycemia can be predicted reliably by the response to acute ACTH stimulation—a safer, cheaper, and quicker test (Stewart, 2003). The ITT is used mainly as a second-line measure to further evaluate those patients who had a borderline response to the ACTH stimulation test.

In the days before the commercial availability of a reliable assay to measure ACTH, it was common to perform a prolonged ACTH stimulation test (ACTH infusion over a 2-day period) to distinguish central from primary adrenal insufficiency. In other hormone systems, lack of stimulation normally leads to upregulation of the end-organ receptors; however, the adrenals downregulate their ACTH receptors in response to lack of stimulation. A short ACTH stimulation test would typically produce an

inadequate response. By priming the system with prolonged exposure to ACTH, those with hypothalamic disease display a delayed but normal rise in cortisol.

Overnight Metyrapone Test. Metyrapone has also been used to assess the integrity of the HPA axis. Metyrapone inhibits 11- β -hydroxylase, preventing the conversion of 11-deoxycortisol (compound S) to cortisol. Under normal circumstances, the metyrapone-induced drop in cortisol is detected at the level of the hypothalamus and pituitary; a compensatory increase in CRH and ACTH secretion occurs, stimulating steroidogenesis and leading to a buildup of 11-deoxycortisol, the hormone preceding the block. Patients with central adrenal insufficiency fail to increase CRH and/or ACTH, steroidogenesis is not stimulated, and 11-deoxycortisol fails to increase. Metyrapone 30 mg/kg is administered orally at midnight; blood for cortisol and 11-deoxycortisol is collected the following morning at 8 AM. A rise in 11-deoxycortisol to greater than 7 $\mu\text{g/dL}$ (200 nmol/L) is normal (Fiad, 1994; Grinspoon, 1994). An abnormal response is defined by 11-deoxycortisol less than 7 $\mu\text{g/dL}$ accompanied by cortisol less than 5 $\mu\text{g/dL}$. This test should be performed with caution as it may provoke an Addisonian crisis in those with central hypocortisolism.

Corticotropin-Releasing Hormone Test. The oCRH test can be used not only to diagnose hypocortisolism, but to localize the site of damage (Schulte, 1984). It is a safe test; however, it is expensive. After blood is drawn for baseline ACTH and cortisol, 100 μg oCRH is administered intravenously. Blood is then collected for cortisol and ACTH every 15 minutes for 60–90 minutes. A normal response is seen as cortisol >20 $\mu\text{g/dL}$. Basal ACTH levels and their change in response to oCRH are used to localize the site of pathology. Plasma corticotropin usually peaks at 15–30 minutes and cortisol usually peaks at around 30–40 minutes post oCRH injection (Oelkers, 1996).

Antibodies against 21-hydroxylase antigen should be assayed in those whose Addison's disease (primary adrenal insufficiency) does not have an obvious explanation. Positive antibodies confirm autoimmune adrenalitis; these patients should be screened and monitored for the development of other autoimmune disorders.

The use of steroids in the treatment of malignant, inflammatory, and immunologic disorders is a common iatrogenic cause of adrenal insufficiency. The degree of adrenal suppression is dependent on the specific glucocorticoid dose, duration, frequency, and route of administration. Assessment of adrenal function in patients being tapered off of exogenous steroids can be performed once they are tapered to the equivalent of a daily dose of 10 mg hydrocortisone. Have them omit the morning glucocorticoid dose, and measure the 8 AM cortisol level. If it is greater than 10 $\mu\text{g/dL}$, routine supplementation of steroids can be ended. Because the adrenal cortex lags behind the pituitary in recovery from steroid suppression, complete adrenal recovery can also be demonstrated by an appropriate rise in serum cortisol following an 8 AM Cosyntropin infusion.

RENIN-ALDOSTERONE AXIS

At least 20 million people in the United States have hypertension, and 90%–98% of cases are classified as essential hypertension. The mortality and morbidity from associated myocardial, cerebrovascular, and renal complications necessitate aggressive treatment of this disorder. Investigation into the etiology of hypertension revealed the importance of the

renin-angiotensin-aldosterone system, not only in the origin and persistence of hypertension but also as a guide to its treatment. The role of the renin-aldosterone axis is to maintain blood pressure within normal limits by sensing and responding to changes in plasma volume, salt balance, and renal perfusion pressure.

Renin is a proteolytic enzyme which, although formed by other tissues throughout the body, is mainly formed and stored by juxtaglomerular (JG) cells within the macula densa of the kidney. Renin is synthesized from a larger precursor protein, prorenin (big renin), and is converted to its active form within the JG cells. The release of renin into the circulation occurs in response to a variety of triggers: a drop in renal hydrostatic pressure, hyponatremia, hypokalemia, or a decrease in catecholamines, angiotensin II, or atrial natriuretic hormone. Both suppression of plasma renin activity induced by potassium administration and stimulation of renin activity following potassium depletion occur independently of changes in aldosterone secretion or in sodium balance (Brunner, 1970).

Several isoenzymes of rennin are known. Their release is regulated by cAMP. Renin acts on angiotensinogen (renin substrate), an α_2 -globulin formed by the liver, converting angiotensinogen to angiotensin I. Angiotensin I in turn is converted into angiotensin II by the angiotensin-converting enzyme (ACE). ACE is found in the pulmonary and vascular endothelia, as well as in cell membranes of the kidney, heart, and brain (Brewster, 2004). It is believed that angiotensin II is the peptide responsible for the physiologic effects on target tissue. Angiotensin II not only stimulates the release of aldosterone, but it is also a very potent vasoconstrictor that can stimulate the release of catecholamines from the adrenals and norepinephrine from the sympathetic nervous system, and stimulate the release of vasopressin. The octapeptide angiotensin II is further split to a heptapeptide, angiotensin III; in addition, angiotensin I may be changed directly to angiotensin III without being converted to angiotensin II. Although speculation about the functions of angiotensin III is ongoing, it appears to modulate aldosterone secretion in a similar manner to angiotensin II. The active angiotensins are rapidly cleared by various aminopeptidases (angiotensinases) within the circulation and during transit through tissues. These relationships are shown in Figure 24-18.

Renin, through its product, angiotensin II, directly stimulates the synthesis and secretion of aldosterone by the adrenal zona glomerulosa. Renin release, the rate-limiting step in the renin-aldosterone axis, is dependent on changes in effective plasma volume, which, in turn, are dependent on tubular reabsorption of sodium by the kidney. Low plasma volume and low serum sodium stimulate the secretion of renin, resulting in aldosterone release, which, in turn, causes sodium retention along with an increase in plasma volume and blood pressure, and potassium loss. Conversely, an increase in effective blood volume or acute elevation in blood pressure results in low renin, low angiotensin, low aldosterone, and subsequent sodium loss. In contradistinction to aldosterone, renin secretion is inhibited by hyperkalemia (Fig. 24-19).

Aldosterone and glucocorticoids act at the mineralocorticoid receptor located in the cells lining the collecting ducts of the kidney to cause reabsorption of sodium, leading to an increase in intravascular volume. Aldosterone also causes renal potassium loss. Studies have suggested a role for aldosterone in the development and perpetuation of vasculopathy; it has been shown to stimulate genes for collagen synthesis, tissue growth factors, inflammatory factors, and plasminogen activator inhibitor type 1 (Brilla,

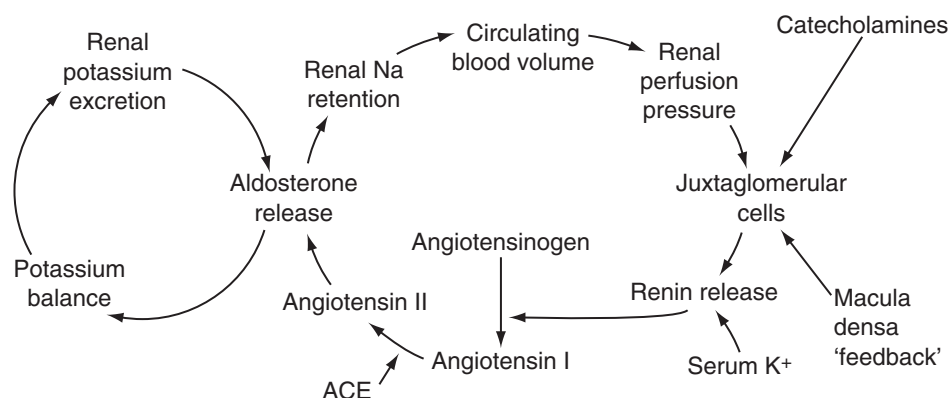

Figure 24-18 Renin-aldosterone axis. Elevated K^+ inhibits renin secretion but has a stimulatory effect on aldosterone. Catecholaminergic influence is variable; β -adrenergic activity stimulates and α -adrenergic activity inhibits renin secretion from the juxtaglomerular cells. (Redrawn from Braunwald E, Fauci AD, Kasper D, et al, editors. *Harrison's principles of internal medicine*. 15th ed. New York: McGraw-Hill; 2001, p. 2087.) ACE, Angiotensin-converting enzyme.

Figure 24-19 The normal renin-angiotensin-aldosterone axis. Renin, secreted by the kidney, cleaves angiotensin I from renin substrate (angiotensinogen) produced by the liver. Angiotensin I is converted to angiotensin II by angiotensin-converting enzyme (ACE), mainly in the lung. Angiotensin II increases peripheral vascular resistance and, together with angiotensin III, stimulates aldosterone (ALDO) secretion, which results in sodium retention and increased plasma volume. (Adapted from Stewart PM. *The adrenal cortex*. In: Larsen PR, Kronenberg HM, Melmed S, Polansky KS, editors. *Williams textbook of endocrinology*. 10th ed. Philadelphia: WB Saunders; 2003, p. 499.)

1994; Schunkert, 1997; Brown, 2000; Rocha, 2000; Luft, 2002). The synthesis of aldosterone is restricted to the zona glomerulosa; here the enzyme aldosterone synthetase (CYP11B2) converts corticosterone to aldosterone. The major stimuli for aldosterone secretion are angiotensin II and hyperkalemia. ACTH is a much weaker stimulus. Somatostatin, atrial natriuretic hormone, dopamine, and heparin directly inhibit aldosterone synthesis. Cortisol circulates at a much higher concentration than aldosterone, and although it binds with equal affinity to the mineralocorticoid receptor, it does not normally function as a major mineralocorticoid. The reason is that the enzyme 11- β -hydroxysteroid dehydrogenase II (11-HSD-2, also known as CYP11B2), expressed by the mineralocorticoid targets cells in the collecting tubules acts to convert cortisol to cortisone, an inactive metabolite.

RENIN AND HYPERTENSION

The work of Laragh has indicated that essential hypertension can be classified on the basis of renin measurements as high, low, or normal renin, and that drug selection can be based on this classification (Laragh, 1972; Laragh, 1993). About 15% of patients with essential hypertension have high-renin hypertension. Hyperreninemia resulting from renal parenchymal disease or renal vasculopathy leads to increased aldosterone production and the subsequent retention of sodium and enhanced potassium excretion. Patients with this condition are hypervolemic, intensely vasoconstrictive, and more prone to ischemic injury. Renin profiling has shown renin to be an independent risk factor for myocardial infarction. Even if pressures are controlled by antihypertensives, if they do not address plasma renin activity, such patients fare worse than individuals with lower renin levels (Alderman, 1991). Increased aldosterone (secondary aldosteronism) may contribute significantly to the symptoms and course of high-renin hypertension. Some of the causes of high-renin hypertension are listed in Table 24-23.

Renin-secreting tumors are extremely rare and can be difficult to diagnose. They can be benign or malignant, renal or extrarenal. The most common location is in the juxtaglomerular apparatus. A young patient with markedly elevated plasma renin activity, hyperaldosteronism, and hypokalemia in the absence of a renovascular lesion typifies the classic clinical presentation (Corvol, 1994). Malignant hypertension is also associated with high plasma renin activity and aldosterone. When such patients are

TABLE 24-23

Major arterial lesions	Vasodilating agents
Segmental lesions	Glucocorticoids
Chronic renal failure	Estrogens
End stage	
Transplant rejection	

given medications that interrupt the renin-aldosterone axis, such as ACEIs, blood pressure often normalizes. In renal vascular hypertension, the renin and aldosterone levels are also elevated. However, in contradistinction to malignant hypertension, treatment with ACEs usually results in further deterioration of renal function. Patients suspected of having renal artery stenosis should undergo further testing (e.g., captopril-induced renogram, renal duplex ultrasound, magnetic resonance angiography). A positive test leads to renal vein angiography and catheterization for selective blood sampling. In unilateral renal disease, both plasma renin and aldosterone are elevated. Asymmetry in the renin levels obtained during renal vein catheterization offers one of the best measurements to judge the likelihood of blood pressure response to corrective surgery. When the ratio of plasma renin in the renal vein of the affected to the nonaffected side is at least 1.5 : 1, surgery may lead to improvement. With suppression of renin release from the nonaffected side, renal vein renin levels approximating those found in blood specimens obtained from the inferior vena cava also indicate probable success of curative surgery. Almost 40% of these patients have peripheral blood plasma renin activity that is within the reference interval (Streeten, 1979); consequently, peripheral plasma renin is a poor predictor of response to surgery. Renin secretion can be found in lung cancer, hepatic hamartoma, and other rare conditions (Anderson, 1989).

When an acceleration of hypertension occurs, renin is usually markedly increased; however, with chronic renal failure, almost any renin level can be expected. A small number of hypertensive patients on dialysis have intractable, accelerated hypertension. In those patients in whom dialysis cannot control the hypertension, markedly elevated plasma renin levels can be lowered by nephrectomy or, in the case of renal artery stenosis, angioplasty or revascularization (Whitehouse, 1981; Sonkodi, 1990; Tullis, 1999). ACEIs can be used to mitigate the rise in aldosterone; however, in the setting of renal disease, they can precipitate or worsen hyperkalemia. In renal transplant patients, elevated plasma renin may be indicative of renal ischemia and rejection.

Systemic hypertension occurs in patients with Cushing's syndrome. Some of these patients have increased plasma renin and renin substrate. Other Cushing's syndrome patients have hypokalemia associated with secretion of a minor mineralocorticoid (such as DOC or corticosterone) that causes hypertension (Krakoff, 1975). In still other patients, severely elevated cortisol levels overwhelm the capacity of 11-hydroxysteroid dehydrogenase (11-HSD) to convert cortisol to its metabolically inactive form, cortisone, leading to a picture of excess mineralocorticoid activity with suppressed plasma renin activity. Other causes of high-renin hypertension include treatment with medications such as diuretics, vasodilators, or other antihypertensives. Hormonal agents such as glucocorticoids, as well as some estrogen-containing oral contraceptives, have been found to increase renin substrate activity.

Even though plasma renin activity, aldosterone, and urinary sodium excretion may be normal in 60% of hypertensive patients, evidence indicates that renin-angiotensin plays a significant part in normal-renin hypertension. The response of many hypertensive patients with normal renin to angiotensin-converting enzyme inhibitors or angiotensin II antagonists (saralasin) has implicated renin and angiotensin II in sustaining hypertension in these patients. Moreover, Ames showed that once blood pressure was increased by angiotensin infusion, it could be maintained with only one fifth of the original dose (Ames, 1965).

It was found that low-renin essential hypertension, which involves chronic expansion of plasma and extracellular fluid volume, is characterized by aldosterone oversecretion and responds to diuretic therapy. At least 25% of patients with essential hypertension are found to have low-renin hypertension. Most investigators have characterized this state as hyporesponsive, meaning that low-renin hypertensive patients fail to respond as well as healthy subjects do with upright posture, sodium restriction,

CAH, Congenital adrenal hyperplasia.

diuretics, vasodilators, or a combination of these. Atrial natriuretic peptide may be elevated in these patients, and the response of aldosterone to renin may be exaggerated (Sergev, 1990). Renin suppression increases with age and appears to be more common in women and in the black population.

Listed in Table 24-24 are a group of syndromes associated with low levels of plasma renin. These have been divided into a subgroup that is of adrenal origin (primary) and a subgroup that is nonadrenal or secondary in origin. Primary aldosteronism is uncommon compared with renin hypertension. It is characterized by (1) systolic and diastolic hypertension caused by oversecretion of aldosterone by an adrenal adenoma (aldosterone-producing adenoma [APA]) or hyperplasia (idiopathic hyperaldosteronism [IHA]), (2) low renin or a high aldosterone/renin ratio (>50), (3) renal potassium wasting, and (4) sodium retention. It should be suspected in patients with hypertension and spontaneous or diuretic-induced hypokalemia, resistant hypertension requiring more than three medications, onset younger than age 30, or an incidentally found adrenal mass. Several potential screening tests have been used to detect primary aldosteronism and to separate unilateral aldosterone-producing adenomas from other causes of primary aldosteronism. A low-salt diet (<2 g/day), stress, upright posture, and diuretics all increase plasma aldosterone, whereas a high-salt diet and lying in a supine position suppress aldosterone secretion in healthy subjects. Combinations of these maneuvers have been used in the diagnosis of excessive aldosterone secretion; however, they do not reliably distinguish APA from IHA. When healthy subjects are placed on a high-salt diet and lie in the supine position, they suppress their plasma aldosterone levels to less than 10 ng/dL (278 pmol/L).

Primary Hyperaldosteronism—Screening and Confirmation Tests

The algorithm proposed by Blumenfeld for evaluating hypertensive patients suspected of having primary hyperaldosteronism is to initially measure the serum potassium (Blumenfeld, 1994). If it is less than 3.6 mmol/L, then plasma renin activity is measured. Plasma renin activity of <1.0 ng/mL/hour leads to 24-hour urine collection for aldosterone and potassium excretion. Findings of 24-hour urinary potassium greater than 30 mmol/24 hours in the face of hypokalemia and of aldosterone greater than 15 mg/24 hours lead to the localization of the underlying pathology to the adrenal.

A more recent set of guidelines for the detection and diagnosis of primary hyperaldosteronism, as proffered by the Endocrine Society, include the following (Funder, 2008). Although patients with primary hyperaldosteronism classically present with spontaneous or easily provokable hypokalemia, many in fact will have serum potassium levels that are within the normal range. Thus, the preferred screening test is a plasma aldosterone concentration/plasma renin activity (PAC/PRA) ratio, PAC expressed in ng/dL, and PRA in ng/mL/hour. This is performed after the patient has remained upright for at least 2 hours. The patient should have stopped spironolactone and eplerenone for 4–6 weeks and other diuretics for at least 2 weeks before testing. Hypokalemia should be corrected (as it may suppress aldosterone secretion), and the patient should not be on a sodium-restricted diet. A PAC/PRA ratio greater than 30 is suggestive of primary hyperaldosteronism; a value greater than 50 is virtually diagnostic

(Weinberger, 1993; Blumenfeld, 1994). It is of note that the lower limit of normal for the PRA assay varies by laboratory; therefore, the diagnosis is supported only when both the PAC/PRA ratio and the PAC are elevated. The preferred technique for measuring PRA is a validated immunometric assay. HPLC tandem mass spectrometry is preferred for measuring plasma and urine aldosterone (Funder, 2008). The PAC/PRA ratio is highly dependent on the renin concentration; as such, it is important to use an assay with sufficient sensitivity in the lower ranges (e.g., <0.2 – 0.3 ng/mL/hour).

The diagnosis of primary hyperaldosteronism is confirmed by performing one of the four following confirmatory tests: oral sodium loading test, saline infusion test, fludrocortisone suppression test, or the captopril challenge test (Funder, 2008). Saline suppression can be accomplished by infusing 2 L of 0.9% saline over 4 hours, or by administering sodium chloride tablets 10–12 g daily for 3 days. PAC at the end of the 4-hour infusion of less than 5 ng/dL (140 pmol/L) makes the diagnosis of hyperaldosteronism unlikely. A PAC greater than 10 ng/dL (280 pmol/L) strongly supports the diagnosis of primary hyperaldosteronism, whereas values greater than 5 ng/dL (140 pmol/L) but less than 10 ng/dL (280 pmol/L) are considered indeterminate and may be seen with IHA. On the last day of oral sodium administration, a 24-hour urine is collected for aldosterone, creatinine (to assess for adequacy of the collection), and sodium (>200 mmol/day confirms adequate sodium intake). An aldosterone greater than 10 mg/24 hours (28 nmol/24 hours) following 3 days of sodium loading confirms the diagnosis (Bravo, 1983, 1994; Holland, 1984). For the fludrocortisone suppression test, 0.1 mg fludrocortisone is given orally every 6 hours for 4 days, together with slow-release potassium chloride supplements (in doses sufficient to maintain the plasma potassium close to 4.0 mmol/L) and slow-release sodium chloride (30 mmol three times a day) and liberalization of dietary sodium intake (enough to maintain a urinary sodium excretion of at least 3 mmol/kg). On day 4, an upright plasma cortisol is measured at 7 AM and 10 AM, and PAC and PRA are measured at 10 AM. A PAC greater than 6 ng/dL with a PRA less than 1 ng/mL/hour confirms the diagnosis, provided that the 10 AM cortisol is less than the 7 AM value. For the captopril challenge, baseline blood is collected for PRA, PAC, and cortisol; then 25–50 mg of captopril is administered orally. PRA, PAC, and cortisol are again collected at 1 and 2 hours post captopril. The patient is kept seated throughout the entire test. PAC is normally suppressed to greater than 30%; however in primary hyperaldosteronism, the PAC remains elevated and the PRA suppressed. The choice of test depends on several factors, including patient compliance, presence of uncontrolled hypertension, renal insufficiency, congestive heart failure, and local expertise.

Differentiating Among the Different Causes of Primary Hyperaldosteronism

APA differs from IHA by more extreme blood pressures, greater potassium wasting, and higher atrial natriuretic peptide levels. Also, urinary and serum levels of 18-oxocortisol, 18-hydroxycortisol (serum >300 ng/dL), and 18-hydroxycorticosterone (serum >100 ng/dL) tend to be higher. A positive postural stimulation test (plasma aldosterone: ambulating rising to $<130\%$ of the supine level) has a moderate sensitivity and specificity for adenoma, but not for hyperplasia. Once the diagnosis of primary hyperaldosteronism is confirmed, the next step is to image the adrenals by CT or MRI, looking for bilateral hyperplasia or a unilateral hypodense adenoma. The specificity of imaging to correctly categorize patients as having APA versus IHA varies from 67%–84% (Doppmann, 1992; Gleason, 1993; Harpe, 1999; Magill, 2001). Removal of the adenoma is curative in 35% of cases and leads to improvement in another 55% (Blumenfeld, 1994). Surgery can cure or improve hypertension in patients with unilateral disease. For those in whom the disease is bilateral, medical treatment with drugs such as spironolactone leads to improvement in 76% of cases. Hyperplasia is not always bilateral.

As a result of multiple factors, including the increased incidence of nonfunctioning adrenal adenoma after age 40, and the fact that hyperplasia may present as a unilateral adenoma on imaging, it is highly recommended that bilateral adrenal vein sampling be performed in individuals over age 40 who are contemplating surgery. Bilateral adrenal vein sampling is technically demanding and entails risk; however, as performed by an experienced radiologist, it is the gold standard for distinguishing adenoma from hyperplasia. An intravenous infusion of ACTH at 50 μ g per hour is started 30 minutes before sampling and is continued throughout the procedure. This serves to mitigate any stress-induced fluctuations in aldosterone during the sampling, accentuate the gradient in cortisol from adrenal vein

to inferior vena cava, and maximize the difference in secretion of aldosterone between the right and left adrenals in instances of APA. Samples for aldosterone and cortisol are obtained from each adrenal vein and from the periphery. An adrenal vein/peripheral vein cortisol of greater than 10:1 ensures that the samples are taken from the adrenal veins. There should be a <20% difference in cortisol measurements between both adrenals.

To correct for dilutional effects, the **cortisol-corrected aldosterone ratio** (i.e., aldosterone/cortisol) is utilized. In APA, the cortisol-corrected aldosterone ratio is usually at least fivefold higher on the side with the adenoma, and no gradient is seen in hyperplasia (Doppmann, 1996). As per the recent Endocrine Society guidelines, a cortisol-corrected aldosterone ratio from high side to low side of greater than 4:1 indicates APA, a ratio of less than 3:1 suggests IHA, and values between 4:1 and 3:1 are indeterminate and need to be interpreted in conjunction with imaging studies and clinical settings. Using these cutoffs, a sensitivity of 95% and a specificity of 100% are achieved (Funder, 2008).

Several studies have shown a discrepancy between radiologic findings and surgical findings in up to a third of all cases. Kempers found that when compared with adrenal vein sampling, CT and MRI misdiagnosed the cause of primary hyperaldosteronism in 37.8% of patients (Kempers, 2009). Given the increased prevalence (5%–10%) of adrenal incidentalomas (nonfunctioning adrenal tumors) with increasing age, many authorities are recommending adrenal vein sampling for those patients with hyperaldosteronism who are older than age 40 and have a unilateral hypodense adrenal nodule >1 cm on CT scan (Young, 1999). Based on the findings of large prospective studies, others have suggested that the major strength of this technique may be its use in evaluating those patients with a high probability of APA but with normal findings or bilateral nodular disease on CT. It should be stressed that this test is technically difficult, and even in the very best of hands is successful in only approximately 92%–96% of cases (Doppmann, 1992; Radin, 1992; Young, 1999).

The syndrome of **inapparent mineralocorticoid excess** is due to dysfunction of 11- β -hydroxysteroid dehydrogenase type 2 (11- β -HSD2). Cortisol can function as a potent mineralocorticoid, binding to the mineralocorticoid receptor in the kidney with the same affinity as aldosterone. 11- β -HSD2 mitigates the mineralocorticoid action of cortisol by converting it to the metabolically inactive form, cortisone. When activity of this enzyme is decreased because of hereditary factors, the ingestion of large quantities of licorice (which has a high content of glycyrrhizic acid) or chewing tobacco, hypertension, hypokalemia, low PRA, and low PAC may result. An elevated cortisol/cortisone concentration on a 24-hour urine collection confirms the diagnosis.

Renin may be suppressed by excessive sodium intake. It is also suppressed in the syndrome of hyporenin hypoaldosteronism, which is most commonly seen in patients with diabetes mellitus and renal disease. Secondary aldosteronism results from nonadrenal disease, in which both adrenal glands are stimulated (Table 24-25). Typically, these patients are not hypertensive.

Conditions such as nephrosis, cirrhosis, and heart failure are associated with decreased renal perfusion, causing a compensatory increase in renin and aldosterone levels (secondary hyperaldosteronism). The response of the renin-aldosterone system in pregnancy is especially complex; renin, renin substrate, angiotensin II, and aldosterone appear to be increased.

There are two variants of familial hyperaldosteronism (FH), FH-1, which is also known as glucocorticoid remedial hyperaldosteronism (GRA), and FH-2. GRA is an autosomal dominant inherited disorder characterized by hyperaldosteronism, hyporeninemia, and severe, usually refractory,

hypertension, with onset typically occurring in those younger than age 20 with a positive family history of early hypertension and/or hemorrhagic stroke. It is the result of translocation of aldosterone synthetase (CYP18, CYP11B2) onto the ACTH-sensitive promoter sequence of the 11- β -hydroxylase (CYP11B1) gene within the zona fasciculata. Thus, aldosterone synthesis is stimulated by ACTH. In addition to increased aldosterone, these individuals produce excess 18-OH cortisol and 18-oxycortisol. Diagnosis can be confirmed by normalization of aldosterone following 4–6 weeks of steroid suppression, or by genetic testing using Southern blot or long polymerase chain reaction (Lifton, 1992; Kurtz, 1993). FH-2 is an autosomal dominant condition that is associated with APA, IHA, or both. Unlike FH-1, aldosterone does not suppress in response to glucocorticoid treatment.

Liddle syndrome is a rare autosomal dominant disorder characterized by hypertension and hypokalemia; however, unlike in primary hyperaldosteronism, PRA and PAC are both low. The defect is due to a mutation in the amiloride-sensitive sodium channel within the renal collecting ducts, leading to enhanced sodium reabsorption and increased potassium secretion. Liddle syndrome can be diagnosed by genetic testing or, if genetic testing is unavailable, by good clinical response to amiloride or triamterene, and by lack of response to dexamethasone or aldosterone antagonists.

ALDOSTERONE MEASUREMENTS

An isolated aldosterone measurement with no attention to patient preparation is of little clinical value. Even when time of sampling, posture, and dietary sodium and potassium are controlled, it is difficult to discriminate with certainty between primary aldosteronism and other forms of hypertension with the use of plasma aldosterone measurements alone. Interpretation of the aldosterone level must be done in the context of a simultaneously collected plasma renin and serum potassium.

Aldosterone assays are performed on plasma using extraction to remove aldosterone from plasma proteins, followed by chromatography and immunoassay or, preferably, LC-MS/MS. Urine is assayed following acid hydrolysis and extraction. Normative values exist for different age groups, postures, and sodium intakes (Table 24-26). HPLC with tandem mass spectrometry affords greater consistency and is gradually replacing older methods.

RENIN MEASUREMENTS

Important technical differences have been noted in assessment of renin using current methods. Renin measurements are of two types: PRA and SRC. The PRA is a bioassay wherein a plasma specimen containing renin is allowed to react with its substrate, angiotensinogen; after a specified period of time, the reaction is terminated, and generated angiotensin I is measured by RIA. For estimation of PRA, the endogenous substrate is not eliminated. Therefore, the rate of generation of angiotensin I is influenced by the concentrations of endogenous renin and its substrate. This type of assay is the most widely used method for the determination of renin. Comparison of results among laboratories is not possible because of procedural differences, such as variations in pH, ionic strength, length of the assay, the angiotensinase inhibitor, the conditions under which the specimen was obtained, and because of the lack of a specific reference preparation. In addition, the literature on renin assays reveals confusion regarding units of measurements employed; even when an attempt is made to express the many arbitrary units in the same terms (nanograms of angiotensin liberated per milliliter per hour), wide ranges are reported for human plasma renin activity in reference populations.

When PRC rather than PRA is measured, the effect of substrate is eliminated. The PRC assay is an immunoassay directed to the renin molecule itself.

Assays of PRA and PRC provide similar information, except in a few clinical situations. With oral contraceptive administration, PRC remains within the reference interval, whereas PRA increases owing to the increase in substrate. Other procedures such as freezing, thawing, and acidification have been found to convert prorenin to rennin, thereby increasing the values in PRC assays.

Because renin release is controlled by many physiologic and pharmacologic variables, it is extremely important to know the conditions under which the blood specimen was obtained. Such conditions as upright posture, the administration of diuretics, and low-sodium diets are potent stimuli of renin release and should be adequately controlled before plasma

renin is measured. Renin also appears to be extremely labile, so the variables involved in specimen processing should be vigorously controlled. Blood should be drawn into an iced EDTA tube, which inactivates the enzymes (e.g., angiotensinases); it should be centrifuged at 4° C, and the plasma should be separated promptly from the cells, frozen immediately, and kept frozen until ready to be analyzed; with this technique, the specimen is stable for several months at -20° C.

Direct measurement of renin substrate, angiotensin I, or angiotensin II is not used widely in clinical practice because of tedious extraction or concentration steps, as well as difficulty in eliminating formation or degradation of these compounds by proteases and other enzymes involved in the renin system. Although ACE levels can be measured easily, they are of little use in the diagnosis of hypertensive disorders.

KEY POINTS

- Reproductive function and pregnancy are regulated by the complex interaction of a variety of hormones; they are synthesized and secreted by the testis (testosterone), ovary (estradiol and progesterone), pituitary (follicle-stimulating hormone [FSH] and luteinizing hormone [LH]), hypothalamus (gonadotropin-releasing hormone), and placenta (human chorionic gonadotropin [hCG], estrogens, and progesterone).
- Laboratory evaluation of reproductive function in the male typically begins with semen analysis. If the results are normal, further evaluation may be unnecessary. If the results are abnormal, then serum hormone measurements, particularly of testosterone, FSH, and LH, are important.
- Reproductive dysfunction in the female is often indicated by amenorrhea and/or infertility. Laboratory evaluation, as in the male, involves serum hormone measurements, particularly of hCG, prolactin, thyroid-stimulating hormone, free thyroxine, FSH, LH, and androgens.
- Infertility can be treated by several assisted reproductive technologies. These involve a variety of clinical manipulations, all of which are directed at externally controlling as much of the reproductive process as possible to achieve pregnancy and bring it to term. Laboratory monitoring of serum hormone levels (estradiol, progesterone, and hCG) plays an important role in these protocols.
- Early pregnancy is monitored by measuring serum hCG concentrations and determining that the pattern of dramatic increase during the first trimester is as expected.
- The risk for the most common birth defects, neural tube defects, and chromosomal aneuploidy is determined during the first- and second-trimester screenings.
- Fetal hemolytic disease is monitored by spectrophotometric estimation of the level of bilirubin in amniotic fluid or Doppler measurements of peak systolic velocity in the fetal middle cerebral artery.

- The status of fetal lung maturation is estimated from the evaluation of pulmonary surfactant in amniotic fluid. This can be accomplished by several methods, including determination of (1) the lecithin/sphingomyelin ratio and phosphatidyl glycerol by chromatography, or (2) microviscosity by fluorescence polarization.
- Toxemia of pregnancy, or preeclampsia, is characterized by hypertension and proteinuria, and consequently can be monitored by urine protein measurements.
- Risk for preterm delivery and the need for medical intervention can be evaluated by checking levels of fetal fibronectin in the cervical secretions.

NORMAL PHYSIOLOGY

Normal reproductive function is mediated by a variety of hormones synthesized and secreted by the gonads (testes and ovaries), adrenals, pituitary, hypothalamus, and placenta. In addition, peripheral nonglandular tissues can contribute to hormone synthesis. Paracrine and autocrine mediators are also involved, but in almost all cases their exact roles are not well understood.

SEX STEROIDS

The testes and ovaries synthesize sex steroids (androgens and estrogens) from cholesterol via the same initial pathway used in the adrenal glands to synthesize mineralocorticoids, glucocorticoids, and androgens (Fig. 25-1). The specific hormone secreted by an endocrine gland depends on the presence and relative activities of various enzymes in the steroid pathway. Whereas the adrenal synthesizes androgens like dehydroepiandrosterone (DHEA), DHEA-sulfate (DHEAS), and androstenedione, the testis metabolizes these steroids primarily to testosterone. The ovary converts testosterone to estradiol, and androstenedione to estrone. Peripheral tissues (including those targeted by androgens) reduce testosterone to dihydrotestosterone (DHT). Because DHT is two to three times more

Figure 25-1 Steroid hormone synthesis. *Arom*, Aromatase; *16 α -OH*, 16 α -hydroxylase; *17 α -OH*, 17 α -hydroxylase; *5 α -Red*, 5 α -reductase; *3 β -HSD*, 3 β -hydroxysteroid dehydrogenase; *17 β -HSD*, 17 β -hydroxysteroid dehydrogenase; *11- β -OH*, 11- β -hydroxylase; *20,22-Des*, 20,22 desmolase; *18-HSD*, 18-hydroxysteroid dehydrogenase; *18-OH*, 18-hydroxylase; *21-OH*, 21-hydroxylase; *ST*, sulfotransferase.

potent than testosterone, this process yields an enhanced or activated androgenic effect. Peripheral tissues, such as liver, also hydroxylate estradiol to estriol, a metabolite with only one-hundredth the estrogenic potency of its precursor. Thus, this conversion is an inactivation process. During pregnancy, estriol is synthesized via a different pathway, and it may

play a different role than estradiol (see later). Peripheral tissues also convert adrenal androgens to testosterone and androgens to estrone and estradiol, the latter occurring in adipose tissue. Estrone is about one tenth as potent as estradiol, which likely further modulates estradiol potency. Note that, although progesterone serves as an intermediate in the synthesis

Figure 25-2 Regulation of reproduction in the male. FSH, Follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

of all other steroid hormones, it also functions as a sex steroid in its own right in females.

As with any hormone, sex steroids act at tissue sites distant from their sites of synthesis and secretion. Once in the blood, most of the hydrophobic sex steroids become reversibly and noncovalently bound to plasma proteins. This interaction includes low-affinity, nonspecific binding to hydrophobic sites on albumin and high-affinity binding to specific transport proteins that are synthesized by the liver. Sex hormone-binding globulin (SHBG) transports androgens and estrogens, and corticosteroid-binding globulin (CBG) transports progesterone (as well as glucocorticoids). In blood, only about 1%–2% of the sex steroids are free (unbound). About half of the remainder are bound to SHBG or CBG, and about half are bound to albumin. Only the free fraction is biologically active, because only the free hormone can exit the vascular system (by diffusion) and interact with target cells.

Each steroid binds with high affinity to specific receptor proteins that activate or inactivate genes in the target cell. Thus, the same hormone can elicit a different response in each type of target cell. The potency of a steroid's hormonal effect (e.g., androgenic effect) is primarily a function of its affinity for the specific receptor protein and the affinity of that complex for the chromatin acceptor sites. Thus DHT is a more potent androgen than testosterone. DHEA and androstenedione bind only weakly, if at all, to the androgen receptor; hence their androgenic effect is low, and most if not all of their androgenic activity derives from their peripheral conversion to testosterone.

REGULATION OF MALE REPRODUCTION

Figure 25-2 summarizes the regulation of reproduction in the human male. Gonadotropin-releasing hormone (GnRH) is a decapeptide that is synthesized and secreted by neuroendocrine cells of the hypothalamus, primarily in the arcuate nucleus. GnRH binds to specific cell membrane receptors on gonadotrophs in the anterior pituitary, resulting in the synthesis and secretion of two protein hormones—FSH and LH—both named for their effects in females. Both FSH and LH are similar to thyroid-stimulating hormone (TSH), in that all three consist of two subunits and all of them share the same α subunit. Each has a different β subunit, however, which thus confers their functional specificity.

The seminiferous tubules of the testis contain cells in various stages of spermatogenesis (spermatogonia, spermatocytes, spermatids), along with

Figure 25-3 Regulation of reproduction in the female. FSH, Follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

Sertoli cells and Leydig cells. FSH induces Sertoli cells to synthesize and secrete androgen-binding protein into the lumen of the seminiferous tubule, and this maintains the high testosterone concentration required for normal spermatogenesis. LH induces Leydig cells to synthesize testosterone; some enters the general circulation and is transported to other target tissues, such as skeletal muscle, where it has an anabolic effect. Some is also transported to the hypothalamus and anterior pituitary, where the testosterone has a negative-feedback effect, that is, it decreases the synthesis and secretion of GnRH, FSH, and LH, and this decreases testosterone synthesis by Leydig cells. Sertoli cells also synthesize and secrete another protein hormone, inhibin. It interacts with gonadotrophs in the anterior pituitary, where it has a negative feedback effect: It decreases the synthesis and secretion of FSH, but not LH. The exact role of inhibin in the regulatory process is not understood.

REGULATION OF FEMALE REPRODUCTION

Figure 25-3 summarizes the regulation of reproduction in the human female. As in the male, GnRH from the hypothalamus increases the synthesis and secretion of FSH and LH from the anterior pituitary. Unlike in the male, however, the regulatory process in the female is cyclic and is referred to as the menstrual cycle. Pituitary, ovarian, and uterine changes that occur during the 28-day menstrual cycle are summarized in **Figure 25-4**. As illustrated, the cycle begins with menses, or shedding of uterine endometrium. During this period in the ovary, a cohort of follicles is recruited to begin further growth and development. From this cohort, one follicle (usually) is selected to be the dominant follicle and to continue growth and development. The other recruited follicles undergo regression, or atresia. These processes occur during the follicular phase of the ovarian cycle, primarily as a result of the action of FSH. As the follicle grows, increasing amounts of estradiol are synthesized and secreted. Estradiol restores the endometrium via cell proliferation and growth; hence the proliferative phase of the uterine endometrial cycle. Estradiol also has a negative-feedback effect on the hypothalamus and the anterior pituitary, causing a decline in FSH levels during the latter part of the follicular phase.

Figure 25-4 Pituitary, ovarian, and uterine changes during the human menstrual cycle. FSH, Follicle-stimulating hormone; LH, luteinizing hormone.

Near the end of the follicular phase, when estradiol levels are at their highest, its feedback effect on the hypothalamus and anterior pituitary switches to positive. The mechanism for this change to positive feedback is not understood. Its effect, however, is dramatic. It causes a surge in the secretion of GnRH, FSH, and particularly LH, which culminates in ovulation. The oocyte enters the oviduct. Owing to disruption of the follicle, estradiol synthesis and secretion drop dramatically. The disrupted follicle begins to differentiate into the corpus luteum; thus begins the luteal phase of the ovarian cycle. The corpus luteum synthesizes estradiol and progesterone as a result of the action of LH. The combination of the two steroids acts on the uterine endometrium to cause development of numerous exocrine glands, producing the secretory phase of the uterine endometrial cycle. This phase prepares the endometrium for implantation, should fertilization and early development occur. LH levels decline gradually during the luteal phase, indicating restoration of negative-feedback regulation of the hypothalamus and anterior pituitary by estradiol and progesterone.

As in the male, inhibin has a selective negative-feedback effect on FSH. In the female, however, there are two different forms. One is synthesized and secreted by the developing follicles (inhibin B), and the other is from the corpus luteum (inhibin A) (Welt, 1999). Again, the exact regulatory roles they play are not understood.

In an infertile cycle, the corpus luteum begins to regress near the end of the luteal phase. This results in a decrease in estradiol and progesterone

Figure 25-5 Serum hCG levels during normal pregnancy. (From Lau HL. *Testing for pregnancy*. In: *Practice of medicine*, vol II. Hagerstown, Md.: Harper & Row; 1975, Chapter 29; and Braunstein GD, Rasor J, Adler D, Danzer H, Wade ME. *Am J Obstet Gynecol* 1976;126:678.) hCG, Human chorionic gonadotropin.

synthesis and secretion. Because these steroids are required for maintenance of the secretory endometrium, it begins to deteriorate and is ultimately shed during menstruation. With the drop in estradiol and progesterone, their negative-feedback effects decrease, and FSH and LH rise to begin another cycle.

PREGNANCY

If the oocyte is fertilized during its transit down the oviduct, it develops into a multicellular blastocyst by the time it reaches the uterus. Around the time of implantation (about 9 days after ovulation), and before the corpus luteum begins to regress, increasing amounts of an LH-like hormone, hCG, are found in maternal blood. hCG is synthesized and secreted by the trophoblast cells of the developing placenta. It is a dimeric protein hormone that has the same α subunit as LH, FSH, and TSH, but a different β subunit. The β subunit of hCG is very similar to that of LH, but larger. Hence, hCG can interact with LH receptors on luteal cells. This interaction prevents regression of the corpus luteum and allows it to continue synthesis and secretion of estradiol and progesterone, both of which are required for appropriate maintenance of the uterine endometrium throughout pregnancy.

During the first trimester of pregnancy, hCG increases from <5 mIU/mL serum to $>100,000$ mIU/mL (Fig. 25-5). This increase is responsible for the similarly dramatic increases in the levels of estradiol and progesterone. By the end of the first trimester, however, hCG levels begin to decline significantly. Estradiol and progesterone continue to increase, because, by this time, the placenta has assumed most steroid synthesis, including significant amounts of estrone and estriol. Unlike hCG, these steroid levels increase as placental mass grows. Steroid intermediates from the fetal adrenal gland and the fetal liver also contribute to this process. For example, estriol is synthesized not by hydroxylation of estradiol (see Fig. 25-1), but rather by conversion from fetal 16-hydroxy-DHEAS; this is why maternal estriol measurements were historically used to assess fetal well-being in late pregnancy (Carr, 2004). The estrogenic potency of estriol is only about one-hundredth that of estradiol and only one-tenth that of estrone. However, estriol promotes uteroplacental blood flow as potently as other estrogens, and this may be the reason for its dramatic increase during the last two trimesters (Resnik, 1974).

Another hormone synthesized in large quantities by the placenta during the last two trimesters is human placental lactogen (HPL). It is structurally similar to both prolactin and growth hormone and has both lactogenic and growth-promoting activities, although both are relatively weak. In addition, HPL is an insulin antagonist and thus may play a role in maternal glucose utilization. However, its exact role is unclear because apparently normal pregnancies have been described in which HPL is not detectable in maternal blood or placenta (Sideri, 1983). Unlike hCG, the increase in HPL also parallels the steady increase in placental mass (Carr, 2004).

The placenta also synthesizes inhibin. Whereas gonadal (testicular and ovarian) inhibin functions as an endocrine inhibitor of pituitary FSH secretion, placental inhibin may function as a paracrine or autocrine inhibitor of placental hCG secretion (Mesiano, 2004). Its exact regulatory role, however, has not been elucidated.

Parturition is the process by which the fetus is expelled from the internal environment of the maternal uterus to the external environment.

TABLE 25-1

Changes in Reproductive Hormone Levels in Different Disease States

DISEASE STATE		HORMONE LEVEL			
Classification	Example	FSH	LH	Testosterone	Estradiol
Male					
Primary deficiency	Klinefelter's syndrome	High	High	Low	—
Secondary deficiency	Panhypopituitarism	Low	Low	Low	—
Primary excess	Testicular tumor	Low	Low	High	—
Secondary excess	Precocious puberty	High	High	High	—
Other	Seminiferous tubule failure	High	Normal	Normal	—
Other	Partial androgen insensitivity	Normal	High	High	—
Female					
Primary deficiency	Menopause	High	High	—	Low
Secondary deficiency	Sheehan's syndrome	Low	Low	—	Low
Primary excess	Feminizing ovarian tumor	Low	Low	—	High
Secondary excess	Gonadotropin-producing tumor (rare)	High	High	—	High
Other	Polycystic ovarian syndrome	Normal	High	High	—
Other	Masculinizing ovarian tumor	Low	Low	High	—

From Nickel KL. The gonads. In: Kaplan LA, Pesce AJ, editors. Clinical chemistry—theory, analysis, and correlation. 3rd ed. St Louis: Mosby; 1996, p. 892–911, with permission. FSH, Follicle-stimulating hormone; LH, luteinizing hormone.

This occurs as a result of a change in the activity of the uterine myometrium (smooth muscle), from irregular, long-lasting, low-frequency contractions to regular, high-intensity, high-frequency contractions. The initiation of this process in humans is not well understood and seems to differ from that in other mammals. For example, progesterone inhibits uterine contractions during gestation, and in most other mammals, the onset of parturition is preceded by a significant decrease in maternal plasma progesterone; in humans, however, this does not occur. A **parturition cascade** has been postulated for humans that involves multiple and redundant endocrine, paracrine, and autocrine mediators. These mediators are thought to include fetal cortisol and DHEAS; placental estriol, oxytocin, prostaglandins, and corticotropin-releasing hormone; and maternal oxytocin. The effects of these mediators may also be modulated by changes in their receptor levels (Norwitz, 2004).

Parturition is followed by lactation. Initial development of the mammary gland occurs at puberty, when estradiol causes growth and branching of the ducts, and progesterone causes formation of the alveoli. Similarly, during pregnancy, the high concentrations of estrogens and progesterone cause further branching of the ducts and growth of the alveoli. The secretory capability of the alveolar epithelial cells is induced by prolactin, which increases during pregnancy, and by HPL. At parturition, the decrease in estrogen and progesterone eliminates their inhibitory effects on milk secretion, which still requires prolactin. Milk ejection, however, requires oxytocin, acting as part of a neuroendocrine reflex. This reflex is initiated by the suckling stimulus, which generates nerve impulses that travel from the nipple to the hypothalamus. There they cause secretion of oxytocin from neuroendocrine cells in the posterior pituitary. The oxytocin travels to the mammary gland, where it stimulates the contraction of smooth muscle cells surrounding the alveoli, causing milk ejection. Prolactin also participates in this neuroendocrine reflex, in that nerve impulses reaching the hypothalamus also inhibit the synthesis and secretion of dopamine, which functions as a prolactin release-inhibiting hormone. This then promotes the release of prolactin from the anterior pituitary, which then travels to the mammary gland, where it stimulates milk secretion, to replace that lost by ejection. As long as lactation continues, plasma prolactin concentrations remain elevated. This postpartum hyperprolactinemia causes postpartum amenorrhea due to interference with normal regulation by GnRH of FSH and LH secretion. Although this hypogonadotropic state will prevent pregnancy, it is not considered a reliable means of contraception, particularly in modern societies where breastfeeding is variable.

LABORATORY EVALUATION OF REPRODUCTIVE FUNCTION

Table 25-1 describes laboratory findings in various male and female reproductive disease states typically categorized according to (1) hormone

deficiency or excess, and (2) primary (gonad) or secondary (pituitary) dysfunction. In primary disease states, gonadal steroid levels are inversely related to pituitary gonadotropin levels, whereas in secondary disease states, they are directly related (e.g., both high or both low), as discussed in the endocrine section of Chapter 8 and in Chapter 24. These changes occur because gonadal steroids provide negative feedback to gonadotropins. For example, in primary ovarian failure, the decrease in estradiol reduces its negative-feedback effect on the hypothalamic-pituitary axis, resulting in increases in FSH and LH.

MALE EVALUATION

The evaluation of reproductive dysfunction in the male usually begins with semen analysis, because it is a cost-effective and relatively simple procedure. In addition, if the results are normal, further evaluation is often unnecessary. If semen analysis is abnormal, then hormone analyses are performed.

Semen Analysis

In addition to its use in the evaluation of reproductive dysfunction, particularly infertility, semen analysis is used to select donors for therapeutic insemination and to monitor the success of surgical procedures, such as varicocele and vasectomy. Semen analysis consists of microscopic and macroscopic components, and the latter include measuring physical (e.g., volume) and chemical (e.g., pH) properties. Useful guides and references for the procedure are available (Gilbert, 1992; Mortimer, 1994; Tomlinson, 1999; World Health Organization, 1999; Andrade-Rocha, 2003; Rylander, 2009).

Sample Collection

The patient should be instructed to collect semen after 3 days of sexual abstinence. Longer periods of abstinence usually result in a higher semen volume but reduced sperm motility. In such a case, a second semen specimen may be collected 2 hours after the first sample is collected. The bladder should be evacuated before ejaculation occurs. For semen collection, the laboratory should provide a preweighed sterile plastic (polypropylene) container with a screw top. The semen specimen should be delivered to the laboratory within 1 hour of collection and kept warm during transportation. A postejaculate urine sample may be collected at this time if retrograde ejaculation is suspected. Two specimens collected within 2- to 3-week intervals should be used for evaluation, and if they are markedly different, additional specimens should be collected. Ideally, semen specimens should be collected in the privacy of a room adjacent to the laboratory, because some samples require sperm to be separated from seminal plasma as soon as possible. Assisted reproductive technologies (ARTs; see later), such as in vitro fertilization (IVF), require that motile sperm be isolated from seminal plasma within 1 hour of ejaculation to protect sperm from the inhibitory effects of seminal plasma on fertilization. Semen should be obtained by masturbation, and if

circumstances preclude such collection, special Silastic condoms should be made available for semen collection with intercourse. Incomplete semen specimens should not be analyzed.

Macroscopic examination should be performed after liquefaction, which usually occurs in less than 20 minutes at room temperature. Failure to liquefy may indicate inadequate prostate secretion. Semen should be thoroughly mixed before examination, and its viscosity recorded. The volume of ejaculate can be measured by weighing the collection cup before and after specimen collection. The appearance of a yellow hue in a semen specimen is associated with pyospermia, and a rust color with small bleedings in the seminal vesicle. The pH ranges from 7.2–7.8, but may be 8.0 or higher with acute infection in the prostate, seminal vesicle, or epididymis. The pH will be 7.0 or lower if there is contamination with urine or an obstruction in the ejaculatory ducts, or if the specimen consists of mainly prostatic fluid.

Microscopic examination should be performed to obtain estimates of sperm concentration, motility, and agglutination. Other cellular elements such as polygonal cells of the urethral tract and **round cells** such as spermatogenic cells and leukocytes can also be observed when sperm are counted in a hemocytometer. Because sperm motility and velocity are temperature dependent, these parameters must be assessed on a microscope with a warm stage. Typically, 8 μ L of semen (of normal viscosity) placed under a 22 \times 22-mm glass coverslip will yield a wet preparation that is 16.5 μ m deep. Alternatively, 4 μ L of sample added to disposable slides with two wells (used with thick glass coverslips) produces a 20- μ m-deep preparation. A hemocytometer or microchamber may be used for the sperm count. At least four different fields in each of the two specimen aliquots should be counted, and the mean of the eight separate readings recorded. Total sperm count is then calculated by multiplying the dilution factor (normal concentration range, 20–50 million/mL) by its volume (normal range, 2–5 mL).

Motility (normal range 50% or above) is expressed as the percentage of sperm that move. In addition, forward movement is graded. Sperm moving rapidly in a straight line with little yaw and lateral movement are grade 4, or if they move more slowly, grade 3. Grade 2 sperm moves even more slowly and with substantial yaw. Grade 1 sperm has no forward progression. Zero progression denotes absence of any motility. If motility is less than 50%, a viability stain of eosin Y with nigrosin as a counterstain is done. In bright-field microscopy, dead sperm will stain red, whereas live sperm will exclude the dye and appear unstained. In samples with no visible sperm, such as postvasectomy semen, the entire sample should be centrifuged and the pellet examined for intact or damaged sperm fragments. The analysis should be repeated in 4–6 months.

Agglutination occurs when motile sperm stick to each other in an orientation that is reproducible within a given specimen, such as head to head, tail to tail, midpiece to midpiece, or mixed ways depending on the specificity of sperm antibodies. Agglutination suggests an immunologic cause of infertility, and a description of the type of agglutination should be recorded. This can usually be distinguished from clumping due to bacterial infection or tissue debris, which typically involves nonspecific orientation of the sperm.

Round cells should be differentiated into two classes: immature germ cells with a single or double highly condensed nucleus with a relatively large area of cytoplasm; and polymorphonuclear leukocytes, which are smaller than the germ cells and have a lower nuclear/cytoplasmic ratio. Peroxidase staining specifically identifies the polymorphonuclear leukocytes in the presence of lymphocytes and other cells that normally occur in semen. Bacterial contamination should be noted, as should the presence or absence of epithelial cells. If no sperm are seen in association with a low semen volume, a fructose test should be performed to confirm the presence of fluid from the seminal vesicle, and the same test should be performed on postejaculate urine to rule out retrograde ejaculation. However, the significance of a fructose test result has declined over the years because of the availability of more direct diagnostic tools such as transrectal ultrasonography.

Sperm morphology can predict fertility (Ombelet, 1997). Typically, >50% of the sperm in a semen specimen should exhibit normal morphology. Kruger and colleagues (1988) developed strict criteria for normal sperm morphology. Morphologically abnormal sperm usually have multiple defects, and the average number of defects per sperm, designated as the teratozoospermic index, is a significant predictor of sperm function both in vivo and in vitro. Strict morphology score greater than 14% of normal indicates excellent fertilizing capacity. Scores between 0 and 3% predict probable inability to fertilize. Wide variability in the size of the acrosomal cap is the most obvious characteristic of abnormal sperm. An

acrosomal cap less than one third of the head surface is considered abnormal, as are retention of a cytoplasmic droplet greater than half of the head size and a tail less than 45 μ m long. Of particular note is the direct relationship between acrosome size and the frequency of fertilization or pregnancy.

Immunologic Tests

Sperm antibody binding to head or tail antigens is considered specific for immunologic infertility. The antibodies are usually of the immunoglobulin (Ig)A or IgG class, and rarely, the IgM class; IgA antibodies are the most clinically significant. Current methods detect sperm-bound antibodies by direct or indirect mixed agglutination reaction (MAR) tests for IgG and IgA, or by immunobead assay, which detects all classes but with varying sensitivity. Both tests require motile sperm. The direct MAR test can be performed on fresh semen, and the result can be read within a few minutes with a light microscope.

Semen is mixed with latex particles coated with nonspecific human IgG, and then monospecific antisera to human IgG is added. The anti-IgG bridges the sperm-bound IgG, if present, and the particle-bound IgG to form mixed agglutinates. In the absence of sperm-bound IgG, the anti-IgG agglutinates only the latex particles. Under light microscopy, localized binding of the particles identifies the antibody as specific to head, tail, or any other region of the sperm structure. An indirect test can also be done with this reagent to detect the presence of sperm antibody in semen, cervical mucus, or serum.

The immunobead assay can detect all three immunoglobulin classes when beads are coated with monospecific antisera to each class. Therefore, sperm are washed to remove all free immunoglobulin before the beads are added. An indirect assay can also be designed with this reagent. The test is best read under phase microscopy. Increased risk of men developing sperm antibody is associated with vasectomy, repeat infections, obstruction of the ducts, cryptorchidism, varicocele, testicular biopsy, trauma, torsion, cancer, and genetic predisposition (Gilbert, 1992; Chamley, 2007). In women, sperm antibody is usually associated with intense mucosal inflammation of the genital tract.

Genital tract infections (see Part 7) may have significant adverse effects on male and female fertility (Pellati, 2008). For example, *Escherichia coli* can cause sperm agglutination and immobilization, and adherence of *E. coli* to sperm is mediated by mannose and mannose-binding cell surface structures present on both cell types (Sarkar, 1974; Wolff, 1993). Special precautions should be taken when collecting a semen specimen for detection of bacteria or yeast, to eliminate the possibility of external sources of contamination. Seminal plasma cultures may help diagnose male accessory gland infection, particularly of the prostate. If the concentration of bacteria exceeds 1000 colony-forming units per milliliter, the colonies should be identified and tested for antibiotic sensitivity.

Accessory Glands

Seminal vesicle, prostate, and epididymis function can be evaluated by analyzing unique constituents of each. Prostate secretions, for example, are acidic and contain acid phosphatase. Seminal fluid that is more alkaline than normal (pH >8.0) and that has reduced acid phosphatase suggests prostate dysfunction. Fructose is a measure of seminal vesicle secretory function. In azoospermia caused by the congenital absence of vasa deferentia, a low fructose level may indicate an associated dysgenesis of the seminal vesicles. Ejaculatory duct obstruction, or agenesis of the vasa deferentia and seminal vesicles, may result in the production of semen with low volume, low pH, lack of coagulation, and absence of characteristic semen odor. Neutral α -glucosidase originates solely from the epididymis, and its measurement is of diagnostic value for distal ductal obstruction when considered with hormonal and testicular findings.

Image Analysis

Routine semen evaluation can be carried out by an automated image analysis system that uses sperm head movement to derive the magnitude of various swimming parameters. However, human sperm are extremely heterogeneous with respect to morphology, swimming characteristics, and sperm DNA content. Thus no reference is made to evaluating specimens as normal or abnormal, fertile or infertile. Hence, semen evaluation by manual methods performed by trained technical staff remains a standard practice of andrology laboratories.

Hormone Analysis

If multiple semen analyses demonstrate azoospermia (no sperm), oligospermia (<20 million sperm per mL), or another abnormality, then

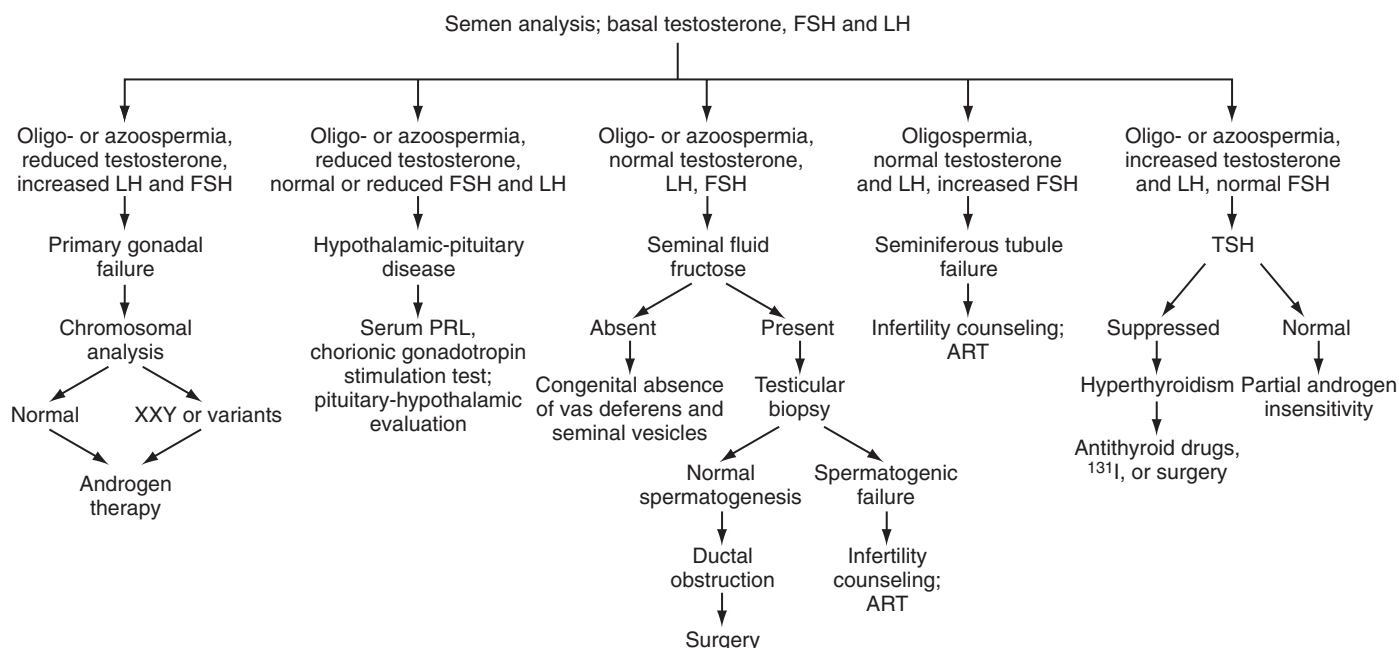

Figure 25-6 A diagnostic algorithm for male hypogonadism. (From Braunstein GD. *Testes*. In: Greenspan FS, Gardner DG, editors. *Basic and clinical endocrinology*. 7th ed. New York: Lange Medical Books/McGraw-Hill; 2004, p. 478–510, with permission.) ART, Assisted reproductive technology; FSH, follicle-stimulating hormone; LH, luteinizing hormone; PRL, prolactin; TSH, thyroid-stimulating hormone.

hormone analyses are performed to help identify the specific dysfunction. An example of a diagnostic algorithm is shown in Figure 25-6.

Decreased testosterone accompanied by increased LH and FSH indicates primary testicular failure. This can be an acquired or a genetic disease (Klinefelter's syndrome; see Chapter 68). Decreased testosterone accompanied by decreased or inappropriately normal LH and FSH indicates hypothalamic-pituitary disease, resulting in secondary testicular failure. When LH and FSH levels are normal, secondary disease can be confirmed with an hCG stimulation test. hCG interacts with LH receptors, and in the male, such interaction stimulates Leydig cells, if they are normal, to synthesize and secrete testosterone. Thus, administration of hCG should cause an increase in serum testosterone in secondary testicular failure, but not in primary testicular failure.

If hypothalamic-pituitary disease is suspected, then prolactin (PRL) should also be measured. Hyperprolactinemia interferes with the normal regulation of FSH and LH secretion by GnRH, and prolactinomas are the most common type of pituitary tumor. However, if prolactin is elevated, primary hypothyroidism must be excluded as a possible cause. In primary hypothyroidism, TSH and thyrotropin-releasing hormone (TRH) are elevated. Although the function of TRH is to stimulate the synthesis and secretion of TSH, TRH also stimulates the synthesis and secretion of prolactin. Thus, an elevated TSH suggests that primary hypothyroidism is the cause of the hyperprolactinemia, whereas a normal TSH suggests that a prolactinoma is the cause. If the latter were the case, then imaging techniques would be used to further evaluate the hypothalamic-pituitary axis.

If normal testosterone, LH, and FSH levels accompany oligospermia or azoospermia, then seminal fluid fructose should be evaluated. Its absence suggests the congenital absence of vasa deferentia and seminal vesicles. Its presence suggests ductal obstruction or spermatogenic failure, which can be distinguished using testicular biopsy. Oligospermia accompanied by normal testosterone and LH along with increased FSH suggests seminiferous tubule failure. The increase in FSH is likely due to reduced negative-feedback inhibition by decreased Sertoli cell inhibin. Increased testosterone and LH with normal or elevated FSH suggest partial or complete androgen insensitivity. Testosterone provides negative feedback on GnRH secretion at the level of the hypothalamus through androgen receptors. Genetic mutations of androgen receptors in hypothalamic neurons result in increased pituitary release of LH, resistance to testosterone, hypogonadism, and oligospermia.

In evaluation protocols such as that shown in Figure 25-6, it is becoming more common to measure not just total testosterone, but also free and/or bioavailable testosterone. The latter represents the sum of free testosterone plus that bound weakly to albumin. The remaining testosterone is bound tightly to SHBG. Free or bioavailable testosterone more accurately

represents the biologically active hormone in conditions where the concentration of SHBG is altered. For example, SHBG levels are increased with decreased testosterone, increased estrogen, hyperthyroidism, and liver disease, whereas they are decreased with increased testosterone, hypothyroidism, and acromegaly. Thus, if SHBG is high, total testosterone may be normal, but free or bioavailable hormone may be low. Conversely, if SHBG is low, total testosterone may be normal, but free or bioavailable hormone may be high (Ismail, 1986; Yeap, 2009). Methods for measuring total testosterone are readily available on automated immunoassay analyzers, but methods for measuring free and bioavailable testosterone are much more labor intensive. Consequently, free and bioavailable testosterone analyses are usually performed in a reference laboratory. The same considerations apply to testosterone measurements in females (see later).

Gynecomastia, or breast development in males, is thought to be due to a relative imbalance of androgen (decreased) and estrogen (increased) acting at the mammary gland. The decrease in androgen action can be due to a concentration deficiency and/or a receptor deficiency (insensitivity). The condition is not uncommon during the neonatal and pubertal periods. A variety of other causes have been identified, including endocrine abnormalities, tumors, systemic diseases, and many drugs. Discontinuing or changing medications can exclude drug-induced disease, and liver or kidney disease can be identified through biochemical blood screens. Measuring serum testosterone, estradiol, LH, hCG, prolactin, and TSH can reveal an endocrine abnormality or hormone-secreting tumor. Results from these tests together with imaging methods can help differentiate among the following as possible causes of gynecomastia: primary or secondary testicular failure, hyperthyroidism, androgen resistance, prolactinoma, testicular or extratesticular germ cell tumor, Leydig or Sertoli cell tumor, or adrenal tumor (Braunstein, 2004).

FEMALE EVALUATION

Evaluation of the female reproductive system can be simplified to confirmation of ovulation and normal female reproductive anatomy (Strauss, 2004). The abnormal menstrual cycle pattern is one of the best predictors of anovulation. Amenorrhea can be defined as the absence of menstrual flow by age 16, or by age 14 if no breast development occurs (Speroff, 2005). In patients who have not exhibited menses by age 16, this is often due to a genetic and/or anatomic abnormality. In such cases, however, an endocrine abnormality is still a possible cause, and the presence or absence of secondary sexual characteristics (e.g., breast development) is an important indicator in the evaluation. An endocrine abnormality is a more likely cause in patients who have a history of menstruation, but who have not experienced menses for >3 months. A stepwise approach to evaluating amenorrhea (Fig. 25-7) is based on measuring hCG, PRL, TSH, free

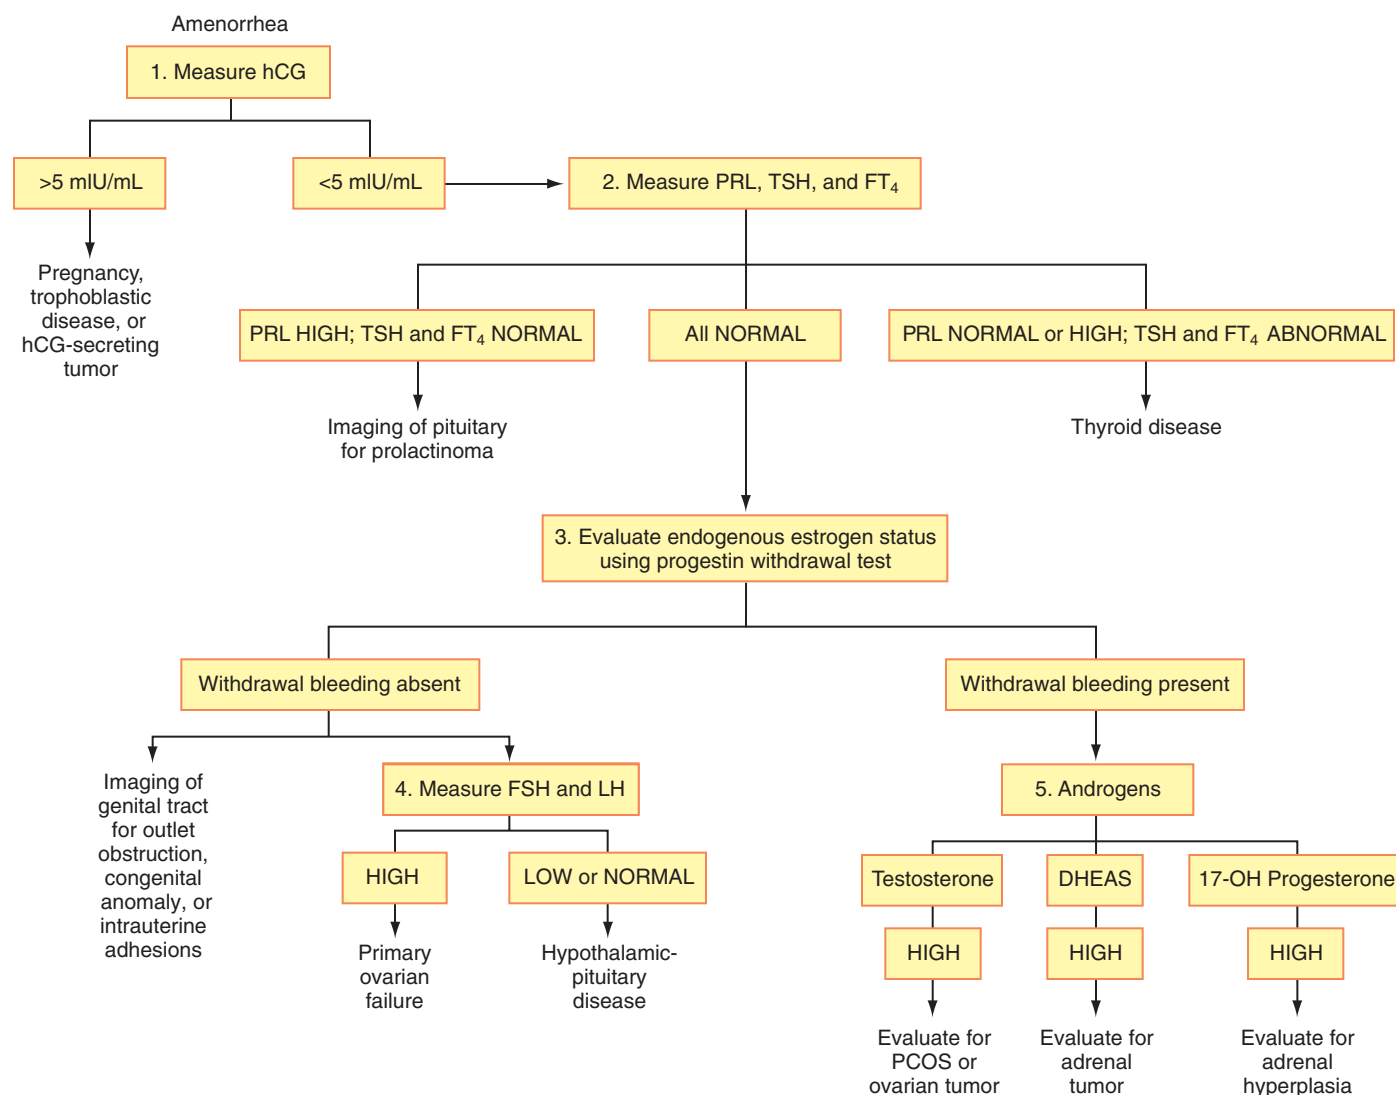

Figure 25-7 A diagnostic algorithm for amenorrhea. Sequential steps in the evaluation are numbered. *DHEAS*, Dehydroepiandrosterone-sulfate; *FSH*, follicle-stimulating hormone; *FT₄*, free thyroxine; *hCG*, human chorionic gonadotropin; *LH*, luteinizing hormone; *PCOS*, polycystic ovarian syndrome; *PRL*, prolactin; *TSH*, thyroid-stimulating hormone.

thyroxine (FT₄), FSH, LH, and androgen levels and assessing estrogen status.

Step 1: hCG is measured to exclude the most common cause of secondary amenorrhea—pregnancy. Although a result >5 mIU/mL is typically indicative of pregnancy, an elevated result can also be obtained with trophoblastic disease or an hCG-secreting tumor.

Step 2: PRL, TSH, and FT₄ are measured to exclude the endocrine disorders. Increased prolactin accompanied by normal TSH and FT₄ results suggests a prolactinoma, which would be further evaluated by imaging techniques. Hyperprolactinemia, however, can also be caused by primary hypothyroidism, as indicated by high TSH and low FT₄ (see *Male Evaluation*, earlier). The mechanism by which increased prolactin causes amenorrhea is the same as that discussed previously for postpartum amenorrhea in females and for hypogonadism in males. Low TSH and FT₄ suggest secondary hypothyroidism, in which case the patient should be evaluated for panhypopituitarism, a deficiency of all anterior pituitary hormones. Hyperthyroidism (increased FT₄) can also be associated with amenorrhea.

Step 3: If hCG, PRL, TSH, and FT₄ are all normal, then endogenous estrogen status is evaluated with the progestin withdrawal test. Progestin may be administered orally for 5–7 days or in one intramuscular injection (progestin dissolved in oil). The presence of withdrawal bleeding within 7 days after treatment indicates (1) that the outflow tract is intact, and (2) that sufficient estrogen was present at the outset to stimulate endometrial growth. If withdrawal bleeding is absent, the genital tract should be evaluated using imaging techniques.

Step 4: Serum FSH and LH levels should be determined. Elevated FSH and LH indicate primary ovarian failure, whereas low or

inappropriately normal FSH and LH indicate secondary ovarian failure. The latter is of hypothalamic-pituitary origin and can result from a variety of clinical disorders, including Sheehan's syndrome, eating disorders, weight loss, and stress. If withdrawal bleeding is present, then Step 5 is followed.

Step 5: Androgen excess should be evaluated. Elevated testosterone (>150 ng/mL) indicates an ovarian tumor or polycystic ovarian syndrome. The latter is a clinical entity often associated with enlarged ovaries and infertility, as well as amenorrhea. Increased DHEAS suggests an adrenal tumor. 17-OH progesterone is an androgen precursor (see *Fig. 25-1*), and an increase in serum levels can indicate congenital or adult-onset adrenal hyperplasia due to 21-hydroxylase deficiency. These abnormalities may be accompanied by hirsutism (i.e., male pattern of hair growth in females).

The tests in Step 5 can also be used to evaluate hirsutism when it is the primary clinical presentation. Because amenorrhea or oligomenorrhea is often associated with infertility (Lobo, 1997), the latter can be evaluated with the type of diagnostic algorithm shown in *Figure 25-7*. Evaluation of the ovulatory function is an important step in the infertility workup. One of the methods used to confirm ovulation is monitoring the basal body temperature. A rise in progesterone after ovulation increases basal body temperature by 0.4°–0.8° F. More reliable are urinary ovulation predictor kits, which measure urinary luteinizing hormone by colorimetric assay.

Testing should be started 2 to 3 days before the LH surge and should be continued daily. LH has a short half-life and is rapidly excreted in the urine. In most cases, the test will be positive for only 1 day of the menstrual cycle. Another method that is reliable and widely available involves measurement of midluteal phase serum progesterone levels on day 21 of the

menstrual cycle. Values above 3 ng/mL indicate ovulation and production of progesterone by the corpus luteum (Besser, 2002). Inadequate progesterone levels result in luteal phase deficiency, in which maturation of the secretory endometrium is delayed so that implantation of the blastocyst does not occur. In many cases, but not all, such an **out-of-phase endometrium** can be demonstrated by histologic evaluation of an endometrial biopsy from the late luteal phase (Noyes, 1975). However, endometrial histologic dating is not a valid diagnostic tool and should not be considered in management of the infertile patient (Speroff, 2005). When the diagnosis of ovarian failure is suspected, levels of FSH in the early follicular phase (on day 3) should be determined. Concentrations greater than 10 mIU/mL are associated with diminished ovarian reserve, which is defined by low numbers of normal oocytes and the presence of poor quality oocytes. Diminished ovarian reserve is associated with decreased probability of live birth with a natural or IVF cycle (Scott, 1995). Additional information can be obtained by measurement of estradiol levels on the same day of each menstrual cycle (Buyalos, 1998). Levels greater than 80 pg/mL are considered abnormal and indicate ovarian stimulation of steroidogenesis by elevated FSH, which is typically seen in ovarian failure.

More extensive testing of ovarian reserve includes the clomiphene citrate challenge test. Clomiphene citrate, the nonsteroidal estrogen receptor modulator, is administered on day 5 through day 9 of the cycle; this is followed by measurements of estradiol and FSH on day 3 and on day 10. Women with a poor cohort and aging follicles cannot generate enough estradiol or inhibin B to suppress FSH. Therefore FSH remains high.

ASSISTED REPRODUCTIVE TECHNOLOGY

Infertility is defined as 1 year of unprotected intercourse without conception (Speroff, 2005). Initial treatments may include artificial insemination with washed and concentrated sperm and/or ovulation induction with clomiphene citrate. If these are unsuccessful, then one of several ARTs may be attempted. ARTs involve techniques of direct manipulation of oocytes that are performed to control as much of the reproductive process as possible to achieve pregnancy and bring it to term (Tounson, 2000). Much of this external control requires significant monitoring through laboratory analyses.

Indications for ART include male infertility, ovarian failure, unexplained infertility, and tubal disease and endometriosis. It is not uncommon for several causes of infertility to be present in one couple. ART can also be applied in infertile couples requiring oocyte donation. The latter involves two distinct groups of patients: (1) females without gonadal function because of gonadal dysgenesis, premature menopause (which may occur spontaneously or after surgical castration or castration induced by chemotherapy or radiotherapy), or resistant-ovary syndrome, and (2) women with functional ovaries who do not wish to use their own oocytes to become pregnant because of the risk of transmitting chromosomal abnormalities to the offspring (e.g., if there is a history of autosomal dominant disease or X-linked disease, or when both partners are carriers of an autosomal recessive disease) (Van Steirteghem, 1992; Pados, 1994). The most common form of ART is IVF; other forms involve gamete intrafallopian transfer, zygote intrafallopian transfer, or tubal embryo transfer, all performed with the use of laparoscopy.

A typical ART protocol has four steps: ovarian hyperstimulation with exogenous gonadotropins, retrieval of oocytes from ovaries, fertilization in the laboratory, and transfer of embryos into the uterus. Initially, a GnRH analog (Lupron) may be given to suppress normal FSH and LH synthesis and secretion, although this is not always necessary. Lupron downregulates FSH and LH secretion by paradoxically inducing initial hypersecretion of these two hormones, which, however, ultimately results in their depletion. The next step is to stimulate follicular growth using a human menopausal gonadotropin preparation, which will have FSH and LH activity, or predominantly FSH activity, depending on the specific material used. Unlike a normal reproductive cycle in which typically only one dominant follicle matures, in an ART cycle multiple follicles undergo growth and maturation. The number of follicles and their increase in size are monitored by regular ultrasound analysis. The function of the developing follicles is monitored by sequential serum estradiol measurements. When sufficient follicular maturation is achieved, according to ultrasound and estradiol analyses, a bolus of hCG is administered. This hCG functions as a surrogate LH surge, and the hCG interacts with follicular LH receptors to initiate the process of ovulation. This process is not allowed to progress to completion. Ovulation would normally occur approximately 48 hours after hCG administration. Therefore, 12 hours before induced ovulation, the oocytes are “retrieved” from the stimulated follicles. Each

oocyte is then mixed with sperm. ART also includes methods for assisted fertilization by intracytoplasmic sperm injection obtained from ejaculate or extracted from epididymis or testis. Depending on the type of ART used, the gametes may be transferred immediately to the fallopian tube, or they may be incubated together for up to 48 hours; the resulting zygotes or embryos are transferred to the fallopian tube or uterus.

Oocyte retrieval disrupts the follicles, as does normal ovulation, and, as a consequence, estradiol levels drop immediately afterward. As the follicles differentiate into corpora lutea, however, estradiol levels rebound and serum progesterone increases. This process may require “boosting,” however, with additional injections of hCG (lower dose than that used for oocyte retrieval) and/or injections of progesterone. As in a normal cycle, estradiol plus progesterone is required to prepare the uterine endometrium for implantation. Therefore, serum levels of the two steroids are monitored after transfer. Serum hCG measurements begin about 10 days after transfer to determine whether pregnancy has been achieved. About 20 days after transfer, ultrasound examination can be used to confirm the presence of a gestational sac.

ART may offer the preimplantation genetic diagnosis (PGD). PGD can be performed on polar bodies removed from oocytes before fertilization or on blastomeres removed from embryos before transfer. Preimplantation genetic testing may be indicated to detect chromosomal abnormalities and inherited single-gene disorders, as well as to determine gender. However, conventional prenatal diagnosis is still recommended later in pregnancy because of numerous potential errors associated with PGD (Speroff, 2005).

LABORATORY EVALUATION OF PREGNANCY

On a patient's first visit to an obstetrician, ideally early in the first trimester, a number of clinical laboratory tests are routinely ordered to identify disorders that can be treated or prevented (Willett, 1994). Simple, inexpensive blood and urine tests are carried out for anemia, red cell alloimmunization, and suspected viral or bacterial infection. Sometimes, the clinical history, physical examination, or test results indicate additional studies for genetic disease, disorders of coagulation or thrombosis, causes of spontaneous abortion, and other conditions. Laboratory procedures used routinely to monitor pregnancy are summarized in Figure 25-8.

hCG AND EARLY PREGNANCY

Elevated hCG in maternal serum and urine is a reliable indicator of pregnancy. The discovery of monoclonal antibodies in the late 1970s led to the development of simple and cheap immunoassays, such as agglutination-inhibition-based assays and sandwich enzyme-linked immunosorbent assay, used in home pregnancy tests.

Currently, most serum assays measure both the free β subunit and intact hCG (α -plus- β subunit), utilizing two different antibodies directed at different epitopes on the β subunit. These assays can quantify hCG as low as 1–2 mIU/mL. Typically, urine assays use one antibody directed at the β subunit and the other directed at the α subunit, allowing these assays to measure intact hCG and fragments that appear in urine. Serum hCG increases above the reference interval (typically by 4–6 mIU/mL) by implantation, 6–12 (mean, 9.1) days after ovulation (Wilcox, 1999). Urine hCG levels are commonly measured by qualitative immunoassay test kits with detection limits of approximately 20 mIU/mL. These methods can detect elevated urine hCG 2–3 days later than serum methods. Qualitative assays meant for home use have detection limits of about 50 mIU/mL, and thus can detect elevated urine levels several days later, or shortly after the first missed menses.

Serum hCG increases dramatically during the first trimester, reaching a peak at about 10 weeks of gestation (see Fig. 25-5). Throughout pregnancy, intact hCG is the predominant form present. However, a small quantity of free β subunit is present in the first trimester. Free α subunit appears in the second trimester and steadily increases in the last trimester (Ozturk, 1987).

Some cancers and medical conditions may be associated with increased levels of hCG. These include germ cell tumors and gestational trophoblastic disease. Tumor production often includes significant amounts of free β subunit, in addition to intact hCG. The use of hCG as a tumor marker is discussed more fully in Chapter 73. False-positive β -hCG is usually due to interference by heterophilic Ig antibodies; it is characterized by large molecular weight and is not filtered by renal glomeruli. Serum

concentrations of β -hCG are typically less than 150 mIU/L with negative urine testing.

Quantitative measurements of hCG are indicated when a patient presents with early gestational vaginal bleeding or abdominal pain that may suggest the presence of ectopic pregnancy or spontaneous abortion. A simple protocol using only ultrasound and quantitative hCG examinations allows more accurate diagnosis and sound management than are obtained by clinical judgment alone (Koh, 1997). Because hCG concentrations rise quickly in normal early pregnancy, serial measurements can be used to ensure that an intrauterine implantation has occurred. Doubling of hCG in 2 days provides a greater than 80% probability of intrauterine implantation of the fertilized ovum. Increases in serum hCG of less than 53% in 2 days indicate abnormal pregnancy with 99% sensitivity (Barnhart, 2004).

Because circulating hCG increases very rapidly in the first days post-implantation, it is important to consider diverse causes of low-level quantitative results, including normal production of hCG in the pituitary, especially in post-menopausal females (Odell-Griffin, 1987); early abortion ("microabortion") (Wilcox, 1988); use of hCG as a drug; and assay interference, as mentioned previously.

When hCG concentrations exceed **discriminatory zone** values of 1500–2000 mIU/mL, an intrauterine gestational sac becomes visible on ultrasound examination in a normal singleton pregnancy (Kadar, 1994). Multiple gestations have higher hCG levels than singletons, and hCG levels may rise above 2000 mIU/mL before ultrasound findings of intrauterine gestational sac are obtained (Goldstein, 1988). Absence of an intrauterine gestational sac and failure to double the serum hCG or the presence of an adnexal mass indicates a possible ectopic pregnancy. Furthermore, failure to double the serum hCG suggests a loss of pregnancy.

Estradiol and progesterone measurements may provide additional information. Low serum progesterone (<15 ng/mL) or estradiol (<200 ng/mL) indicates a blighted ovum with 90% likelihood. If hCG is less than 1000 mIU/mL in a patient with vaginal bleeding, a progesterone value less than 5 ng/mL is 94% predictive of an abnormal pregnancy.

Progesterone measurements may provide additional information about abnormal pregnancy. Serum levels higher than 20 ng/mL usually are associated with normal intrauterine pregnancy. Low serum progesterone—less than 5 ng/mL—indicates an abnormal pregnancy with a specificity of 100% (Stovall, 1992). Serum progesterone levels are not helpful in assessment of the ectopic pregnancy, because most of the time values range between 10 and 20 ng/mL.

Medical intervention using intramuscular methotrexate for unruptured ectopic pregnancy is less costly than surgery, may be a less complicated procedure, and may improve the patient's fertility. Cases may be selected for methotrexate treatment by using ultrasound to ascertain a tubal implantation and differentiate it from an interstitial one, for which methotrexate is not indicated. Ultrasound also ensures a small volume (<3 cm) of conceptual tissue with absent fetal heart motion. A serum progesterone decrease to less than 1.5 ng/mL may be a better predictor of resolution because hCG concentrations do not decline as rapidly after surgery (and sometimes may increase) (Saraj, 1998).

The laboratory can provide testing to help determine why an early pregnancy aborted spontaneously. For example, recurrent abortion caused by the antiphospholipid syndrome can be diagnosed by the presence of anticardiolipin and specific phospholipid antibodies in the first trimester. Recurrent abortion due to inherited thrombophilia may be diagnosed by detection of factor V Leiden gene mutation, methylenetetrahydrofolate reductase gene mutation, prothrombin gene mutation, levels of proteins C and S, and activated protein C activity.

NEURAL TUBE DEFECTS

Neural tube defects (NTDs) are among the most common congenital malformations in the United States and worldwide. The incidence of NTDs in the United States has been reported at approximately 1 per 1000 pregnancies. Caucasians in the United States have an average occurrence of 0.96 per 1000, and Hispanics 1.2 per 1000; the lowest prevalence was reported in African Americans, with an incidence of 0.75 per 1000 (Feuchtbaum, 1999). An increased risk of recurrence has been noted in families. For example, when a couple has had one offspring with an NTD, the risk in each subsequent pregnancy for any type of NTD increases to approximately 1%–3% (Toriello, 1983). However, recent data suggests a decline in these rates due to increased education within the medical community and towards women of childbearing age regarding the benefits of folic acid consumption along with the mandated fortification of grain products in certain states (New York State Dept. of Health, 2005; for review see http://www.health.state.ny.us/diseases/congenital_malformations/docs/98report.pdf).

NTDs result from failure of the neural tube to close by the 27th day after conception. Anencephaly comprises 50% of NTDs and involves absence of the calvarium, cranial vault, and cerebral hemispheres; it is incompatible with life. Abnormalities of the caudal portion of the neural

tube, known as spina bifida, present as a lumbar (or cervical) meningocele, with herniation of meninges, spinal cord, and nerve roots. The severity of complications such as paralysis or muscle weakness, fecal and/or urinary incontinence, and intellectual impairment is dependent on the vertebral level and extent of spina bifida, which may be open in 80% of cases (referring to whether the defect is completely uncovered or is covered only by a very thin membrane) or closed (covered by skin or a thick membrane). This distinction is important because maternal serum screening will detect only open defects.

Screening for fetal structural defects using maternal serum biochemical markers has become routine obstetric practice. The American College of Obstetricians and Gynecologists (2003) recommends that all pregnant women should be offered second-trimester maternal serum α -fetoprotein (MSAFP) screening at 15–20 weeks gestational age. NTDs are sporadic in 90% of cases and represent isolated defects with a multifactorial origin, involving both genetic and nongenetic factors. The incidence of NTD is associated with geographic region, ethnicity, diet, teratogen exposure (mainly from drugs, such as maternal valproic acid ingestion), maternal diabetes, and first-trimester maternal hyperthermia. Although NTDs are typically isolated defects, it is important to rule out fetal chromosomal abnormalities and single-gene disorders that may be associated with a different prognosis and a different recurrence risk.

Folic Acid Prevention

Of great interest is the finding that folic acid is a major preventive agent against NTD. Many clinical studies have established that folic acid supplementation before conception reduces the recurrence of fetal NTDs (Pitkin, 2007). The largest of these studies was a randomized prospective study by the British Medical Research Council (MRC Vitamin Research Group, 1991), which found that preconceptional folic acid supplementation decreased the recurrence of NTDs by 72%.

Screening for NTD

The now well-established finding that AFP is a maternal serum marker for NTD was first reported in 1974 (Brock, 1974). AFP, produced initially by the fetal yolk sac and later by the fetal liver, is the most abundant protein in fetal serum. Its concentration increases in both fetal serum and amniotic fluid until about 13 weeks gestation, after which the liver gradually shifts to production of albumin. In NTDs, AFP becomes elevated because fetal serum from exposed neural membranes and blood vessels leaks into amniotic fluid (AF), producing a concentration in AF that is approximately 100-fold less than in fetal serum. Small amounts of AFP are also transferred across the placenta from fetal serum and across the amniotic membranes from AF to maternal serum (MS), where concentrations of AFP are nearly 1000-fold less than in AF. Amniotic fluid AFP peaks at 13–14 weeks and decreases in the second trimester by about 10% per week. Assays for AFP are based on immunochemical determinations using monoclonal antibodies against AFP and are available on autoanalyzers.

In the second trimester, when maternal screening is performed, MSAFP levels increase by approximately 15% per gestational week. This MSAFP increase, while AF levels are decreasing (see earlier), is due to combined changes in transfer to MS and maternal clearance (Ashwood, 1999). This measurable increase serves as the basis of midtrimester MSAFP screening for open NTDs (UK Collaborative Study, 1977).

MSAFP screening is based on comparison of serum AFP levels from pregnant women in the midtrimester of pregnancy versus median AFP values from women with normal fetuses at comparable gestational ages. These comparisons are subsequently expressed as multiples of the median (MoM). Median values are based on data from the reference population that is screened. Expressing patient results as MoMs normalizes the values, allows for direct comparison of results between laboratories, and adjusts for the large changes in expected values with increasing gestational age. The goal of any maternal serum-screening program is to identify those women at sufficient risk for a fetal disorder to warrant further evaluation and follow-up. Large prospective trials of MSAFP screening showed that most affected pregnancies can be identified by elevated MSAFP levels greater than 2.5 times the normal median for singleton pregnancies. Most laboratories set the cutoff at 2.0–2.5 MoM, such that the detection rate is about 85% of all NTDs with a false-positive rate less than 5% (Wald, 1977; Milunsky, 1980). Only 2% of all women with positive test results are carrying affected fetuses. Thus further evaluation with genetic counseling should be considered.

If MSAFP screening suggests an increased risk for an NTD, then a detailed fetal anatomic survey has to be performed. Normal findings on ultrasound results usually indicate the need for further evaluation, and the

patient should be offered diagnostic amniocentesis to determine the amniotic fluid AFP and the fetal karyotype. If amniotic fluid AFP is elevated, then the presence or absence of acetylcholinesterase is determined. Acetylcholinesterase (AChE) is an enzyme that is derived only from neural tissue (see Chapter 20) and is consequently present in very high concentration in cerebrospinal fluid. The presence of AChE and elevated AFP are diagnostic for fetal NTDs and discriminate NTDs from other fetal defects with increased AFP, such as open ventral wall defects (gastroschisis and omphalocele), congenital nephrosis, benign obstructive uropathy, and fetal skin anomalies. Placental abnormalities can result in elevated MSAFP levels because of compromise in the fetomaternal membranes or placental structure. Elevated MSAFP levels that are not explained by a genetic or congenital problem are frequently associated with obstetric complications during pregnancy, including threatened abortion, low birth weight, preeclampsia, and oligohydramnios (Burton, 1988).

Clinical factors must be considered when patient-specific results are calculated (Ashwood, 1999). Laboratories routinely adjust for the following factors:

1. Maternal weight: MSAFP concentration decreases with increasing maternal weight. Although the fetus itself produces a constant amount of AFP, the maternal blood volume will vary according to the weight of the mother. Failure to adjust for maternal weight causes increases in both false-positive and false-negative results and affects the sensitivity and specificity of the test (Johnson, 1990a).
2. Race: Although the reasons are not known, African American women have MSAFP values that are approximately 10%–15% higher than those of Caucasian women (Johnson, 1990b). It is necessary to mathematically correct for this difference, or to correct by comparing African American patients versus normal median values generated from that reference population.
3. Insulin-dependent diabetes mellitus (IDDM): MSAFP levels in otherwise normal women with IDDM are approximately 20% lower than in the general population; therefore, the MoM values must be adjusted upward to reflect this phenomenon. This is typically accomplished by multiplying the initial MoM value by a factor, using a mathematical constant to increase the initial MoM result.
4. Multiple gestation: Multiple gestation (e.g., twins) will yield higher MSAFP levels because each fetus contributes its own AFP to the maternal blood. The MSAFP level is approximately proportional to the number of fetuses, and the effect can be factored into the laboratory calculation and interpretation of the results. Screening for fetal defects is not as reliable as for single pregnancies, in that one cannot determine the individual AFP contributions of each fetus. Therefore, the NTD detection rate is lower for multiple pregnancies than for single ones. The same principle applies to MoM adjustments for serum analytes in second-trimester screening for fetal chromosomal abnormalities (see later).
5. Gestational age determination: To establish a valid MoM value, a reliable estimate of gestational age is essential. The most common reason for abnormal MSAFP screening results is incorrect estimation of gestational age. Typically, laboratories follow specific protocols based on information obtained from the obstetric care provider to determine the most reliable gestational age. If pregnancy is initially dated using ultrasound, the sensitivity and specificity of the screening are accurate (Wald, 1994); however, ultrasound information frequently is not available at the time of MSAFP screening. Pregnancies with positive screening results that originally were dated by using the last menstrual period should have the gestational age verified by ultrasound. If the two estimated gestational ages differ by a defined amount (laboratory protocols vary, but usually by more than 9 days), then the results are recalculated based on the ultrasound results.
6. Fetal viability: Fetal demise raises the MSAFP levels. In cases of fetal demise, MSAFP does not have diagnostic value.

An algorithm for detection of NTD is summarized in Figure 25-9.

DOWN SYNDROME

All women should be offered screening for fetal chromosomal abnormalities before age 20 weeks, regardless of maternal age (ACOG, 2007). Many multicenter trials have evaluated the different approaches to screening for aneuploidy in the first and second trimesters. First-trimester screening, performed between 12 and 13 weeks, includes nuchal translucency measurement combined with two maternal serum analytes: β subunit of human chorionic gonadotropin with pregnancy-associated plasma protein A

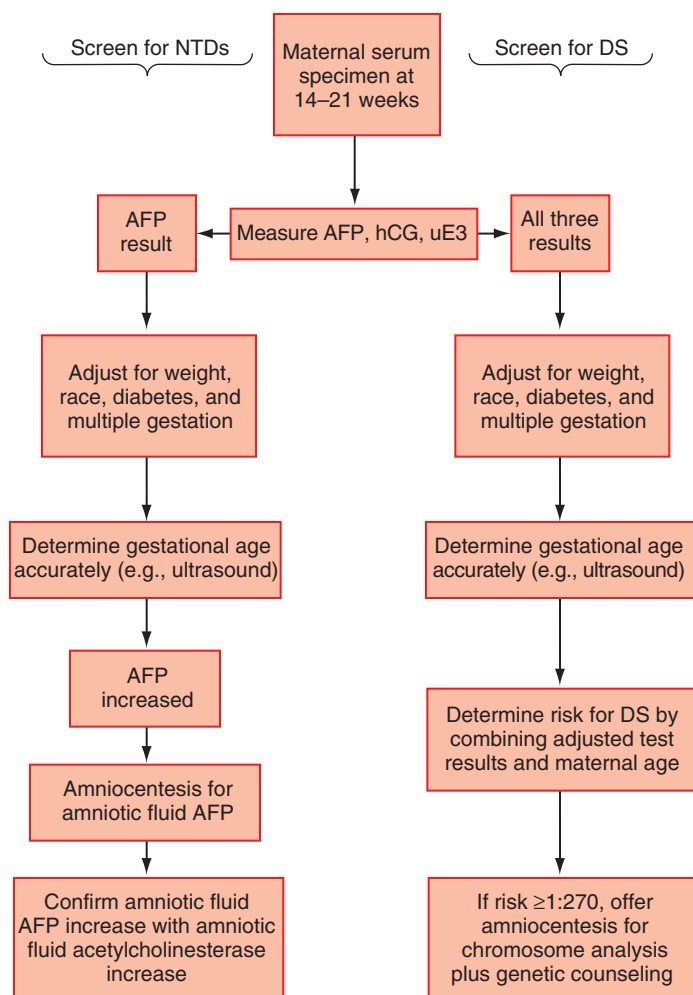

Figure 25-9 A diagnostic algorithm for the simultaneous screening of fetuses for neural tube defects (NTDs) and Down syndrome (DS). AFP, α -fetoprotein; hCG, human chorionic gonadotropin; uE3, unconjugated estriol.

(PAPP-A), and maternal age. An increase in the size of nuchal translucency, which refers to a fluid collection at the back of the fetal neck in the first trimester, is characteristic of fetal chromosomal and structural abnormalities. Serum levels of analytes are changing with advancing maternal age. Patient data are converted to MoM based on population and gestational age. PAPP-A is a glycoprotein produced by the trophoblast; its levels are reduced to 0.48 MoM in affected pregnancies, whereas levels of β -hCG are elevated to 1.98 MoM in comparison with normal pregnancies (Spencer, 1999). Nuchal translucency, as a single ultrasonographic marker, has a detection rate of 64%–70% for Down syndrome, trisomy 18, trisomy 13, and Turner's syndrome. Adding the calculation of maternal serum PAPP-A and β -hCG improves the detection rate to 82%–87%. Women with increased risk of aneuploidy on first-trimester screening should be offered genetic counseling and the option of diagnostic testing, such as chorionic villous sampling or second-trimester amniocentesis (ACOG, 2007).

Other approaches to screening for fetal chromosomal abnormalities include the second-trimester triple screen with MSAFP, β -hCG, and unconjugated estriol performed between 15 and 20 weeks. The level of MSAFP in pregnancies with Down syndrome is reduced to 0.74 MoM and the uE3 level to 0.75 MoM, whereas β -hCG is increased to 2.06 MoM (Wald, 2003).

The detection rate of triple screen can be improved from 69% to 81% by adding the inhibin A (quadruple screen) dimeric protein produced by placenta and fetus. The level of inhibin A shows the same trend as β -hCG and is increased in pregnancies with Down syndrome at 1.77 MoM (Spencer, 1999).

Adjustments can be made to the multiple of median for special populations in which analytes are affected differently. For example, serum concentrations of each biomarker are approximately double in twin pregnancy but cannot be interpreted in higher-order multiples. In

pregestational diabetes, MSAFP, E3, and inhibin A levels are reduced. As body weight increases, analyte levels decrease. In smokers, MSAFP and inhibin A levels are higher, while E3 and β -hCG levels are lower.

An algorithm for detecting Down syndrome is shown together with that for NTD in Figure 25-9.

Several strategies incorporating the results of first- and second-trimester screening have been proposed by American College of Obstetricians and Gynecologists (ACOG). The highest sensitivity rate with the lowest false-positive rates is achieved by using integrated first- and second-trimester screening with a detection rate of 94%–96% and a 5% false-positive rate (Malone, 2005). Results are reported to the patient after first- and second-trimester screening is completed. Those found to have increased risk of aneuploidy should be offered amniocentesis. With another approach, called **sequential screening**, the patient is informed about first-trimester results. Early diagnostic testing (chorionic villous sampling) is offered after a positive result, whereas patients with negative results may undergo additional second-trimester screening and may benefit from its higher sensitivity. The advantage of integrated and sequential screening is a lower false-positive rate that leads to fewer diagnostic procedures. Additionally, all patients who elected to have only first-trimester screening for chromosomal abnormalities should undergo neural tube defect screening in the second trimester (ACOG, 2007).

ERYTHROBLASTOSIS FETALIS

Severe hemolytic disease in a fetus is marked by anemia accompanied by normoblastic hyperplasia (erythroblastosis) and may be followed by congestive heart failure (hydrops) and intrauterine death. The role of transfusion medicine in the management of immunized (sensitized) RhO-negative mothers is reviewed in Chapter 36.

Hemoglobin (Hb), released by hemolysis, is catabolized to unconjugated bilirubin. A fetus with hemolytic disease does not develop hyperbilirubinemia or become jaundiced because the placenta normally removes the bilirubin. However, some bilirubin appears in the amniotic fluid. The measurement of amniotic fluid bilirubin levels using spectral analysis at 450 nm (ΔOD_{450}) was introduced to clinical practice by Liley in 1961 and has been the accepted method of assessing the severity of erythroblastosis in utero. Bilirubin absorbs light maximally at a wavelength of 450 nm and imparts a yellow color to AF. Some of the absorbance at this wavelength is due to Hb. Both bilirubin and Hb can be maternal and fetal in origin, so that pigmentation will not discriminate between a hemolytic process in the mother and one in the child.

In erythroblastosis, the net absorbance of light at 450 nm (A or ΔOD) due to bilirubin correlates with the severity of anemia (or hemolytic rate). Bilirubin is bound to albumin; its concentration is dependent on the turnover of the protein, and its concentration in AF does not change rapidly. To determine whether the net bilirubin concentration in amniotic fluid is elevated, a specimen of AF (5 mL) is collected, protected from light, and centrifuged or filtered. Light absorbance of the AF is scanned continuously between wavelengths 350 nm and 700 nm. The resulting spectrophotometric curve can be used to determine whether or not the fluid contains bilirubin and/or other pigmented products of hemolysis, and to quantify the bilirubin pigment that is present as follows.

Because the absorbance at 450 nm is due to both bilirubin and Hb, if hemolysis occurs, both of these molecules will be elevated in concentration above the background values for their combined absorbance at 450 nm. To determine whether the bilirubin in AF is elevated, both background absorbances at 450 nm must be determined, and the contribution of Hb must also be computed.

To determine the background absorbance of the AF (i.e., what the absorbance would have been with no hemolysis and hyperbilirubinemia), a straight line is drawn between the two absorbances from the scan—at 350 nm and 700 nm. Absorbances at these two wavelengths are not affected by bilirubin or Hb, and, in normal AF, absorbance changes linearly with wavelength between 350 and 700 nm. The absorbance from the straight line at 450 nm is therefore subtracted as the background value from the observed absorbance at 450 nm. This net absorbance still contains a contribution from Hb.

To correct for Hb absorbance, use is made of the fact that Hb uniquely absorbs at 410 nm—a wavelength at which bilirubin does not absorb. From scans of the absorbance of Hb versus wavelength, it is known that the absorbance of Hb at 450 nm is 0.05 of its absorbance at 410 nm. Thus by knowing the net absorbance of Hb at 410 nm, its absorbance at 450 nm can be calculated as $0.05 \times \text{absorbance at 410 nm}$. To obtain the net absorbance of Hb at 410 nm, the background absorbance at 410 nm must be

Figure 25-10 Graph for interpretation of net absorbance at 450 nm of amniotic fluid. The four zones are indicative of the relative level of fetal hemolytic disease. (From Queenan JT, Tomai TP, Ural SH, et al. Deviation in amniotic fluid optical density [OD] at a wavelength of 450 nm in Rh-immunized pregnancies from 14–40 weeks gestation: a proposal for clinical management. *Am J Obstet Gynecol* 1993;168:1370–6, with permission.)

subtracted from the observed absorbance. This value, similar to the one at 450 nm, is obtained from the straight line drawn between the absorbances at 350 and 700 nm. The net absorbance at 410 nm is then multiplied by 0.05 to obtain the Hb contribution at 450 nm. The resulting value is subtracted from the net absorbance at 450 nm to obtain the net absorbance of bilirubin in AF. These computations may be summarized in the following equation:

$$A_{\text{Bili}450} = (A_{450} - A_{450\text{background}}) - 0.05(A_{410} - A_{410\text{background}}) \quad (25-1)$$

where the background values are determined from the straight line between 350 nm and 700 nm as described previously.

The net bilirubin absorbance is recorded on a so-called **Liley graph**, an example of which is shown in **Figure 25-10**, which denotes weeks of gestation on the linear abscissa and net absorbance on the log scale ordinate (Ashwood, 1999). Spectrophotometry of aspirated fluid is most accurate after 26–28 weeks. Net absorbance at 450 nm decreases as the duration of an unaffected pregnancy increases after 28 weeks (before 26 weeks, background absorbance is relatively constant). Decreasing absorbance reflects fluid dilution by fetal urine and accounts for the negative slopes of lines demarcating Liley's prediction zones (lower = zone 1, mid = zone 2, upper = zone 3) for mild, moderate, and severe hemolysis, respectively, as shown in **Figure 25-10**. The greater the net absorbance at 450 nm, the greater is the hemolysis. Although Liley's method originally applied only to the third trimester of pregnancy, a modified curve for the second trimester has been proposed by Queenan (1993) and involves four zones instead of three (see **Fig. 25-10**). Serial testing (every 14 days or less often) allows for trending of net absorbance values.

Trends are usually unidirectional, either paralleling the negatively sloped lines on Liley's graph or showing a positive slope. A rising or plateauing trend of ΔOD_{450} values that reaches the 80th percentile of zone two on the Liley curve, or enters the intrauterine transfusion zone of the Queenan curve, necessitates investigation by fetal blood sampling. Cordocentesis is performed with blood readied for intrauterine transfusion if the fetal hematocrit is found to be less than 30%, or delivery is indicated if gestational age is 35 weeks or greater. If no rise in ΔOD_{450} values is detected, the last amniocentesis should be performed at 37 weeks with testing for fetal lung maturity and anticipated induction of labor (Moise, 2002).

Maternal and fetal acid-base imbalances can alter AF pH and shift the wavelengths of pigment absorbance maxima. Pigments that may be present other than bilirubin and that may affect the results include Hb, methemalbumin, and meconium. Each produces a characteristic spectrophotometric effect. Blood contamination (with interference by hemolysis) is encountered frequently. Less often, in vivo maternal jaundice or hemolysis can cause misinterpretation. The presence of fetal red cells in AF indicates worsening of anemia by blood loss, or may explain a rise in maternal antibody titer (anamniotic response to a new fetomaternal hemorrhage), development of new antibodies, and subsequent increase in the net absorbance of AF at 450 nm. Exposure of AF to light and maternal use of steroids,

markedly increased AF Hb concentration, or poor calibration of a spectrophotometer may cause inaccurate net absorbance measurements.

The current trend in the management of Rh immunization is the use of Doppler measurements of peak systolic velocity in the fetal middle cerebral artery (MCA). This has proved to be an accurate noninvasive method of assessing and monitoring the degree of fetal anemia in pregnancies complicated by Rh immunization (ACOG, 2006). Based on one study, a value above 1.5 MoM for gestational age detects all cases of anemia, with a false-positive rate of only 12% (Mari, 2000). A rise in peak velocity of fetal MCA greater than 1.5 MoM is an indication for fetal blood sampling. If Doppler measurements were used as the method of fetal monitoring during pregnancy, ΔOD_{450} spectrophotometry with fetal lung maturity testing should be considered after 35 weeks to assess fetal status, because higher false-positive rates have been reported with determination of MCA after 35 weeks of gestation, followed by induction of labor at 37–38 weeks (Moise, 2002).

GESTATIONAL DIABETES

Any glucose intolerance in a pregnant woman is termed gestational diabetes (see Chapter 16), regardless of the state of glucose tolerance antepartum or postpartum. Prompt diagnosis and treatment of gestational diabetes may help to avoid maternal and fetal complications such as preeclampsia, fetal congenital malformation, fetal macrosomia (abnormally large body size), and fetal demise.

FETAL LUNG MATURITY

Fetal lung maturation is marked by production of surface-active phospholipid compounds called surfactant. The presence of surfactant decreases surface tension within the alveolar space during inspiration, allows continuous and effective gas exchange, and prevents alveolar collapse during expiration. It is produced by type II pneumocytes in the form of lamellar bodies. Deficiency of surfactant leads to neonatal respiratory distress syndrome (RDS), a disorder that results in hypoxia, acidemia, and vascular protein transudation into alveolar air spaces (hyaline membrane disease). Fetal lung maturity testing should be performed before scheduled delivery at less than 39 weeks and uncertain gestational age. It is contraindicated when delivery is necessary for maternal or fetal indications, or before 32 weeks, when most results show immaturity (ACOG, 2008). Although exogenous surfactant is available for prophylaxis and therapy in newborn RDS, the incidence and severity of the disease can be prevented by maternal antenatal steroid administration to enhance fetal lung maturity.

In the third trimester, fetal respiratory activity allows the passage of surfactant into amniotic fluid, and its quantity may be evaluated using tests of amniotic fluid samples. Before 35 weeks gestation, the major component of surfactant is α -palmitic β -myristic lecithin. After that time, dipalmitic lecithin predominates, and phosphatidyl glycerol (PG) appears about a week later. PG increases until term and maintains alveolar stability. Minor phospholipid components of surfactant include phosphatidyl inositol, phosphatidyl ethanolamine, phosphatidyl serine, and sphingomyelins. The concentrations of components of surfactant are determined by biochemical tests that measure the phosphatidyl glycerol presence and the lecithin/sphingomyelin ratio. Biophysical tests, like fluorescence polarization, lamellar body counts, foam stability index, and optical density, use the surface-active properties of the phospholipids. The lecithin/sphingomyelin ratio (L/S) test was the first practical chemical test to assess fetal pulmonary status (Gluck, 1971). It estimates the ratio of lecithin to sphingomyelin in amniotic fluid. Concentrations of sphingomyelin remain constant throughout the pregnancy, and levels of lecithin are increasing. Following extraction and purification with solvents, amniotic fluid surfactant lipids are chromatographed on thin-layer silica (see Chapter 23 for discussion of this technique). The phospholipids are made visible by heat charring or staining. Densitometric quantification determines the L/S ratio. L/S ratios >2.0 usually indicate maturity, and ratios <1.5 immaturity. In the presence of newer tests, assessment of L/S ratios becomes less cost effective with longer turnaround time. Some believe that the test is unsatisfactory in diabetic women, in whose neonates RDS can occur when L/S ratios are greater than 2.0 (Dubin, 1992).

The presence of phosphatidyl glycerol on the thin-layer chromatogram, in addition to an L/S ratio >2.0 , indicates fetal pulmonary maturity with virtual certainty in any patient. The presence of phosphatidyl glycerol can be determined using a newer slide agglutination test with antisera specific to phosphatidylglycerol.

A test for fetal lung development using the principle of fluorescence polarization came into widespread use after it was automated on the Abbott TDx analyzer. The fluorescence polarization technique measures the tumbling rate of a fluorescent molecule (see Chapter 23). The tumbling rate of a fluorophore added to amniotic fluid will depend on how much of it binds to albumin (causing slow tumbling) versus dissolving in the surfactant produced by the fetal lungs (rapid tumbling). Values of surfactant greater than 55 mg per 1 g of albumin are consistent with fetal lung maturity, and values below 40 mg suggest immaturity. However, the manufacturer has announced the discontinuation of this methodology in 2011.

A recently developed method under investigation is the lamellar body count test, which uses the standard hematologic counter to establish lamellar body concentrations. Thresholds representing fetal lung maturity are still under investigation. The most common accepted cutoffs with high negative predictive value for RDS are between 30,000 and 40,000.

Overall, the following factors may affect fetal lung maturity tests:

1. Blood contamination appears to increase the number of false-positive test results (Carlan, 1997), except for those using phosphatidyl glycerol presence.
2. Meconium does not affect lamellar body counts and determination of phosphatidyl glycerol.
3. Amniotic fluid volumes: L/S ratios, lamellar body counts, and phosphatidyl glycerol levels are lower in polyhydramnios (Piazzese, 1998).
4. Diabetes mellitus: Studies have shown delayed production of phosphatidyl glycerol in the fetuses of pregnant women with diabetes; however, the same thresholds apply to pregnancies of diabetic and nondiabetic women (Melanson, 2007).
5. Method of collection of AF: Comparing the AF collected vaginally with that collected by amniocentesis shows whether results of fluid collected vaginally are mature. The test is more reliable (Edwards, 2000).

Comparison of previous tests in many studies has shown similar characteristics, with high sensitivity between 81% and 92%, and typical negative predictive value from 95%–100% (Neerhof, 2001; Winn-McMillan, 2005; Haymond, 2006).

TOXEMIA OF PREGNANCY (PREECLAMPSIA)

Preeclampsia is a syndrome characterized by hypertension of 140 mm Hg systolic or higher or 90 mm Hg diastolic or higher, with proteinuria greater than 0.3 g/L in a 24-hour urine specimen that occurs after 20 weeks of gestation in previously normotensive women (National High Blood Pressure Education Program Working Group Report on High Blood Pressure in Pregnancy, 2000). The incidence of preeclampsia is 5%–8% of all pregnant women. Preconceptional risk factors associated with preeclampsia include first pregnancy, chronic hypertension, renal disease, antiphospholipid syndrome, diabetes, obesity, advanced maternal age, thrombophilia, partner who fathered preeclamptic pregnancy in another woman, and history of preeclampsia in previous pregnancies.

Conditions that can mimic preeclampsia include systemic lupus erythematosus, idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, cholestasis of pregnancy, and fatty liver disease (Sibai, 2004).

Life-threatening manifestations of preeclampsia that remain a cause of maternal mortality are eclampsia and HELLP syndrome (stands for hemolytic anemia, elevated liver enzymes, low platelet count). Eclampsia, which is defined as new onset of grand mal seizures in women with preeclampsia, may result in intracranial hemorrhage.

The cause of preeclampsia remains unknown. Pathophysiologic abnormalities include abnormal trophoblastic invasion by placenta, resulting from imbalance between proangiogenic and angiogenic factors (Barton, 2008). Impaired uteroplacental flow causes intrauterine growth restriction, oligohydramnios, and placental abruption. The interaction of various vasoactive agents such as prostacyclin, thromboxane A_2 , nitric oxide, and endothelins causes the vasospasm that leads to depleted intravascular volume and hepatic and renal changes. Hematologic changes usually are seen as hemoconcentration, thrombocytopenia, and hemolysis. Hepatic involvement manifests as elevation of aminotransferases, usually twice above normal limit. Lactate dehydrogenase (LD) is increased primarily because of hepatic disease (mostly LD₃) or as the result of hemolysis with increases in LD₁ and LD₂. Hyperbilirubinemia occurs in the presence of hemolysis as well. The proteinuria in preeclampsia is of a glomerular type (mostly albumin), and the urine sediment contains hyaline and finely granular

casts. Mild to moderate increases in urea (>15 mg/dL) and creatinine (>0.8 mg/dL) are noted, as is a marked increase in uric acid.

Severe preeclampsia is diagnosed if one or more of these criteria are met: Blood pressure systolic of 160 or greater, diastolic of 110 or greater; proteinuria of 5 g or higher in 24-hour urine specimen; oliguria (<500 mL/24 hours); cerebral or visual disturbances; pulmonary edema; right upper quadrant pain; impaired liver function; thrombocytopenia (<100 K/ μ L); or fetal growth restriction (ACOG, 2002).

In the past decade, many biophysical and biochemical markers have been proposed to predict which women are likely to develop preeclampsia, but none of the screening tests has been found to be reliable and cost effective. Several studies have analyzed the levels of angiogenic factors in preeclampsia. Results revealed decreased levels of placental growth factor, placental protein-13, and pregnancy-associated plasma protein A, along with elevation of fms-like tyrosine kinase-1, endoglin (a transmembrane receptor that is vital for angiogenesis), and dimethylarginine (Levine, 2006) (a marker for atherosclerotic heart disease). However, because of differences in study design and methods of analysis, these markers have poor predictive value and specificity. A more promising test is Doppler velocimetry of the uterine arteries (Espinoza, 2007).

Mild preeclampsia can be managed expectantly and followed by delivery at term. Delivery at any gestational age is indicated for the following conditions: eclampsia, HELLP, placental abruption, non-reassuring fetal heart pattern, pulmonary edema, severe hypertension, worsening of renal function, persistent symptoms of headaches, visual disturbances, and epigastric pain.

PREMATURE RUPTURE OF MEMBRANES

Premature rupture of membranes is rupture of membranes before the onset of labor. It may be followed by a variety of complications, including chorioamnionitis, fetal pulmonary hypoplasia, placental abruption, and neonatal respiratory distress. The diagnosis of membrane rupture is made upon visualization of fluid passing from the cervical canal on the sterile speculum examination. Amniotic fluid constitutes part of the posterior vaginal fluid pool, and identification of the amniotic component is optimally carried out within 2 hours of membrane rupture. Unlike vaginal secretions, whose pH is acidic (pH, 4.5–5.5), amniotic fluid is alkaline, with pH of 7.0–7.5. The vaginal pool aspirate can be tested with nitrazine paper to estimate pH visually. A positive test is indicated by a blue color, and a negative one by a yellow-green color. Among false-positives, 5% are related to the presence of blood, mucus, semen, bacterial vaginosis, alkaline urine, or soap. False-negatives are less likely (1%) but may be seen with membrane rupture that occurred more than 24 hours earlier, or if sampling was inadequate. The nitrazine test is usually performed at the bedside and is said to have an overall accuracy of about 90% in the absence of bloody show, vaginal discharge, or prolonged membrane rupture (Friedman, 1969). An aliquot of the aspirated fluid can be applied to a glass microscope slide, dried for 5 minutes, and examined microscopically for arborization (ferning), which indicates the presence of amniotic fluid in the vaginal fluid pool. False-positive ferning occurs in less than 2% of cases and is associated with the presence of blood, urine, or cervical mucus. False-negatives occur in less than 5% of cases. An alternative method for detecting amniotic fluid in vaginal secretions is rapid immunoassay of placental alpha-1 microglobulin, currently marketed as the AmniSure test (N-Dia Inc., New York).

PRETERM LABOR

Numerous biochemical markers and biophysical tools have been evaluated for predicting preterm delivery. In 1991, Lockwood and colleagues discovered an association between the presence of fetal fibronectin (fFN) in cervical secretions and risk of preterm delivery. fFN is a glycoprotein produced by fetal membranes and found in the chorionic junction amniotic fluid; it is released as cervical secretions at up to 20 weeks of gestational age. It has been identified in malignant cell lines and is recognized by antibody FDC-6 (Lockwood, 1991). Fibronectin is responsible for the cellular adhesiveness of placenta and membranes to the decidua. Disruption of the chorion from the decidua layer of the uterus leads to the release of intact or degraded chorionic components of the extracellular matrix into the cervical and vaginal secretions. The fFN enzyme immunoassay is a U.S. Food and Drug Administration-approved test for assessment of the risk for preterm delivery in women between 24 and 35 weeks gestational age. The purposes of the test are to identify asymptomatic women who are at risk for preterm delivery and to predict the risk of delivery in symptomatic women with preterm contractions. The specimen

is collected during sterile speculum examination with a swab from the posterior fornix of the vagina or the region of the external cervical os for 10 seconds. Concentrations of fFN in the cervicovaginal fluid greater than 50 ng/mL are considered positive (Garite, 1996). The swab should be performed before procedures that may disrupt the cervix, such as the digital examination, Papanicolaou smear, cervical culture, and vaginal ultrasound. The following criteria should be met: cervical dilation less than 3 cm, intact membranes, absence of uterine bleeding, sexual intercourse more than 24 hours before, and absence of cervical cerclage. A meta-analysis of many studies on patients with symptoms suggestive of preterm labor showed that cervicovaginal fFN is an effective predictor of preterm delivery (Leitch, 1999). Testing for fFN can reduce unnecessary hospitalization and avoid intervention in symptomatic pregnant women. Detection of fFN can also help in the management of pregnancy in asymptomatic women who have known risk factors for preterm labor, such as previous preterm delivery or short cervix.

It appears to be most valuable in ruling out imminent delivery in patients with symptoms with negative predictive values for delivery within 7, within 14, and at less than 37 weeks (99.5%, 99.2%, and 84.5%, respectively) (Peaceman, 1997). The test is often performed with sonographic assessment of cervical length. An fFN test has limited application for screening of asymptomatic women and those with no risk factors because of the low incidence of preterm labor in this population (Leitch, 1999). Future applications of fFN as a tool in predicting successful labor induction are under investigation.

INTRAPARTUM ASSESSMENT OF FETAL STATUS

The goal of intrapartum fetal surveillance is to recognize if the fetus with a nonreassuring fetal heart tracing on external monitoring is acidotic and at risk for neurologic impairment or death. Usually, episodes of hypoxemia are transient and well tolerated by the fetus. However, prolonged or repeat episodes may lead to hypoxic-ischemic encephalopathy. Available tests can help to ensure fetal well-being and reduce false-positive findings on external fetal heart monitoring. Noninvasive and preferred tests, such as digital scalp stimulation and vibroacoustic stimulation of the fetus, followed by the presence of reassuring fetal heart monitoring, indicate that the fetus is not acidotic. The direct method for evaluation of fetal acid-base status is fetal scalp blood sampling. This test is performed using the amnioscope with a light source; blood is collected from a punctured fetal scalp and is transferred in a heparinized capillary tube. A pH value less than 7.20

identifies fetal acidosis. However, the test has low sensitivity (36%) and poor predictive value (9%) in predicting fetal acidemia of pH less than 7.0 (Kruger, 1999). The use of fetal scalp pH assessment is decreasing in many institutions because of the difficulty involved in obtaining and processing samples and in obtaining standardized laboratory equipment.

Another method of predicting fetal acidosis involves the measurement of fetal lactate concentrations with the use of rapid enzymatic assays. Blood samples are collected by using techniques similar to those used in fetal scalp pH. Recently, a large, multicenter, randomized trial compared the effectiveness of pH analysis of fetal scalp blood versus use of lactate levels in identifying hypoxia at birth, and showed no differences between the two groups in obstetric and neonatal outcomes (Wiberg-Itzel, 2008).

The most objective tool for determining intrapartum fetal status and obtaining information related to obstetric management is umbilical cord sampling. Immediately after delivery, arterial blood is drawn from a segment of clamped umbilical cord to a heparinized capillary syringe and is analyzed for cord blood pH and blood gas values. ACOG (2006) recommends analysis of umbilical cord blood in neonates with low Apgar scores to differentiate hypoxia from metabolic acidemia and other causes of low Apgar scores. Significant metabolic acidosis is defined by umbilical cord blood pH values less than 7.0; base deficits of 12 mmol/L or greater are predictive of adverse neurologic outcomes and are included in the criteria for an acute intrapartum hypoxic event.

OTHER EVALUATIONS

Infection During Pregnancy

Viral, bacterial, and parasitic infections can have a significant impact on the mother, fetus, or both. Important examples are human immunodeficiency virus, hepatitis virus (A, B, and C), rubella virus, varicella virus, parvovirus B19, cytomegalovirus, *Chlamydia trachomatis*, group B *Streptococcus*, *Neisseria gonorrhoeae*, syphilis, tuberculosis, toxoplasmosis, and malaria. These are discussed in Part 7 of this text.

Hematologic and Coagulation Disorders

Various disorders can have a negative effect on mother, fetus, or both, including maternal anemias (nutritional, sickle cell), maternal and fetal thrombocytopenias (idiopathic thrombocytopenic purpura, fetal alloimmune thrombocytopenia, thrombotic thrombocytopenic purpura), maternal coagulopathies (acute disseminated intravascular coagulation, von Willebrand disease), and maternal thrombophilias. These are described in Parts 4 and 5.

KEY POINTS

- Very small quantities of vitamins and trace elements are needed to satisfy metabolic requirements. Adequate supplies are essential for health.
- Vitamins and trace elements should be obtained from foods rather than from supplements.
- Vitamins are present in almost all foods, but no one food group is a good source of all vitamins.
- Several groups, including pregnant women, neonates and infants, the elderly, those receiving long-term parenteral nutrition or hyperalimentation, those on hemodialysis, and those with a disease causing malabsorption, warrant selective micronutrient supplementation.
- These heterogeneous essential micronutrients are unrelated organic catalysts and elements.
- Vitamins are essential organic substances that the body cannot synthesize, or does not sufficiently synthesize. This is species specific. Vitamins may function variously as enzymatic cofactors, antioxidants, or hormones and are active in energy metabolism, protein metabolism, blood cell maturation, and bone formation. Vitamins are unrelated chemically and have different physiologic activities and food sources.
- Vitamins may be single chemicals (e.g., ascorbic acid) or may include a family of closely related compounds (e.g., vitamins A, D, E, and K, cobalamin). They may be classified according to water or lipid solubility, which affects absorption and transport, storage, toxicity, excretion, and disease conditions that cause deficiencies, even when nutritional intake is sufficient.
- Deficiencies are most often due to malnutrition.
- Dietary reference intake includes reference values for each essential nutrient.
- The tolerable upper intake level is the maximum daily nutrient intake that is unlikely to have adverse effects for almost everybody.
- Assessment of both dietary intake and body stores requires different test strategies for diagnosis of deficiency or toxicity. Deficiencies are especially important at the age extremes of life and in malnutrition of whatever cause.
- A therapeutic trial of the nutrient considered deficient is the most reliable approach to diagnosis and treatment.
- Body stores of vitamins and minerals vary tremendously.
- Essential trace elements have specific metabolic functions that cannot be replaced by other minerals.

- Disease states significantly change the requirements for vitamins and trace elements.
- Deficiencies of trace elements may result from insufficient ingestion because soil, water, or plants in the region are inadequate in a specific element; other dietary substances interfere with absorption; or the protein needed for absorption or metabolism is lacking.
- Overt deficiencies of micronutrients are rare in Western countries, except in chronic illness or alcoholism.
- Immune function is adversely affected by poor intakes of almost all of the micronutrients.
- Micronutrients are often insufficient for displaced populations during violence or famine.
- Trace elements have structural, signal transduction, and catalytic functions. Some are components of metalloenzymes; they may function as enzyme cofactors or provide electron and oxygen transport, or they may be active in the maintenance of macromolecule conformation or vitamin or hormonal activity.
- To avoid contamination, trace elements must be analyzed with considerable care because they are widely distributed in the environment and are present in very minute concentrations in body fluids and tissues. Thus, techniques must be sensitive enough to analyze concentrations of µg/L or even ng/L.
- For most micronutrients, concentrations in body fluids indicate only the adequacy of recent intake because of lack of correlation with body tissue concentrations.
- Trace element concentrations in body fluids correlate poorly with amounts in body stores. Serum levels are unreliable because of the influence of unrelated conditions. No particularly good assays are available for trace element dietary status. Test results need be interpreted with caution.
- The only definitive test of human trace element deficiency is assessment of clinical response to controlled supplementation when the element is considered deficient.
- The intake required to cause toxicity is highly variable for the different trace elements.
- Toxicity rarely results from excessive dietary intake.
- Toxicity is usually due to overdoses of vitamin supplements.
- A poison is too much of anything. Toxicity is never a question of presence, only of amount.

Twenty-three vitamins and trace elements are collectively termed essential micronutrients. Adequate supplies of these heterogeneous nutrients are critical for health, development, and longevity. They are needed in small amounts for metabolism of proteins, carbohydrates, and fats, and for the body's structure (e.g., vitamin K in bone matrix). Many micronutrients are important antioxidants (e.g., vitamins C and E) or are cofactors for antioxidant enzymes (e.g., selenium in glutathione peroxidase). Recommended allowances reconcile optimum nutrition and the prevention of deficiency symptoms or diseases. The requirements for most essential nutrients to maintain health are now fairly well characterized.

Dietary reference intake (DRI) is an umbrella term that includes reference values or estimates of the dietary level for each essential nutrient. DRI was introduced by the Food and Nutrition Board, Institute of Medicine of the National Academy of Sciences (IOM, 1997, 1998, 2000, 2002), and provides four dietary reference values, primarily intended for nutritionists (Barr, 2002). **Recommended dietary allowance (RDA)** is the average daily dietary amount sufficient for the nutrient requirements of most (97%–98%) healthy people categorized by age, gender, and physiologic need. The RDA is derived from the **estimated average requirement**, that is, the average daily nutrient intake level estimated to meet the requirements of half the healthy individuals in a particular life stage and gender group. **Adequate intake** is an estimate of average recommended daily intake when the RDA cannot be determined. The **tolerable upper intake level (TUL)** is the maximum daily nutrient intake that is likely to pose no risk of adverse health effects for almost all individuals in the general population (IOM, 1998). As intake increases above the TUL, the potential risk of adverse effects increases. Also, the amounts recommended for enteral and intravenous nutritional support are available.

Because of a plentiful and inexpensive food supply, overt deficiencies of vitamins or trace elements (e.g., pellagra) are rare in Western countries, except in the chronically ill or alcoholic. Very small amounts of micronutrients are required to satisfy their diverse physiologic roles, and their functions are as varied as their compositions (Mason, 1996). They are usually ingested as foods and consumed in meals rather than as individual nutrients or molecules. Patients should obtain the vitamins and trace elements from foods rather than from supplements (Lichtenstein, 2005; Barnard, 2009). These essential nutrients are unrelated organic catalysts and elements that are not endogenously synthesized in sufficient amounts (Rubin, 2005). Insufficient micronutrient intake has short-term and long-term disease implications. For example, immune function is adversely affected by poor intakes of almost all of the micronutrients. Body stores of vitamins and minerals vary tremendously. Vitamin B₁₂ and vitamin A stores are large, and an adult might not become deficient for 1 or more years after being on a depleted diet. However, folate and thiamine may become depleted within weeks when eating a deficient diet. Both deficiency and toxicity states are often insidious and may be attributable to inappropriate intake or defective utilization. Deficiencies are most often due to malnutrition (McLaren, 1994). Initial interest focused on the prevention of deficiency diseases and elucidation of the biochemical roles of these micronutrients as coenzymes and cofactors. Research on the assessment of vitamin and trace element nutriture has further identified their many other important functions, such as antioxidant activity and hormone-like stimulation, along with their regulatory roles (Machlin, 1992).

Micronutrients are often insufficient for displaced populations or refugees in instances of domestic upheaval, violence, or famine. Determination of the extent to which metabolic demands for micronutrients have been met is complex and very difficult. A clinical history obtained by an experienced practitioner or dietitian can provide only a crude assessment. Even a complete 3-day dietary diary is limited because of the problem of recording sizes of food portions and amounts consumed (Nelson, 2000).

Measurement of vitamin and trace element levels is sometimes helpful in nutritional assessment. Clinical assessment of their status is often poor. Disease conditions, infections, and trauma alter metabolism and significantly change the requirements for vitamins and trace elements in ways that are poorly understood (Shenken, 1997, 2000; Elia, 2001). Disease states may increase demand, but the effects of illness on the requirements are not well quantified. Laboratory studies improve the assessment of the balance of supply and demand but are limited (Gidzen, 2000). Subclinical deficiencies are known to occur, but the extent of depletion that occurred before significant biochemical, physiologic, or histologic changes were noted can only be surmised. Analytic improvements in this field are greatly needed. Interpretation of tests of nutritional status requires reference intervals with provisions for relevant factors such as ethnicity, geographic variation, time of sampling, and development of functional tests.

Subclinical vitamin and trace element deficiencies can be diagnosed by laboratory testing for some elements (e.g., zinc, folate, iron, vitamins B₆ and B₁₂), especially in geriatric age groups.

Concentrations of micronutrients are usually measured in plasma or serum, but these data provide a reliable indication of their status for only a few vitamins and trace elements. For most, concentrations in body fluids indicate only the adequacy of recent intake, because of lack of correlation with body tissue concentrations. For mobilization, binding proteins and concentrations in various body tissues (e.g., vitamin A in the liver) seem to be most significant. For some elements (e.g., manganese, chromium), the data permit assessment of toxicity. Tissue or blood cell concentrations can assess certain significant conditions (e.g., copper concentration in liver biopsy in suspected Wilson's disease; red cell folate or leukocyte vitamin C concentration for clinical evaluation). Urine measurements of the concentrations of most vitamins and trace elements are rarely helpful in that most are not under homeostatic control and indicate only the amount ingested. The time course for the development of a subclinical deficiency is variable for each vitamin and is affected by body stores. The extent of depletion and any subsequent progression to functional effects and clinical disease have been poorly characterized (Shenkin, 2006).

Vitamins and trace minerals have been invested with a magical aura. The misguided belief that megadoses can provide a panacea is widespread. Perhaps this reflects an awareness of the extraordinary physiologic prowess of these micronutrients, but they also pose a hazard. A risk of toxic overdose is present, although they are safe within TUL (IOM, 1998).

Several groups of people warrant selective micronutrient supplementation. These include pregnant women, neonates, and infants; elderly persons; patients receiving long-term parenteral nutrition or hyperalimentation; those with a disease causing malabsorption; and those with altered nutritional or metabolic states. Hemodialysis removes water-soluble vitamins. Poverty and food faddism are continued sources of deficiencies. Other at-risk groups likely to be deficient in micronutrients include alcohol-dependent patients with deficient vitamins C, E, and the B vitamins, particularly thiamine; and those following unsupplemented vegan diets.

Drug-Diet Interactions. Folic acid deficiency may result from anticonvulsant therapy (e.g., phenytoin, phenobarbital). Vitamin B₁₂ absorption is decreased by acid suppression (e.g., proton pump inhibitors).

For the general population, with only certain exceptions, vitamin and trace element supplementation is not required and is unnecessary and even wasteful, because of their ubiquitous distribution and ready availability from a variety of food sources.

This section will review the micronutrients, which include vitamins and essential trace mineral elements. The thirteen vitamins are outlined in Table 26-1, along with their functions and summaries of deficiency and toxicity states. Table 26-2 lists RDAs and food sources for the vitamins, as well as laboratory assessments for subclinical deficiency states. Table 26-3 tabulates a classification of trace elements. Table 26-4 lists the 10 essential trace elements, along with their functions and summaries of the effects of deficiency and toxicity. Table 26-5 lists the properties of the essential trace elements.

VITAMINS

These organic molecules are required in trace amounts for health, growth, and reproduction (McCormick, 1994). Except for vitamin D, the body depends completely on dietary intake of vitamins, although some enteric bacterial production of vitamin K, nicotinic acid, riboflavin, biotin, cobalamin, and folic acid has been noted (Eastwood, 2003; Grodner, 2004). These syntheses occur mostly in the colon and are not nutritionally significant because these vitamins are poorly absorbed. The lack of each vitamin results in a clearly identifiable metabolic deficit, causing a clinical deficiency syndrome. This is species specific; differences in the synthesizing capabilities of different species have been observed. Many lower animals can produce their own ascorbic acid. Humans, however, cannot synthesize ascorbic acid and require ascorbate to prevent scurvy (Combs, 1998).

Vitamins may be classified according to their properties, such as function, nutritional source, or solubility in water (Table 26-1). Vitamins have been divided into two groups on the basis of solubility, which affects absorption and transport. Water-soluble vitamins are easily absorbed, which allows for minimal storage. However, deficiencies can develop quickly—within weeks (Grodner, 2004). Thiamine, riboflavin, niacin, pyridoxine, cobalamin, vitamin C, folate, pantothenic acid, and biotin are water

TABLE 26-1

Vitamins: Functions, Deficiency Syndromes, and Toxicity

Water-soluble vitamin	Functions	Deficiency syndromes	Toxicity
Ascorbate (vitamin C)	Many redox reactions Hydroxylation of collagen	Scurvy	Chronic megadoses of 10–150 times the RDA (1–15 g), cramps, diarrhea, nausea, kidney stones. With megadoses, body accelerates drug metabolism. Can produce scurvy if megadoses abruptly stop
Biotin	Cofactor in carboxylation reactions	Rare. Caused by lack of biotin in total parenteral nutrition. Also, avidin in raw egg whites binds biotin in gut, preventing absorption. Dermatitis, glossitis, hair loss, anorexia, depression, and hypercholesterolemia	No known toxicity
Cobalamin (vitamin B ₁₂)	Folate metabolism and DNA synthesis, maintenance of myelination of spinal tracts	Megaloblastic anemia, peripheral neuropathy	No appreciable toxicity
Folate	Transfer and use one-carbon units in DNA and amino acid synthesis	Megaloblastic anemia, neural tube defects	Teratogenic effect in rodent model. No adverse effects at high oral doses
Niacin (nicotinic acid)	Incorporated into NAD and NAD phosphate, redox reactions	Pellagra: Dementia, dermatitis, diarrhea	Excess pre-formed niacin and nicotinic acid cause vascular dilation, “flushing”; hepatotoxic
Thiamine (vitamin B ₁)	As pyrophosphate, is coenzyme in decarboxylation reactions	Dry (neuromuscular) and wet (cardiac failure) beriberi, Wernicke-Korsakoff syndrome	Only when given parenterally. Headache, muscle weakness, cardiac arrhythmia, convulsions
Pantothenic acid (vitamin B ₅)	Incorporated in coenzyme A	No syndrome recognized	Very high doses: Diarrhea
Pyridoxine (vitamin B ₆)	Derivatives are coenzymes in many intermediary reactions; amino acid, phospholipid, and glycogen metabolism	Cheilosis, glossitis, dermatitis, peripheral neuropathy, convulsions	Long-term megadose supplementation causes ataxia and sensory neuropathy. The UL is 100 mg/day
Riboflavin (vitamin B ₂)	Converted to flavin coenzymes. Cofactor for many enzymes in intermediary metabolism	Ariboflavinosis, cheilosis, angular stomatitis, glossitis, dermatitis, corneal vascularization	Toxicity to riboflavin has not been reported. Absorption limited normally
Vitamin A (retinol)	A component of retinal rod pigment. Role in vision in dim light, growth; reproduction. Maintenance of resistance to infection	Squamous metaplasia, especially glandular, follicular hyperkeratosis; xerophthalmia; night blindness, reproductive disorders, vulnerability to infection	Livers of polar bears and large animals have very high levels of vitamin A. Acute: Can cause drowsiness, headache, vomiting, stupor, skin peeling, and papilledema. Chronic: Teratogenic, osteoporosis, hepatotoxicity. Carotenoids in excess, distinct orange-yellow skin color
Vitamin D (cholecalciferol)	Promotes absorption of calcium and phosphorus; mineralization of bones and teeth	Rickets in children; osteomalacia in adults; hypocalcemia, tetany	High intake of vitamin D: Hypercalcemia and hypercalciuria, toxicity above UL of 50 µg. Bone demineralization, constipation, muscle weakness, renal calculi
Vitamin E (tocopherol)	Antioxidant, scavenges free-radicals; cellular respiration, primarily in muscle, RBC integrity	Spinocerebellar degeneration, ataxia	Mild GI distress, nausea, coagulopathies in patients receiving anticonvulsants
Vitamin K (phytyomenadione)	Cofactor of procoagulants—hepatic factors II (prothrombin), VII, and X, proteins C and S	Defective clotting, bleeding disorder	Foods containing vitamin K cause no toxicity problems. Excess amounts of vitamin K may decrease clotting time

Data from Berdanier, 1998; Combs, 1998; Eastwood, 2003; Grodner, 2004; Kane, 2005.

DNA, Deoxyribonucleic acid; GI, gastrointestinal; NAD, nicotinamide adenine dinucleotide; RBC, erythrocyte; RDA, recommended dietary allowance; UL, upper limit.

soluble. Vitamins A, D, E, and K are considered water insoluble or fat soluble, and they depend on normal lipid digestion and micellar solubilization, such as the presence of bile, for absorption. Malabsorption of fat may result in deficiencies of the fat-soluble vitamins, despite adequate dietary intake.

Vitamins are found in almost all foods, but no one food group is a good source for all vitamins (Table 26-2) (Grodner, 2004). The vitamin B complex includes thiamine, riboflavin, niacin, pyridoxine, and cobalamin. Cobalamin is present only in animal products, including meat, especially liver, milk, cheese, eggs, and other animal proteins. All of the other B complex vitamins are found in leafy green vegetables, milk, and liver. Vitamin A and niacin have precursor substances that can be converted to the active vitamin form in humans. Vitamin K and biotin are produced by the gut microflora, but in insufficient quantities to sustain metabolism. Niacin and vitamin D can be made in the human body. Both thiamine and biotin have natural antagonists.

Deficiencies are particularly important at the extremes of life. They are a matter of concern for the developing fetus and infant, and for the aged (Seymour, 2000). Deficiencies are also frequent among those with protein-energy malnutrition in developing nations. In developed countries, conditions resulting in vitamin deficiencies include decreased intake, absorption, or production. Decreased intake characteristically occurs in patients suffering from alcoholism (e.g., thiamine) or small bowel disease (e.g., folate and the fat-soluble vitamins; vitamins A, D, E, and K), as well as in vegans (vitamin D, cobalamin) and the elderly (e.g., vitamin D, folate). Conditions that result in decreased absorption in liver and in biliary tract disease (e.g., vitamins A, D, E, and K) are due to ileal disease or resection (e.g., cobalamin). Conditions that cause decreased production occur in renal disease (e.g., vitamin D) and with drugs such as methotrexate (e.g., folate). Deficiencies also occur in those with long-term chronic disease such as acquired immunodeficiency syndrome. Assessment of body stores and of the chronic nutritional state for micronutrients continues to present difficulties.

TABLE 26-2

Vitamins: RDA, Food Sources, and Analysis of Body Levels

Water-soluble vitamin	RDA	Food sources	Laboratory assessment for subclinical deficiency states
Ascorbic acid (vitamin C)	M: 90 mg F: 75 mg Smokers: 125 mg	Fruits and vegetables: Citrus fruits, red and green peppers, strawberries, tomatoes, broccoli, potatoes, green leafy vegetables	Fasting specimen required. S—ascorbic acid, deficient <11.4 $\mu\text{mol/L}$ WBC—ascorbic acid by HPLC, reflects tissue stores, preparation and assay difficult. <11.4 nmol/ 10^8 cells associated with scurvy 24-hour U-ascorbic acid, reflects recent dietary intake Vitamin C load test U
Biotin	AI 30 μg	Liver, kidneys, peanut butter, egg yolks, yeast	Microbiological assay
Cobalamin (vitamin B ₁₂)	M/F: 2.4 μg	Meat, fish, poultry, eggs, and dairy products	S—vitamin B ₁₂ by CPBA, deficiency <200 ng/L U—methylmalonic acid
Folate	M/F: 400 μg Pregnancy: 600 μg Lactation: 500 μg	Leafy green vegetables, legumes, cereals, some fruits and juices	Hemolysis interferes. RBC—folate; S—folate S—methyltetrahydrofolate, reflects recent intake, not stores. Cutoff point, negative folate balance <6.8 nmol/L Polyglutamate forms of folate present, reflect body folate stores Folate (nmol/L): depleted <368 deficient <322 anemia <227 U—FIGLU Histidine load test U
Niacin (nicotinic acid)	NE = 1 mg niacin or 60 mg tryptophan M: 16 mg NE/day F: 14 mg NE/day	Protein-containing foods are good sources of both niacin and tryptophan. Meats, poultry, fish, legumes, enriched cereals, milk, coffee, and tea	Ratio of RBC—NAD and NADP nucleotide, <1 may indicate risk of niacin deficiency Ratio 2—pyridone (40%–60%): N'-Methyl nicotinamide (20%–30%), deficiency of niacin when ratio <1
Pantothenic acid	AI 5 mg	Whole grain cereals, legumes, meat, fish, poultry	Whole blood—pantothenic acid, inadequate intake <100 $\mu\text{g/dL}$ 24-Hour U—pantothenic acid, abnormally low <1 mg/day
Pyridoxine (vitamin B ₆)	M/F: 1.3 mg	Whole grains, cereals, legumes, chicken, fish, pork, and eggs	P-pyridoxal-5'-phosphate, cation exchange HPLC, assay by fluorometry B6 status: >30 nmol/L adequate ≥0.8 acceptable <0.5 marginal or inadequate RBC—aminotransferases, reflect long-term pyridoxine status; ALT more sensitive to B ₆ deficiency than ALT U—pyridoxic acid, dietary intake of B ₆ U—xanthenuic acid, tryptophan metabolite Tryptophan load test U
Riboflavin (vitamin B ₂)	M: 1.3 mg F: 1.1 mg Riboflavin destroyed by light	Milk, enriched grains, broccoli, asparagus, dark leafy greens, whole grains, enriched breads, cereals. Also dairy products, meats, fish, poultry, and eggs	RBC—glutathione reductase, expressed as ratio of assays with and without flavin adenine dinucleotide 24-Hour U—riboflavin measures recent intake, not body stores, nonspecific; varies with physical activity
Thiamine (vitamin B ₁)	M: 1.2 mg F: 1.1 mg	Whole or enriched grains and flour, lean pork, legumes, seeds, and nuts	RBC—transketolase activity, expressed as ratio of assays with and without thiamine pyrophosphate 24-Hour U—thiamine measures recent dietary intake, not body stores
Fat-soluble vitamin	RDA	Food sources	Laboratory assessment for subclinical deficiencies
Vitamin A (retinol)	M: 900 μg RAE F: 700 μg RAE	Natural pre-formed vitamin A only in fat of animal-related foods: Whole milk, butter, liver, egg yolks, and fatty fish Carotenoids are found in deep green, yellow, and orange fruits and vegetables (broccoli, cantaloupe, sweet potato, carrots, tomatoes, spinach)	Hemolysis interferes Liver retinol stores: S-retinol, insensitive test Dose response: S-retinol and dehydroretinol by HPLC 4–6 hours after oral 3,4-didehydroretinylacetate (100 $\mu\text{g/kg}$); more sensitive index than S-retinol of marginal retinol status RDR: Retinol-binding protein RBP, low specificity In Vitamin A deficiency, RBP accumulates in liver as apo-RBP (RBP not bound to retinol). After retinol dose, retinol binds to apo-RBP in liver, holo-RBP (RBP bound to retinol) released from liver, causing increased S-retinol. Blood sample at baseline and 5 hours after oral vitamin A. Calculate RDR (%), >14%–20%, marginal vitamin A status S—Carotenoids indicate current intake of carotenoids RDA for night blindness
Vitamin D	AI M/F: 5 μg Ages: 51–70 years, 10 μg >70 years, 15 μg	Butter, egg yolks, liver, and fatty fish Vitamin D-fortified milk Sunlight exposure converts precursor to active vitamin D	S—25-Hydroxy vitamin D: Deficiency <3 nmol/L Toxicity >500 nmol/L Separate S—25(OH)-D by HPLC, assay by CPBA, indicates total endogenous and exogenous vitamin D, reflects vitamin D content of liver

TABLE 26-2

Vitamins: RDA, Food Sources, and Analysis of Body Levels—Cont'd

Fat-soluble vitamin	RDA	Food sources	Laboratory assessment for subclinical deficiency states
Vitamin E (tocopherol)	α -tocopherol equivalents = α -TE M/F: 15 mg α -TE	Vegetable oils, corn, soy, safflower. Whole grains, seeds, nuts, wheat germ, green leafy vegetables	Ratio S—tocopherol: S—lipids; reverse-phase HPLC with high-sensitivity fluorescence detector; levels correlate with S—cholesterol deficiency when ratio <0.6 mg total tocopherol/g serum lipids
Vitamin K	AI M: 120 μ g F: 90 μ g	Vitamin K synthesized by bacteria in jejunum and ileum; dietary intake is still required. Dark green leafy vegetables	PT

Data from McCormick, 1994; Gibson, 2002; Grodner, 2004.

AI, Adequate intake; ALT, alanine aminotransferase; CPBA, competitive protein binding assay; F, female; FIGLU, formiminoglutamic acid; HPLC, high-performance liquid chromatography; M, male; M/F, male/female; NAD, nicotinamide adenine dinucleotide; NE, niacin equivalent; P, plasma; PT, prothrombin time; RAE, retinol activity equivalents; RBC, erythrocyte; RBP, index of retinol; RDA, recommended dietary allowance; RDR, relative dose response; S, serum; U, urine; WBC, leukocyte.

Concentrations in plasma often indicate only recent nutritional intake. A therapeutic replacement trial of the nutriment considered deficient is often the easiest and most reliable approach. Specific diagnostic strategies are helpful (see Table 26-2) (Feldman, 1994; Gibson, 2002). Mobilization into plasma is affected by the availability of appropriate binding proteins, irrespective of vitamin or trace element stores (Shenkin, 2006).

Toxicity rarely results from excessive dietary intake. Toxicity is usually due to overdoses of vitamin supplements. Single large doses of the water-soluble vitamins are rarely toxic because they are rapidly excreted, but repeated doses can cause toxicity. Vitamin A has a toxic potential greater than that of the other hypervitaminoses, although the actual incidence is low. Intakes as low as 25 times the RDA are considered potentially toxic for vitamin A. Carotenoids have low toxicity. Vitamin D is the other vitamin that has a relatively high potential for toxicity. Intakes of about 50 times the RDA have been reported as toxic in humans. Children have been particularly sensitive when large doses of vitamin D were used for prophylaxis or treatment of rickets, and hypervitaminosis D has been exacerbated by high intakes of calcium and phosphorus (Combs, 1998).

WATER-SOLUBLE VITAMINS

Thiamine (Vitamin B₁)

Thiamine pyrophosphate (TPP) is an essential cofactor of enzymes involved in carbohydrate amino acid intermediary metabolism, and is important in brain function. It is an essential cofactor in the decarboxylation of α -keto acids such as pyruvate in its conversion to acetyl coenzyme A. Good sources include yeast, legumes, enriched grain products, and pork. Early signs of deficiency include anorexia, weight loss, muscle weakness, apathy, confusion, and irritability. Later consequences include edema and high-output cardiac failure (wet beriberi), polyneuropathy with depressed reflexes, paresthesias, weakness and muscle atrophy (dry beriberi), and psychosis (Wernicke-Korsakoff syndrome) characterized by dementia, ataxia, and ophthalmoplegia. Lesions of the mamillary bodies and the area that abuts the third ventricle are distinctive findings (Rubin, 2005). The infantile form occurs in infants that are breastfed for months without supplementation. Cardiac failure in young infants may be sudden and rapidly fatal. Alcohol abuse in adults is often associated with deficiency, perhaps because alcohol interferes with thiamine uptake and metabolism. Thiamine deficiency is also seen in those with poor nutrition. No toxicity is described from high oral doses. Antithiamine factors are present in betel, tea, and some foods. In the United States, all breads and flours are enriched with thiamine. Significant loss of thiamine occurs when foods are cooked in water. Thiamine is unstable at high temperatures and is produced in the colon by normal enteric bacteria, but the contribution is apparently slight. Thiamine is absorbed throughout the small intestine and is bound to albumin in the plasma. At high thiamine intakes, the excess is excreted in the urine (Kohlmeier, 2003). Red blood cell transketolase activity with or without TPP added is a useful test for assessing thiamine deficiency. Heparinized whole blood is required, and the test is best run on a fresh specimen (Truswell, 2002a). The most reliable test for thiamine deficiency is the response to parenteral administration of thiamine (Rubin, 2005).

Riboflavin (Vitamin B₂)

Riboflavin normally forms two coenzymes: flavin mononucleotide and flavin adenine dinucleotide. These have an important role in electron

transport in several oxidative systems. Dietary sources include milk and dairy products, meat, poultry, fish, and green vegetables. Breads and cereals are fortified with riboflavin. Absorption occurs mostly in the jejunum. In humans, riboflavin is so prevalent in the diet that deficiency severe enough to cause marked debilities is not known. Mild riboflavin deficiencies are probably commonplace. Deficiency frequently occurs in association with lack of thiamine and/or niacin (Guyton, 1997). With prolonged deficiency, cracking and swelling of the lips (cheilosis), cracking and inflammation of the angles of the mouth (angular stomatitis), deep-red smooth tongue (glossitis, atrophy), greasy scaling of the cheeks and the areas behind the ears (seborrheic dermatitis), and normocytic anemia (Kohlmeier, 2003) may occur. Interstitial keratitis of the cornea, the most troubling lesion, results in corneal opacification and ulceration (Rubin, 2005). Deficiencies during infancy and childhood impair growth. There is little danger of toxicity because excess riboflavin is rapidly lost. 24-hour urine indicates recent riboflavin intake (Kohlmeier, 2003).

Niacin (Nicotinic Acid)

Niacin has a major role in the formation of nicotinamide adenine dinucleotide and its phosphate, which are important in intermediary metabolism and in a large number of oxidation–reduction reactions. Animal proteins are foods high in tryptophan such as meat, eggs, and milk. They are good sources for endogenously synthesized niacin. Urine is the main excretory path for niacin metabolites. Niacin is found in many grains. Deficiency causes pellagra, which is now uncommon but is seen these days in malnourished alcoholics and in food faddists who do not eat sufficient protein, are tryptophan deficient, and are not taking exogenous niacin. Malabsorption of tryptophan, as seen in Hartnup disease, or the carcinoid syndrome, in which tryptophan is consumed to make serotonin, may produce mild symptoms of pellagra. Pyridoxine and riboflavin deficiencies increase the requirement for niacin because they are both cofactors required for the synthesis of niacin. Corn is a poor source of tryptophan, and the niacin in corn is bound and poorly available. Pellagra is prevalent in areas where corn (maize) is the staple food, as in certain parts of Africa (Guyton, 1997).

Pellagra is characterized by dermatitis, diarrhea, dementia, and, if untreated, death. It occurs as scaly dermatitis of those areas exposed to light or pressure, such as the knees and elbows. The hands show a rough scaly dermatitis with a glove-like distribution, along with a pattern of hyperkeratosis, vascularization, and chronic inflammation. Similar lesions are seen in the mouth and the vaginal mucous membranes (Rubin, 2005). Excessive intake of niacin causes flushing (burning and itching of the face, chest, and arms) and gastric irritation. Liver damage may result from continued, very high doses. Niacin has been used as a cholesterol-lowering drug.

Pyridoxine (Vitamin B₆)

Pyridoxine is a coenzyme that participates in more than 100 transaminations, decarboxylations, and other reactions, including the initial steps of porphyrin synthesis, glycogen mobilization, amino acid transsulfuration, and neurotransmitter synthesis. Good food sources include fortified cereals, organ meats, muscle foods, potatoes, and fruits other than citrus. Cooking results in leaching of pyridoxine into the discard water. Urine is the major excretory pathway. Deficiencies are usually seen with other vitamin or protein deficiencies that occur in alcoholics (see Chapter 21). Deficiency of pyridoxine is uncommon and may cause a microcytic hypochromic anemia in which iron stores are saturated, epileptic seizures,

electroencephalographic abnormalities, depression, confusion, seborrheic dermatitis, and possibly platelet and clotting abnormalities. Several inborn errors of amino acid metabolism respond to very high doses of pyridoxine. Homocystinuria, which is associated with increased risk of cardiovascular disease, responds to supplements of folate, cobalamin, and sometimes pyridoxine. Tests include measurement of pyridoxal phosphate (normal >30 nmol/L); increased urinary xanthurenic acid after a tryptophan load; erythrocyte alanine aminotransferase; and urinary 4-pyridoxic acid (Truswell, 2002a). Very high doses of pyridoxine (>100 mg/day in adults) may cause a peripheral sensory neuropathy, possibly with skin lesions (Kohlmeier, 2003).

Cobalamin (Vitamin B₁₂)

Cobalamin is a complex cobalt-containing molecule, synthesized only by bacteria. It comprises several “vitamers”: cyanocobalamin and hydroxycobalamin are pharmacologic forms, whereas adenosylcobalamin and methylcobalamin are the main biological forms. The main known cofactor roles of cobalamin are in the synthesis of succinate from methylmalonate and the synthesis of methionine from homocysteine. Hence cobalamin deficiency results in increased levels of methylmalonate and homocysteine. Clinically, many manifestations of deficiency are similar to those of folate deficiency and can be overcome by large amounts of folate. These include impaired deoxyribonucleic acid (DNA) synthesis, which results in megaloblastic anemia. Cobalamin deficiency also causes neuropsychiatric damage, largely related to demyelination in the posterior columns of the spinal cord, peripheral nerves, and even the cerebrum. Neurologic damage is not relieved, and may even be worsened, by treatment with folate.

Absorption of cobalamin is unique in that it requires formation of a complex between it and a glycoprotein called **intrinsic factor**, secreted by the parietal cells of the stomach. The complex is then absorbed in the terminal ileum. Inadequate dietary intake is not the usual cause of cobalamin deficiency. Most common is malabsorption due to atrophy of the gastric mucosa, so that inadequate intrinsic factor or disease of the terminal ileum may prevent absorption. It is important to note that any disease affecting the gastric epithelium can cause diminution of intrinsic factor release. One of these diseases is gastric cancer. The onset of sudden, unexplained macrocytic anemia caused by decreased vitamin B₁₂ is therefore a serious finding in an adult and must be followed by appropriate examination of the stomach and the small bowel.

Normal body stores of cobalamin are sufficient to last for 3 to 6 years. Food sources include liver, shellfish, fish, meat, eggs, milk, cheeses, and yogurt. Vegans are at risk for cobalamin deficiency (Eastwood, 2003). Plasma cobalamin <80 pg/mL indicates a cobalamin deficiency. Elevated serum or urinary methylmalonate and raised plasma homocysteine also indicate that cobalamin is low. The classical Schilling test uses radiolabeled cobalamin to measure its absorption on different days, with and without intrinsic factor (West, 2002), but is not generally available today. Cobalamin has extremely low toxicity, and doses as large as 3 mg/day are tolerated without toxic effect. The average dietary intake of cobalamin is <1 µg/day (Eastwood, 2003).

Ascorbate (Vitamin C)

Ascorbate is a powerful reducing agent that is involved in many oxidation-reduction reactions and in the transfer of protons. Ascorbate participates in the synthesis of chondroitin sulfate and in formation of the hydroxyproline of collagen. It has an important role in wound healing, the biosynthesis of some neurotransmitters, and immune function (Rubin, 2005). It is essential for gums, arteries, and other soft tissues and bone (collagen synthesis), and for brain and nerve function (neurotransmitter and hormone synthesis), as well as for nutrient metabolism (especially iron, protein, and fat) and antioxidant defense and free-radical scavenging (directly and by vitamin E activation). Ascorbate is found in high concentrations in leukocytes, adrenal gland, pituitary, and brain. Food sources include citrus fruits, berries, tomatoes, and many fruits and vegetables. Prolonged storage and overcooking may cause significant vitamin loss. The RDA is 90 mg/day for men and 75 mg/day for women. Deficiency, termed scurvy, presents with symptoms of bleeding gums (if there are teeth), painful swollen joints, poor wound healing, confusion, fatigue, and diminished immune function. Now, scurvy is most often seen in alcoholics and in the aged poor living alone. The symptoms of scurvy have been described since antiquity. The disease was widespread among sailors in the 16th to 18th centuries, and the typical pattern consisted of bleeding gums, painful swollen joints, and muscle weakness. Onset occurred within months of the start of a voyage. British expeditions reported devastating losses of men due to scurvy. The carnage prompted the Admiralty to seek a cure, and in 1747, James Lind,

a Scottish surgeon, performed a clinical nutrition experiment on board ship to test six different diet supplements given to six pairs of scorbutic sailors. Oranges and lemons cured scurvy, which he described in his 1753 *Treatise of the Scurvy* (Jacob, 1994). Lind believed that scurvy was caused by dampness and crowding. Only subsequently was it understood that scurvy was due to ascorbate deficiency. Daily ingestion of 2000 mg or more may cause gastric and intestinal irritation or kidney stones, and may interfere with copper metabolism. Unlike other vertebrates, humans are not able to complete the synthesis of ascorbate (Kohlmeier, 2003). Testing to assess ascorbate status can be done using serum or leukocytes. Both correlate well with dietary intake. Urine assays tend to reflect recent dietary intake (Skeaff, 2002).

Folate

Folate is the generic name for compounds related to folic acid (pteroylglutamic acid). Like cobalamin, it plays a coenzyme role in one-carbon transfer reactions, and deficiency leads to impaired synthesis of purines and pyrimidines and hence of DNA (Guyton, 1997). It is widely available from plants and, to a lesser extent, organ meats. More than half of the folate content of food is lost during cooking. Deficiency may result in megaloblastic anemia, similar to vitamin B₁₂ deficiency, and leukopenia. In pregnancy, fetal neural tube defects are associated with low folate levels, and periconceptional supplementation has markedly reduced the incidence (Wildman, 2000).

Pantothenic Acid

Pantothenic acid is part of coenzyme A (CoA) and of acyl carrier protein (ACP). Both are carriers of acyl groups. Acetyl-CoA is involved in the tricarboxylic acid cycle, and CoA in the synthesis of lipids. Pantothenic acid is transported in erythrocytes as CoA. The highest tissue concentrations are found in liver, adrenals, kidneys, brain, heart, and testes. CoA and ACP are metabolized to free pantothenic acid and excreted in the urine. Urine levels indicate dietary intake and range from 2–7 mg/day. Pantothenic acid is widely present in foods, and dietary deficiency occurs only in severe malnutrition with other nutrient deficiencies. The **burning feet syndrome** that was seen in malnourished prisoners of war during World War II responded to large doses of Ca-pantothenate (Truswell, 2002a).

Biotin

Biotin is a coenzyme for several carboxylase enzymes: pyruvate carboxylase (provides oxaloacetate for tricarboxylic acid cycle), acetyl CoA (coenzyme A), and carboxylase (fatty acid synthesis). Biotin deficiency is rare because it is widely distributed in foods, and large intestine bacterial production supplements dietary intake. Avidin, an antivitamin, is found in uncooked egg white and can produce a deficiency of biotin when large amounts are ingested, because avidin binds biotin in the gut, preventing absorption. Biotin deficiency in humans has resulted from failure to include biotin in total parenteral nutrition; it is characterized by scaly dermatitis, glossitis, hair loss, anorexia, depression, and hypercholesterolemia (Truswell, 2002a).

FAT-SOLUBLE VITAMINS

Vitamin A (Retinol)

Vitamin A activity is derived from two compound classes: pre-formed vitamin A, retinol, and related compounds; and the precursors β-carotene and related carotenoids. The latter are the provitamins that are found in yellow and red vegetable pigments abundant in vegetables like carrots, and in some fruits. Retinol is the principal vitamin A vitamer. The term retinoids refers to retinol, its metabolites, and synthetic analogs with similar structure. Retinol is essential for vision at low light intensities, synthesis of **active sulfate**, and reproduction. Functions in which retinoic acid participates include cellular differentiation, involvement in morphogenesis, synthesis of glycoproteins, gene expression, immunity, growth, and prevention of cancer and heart disease (Semba, 1998; Truswell, 2002b). Vitamin A is needed to maintain certain specialized cell membranes, facilitate skeletal maturation, and participate in forming light-sensitive rods of the retina and the structure of cell membranes (IOM, 2002). Vitamin A deficiency is unusual in developed countries but continues to be a frequent cause of blindness due to corneal damage in the poorer regions of the world, particularly parts of Africa, the Middle East, and Southeast Asia. Retinol is present in high concentration in liver, and fish oil and leafy, green vegetables are rich sources of carotene (Rubin, 2005). Hippocrates (466–377 BCE) wrote that liver could cure night blindness (West, 2002). Vitamin A deficiency is seen when the diet has lacked dairy, produce, and

vegetables for a long time, or with malabsorption syndromes (Eastwood, 2003) and with steatorrhea, as in celiac disease, chronic pancreatitis, and Crohn's disease. Because hepatic accumulation of vitamin A occurs during the last trimester of pregnancy, preterm infants are relatively vitamin A deficient. Deficiency results in squamous metaplasia; as a result, the sweat and tear ducts are blocked by squamous debris. The epithelia of the trachea, bronchi, renal pelvis, pancreatic ducts, uterus, and salivary glands are often affected. The earliest sign of vitamin A deficiency is vision loss in dim light (night blindness). Liver disease diminishes retinol binding protein (RBP) synthesis, as does severe zinc deficiency. Zinc is required for the production of RBP, which transports vitamin A from the liver to body tissues.

Toxicity is usually produced by excessive vitamin A supplements, especially in children (IOM, 2001). Vitamin A toxicity occurred in explorers who ate polar bear livers, which have an exceptionally high concentration of vitamin A. In toxicity, the liver and spleen are enlarged with lipid-laden macrophages. Vitamin A is in the hepatocytes, and prolonged toxicity causes cirrhosis. Headache, hyperexcitability, and bone pain are early symptoms (Bendich, 1989). The lesions are most often reversible, early in the course, upon discontinuation of excessive dosing. High doses of synthetic derivatives of retinoic acid are teratogenic. Excessive carotene is benign and causes a jaundice-like discoloration of the skin (Rubin, 2005).

Circulating retinol concentrations do not consistently correlate with retinol total body stores. The relative dose-response test (Loerch, 1979) indirectly assesses the stores. Two blood samples are collected—one before and one 5 hours after a physiologic dose of vitamin A. In vitamin A-depleted subjects, a rapid sustained rise in serum retinol concentration occurs, compared with a lower, shallow rise in those who are vitamin A sufficient (Loerch, 1979).

Vitamin D (Cholecalciferol)

Vitamin D plays an essential role as a hormone in the control of calcium and phosphorus metabolism. Ultraviolet light exposure of the skin converts naturally occurring 7-dehydrocholesterol to cholecalciferol or vitamin D₃. Because the body can produce vitamin D, some have termed this a hormone. It is a vitamin for those who are mostly indoors, especially in Northern latitudes, as well as those whose clothing completely covers their skin, blocking sunlight. Cholecalciferol is diet-derived from animal sources, particularly fish liver and oils. Ergocalciferol, or vitamin D₂, which is of equal potency in humans, is derived from its provitamin ergosterol, which occurs in fungi and plants and is the major synthetic form used to fortify milk and margarine. Both vitamins D₂ and D₃ require two hydroxylations to the active form. The first is a 25-hydroxylation in the liver, and the second is a 1-hydroxylation in the kidneys. The resulting active vitamin D is called **1,25-dihydroxycholecalciferol** or **calcitriol**. Fortified foods (milk, orange juice, yogurt, margarine) provide most of the dietary vitamin D in the American diet. Vitamin D promotes absorption of calcium and phosphate from the small intestine (Truswell, 2002b). Deficiency results from an inadequate diet; insufficient sunlight reaching the skin; inadequate absorption as occurs in fat malabsorption syndromes; or failure of conversion to the active metabolite due to chronic hepatic or renal disease. In children, before the epiphyses have closed, the bone lesion syndrome is called **rickets**; in the adult, osteomalacia. The incidence has declined with the addition of ergosterol to milk and other foods (Rubin, 2005). The major function of vitamin D is the homeostasis of Ca⁺⁺ and phosphate (regulating intestinal adsorption), bone mineralization and mobilization, and renal excretion (Combs, 1998). Vitamin D is essential for promoting calcium absorption from the gut and for maintaining adequate serum calcium and phosphate concentrations to enable normal mineralization of bone and prevent hypocalcemic tetany. Sufficient vitamin D helps prevent rickets in children and osteomalacia in adults with calcium osteoporosis. Hypervitaminosis D is often due to ingestion of excessive vitamin D preparations. Abnormal conversion of active metabolites occurs sometimes in sarcoidosis. Hypervitaminosis D causes hypercalcemia. Early symptoms are weakness and headache. The sequelae of hypercalcemia include hypercalciuria, nephrocalcinosis, nephrolithiasis, and ectopic calcification of blood vessels, heart, and lungs (Rubin, 2005). Overexposure to ultraviolet light will result in sunburn of the skin but will not cause hypervitaminosis D. Plasma calcium and phosphate fall in vitamin D deficiency, and plasma alkaline phosphatase (bone isoenzyme) is increased in rickets and osteomalacia. As noted in Chapter 8, immunoassays for 25-hydroxy- and 1,25-dihydroxycholecalciferol are performed (Truswell, 2002b). However, because the half-life of the 1,25-dihydroxy vitamin D is brief (several hours) and the half-life of its 25-hydroxy vitamin D “parent” is much longer, most assays for vitamin D are used for the longer-lived

25-hydroxy vitamin D. As is also discussed in Chapter 8, vitamin D has now been implicated in a variety of important functions, in addition to calcium homeostasis. It induces apoptosis in breast cancer and in a variety of other malignancies and has been found to be effective in the treatment of a rather wide range of diseases such as heart failure, asthma, Crohn's disease, psoriasis, and multiple sclerosis. In view of these developments, monitoring of vitamin D serum levels has greatly increased over the past several years.

Vitamin E (Tocopherol)

This fat-soluble antioxidant, or free-radical scavenger, inactivates oxygen free-radicals. Eight naturally occurring forms have been identified. Vitamin E is the only known lipid-soluble antioxidant in plasma and red blood cell membranes. Fat-soluble antioxidant stops the production of reactive oxygen species formed when fat undergoes oxidation. The principal sources of vitamin E are oils and fats, particularly wheat germ oil and sunflower oil absorbed in the small intestine in the presence of bile. Deficiency is very uncommon but may occur as a result of malabsorption, in total parenteral nutrition, or in premature infants. Premature and low-birthweight infants are particularly susceptible to development of vitamin E deficiency. Signs of deficiency include irritability, edema, and hemolytic anemia. Vitamin E is necessary for neurologic and reproductive functions, for protecting red cells from hemolysis, and for prevention of retinopathy in premature infants (Brigelius-Flohe, 2002). The best defined role for vitamin E is inhibition of free-radical chain reactions of lipid peroxidation within polyunsaturated fatty acids of membrane phospholipids. No toxicity is known (Eastwood, 2003).

Vitamin K (Phytomenadione)

Vitamin K promotes clotting and is involved in the activation of important proteins in blood coagulation, prothrombin (II), factor VII, factor IX, and factor X, as well as protein C and protein S (see Chapter 42). Deficiency of the factors listed can result in defective clotting and a bleeding disorder. Prothrombin time (PT) functionally monitors vitamin K activity. Monitoring of vitamin K is discussed in Chapter 42. Vitamin K occurs in two forms. Vitamin K₁ is present in fresh green vegetables, for example, broccoli, cabbage, and spinach, and beef liver. Intestinal bacteria produce vitamin K₂. Dietary deficiency is uncommon. It does occur in fat malabsorption, as in sprue and biliary obstruction. Also, antibiotic sterilization of the intestinal flora may result in vitamin K deficiency. Use of high doses of naturally occurring vitamin K appears to have no untoward effect. No adverse effects are associated with vitamin K.

Because of low plasma concentration, vitamin K has been assessed by functional methods, using PT to determine its effect on clotting time.

TRACE ELEMENTS

Trace mineral elements consist of metals, except selenium, the halogens, fluoride, and iodine. Individually, these elements are found in tissue concentrations of <1 µg/g of wet tissue (Kane, 2005), and they constitute <0.01% of dry body weight (Gibson, 1990; Taylor, 1996). They were referred to as trace elements because quantitation using the analytic methods then available was not possible (O'Dell, 1997). Essential trace elements are those that result in impairment of normal health, function, or development when a deficiency is corrected by supplementation with physiologic levels of that element (Mertz, 1981a; Gibson, 1990). Trace elements have specific *in vivo* metabolic functions that cannot be effectively performed by other similar elements (Milne, 1994).

Various essential trace elements have been discovered by several different means. Deficiencies of some of these elements have been found in areas where the soil, water, or plants were inadequate in a specific element, such as iodine, fluorine, cobalt, or copper. Deficiencies were also identified when essential elements became biologically unavailable because of interference from other dietary ingestants, such as zinc deficiency, seen especially in males in the Middle East and in Hispanics in Denver, which results from eating unleavened bread high in phytate and is compounded by the high fiber content and low meat intake of their diets (Wildman, 2000) and the anemia of zinc-induced copper deficiency (Milne, 1994). Other deficiencies were caused by a mutation that resulted in the lack of a protein needed to absorb or metabolize the element. The symptoms of still other deficiencies were identified in patients on total parenteral nutrition not supplemented with an essential trace element (O'Dell, 1997).

Ten trace mineral elements have generally been recognized as essential in humans, as summarized in Table 26-3. Only copper, iodine, iron, selenium, and zinc are associated with well-characterized deficiency states

TABLE 26-3

Classification of Trace Mineral Elements

Essential in humans and animals	Essential in some animals and possibly in humans	Possibly essential in some animals	Not essential
Chromium	Arsenic	Bromine	Aluminum
Cobalt	Boron	Cadmium	Antimony
Copper	Lithium	Lead	Bismuth
Fluorine	Nickel	Strontium	Germanium
Iodine	Silicon	Tin	Mercury
Iron	Vanadium		Silver
Manganese			Thallium
Molybdenum			Titanium
Selenium			
Zinc			

Data from Gibson, 1990; O'Dell, 1997.

(Kane, 2005). A necessary biochemical role has not been conclusively demonstrated for fluorine or manganese, although signs of deficiency have been described (Mertz, 1981b). It is difficult to create a deficiency model because of the ubiquitous distribution of these elements in the environment and food supply, which frequently causes contamination of the testing system, and because only minute amounts are needed to support physiologic processes. It remains uncertain whether other trace mineral elements are essential in animals and humans. Some authors have concluded that arsenic, boron, lithium, nickel, silicon, and vanadium, which have been shown to have essential biochemical roles in some animal species, are presumptively essential in humans as well (Milne, 1994).

The roles of trace mineral elements include structural signal transduction and especially catalytic properties. These properties and the effects of deficiencies and toxicities of these trace elements are summarized in Tables 26-4 and 26-5. Some of the trace mineral elements are components of metalloenzymes, function as enzyme cofactors, provide electron and oxygen transport, and are active in the maintenance of macromolecule conformation, or vitamin and hormonal activity. These trace minerals are avidly accumulated by cells under the control of several families of proteins (Finney, 2003). Normally, homeostasis of these elements is tightly controlled. Only some of the biochemical mechanisms of the clinical effects of trace element deficiencies have been determined (Mertz, 1981b). Trace elements interact with available ligands, mainly the electron donors nitrogen, sulfur, and oxygen, to form a wide variety of compounds.

Deficiencies of trace elements are usually due to: nutritional deficiency; inadequate supplementation in total parenteral nutrition; or a disease state in which there is insufficient intestinal absorption, or increased excretion or utilization. Deficiencies can also be due to interactions between trace elements (e.g., zinc, copper) and with other nutrients (e.g., zinc, vitamin A), interfering with absorption or adversely affecting metabolic utilization. Large amounts of dietary zinc interfere with intestinal copper absorption, resulting in copper deficiency and anemia (Milne, 1994; Willis, 2005).

Genetic defects in trace element metabolism include Menkes' kinky hair syndrome (copper), congenital atransferrinemia (iron), acrodermatitis enteropathica (zinc), and xanthine and sulfite oxidase deficiencies (molybdenum) (Gibson, 1990).

Trace elements must be analyzed with considerable care because they are widely distributed in the environment (e.g., water, air), and the materials of biological devices (e.g., needles, syringes, stoppers) can readily contaminate a sample. Special collection and handling are necessary. Clean room techniques and ultra-pure reagents must be used. Reference materials and strict quality control are requisite with each assay run to ensure analytic accuracy. It is especially important that trained technical personnel perform the testing (Veillon, 1986). Improved materials are now available for collection, processing, and analysis of trace elements that reduce contamination. These include trace element-free syringes, evacuated tubes with fitted siliconized needles, acid-washed glassware, and standard reference materials with certified values (Casey, 1983; Gibson, 1990).

Major advances in understanding and managing the dynamics of trace mineral elements have been achieved during the past two decades by the extraordinary precision and sensitivity of the improved analytic instruments. Atomic absorption spectrometry (AAS) is the most widely used instrument for clinical trace element analysis in biological samples. Graphite furnace AAS has improved the limit of quantitation (LOQ) to parts per billion (ppb, $\mu\text{g/L}$) and permits the simultaneous measurement of multiple

elements. Zeeman effect background correction improves element signal measurement when testing in complex specimens such as serum, plasma or blood, and other specimen handling enhancements have further improved sensitivity and precision. Flame AAS (FAAS) has an LOQ of parts per million (ppm, mg/L). Atomic emission spectrometry consists of FAAS and plasma source emission spectrometry, which measures photon output rather than photon absorption, as in AAS, and is supplanting AAS as the standard instrument for analysis. The emission lines of excited electrons are measured. The LOQ is ppm (mg/L) (Rahil-Khazen, 2000). The sample in neutron activation analysis (NAA) is irradiated with low-energy neutrons for the production of radioactive nuclides. In NAA, there is excitation of the atomic nucleus, so that the trace element is determined independent of its physical or chemical state. The newly formed radionuclide emits X-rays or γ rays. The LOQ is ppb ($\mu\text{g/L}$) to parts per trillion (ppt, ng/L) with multielement detection, but with a limited dynamic range. This technique is especially suited for in vitro trace element determination in biological matrices. In instrumental neutron activation analysis, there is direct measurement of the emitted X-ray or γ radiation. Inductively coupled plasma-mass spectrometry (ICP-MS) is a highly sensitive and specific method for measurement of multiple trace elements in a single run over an especially broad dynamic range with low background interference and LOQs of ppb ($\mu\text{g/L}$) to ppt (ng/L). An internal standard is used for enhanced precision (Milne, 1994; Chan, 1998a).

Assessment of trace element status requires measurement of either the concentration in accessible tissues (hair, nails) and body fluids (serum, urine) or the activity of a trace element-dependent enzyme. There are no particularly good indicators for the determination of trace element dietary status because of poor correlation with total body stores. The only definitive test of human trace mineral element deficiency is the clinical response to controlled supplementation, with the element of concern followed by evaluation of improvement of an impaired function (Milne, 1994; Eastwood, 2003). Combination testing yields a more reliable interpretation, especially when the findings are concordant. Interpretation of plasma or serum levels can be deceptive because of the response to stress, or when expansion of blood volume or a decrease in serum albumin occurs, as, for example, in the third trimester of pregnancy. Also, hemolysis interferes with assays. Serum chromium, copper, manganese, molybdenum, and zinc levels are not reliable for assessing nutritional status or dietary intake because the results do not reflect body stores. Both serum and urine concentrations indicate recent dietary intake. Table 26-5 summarizes the primary tissue locations and metabolic properties of the major trace elements.

Hair and nail clippings should be collected with care and washed to avoid surface contamination.

Trace element assays in blood, serum, or urine usually reflect the current nutriture. The first morning void urine is less affected by recent dietary intake. Load tests measure the change in urine concentration following a loading dose of the mineral element. When tissue levels are low, the deficiency will cause retention of the element. Similarly, tolerance tests measure the change in plasma concentration following a challenge dose. Usually, the dose is in the pharmaceutical range rather than at the physiologic level normally experienced. Hair, fingernail, or toenail analyses provide a retrospective window or an assessment of chronic exposure for the period of hair or nail growth (Gibson, 2002). Because of the risk of environmental contamination, hair and nail clippings are of limited

TABLE 26-4

Function, Deficiency and Toxicity of Essential Trace Mineral Elements

Element	Function/enzyme component	Effects of deficiency	Effects of toxicity
Chromium (Cr)	Potentiates insulin action, glucose and lipid metabolism, Cr(III) low toxicity, poorly absorbed Component of glucose tolerance factor	No method to determine deficiency in humans; impaired glucose tolerance in type 2 diabetes, insulin resistance, hyperglycemia, peripheral neuropathy, hyperlipidemia	Cr(VI) toxic, oxidative damage, skin ulcers, contact dermatitis, asthma, renal and hepatic necrosis, lung cancer
Cobalt (Co)	Hemoglobin synthesis, Component of vitamin B ₁₂	Cobalt deficiency, as such, not in humans; symptoms due to lack of vitamin B ₁₂ : Anemia, anorexia, growth depression	Cardiomyopathy, heart failure, goiter, hypothyroidism; warm sensation, vomiting, diarrhea
Copper (Cu)	Cellular respiration, neurotransmitter regulator, oxidation reaction, electron transport, collagen synthesis, development of vascular and skeletal structures and CNS, antioxidant Component of CuZnSO ₄ , metallothionein, cytochrome c, tyrosinase, dopamine β-hydroxylase, lysyl oxidase	Menkes' kinky hair syndrome, X-linked, congenital failure of Cu absorption; abnormal collagen cross-linking, muscle weakness Iron refractory hypochromic anemia, leukopenia, neurologic defects, hypopigmentation. In prematurity: Bone fractures, skeletal defects Occurs in malnourished children and premature infants not supplemented	Relatively nontoxic Wilson disease: Autosomal recessive, failure to excrete Cu in bile: Excess Cu in liver, kidneys, brain, eyes, hepatic necrosis, hypertension, Kayser-Fleischer rings in eyes Cu interferes with absorption of iron and zinc
Fluorine (F)	Prevents tooth decay.	Increased dental caries	Mottled enamel, fluorosis
Iodine (I)	Component of thyroid hormone	Goiter, hypothyroidism, cretinism in infants, myxedema in adults	Goiter, thyrotoxicosis
Iron (Fe)	Oxygen transport, respiration, amino acids and free-radical metabolism, lipids, oxidative phosphorylation Component of hemoglobin, metalloenzymes, vitamin A	Hypochromic microcytic anemia, glossitis, angular stomatitis, cheilosis, koilonychia Blood loss or inadequate iron intake; iron deficiency anemia: <7 g/100 mL blood	Hemochromatosis: Genetic, primary, autosomal recessive; acquired, secondary, iron overload Iron deposition in liver, pancreas, heart, and skin
Manganese (Mn)	Bone and connective tissue Component of metalloenzymes: Hydrolases, oxidoreductases and lipases, pyruvate carboxylase, superoxide dismutase, and arginase	Not well defined in humans; skeletal and cartilage defects	Least toxic of trace elements Psychiatric disorders: Memory, speech, hallucinations; syndrome resembles Parkinson's and Wilson's diseases
Molybdenum (Mo)	DNA metabolism, essential for uric acid production Component of sulfite and xanthine oxidase	Naturally occurring deficiency not known, growth depression, hypercuprinemia, defective keratin form, goiter, cretinism	Anemia, goiter, thyrotoxicosis, hypouricemia, hyperoxypurinemia
Selenium (Se)	Protects against oxidative damage of lipid, gene expression, thyroxine deiodinase Component of glutathione peroxidase	Keshan disease: Cardiomyopathy, cardiomegaly, heart failure, cataracts, osteoarthritis in children, myopathy, discolored/thickened nails, impaired growth	Hair and nail loss, selenosis, tooth decay, neuropathy, liver failure, garlic odor on breath
Zinc (Zn)	Protein synthesis, zinc finger proteins—gene expression, immunity, needed for normal skin, bones, and hair Component of metallothionein ≈300 enzymes	Acrodermatitis enteropathica; causes cardiomyopathy in children In children, low height, hypogeusia, growth retardation, infertility, immune deficits, delayed wound healing, glossitis, seborrheic-like dermatitis, osteoporosis	Relatively nontoxic: Nausea, vomiting, and GI irritation; causes copper deficiency

Data from da Silva, 1991; Kane, 2005; Alcock, 1996.

CNS, Central nervous system; DNA, deoxyribonucleic acid; GI, gastrointestinal.

use in determining dietary intake or body status, except when reduced (Eastwood, 2003).

"All substances are poisons ... dose differentiates a poison."

Paracelsus (1493–1541)

Toxicity is never a question of presence, only of amount. Each of the essential and nonessential trace mineral elements can be toxic when present in high concentrations. A poison is too much of anything. Toxicity is quite variable for the different trace elements. Some have a high toxicity. The toxic effects of selenium are produced by intake of only 10 times the nutritional requirement. In contrast, chromium toxicity has never been reported after oral pharmacologic doses (Gibson, 1990).

CHROMIUM

Chromium (Cr) is known to enhance the action of insulin (Mertz, 1998). Absorption of chromium from the intestine is low. Chromium sources include meats, whole grains, green beans, broccoli, and some spices. After absorption, chromium binds to plasma transferrin and then concentrates in liver, spleen, heart, other soft tissues, and bone. Clinical signs of chromium

deficiency were first described in patients receiving parenteral nutrition. Only a few cases have been reported in which absence of chromium was associated with insulin resistance, glucose intolerance, weight loss, and sometimes neurologic deficits that were reversed on chromium supplementation. Chromium depletion is thought to be associated with increased cardiovascular risk, and supplementation has demonstrated increased high-density lipoprotein cholesterol and decreased insulin.

Hexavalent chromium Cr⁶⁺ is a recognized carcinogen. Industrial exposure to metal fumes and dust is associated with lung cancer, dermatitis, and skin ulcers. Health risks are caused by soil contamination by Cr⁶⁺ waste disposal sites left by the leather tanning and dyestuff industries. Chromium is used extensively in the manufacture of stainless steel, in chrome plating, in tanning of leather, as a dye for printing, and as an anticorrosive in cooling systems. Air monitoring for Cr⁶⁺ is the usual way to test. Increased chromium in urine serves as confirmation of recent occupational or environmental exposure to excess chromium (Halls, 1988).

COBALT

Cobalt (Co) is essential for humans only as an integral part of vitamin B₁₂ (cobalamin). Cobalt has no other known function in humans. Diet has to

TABLE 26-5
Properties of Essential Trace Mineral Elements

Element	Tissue distribution	Body content	Transport (reference value)	Excretion
Chromium (Cr)	Spleen, heart	4–6 mg Cr(III)	Transferrin-P 0.15 µg/mL Cr (0.12–2.1 µg/L)	Urine 100–200 ng/day
Cobalt	Muscle, liver, fat	1.1 mg	Albumin (0.11–0.45 µg/L)	Urine 80%
Copper (Cu)	Muscle and liver Liver 30–50 µg/g dry; 50%–70% of body Cu	50–80 mg (1.2–2.5 µg/g fat-free tissue)	Ceruloplasmin 60%–95%, albumin, transcuperin (Cu-S 70–140 µg/dL)	Feces includes bile and unabsorbed dietary Cu
Iodine (I)	Thyroid: 70%–80% of total body I in thyroxine bound to thyroglobulin	15–20 mg (11–15 mg in thyroid)	Thyroxine-binding protein 80% thyroxine-binding prealbumin (transthyretin)	Urine 100–150 µg/day
Iron (Fe)	RBC Hb 400–600 mg/L, liver, spleen, bone marrow 25%, myoglobin	4–5 g (¾ in Hb) 50 mg/kg 2.5 g in RBCs	Transferrin-P (2–2.5 g/L) Ferritin-S 1 µg/L = 10 mg tissue iron stores Hemosiderin 1 g iron	Bile 84 µg/kg, blood loss, menses, GI mucosal cells
Manganese (Mn)	Liver, bone, pancreas	12–20 mg	Mn-Blood 200 nmol/L	Bile and intestinal secretions
Molybdenum (Mo)	Liver, kidney, bone, adrenal	Blood 30–700 nmol/L	RBC protein, α-1-macroglobulin (S: 8–34 µg/L)	Urine 90%, bile 10%
Selenium (Se)	Liver, kidney, muscle	15 mg	Protein (Se-P: 7–30 µg/dL)	Urine 60%, feces 40%
Zinc (Zn)	Muscle 60%, bone 30%, liver, prostate, semen	1.2–2.3 g	Albumin 60%–70%, α-2-macroglobulin (Zn-P 11–22 µmol/L)	Feces, gut secretions, GI mucosal cells

Data from da Silva, 1991; Milne, 1994; O'Dell, 1997; Kohlmeier, 2003. *GI*, Gastrointestinal; *Hb*, hemoglobin; *RBC*, red blood cell.

supply human vitamin B₁₂ needs. The microflora of the human intestine is not able to use cobalt to synthesize cobalamin; free cobalt does not interact with the body's vitamin B₁₂ pool.

COPPER

Copper (Cu) is the third most abundant trace element in the human body, following zinc and iron. It is a very effective cation in reactions that involve electron transfer and binding to organic molecules (Samman, 2002). Copper is involved in electron transport and oxidation reactions and is essential for cellular respiration, neurotransmitter regulation, collagen synthesis, and nutrient metabolism, especially iron, and as an antioxidant against free radicals (Kohlmeier, 2003). Copper is present in all living cells (Marston, 1992) and functions mostly as a component of the cuproenzymes and copper-containing proteins. Copper-containing plasma amine oxidases catabolize some active amines such as tyramine, histidine, and polyamines, and inactivate the catecholamines (norepinephrine, tyramine, dopamine, and serotonin). Another cuproenzyme, **lysyl oxidase**, helps collagen proteins cross-link into larger fibers. This enzyme, which is encoded by the *ras*-recision gene (*rrg*), has also been found to have anticancer activity caused by its ability to block insertion of the *ras*-gene-encoded p21 protein into the cell membrane (Krzyzosiak, 1992).

Also, copper is a component of **cytochrome c oxidase**, which catalyzes the cellular utilization of oxygen (Wildman, 2000). Extracellular **superoxide dismutase** is present in high concentration in the lungs, thyroid, and uterus. Copper/zinc dismutases are in the cytosol of most cells, especially brain, thyroid, liver, pituitary, and erythrocytes. Both dismutases scavenge and reduce superoxide radicals. Copper-containing proteins include ceruloplasmin, albumin, and transcuperin, which transport copper; metallothionein, which sequesters and stores copper; and clotting factor V (Chan, 1998b).

Rich sources of copper include liver, shellfish, chocolate, nuts, and seeds. Copper pipes or vessels do not increase the copper content of water unless exposed to acids (Kohlmeier, 2003). The average daily copper intake of American adults is about 1.6 mg in males and 1.2 mg in females. Adults should get at least 0.9 mg/day (IOM, 2002). Smoking, strenuous exercise, infection, and injury increase the need for copper.

Copper absorption occurs in the stomach, especially in the small intestine (Wapnir, 1998). Bile adds about 5 mg/day to ingested copper. Absorption is decreased by excessive zinc or iron intake. Too much copper may cause iron deficiency. Histidine, as well as gluconate and citrate enhances copper absorption (Wildman, 2000). Ascorbate decreases copper absorption by reducing Cu⁺⁺ to Cu⁺ (Kohlmeier, 2003).

Newly absorbed copper is transported bound to albumin and transcuperin and is rapidly cleared from the blood circulation by the liver. When copper reenters the circulation, it is bound to ceruloplasmin, which transports 65%–90% of the plasma copper, and metallothionein and other

copper-containing proteins. Ceruloplasmin is not a transporter protein in that the copper is not exchangeable (Eastwood, 2003). Metallochaperones are specific binding proteins that provide targeted intracellular copper transport to shuttle copper for metabolic needs (Kohlmeier, 2003). Excess copper is bound to thionein, decreasing the potential for copper toxicity (Wildman, 2000). Free copper ions are a source of oxygen free-radicals, and intracellular free copper is kept at a very low concentration.

Total copper in an adult human measures 50–80 mg, mainly concentrated in muscle and liver. The liver has the highest copper concentration, averaging between 30 and 50 µg/g dry tissue. Reference ranges for serum copper concentration are age and sex dependent and are higher in pregnancy. Diurnal variation occurs with peak values in the morning. Copper as measured by ICP-MS is as follows: women: 49–184 µg/dL (7.7–29.0 µmol/L); men: 59–118 µg/dL (9.3–18.6 µmol/L) (Chan, 1998b). The most widely used clinical analytic method is FAAS. Serum and plasma copper levels are insensitive to the diagnosis of copper deficiency and are decreased only in severe deficiency (Gibson, 2002). Lower concentrations may indicate depleted copper stores. However, circulating copper levels are affected by factors unrelated to nutrition. Pregnancy, infection, inflammatory conditions, stress, and oral contraception increase the circulating copper level. Corticosteroids and corticotropin lower the circulating copper level (Jacob, 1993). Reduced serum proteins due to nephrosis, malabsorption, and malnutrition cause the serum copper to be low, without reflecting inadequate liver copper stores. Ceruloplasmin, a copper-containing protein, is a useful indicator of copper status. It is an α-2-globulin acute phase reactant. Ceruloplasmin is sensitive to the same factors that affect plasma copper and may be measured immunochemically or by its oxidase activity (Milne, 1994). It is increased in patients with infection, neoplasm, pregnancy, or hormonal contraception (Kohlmeier, 2003). Measurement of erythrocyte superoxide dismutase is useful for assessing copper status. The activity is reduced in copper-deficient states.

Excretion occurs primarily in the feces, which include unabsorbed dietary copper, and in biliary and gastrointestinal secretions, although small amounts are also lost in sweat, urine, and saliva.

Menkes' syndrome and Wilson's disease are genetic defects in copper metabolism. **Menkes' syndrome** is a rare X-linked recessive congenital defect of copper absorption that usually has clinical onset by 3 months of age. The condition is characterized by poor mental development, failure to keratinize hair, skeletal problems, and degenerative changes in the aorta. The brittle hair (steely) is kinky or twisted, and poor skin and hair pigmentation, hypothermia, and seizures have been reported. Hair resembles wool from sheep that graze in pastures lacking copper. Affected infants are copper deficient with decreased serum and liver copper. Red blood cell copper is normal (Wildman, 2000).

Wilson's disease (hepatolenticular degeneration) is an autosomal recessive disease that results from impaired biliary copper excretion. It presents in children and young adults between the ages of 6 and 40 years.

Excess copper is deposited in the liver and in the basal nuclei of the brain, causing sclerosis, and abnormalities of kidney, cornea, and brain may occur. Most often, the presenting disease pattern is that of acute, chronic, or fulminant hepatitis. Symptoms include neurologic disorders, cirrhosis of the liver, and Kayser-Fleischer rings caused by deposition of copper in the corneas. Urinary copper is increased to $>100 \mu\text{g}/24$ hours, and serum ceruloplasmin is usually decreased. Clinical severity of the disease correlates poorly with the ceruloplasmin level, because ceruloplasmin may be normal or increased in response to hepatic inflammation. Serum copper is generally decreased because of the low ceruloplasmin, and serum copper levels are not useful diagnostically. Serum ceruloplasmin $<20 \text{ mg/dL}$ with increased hepatic copper of $>250 \mu\text{g/g}$ dry weight is diagnostic. Chelation is an effective treatment in promoting excretion of the copper (Milne, 1994).

Deficiency is unlikely except in people with rare genetic disorders or prolonged malnutrition or starvation. Deficiencies have been observed in premature babies, patients with malabsorption syndromes (celiac disease, tropical sprue, cystic fibrosis), malnourished infants and adults, those with long-term hyperalimentation with infusates deficient in copper, patients with sickle cell disease receiving zinc therapy, and those treated with copper-chelating agents like penicillamine (Milne, 1994). Excessive intake of oral zinc supplements causes induction of metallothionein in the intestinal mucosa, which then sequesters dietary copper, blocking absorption (Gyorffy, 1992; Igic, 2002). Reduced copper levels have been found in elderly patients with femoral neck fractures (Conlan, 1990). Symptoms of copper deficiency include hypochromic anemia, ataxia, neutropenia, osteoporosis and bone and joint abnormalities, decreased skin pigmentation, and neurologic abnormalities. Body stores last only a few weeks when intake is low.

Copper toxicity from food intake has not been reported. Doses in excess of 10 mg/day cause nausea, vomiting, abdominal cramps, and diarrhea, and can cause liver injury, especially in infants. Acute poisoning may present with hemolysis and brain and hepatic cellular damage (Eastwood, 2003). Higher doses can cause coma and death. Excess supplements and ingestion of contaminated water are the usual sources. Ingestion of fungicides containing copper sulfate or industrial exposure sometimes causes acute copper poisoning.

FLUORIDE

Fluoride (F^-) is used to prevent dental caries. Fluoridation of drinking water reduces the incidence of tooth decay now for more than 60% of the U.S. population and reduces the incidence of tooth decay by more than 60%. Dental fluorosis, the unsightly mottling of dental enamel, is seen in erupting teeth of children and is caused by excessive fluoride possibly from ingestion of fluoride-containing toothpaste. Occupational exposure to inhaled fluoride dust during aluminum refining causes severe bone abnormalities; safety equipment now limits such exposure. No cases are attributable to the controlled fluoridation of water supplies. A fluoride-specific electrode is used for water and urine analysis.

IODINE

Dietary iodine (I) is normally ingested as iodide and is the basic element in the synthesis of thyroid hormones, as described in detail in Chapter 24. It is transported to the thyroid follicles, where it is trapped and concentrated to several hundred-fold over its concentration in serum. The gland is stimulated by the pituitary hormone, thyroid-stimulating hormone, to incorporate iodide into tyrosine to form thyronines within the thyroglobulin in the follicular lumen. Proteolytic cleavage of thyroglobulin releases the iodothyronine hormones into the circulation. A tightly controlled feedback system between the thyroid, the hypothalamus, and the pituitary maintains the thyroid hormone concentration within physiologic limits.

Deficiency results in inadequate thyroid hormone and hypothyroidism. Depending on the patient's age, congenital hypothyroidism can cause mental retardation, cretinism, myxedema hypothyroidism in adults with mental status changes, and hypotension. Often, patients develop a goiter.

IRON

Body iron (Fe) is present in hemoglobin, myoglobin, storage iron, and tissue iron. Iron is stored as ferritin and hemosiderin. Normally, very small amounts of iron are present in most cells and in body fluids. No excretory system is used for excess iron. Rather, rigorous conservation of iron occurs. Ferritin is present in nearly all cells in the body. In hepatocytes and macrophages of the marrow, ferritin provides a reserve of iron for the

formation of hemoglobin and other heme proteins. Hemosiderin is formed when ferritin is broken down. Iron is transported from one organ to another by the transport protein apotransferrin.

MANGANESE

Manganese (Mn) is associated with the formation of connective and bony tissue and carbohydrate and lipid metabolism. Food sources include whole grain foods, nuts, leafy vegetables, soy, and teas. Manganese is absorbed from the small intestines and transported to the liver, bound to albumin. Excretion occurs via bile into feces. Manganese is a constituent of many important metalloenzymes, including superoxide dismutase, pyruvate carboxylase, arginase, and glycosyl transferases. On a normal diet, deficiency has not been documented. Diet deficiency results in low plasma cholesterol, impaired glucose tolerance, skeletal abnormalities, dermatitis, color changes in hair, and reduced blood-clotting function not responsive to vitamin K.

Toxic exposure to manganese-containing dust produces neurologic symptoms resembling Parkinson's disease. Manganese deposition in the brain is seen with biliary atresia in children. Serum manganese and brain magnetic resonance imaging are used to detect excessive exposure. Plastic cannulas prevent sample contamination.

MOLYBDENUM

Molybdenum (Mo) is incorporated into metalloenzymes and several important enzymes, including sulfite oxidase and xanthine dehydrogenase. Grains, nuts, and legumes such as peas, lentils, and beans are good sources. Renal homeostatic regulation occurs, and urine output directly reflects dietary intake. Deficiency has not been observed in healthy people on a normal diet. Evidence suggests that for most patients, sufficient molybdenum acts as a contaminant in total parenteral nutrition fluids. A diagnosis of molybdenum deficiency is based on demonstration of excess sulfite in the urine. Molybdenum compounds have low toxicity in humans. Excess intake induces copper deficiency, blocking copper absorption.

SELENIUM

Selenium (Se) is a constituent of glutathione peroxidase that is associated with vitamin E in its functions. It is a nonmetal and is important in defense against oxidative stress and regulation of thyroid hormone action. Deficiency in pediatric patients can cause endemic cardiomyopathy (Keshan disease) in areas with low soil selenium level, as well as skeletal muscle disorders with proximal weakness and serum creatinine elevation. Immunodeficiency can result from selenoprotein deficiency. Toxicity from selenium includes hair loss, garlic breath, irritability, mild nerve damage, and nail damage. Whole blood selenium can be quantitated by CFAAS.

ZINC

Zinc (Zn) is second to iron as the most abundant trace element in the body. It is the most common catalytic metal ion in the cytoplasm of cells. Total body stores of zinc in adult women are 1.5 g and in men 2.5 g , which is distributed in all tissues. It is almost entirely intracellular (King, 1994). Most zinc is found in skeletal muscle ($\approx 60\%$) and in bone ($\approx 30\%$) (Wildman, 2000). It is a cofactor for almost 300 enzymes and is involved in almost all aspects of metabolism. Zinc is important in protein and nucleic acid synthesis, and is essential for gene activation (Kohlmeier, 2003) and for the synthesis and action of insulin (Samman, 2002). Zinc is present only in the divalent state in biological systems, and oxidation-reduction functions are not possible. Important zinc-containing metalloenzymes include carbonic anhydrase, alkaline phosphatase, RNA and DNA polymerases, reverse transcriptase, thymidine kinase, carboxypeptidases, alcohol dehydrogenase, and superoxide dismutase.

Zinc is ubiquitous in food. Oysters are especially rich in zinc. Other shellfish and meats are also good sources. Plants have much lower concentrations. Phytate from whole grains and some vegetables interferes with zinc absorption (Kohlmeier, 2003). The estimated average requirement to maintain adequate stores is 8 mg/day for women eating a mixed diet and 11 mg/day for men (IOM, 2002). Vegetarians and pregnant or nursing woman need slightly more. Zinc is excreted primarily by the intestine.

Zinc is absorbed mainly from the duodenum, although some is absorbed from the small intestine. Some zinc enters the intestinal lumen with pancreatic secretions. Intraluminal digestion by proteases, DNases, and

RNases frees zinc so that complexes with histidine, cysteine, and nucleotides that improve absorption are formed. Phytate reduces absorption. High dietary calcium and low protein also reduce zinc absorption (Samman, 2002). Metallothionein regulates zinc transfer into the portal blood. In blood, zinc is bound to albumin and α -2-macroglobulin, with zinc blood concentrations of 10–17 $\mu\text{mol/L}$.

Muscle and bone, which contain most of the body's zinc stores, have a slow turnover and a half-life of 300 days (Wastney, 2000). The half-life of metallothionein-bound zinc in the liver is about 2 weeks; it can be readily mobilized to cover for an insufficient dietary intake. However, the liver pool is small and contains less than 170 mg. Zinc deficiency can become functionally significant within a week (Milne, 1994).

Almost all blood zinc is complexed to the large proteins, albumin and α -2-macroglobulin, so that little zinc is present in the glomerular filtrate. Urine losses total about 0.5 mg/day (Kohlmeier, 2003). About 1 mg/day is lost in sweat, skin, and hair. Fecal losses, which include diet and endogenous secretions, can be less than 1 mg/day (Sian, 1996). Each ejaculate contains about 0.5 mg, probably from prostatic secretions.

Inadequate zinc impairs DNA replication, food digestion and absorption, taste and appetite, growth and wound healing, synaptic transmission, gene expression, response to oxidant stress, immune function, and other functions.

Zinc fingers are looped sequence-specific DNA-binding proteins that act as transcriptional mediators for nucleic acids. Zinc chelates with cysteine and/or histidine that bind to a specific DNA region and control gene expression or repression, primarily by targeting promoter regions of the genes (Wildman, 2000).

Zinc deficiency is common in patients with diabetes mellitus, alcohol abuse, and malabsorption syndromes, as well as liver and kidney diseases. Symptoms are general because of the many enzymes and tissues affected. Severe deficiencies are characterized by hypogonadism, dwarfism, deformed bones, poor wound healing, abnormal hair and nails, loss of taste, gastrointestinal disturbances, poor chylomicron formation, central nervous system abnormalities, immunodeficiencies, and malabsorption. Zinc deficiency may cause teratogenicity during pregnancy, with congenital malformations, fetal dysmaturity, prematurity, neural tube defects, and spina bifida (Chan, 1998).

Nutritional zinc deficiency is fairly prevalent despite the wide availability of zinc in foods. Zinc deficiency produces a syndrome of growth retardation, male hypogonadism, skin changes, mental lethargy, hepatosplenomegaly, iron deficiency anemia, and geophagia (eating clay). It has been encountered most often in male children in Iran and Egypt as a result of a low-zinc diet and a high fiber content that decrease available zinc for absorption. Zinc deficiency has been reported from Turkey, Portugal, Morocco, and Yugoslavia (Milne, 1994). In some areas of the Middle East, people frequently eat unleavened bread that is high in phytate. Yeast contains phytase. However, the recipe for the dough of the unleavened bread does not include yeast. The high fiber content and the low meat and low protein intakes in this population result in zinc deficiency. Individuals respond well to dietary zinc sulfate supplementation (Eastwood, 2003). Growth failure, reduced taste acuity, and hypogonadism in young adults in New York and Tennessee and in school children in Colorado have been ascribed to zinc deficiency (Milne, 1994). Zinc deficiency has also been reported in old age, pregnancy, lactation, steatorrhea, extensive burns, renal disease, and diuretic and antimetabolite therapies. Zinc deficiency in alcoholic and cirrhotic individuals leads to low serum zinc concentrations and increased urinary excretion (Eastwood, 2003).

Acrodermatitis enteropathica is a rare autosomal recessive disorder with impaired intestinal absorption and transport of zinc. Symptoms

include hyperpigmented skin lesions, pustular and bullous dermatitis, alopecia, growth retardation, diarrhea, secondary infection, irritability, lethargy, and depression. Plasma or serum zinc is below 40 $\mu\text{g/mL}$. Oral zinc therapy results in rapid and complete remission (Chan, 1998b).

A case of zinc deficiency called **acquired acrodermatitis enteropathica** was reported in a 41-year-old woman with alcohol abuse and type 1 diabetes mellitus, complicated by retinopathy, nephropathy, and end-stage renal disease. The case included a 5-month history of alopecia, brittle scalp hair, diarrhea, angular cheilitis, and a pruritic, scaly erythematous eruption involving the extremities, perineum, and buttocks. A skin biopsy disclosed confluent parakeratosis with absence of the granular layer. Serum zinc levels were markedly reduced at 0.35 $\mu\text{g/mL}$ (normal, 0.66–1.10 $\mu\text{g/mL}$) 5.4 $\mu\text{mol/L}$ (normal, 10.1–16.8 $\mu\text{mol/L}$). Oral zinc sulfate resolved her diarrhea and her skin eruption cleared and hair began to regrow (Wang, 2005).

Zinc toxicity is rare in humans. Animals given high levels of supplementation manifest dysphagia. Other effects, like weight loss, are attributed to reduced food intake. Inhalation of zinc oxide fumes is the most common cause of metal fume fever. Symptoms are of a flu-like illness with onset 4 to 6 hours after exposure to the fumes. Fatigue, chills, myalgias, cough, dyspnea, leukocytosis, thirst, metallic taste, and salivation characterize this self-limited illness, with resolution of symptoms in 36 hours.

No single test is definitive for the status of zinc stores. Two groups of tests are available: Analysis of zinc in a body tissue or body fluid, such as plasma, serum, blood cells, or urine; and testing of a zinc-dependent function, such as taste acuity, or measurement of the activity of zinc-containing enzymes. In most instances, assays will show a decrease with zinc deficiency. Test results should be interpreted with caution because levels may be affected by unrelated conditions. Diurnal variation in zinc levels has been noted. Zinc levels decrease after meals and are elevated after fasting. Albumin levels significantly affect the circulating zinc level. Also, many steroids, including adrenocortical and gonadal, depress the zinc level. Erythrocyte levels are 10 times that of serum, and hemolysis is a serious problem affecting the usefulness of the results.

FAAS is the method of choice for clinical testing for zinc in body fluids. ICP-MS is the reference testing method used for zinc testing in serum or plasma.

The zinc plasma level reference range is around 70–120 $\mu\text{g/dL}$ (10.7–18.4 $\mu\text{mol/L}$), of which a third is bound to α -2-macroglobulin and the rest to albumin. Ten percent to 20% of blood zinc is present in the plasma. The remainder is associated with carbonic anhydrase in the erythrocytes. Hemolysis must be avoided. Fasting morning levels of zinc below 70 $\mu\text{g/dL}$ (10.7 $\mu\text{mol/L}$) suggest marginal deficiency. Serum zinc values are 5%–10% higher than in plasma. Zinc levels are lower in nonfasting states, infection, inflammation, steroid administration, pregnancy, and hypoalbuminemia.

Zinc in erythrocytes and hair provides a long-term assessment of body zinc status. Lowered hair zinc has been demonstrated in several different zinc-deficient conditions. Care must be taken to avoid environmental contamination and to sample hair grown during the condition under study—not during the previous time period (Milne, 1994). Urinary zinc excretion reference values are around 0.15–1.00 mg/day (2.3–15.3 $\mu\text{mol/day}$). Urinary zinc excretion is usually decreased in zinc deficiency. In some conditions associated with zinc deficiency, such as cirrhosis, severe alcoholism, sickle cell anemia, postsurgical periods, and total parenteral nutrition, urinary zinc excretion is often increased (Jacob, 1993).

Hyperzincaemia is a familial disorder that results in elevated serum zinc levels but does not cause any apparent toxicity. In contrast, zinc overdoses that result in similar plasma zinc levels have been known to be fatal (Wildman, 2000).

KEY POINTS

- The clinical chemistry metabolic profile gives important quantitative information for more than 25 serum analytes, often facilitating diagnosis of disease.
- Serum electrolyte concentrations for sodium, potassium, chloride, and sometimes calcium are most commonly assayed using ion-selective electrodes.
- Assays for other analytes, including total protein, albumin, bilirubin, creatinine, calcium, iron and iron-binding capacity, magnesium, and phosphate, are performed using spectrophotometry on complexes that are formed by each analyte with simple reagents. These complexes absorb light at wavelengths at which the analyte itself and the reagent have minimal absorbance. The concentration of the analyte is determined using Beer's Law.
- Assays for a number of serum analytes, including ammonia, bicarbonate, cholesterol, glucose, lactate, triglycerides, and urea and uric acid, utilize enzymes that catalyze reactions in which the analytes are converted into products whose concentrations can be measured conveniently.
- Spectrophotometric assays can be performed by waiting for the point at which the increase or decrease in absorbance of a complex at a particular wavelength ceases to change (endpoint method) or by determining the initial rates of complex formation (rate method).
- Assays for specific enzymes are performed using substrates that are specific for these enzymes. Concentrations of the products of the enzyme-catalyzed reactions are determined spectrophotometrically as described in Chapter 20, allowing for direct determination of enzyme activity.
- Often, the products of enzyme-catalyzed reactions are measured in coupled reactions in which the product of the enzyme-catalyzed reaction is the substrate for another enzyme added at high concentration, allowing for the rapid conversion of the product of the first reaction to another product whose concentration can be easily determined.

In many of the preceding chapters, we have discussed the chemical bases for the assays employed for the diagnosis of specific diseases. In this chapter, we present a consolidation of the methods used in the typical so-called **metabolic panel** in clinical chemistry, a panoply of chemical assays that are often requested for patients who are undergoing outpatient annual checkups or are being admitted to the hospital. We summarize and discuss the chemical bases for these assays in a concise manner, so that the reader can refer to these methods conveniently and can understand the assays and their limitations. Understanding of the assays contributes to an understanding of why certain substances interfere with particular assays and can give rise to misleading results. It should be kept in mind that, for many of the assays described here, more than one method can be used. Because it is impossible to cover all variations of methods used to quantitate each analyte, we describe the principles that underlie commonly employed methods and refer, where possible, to alternate approaches.

Metabolic panels consist of serum electrolytes (sodium, potassium, and chloride), bicarbonate, calcium, phosphate, magnesium, urea, creatinine, glucose, uric acid, total protein, albumin, total and direct bilirubin, cholesterol, high-density lipoprotein (HDL) and low-density lipoprotein (LDL), triglycerides, ammonia, iron and iron-binding capacity, and the enzymes, including: creatine kinase, aspartate aminotransferase, alanine aminotransferase (ALT), alkaline phosphatase, lactate dehydrogenase (LD), γ -glutamyl transferase (GGT), amylase, and lipase. The reader may recognize various panels that measure the functioning of specific tissues such as kidney (i.e., the renal **profile**, consisting of urea, creatinine, calcium, and phosphate). These panels are of great use in diagnosing disease states, as discussed in Chapter 8.

We divide the basic assays for these analytes functionally into four method-based groups:

1. Ion-selective electrodes.
2. Spectrophotometric assays based on color complexes for specific molecules (e.g., the color noncovalent complex of albumin with bromocresol green dye and bilirubin covalently reacted with diazotized sulfanilic acid to give azo-derivatized forms of the indole rings of bilirubin).

3. Analyte concentrations using enzymes as reagents. In Chapter 20, we discussed how small molecule substrates are used to determine serum enzyme concentrations. In a similar manner, this process can be reversed; enzymes can be used to determine the concentrations of small or large molecules (like proteins). If an analyte is a specific substrate for an enzyme, and if formation of the product or disappearance of the substrate can be conveniently followed, this method can be used effectively.
4. Enzyme assays (i.e., use of substrates to determine enzyme concentrations), as described in Chapter 20. Almost all of these assays are also based on spectrophotometric measurements, which depend on the substrates used in the assays and, in many cases, the need for the use of indicator enzymes in so-called **coupled reactions**.

ION-SELECTIVE ELECTRODES

As explained in Chapter 4, this technique is used to measure the concentrations of specific ions by an electrochemical method. This method is non-specific in that it does not discriminate between ions in causing voltage differences between the measuring electrode and the standard electrode. It is the presence of an ion perm-selective membrane barrier on the measuring electrode that allows only a specific ion to pass through permitting contact with the measuring electrode. Each ion requires a different material that will be selectively permeable to this ion and to this ion only. Thus glass is perm-selective to hydrogen ion. A special polymer of the poly-amino acid antibiotic valinomycin is perm-selective to potassium ions. A polymer resin of polyvinylchloride (PVC) is perm-selective to sodium ions. Recently, an anodized indium tin oxide membrane has been found to be even more perm-selective to sodium ions (Lin, 2010). Similarly, calcium-chelating organic molecules impregnated into PVC membranes serve as perm-selective membranes for calcium ions. In addition, dioctylphenyl phosphates, as shown in Figure 27-1, C, have been found to chelate calcium ions selectively and to serve as effective ion-selective electrodes.

Three basic causes of malfunctions of ion-selective electrodes have been identified. The first and most common consists of defects in the perm-selective membrane itself. This allows ions other than the one whose concentration is being measured to be present at the measuring electrode. The result is seen as ion concentrations that are falsely elevated. This defect is almost always detected in routine quality control

that shows a strong upward drift in the controls despite frequent calibrations.

The second cause of inaccuracy in ion-selective electrodes is buildup of countervoltages from liquid junction potentials present at the salt bridge connecting the measuring electrode with the reference electrode. Because these voltages oppose the voltage between the two electrodes, the voltages are diminished, yielding lower than expected ion concentrations. Buildup of liquid junction potentials occurs over time and affects the lifetime of electrodes. It is therefore vital to change electrodes at the times specified by the manufacturer to avoid erroneous results.

The third cause of malfunctioning electrodes is buildup of proteins on the electrodes, resulting in alteration of the voltage between testing and reference electrodes. This phenomenon gives rise to erratic results and lack of reproducibility of ion concentrations in a single specimen. This problem can be avoided by performing washes of the electrodes at manufacturer-specified times.

SPECTROPHOTOMETRIC DETERMINATIONS

These are by far the most common types of assays. We discuss each analyte measured by this method.

BEER'S LAW

We remind the reader that all spectrophotometric determinations are made using the Beer-Lambert law (see Chapter 4), which states that the absorbance, A , of an analyte at a particular wavelength is proportional to its concentration, C , and the length of the light path, L , in the cuvette in which the analyte is dissolved in a solvent (usually water or aqueous buffer), that is,

$$A = \epsilon \times C \times L \quad (27-1)$$

where ϵ is the proportionality constant, also called the extinction coefficient.

ENDPOINT VS. RATE METHOD

As we now describe, the spectrophotometric determination of the concentration of an analyte requires the addition of another compound or reagent

Figure 27-1 Structures of agents that bind selectively to Ca^{++} ions, with the exception of 8-hydroxyquinolone, which binds and precipitates Mg^{++} ions.

with which the analyte of interest reacts covalently or noncovalently. The reagent is always added in excess. The resulting complex absorbs light at a wavelength at which neither the free analyte nor the unbound reagent absorbs, or at which each species absorbs only minimally. If the reaction is allowed to proceed to completion and the absorbance is then determined, the method is referred to as an endpoint method. In some cases, the rate of formation of the complex is slow.

To avoid long waiting periods, the rate of the reaction over a short period is determined and is used to compute the concentration of the analyte. In Chapters 20 and 23, we discussed the order of reactions. In the case of formation of colored complexes, the analyte, A, reacts with the reagent, R, to form the measured product, that is, the color complex, or AR, as follows:

The rate equation describing the rate of formation of AR, that is, $d(AR)/dt$, is

$$d(AR)/dt = k(A)(R) \quad (27-3)$$

where k is the rate constant.

This is referred to as a *second-order rate process* because the rate depends on the concentrations of both A and R. However, because R is added in excess of A, at least initially, the concentration of R does not change appreciably, so that it may be considered constant. The reaction then becomes a *pseudo-first-order reaction*. In this case,

$$d(AR)/dt = kR_0(A) \quad (27-4)$$

where R_0 is the defined added concentration of reagent, so that

$$d(AR)/dt = k'(A) \quad (27-5)$$

where $k' = kR_0$.

Thus the rate of formation of AR is proportional to the concentration of A. Plots of AR versus time should be linear for the initial time periods (which can range from seconds to minutes). The slope is $k' = kR_0$, whose value is known. Therefore, A must be equal to the slope of the initial straight line divided by k' . This process is similar to the one described in Chapter 20 for computing enzyme concentrations in serum at low substrate concentrations.

In the same manner in which we determine the concentrations of enzymes in serum by observing the *initial* rate of the enzyme-catalyzed reaction in the presence of saturating concentrations of substrate, where the concentration of the substrate is known, we can likewise determine the initial concentration of A by measuring the initial rate at which AR forms. This rate is proportional to the initial concentration of A, the desired quantity.

INTERFERENCES

Many color complex absorbances are determined at wavelengths higher than 500 nm, approaching the visible region of the electromagnetic spectrum, where most small molecules such as drugs and cofactors, such as nicotinamide adenine dinucleotide (NADH), flavine adenine dinucleotide, and pyridoxal phosphate, do not absorb. However, hemoglobin has strong absorbances in this range. Therefore, if hemolysis occurs, appreciable concentrations of hemoglobin may occur in serum, giving falsely elevated absorbances and hence analyte concentrations. In addition, the presence of lipids such as the triglycerides and cholesterol esters in appreciable concentrations in serum can cause falsely elevated concentrations of analytes at virtually any wavelength as the result of scattering of light, which leads to decreased transmittance and therefore increased absorbance. Although fortunately not common, the presence of certain drugs can interfere with spectrophotometric determination of the levels of some of the analytes.

QUANTITATION OF ANALYTES

We now discuss commonly used methods to determine the concentrations of analytes by formation of color complexes.

Albumin and Total Protein

Albumin

As noted in Chapter 19, albumin is the most anionic of the major serum proteins, and it migrates toward the anode on serum protein electrophoresis. It binds with high affinity to cationic dyes, among which are bromocresol green (BCG), a derivative of triphenyl methane, and bromocresol purple (BCP). The reaction with bromocresol green is as follows:

The amount of albumin present in the sample is measured as an endpoint reaction at 628 nm. A similar reaction with BCP yields a color complex whose absorbance is read at 603 nm. BCG reacts also to some extent with α_1 - and α_2 -proteins, sometimes tending to overestimate the concentration of albumin. BCP does not react with these proteins and so is considered to be more specific in quantitation of albumin. Interferences include hemolysis and lipemia.

Total Protein

From Chapter 19, it will be remembered that all proteins are polyamino acids linked together by peptide (CONH) bonds. These peptide bonds form complexes with cupric ions in cupric sulfate to form a color complex in alkaline solution, the so-called **Biuret reaction**, as shown below:

Note that this occurs for every four consecutive peptide units. Because most proteins contain at least 150–200 amino acid residues, and many of them more than 300 amino acid residues, many of these complexes are formed for each protein. Because large numbers of proteins are present in serum, this reaction is multiplied many-fold, making the Biuret method quite sensitive. The absorbance of the colored complex is determined at 540 nm. Major interferences with this reaction include hemolysis and lipemia.

Bilirubin

As discussed in Chapter 21, the most common method for measuring serum bilirubin is the Jendrassik-Grof method. In this method, diazotized sulfanilic acid reacts with two pyrrole rings of bilirubin to give two phenylazo adducts, as shown in Equation 27-8 (Natelson, 1971):

In this equation, Me is the methyl group, V is the vinyl group, and P is the 3-substituted propionic acid moiety. Note that electrophilic aromatic substitution occurs increasingly on the pyrrole rings, such that the central methylene carbon is removed altogether, giving the two sets of phenylazo adducts.

As discussed in Chapter 21, bilirubin is conjugated to glucuronic acid at either or both propionic acid moieties. Unconjugated bilirubin is much less soluble than are the conjugated forms. Most of the unconjugated bilirubin is bound tightly to albumin, making it largely unavailable for reaction with the diazotized sulfanilic acid reagent. However, addition of agents such as ethanol, methanol, or caffeine-benzoate induces the dissociation of unconjugated bilirubin from albumin, allowing it to react with the reagent. Caffeine-benzoate is preferred because methanol and ethanol can induce protein precipitation and increased turbidity. Interference by hemoglobin as the result of hemolysis can also occur. The soluble bilirubins (mostly conjugated, but see later) that react in the absence of dissociating reagents are termed **direct bilirubin**, and the bilirubin that reacts in the presence of the dissociating agent is **total bilirubin**. So-called **indirect bilirubin** (mostly unconjugated bilirubin bound to albumin) is obtained by subtracting direct bilirubin from total bilirubin (Tolman, 1999). As noted in Chapter 21, not all conjugated bilirubin is detected as direct bilirubin, and a small amount of unconjugated bilirubin may be detected as direct bilirubin.

Calcium

Most methods rely on the formation of a color complex of Ca^{++} ions with an appropriate chelating agent with which it forms a color complex. Because approximately half of total calcium is bound to protein, mainly to albumin, lowering the pH of the sample liberates calcium ions. The calcium ions are then reacted with a strong chelating compound, with which they form a color complex. The two major calcium-chelating compounds currently used are ortho-cresolphthalein (forms a red complex) and arsenazo III (Rowatt, 1989; Morgan, 1993), whose structures are shown in Figures 27-1, A and B, respectively. The reaction is shown below:

where the dye may be ortho-cresolphthalein or arsenazo III.

Use of ortho-cresolphthalein is often accompanied by an additional step in which the reaction solution is treated with the compound 8-hydroxyquinoline, whose structure is shown in Figure 27-1, D, at alkaline pH, to prevent the formation of any possible complex with magnesium ion. The amount of complex that forms is rather strongly dependent on the temperature, which must therefore be carefully maintained. At low calcium concentrations, a one-to-one complex forms, whereas at higher calcium concentrations, 2 moles of calcium bind to 1 mole of dye. Because the extinction coefficients of monocalcium and dicalcium dye complexes differ, absorbance is nonlinear with respect to calcium concentration. However, a modified Beer's Law equation can be used to compute concentration from absorbance, or nonlinear methods can be used for this purpose.

Arseno III has a high affinity for calcium ions, but the amount of complex formed is strongly pH dependent. Usually, imidazole buffers at pH 6.0 are employed for this reaction. It is important to note that citrate, which is a tricarboxylic acid that can chelate calcium ions, has been found

to interfere with this reaction. It has been observed that absorbance at 650 nm is the optimal wavelength for determination of the concentration of calcium ion complex with arseno III, at which little interference by other analytes is seen, other than in hemolyzed samples.

Ion-Selective Electrodes for Calcium Determinations

Because calcium can be released from its normally bound states by acidification, addition of acid to a serum sample will convert all calcium to readily measurable ionic forms. Thus total calcium can be measured volumetrically. The electrode is a specific calcium-ion exchanger, of which there are several types, including ETH 1001 and bis-di-(n-octylphenyl) phosphate. The structure of the latter is shown in Figure 27-1, C (Endres, 1999). Ionized calcium, that is, calcium that is not bound to protein or in complex formation with strong chelators, can be measured directly with ion-selective electrodes without the prior acid treatment step.

Creatinine

Creatinine has been found to form a complex with picric acid (2,4,6-trinitrophenol) under alkaline conditions, as shown below in the Jaffe reaction:

The actual structure of the complex is not completely known. Most studies suggest that it is a noncovalent ionic complex, as shown in Equation 27-10 (Vasillades, 1976). However, some evidence suggests that the carbonyl oxygen (in its enolate form) of creatinine can attack the 1-carbon of picric acid to form a covalent (so-called **Janovsky-like**) adduct (Kroli, 1987). Irrespective of the structure(s) of this complex, its absorbance is determined to be between 490 and 500 nm. The reaction is sensitive to temperature. Possible interferences include ketones, keto acids, and bilirubin. The enolate forms of ketones can react with picric acid much in the same manner as those of creatinine. The reaction of picric acid with bilirubin can be minimized by treatment with ferricyanide or small amounts of surfactant.

Iron

Serum iron levels can be readily determined by a specific reaction of ferrous iron (Fe^{++}) with the compound ferrozine, the structure of which is shown in Equation 27-11. The reaction is performed in an acid medium, so that ferrous ions can be dissociated from transferrin and maintained in the reduced state. Actually, each ferrous ion complexes with three ferrozine molecules to form a magenta-colored complex, remarkably insensitive to pH, whose absorbance can be determined at 562 nm. As might be expected, hemolysis can cause major interferences with this assay because of red cell iron and release of hemoglobin that can compete with ferrozine for binding to serum iron.

Total Iron-Binding Capacity

This is a measure of the total number of functional ferrous ion-binding sites in transferrin. As discussed in Chapter 23, the basic approach is to strip serum transferrin of all bound iron and then to add an excess of iron to the serum sample to determine the concentration of transferrin-bound iron. To accomplish this, the serum sample is added to an acidic buffer that dissociates all transferrin-bound iron and contains excess ferric chloride and ferrozine. All of the iron is now bound to ferrozine. The pH of the solution is raised into the neutral range, where the affinity of iron for transferrin is greatly increased over that for ferrozine. All iron that can bind to available sites on transferrin does so. This results in a decrease in the magenta color at 562 nm. This decrease is proportional to the total concentration of functional transferrin-binding sites. This set of reactions is summarized as follows:

Magnesium

Several dyes that form specific complexes with Mg^{++} ions are used to determine the serum concentrations of this metal ion. They include calmagite (530–550 nm), as shown in Figure 27-2, methylthymol blue (600 nm), and xylydyl blue (600 nm). The numbers in parentheses in the preceding sentence indicate the wavelengths at which complex concentrations are determined for each dye (Endres, 1999). In the case of calmagite, the calcium-chelating compound, ethylene glycol tetraacetic acid, can be used to remove interference from calcium ions, potassium cyanide can be added to remove interference from heavy metal ions, and polyvinylpyrrolidone can be added to the reaction solution to minimize interference from proteins.

Phosphate

Phosphate may be inorganic, mainly orthophosphate, or organic, such as glucose-6-phosphate, nucleic acids, phosphoproteins, and so forth. Most phosphate in serum is inorganic; organic phosphates are mainly intracellular. Phosphoric acid is a tribasic acid, and the main forms of phosphate at blood pH are $\text{H}_2\text{PO}_4^{-1}$ and HPO_4^{-2} . The most commonly used method to measure total serum inorganic phosphate is the phosphomolybdate method, in which ammonium molybdate is reacted with inorganic phosphate to form an ammonium-phosphomolybdate complex (Endres, 1999). The unreduced form of this complex can be determined readily by the increase in absorbance at 340 nm. The pH must be maintained in the acid range because alkaline conditions can result in reduction of the complex. In fact, reduction of this complex yields a blue product whose absorbance can be determined in the 600–700 nm range (the Fiske-Subbarow method). Reducing agents used include ascorbic acid, stannous chloride, ferrous

Calmagite for Mg^{+2} determination

Figure 27-2 Structure of calmagite, an agent that forms a selective color complex with Mg^{++} ions.

ammonium sulfate, 1-amino-2-naphthol-4-sulfonic acid (used originally), and many others. Most methods use the direct 340-nm determination because of its speed and the fact that it involves only one step.

USE OF ENZYMES AS REAGENTS TO DETERMINE ANALYTE CONCENTRATIONS

GENERAL FEATURES

Rate vs. Endpoint Methods

These are similar to the methods discussed earlier in the section on spectrophotometric determinations. For rate methods, the total amount of enzyme is added to the serum sample, so that, unlike in enzyme assays, total enzyme concentration is known. Note, though, that the substrate concentration is not known (we seek to determine this). It is not known whether or not saturation conditions prevail. Therefore, to compute the substrate concentration for an observed initial rate, the Michaelis-Menten equation is solved to determine substrate concentration. This is possible because K_m and V_{max} are known for the enzyme reagent used. As with dye-based methods, endpoint methods using enzymes are based on determination of the point at which the product concentration remains constant; this concentration is the total substrate or analyte concentration.

NADH and NADPH as Quantitative Indicators

In this section and in the following section, it will be seen that a common approach used in determining the serum concentrations of analytes and of enzymes is to follow the reduction of NAD or NADP to NADH or NADPH, respectively. NAD[P]H has strong absorbance at 340 nm, but the oxidized forms, that is, NAD[P], have no absorbance. Thus determination of the *increase* in absorbance at 340 nm for an enzyme-catalyzed reaction in which NAD[P] is converted to NAD[P]H, or of the *decrease* in absorbance at 340 nm for an enzyme-catalyzed reaction in which NAD[P]H is converted to NAD[P], is a very convenient means of measuring analyte concentration.

In some assays in which NAD[P]H is an end-product, the sensitivity of the level of NAD[P]H produced is enhanced by adding another step, wherein a dye reagent, a tetrazolium derivative, is reduced by NAD[P]H to yield a formazan that strongly absorbs at wavelengths around 500 nm. This reaction can be catalyzed by an electron transfer agent, such as the enzyme diaphorase (lipoamide dehydrogenase, EC 1.6.4.3) or phenazine methosulfate. A prototypical reaction is shown in Figure 27-3. This reaction can, in principle, be used for any reaction in which NAD[P]H is generated.

ANALYTES WHOSE CONCENTRATIONS ARE DETERMINED BY ENZYME REACTIONS

Ammonia

Ammonia is measured by using the versatile enzyme glutamate dehydrogenase (GLD). In this reaction, ammonia reacts with α -ketoglutarate to form glutamate in a reductive amination reaction. In the first step of this reaction, a Schiff base forms between ammonia and the α -keto group of α -ketoglutarate. In the second step, the resulting double bond is then reduced by NADPH, giving the primary amine in glutamate, plus NADP. The overall reaction is shown in Figure 27-4. Ammonia concentration can therefore be determined by the decrease in absorbance at 340 nm as NADPH is converted to NADP. This enzyme can be used in any reaction in which ammonia is generated.

Bicarbonate Ions

One of the glycolytic enzymes, phosphoenolpyruvate carboxy kinase (PEPK), utilizes bicarbonate ion (HCO_3^-) to carboxylate phosphoenolpyruvate to form oxaloacetate (OAA), a Krebs cycle intermediate, with attendant dephosphorylation (Equation 27-13). Thus, advantage can be taken of this reaction to consume serum bicarbonate in the reaction, thereby enabling us to determine its concentration. PEPK is added to the serum. The resulting OAA is then reduced by added malate dehydrogenase to form malate. In this second reaction, NADH is oxidized to NAD, so that the decrease in absorbance of NADH can be monitored at 340 nm. Often, an NAD analog is used, so that decreased absorbance at 410 nm, rather than at 340 nm, is monitored.

Figure 27-3 Reduction of a tetrazolium to a formazan in which NADH or NADPH is converted to NAD or NADP, respectively, in the presence of a catalyst, that is, the enzyme diaphorase, or phenazine methosulfate. The formazan strongly absorbs at 500 nm. This reaction can be used to enhance the sensitivity of reactions in which NADH or NADPH is generated. *NADH*, Nicotinamide adenine dinucleotide.

Figure 27-4 Reductive amination reaction, catalyzed by glutamate dehydrogenase, in which ammonia reacts with α -ketoglutarate to form the amino acid glutamic acid. In this reaction, NADH is converted to NAD, allowing the ammonia concentration to be determined by the total decrease in absorbance of light at 340 nm—the wavelength at which NADH absorbs. *NADH*, Nicotinamide adenine dinucleotide.

Cholesterol

As discussed in Chapter 17, cholesterol circulates as both free (mainly in LDL particles) and cholesterol ester (mainly in HDL particles). To determine the serum concentration of total cholesterol, therefore, all cholesterol ester is first converted to free cholesterol using cholesterol esterase

(Equation 27-14, *A*). The resulting total free cholesterol is then oxidized to 7- α -hydroxy-cholesten-3-one with cholesterol oxidase, as is shown in Equation 27-14, *A*. As can be seen, hydrogen peroxide (H_2O_2), a strong oxidizing agent, is generated in this reaction. Advantage can be taken of this property to generate strongly absorbing chromophores, as we now describe.

(27-14B)

The Quinoneimine Strategy

H₂O₂ can be reacted, in the presence of a peroxidase, with a phenazone, usually 4-aminoantipyrine, which forms a highly colored quinoneimine dye with phenol, as shown in Equation 27-14, *B*. This is a prototypical reaction in which the phenol is oxidized to the quinone, and in which the exocyclic -NH₂ group of 4-aminoantipyrine then adds to the quinone to form a strongly absorbing color complex. Phenol is one of many compounds that can be used to form a quinone or an oxidized aromatic ring, known collectively as Trinder reagents. Several of these are aniline derivatives and include *N*-ethyl-*N*-(2-hydroxy-3-sulfopropyl)-*m*-toluidine (absorbance is determined at 545 nm) and *N*-(2-hydroxy-3-sulfopropyl)-3,5-dimethoxyaniline, among other, similar compounds. We will have occasion to refer to this set of reactions in determining the concentrations of a number of analytes, in addition to cholesterol, as described in the following section.

For cholesterol determination, H₂O₂ is generated and is reacted with 4-aminoantipyrine and, generally, **phenol** in the presence of a peroxidase to yield the quinoneimine, shown in the previous equation, whose absorbance is determined at 505 nm.

HDL Cholesterol

(Jensen, 2002; Sugiuchi, 1995).

Until relatively recently, methods were used in which LDL or HDL fractions were selectively precipitated and centrifuged, and the cholesterol in the supernatant assayed. For example, to assay HDL cholesterol, fractions containing apo-B proteins as in LDL and very-low-density lipoprotein (VLDL) particles (see Chapter 17) were precipitated using a polyanion and a divalent cation, such as dextran sulfate-MnCl₂ or phosphotungstate-MgCl₂ combinations. The remaining cholesterol in the supernatant, presumably only HDL cholesterol, was then assayed using the method summarized previously in Equation 27-14. These methods are somewhat time consuming and require manual procedures that cannot be automated.

It was found that enzymes used in the two assays, as shown in Equation 27-14, could be made relatively specific for reacting with HDL cholesterol by the relatively simple expedient of adding polyethylene glycol (PEG 6000) to the free amino groups of basic amino acids of the polypeptide chains of these enzymes. Also, the addition of α -cyclodextran sulfate (average of 6 glucose units with an average of 2 sulfates per glucose unit) in the presence of Mn⁺⁺ ions greatly reduces the reactivity of the cholesterol in LDL, VLDL, and chylomicron fractions. Thus addition of the two PEGylated enzymes with sulfated cyclodextran and MnCl₂ allows direct determination of HDL cholesterol. The indicator reaction with H₂O₂ is the same as in Equation 27-14, *B*. The overall method is summarized in Equation 27-15, *A* as follows:

where NR is no reaction.

LDL Cholesterol

(Nauck, 2002).

The basic strategy for direct determination of LDL cholesterol (LDL-C) is first to add a reagent that protects LDL-C from reacting with the two enzymes cholesterol esterase and cholesterol oxidase, then to react cholesterol from all of the other fractions, so that it is completely consumed, and finally to add a deprotecting agent that allows LDL-C to undergo reaction with the two enzymes. Charged surfactants have been found to block cholesterol in LDL from reacting with the two enzymes cholesterol esterase and oxidase. The release agent is also a surfactant that, in contradistinction to the protecting agent, is neutral.

In practice, two composite reagents are added to serum sequentially. The first contains protective surfactant and polyanions, which block the reaction of LDL-C with cholesterol esterase and oxidase, and catalase, which consumes the H₂O₂ generated in the reactions of all of the non-LDL-C, as summarized in Equation 27-15, *B*. Then a second reagent is added that consists of 4-aminoantipyrine, as described previously, sodium azide, which blocks catalase, peroxidase, the deprotecting surfactant that releases LDL-C, and an appropriate Trinder agent (i.e., chromophore-producing compound that reacts with the 4-aminoantipyrine to form the color complex). These reactions are summarized as follows in Equations 27-15, *B* and 27-15, *C*:

This set of reactions has multiple variations, all of which are based on the overall strategy described here.

Glucose

The most commonly used method to determine serum glucose levels is to induce phosphorylation of glucose, by hexokinase and adenosine triphosphate (ATP), to yield glucose-6-phosphate. By adding glucose-6-phosphate dehydrogenase, glucose-6-phosphate is converted into gluconolactone-6-phosphate (first step in the pentose phosphate pathway). This is an oxidation reaction. NADP is reduced to NADPH, whose absorbance can be determined directly at 340 nm. These reactions are summarized in Equation 27-16.

In Equation 27-16, the circled P represents the phosphate moiety. This reaction sequence is perhaps the one most commonly used. Other methods for glucose determination are also available and are used most commonly in point-of-care testing (Yoo, 2010). In these reactions, glucose oxidase is used to convert glucose to gluconolactone. In this reaction, flavine adenine dinucleotide (FAD) is reduced to FADH₂. In the presence of oxygen, FAD is regenerated, and oxygen is reduced to H₂O₂. The latter is oxidized in the presence of a platinum electrode to yield 2H⁺ + O₂ + 2e⁻ (electrons). The electrons flow through a circuit, giving rise to a current, which is proportional to the glucose concentration. Several variants of this strategy may be noted. In one of these, glucose dehydrogenase bound to the dye, pyroquinolinequinone (PQQ), oxidizes glucose to gluconolactone plus the reduced form of PQQ, which has an intense red color that can be measured spectrophotometrically. Most commonly, the reduced dye is reoxidized and the released electrons measured as current electrochemically, as described earlier. Electrochemical methods for point-of-care testing use whole blood for glucose determination. Thus the hematocrit has an effect on the concentration of glucose that must be included in obtaining the whole blood glucose value (D'Orazio, 2009; Yoo, 2010).

Lactate

As discussed in Chapter 20, lactate reacts almost exclusively with LD, as shown:

Because NAD is converted to NADH, as shown in the box, the increase in absorbance of NADH at 340 nm is followed until it becomes constant. After subtraction of a blank for background absorbance of the serum sample at 340 nm, the total absorbance is used to compute directly the increased concentration of NADH due to lactate oxidation.

Triglycerides

These are a heterogeneous group of triesters of fatty acids with glycerol (see Chapter 17). The nature of the fatty acid esters can differ widely in terms of chain length, presence and number of unsaturated bonds in the aliphatic chains, and chain arrangement. The strategy for determining triglyceride concentration is to hydrolyze all of the fatty acid esters of triglycerides to produce glycerol. The resulting total concentration of glycerol is taken as the total triglyceride concentration. Technically, this requires the use of a serum blank to determine the level of endogenous glycerol, but the level of glycerol in serum has been found to be quite low, so that these blank determinations are not usually performed (Rifai, 1999).

In the reference method for determining triglyceride concentration, the triglycerides are first extracted into chloroform; the extract is then treated with silicic acid to extract phospholipids from the chloroform extract. The chloroform extract is then treated with strong potassium hydroxide base to hydrolyze all of the fatty acid esters of glycerol in a process referred to as **saponification**. The resulting glycerol is treated with sodium periodate, resulting in the formation of 2 moles of formaldehyde and 1 mole of formic acid. The formaldehyde is then treated with chromotropic acid to obtain a chromogen whose structure has not been proved as yet, but that contains two chromotropic acid molecules linked together by a formaldehyde carbon bridge. This adduct absorbs strongly at 580 nm. Of course, this is a time-consuming, manual method that serves only as a reference method and cannot be automated.

In the automated methods performed directly on serum, triglycerides are hydrolyzed to glycerol plus free fatty acids using lipase. Here we point out that lipase cleaves the fatty acid esters of glycerol at positions 1 and 3 of glycerol but not at position 2. However, the two-acid esters of glycerol spontaneously rearrange to form the one- or three-fatty acid esters that are then hydrolyzed by lipase. This allows complete hydrolysis of the fatty acid esters of glycerol.

To determine the total glycerol concentration, the glycerol is converted by the enzyme α -glycerokinase to form 1-phosphoglycerol. This product is converted, in turn, to dihydroxyacetone by glycerophosphate oxidase in the presence of oxygen. This is an oxidation-reduction reaction that generates H₂O₂, which is used to oxidize phenol or *m*-chlorophenol in the presence of 4-aminoantipyrene to form a conjugated adduct, as described earlier. The absorbance (usually at 505 nm) of this adduct is proportional to the concentration of generated glycerol. These reactions are summarized here:

Variants of this basic approach include subjecting the glycerophosphate shown in Equation 27-18, *B* to glycerophosphate dehydrogenase to produce dihydroxyacetone phosphate, in a reaction in which NAD is converted into NADH. The NADH can be directly determined at 340 nm.

Urea

The reactions here use ultimately the same GLD enzyme as was described previously for ammonia determination. Here, urea is hydrolyzed into carbon dioxide and ammonia in a reaction catalyzed by the enzyme urease. The resulting ammonia is then reacted with α -ketoglutarate to obtain glutamate in the reductive amination reaction shown in the following equations:

The use of hemolyzed samples may cause significant interference with this method.

Uric Acid

As shown in Equation 27-20, *A*, uric acid is converted into allantoin by the enzyme uricase.

In this reaction, H_2O_2 is generated. As shown in Equation 27-20, *B*, the resulting H_2O_2 can then be used to oxidize a Trinder reagent, in this case, TOOS (see earlier), which reacts with 4-aminoantipyrine to form a quinoneimine. Another approach is to use the resulting H_2O_2 to oxidize a convenient substrate such as ethyl alcohol to acetaldehyde by the enzyme catalase. The resulting acetaldehyde can then be further oxidized to acetate by the enzyme alcohol dehydrogenase. In this reaction, NADP is converted to NADPH, resulting in increased absorbance at 340 nm.

ASSAYS FOR ENZYMES

Enzyme assays are discussed in Chapter 20. As discussed in that chapter, most enzyme reactions are carried out under saturating conditions in which the substrate concentration is significantly greater than K_M . This ensures that the initial rate of the reaction is proportional to the total enzyme concentration. Most enzyme assay results are expressed in activities (i.e., international units [IU]), with slopes of the plots of product formed versus time, as described in Chapter 20.

ALANINE AMINOTRANSFERASE AND ASPARTATE AMINOTRANSFERASE

ALT

As described in Chapter 21, this enzyme, which is expressed mainly in liver, reversibly catalyzes the transamination reaction between alanine and α -ketoglutarate to obtain pyruvate and glutamate. It is vital that the cofactor B_6 , pyridoxal phosphate, be present because it is the moiety that is involved in the actual reaction. As shown in Equation 27-21, *A*, the pyruvate that is produced is then reacted with LD in the presence of NADH to produce lactate. Because in this reaction NADH is converted to NAD, the decrease in absorbance of NADH at 340 nm is measured.

The use of icteric and lipemic samples may cause significant interference with this method.

AST

As is also described in Chapter 21, this enzyme, which, similar to ALT, requires cofactor B₆ (pyridoxal phosphate), reversibly catalyzes the reaction of aspartic acid with α -ketoglutarate to yield OAA and glutamate. The resulting OAA is then reacted with malate dehydrogenase, which converts the OAA to malate. As in the detection reaction for ALT in the preceding paragraph, NADH is converted to NAD, resulting in decreased absorbance at 340 nm. These reactions are summarized in the following equations.

ALKALINE PHOSPHATASE

As discussed in Chapter 20, the quantitative determination of serum alkaline phosphatase is based on the colorimetric measurement of the rate of formation of *p*-nitrophenol as the *p*-nitrophenoxide anion, a yellow compound, at 410 nm, from hydrolysis of para-nitrophenylphosphate by alkaline phosphatase, as shown in the following equation:

P_i represents inorganic phosphate cleaved from the substrate. The use of hemolyzed specimens may cause significant interference with this method.

AMYLASE

(Moss, 1999).

This enzyme hydrolyzes poly α -1,4-linked glucose polymers, as are found in starch, amylopectin, and glycogen, such that hydrolysis occurs at every second glucose residue. Two types of amylases are known: α and β . β -Amylase cleaves maltose units (glucosyl[α -1,4]glucose) from the reducing to the nonreducing end, as an exoamylase; α -amylase cleaves internally while cleaving from the reducing end of the α -1,4-linked glucose polymer. Serum amylase is of the α type. The two major sources of this enzyme are pancreas and salivary glands. Thus serum amylase levels can be used as markers for pancreatic and salivary gland function. Both strongly

homologous isozymes are present in serum. More than 200 methods for assaying of these enzymes have been described. Older methods used starch as the substrate. The glucose polymer forms a well-defined helix in solution. Iodine can bind within this helical structure to form a colored complex. In the presence of amylase, the polymer is degraded, resulting in lower iodine binding and hence less color complex formation. This decrease in color over time can be followed. In addition, as starch is hydrolyzed by amylase, the turbidity of the solution decreases, allowing turbidimetry (see Chapter 4) to be used to measure amylase activity.

Chromogenic substrate polymers of glucose in which a dye is bound covalently to the polymer have been synthesized. In the presence of amylase, the polymer is hydrolyzed, releasing small dye-labeled oligosaccharides. In the Johnson and Johnson slide technology system, the oligosaccharide is bound to an anionic dye—drimarene red Z2B; the dye-labeled oligosaccharides from amylase cleavage diffuse into the reagent layer, where they are bound to a cationic polymer, so that their concentrations can be determined spectrophotometrically. The parent polysaccharide cannot diffuse into this layer and is thus excluded. On Abbott analyzers, the parent polymer is labeled with a fluorescent probe. Because the structure of the long polymer is rigid (a helical structure), the fluorescence is polarized when the probe is stimulated with polarized light. (See Chapter 23 for a description of fluorescence polarization.) When the polymer is hydrolyzed by amylase, probe-bound fragments are released that are much smaller than the parent polymer, and whose “tumbling times” are much faster, resulting in a major decrease in fluorescence polarization. Thus, decreased fluorescence polarization can be followed over time to determine the enzyme activity.

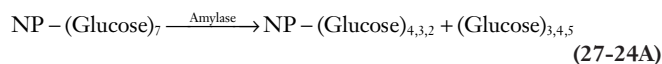

Digestion of glucose polymers by amylase results in the formation of oligosaccharides like maltose and maltotriose (three glucose units in α -1,4 linkage). Oligosaccharides with three or fewer glucose units can be hydrolyzed to glucose with α -glucosidase. The resulting glucose formed can be assayed as described earlier. A problem with this approach is the presence of endogenous glucose. This provides a high blank background. Endogenous glucose can be removed with a gel filtration column, although this does not lend the method to automation.

The methods already discussed use natural polymers of starch or amylopectin as substrates. This leads to the problem of standardization of the substrate material from lot to lot. In addition, the inhomogeneous substrate forms sols in aqueous solution that are easily contaminated. They are temperature sensitive and have limited stability. Newer methods involve the use of synthetic substrates.

In one such method, synthetic maltopentaose (5 α -1,4-linked glucose residues) is hydrolyzed by amylase to yield maltotriose and maltose. These are directly hydrolyzed to glucose by α -glucosidase. Because the endogenous glucose background is high, this glucose is removed by a gel filtration column.

To obviate the endogenous glucose problem, synthetic maltotetraose (4 α -1,4-linked glucose residues) is used as the substrate. Amylase cleaves this substrate into two maltose units. These are then treated with the enzymes maltose phosphorylase and inorganic phosphate to form glucose-1-phosphate + glucose. Glucose-1-phosphate is then converted to glucose-6-phosphate by phosphoglucomutase. The resulting glucose-6-phosphate is treated with glucose-6-phosphate dehydrogenase, so that the formation of NADPH at 340 nm can be followed over time. It may be noted that, because the glucose-6-phosphate is generated from maltose and not from any endogenous glucose, endogenous glucose does not interfere with this reaction. However, unfortunately, amylase is not completely specific for generating two maltose sugars from maltotetraose and also cleaves the substrate, to a more minor extent, to glucose and maltotriose. Thus for this reason, the assay somewhat underestimates the level of amylase.

Recently, chromogenic substrates have been synthesized. These contain oligo- α -1,4-linked glucose units with 4(or *p*)-nitrophenol (4-NP) in α -acetal linkage to the reducing sugar of the oligosaccharide. In one assay, maltoheptaose (seven glucose units in α -1,4 linkage), attached to 4-NP at its reducing end, is used as the substrate, as illustrated in Figure 27-5. Amylase hydrolyzes this substrate mainly into (glucose)₄-NP, (glucose)₃-NP, and (glucose)₂-NP plus (glucose)₃, (glucose)₄, and (glucose)₅, respectively. These reactions are summarized in the following equations:

Figure 27-5 Structure of a synthetic substrate for amylase assays. This is the *p*-nitrophenyl glycoside of maltoheptaose. In practice, to enhance reaction specificity and to ensure more efficient cleavage by α -glucosidase, a protecting 4,6-ethylidene or benzylidene group is introduced on the seventh glucose unit on the nonreducing end.

As shown in Equation 27-24, *B*, the -NP -linked fragments are then further degraded with α -glucosidase to yield 4(or *p*)-nitrophenol, which, at alkaline pH, forms the *p*-nitrophenoxide anion that absorbs strongly at 405–410 nm, as discussed previously for alkaline phosphatase.

Note that Equation 27-24 assumes that a limit digest occurs for the tetra-, tri-, and disaccharides, always liberating 1 mole of *p*-nitrophenoxide anion per mole of each saccharide. In practice, this does not occur. In fact, hydrolysis of (glucose)₄-NP by α -glucosidase is slow, although the rate can be enhanced by blocking OH-groups of the terminal nonreducing glucose unit. Thus, 4,6-ethylidene, 4,6-benzylidene, and other blocking groups have been found to enhance α -glucosidase activity.

Other problems with this approach include the consideration that the pK_a of nitrophenol is close to the pH of the assay reactions, so that only about half of the released *p*-nitrophenol will be present as the oxyanion. In addition, the method is sensitive to ionic strength effects and the concentration of protein present in the assay mixture, both of which affect the pK_a of the *p*-nitrophenol. It may also be subjected to interference by hemoglobin.

It has been found that these problems are largely removed by the use of 2-chloro,4-nitrophenol, called **CNP**, in place of 4-NP. Because of the

ortho electron-withdrawing property of the *o*-Cl group, the pK_a of the liberated phenol is lowered, so that 100% of it exists as the colored phenoxide anion. It also minimizes the other complications listed above (except hemoglobin interference), and, because it is a better leaving group in the mechanism of α -glucosidase-induced hydrolysis, higher yields of the smaller saccharides, and thus of CNP, are obtained, allowing for higher yields of the colored final product.

CREATINE KINASE

As discussed in Chapter 20, creatine kinase reversibly catalyzes the reaction between creatine and ATP to yield creatine phosphate and adenosine diphosphate (ADP). This reaction occurs prominently in muscle tissue, allowing for storage of the so-called **high-energy phosphate bond** as creatine phosphate. For the purposes of the enzyme assay, the reaction is reversed (i.e., ADP and creatine phosphate are added to the sample to generate ATP + creatine). The product, ATP, is coupled into hexokinase–glucose-6-phosphate dehydrogenase reactions and generates NADPH, as shown in the equations that follow. The creatine kinase activity is proportional to the absorbance increase in NADPH at 340 nm.

The use of hemolyzed samples may cause significant interference with this method and should be avoided.

γ -GLUTAMYL TRANSFERASE

This enzyme occurs on the canalicular surface of the hepatocyte (see Fig. 21-3) and catalyzes the transfer of the γ -glutamyl residue of glutathione (γ -glutamyl-cysteinyl-glycine) to another amino acid, or to an exogenous agent such as a drug. As it happens, GGT transfers the γ -glutamyl residue from the synthetic substrate 1- γ -glutamyl-3-carboxy-4-nitroanilide to glycylglycine to yield γ -glutamyl-glycylglycine and free 5-amino-2-nitrobenzoate (ANB), as shown in the equation below. Free ANB, which is a substituted aniline, absorbs at 410 nm. The rate of formation of ANB is measured as the increase in absorbance at 410 nm divided by the time interval over which it is measured, directly yielding GGT activity.

LACTATE DEHYDROGENASE

This enzyme, the reactions that it catalyzes, and assays for this enzyme are discussed in Chapter 20. Here we note that the reaction scheme shown in Equation 27-17 for the assay for lactate is the same scheme as for the assay for LD. In this case, lactate is added to the serum sample at a concentration above its K_M , and the activity is determined by the rate of increase of NADH absorbance at 340 nm.

LIPASE

As discussed previously, lipases cleave fatty esters of glycerol, and, as discussed in Chapters 17 and 22, there are several isozymes of lipase, including pancreatic lipase, intestinal lipase, lipoprotein lipase, and gastric lipase. The first three of these forms have strong homology to one another and significantly less homology to the gastric isozyme. These lipases hydrolyze triglycerides that are long-chain fatty acid esters of glycerol. In addition, aryl and aliesterases hydrolyze short-chain fatty acid esters and such simple esters as ethylacetate (aliesterase) and phenyl acetate (arylesterase) (Moss, 1999). In serum, pancreatic lipase is very much the predominant form. Thus, assays for lipase are used for the purpose of evaluating pancreatic function.

To be active, all lipases require a water-fat emulsion interface, the emulsion containing the substrate triglycerides. To attach to this interface, lipase requires the presence of a detergent, like cholate, and another protein to which it binds, colipase. The latter binds both to lipase and to the detergent-emulsion complex, allowing lipase to interact with the triglycerides. Thus, all assay mixtures for lipase must contain both the detergent and the colipase.

Assays for lipase can be performed by adding long-chain fatty acid esters to serum, and the reaction monitored titrimetrically. In this case, dilute sodium hydroxide solution is added to serum to neutralize the long-chain fatty acids that are released, but the pH of the reaction mixture is maintained constant. The amount of base added over a given time period is a measure of the increased concentration of fatty acids over the time period, yielding a rate that should be proportional to the total lipase concentration. The long-chain fatty acids used are contained in olive oil that has been treated to remove contaminating substances. This approach is also used with the pure triglyceride triolein as the substrate.

Although this is a reference method, it is difficult to adapt to continuously used autoanalyzers. Thus other approaches have been devised. In one of these, 1-oleoyl-2,3-diacetyl glycerol is hydrolyzed by lipase to yield oleic acid and diacetyl glycerol. The latter is then reacted with an enzyme called *diacetylase* that hydrolyzes the two acetyl esters to yield glycerol and 2 moles of acetate. The glycerol generated in this reaction sequence is then treated with α -glycerol kinase + ATP, and the reaction sequences shown in Equations 27-18B through 27-18D are then carried out. In a variant of this sequence, a 1,2-diacylglycerol is used as the substrate to yield the 2-acylglycerol that is then hydrolyzed by monoglyceride lipase (to accelerate the reaction) to yield glycerol that is subjected to the reactions described earlier.

A recently developed assay for lipase that is being used successfully utilizes the artificial substrate for lipase, 1,2-O-dilauryl-rac-glycero-3-glutaric acid-(6'-methylresorufin) ester, as shown in Figure 27-6. Lipase cleaves this substrate such that it generates 1,2-O-dilauryl-rac-glycerol and an unstable intermediate, the hemi-glutaric acid-(6'-methylresorufin) ester, which spontaneously degrades to glutaric acid and methylresorufin. The oxyanion of this dye that forms under basic conditions is red and strongly absorbs at 580 nm. Thus the absorbance increase in the red methylresorufin at 580 or 581 nm is proportional to the lipase activity. These reactions are summarized in Figure 27-6.

Figure 27-6 Artificial substrate for serum lipase resulting in liberation of methylresorufin, whose absorbance can be determined at 580 nm.

To obtain soluble substrates for lipase, artificial substrates with shorter-chain fatty acids are used. One of these is butyrin, the triester of *n*-butyric acid with glycerol. The glycerol generated by lipase is subjected to the reactions described previously. In a variant of this approach, the *n*-butyric acid ester of 2,3-dimercapto-1-ol, that is, a dithioester, is used. The limit digest of this substrate by lipase is 2,3-dimercapto-1-propanol. The two vicinal -SH groups can then be reacted with Ellman's reagent,

5,5'-dithio-bis-(2-nitrobenzoic acid), to form a color complex that absorbs strongly at 412 nm. A problem with the use of these shorter-chain substrates is that they are also substrates for the ali- and arylesterases in serum (Moss, 1999). To block the reaction of these enzymes, the covalent inhibitor phenylmethylsulfonylfluoride is added; this compound is a strong esterase (but not lipase) inhibitor.

KEY POINTS

- Many different diseases can display abnormalities in the urine. Therefore, examination of the urine is an important laboratory function.
- Basic urinalysis consists of gross examination of the urine, as well as a dipstick analysis for blood, white cells, sugar, and other substances. The dipstick may be read manually or by an automated instrument.
- A microscopic analysis of urine may be necessary in many cases. This is done to detect cellular elements, casts, and crystals. Each of these items can be caused by several different disease states.
- Although microscopic examination of the urine is usually performed manually, several automated instruments can perform this analysis.
- Red blood cells within the urine can come from any point along the urinary tract. Dysmorphic red blood cells are often a sign of glomerular disease.
- The first voided morning urine, because it is the most concentrated, is often the best specimen for analysis. Some procedures may require a 12- or 24-hour urine sample.
- Specific gravity and osmolality measurements reflect the concentrating ability of the kidneys. After a period of dehydration, the osmolality should be three to four times that of plasma.
- Proteinuria greater than 4 g/day is seen in the nephrotic syndrome. Although nephrotic syndrome is usually seen in primary renal disease, it is occasionally seen in a systemic disease that affects the kidneys.
- Ketonuria can be seen in diabetic individuals. It can also be seen in other states, such as febrile illness and cachexia.
- The dipstick nitrite and leukocyte esterase tests are used to help diagnose urinary tract infection. Positive results should be confirmed by microscopic analysis of the urine.
- Urinary calculi are most commonly formed from calcium. Workup of habitual stone formers should include analysis of both the urine and the stone.

A significant amount of information can be obtained through the examination of urine. Careful examination enables the detection of disease processes intrinsic to the urinary system, both functional (physiologic) and structural (anatomic), and sometimes unsuspected (Takemura, 2000). The progression or regression of various lesions can be monitored with only minimal distress to the patient. Furthermore, systemic disease processes, such as endocrine or metabolic abnormalities, can be detected through the recognition of abnormal quantities of disease-specific metabolites excreted in the urine. Laboratory urine tests will continue to play an essential role in clinical medicine.

The purpose of this chapter is to highlight the pertinent information that can be provided by the most common urine tests. Two main types of urinalysis are currently performed. These include (1) the dipstick (reagent strip) urinalysis, which is commonly performed in screening laboratories, in physician offices, and as patient home testing; and (2) the basic (routine) urinalysis, which adds a microscopic examination of urine sediment to the reagent strip urinalysis. These examinations utilize various laboratory disciplines, particularly chemistry and microscopy. In addition to these front-line diagnostic procedures, new technologies including immunocytochemistry, molecular diagnostics, DNA ploidy, and cell cycle analysis are constantly evolving to provide additional diagnostic and prognostic information. Urine microbiology studies, crucial to the diagnosis of infectious pathogens of the urinary tract, are addressed elsewhere in this text. It is important to remember that each of these modalities has a certain clinical utility. Table 28-1 lists the benefits of commonly ordered urine laboratory examinations.

Dipstick urinalysis provides information about multiple physicochemical properties of urine. Used predominantly in screening, dipstick testing requires less sophisticated training of personnel, and results are obtainable in only a few minutes. It has been shown that in certain situations, particularly when evaluating patients with signs or symptoms that prompt a urinalysis for the detection of blood or infection, urinalysis dipsticks can be substituted for a full routine urinalysis, with urine microscopy reserved for patients with discordance between clinical presentation and dipstick results (Jou, 1998). The routine urinalysis consists of two major components: (1) physicochemical determinations (appearance, specific

gravity, and reagent strip measurements), and (2) a bright-field or phase-contrast microscopic examination of urine sediment for evidence of hematuria, pyuria, casts (cylindruria), and crystalluria. The latter examination is typically more time consuming and necessitates expertise in microscopy for an accurate interpretation; however, instrumentation is now available that automates routine urinalysis partially or completely. Cytopathologic urine sediment examination also requires special training and is the mainstay for diagnosis and follow-up of urinary tract neoplasms, as well as some nonneoplastic conditions, particularly renal allograft rejection.

We present in detail the pertinent components of the routine urinalysis. Various methods, including sample preparation, reagent strip reactions, confirmatory testing, and microscopic methods, are briefly reviewed. Major emphasis is given to clinicopathologic correlations related to the laboratory findings obtained from these urine tests.

URINE FORMATION

In the normal adult, approximately 1200 mL of blood perfuses the kidneys each minute, which accounts for about 25% of the cardiac output. The glomeruli (normally numbering at least 1 million per kidney) receive blood through afferent arterioles, and an ultrafiltrate of the plasma passes through each glomerulus into Bowman's space. From here, the filtrate is passed through the tubules and collecting ducts, where reabsorption or secretion of various substances and the concentration of urine can occur. Ultimately, the original glomerular filtrate volume of about 180 L in 24 hours is reduced to about 1–2 L, depending on the status of hydration. This urine formed in the kidneys passes from the collecting ducts into the renal pelvis, ureters, bladder, and urethra to be voided.

The kidneys take part in several regulatory functions. Through glomerular filtration and tubular secretion, numerous waste products, including nitrogenous products of protein catabolism, and both organic and inorganic acids and bases, are eliminated from the body. Fluid, electrolytes (including sodium, potassium, calcium, and magnesium), and acid-base status are regulated in homeostasis. Furthermore, the kidneys provide important hormonal regulation with erythropoietin and renin production, as well as vitamin D activation. Any derangement of these functions by renal or systemic disease can be reflected as chemically or cytologically altered urine.

COMPONENTS OF BASIC (ROUTINE) URINALYSIS

The basic (routine) urinalysis consists of four parts: specimen evaluation, gross/physical examination, chemical screening, and sediment examination.

SPECIMEN EVALUATION

Before one proceeds with any examination, the urine specimen must be evaluated in terms of its acceptability. Considerations include proper labeling, proper specimen for the requested examination, proper preservative, visible signs of contamination, and whether any transportation delays may have caused significant deterioration. Each laboratory should have written and enforced guidelines for the acceptance or rejection of specimens. A properly labeled specimen must have the patient's full name and the date and time of collection. Additional information may be required by the institution, but these three essentials constitute minimum labeling requirements.

The first voided morning urine, which is the most concentrated, is best for routine urinalysis. At times, a catheterized specimen or suprapubic collected urine specimen is received. If a single specimen is submitted for multiple measurements, bacteriologic examination should be done first, provided that the urine has been properly collected. With pediatric patients and persons in acute renal failure, only a small volume of urine may be available for processing, and in such cases, a notation should be made and the measurements most pertinent to the diagnosis should be performed first. For quantitative measurements, timed (12- or 24-hour) urinary collection is preferred to random specimens.

GROSS/PHYSICAL EXAMINATION

Appearance

Some of the more important changes in the gross appearance of urine are described in this section. A comprehensive list is provided in Table 28-2.

Color

The yellow color of urine is due largely to the pigment urochrome, excretion of which is generally proportional to the metabolic rate. It is increased

TABLE 28-2

Appearance and Color of Urine

Appearance	Cause	Remarks
Colorless	Very dilute urine	Polyuria, diabetes insipidus
Cloudy	Phosphates, carbonates	Soluble in dilute acetic acid
	Urates, uric acid	Dissolve at 60° C and in alkali
	Leukocytes	Insoluble in dilute acetic acid
	Red cells ("smoky")	Lyse in dilute acetic acid
	Bacteria, yeasts	Insoluble in dilute acetic acid
	Spermatozoa	Insoluble in dilute acetic acid
	Prostatic fluid	
	Mucin, mucous threads	May be flocculent
	Calculi, "gravel"	Phosphates, oxalates
	Clumps, pus, tissue	
	Fecal contamination	Rectovesical fistula
	Radiographic dye	In acid urine
Milky	Many neutrophils (pyuria)	Insoluble in dilute acetic acid
	Fat	
	Lipiduria, opalescent	Nephrosis, crush injury—soluble in ether
Yellow	Chyluria, milky	Lymphatic obstruction—soluble in ether
	Emulsified paraffin	Vaginal creams
	Acridavine	Green fluorescence
Yellow-orange	Concentrated urine	Dehydration, fever
	Urobilin in excess	No yellow foam
	Bilirubin	Yellow foam if sufficient bilirubin
Yellow-green	Bilirubin-biliverdin	Yellow foam
Yellow-brown	Bilirubin-biliverdin	"Beer" brown, yellow foam
Red	Hemoglobin	Positive
	Erythrocytes	Positive
	Myoglobin	Positive
	Porphyria	May be colorless
	Fuscin, aniline dye	Foods, candy
Red-purple	Beets	Yellow alkaline, genetic
	Menstrual contamination	Clots, mucus
	Porphyria	May be colorless
Red-brown	Erythrocytes	
	Hemoglobin on standing	
	Methemoglobin	Acid pH
	Myoglobin	Muscle injury
Brown-black	Bilifuscin (dipyrrole)	Result of unstable hemoglobin
	Methemoglobin	Blood, acid pH
	Homogentisic acid	On standing, alkaline; alkaptonuria
Blue-green	Melanin	On standing, rare
	Indicans	Small intestine infections
	<i>Pseudomonas</i> infections	
	Chlorophyll	Mouth deodorants

during fever, thyrotoxicosis, and starvation. Small quantities of urobilins and uroerythrin (pink pigment) also contribute to urine coloration. In normal individuals, both pale and dark yellow urine can be produced, and these differences are rough indicators of hydration and urine concentration. Pale urine, typically of low specific gravity, is excreted following high fluid intake; darker urine is seen when fluids are withheld. Note that pale urine of high specific gravity may be found in diabetes mellitus. For color changes of urine in pediatric patients, see Cone (1968). Table 28-3 lists the urine color changes associated with commonly used drugs.

Red Urine. The most common abnormal color is red or red-brown. When seen in females, menstrual flow contamination should be considered. Hematuria (presence of red blood cells [RBCs]), hemoglobinuria, and myoglobinuria may produce pink, red, or red-brown coloration. All three of these conditions are easily detectable on reagent strip testing; however, further evaluation is necessary for absolute differentiation (see later under Blood, Hemoglobin, Hemosiderin, and Myoglobin in Urine).

In the porphyrias, urine coloration is variable. It is usually red in congenital erythropoietic porphyria and porphyria cutanea tarda, but in lead porphyria, the urine color is generally normal. In acute intermittent hepatic porphyria, it is normal but darkens on standing. Red urine also

may be associated with the use of drugs and dyes in diagnostic tests, for example, phenolsulfonphthalein, which is sometimes used in assessing renal function, will cause a red color in alkaline urine. Patients with an unstable hemoglobin may produce urine with red-brown color that does not give a positive indication of hemoglobin or bilirubin. The pigment is probably a dipyrrole or bilifuscin. An innocuous red urine associated with ingestion of beets is seen in genetically susceptible persons.

Yellow-Brown or Green-Brown Urine. Yellow-brown or green-brown urine is generally associated with bile pigments, chiefly bilirubin. On shaking the urine specimen, a yellow foam may be seen, which distinguishes bilirubin from a normal, dark, concentrated urine, which will have white foam. In severe obstructive jaundice, the urine may be dark green.

Orange-Red or Orange-Brown Urine. Excreted urobilinogen is colorless but is converted in the presence of light and low pH to urobilin, which is dark yellow to orange. Urobilin will not color the foam on shaking, and in this way may be confused with a concentrated normal urine; reagent strip testing would be confirmatory in this situation.

Dark Brown or Black Urine. Acid urine containing hemoglobin will darken on standing because of the formation of methemoglobin. "Cola-colored" urine may be seen with rhabdomyolysis (Keverline, 1998) and in some patients taking L-dopa. Rarer causes of dark brown urine are homogentisic acid (alkaptonuria) and melanin. Urine-containing homogentisic acid will darken more rapidly when alkaline.

Clarity (Character)

Urine is normally clear, and the presence of particulate material in an unspun specimen warrants further investigation. The differential diagnosis for cloudy urine is broad and includes several nonpathologic entities. Turbidity may simply be due to the precipitation of crystals or nonpathologic salts referred to as amorphous. Phosphate, ammonium urate, and carbonate can precipitate in alkaline urine; these redissolve when acetic acid is added. Uric acid and urates cause a white, pink, or orange cloud in acid urine and redissolve on warming to 60° C.

Cloudy urine can be attributed to the presence of various cellular elements. Leukocytes may form a white cloud similar to that caused by phosphates, but the cloud remains after acidification. Likewise, bacterial growth may cause a uniform opalescence that is not removed by acidification or by filtration, and it has been suggested that turbidimetric assessment using a double-beam turbidimeter may be useful for urine infection screening (Livsey, 1995). Turbidity may also be due to RBCs, epithelial cells, spermatozoa, or prostatic fluid. Prostatic fluid normally contains a few leukocytes and other formed elements.

Miscellaneous causes for cloudy urine include mucus from the lower urinary tract or genital tract, blood clots, menstrual discharge, and other particulate material such as pieces of tissue, small calculi, clumps of pus, and fecal material. Fecal material in urine may occur with a fistulous connection between the colon or rectum and bladder. Contamination with powders or with antiseptics that become opaque with water (phenols) will also cause a turbid urine.

Chyluria. This is a rare condition in which the urine contains lymph. It is associated with obstruction to lymph flow and rupture of lymphatic vessels into the renal pelvis, ureters, bladder, or urethra. Although parasitic infection with *Wuchereria bancrofti* (filariasis) is the prevailing cause (Cortvriend, 1998), abdominal lymph node enlargement and tumors have also been associated with chyluria. Even with filariasis, this condition is rare.

The appearance of the urine varies with the amount of lymph present, ranging from clear to opalescent or milky. Clots may form, and if sufficient lymph is present, the urine may layer with the chylomicrons on top, and fibrin and cells beneath. Chylomicrons may not be apparent microscopically unless they have coalesced as microglobules. This fatty material can be extracted from urine using an equal volume of ether or chloroform. Urine phosphates, in contradistinction, will not clear with this method. Pseudochyluria occurs with the use of paraffin-based vaginal creams for the treatment of *Candida* infection.

Lipiduria. Fat globules appear in the urine most often with the nephrotic syndrome; these consist of neutral fats (triglycerides) and cholesterol. Lipiduria can also be present in patients who have sustained skeletal trauma with fractures to major long bones or the pelvis. Presumably, the source of lipid is exposed fatty marrow. Keep in mind that in addition to these endogenous lipids, oily contaminants such as paraffin may float on the

TABLE 28-3

Urine Color Changes with Commonly Used Drugs*

Drug	Color
Alcohol, ethyl	Pale, diuresis
Antraquinone laxatives (senna, cascara)	Reddish, alkaline; yellow-brown, acid
Chlorzoxazone (Paraflex) (muscle relaxant)	Red
Deferoxamine mesylate (Desferal) (chelates iron)	Red
Ethoxazene (Serenium) (urinary analgesic)	Orange, red
Fluorescein sodium (given IV)	Yellow
Furazolidone (Furoxone) (Tricofuron) (an antibacterial, antiprotozoal nitrofurantoin)	Brown
Indigo carmine dye (renal function, cystoscopy)	Blue
Iron sorbitol (Jectofer) (possibly other iron compounds forming iron sulfide in urine)	Brown on standing
Levodopa (L-dopa) (for parkinsonism)	Red then brown, alkaline
Mepacrine (Atabrine) (antimalarial) (intestinal worms, <i>Giardia</i>)	Yellow
Methocarbamol (Robaxin) (muscle relaxant)	Green-brown
Methyldopa (Aldomet) (antihypertensive)	Darkens; if oxidizing agents present, red to brown
Methylene blue (used to delineate fistulas)	Blue, blue-green
Metronidazole (Flagyl) (for <i>Trichomonas</i> infection, amebiasis, <i>Giardia</i>)	Darkening, reddish brown
Nitrofurantoin (Furadantin) (antibacterial)	Brown-yellow
Phenazopyridine (Pyridium) (urinary analgesic), also compounded with sulfonamides (Azo Gantrisin, etc.)	Orange-red, acid pH
Phenindione (Hedulin) (anticoagulant) (important to distinguish from hematuria)	Orange, alkaline; color disappears on acidifying
Phenol poisoning	Brown; oxidized to quinones (green)
Phenolphthalein (purgative)	Red-purple, alkaline pH
Phenolsulfonphthalein (also sulfobromophthalein)	Pink-red, alkaline pH
Rifampin (Rifadin, Rimactane) (tuberculosis therapy)	Bright orange-red
Riboflavin (multivitamins)	Bright yellow
Sulfasalazine (Azulfidine) (for ulcerative colitis)	Orange-yellow, alkaline pH

*Other commonly used drugs have been noted to produce color change once or occasionally: amitriptyline (Elavil)—blue-green; phenothiazines—red; triamterene (Dyrenium)—pale blue (blue fluorescence in acid urine). An extensive list may be found in Young et al. Clin Chem 1975;21:379.

urine surface. Microscopic examination of the urine may be required to classify fatty materials as Oil Red O positive droplets or cholesterol esters with polarization.

Odor

Urine normally will have a faint, aromatic odor of undetermined source. Specimens with extensive bacterial overgrowth can be recognized by an ammoniacal, fetid odor. Additionally, ingestion of asparagus or thymol produces distinctive odors in urine.

Characteristic urine odors associated with amino acid disorders include the following:

Isovaleric acidemia and glutaric acidemia	Sweaty feet
Maple syrup urine disease (MSUD)	Maple syrup
Methionine malabsorption	Cabbage, hops
Phenylketonuria	Mousy
Trimethylaminuria	Rotting fish
Tyrosinemia	Rancid

Lack of odor in urine from patients with acute renal failure suggests acute tubular necrosis rather than prerenal failure.

Urine Volume

Under ordinary conditions, the main determinant of urine volume is water intake. The average adult produces from 600–2000 mL of urine per day, with night urine generally not in excess of 400 mL. In pregnancy, the usual diurnal variation may be reversed. Young children, compared with adults, may excrete about three to four times as much urine per kilogram of body weight. Measurement of urine output during timed intervals may be valuable in clinical diagnosis.

Increases in Urine Volume

Production of more than 2000 mL of urine in 24 hours is termed **polyuria**; **nocturia** is excretion of more than 500 mL of urine at night with a specific gravity of less than 1.018. In general, high volumes of urine tend to result in a low specific gravity.

Excessive intake of water (polydipsia) will result in polyuria, as will consumption of certain drugs with a diuretic effect, such as caffeine,

alcohol, thiazides, and other diuretics. Intravenous solutions may increase the urine output. Increased salt intake and high-protein diets will require more water for excretion.

Pathologic states that result in excess renal fluid loss/urine excretion can be divided into three groups.

Defective Hormonal Regulation of Volume Homeostasis. Diabetes insipidus can be due to a deficiency (central/pituitary variety) of, or renal unresponsiveness (nephrogenic) to, antidiuretic hormone. In either situation, excessive thirst and water intake occur, together with marked polyuria and nocturia. Up to 15 L of urine per day may be produced.

Defective Renal Salt/Water Absorption. This can be due to the administration of diuretic agents, or an abnormality of the renal tubules, resulting in sodium wasting or impairment of the countercurrent mechanism. In progressive chronic renal failure, functioning renal tissue is diminished, and the ability to concentrate urine is gradually lost. To excrete the daily renal water and solute load, an increase in urine volume per residual nephron results, and the urine eventually becomes isoosmotic with the plasma ultrafiltrate.

Osmotic Diuresis. In diabetes mellitus with hyperglycemia, an excessive amount of glucose is excreted, causing a solute diuresis.

Decreases in Urine Volume

Oliguria is the excretion of less than 500 mL of urine per 24 hours, and anuria is the near-complete suppression of urine formation. Water deprivation will cause a decrease in urine volume even before signs of dehydration appear. Oliguria can be rather abrupt in onset, as can acute renal failure, or it may be due to a chronic progressive renal disease. In either case, retention of nitrogenous waste products (azotemia) can occur (see Chapter 14).

The causes of acute renal failure are classically categorized as follows.

Prerenal. Loss of intravascular volume may result from hemorrhage, or from dehydration associated with prolonged diarrhea, vomiting, excess sweating, or severe burns. So-called **third spacing** is the shifting of

intravascular fluids to extracellular spaces. Additionally, conditions such as congestive heart failure, sepsis, anaphylaxis, or renal artery embolic occlusion may result in a decrease in renal blood flow.

Postrenal. Bilateral hydronephrosis, resulting from high-grade or long-standing obstruction of the urinary tract, may be associated with a marked decrease in urine flow and even anuria. This can occur with prostatic hyperplasia and carcinoma. Bilateral ureteral obstruction due to stones, clots, and sloughed tissue, and urethral obstruction due to stricture or valves, are other forms of obstruction. The anuria associated with sulfonamide therapy and dehydration is due to obstruction caused by the precipitation of crystals in the renal tubules when the urinary pH is acidic.

Renal Parenchymal Disease. This should be considered after other prerenal and postrenal causes of oliguria have been ruled out. The list of conditions is extensive and includes various vascular disorders, glomerulonephritis, interstitial nephritis, and acute tubular necrosis (ATN). A common cause of ATN is renal ischemia due to heart failure or hypotension. Numerous nephrotoxic agents may produce ATN, including several antibiotics, mercury, cadmium, carbon tetrachloride, and glycerol. Other causes include hemoglobinuria and myoglobinuria, associated with hemolysis and muscle damage, respectively, as well as excessive quantities of intratubular proteins or crystals.

Chronic renal failure, a progressive and irreversible loss of renal function, results from several disease entities. These include hypertensive and diabetes-associated nephrosclerosis, chronic glomerulonephritis, polycystic kidney disease, and other urologic disorders. Urinary specific gravity is low, and proteinuria, casts, and renal cells may be evident. Pyelonephritis or interstitial nephritis will cause predominantly tubular dysfunction with polyuria early in the disease, but later oliguria of chronic renal failure supervenes.

Specific Gravity and Osmolality

The volume of excreted urine and the concentrations of its solutes are varied by the kidney to maintain the homeostasis of body fluid and electrolytes. Specific gravity and osmolality measurements reflect the relative degree of concentration or dilution of a urine specimen. This in turn aids in evaluating the concentrating and diluting abilities of the kidneys. Both of these indices, as well as urine color, have been found to be reliable indicators of hydration status (Armstrong, 1998).

The specific gravity of a specimen indicates the relative proportions of dissolved solid components to total volume of the specimen; in other words, it reflects the density of the specimen. Osmolality, on the other hand, indicates the number of particles of solute per unit of solution. Larger particles, such as proteins and sugars, tend to elevate the specific gravity more than smaller electrolytes. In critical circumstances, the measurement of osmolality of urine (and plasma) is preferred to the measurement of specific gravity.

Specific Gravity

Urea (20%), sodium chloride (25%), sulfate, and phosphate contribute most of the specific gravity of normal urine. Normal adults with adequate fluid intake will produce urine of specific gravity 1.016–1.022 over a 24-hour period; however, normal kidneys have the ability to produce urine with specific gravity that ranges from 1.003–1.035. If a random specimen of urine has a specific gravity of 1.023 or more, concentrating ability can be considered normal. Minimum specific gravity after a standard water load should be less than 1.007.

Urines of low specific gravity are called hyposthenuric, with the specific gravity less than 1.007. In diabetes insipidus, loss of concentrating ability (as described earlier) results in production of large volumes of urine with specific gravity as low as 1.001 (specific gravity of water is 1.000). Prolonged excretion of urine with low specific gravity can also be seen with various renal abnormalities, including pyelonephritis and glomerulonephritis. High specific gravity can be seen after excess water loss/dehydration, adrenal insufficiency, hepatic disease, or congestive heart failure. When little or no variability is noted between several specimens from a patient, and the specific gravity is fixed at about 1.010, this is known as **isosthenuria**. This finding is indicative of severe renal damage with disruption of both concentrating and diluting abilities.

Methods. Several methods are available to measure specific gravity—reagent strip, refractometer, urinometer, and the falling drop method.

Reagent Strip. This is an indirect method for measuring specific gravity. The reagent area has three main ingredients present: polyelectrolyte,

indicator substance, and buffer. The principle of this method is based on the pKa change of pretreated polyelectrolytes in relation to the ionic concentration of the urine. When the ionic concentration is high, the pKa (acid dissociation constant) is decreased, as is the pH. The indicator substance then changes color relative to ionic concentration, and this is translated to specific gravity values. This method is not affected by high amounts of glucose, protein, or radiographic contrast material, all of which tend to elevate the specific gravity readings obtained from refractometers and urinometers, described in the following sections.

Refractometer. This is also an indirect method. The refractive index of a solution is related to the content of dissolved solids present. The index is the ratio of the velocity of light in air to the velocity of light in a solution. It varies directly with the proportion of particles in solution and, therefore, with the specific gravity.

The clinical refractometer is a device that requires only a few drops of urine (unlike the 15 mL of urine necessary with the urinometer). Although the refractometer measures the refractive index of a solution, the scale used is valid only for urine and cannot be used to indicate the specific gravity of salt or sugar solutions. This should be kept in mind if salt solutions are to be used for calibration. Special graphs or tables are required to convert refractive index scale numbers to solute concentrations in aqueous solutions if this should be required (American Optical Catalog Number 10403). The specific gravity reading on the refractometer is generally slightly lower than a urinometer reading on the same urine specimen by about 0.002.

Procedure. A temperature-compensated hand model is available. The instrument is temperature compensated between 60° and 100° F (15° to 38° C). It is damaged by heat above 150° F (66° C) and by immersion of the eyepiece and focusing ring in water. It should read zero with distilled water; the zero reading can be reset if necessary by breaking the seal over the setscrew, turning it with a small screwdriver, and resealing. Check calibration daily. Copper sulfate solutions can be adjusted to monitor a high specific gravity level as an additional check.

To make a specific gravity determination of urine, clean the surfaces of the cover and prism with a drop of distilled water and a damp cloth, and allow them to dry. Close the cover. Hold horizontally, and apply a drop of urine at the notched bottom of the cover, so that it flows over the prism surface by capillary action. Point the instrument toward a light source at an angle that gives optimal contrast. Rotate the eyepiece until the scale is in focus. Read directly on the specific gravity scale the sharp dividing line between light and dark contrast. The entire procedure should be repeated with a second drop of urine from the same sample.

Urinometer. This is a hydrometer that is adapted to directly measure the specific gravity of urine at room temperature. It should be checked each day by measuring the specific gravity of distilled water. If the urinometer does not give a reading of 1.000, an appropriate correction must be applied to all readings taken with that urinometer. The accuracy of a urinometer may be further checked with solutions of known specific gravity.

Because temperature influences the specific gravity, urine samples should be allowed to come to room temperature before a reading is made, or a correction of 0.001 should be made for each 3° C above or below the calibration temperature indicated on the urinometer. Corrections must also be made for protein or glucose present; subtract 0.003 for every 1 g/dL of protein, and 0.004 for every 1 g/dL of glucose.

Procedure. The urinometer vessel is filled three-fourths full with urine (minimum volume required is about 15 mL). The urinometer is inserted with a spinning motion to make sure that it is floating freely. (When reading the urinometer, be sure that it is not touching the sides or the bottom of the cylinder. Avoid surface bubbles, which obscure the meniscus.) Read the bottom of the meniscus.

Falling Drop Method. This is a direct method for measuring specific gravity. It is more accurate than the refractometer, and is more precise than the urinometer. This method utilizes a specially designed column filled with water-immiscible oil. A measured drop of urine is introduced into the column, and as this drop falls, it encounters two beams of light; breaking the first beam starts a timer, and breaking the second turns it off. The falling time is measured electronically and is expressed as a specific gravity (Free, 1996).

Osmolality. The normal adult with a normal fluid intake will produce urine of about 500–850 mOsm/kg water. The normal kidney is able to produce a urine osmolality in the range of 800–1400 mOsm/kg water in dehydration, and a minimal osmolality of 40–80 mOsm/kg water during water diuresis. After a period of dehydration, the osmolality of the urine

TABLE 28-4

Recommendations for Reagent Strips

Storage

- Protect from moisture and excessive heat.
- Store in cool, dry area but not in a refrigerator.
- Check for discoloration with each use; discoloration may indicate loss of reactivity.
- Do not use discolored strips or tablets.
- Keep container tightly stoppered.
- Check manufacturer's directions with each new lot number for changes in procedure.

Testing

- Test urine as soon as possible after receipt.
- Remove only enough strips for immediate use; recap tightly.
- Test a well-mixed, unspun urine sample.
- Urine samples must be at room temperature before testing.
- Do not touch the test area with fingers.
- Do not use reagent strips in the presence of volatile acids or alkaline fumes.
- Dip reagent strip into urine briefly—no longer than 1 second.
- Drain excess urine off—run edge of strip along rim of tube, or blot edge on absorbent paper.
- Do not allow reagents to run together.
- Do not lay reagent strip directly on workbench surface.
- Follow exact timing recommendations for each chemical test.
- Hold reagent strip close to the color chart, and read under good lighting.
- Know sources of error, sensitivity, and specificity of each test on the reagent strip.
- Think! Make correlations between patient history and individual test, then follow through.

should be three to four times that of the plasma (e.g., with a plasma osmolality of 285 mOsm/kg water, the urine osmolality should be at least 855 mOsm/kg water).

Methods. The freezing-point depression method is commonly employed. A solution containing 1 osmol or 1000 mOsm/kg water depresses the freezing point 1.86° C below the freezing point of water. For methods, see Chapter 4.

CHEMICAL SCREENING

Reagent strips are the primary method used for the chemical examination of urine. Although easily used, they represent multiple complex, state-of-the-art chemical reactions. Table 28-4 lists recommendations for both storage and use of reagent strips. Although reading of the strips has traditionally been done manually, automated instruments, such as the Bayer Atlas (Siemens Medical Solutions Diagnostics, Tarrytown, NY), are now available that will aspirate a precise amount of urine, deposit it on the dipstick, and read the chemical reactions on the reagent strip by reflectance (Lyon, 2003; Penders, 2002). These systems provide excellent reproducibility of results and are not prone to some of the inconsistencies that occur when human hands try to time the reactions, and when human eyes attempt to discriminate different shades of color reactions.

It should be noted that reagent strip methods are changed periodically, sensitivities and color reactions altered, and new measurements added. Manufacturers supply tables of common interfering substances, and these should be consulted. Interference with ascorbic acid and drugs producing colored urines such as phenazopyridine (Pyridium) and other azo compounds, as well as methylthioninium chloride (methylene blue), may be encountered. More detailed information on drug interference is listed in Young (1990).

The chemical measures most commonly found on reagent strips will be discussed first, with less commonly measured chemical parameters following. A discussion on the clinical application of each analyte will precede reagent strip and other methods. Confirmatory methods will be included when available and necessary.

Urine pH

The kidneys and lungs normally work in concert to maintain acid-base equilibrium. The lung excretes carbon dioxide, whereas the renal

contribution is that of reclaiming and generating bicarbonate and secreting ammonium ions. The proximal renal tubule is responsible for the bulk of the bicarbonate reabsorption/generation, and the distal tubule provides the remaining function.

The tubular cells exchange hydrogen ions for sodium of the glomerular filtrate. The metabolic activity of the body produces nonvolatile acids, principally sulfuric, phosphoric, and hydrochloric acids, but also small amounts of pyruvic, lactic, and citric acids and ketone bodies. These are excreted by the glomerulus as salts (sodium, potassium, calcium, and ammonium salts) and, together with ammonia produced by the proximal tubules, can then go on to trap secreted hydrogen ions for elimination in the urine (see Chapter 14).

Normal pH

The average adult on a normal diet excretes about 50–100 mEq of hydrogen ions in 24 hours to produce urine of about pH 6. In healthy individuals, urine pH may vary from 4.6–8.

Acid Urine

Acid urine may be produced by a diet high in meat protein and with some fruits such as cranberries. During the mild respiratory acidosis of sleep, a more acid urine may be formed. Also, therapeutic acidification of the urine by various pharmacologic agents, including ammonium chloride, methionine, and methenamine mandelate, is used in the treatment of some calculi. This would include phosphate and calcium carbonate stones, which tend to develop in alkaline urines.

In acid-base disturbances, the pH of the urine reflects attempts at compensation by the kidneys. Patients with metabolic or respiratory acidosis should produce acid urine with increased titratable acidity and ammonium ion concentration. In diabetic ketoacidosis, large quantities of hydrogen ions are excreted, much as ammonium ion. In potassium depletion, such as in hypokalemic alkalosis of prolonged vomiting or in hypercorticism, or with prolonged use of diuretics, paradoxical aciduria with slightly acid urine may occur in the presence of a metabolic alkalosis.

Alkaline Urine

Alkaline urine may be induced by a diet high in certain fruits and vegetables, especially citrus fruits. The urine tends to become less acid following a meal (the so-called **alkaline tide**). This was long believed to be a urinary compensation for gastric acid secretion; however, recent studies do not support this view (Johnson, 1995). Sodium bicarbonate, potassium citrate, and acetazolamide may be used to induce alkaline urine in the treatment of some calculi, particularly those composed of uric acid, cystine, or calcium oxalate. These agents may also be used in some urinary tract infections (the antibiotics neomycin, kanamycin, and streptomycin are more active in alkaline urine), in sulfonamide therapy, and in the treatment of salicylate poisoning.

The capacity to exchange hydrogen ion for cation and the formation of ammonia are decreased when tubular function is impaired. In classic renal tubular acidosis, glomerular filtration is normal, but the distal tubular ability to form ammonia and exchange hydrogen ions for cations is defective. Systemic acidosis results. The urine is relatively alkaline, and the pH cannot be lowered below 6–6.5, even with administration of an acid-loading substance. Additionally, titratable acidity and the concentration of ammonium are decreased (Singh, 1995). In proximal renal tubular acidosis, bicarbonate wasting occurs. This can also be seen in Fanconi's syndrome.

In metabolic alkalosis, an alkaline urine with higher levels of urinary bicarbonate is produced, and ammonia production is decreased. The kidney may produce urine with a pH as high as 7.8. In respiratory alkalosis, an alkaline urine is produced that is associated with increased excretion of bicarbonate.

Methods

Reagent Strip. Indicators methyl red and bromothymol blue give a range of orange, green, and blue colors as the pH rises, permitting estimation of pH values to within half a unit within the range of 5–9. It should be read immediately, but time is not critical. Care should be taken not to have excessively wet strips where acid buffer from the protein patch runs into the pH patch, causing it to become orange.

Measurement of urine pH and acidity must always be made on freshly voided specimens. If precise measurements are required, the container should be filled to minimize the amount of dead space, and the urine covered tightly. The container should be kept cold, preferably on ice, but

not frozen. On standing, the pH tends to rise because of loss of carbon dioxide and because bacterial growth produces ammonia from urea.

pH Electrode. Although the estimate of the pH obtainable by indicator strip is usually sufficient, in patients with disturbances of acid-base balance, urinary pH may be accurately measured with a pH meter with a glass electrode. Because the pH meter may tend to drift, it must be standardized with three buffers of known pH immediately before use. After standardization, spray the electrodes with distilled water, clean, and dry with tissue. Immerse the electrode in the urine sample, and report the pH of urine at the temperature of measurement.

Titrateable Acidity of Urine. The pH of the urine is largely dependent on the amounts of monobasic and dibasic phosphate present. Titrateable acidity is measured by titrating an aliquot of 24-hour urine (collected on ice) with 0.1N NaOH with pH 7.4 as an endpoint. Measurement may be used, together with urinary ammonia determination, in patients with chronic acidosis of obscure origin. Normal titrateable acidity is in the range of 200–500 mL 0.1N NaOH (or 6 mL 0.1N NaOH per kg body weight) or 20–40 mEq/24 hours. This procedure is described in previous editions of this book (Henry, 1996).

Protein in Urine

Normally, up to 150 mg of protein is excreted in the urine daily, with the average urine protein concentration varying from 2–10 mg/dL, depending on urine volume. Anderson has demonstrated more than 200 urinary proteins, derived from both plasma and the urinary tract (Anderson, 1979). About one third is albumin, and the remaining plasma proteins include small globulins, such as α -, β -, and γ -globulins. Plasma proteins with molecular weight less than 50,000–60,000 pass through the glomerular basement membrane and are normally reabsorbed by proximal tubular cells. Albumin, molecular weight 69,000, is apparently filtered but only in very small amounts. Retinol binding, β_2 -microglobulin, immunoglobulin light chains, and lysozyme are excreted in small amounts. Tamm-Horsfall glycoprotein (uromucoid), secreted by distal tubular cells and cells of the ascending loop of Henle, constitutes one third or more of the total normal protein loss. Immunoglobulin A (IgA) in secretions of the urinary tract, enzymes, and proteins from tubular epithelial cells, other desquamated cells, and leukocytes also contribute to urine protein.

Detection of an abnormal amount of protein in urine is an important indicator of renal disease because protein has a very low maximal tubular rate of reabsorption; increased filtration of protein quickly saturates the reabsorptive mechanism. Screening methods are routinely used to differentiate normal protein excretion from abnormal, and therefore should not detect less than about 8–10 mg/dL in a normal adult with a normal rate of urine flow. The reagent strip method is sensitive to albumin; acid precipitation methods detect all proteins and therefore will indicate the presence of globulins, as well as albumin. It should be noted that a very dilute random urine specimen may have a falsely low protein value. Because a positive result for protein is significant, it should be confirmed by a second method and on repeated specimens. Depending on the history and examination, confirmatory measurements for elevated protein should be accompanied by the evaluation of renal function, examination of the urine sediment, and urine culture.

Functional proteinuria is usually less than 0.5 g/day and can be seen in various situations in which dehydration contributes to the level of protein measured in urine. With strenuous exercise, a mixture of high and low molecular weight proteins appears in the urine, and many casts, both hyaline and granular, can be seen. Functional proteinuria may also accompany congestive heart failure, cold exposure, and fever. In any event, the proteinuria resolves with appropriate treatment or rest within 2–3 days.

Intermittent, transient proteinuria can occasionally be seen in patients with a normal history, normal physical examination findings, and otherwise normal renal function. Except for the occasional proteinuria, urinalysis is also normal. These patients are typically followed every 6 months to check for hypertension or other abnormalities, and the overall prognosis is good. A transient proteinuria may also occur in normal pregnancy, but any proteinuria in pregnancy is an important finding and requires investigation. Persistent proteinuria of 1–2 g/day in an asymptomatic person, or when accompanied by hematuria, has a poorer prognosis than intermittent (transient) or postural proteinuria.

Recent interest has focused on the importance of proteinuria in determining risk of adverse outcomes in chronic kidney disease (CKD). Current guidelines for classifying stages of CKD are based on estimated glomerular

filtration rate; however, heavy proteinuria was found to be independently associated with a twofold or greater increase in all-cause mortality, myocardial infarction, and progression to renal failure (Hemmelgarn, 2010). A systematic review and meta-analysis of 26 cohort studies involving 169,949 individuals showed a strong and continuous association between proteinuria and risk of coronary artery disease, leading those authors to suggest the routine incorporation of testing for proteinuria into assessment of cardiovascular risk (Perkovic, 2008).

Hereditary proteinuria syndromes are rare and have heterogeneous forms ranging from congenital nephrotic syndrome with severe proteinuria to focal segmental glomerulosclerosis with moderate proteinuria. Progression to end-stage renal disease is a common outcome. Specific diagnosis is possible with genetic testing for mutations in the genes for various structural proteins of the glomerulus (Tryggvason, 2006).

Postural Proteinuria

Postural proteinuria (orthostatic) occurs in 3%–5% of apparently healthy young adults. In this condition, proteinuria is found during the day but not at night when a recumbent position is assumed. Persistent proteinuria may develop in some of these healthy subjects at a later date, and renal biopsies have shown abnormalities of the glomerulus in a few cases (Robinson, 1961). Proteinuria is apparently related to an exaggerated lordotic position and may result from renal congestion or ischemia. The total daily excretion of protein rarely exceeds 1 g, and in most instances, no other evidence of renal disease develops is apparent.

To evaluate the possibility of postural proteinuria, the patient is instructed to empty his or her bladder upon going to bed in the evening. Immediately upon arising in the morning, the patient voids and saves this specimen. After 2 hours of standing and walking about, the patient voids again and saves the specimen. The two urine specimens are assessed for protein, and if the first is negative and the second positive, the patient may have postural proteinuria. Frequent examination of the patient should be made to reevaluate this condition.

Proteinuria in the Elderly

The incidence of significant proteinuria found on urinalysis in the elderly population is substantially increased when compared with patients below age 60. It has been estimated that the elderly population in general has a threefold to fourfold greater incidence of glomerulonephritis, and approximately one quarter of those affected have a minimal change–like disorder that may respond to steroid therapy. Occult malignancies in this population may also give rise to membranous glomerulonephritis, with resultant proteinuria (Threatte, 1986).

Proteinuria Quantification

More useful information for the diagnosis of kidney disease and for following the response to treatment is obtained by quantitatively analyzing the amount of protein excreted over a 24-hour period. It should be noted that the accuracy of measurements of any quantitative urine determination depends on the adequacy and completeness of the urine collection. Erroneous results are often related to collection problems. Repeat measurements may be needed to decide whether the proteinuria is intermittent or persistent.

Heavy Proteinuria (>4 g/day). Heavy protein loss is characteristically seen with the nephrotic syndrome. Classically, a low serum albumin level, generalized edema, and increased serum lipids (cholesterol, triglycerides, and phosphatides) accompany this disorder. Lipoproteins, low-density and very-low-density, are increased in serum, whereas high-density lipoprotein, a smaller molecule, has been demonstrated in the urine (de Mendoza, 1976). It has been suggested that loss of lipoprotein lipase in urine contributes to the rise in serum lipid levels. γ -Globulin is also lost in the urine, and this may contribute to susceptibility to bacterial infections commonly found in nephrotic patients. When lipid is lost in urine, many granular casts, fatty casts, and fat-filled renal tubular epithelial cells (oval fat bodies) are found in the sediment. Cholesterol ester droplets may be demonstrable by polarization.

Nephrotic syndrome is principally associated with glomerular dysfunction/damage due to (1) primary renal diseases, including idiopathic disease, and (2) systemic diseases with renal involvement. Transient or mechanical causes include severe congestive heart failure, constrictive pericarditis, and renal vein thrombosis. The last can be a consequence of the nephrotic syndrome because of losses of ant clotting factors in urine and elevation of serum fibrinogen. In children, a common cause of nephrotic syndrome is minimal change disease (also known as nil lesion), a

steroid-responsive glomerular disorder. Acute, rapidly progressive, and chronic types of glomerulonephritis are causes of heavy proteinuria and may be accompanied by urinary erythrocytes or erythrocyte casts. Diabetes mellitus and lupus erythematosus are systemic diseases that frequently cause glomerular injury and heavy proteinuria. Urine sediment may be “telescoped,” that is, may display all types of cells and casts in lupus nephritis or with a hypersensitivity reaction. Malaria, malignant hypertension, toxemia of pregnancy, heavy metals (gold, mercury), drugs (penicillamine), neoplasia in general, amyloidosis, sickle cell disease, renal transplant rejection, and rarely primary antiphospholipid syndrome (Levy, 1998) are additional causes of heavy proteinuria.

Moderate Proteinuria (1.0–4.0 g/day). Moderate proteinuria may be found in the vast majority of renal diseases, including those mentioned previously, as well as nephrosclerosis, multiple myeloma, and toxic nephropathies. Also included are degenerative, malignant, and inflammatory conditions of the lower urinary tract, including irritative conditions such as the presence of calculi.

Minimal Proteinuria (<1.0 g/day). Minimal proteinuria may be noted in chronic pyelonephritis, in which case it may be intermittent, and in relatively inactive phases of glomerular diseases. It is also seen with nephrosclerosis, chronic interstitial nephritis, congenital diseases such as polycystic disease and medullary cystic disease, and renal tubular diseases. In tubular diseases, the urinary sediment usually is not abnormal, but erythrocytes, leukocytes, and tubular cells may be seen with interstitial nephritis. However, significant sediment findings may sometimes accompany trace protein results. Minimal proteinuria is also present in postural proteinurias and transient proteinuria.

Qualitative Categories of Proteinuria

Detection of the types of protein present in urine requires electrophoretic separation of urine proteins. Based on these and on clinical findings, proteinuria may be separated into a glomerular pattern and a tubular pattern, indicating which part of the nephron is primarily involved. However, these anatomic entities tend to merge as disease progresses.

Glomerular Pattern. Glomerular disease causes proteinuria, which may be heavy (>3–4 g/day). Loss or reduction of the fixed negative charge on the glomerular basement membrane allows albumin to permeate into Bowman’s space in large quantities, more than can be reabsorbed by the proximal tubular cells. When serum albumin is lost in urine, other proteins of similar size or charge are also lost (e.g., antithrombin, transferrin, prealbumin, α_1 -acid glycoprotein, α_1 -antitrypsin). Because tubular function may still be normal, very small plasma proteins are largely reabsorbed. Large proteins, in contradistinction, are not seen in urine while the glomerulus is still selective (e.g., α_2 -macroglobulin, β -lipoprotein). As larger proteins appear, the proteinuria is less selective, indicating greater damage to the glomerulus (e.g., with membranous nephropathy and proliferative glomerulonephritis).

Mechanisms of proteinuria in diabetic kidney disease with specific attention to glomerular damage were recently reviewed with special recognition that chronic kidney disease is actually a combination of both glomerular and tubulointerstitial scarring (Jefferson, 2008).

Tubular Pattern. This is associated with loss of a small amount of urinary protein that would otherwise be largely reabsorbed. These proteins most often are of low molecular weight (e.g., α_1 -microglobulin, β -globulins such as β_2 -microglobulin, light chain immunoglobulins, and lysozyme), usually without a clear predilection for albumin-sized molecules. By radioimmunoassay, β_2 -microglobulin excretion has been measured in microgram amounts in urine as an indication of tubular damage; its normal excretion is about 100 μ g/day. A tubular pattern proteinuria occurs with renal tubular diseases such as Fanconi’s syndrome, cystinosis, Wilson’s disease, and pyelonephritis, and with renal transplantation rejection. The amount of proteinuria is typically lower than that seen with glomerular disease, at about 1–2 g/day. Tubular proteinuria may be missed by the reagent strip test because of the absence or very low amounts of albumin, but it may be detected by an acid precipitation method.

Overflow Proteinuria. Overflow proteinuria is due to the overflow of excess levels of a protein in the circulation, and can be seen with hemoglobin, myoglobin, or immunoglobulin loss into the urine. These proteins are not initially associated with glomerular or tubular diseases, but may themselves cause renal damage. Myoglobin may cause acute tubular

necrosis (see under Myoglobin). Hemoglobin in low amounts is not thought to be toxic unless hypovolemia is present.

Bence Jones Proteinuria. Bence Jones proteinuria is associated with multiple myeloma, macroglobulinemia, and malignant lymphomas. The incidence of Bence Jones proteinuria in multiple myeloma has been estimated as 50%–80%; however, its demonstration depends greatly on the technique used. Bence Jones protein may be missed altogether if only a reagent strip test for protein is used. Electrophoresis and immunofixation electrophoresis methods are the best detection and quantification methods, along with the immunoassay measurement of free light chains (see Chapter 46).

Excretion of Bence Jones protein in large amounts, sometimes several grams in 24 hours, causes the tubular cells to deteriorate because of the high levels of protein reabsorbed. Inclusions may form in the cells, and desquamated cells may form casts in the tubular lumen. Casts also form from immunoglobulin and Tamm-Horsfall protein mixtures. With renal failure, less protein is reabsorbed and more Bence Jones protein and other proteins appear in the urine. The damaged kidney is sometimes called a myeloma kidney, and the nephrotic syndrome may follow.

Microalbuminuria. Microalbuminuria is the presence of albumin in urine above the normal level but below the detectable range of conventional urine dipstick methods. Several authors have suggested that these lower urine albumin levels ranging from 20–200 mg/L (or an approximate rate of excretion of 20–200 μ g/min) are an indicator of early and possibly reversible glomerular damage (Viberti, 1982; Mogensen, 1984). In diabetic patients, microalbuminuria is associated with a four- to sixfold increase in cardiovascular mortality, and is an independent risk factor for renal mortality (Bakris, 1996; Zelmanovitz, 1998). It is also more prevalent in hypertensive subjects (Gerber, 1998). Various methods have been introduced, including immunologic test systems and dye-binding chemical test strips, both of which are discussed in the next section.

Methods

Several screening methods and quantitative methods are available for the analysis of protein in urine. Because a positive screening test may have serious implications, it is important to be able to confirm results by a second, different method. Common screening tests include the qualitative/semiquantitative colorimetric reagent strip test and precipitation-based testing (Table 28-5).

Accurate results are obtained with reagent strips only when albumin is increased. Because of the lack of sensitivity of the reagent strip to globulins, it may be necessary to use an acid precipitation method for screening purposes. This will depend on the patient population and the diseases being screened. Reagent strips do have the advantage of avoiding false-positive reactions with organic iodides, such as those used for radiograph contrast, and tolbutamides or other drugs.

Most other qualitative screening methods rely on protein precipitation (e.g., with heat and acetic acid, with nitric acid, with sulfosalicylic [SSA] and trichloroacetic acids). These methods will precipitate globulins, as well as albumin. In practice, negative reagent strips with positive SSA methods in urine specimens are attributable to radiograph dye, to penicillins, and, rarely, to an isolated increase in globulins. Sulfosalicylic and trichloroacetic acids are used to precipitate protein in the cold and are used as a convenient screening method. The sensitivity may be as low as 0.25 mg/dL, depending on the technique used.

TABLE 28-5
Screening Test for Detection of Proteinuria

Urine constituents or condition	Reagent strip	Acid precipitation
Highly buffered alkaline urine	May cause FP	May cause FN
Drug metabolites	No effect	May cause FP
Radioccontrast media	No effect	May cause FP
Turbidity	No effect	May cause FP
Quarternary ammonium groups or chlorhexidine	May cause FP	No effect

FN, False negative; FP, false positive.

With the intense interest in utilizing proteinuria as a risk stratifier for both diabetic and nondiabetic nephropathy, as well as other conditions such as coronary artery disease, recommendations for measurement have centered on methods for urine albumin quantification rather than total protein (Lamb, 2009). Urine albumin measurements are considered much more standardized and reliable than total protein at low concentrations, where assessment of risk of progression in chronic kidney disease is important for diagnosis and planning therapy.

Reagent Strip. This method takes advantage of the protein error of pH indicators. Because proteins carry a charge at physiologic pH, their presence will elicit a pH change. The reagent strip is impregnated with tetrabromophenol blue buffered to an acid pH of 3, or tetrachlorophenol-tetrabromosulfophthalein. In the absence of protein, the strip is yellow; 30–60 seconds following urine application, variable shades of green develop, depending on the type and concentration of protein present. Results may be read in a “plus” system as negative, trace, and 1+ to 4+. Most methods will detect 5–20 mg of albumin per deciliter.

As stated previously, reagent strips tend to be more sensitive to albumin than to globulins, Bence Jones protein, or mucoprotein. “Trace” results may be seen with physiologic normal excretion of protein in concentrated urine specimens from healthy individuals. High salt levels will lower results. Exceptionally alkaline and/or highly buffered urine samples may give positive results in the absence of significant proteinuria (e.g., with a patient on alkaline medication or with bacterial contamination). False-positive results can occur with quaternary ammonium compounds, amidoamines in fabric softeners, and chlorhexidine, and with excessive leaching of the acid buffer of the test strip by excessive wetting. The method is unaffected by urine turbidity, radiographic media, and most drugs or their metabolites.

Sulfosalicylic Acid Method—Qualitative. This method depends on formation of a precipitate for determination of the presence of protein.

Procedure. Specimens should be centrifuged, and a clear supernatant used. To approximately 3 mL of supernatant urine in a clean test tube, aliquot an equal amount of 3% SSA. Invert to mix. Let stand exactly 10 minutes. Invert again twice. Using ordinary room light (not a lamp), observe the degree of turbidity and/or precipitation, and grade the results according to the following descriptions:

Negative—no turbidity (≈ 5 mg/dL or less)

Trace—perceptible turbidity (≈ 20 mg/dL)

1+—Distinct turbidity, but no discrete granulation (≈ 50 mg/dL)

2+—Turbidity with granulation, but no flocculation (≈ 200 mg/dL)

3+—Turbidity with granulation and flocculation (≈ 500 mg/dL)

4+—Clumps of precipitated protein, or solid precipitate (≈ 1.0 g/dL or more).

This method will detect about 5–10 mg/dL. Albumin, globulins, glycoproteins, and Bence Jones proteins are all detected. High levels of detergents may decrease the result. When radiographic dye is present, SSA precipitate will increase on standing, and typical crystals are seen on microscopic examination of the precipitate. In this situation, another urine specimen from the patient should be assayed. However, the effects of the radiographic media may persist for up to 3 days. A reagent strip test may be substituted, or heat and the acetic acid method may be used. In the acetic acid method, radiographic contrast media will clear with heat, whereas protein will increase.

Quantitative Protein Determinations and Confirmatory Methods. Quantitative measurements of urine protein are typically adaptations of one of the various precipitation methods, or are colorimetric in nature. SSA and trichloroacetic acid (TCA) are commonly used as precipitants; the resultant turbidity can be measured by a photometer or a nephelometer. If a visual interpretation is performed, a set of gelled commercial standards that correspond to 10, 20, 30, 40, 50, 75, and 100 mg/dL may be used, with results reported in milligrams per deciliter as opposed to the “plus” method of screening precipitation tests. With SSA, the turbidity produced with albumin is 2.4 times that produced with globulin; polypeptides, glycoproteins, and Bence Jones proteins are also precipitated with this method. Of historic note, Exton’s reagent contains SSA, sodium sulfate, and an indicator—bromphenol blue. TCA, in contradistinction, will cause γ -globulin to be precipitated with greater turbidity than albumin; however, the difference is not marked.

More precise measurements suitable for smaller amounts of protein are available, and in these methods a TCA precipitate is dissolved in sodium hydroxide and measured by use of the biuret reaction. The quantitative

TCA-biuret method is tedious but gives good precision. A color correction blank is used. For a comparison of biuret methods with the SSA turbidity method, see Lizana (1977).

Several dye-binding colorimetric methods are available to quantitate urine protein. These include Coomassie blue, Ponceau S, and benzethonium chloride turbidity methods (McElderry, 1982). Pyrogallol Red-Molybdate will also react with protein to form a bluish purple complex that absorbs at 600 nm.

Methods used to quantitate urinary protein have not been satisfactory. Participants in the College of American Pathologists proficiency testing surveys will be aware that the mean values reported vary twofold between methods, with the SSA method producing high values. Precision is poor, with the SSA turbidimetric method showing the poorest coefficient of variation. The TCA-biuret, Coomassie blue, and TCA turbidity methods show closer agreement and about half the coefficient of variation of the SSA method. Problems arise from nonstandardized methods. With turbidity methods, these include different acid concentrations and timing, along with variation in the protein standard.

Microalbuminuria Determination Methods. Very small amounts of proteins, such as albumin and β_2 -microglobulin, are measured by immunologic means using antibodies to the proteins, nephelometric methods, or radioimmunoassay. The Micral II test strip (Boehringer Mannheim, Indianapolis) is an immunologic test system that gives an almost immediate, reliable semiquantitative determination of low urine albumin concentrations (Kutter, 1998). Oxytetracycline may interfere with this method, causing higher readings. There is no interference with pH. A newer method, the Clinitek microalbumin (Bayer Diagnostics, Tarrytown, N.Y.), is a highly sensitive dye-binding method. It has the further advantage of an additional test pad for simultaneous measurement of creatinine concentration. This method is not absolutely specific for albumin, for the dye compound also reacts with Tamm-Horsfall mucoprotein.

Bence Jones Proteinuria Determination Methods. Methods for detection of Bence Jones protein in urine include protein electrophoresis, immunofixation electrophoresis, and immunoassay for free light chains (see Chapter 46). The traditional electrophoretic procedure employs the Amido black stain on a 200-fold concentrated urine. Newer methods, performed on less concentrated urine, including a modified Coomassie brilliant blue stain, are comparably sensitive and specific (Wong, 1997). The presence of Bence Jones globulin or clonal production of immunoglobulin is indicated by a single sharp peak in the globulin region on protein electrophoresis. Bence Jones globulin represents either the κ or the λ immunoglobulin light chain.

Bence Jones protein precipitates at temperatures between 40° and 60° C, and redissolves at near 100° C. Other methods depend on precipitation in the cold with salts, ammonium sulfate, and acids. In the presence of marked Bence Jones proteinuria, most methods yield positive results. When only a small amount of Bence Jones protein is present, or when other globulins are present, results may be doubtful. False-positive reactions are seen when other globulins are precipitated by acetic acid in the heat precipitation method. A false-negative reaction may occur if the Bence Jones protein is too concentrated and the precipitate does not redissolve on boiling.

Glucose and Other Sugars in Urine

Various sugars may be found in the urine under certain circumstances, both pathologic and physiologic. These include glucose, fructose, galactose, lactose, maltose, pentose, and sucrose. Glucose is by far the most common and will be discussed in the next section.

Glucose

The presence of detectable amounts of glucose in urine is termed **glycosuria**; this condition occurs whenever the glucose level in the blood surpasses the renal tubule capacity for reabsorption. Glucose may appear in the urine at different blood glucose levels, and there is not always a concomitant hyperglycemia. Glomerular blood flow, tubular reabsorption rate, and urine flow also will influence its appearance. When hyperglycemia is present, however, glycosuria usually occurs when the blood level is greater than 180–200 mg/dL. Glycosuria may be seen in several different conditions described in the following sections.

Diabetes Mellitus. Although hyperglycemia alone is not necessarily indicative of diabetes mellitus, the appearance of glucose in the urine necessitates further workup. When glycosuria is present, it is typically

accompanied by polyuria and thirst. Inadequate carbohydrate utilization in these patients results in elevated ketone levels in the blood and urine due to increased fat metabolism.

For diabetic individuals, the advantage of a urine method over a blood test for glucose is that it is painless and inexpensive. Urine glucose measurements are most useful for well-controlled diabetic individuals who do not have to make frequent adjustments in their insulin/hypoglycemic agents. In insulin-dependent diabetes, a negative urine measurement could correspond to a wide range of serum glucose levels; this is attributed to the great variation in renal threshold for glucose in diabetic patients. Therefore, urine measurements may be misleading, and home blood glucose monitoring is preferred.

Monitoring for glycosuria in diabetic patients is not without problems. Reagent strips may be difficult to interpret at the 1-g/dL (1%) and 2-g/dL (2%) glucose levels; copper reduction tests or newer, more sensitive reagent strips may be more efficacious. With the Clinistix tablet method, diabetic patients are able to estimate reducing substance levels in urine to about 10 g/dL, using one drop of specimen rather than two or five drops. In some clinics, the 24-hour urine glucose measurement is found to be useful for monitoring patients. It represents a defined longer time period, and, with blood levels of glycated hemoglobin, it contributes to the regular overall long-term management of the disease.

Several studies have looked at the usefulness of urine dipstick testing for glycosuria as a screening method for diabetes, and the results have been mixed. Bullimore (1997) concentrated on patients over 50 years old in a general practice setting and found this method to be practical and effective, whereas Friderichsen (1997) came to an opposing conclusion. He suggests that if diabetes screening is carried out in general practice, blood glucose measurements should be utilized for patients in selected risk groups. Routine dipstick glucose analysis can identify gravidas at increased risk for gestational diabetes (Gribble, 1995).

Other Causes of Glycosuria. Glycosuria with concomitant hyperglycemia is seen in several endocrine disorders (see Table 16-3). These include pituitary and adrenal disorders such as acromegaly, Cushing's syndrome, hyperadrenocorticism, functioning α - or β -cell pancreatic tumors, hyperthyroidism, and pheochromocytoma. Pancreatic disease with loss of functioning islet cells is also associated with glycosuria—for example, carcinoma, pancreatitis, and cystic fibrosis.

Numerous other causes of glycosuria with hyperglycemia have been recognized. These include central nervous system disorders, including brain tumor or hemorrhage, hypothalamic disease, and asphyxia. Disturbances of metabolism associated with burns, infection, fractures, myocardial infarction, and uremia, as well as liver disease, glycogen storage disease, obesity, and feeding after starvation, may all be associated with glycosuria, as are certain drugs (e.g., thiazides, corticosteroids and adrenocorticotrophic hormone, birth control pills).

In pregnancy, an increase in glomerular filtration rate occurs, and all of the filtered glucose may not be reabsorbed. In this situation, glycosuria may appear at relatively low blood glucose levels. Persistent, or greater than trace amounts of, glycosuria should be investigated. In some patients, diabetes occurs only during pregnancy. Glucose tolerance may also be decreased in the aged, especially when patients have a poor intake of carbohydrate, but this is not necessarily accompanied by glycosuria.

Glycosuria without hyperglycemia is usually associated with renal tubular dysfunction. True inherited renal glycosuria is uncommon and is associated with reduced glucose reabsorption. In renal tubular transport diseases, glycosuria may be accompanied by impaired reabsorption of water, amino acid, bicarbonate, phosphate, and sodium—a pattern seen in Fanconi's syndrome. Galactosemia, cystinosis, lead poisoning, and myeloma are additional examples of conditions associated with renal tubular dysfunction and possible glycosuria.

Other Sugars in Urine

Small quantities of disaccharides are normally excreted in the urine—about 50 mg in 24 hours. With intestinal diseases such as severe sprue or acute enteritis, the level may rise to 250 mg or more. Fructose, galactose, lactose, maltose, and L-xylulose are found in urine in patients with inherited metabolic disorders (Scriver, 1989). If an inherited disorder is suspected, the sugar may be identified by thin-layer chromatography. Qualitative confirmatory tests generally are not satisfactory for sugars.

Fructose. Fructose appears in urine in association with inherited enzyme deficiencies that cause benign essential fructosuria and serious fructose intolerance associated with severe vomiting and liver and kidney disease.

Fructosuria may also be seen with parenteral feedings that include fructose. Urinary fructose has been used as a marker of sucrose intake in dietary intervention studies (Luceri, 1996).

Galactose. Galactose is found in the urine in genetic disorders of galactose metabolism associated with a deficiency of galactose-1-phosphate uridyl transferase or galactokinase. In these diseases, galactose derived from dietary lactose is not converted to glucose, and early detection followed by dietary restriction may control the disease.

Lactose. Lactose may appear in the urine late in normal pregnancy or during lactation. In lactose intolerance, high levels of sugars accumulate in the gut, and lactose will be absorbed and excreted unchanged in the urine.

Pentose. Pentosuria may follow the ingestion of large amounts of fruit, causing the excretion of L-xylulose and L-arabinose in amounts up to 0.1 g/day. It may also be seen with certain drug therapies and with benign essential pentosuria.

Sucrose. Sucrose may appear in the urine after the ingestion of very large amounts of sucrose. Sucrase deficiency is associated with intestinal diseases such as sprue in the same manner as lactase deficiency. Sucrose intolerance is an inherited disorder associated with sucrase and α -dextrinase (isomaltase) deficiencies. Symptoms are similar to those seen with lactase deficiency and occur in the first few weeks of life when sweetened food is ingested. Tolerance may develop, but sucrose may have to be avoided permanently. Factitious sucrosuria may create a high specific-gravity urine with negative glucose oxidase and negative copper reduction tests.

Methods

Reagent Strip. This method is based on a specific glucose oxidase and peroxidase method, a double sequential enzyme reaction; reagent strips differ only in the chromogen used. The method is specific for glucose, and no reaction is seen with lactose, galactose, fructose, or reducing metabolites of drugs. The reagent strips may be used for semiquantitative results, and results should be reported as approximate grams per deciliter. Combination glucose and ketone reagent strips detect not only ketonuria, but also suppression of the glucose reaction by ketones seen with some reagent strips.

False-positive readings may be produced by strongly oxidizing cleaning agents in the urine container. Low specific gravity may falsely elevate results. Sodium fluoride used as a preservative will cause false-negative readings, as can high specific gravity and occasionally ascorbic acid. Glycolytic enzymes from cells and bacteria will reduce glucose levels in urine on standing; prompt refrigeration or testing is essential.

Chemistry

Chromogens utilized in some common dipstick tests include the following:

Clinistix—o-toluidine chromogen. Color changes from pink to purple. This formulation detects 100 mg/dL of glucose and is more sensitive to interfering substances such as ascorbic acid than the following.

Multistix—potassium iodide chromogen. Color changes from blue to brown at 30 seconds.

Chemstrip—an aminopropyl-carbazol chromogen. Color changes from yellow to orange-brown at 60 seconds.

Copper Reduction Tests. As a screening test, the glucose oxidase method will not detect increased levels of galactose or other sugars in urine. It is therefore important that a copper reduction method be used, especially for young pediatric patients. A policy to screen for reducing sugars should be made by the individual laboratory, after consultation with its clinical staff. In many instances, policies related to performing this screening were instituted in the 1960s, before the widespread mandatory screening of newborns for inborn errors of metabolism became routine. With this state-mandated newborn screening, detection of an unsuspected reducing substance in the urine is rare, and the routine performance of this test, without a specific request by the patient's physician, may have outlived its usefulness (Naumova, 2006).

TABLE 28-6

Reactions of Substances to Test for Glucosuria

Constituent	Glucose oxidase reagent strip	Copper reduction tablet test
Glucose	Positive	Positive
Sugars other than glucose	No effect	Positive
Fructose		
Galactose		
Lactose		
Maltose		
Pentose		
Sucrose		
Ketones (large quantities)	May depress color	No effect
Creatine	No effect	May cause false-positive
Uric acid		
Homogentisic acid (alkaptonuria)	No effect	Positive
Drugs*		
Ascorbic acid (large amounts)	May delay color	Trace positive
Cephalosporins (Keflin), etc.	No effect	Positive, brown color
L-Dopa (large amounts)	False-negative	No effect
Nalidixic acid glucuronide	No effect	Positive
Probenecid	No effect	Positive
Pyridium	Orange color may affect result	
Salicylate (large amounts)	May lower reading	No effect
X-ray dye (diatrizoates)	No effect	Black color
Contaminants		
Hydrogen peroxide	False-positive	May inhibit positive test
Hypochlorite (bleach)	False-positive	
Sodium fluoride	False-negative	No effect

Data from Caraway (1962), Wirth (1965), and Young (1975).

*Other drugs implicated in copper reduction are amino acids, caronamide, chloral, chloroform, chloramphenicol, formaldehyde, hippuric acid, isoniazid, thiazides, oxytetracycline, *p*-aminosalicylic acid, penicillin, phenols, streptomycin, phenothiazine, and sulfonamides.

The copper reduction method will detect sufficient quantities of any reducing substances in the urine, including reducing sugars such as lactose, fructose, galactose, maltose, and the pentoses. In those instances in which the copper method is positive and the glucose oxidase method is negative, glycosuria is ruled out; however, before investigation for other sugars is begun, the clinical findings and drug history should be evaluated. Although the copper reduction method will detect nonglucose reducing sugars, the yield for these sugars is extremely low.

Normal neonatal infants during the first 10–14 days of life may excrete urine that yields a positive reaction because of glucose, galactose, fructose, and lactose. Normal pregnant and postpartum women may also have positive reactions because of the presence of lactose.

Of the copper reduction methods used for screening purposes, the qualitative Benedict method is more sensitive to reducing substances in urine than is the single-tablet (Clinitest) copper reduction method. Many substances in urine, metabolites, and drug-related metabolites will influence urinary sugar methods (Table 28-6). Strong reducing substances such as ascorbic acid, gentisic acid, or homogentisic acid may inhibit the enzyme method while contributing to the positivity of the copper reduction method. The tablet method is not affected as much as the Benedict method. Very large doses of ascorbic acid do not affect the two-drop copper reduction method. Drugs, especially the cephalosporins, and radiographic media will give false-positive or unusual colors with Clinitest. Although large doses of ascorbic acid do not affect the two-drop Clinitest for sugars (i.e., do not cause false-positive results), delays in color development may be noted with the glucose oxidase method.

Chemistry. Copper sulfate, sodium hydroxide, sodium carbonate, and citric acid are incorporated into each Clinitest tablet. Copper sulfate reacts with reducing substances in the urine, converting cupric sulfate to cuprous oxide. Based on Benedict's copper reduction reaction,

Heat is caused by the reaction of sodium hydroxide with water and citric acid.

Procedure. Clinitest reagent tablets will detect 250 mg of reducing substance per deciliter of urine. Both five-drop and two-drop Clinitest methods can be used, and corresponding color charts are available

(Belmonte, 1967). The two-drop method was developed in response to a so-called **pass-through phenomenon** that may occur if more than 2 g/dL of sugar is present in the urine. In the pass-through phenomenon, the solution that results after addition of the Clinitest tablet goes through the entire range of colors and back to a dark greenish brown. This final color does not compare with any section of the color chart; however, it corresponds most closely to a significantly lower result. It is important to observe the entire reaction and to continue to observe for 15 seconds after boiling inside the tube has stopped, so that reversion to a different color is not missed and a falsely low result reported.

Five-Drop Method. Place five drops of urine in a dry test tube and add 10 drops of water. Add one Clinitest tablet by easing it into the tube without touching it—it contains strong alkali. Watch while boiling takes place, but do not shake or touch the bottom of the tube—it is hot. Wait for 15 seconds after boiling stops, then shake the tube gently, and immediately compare the color of the solution with the color scale. Results correspond to the following approximate concentrations: Negative; 0.25 g/dL; 0.5 g/dL; 0.75 g/dL; 1.0 g/dL; 2.0 g/dL; and pass-through. It is important to watch the solution carefully while it is boiling. If the solution passes through orange to a dark shade of greenish brown, this indicates that more than 2 g/dL sugar is present; this should be recorded as greater than 2 g/dL without reference to the color scale. Urine samples showing this pass-through phenomenon should be retested with the two-drop method.

Two-Drop Method. Place two drops of urine in a test tube, and add 10 drops of water. Add one Clinitest tablet. Watch while boiling takes place, but do not shake. Wait 15 seconds after the boiling stops, then shake the tube gently; compare the color of the solution with the color scale supplied for the two-drop method. The pass-through phenomenon may also occur with the two-drop method with large concentrations of sugar—over 5 g/dL. Report results as 1 g/dL, 2 g/dL, 3 g/dL, 5 g/dL, and more than 5 g/dL if a pass-through reaction occurs. With negative or low-level results, the five-drop method should be performed.

Precautions. Observe the precautions in the literature supplied with the Clinitest tablets. The bottle must be kept tightly closed at all times to prevent absorption of moisture and kept away from direct heat and sunlight in a cool, dry place. The tablets normally have a spotted bluish white color. If not stored properly, they will absorb moisture or deteriorate from heat, turning dark blue or brown. In this condition, they will not give reliable results. They are also available individually packaged in aluminum

foil to help prevent this absorption of moisture. Although more expensive, such packaging is useful when a limited number of measurements are performed.

Additional Tests for Sugars. As stated above, the copper reduction method will detect the majority of nonglucose sugars that might be present in urine, apart from sucrose, which is not a reducing sugar. It does not, however, differentiate between these sugars, therefore necessitating more complicated testing. Additional confirmatory testing will be discussed here.

Fructose. Fructose is identified by thin-layer chromatography. A qualitative measurement, a resorcinol test, is useful. Fructose will also reduce Benedict's reagent at low temperatures.

Galactose. Thin-layer chromatography is used to identify galactose in urine. However, the disease is usually identified by erythrocyte enzyme assay when suspected.

Lactose. Lactose is identified by thin-layer chromatography or a qualitative lactose test, such as described below.

Procedure. To 15 mL urine in a test tube, add 3 g lead acetate. Shake and filter. Boil filtrate, add 2 mL concentrated NH_4OH (ammonium hydroxide), and boil. Lactose will cause the formation of a brick-red solution and then a red precipitate with clear supernatant.

Pentose. At concentrations of 250–300 mg/dL, L-xylulose will reduce Benedict's qualitative reagent at 50° C (water bath) within 10 minutes or at room temperature in several hours. Generally, the pentoses are identified by thin-layer chromatography.

Sucrose. Sucrose will ferment yeast and can be separated by chromatography but needs to be stained with a substance not dependent on reducing properties.

Ketones in Urine

Whenever a defect in carbohydrate metabolism or absorption or an inadequate amount of carbohydrate is present in the diet, the body compensates by metabolizing increasing amounts of fatty acids. When this increase is large, ketone bodies, the products of incomplete fat metabolism, begin to appear in the blood and are consequently excreted in the urine. In ketonuria, the three ketone bodies present in the urine are acetoacetic (diacetic) acid (20%), acetone (2%), and 3-hydroxybutyrate (about 78%). Acetone is formed nonreversibly from acetoacetic acid; β -hydroxybutyric acid (3-hydroxybutyrate) forms reversibly from acetoacetic acid.

Depending on the methods used, total ketone bodies (as acetone) can range as high as 17–42 mg/dL. According to Killander (1962), up to 2 mg acetoacetic acid per deciliter is normal. Ketonemia and ketonuria are commonly seen in uncontrolled diabetes mellitus, as well as several other conditions to be discussed here.

Diabetic Ketonuria

Ketonuria implies the presence of ketoacidosis (ketosis) and may provide a warning of impending coma. Up to 50 mg of acetoacetic acid per deciliter may be present without clinical evidence of ketosis. Type 1 diabetic patients are more prone to episodes of ketosis, often associated with infection, stress, or other problems in management. Whereas large amounts of ketones and glucose are present in urine in diabetic ketoacidosis, ketonuria is not found with the hyperosmolar hyperglycemic coma that sometimes occurs in type 2 diabetes.

Nondiabetic Ketonuria

In infants and children, ketonuria commonly occurs in a variety of conditions, such as acute febrile diseases and toxic states accompanied by vomiting or diarrhea. Inherited metabolic disease should be suspected when there is severe persistent neonatal ketosis. Ketonuria may be present in hyperemesis of pregnancy, in cachexia, and following anesthesia. In these cases, ketonuria is likely related to increased tissue (especially fat) catabolism in the face of limited food intake. In pregnancy, a normal patient may have a low fasting blood glucose level and mild ketonuria. Occasionally, ketonuria is seen following exposure to cold or severe exercise, or with a low-carbohydrate diet for weight reduction.

Lactic Acidosis

Lactic acidosis may coexist with many conditions, including shock, diabetes mellitus, renal failure, liver disease, and infection, and in response to

certain drugs, especially phenformin and salicylate poisoning. Acetoacetate and 3-hydroxybutyrate may both be highly elevated, although usually the butyrate is high and acetoacetate low. Under these circumstances, ketonuria may not be detected by the usual nitroprusside test.

Methods. Because acetone, acetoacetic acid, and 3-hydroxybutyrate are all present in the urine with ketonuria, methods that indicate the presence of any one of these three ketone bodies are generally satisfactory to detect this condition. Commonly used nitroprusside strip and tablet tests based on the Rothera method detect acetoacetic acid and acetone. Different methods measure acetoacetic acid alone, or both acetone and acetoacetic acid. Ferric chloride (Gerhardt's test) detects acetoacetic acid. These methods do not measure 3-hydroxybutyrate, the predominant ketone body.

In urine and plasma, reagent strips and tablets react to 10 mg of acetoacetic acid per deciliter and are less sensitive to acetone. The blood level of ketone bodies may be estimated by the urine ketone dipstick at the bedside. This is especially helpful in determining the severity of ketosis for the treatment of diabetic acidosis.

When a patient is being followed with qualitative determinations of acetone and acetoacetic acid, repeated reports of marked elevations would not reflect the change that is actually taking place. In such an instance, semiquantitative results can be obtained with either the reagent strip or Rothera's tablet test by measuring several dilutions of each specimen.

Problems can occur with false-negative results because of unstable reagents and labile ketones. Bacterial action will cause loss of acetoacetic acid, which can happen *in vivo* as well as *in vitro*. Acetone is lost at room temperature but not if kept in a closed container in a refrigerator. Refrigerated samples should be brought to room temperature for testing. Preservatives do not prevent decay of ketones. If results are unexpected, fresh reagents, checked against known positive and negative controls, should be used.

Reagent Strip. This method is based on a nitroprusside (sodium nitro-ferricyanide) reaction for ketones. Different formulations are available. Reagent strips without alkali react to acetoacetic acid and not to acetone. With large (3+) results, urine may be diluted and remeasured, reporting a "moderate" result and the dilution factor.

Chemstrip reagent strips contain sodium nitroferricyanide and glycine, which react with acetoacetic acid and acetone in an alkaline medium to form a violet dye. A positive result is indicated by a color change from beige to violet, which is read at 60 seconds. The method detects about 10 mg/dL of acetoacetic acid and 70 mg/dL of acetone, and the sensitivity and reaction of the reagent strip are similar to those of the tablet (Acetest), described below.

Multistix contains buffers and sodium nitroferricyanide, which react with acetoacetic acid, producing a pink-maroon color in 15 seconds. The reagent area detects 5–10 mg acetoacetic acid per deciliter of urine. It does not react with acetone.

Reagent strips correlate only moderately well with quantitative acetoacetate in plasma and poorly with total blood ketones. Color reactions (false-positives) occur after the use of phthaleins (sulfobromophthalein [BSP] or phenolsulfonphthalein [PSP] dye) or in the presence of extremely large quantities of phenylketones and the preservative 8-hydroxyquinoline, or L-dopa metabolites. Acetylcysteine (aerosol) produces a strong red color. The antihypertensive drugs methyldopa and captopril give positive results. False-negative results occur because of loss of reagent reactivity.

Nitroprusside Tablet Test. A tablet test method may be useful if the urine has an interfering color. These tablets are very sensitive to humidity and will deteriorate if not stored properly. The Acetest tablet contains sodium nitroprusside, glycine, and a strongly alkaline buffer. It can be used to assay whole blood, plasma, serum, or urine.

Acetest will detect 5–10 mg acetoacetic acid per deciliter of urine and 20–25 mg acetone per deciliter of urine. Like the reagent strips, it does not react with 3-hydroxybutyrate. It will give positive results with L-dopa and large amounts of phenylketones and with BSP and PSP dyes, which react with the alkali in the tablets.

Procedure. Place the tablet on a clean surface, preferably a piece of white paper. Place one drop of urine, serum, plasma, or whole blood on the tablet. For urine measurements, compare the color of the tablet with a color chart at 30 seconds. For serum or plasma measurements, compare the color of the tablet with the color chart at 2 minutes. For whole blood measurements, remove clotted blood from the tablet and compare the

color of the tablet with the color chart, 10 minutes after application of the specimen.

If acetone and acetoacetic acid are present, the tablet will show a color varying from lavender to deep purple. Report the results as negative, small, moderate, or large. If large, a dilution may be made. Report these analyses in a form such as this: Undiluted “large,” 1:2 dilution “large,” 1:4 dilution “moderate,” and so forth.

Other Tests for Ketones. The Gerhardt ferric chloride test has been used for many years as a measurement for acetoacetic acid. However, ferric chloride methods are not very specific and the sensitivity is low, at about 25–50 mg/dL. The ferric chloride method gives positive results with salicylate and L-dopa. The test tube nitroprusside method of Rothera is sensitive to acetoacetic acid, at about 1–5 mg/dL, and to acetone with a sensitivity of 10–25 mg/dL.

Blood, Hemoglobin, Hemosiderin, and Myoglobin in Urine

The presence of an abnormal number of blood cells in urine is known as **hematuria**, whereas the term **hemoglobinuria** refers to the presence of free hemoglobin in solution in urine. Hematuria is relatively common, hemoglobinuria uncommon, and **myoglobinuria** rare.

Hematuria

Although asymptomatic microscopic hematuria may be detected by dipstick testing in up to 16% of screening populations (Rockall, 1997), many serious diseases of the urinary tract release red blood cells into the urine. A retrospective investigation of microscopic hematuria by renal biopsy disclosed several histopathologic findings, including membranous nephropathy, IgA nephropathy, non-IgA mesangioproliferative glomerulonephritis, focal glomerulosclerosis, and mild glomerular abnormalities. More than 15% of patients in this study showed normal histology (McGregor, 1998). Hematuria can occur with disease (neoplastic and non-neoplastic) or trauma (including calculi) anywhere in the kidneys or urinary tract, as well as with bleeding disorders and anticoagulant usage, and with the use of other drugs such as cyclophosphamide. A rare case of giant cell arteritis presenting with fever and hematuria has been reported (Govil, 1998). Hematuria may also be seen in healthy persons undertaking excessive exercise (marathon runners), in whom bleeding originates from the bladder mucosa.

Because of the diagnostic importance of small amounts of hematuria and because of the tendency of erythrocytes to undergo lysis in urine, a screening test for hemoglobin is a useful adjunct to microscopic examination of the sediment. In fact, some studies suggest that reagent strip hemoglobin screening may be more sensitive than urine microscopy in detecting hematuria (Ooi, 1998). However, a common problem with the method is the inhibition of the hemoglobin reagent strip by interfering substances, commonly ascorbic acid, and this problem emphasizes the need for a routine microscopic examination to screen for hematuria. A positive test for hemoglobin with a normal urinary sediment suggests that a fresh urine sample should be examined for erythrocytes, because an alkaline pH or urine specific gravity of less than 1.010 may cause lysis of erythrocytes.

Hemoglobinuria

Any cause of hemolysis has the potential of causing hemoglobinuria, but the presence of hemoglobinuria indicates significant intravascular hemolysis as opposed to extravascular hemolysis. Hemoglobin binds to plasma haptoglobin, and free hemoglobin will pass through the glomerulus as $\alpha\beta$ dimers (molecular weight [MW], 32,000), once this binding capacity is saturated. Some hemoglobin is reabsorbed by proximal tubular cells, and the remaining hemoglobin is excreted.

Hemoglobinuria may follow severe exertion in which there is direct trauma to small blood vessels; many other causes of acute erythrocyte lysis are summarized in Table 28-7. Plasma appears pink at levels of about 50 mg/dL of hemoglobin, and with marked hemolysis, plasma levels may reach 1 g/dL. The plasma hemoglobin level is more often increased in severe acquired hemolytic anemias than in hereditary hemolytic anemias. However, moderately elevated levels occur with sickle cell disease and homozygous thalassemias. Note that unstable hemoglobins can cause a brown-pigmented urine; this is thought to be due to a dipyrrole or bilifuscin, and no reaction occurs with the reagent strip test for heme. A comparison of expected urine and plasma findings with moderate and marked hemolysis is shown in Table 28-8.

TABLE 28-7

Some Causes of Hemolysis and Hemoglobinuria

Erythrocyte trauma	Prosthetic cardiac valves (especially aortic) Ostium primum repair with patch causing turbulence Extensive burns Severe exercise Marching Severe trauma to muscle and other vascular tissues
Organisms	Malaria <i>Bartonella</i> <i>Clostridium welchii</i> toxin Brown recluse spider bite
Erythrocyte enzyme deficiencies	Glucose-6-phosphate dehydrogenase subjects in the following situations: Exposure to oxidant drugs (acetanilid, sulfamethoxazole, nitrofurantoin), antimalarials (primaquine, etc.), fava beans (<i>Vicia faba</i>) in susceptible groups, with diabetic acidosis, and with infection
Unstable hemoglobin diseases	With exposure to oxidant drugs
Immune-mediated (see Chapters 32 and 33)	Hemolytic-uremic syndrome Thrombotic thrombocytopenic purpura Incompatible blood transfusions Warm antibodies (autoimmune—transient after infection, drug-induced) Cold antibodies IgM—viral anti-i mycoplasma anti-I IgG—paroxysmal, Donath-Landsteiner anti-P Membrane sensitivity, complement-mediated (paroxysmal nocturnal hemoglobinuria) Drugs Acting as haptens (penicillins) Immune complex (quinidine, phenacetin) α -Methyldopa
Normal subjects	Oxidative hemolysis due to drugs, large doses or exposure to naphthalene (mothballs), some sulfonamides, sulfones, nitrofurantoin

TABLE 28-8

Urine and Plasma Findings with Intravascular Hemolysis

Test	Moderate hemolysis	Marked hemolysis
Urine		
Bilirubin (conjugated)	Absent	Absent
Urobilinogen	Normal or elevated	Elevated
Hemoglobin	Absent	Present
Hemosiderin	Absent	Present (late)
Plasma		
Bilirubin (conjugated)	Elevated	Elevated
Haptoglobin	Decreased	Absent
Hemoglobin	Elevated	Elevated (marked)

Hemosiderin in Urine

Free hemoglobin is readily filtered by the glomeruli and can be subsequently reabsorbed by proximal tubular cells, where it can be catabolized into ferritin and hemosiderin. Hemosiderin will be present 2–3 days after an acute hemolytic episode that caused hemoglobinuria. At this time, the reagent strip method for hemoglobin is often negative; however, hemosiderin can be found as yellow-brown granules that are free or in epithelial cells and occasionally in casts (Fig. 28-1). Hemosiderin also appears in the urine sediment in diseases with a true siderosis of kidney parenchyma (hemochromatosis). Although the existence of hemosiderinuria indicates a chronic hemolytic state, its presence is rarely needed to make the diagnosis of hemolysis; other tests, such as serum bilirubin, lactate dehydrogenase, and haptoglobin levels, will usually point to the correct diagnosis.

Figure 28-1 Renal tubular epithelial cell (unstained) containing brown pigment, iron ($\times 260$).

Because of the intermittent presence of hemosiderinuria, urinary iron levels may be quantitated to establish the presence of chronic intravascular hemolysis. Normal urinary iron excretion is about 0.1 mg/day, and this is increased with hemochromatosis and in association with erythrocytes traumatized by prosthetic heart valves. Urinary iron levels are normal with pernicious anemia and in hereditary spherocytosis.

Myoglobinuria

When acute destruction of muscle fibers (rhabdomyolysis) occurs, as with trauma, myoglobin is released, rapidly cleared from the blood, and excreted in the urine as a red-brown pigment. Free myoglobin, a monomer with MW of 17,000, is excreted quickly, whereas the hemoglobin-haptoglobin complex is more slowly removed. Myoglobinuria has been seen following a number of strenuous exercises, such as marathon running and karate. Other less common conditions associated with sustained or recurrent myoglobinuria include dermatomyositis (Rose, 1996), defects of muscle phosphofructokinase and adenosine monophosphate deaminase (Bruno, 1998), and mitochondrial trifunctional protein deficiency (Miyajima, 1997).

The diagnosis of rhabdomyolysis and myoglobinuria is usually made from the history and other laboratory findings as follows. Typically, the patient has muscle tenderness or cramps and voids red-brown urine within a day or two after exertion. The reagent strip urine test for hemoglobin is markedly positive, and protein and a few red blood cells are present. Serum is clear and has a markedly elevated creatine kinase (CK), aldolase, and a normal haptoglobin level. Serum creatinine may be increased. The urine usually clears in 2–3 days, and the serum CK level declines. The serum measurements and history help to distinguish myoglobinuria from hemoglobinuria.

The distinction between hematuria, hemoglobinuria, and myoglobinuria may be difficult to make on examination of the urine. In all three cases, the urine can be dark red to brown, and some erythrocytes are seen in the sediment (to a much greater degree with hematuria). The reagent strip test for blood is also positive in all three cases. If serum can be examined, it will often be pink with hemoglobinemia but a normal color with myoglobinemia because this pigment is cleared so rapidly. Accurate quantitative measurement of urine myoglobin can also be performed by immunoassay; although some slight interference by hemoglobin may occur, this is an excellent way to detect and quantify the presence of myoglobinuria (Loun, 1996). See Table 28-9, which compares hemoglobinuria, myoglobinuria, and hematuria.

Methods

Reagent Strip for Heme Compounds (Hemoglobin, Myoglobin).

This method is based on the liberation of oxygen from peroxide in the reagent strip by the peroxidase-like activity of heme in free hemoglobin, lysed erythrocytes, or myoglobin. Intact erythrocytes are lysed on the strip, causing the hemoglobin to react. Therefore, well-mixed urine must be tested, as intact erythrocytes may be missed if only supernatant urine is used. The reagent area is impregnated with a buffered mixture of an organic peroxide and the chromogen tetramethylbenzidine.

Heme catalyzes the oxidation of tetramethylbenzidine to produce a green color. The strip is read at 60 seconds following sample application.

Multistix and Chemstrip detect 0.05–0.3 mg hemoglobin per deciliter urine. Note that 0.3 mg hemoglobin per deciliter is equivalent to that from 10 lysed erythrocytes per microliter. Normal erythrocytes contain approximately 30 pg of hemoglobin per cell.

TABLE 28-9

Differentiation of Hematuria, Hemoglobinuria, and Myoglobinuria

Condition	Plasma findings	Urine findings
Hematuria	Color—normal	Color—normal, smoky, pink, red, brown Erythrocytes—many Renal—red blood cell casts Protein—marked increase Lower urinary tract—no casts Protein—present or absent
Hemoglobinuria	Color—pink (early) Haptoglobin—low	Color—pink, red, brown Erythrocytes—occasional Pigment casts—occasional Protein—present or absent Hemosiderin—late
Myoglobinuria	Color—normal Haptoglobin—normal Creatine kinase—marked increase Aldolase—increased	Color—red, brown Erythrocytes—occasional Dense brown casts—occasional Protein—present or absent

Sensitivity is reduced in urine specimens with high specific gravity, in which erythrocyte lysis may not occur, and also when protein levels are high. Ascorbic acid in large concentrations may cause a false-negative result, as can formalin when used as a urine preservative. The presence of nitrite in large amounts will delay the reaction. Oxidizing contaminants such as hypochlorites (bleach) or iodine from skin-cleansing preparations may produce false-positive results. Microbial peroxidase, associated with urinary tract infection, potentially causes a false-positive reading.

Other Tests for Hemoglobin and Myoglobin. Qualitative tests have been generally unsatisfactory in separating myoglobin and hemoglobin, and both conditions may be present following crush injuries. Hemoglobin and myoglobin can be bound to proteins in urine, and this contributes to the difficulty of separating them by salt precipitation or electrophoresis. The salt precipitation method of Blondheim (1958) is described below.

Qualitative Test for Myoglobin.

1. Use a fresh urine specimen. Observe the color. Characteristically, urine with myoglobinuria is red when fresh and turns brown on standing, but some myoglobin may be present without color change. Myoglobin is less stable at an acid pH. Neutralize and refrigerate specimen pending testing.
2. Mix 1 mL of urine and 3 mL of 3% sulfosalicylic acid to assay for protein. If the pigment is precipitated, it is a protein. Filter. If the filtrate is a normal color, no abnormal nonprotein pigment is present. (Note: The heat and acetic acid test does not precipitate myoglobin or hemoglobin.)
3. To 5 mL of urine in a test tube, add 2.8 g of ammonium sulfate. Dissolve by mixing. The urine is now 80% saturated with ammonium sulfate. This is optimal for precipitation of hemoglobin. Filter or centrifuge. If the supernatant shows a normal color, the precipitated pigment is hemoglobin. If the supernatant fluid is colored, this is presumptive evidence of myoglobin.

This precipitation test has been largely replaced with specific immunoassays for myoglobin.

Capillary electrophoresis has been shown to successfully separate urinary hemoglobin based on differing electrophoretic mobility (Shihabi, 1995).

Detection of Hemosiderin in Urine. The Prussian blue reaction is used to demonstrate iron in hemosiderin (Fig. 28-2). A dry smear and an alternative wet preparation are described below.

Dry Procedure. When stained with Prussian blue reagent, hemosiderin appears as blue granules, 1–3 μm , singly or in groups, in renal tubular epithelial cells, as amorphous sediment, or as blue granules in casts. An iron stain used for the detection of siderocytes in blood or bone marrow is also suitable. Urine is collected in an iron-free glass container, overnight. Let stand for 2 hours. Decant three fourths of it, and centrifuge the

TABLE 28-10

Urine and Fecal Findings in Jaundice

Finding	Normal	Obstruction to bile flow	Hemolysis, hemolytic anemia	Liver damage, hepatitis, cholestasis
Urinary bilirubin	Absent	Increased, dark urine	Absent	Increased early
Urinary urobilinogen	Present	Neoplasm—low or absent; gallstones—variable	Increased	Decreased early; increased late
Fecal color	Dark	Pale; intermittent with gallstones in common bile duct; persistent with neoplasm in duct or pancreas	Dark	Pale early and dark late in hepatitis; pale with cholestasis

Figure 28-2 Renal tubular epithelial cell positive with Prussian blue stain, hemosiderin (×260).

remainder. Make a smear(s) of the sediment and allow to air dry. (Note: All glassware, slides, coverslips, etc., should be iron free. Water should be demineralized.)

Reagents. The Prussian blue reagent is made fresh.

Prussian blue stain: Add concentrated hydrochloric acid (HCl) to an aliquot of the potassium ferrocyanide solution (20% in demineralized water) until a white precipitate forms that remains stable on shaking. Filter through No. 5 filter paper.

Working counterstain: Dilute 1 mL safranin O stain (0.5 g in 100 mL distilled water) to 50 mL with phosphate buffer (pH, 6.4–4.7).

Procedure

1. Fix the smear in methyl alcohol for 10 minutes.
2. Rinse with iron-free water (demineralized) and air dry.
3. Stain with Prussian blue reagent for 30 minutes.
4. Wash gently for at least 4 minutes with iron-free water and air dry.
5. Counterstain with safranin O for 1–5 minutes.
6. Rinse with iron-free water. Air dry.
7. Mount coverslip.

Wet Procedure

1. Centrifuge a complete morning specimen or random urine sample for 5 minutes and pool the sediment. Examine several drops of sediment microscopically, searching for coarse yellow-brown granules, especially within renal tubular epithelial cells or casts.
2. If such granules are seen, suspend the rest of the sediment in a fresh mixture of 5 mL of 2% potassium ferrocyanide solution and 5 mL of 1% HCl, and allow to stand for 10 minutes.
3. Centrifuge, and discard the supernatant. Examine the sediment microscopically. Coarse granules of hemosiderin appear blue in this preparation in cells, casts, and amorphous material. If granules do not stain, reexamine after 30 minutes (occasionally the reaction is delayed).

Bilirubin in Urine

Bilirubin is a breakdown product of hemoglobin that is formed in the reticuloendothelial cells of the spleen, liver, and bone marrow. It is initially carried in the blood linked to albumin; this unconjugated bilirubin (or indirect bilirubin) is water insoluble and therefore is unable to pass through the glomerular barrier of the kidney. Unconjugated bilirubin is transported to the liver, where it is conjugated with glucuronic acid to form bilirubin glucuronide. This conjugated form of bilirubin (direct bilirubin) is water soluble and is able to pass through the glomerulus of the kidney into the urine. Conjugated bilirubin is normally excreted in the bile into the duodenum, and normal adult urine contains only 0.02 mg of bilirubin per deciliter. This small amount is not detected by the usual testing methods. Excretion of bilirubin is enhanced by alkalosis.

Conjugated bilirubin appearing in urine generally indicates that there is excess conjugated bilirubin in the bloodstream. This can occur when there is either (1) obstruction to bile outflow from the liver (intrahepatic or extrahepatic), or (2) hepatocellular disease with resultant inability of hepatocytes to sufficiently excrete conjugated bilirubin into the bile. For example, bilirubinuria may be present when intracanalicular pressure rises secondary to periportal inflammation, fibrosis, or hepatocyte swelling. Gallstones in the common bile duct and carcinoma of the head of the pancreas are possible sources of extrahepatic biliary obstruction leading to bilirubinuria. Bilirubinuria is often seen with acute viral hepatitis or drug-induced cholestasis before the appearance of jaundice; it typically accompanies jaundice of acute alcoholic hepatitis. In persons exposed to potentially hepatotoxic drugs or toxins, a positive test for bilirubinuria may be an early indication of cholestasis or liver damage. In congenital hyperbilirubinemias, bilirubin will appear in the urine in the Dubin-Johnson and Rotor types, and is not present with Gilbert's disease or Crigler-Najjar disease.

Bilirubinuria is associated with yellow-brown to greenish brown urine that may have a yellow foam, elevated serum bilirubin (conjugated), jaundice, and pale-colored feces. These acholic stools are so called because of the absence of bilirubin-derived pigment. A positive test for urinary bilirubin with a negative test for urobilinogen in urine is indicative of intrahepatic or extrahepatic biliary obstruction. This test is valuable in the differential diagnosis of jaundice, because bilirubinuria is not found with hemolytic jaundice. Table 28-10 summarizes typical urine and fecal findings in jaundice of various causes.

Methods

Reagent Strip. This test is based on the coupling reaction of bilirubin with a diazonium salt in acid medium. When this method is used, normal urine contains no detectable bilirubin. Specific tests differ in the diazonium salt utilized. Multistix uses diazotized 2,4-dichloroaniline as the diazo salt, with a color change from cream-buff to tan at 20 seconds. This system will detect 0.8 mg per deciliter urine; however, the color change may be difficult to read. Chemstrip uses 2,6-dichlorobenzene-diazonium tetrafluoroborate, and the color changes from pink to violet at 30–60 seconds. This test detects 0.5 mg per deciliter urine.

Urine must be fresh because bilirubin glucuronide in urine quickly hydrolyzes to less reactive free bilirubin. Oxidation of bilirubin in specimens that have stood too long, especially when exposed to light, will result in false-negative findings. Large amounts of ascorbic acid and nitrite can also lower bilirubin results. Metabolites of drugs such as phenazopyridine (Pyridium) give a reddish color at the low pH of the strip and mask the result. Rifampin and large amounts of chlorpromazine metabolites may cause false-positives, whereas salicylates do not interfere. Urobilinogen does not affect the result.

Confirmatory Bilirubin Tests. The diazo test method, in which bilirubin is coupled to *p*-nitrobenzene diazonium *p*-toluene sulfonate to form a blue or purple color (in the form of a tablet or reagent strip), is commonly used. The reagent strip test is much less reactive to free bilirubin than is the tablet test, so that a difference in results becomes more apparent as the urine ages. Another test employs a ferric chloride reagent to oxidize bilirubin to a green biliverdin. The diazo tablet method is described below.

Diazo Tablet Method. Tablets contain *p*-nitrobenzene diazonium *p*-toluene, as well as sulfosalicylic acid and sodium bicarbonate. The latter substances provide an acid medium for the reaction and an effervescent mixture that will ensure the solution of a portion of the tablet when water is added. (Ictotest kit, including absorbent mats and reagent tablets, is available through Bayer Corporation, Tarrytown, N.Y.)

Note: Reagent tablets are hygroscopic, and they should be protected from moisture or high humidity. The tablets are packed in a brown bottle because prolonged direct exposure to strong light results in decomposition of the stabilized diazonium compound. Prolonged exposure over several weeks to temperatures of 100° F or more may also result in deterioration of the tablets. A brown discoloration indicates deterioration, and when each new bottle is opened, tablets should be checked for positive and negative reactions.

Procedure

1. Place 10 drops of specimen on an asbestos-cellulose mat provided with the kit. Bilirubin, if present, will be adsorbed onto the mat surface.
2. Place a reagent tablet on the moistened area of the mat.
3. Place one drop of water onto the tablet. Wait 5 seconds, then place a second drop so that the water runs off the tablet onto the mat. If bilirubin is present, there will be a coupling of bilirubin with *p*-nitrobenzene diazonium *p*-toluene sulfonate from the tablet, as shown by the formation of a blue to purple color within 30 seconds. The tablet should be moved to reveal the purple color. A pink or red color is negative.

The diazo test reacts positively to bilirubin in amounts as low as 0.05–0.1 mg per deciliter. No purple reaction is seen with urobilin or other pigments, although high levels of urobilin or indican give a red color. Azo compounds (e.g., Pyridium) cause an atypical color. Rifampin may also interfere. Chlorpromazine metabolites in large amounts produce a purple color, and the metabolites of the antiinflammatory drugs mefenamic and flufenamic acid cause false-positive results.

Wash-Through Tablet Method. When false-positive reactions are suspected (e.g., with chlorpromazine), the contaminant can be diluted out with water in the mat.

Procedure. Prepare duplicate mats with 10 drops of urine on each. Add 10 drops of water to one mat. Place a reagent tablet on each mat and then two drops of water onto each tablet. Bilirubin, if present, is adsorbed into the mat fibers and will appear the same on each mat; an interfering substance produces a light color or no color on the mat with the extra water.

Urobilinogen in Urine

Conjugated bilirubin from the liver eventually reaches the duodenum, complexed with cholesterol, bile salts, and phospholipids within the bile. The conjugated bilirubin is not absorbed from the small intestine but instead passes on into the colon, where resident bacteria hydrolyze the conjugate. The free bilirubin is then reduced to urobilinogen, mesobilirubinogen, and stercobilinogen. Up to 50% of the urobilinogen is reabsorbed into the portal circulation and is reexcreted, unconjugated, into the bile. The vast majority of remaining urobilinogen is excreted in feces as colored urobilins or stercobilin, which are formed after further removal of hydrogen. A small amount is excreted in the urine.

Urobilinogen represents a group of closely related tetrapyrrole compounds, and because a mixture of substances is actually measured, the term **units** is frequently used instead of the more precise milligrams-per-deciliter terminology. These are roughly equivalent. Normal output of urobilinogen in the urine is 0.5–2.5 mg or units/24hours. These substances are colorless and labile, as opposed to the urobilins, the oxidation products of urobilinogen that impart a yellow-orange color to normal urine. Output of urobilinogen is increased in alkaline urine; the level is decreased in acid urine.

Whenever the liver is unable to efficiently remove the reabsorbed urobilinogen from the portal circulation, more urobilinogen than normal is routed through the kidney and hence is excreted in the urine. This can occur when there is hepatocellular damage due to viral hepatitis, drugs, or toxic substances, or in some cases of cirrhosis. With congestive heart failure, liver congestion prevents effective urobilinogen handling, and reexcretion into the bile is impaired. If an infection is present, such as cholangitis associated with obstruction, large amounts of urobilinogen are excreted in urine, together with bilirubin.

In contradistinction, an excess of urobilinogen in urine together with absent bilirubin is typically associated with hemolysis. This can be seen following acute lysis of erythrocytes, as well as with destruction of erythrocyte precursors in the bone marrow with megaloblastic anemias. Increased urobilinogen also accompanies bleeding into tissues and the subsequent formation of excess bilirubin. These jaundiced patients have dark-colored stools because excess urobilinogen is also excreted into the feces. Urinary urobilinogen may be increased when fever is associated with dehydration and concentrated urine.

Persistent absence of urinary urobilinogen occurs with complete obstruction of the outflow of bile into the intestine, accompanied by pale stools. Broad-spectrum antibiotics, which suppress the normal intestinal flora, may prevent the conversion of bilirubin to urobilinogen, and therefore may reduce its excretion in feces and urine.

The brown pigment mesobilifuscin is a dipyrrole that normally contributes to fecal and urine color. It does not react with tests for blood or bilirubin. Although it is not derived from bilirubin, as is urobilinogen, it is a likely byproduct of heme synthesis. Its excess causes a dark brown urine that can be seen with homozygous β -thalassemia, or whenever Heinz bodies form in erythrocytes (e.g., with the unstable hemoglobins).

Methods

Reagent Strip. Testing is based on the Ehrlich aldehyde reaction or on the formation of a red azo dye from a diazonium compound.

Multistix utilizes the former method; its test area is impregnated with an acid buffer solution and *p*-dimethylaminobenzaldehyde, which produces a reddish brown color with urobilinogen. Color varies from light yellow to shades of red-brown, and values from 0.2–1 mg per deciliter are considered normal. This test method is not specific for urobilinogen and will detect substances known to react with the Ehrlich reagent, including porphobilinogen, *p*-aminosalicylic acid metabolites, sulfonamides, procaine, 5-hydroxyindoleacetic acid, indole, and methyldopa (Aldomet). It is not a reliable method for the detection of porphobilinogen.

The Chemstrip urobilinogen test area is impregnated with 4-methoxybenzene-diazonium-tetrafluoroborate, which couples with urobilinogen in an acid medium to form a red azo dye. Results are read at 10–30 seconds, and the test can detect approximately 0.4 mg/dL. This test, unlike the Ehrlich reagent-based methods, is specific for urobilinogen.

A freshly voided sample is best for testing, given that urobilinogen is quite labile and will potentially form nonreactive urobilin in acid urine. Both reagent strips are affected by the metabolites of drugs such as phenazopyridine (Pyridium), which colors the urine orange-red in an acid medium, and other compounds such as Azo-Gantrisin. These may mask the reaction with urobilinogen or give a false-positive result. Bilirubin and blood do not usually affect the test, but bilirubin may occasionally cause a green color.

Other Urobilinogen and Porphobilinogen Tests. Qualitative testing for urobilinogen and porphobilinogen may be performed when reagent strip testing indicates more than 1 mg/dL of Ehrlich-reacting substance present in the urine (see later under Porphyrins for more information on these testing modalities).

Quantitative testing for urobilinogen in urine are seldom performed. Consult Henry (1979) for a 2-hour quantitative urobilinogen method, and Davidsohn (1974) or Schwartz (1944) for 24-hour quantitation. For quantitative comparative purposes in the same patient, a 2-hour test is used in which urine is collected from 2–4 PM after lunch. This period after the meal coincides with heightened excretion of urobilinogen, as the pH of the urine is more nearly neutral. Other 2-hour periods may be tested for comparison.

Indirect Tests for Urinary Tract Infection

It is not uncommon for significant urinary tract infections to be present in patients who do not experience typical symptoms. Given that these infections if untreated can cause severe renal damage, many physicians are finding it prudent to request tests for bacteriuria in high-risk individuals. These would include patients who are elderly, pregnant, or diabetic, and those with a previous history of urinary tract infections. The two most commonly utilized testing modalities for indirect assessment of bacteriuria and leukocyturia are the reagent strip nitrite and leukocyte esterase, respectively. These tests are best used to rule out urinary tract infections (St. John, 2006) and are discussed in the next sections. An immunochromatographic test strip for the measurement of urinary lactoferrin released from leukocytes may also prove useful for the rapid diagnosis of urinary tract infection (Arao, 1999). Microscopic urinalysis serves as a rapid confirmatory test for the presence of leukocytes and bacteria, with bacteriologic culture remaining the “gold standard” for detecting bacteriuria.

Nitrite

Many bacteria that are urinary tract pathogens are able to reduce nitrate to nitrite, and thus will generate a positive urine nitrite test when present in significant numbers ($>10^5$ – 10^6 /mL bladder urine). Common organisms include *Escherichia coli*, *Klebsiella*, *Enterobacter*, *Proteus*, *Staphylococcus*, and *Pseudomonas* species; *Enterococcus* is unable to reduce nitrate to nitrite. If

the nitrite test is positive, a culture should be considered, provided that the specimen was properly collected and stored prior to testing. A first morning clean-voided midstream specimen is best.

According to Kunin (1975), self-administered repeated nitrite tests (three tests) in a small group of patients revealed about 70% overall positive results when compared with cultures. When only *E. coli* was present, bacteriuria detected by a positive nitrite test in any of the three first morning specimens showed 93% agreement with culture results. No significant false-positive nitrite results were reported in his large test group. Other authors report more disappointing results with nitrite dipstick screening for urinary tract infection, particularly in hospital inpatients (Zaman, 1998).

Methods. The test depends on the conversion of nitrate to nitrite by bacterial action in the urine. Because overnight (minimum of 4 hours) bladder incubation is typically required for the infecting bacterial population to convert urinary nitrate to nitrite, a first morning specimen is best. A positive result is an indication for culture, unless the specimen has been improperly stored after collection, allowing contaminant bacterial growth.

Reagent Strip. The nitrite testing area of Multistix is impregnated with *p*-arsanilic acid, which forms a diazonium salt when it reacts with nitrite present in the urine. This compound is then able to couple with benzoquinoline to form a pink azo dye. This method detects 0.075 mg of nitrite per deciliter in solution and is read at 40 seconds. Chemstrip contains a benzoquinoline and sulfanilamide, which produce a pink azo dye with nitrite at 30 seconds, and is able to detect 0.05 mg of nitrite per deciliter. Note that pink spots or edges are interpreted as negative.

False-positive results most commonly occur with poorly collected/stored specimens as the result of contaminants and postcollection bacterial proliferation. False-positives may also be produced by medications that color the urine red or turn red in an acid medium (e.g., phenazopyridine).

False-negative nitrite results may be due to ascorbic acid, urobilinogen, or low pH (<6). Random specimens collected during the day and urine from patients with draining catheters do not show good correlation between the nitrite test and significant bacteriuria, presumably because of the time required for the chemical reduction to nitrite in the bladder urine. Additionally, some false-negative results occur because some nitrate-reducing organisms form compounds other than nitrite, such as ammonia, nitric and nitrous oxide, hydroxylamine, and nitrogen, and therefore give a negative nitrite test result. Lack of dietary nitrate may also produce false-negative results, even when a significant number of organisms are present.

Leukocyte Esterase

Extracts of human neutrophil azurophilic (primary) granules contain up to 10 proteins showing esterolytic activity, and this esterase activity is commonly used as a marker for these cells. Because neutrophils and other cells are labile in urine, leukocyte esterase activity can be indicative of remnants of cells that are not visible microscopically.

The presence of significant numbers of neutrophils in the urine suggests urinary tract infection; however, difficulty has arisen in determining suitable cutoff points for normal and abnormal numbers of these cells. Because quantitative counts are so low, precision is poor. Positive leukocyte esterase results correlate with "significant" numbers of neutrophils, either intact or lysed; with the use of a chamber count of about 10 neutrophils/ μ L of fresh urine as a cutoff point, the numbers of false-negative and false-positive results are low. Likewise, when a concentrated (10:1) urine sediment and a cytocentrifuged stained preparation are used, a negative reagent strip test is associated with fewer than 100 neutrophils in 10 high-power fields (hpf) (450 \times). The leukocyte esterase test may also be useful in the workup of suspected urethritis in male patients; it has a high negative predictive value in this diagnostic setting (Bowden, 1998).

Methods

Reagent Strip. This test is similar in principle to the naphthol chloroacetate reaction used for granulocyte esterase detection in hematology. Neutrophilic esterases catalyze the hydrolysis of esters to produce their respective alcohols and acids. For example, Multistix utilizes 3-hydroxy-5-phenyl-pyrrole-*N*-tosyl-L-alanine ester as a substrate, which reacts in the presence of leukocyte esterase to form pyrrole alcohol. The alcohol then reacts with a diazonium salt to produce a purple color. The intensity of the color produced is proportional to the amount of enzyme present, which is related to the number of neutrophils present.

Cells originating from the urinary tract (i.e., urothelium) and erythrocytes do not contribute to the esterase level. Elevated urine specific gravity,

protein, and glucose may all decrease test results, as can the presence of boric acid and certain antibiotics such as tetracycline, cephalixin, and cephalothin. Very large amounts of ascorbic acid may inhibit the reaction.

Contamination of urine with vaginal fluid may give positive results, and large numbers of squamous epithelial cells and bacteria would be seen on microscopic evaluation. Also, *Trichomonas* and eosinophils may represent alternative cellular sources of esterases, causing false-positive results. Oxidizing agents and formalin may give false-positive colors, and nitrofurantoin and other strong colors may affect color interpretation.

Miscellaneous Chemical Screening Tests

Ascorbic Acid

Large quantities of ascorbic acid may occasionally be found in the urine of individuals taking therapeutic doses of vitamin C or other preparations containing abundant ascorbic acid. Because of its reducing properties, ascorbic acid may inhibit several reagent strip reactions (i.e., glucose, blood, bilirubin, nitrite, and leukocyte esterase). Reagent strips from various manufacturers differ in their susceptibility to this substance, and suspicious results should be investigated. For example, when the microscopic examination of urine sediment shows more than two erythrocytes per high power field, but heme is not detected by the reagent strip method, it may be useful to check for the presence of ascorbic acid.

Urine tests for ascorbic acid have also been used as an indication of adequate ascorbic acid therapy. With the usual Western diet, 2–10 mg/dL is excreted daily, but after ingestion of large amounts of ascorbic acid, levels in urine may rise to 200 mg/dL. Oxalate and sulfate are the metabolites of ascorbic acid, and with ingestion of large quantities (1 g or more per day), oxalate stones may form in susceptible persons.

Methods. Several manufacturers have developed reagent strip methods for detecting ascorbic acid, discussed below. Gas chromatographic/mass spectrometric measurement is a more accurate quantitative method (Deutsch, 1997).

Reagent Strip. The ascorbic acid testing area of C-Stix reagent strips is impregnated with phosphomolybdates buffered in an acid medium. The phosphomolybdates are reduced by ascorbic acid to molybdenum blue, and this test detects 5 mg/dL of ascorbic acid in urine after 10 seconds. Gentisic acid and L-dopa may cause false-positive results.

Stix reagent strips are not as sensitive as C-Stix; they can detect about 25 mg/dL of ascorbic acid at 60 seconds. The reagent in Stix is methylene green, which is reduced to its colorless form with ascorbic acid. Neutral red provides a background color, and the overall color changes from blue to purple at levels of 150 mg/dL. This same testing method is also incorporated into Multistix multiple reagent strips. Large amounts of bilirubin and pH greater than 7.5 interfere with the color. False-positive results are not seen with urates, salicylates, gentisic acid, or creatinine.

5-Hydroxyindoleacetic Acid

Serotonin (5-hydroxytryptamine) is produced by the argentaffin cells of the intestines from tryptophan, and is carried in the blood by platelets. Carcinoid tumors (argentaffinoma) can produce excessive amounts of serotonin, especially when metastatic. Characteristic symptoms include intestinal and vasomotor disturbances and bronchoconstriction; edema, right-sided valvular heart disease, and neurologic symptoms may also be present.

Although serotonin in the urine can be analyzed directly by high-performance liquid chromatographic methods (Panholzer, 1999), screening tests that detect the serotonin metabolite 5-hydroxyindoleacetic acid in the urine are more commonly used. The quantitative method is more sensitive because it eliminates the interfering keto acids and indoleacetic acid. The normal excretion of 5-hydroxyindoleacetic acid in 24 hours is 1–5 mg.

Screening Test. A random urine specimen is usually sufficient for screening purposes; if a 24-hour collection is made, it should be acidified with HCl. Boric acid may also be used as a preservative. Patients should be instructed not to take any drugs for 72 hours before the test; phenothiazines, acetanilid drugs, and mephenesin, a muscle relaxant, will interfere with this test.

The principle of the test is based on the development of a purple color specific for 5-hydroxyindoles with nitrous acid and 1-nitroso-2-naphthol. Ethylene dichloride is used to remove interfering chromogens. For the procedure, see Henry (1984).

Melanin

Normal melanocytes convert tyrosine to dihydroxyphenylalanine (DOPA), then to dopaquinone, and by oxidative steps to melanin. The enzyme tyrosinase is required for the first conversion step and is found in specific organelles in melanocytes called **melanosomes**. Its formation is increased by melanin-stimulating hormone. Melanosomes with pigment are normally transferred from melanocytes to skin and mucous membrane cells. Enlarged melanosomes are found in some neoplastic cells (e.g., nevus, melanoma).

Increased urinary excretion of melanin metabolites occurs as malignant melanoma metastasizes, although it is unusual to find dark-colored urine in these patients, even when the specimen stands at room temperature for 24 hours. These urinary melanogens include indoles, catechols, and catecholamines. DOPA does not appear in large amounts in urine from melanotic patients.

No simple specific test is available for melanuria. Screening tests for melanin should be made on fresh specimens of urine and include tests based on nonspecific color reactions produced with ferric chloride, Ehrlich's aldehyde reagent, and nitroferricyanide. Procedures for the ferric chloride and nitroferricyanide tests for melanin can be found in Henry (1984).

A column cation-exchange chromatographic method allows detection of melanin metabolites in urine. Another approach is to measure DOPA oxidase levels in urine. The enzyme is increased in the urine of patients with melanoma and is markedly increased with liver metastases.

Rarely, cells containing melanin pigment are seen in urine sediment when melanuria with pigment uptake by renal tubular cells or metastatic melanoma to the bladder is present. A ferrous ion uptake stain can be used to color the melanin in cells dark blue.

Porphyryns

The porphyrias are a group of diseases resulting from defects in the synthesis of heme. These are inherited enzyme deficiencies in which the enzyme substrate is usually excreted in excess in urine and/or feces. During the acute porphyric attack, high levels of porphobilinogen are excreted, but between attacks, levels of porphobilinogen may be increased or normal. The patterns of excretion of the various porphyryns vary with the different diseases, and together with the clinical findings help to establish the diagnosis.

The porphyryns are excreted in most of the porphyrias and in lead poisoning. Additionally, porphyrin metabolism may be abnormal in patients with established human immunodeficiency virus infection, particularly when there is a concomitant hepatitis C virus infection (O'Connor, 1996).

Skin photosensitivity and cutaneous lesions frequently accompany high levels of porphyryns. The one entity without skin lesions is acute intermittent porphyria. In patients presenting with neurologic disease and acute abdominal pain—the hepatic group—production and excretion of δ -aminolevulinic acid (ALA) and porphobilinogen are increased during the acute porphyric attack. This is likely due to increased activity of ALA synthase and subsequent increased production of the precursors. Exacerbations of the hepatic diseases are precipitated by drugs known to induce liver enzyme activity (e.g., barbiturates, certain steroids).

Methods. In patients suspected of having an acute porphyric attack, porphobilinogen is sought in urine specimens. The Watson-Schwartz test is used to separate causes of a positive Ehrlich-reacting test and to give an indication of large amounts of urobilinogen or the presence of porphobilinogen. A positive result for porphobilinogen in the Watson-Schwartz test can be further confirmed by the Hoesch test, because the former may show false-positive results for porphobilinogen as a result of drugs such as methyl dopa. When a qualitative porphobilinogen test is specifically requested or a known porphyric patient is being followed, the simpler Hoesch test may be used instead of the Watson-Schwartz test.

Urine specimens for urobilinogen or porphobilinogen must be fresh. If testing will be delayed, the pH should be adjusted to near neutral (pH 7) and the specimen stored in a refrigerator, where it is stable for about 1 week. Urine may darken if the patient has porphyria, especially if left at room temperature.

Watson-Schwartz Test. Ehrlich's aldehyde reaction and Watson-Schwartz tests are based on solubility differences between urobilinogen and porphobilinogen. Urobilinogen can be extracted by chloroform and/or butanol, whereas porphobilinogen will remain in an aqueous phase.

Procedure

1. To 2.5 mL fresh urine, add 2.5 mL Ehrlich's reagent and mix.
2. Add 5 mL saturated sodium acetate and mix. Check with pH paper to confirm that the solution is in the pH range of 4–5. Adjust pH if necessary.
3. Add 5 mL chloroform; insert a stopper and shake vigorously for 1 minute. Permit the phases to separate.
4. Examine the upper (aqueous) phase. If the color is absent, consider the result of the screening test to be negative, and stop.
5. If color is present, separate the upper (aqueous) phase and add 5 mL of butanol. Insert a stopper and shake vigorously for 1 minute. Allow phases to separate.
6. A "pink to rose red" color in the lower aqueous layer indicates a positive result and suggests a concentration of porphobilinogen that is several times normal. A color in the upper butanol layer indicates an increase in urobilinogen concentration (Fig. 28-3).

Hoesch Test. The Hoesch test is based on the inverse Ehrlich's reaction (i.e., of maintaining an acid solution by adding a small urine volume to a relatively large reagent volume), eliminating the problem of urobilinogen reactivity. The sensitivity is similar to that of the Watson-Schwartz test, but the reaction is for porphobilinogen. This test will detect about 20–100 mg/L of porphobilinogen; urobilinogen in amounts up to 200 mg/L does not give a positive result (red color). A yellow color may be caused by urea.

The uroosein urinary pigment related to indoleacetic acid will produce a positive Hoesch test (in response to strong HCl), and the rose color may be confused with a positive porphobilinogen result. Some of the false-positive problems may be excluded by testing the specimen with concentrated HCl (6 mol/L) separately in conjunction with the Hoesch test. Urine from a patient having an acute porphyric attack may be dark red in color, necessitating a 1:10 dilution with water before testing.

The Watson-Schwartz test detects greater than 6 mg/L and the Hoesch test greater than 11 mg/L of porphobilinogen. The Watson-Schwartz test is more sensitive than the Hoesch test for porphobilinogen and may yield a positive result between attacks of acute intermittent porphyria. Large doses of methyl dopa (Aldomet) gave positive results, as did indoles in some patients with intestinal ileus and the drug phenazopyridine (Pyridium), which becomes orange with HCl. A quantitative porphobilinogen test is necessary if the Watson-Schwartz test or the Hoesch test result is questionable; this situation may arise because of the instability of porphobilinogen.

Alternative urine screening tests for porphobilinogen have been described. These include a micellar electrokinetic capillary chromatographic method (Luo, 1996), as well as a semiquantitative kit in which urine is pretreated with ion-exchange resin, and the color of the Ehrlich-porphobilinogen adduct is compared to a set of standards (Deacon, 1998).

Uroporphyrin and coproporphyrin can be detected by fluorescence. An orange-red fluorescence is seen if a positive specimen is placed near an ultraviolet light source.

Fluorescence Screening Procedure for Porphyrin. In this method, the urine is acidified and the extracted porphyrin exposed to ultraviolet light.

1. Place 5 mL urine in a stoppered glass centrifuge tube. Add 3 mL of a mixture of one part glacial acetic acid with four parts ethyl acetate.
2. Shake and allow to separate. Centrifuging will accelerate the separation.
3. Using a Wood's lamp, observe the upper layer for fluorescence. Inspect the tube in a dark room with ultraviolet reflected light. A lavender to violet color indicates the presence of porphyryns; pink to red fluorescence indicates higher levels of porphyrin. Pale blue with no pink color is negative. Normal urine may fluoresce blue.

To increase the sensitivity of the test and remove interfering drug metabolites, transfer the upper layer to a glass tube and acidify with 0.5 mL of 3 M HCl (25 mL concentrated HCl diluted to 100 mL with water). Shake. Porphyrins are extracted into the lower aqueous layer and will produce a red-orange fluorescence.

An alternative screening method utilizes an anion-exchange resin column. Porphyrins are adsorbed, eluted, and exposed to fluorescent light. This method removes interfering substances and is similar in principle to the quantitative method for total porphyryns and for coproporphyrin and uroporphyrin.

Screening tests together with the clinical findings will indicate whether quantitative tests should be done. The latter are usually performed by reference or research laboratories.

Urine specimens for quantitative porphobilinogen should be kept at a near neutral pH (between 6 and 7) and protected from light. Frozen

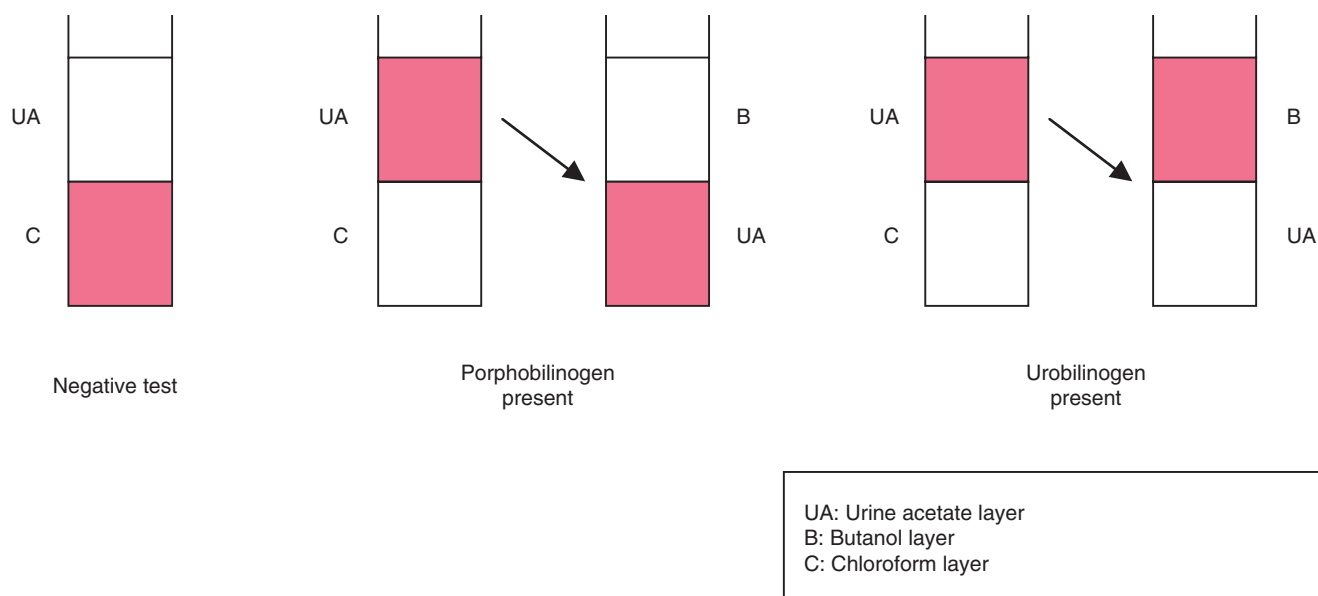

Figure 28-3 Watson-Schwartz test. Interpretation of screening method for urine urobilinogen and porphobilinogen.

specimens are fairly stable, although ALA is more stable if the urine is acidic. If the urine is to be tested for both substances, the near neutral pH is preferred and the urine aliquot is frozen. These substances are quantitated by eluting from different columns and reacting with Ehrlich's reagent. A micellar electrokinetic capillary chromatographic method has been described that allows separation of ALA and porphobilinogen (Luo, 1996).

Urine specimens for quantitative porphyrins are collected in a dark container containing 5 g sodium carbonate for a 24-hour specimen to give a concentration of 0.1% sodium carbonate or to produce urine of neutral pH. Coproporphyrin and uroporphyrin can be separated by thin-layer chromatography or by extraction and fluorometry and quantitated using ion-exchange columns. Additional methods include the Bio-Rad (porphyrin) column test, spectrophotometry (Zuijderhoudt, 1998), capillary electrophoresis (Chiang, 1997), fast atom bombardment mass spectrometry (Luo, 1997), and laser desorption/ionization time-of-flight mass spectrometry (Jones, 1995).

Fecal porphyrins can be qualitatively estimated using extraction and ultraviolet (UV) light, or quantitated. In some porphyrias, erythrocytes may show fluorescence when an unstained blood smear is examined microscopically. The nucleated bone marrow erythrocytes give greater fluorescence.

EXAMINATION OF URINE SEDIMENT

Microscopic examination of urine, in conjunction with dipstick chemical analysis, aids in the detection of renal and urinary tract disease processes. With microscopy, one can detect those cellular and noncellular elements of urine that do not give distinct chemical reactions. Microscopy can also serve as a confirmatory test in some circumstances (e.g., erythrocytes, leukocytes, bacteria) and yields new information 66% of the time (Tworek, 2008). In the routine laboratory, examination of the urine sediment is best reserved and most useful for those samples with abnormal dipstick results (European Urinalysis Guidelines, 2000).

To perform a microscopic evaluation of urine with competence, one must be knowledgeable of numerous morphologic entities (e.g., organisms, hematopoietic and epithelial cells, crystals, casts). Also, microscopists must be aware of the clinical relevance of urine findings, as well as the common chemical abnormalities associated with microscopic interpretations. Discrepancies should be investigated before a report is issued. The quality of the manual microscopic analysis of urine is dependent on the expertise and experience of the examiner (Tsai, 2005).

Centrifuged urine sediment should contain all the insoluble materials (commonly referred to as formed elements) that have accumulated in the urine following glomerular filtration and during passage of fluid through the renal tubules and lower urinary tract. Cellular elements are derived from two sources: (1) Desquamated/spontaneously exfoliated epithelial

lining cells of the kidney and lower urinary tract, and (2) cells of hemogenous origin (leukocytes and erythrocytes). Cellular and noncellular casts may be seen; these are formed in the renal tubules and collecting ducts. Crystals of variable clinicopathologic significance may also be present. Organisms (bacteria, fungi, viral inclusion cells, parasites) and neoplastic cells represent elements that are typically foreign to urine; when detected, further investigation is required.

"Normal" or reference values for formed elements will vary from one laboratory to another because of (1) the variation in concentration of random urine specimens, and (2) the different methods used to concentrate the sediment by centrifugation. No specific standardized procedure is used. Individual laboratories have established their own reference values, often in conjunction with nephrologists and nephropathologists.

Methods for Examining Urine Sediment

In general, randomly collected urine specimens are satisfactory for microscopic evaluation; however, it is recommended that examination take place when the sample is fresh, particularly if no preservative has been added. Cells and casts begin to lyse within 2 hours of collection. Refrigeration (2°–8° C) helps prevent the lysis of pathologic entities; however, this may increase the precipitation of various amorphous and crystalline materials. Midstream collection is recommended for females to reduce contamination from vaginal elements.

Bright-field Microscopy

Although bright-field microscopy can be performed to a limited extent on unstained urine preparations, identification of leukocytes, histiocytes, epithelial cells, and cellular casts may be difficult. Subdued light is more effective in delineating translucent structures of the urine, such as hyaline casts, crystals, and mucous threads. A crystal-violet safranin stain is commonly used to aid in delineation of formed elements in urine.

Supravital Stain Reagents

Solution I:	Crystal violet	3.0 g
	Ethyl alcohol (95%)	20.0 mL
	Ammonium oxalate	0.8 g
Solution II:	Safranin O	1.0 g
	Ethyl alcohol (95%)	40.0 mL
	Distilled water	400.0 mL

Three parts of solution I and 97 parts of solution II are mixed and filtered. The mixture should be clarified by filtering every 2 weeks and discarded after 3 months. Separately, solutions I and II can be kept indefinitely at room temperature.

Several commercially available staining reagents are available. A 2% solution of methylene blue and toluidine blue may be used as a simple, quick supravital stain.

Figure 28-4 A, Hyaline casts. Bright-field ($\times 100$). B, Hyaline casts. Phase-contrast microscopy ($\times 100$).

Procedure. Add one or two drops of stain to approximately 1 mL of concentrated urine sediment. Mix with a pipet, and place a drop of this suspension on a slide and coverslip.

Phase-Contrast Microscopy

Phase-contrast microscopy is beneficial for the detection of more translucent formed elements of the urinary sediment, notably casts that may escape detection under ordinary bright-field microscopy. Phase-contrast microscopy has the advantage of hardening the outlines of even the most transparent formed elements, making detection simple (Fig. 28-4, A and B). Scanning time is decreased, and the yield increased. Several microscopes have been designed to allow the operator to perform bright-field or phase-contrast examinations, depending on which objectives or condensers are utilized.

Polarized Microscopy

This is used to distinguish crystals and fibers from cellular or protein cast material. Lipid droplets or spherocrystals containing cholesterol esters are anisotropic in polarized light, show up brightly against a dark field, and form Maltese crosses with crossed polars. Visible evidence of anisotropy depends on the orientation of the crystal in the field; not all will be seen. If a red retardation plate is inserted, the cholesterol droplet will show typical blue and yellow quadrants against a red background. Starch granules will have a similar appearance when polarized but are much larger. Crystals, hair, and clothing fibers also show up brightly but do not exhibit Maltese cross forms. Fatty acids and triglycerides do not form liquid spherocrystals and do not show anisotropy, but glycosphingolipids in Fabry's disease are birefringent and may be seen in urinary sediments.

Quantitative Counts

The hemocytometer is used in many laboratories to quantify the elements of urine sediment. Cells and casts from undiluted well-mixed urine are counted and reported as the number of cells per microliter. Normal values for neutrophils vary from 5–30/ μL according to different workers; upper limits for erythrocytes range from 3–20/ μL and for casts as few as 1–2/ μL . Counting cells from an unspun sample of urine in a hemocytometer has advantages over the examination of cytocentrifuged spun urine. These include decreased variability caused by centrifugation and suspension, a fixed volume of urine for examination, and a marked visual field for accurate counting. Kesson (1978) provided evidence that chamber counts on centrifuged urine sediments are more reliable in predicting renal functional abnormalities than is a conventional method using cells per high-power field. Recovery of cells may vary depending on centrifuge speed, specific gravity, and pH.

Microscopic Components in Urine Sediment

Cells

Erythrocytes. Under high power, unstained erythrocytes (RBCs) appear as pale biconcave disks that may vary somewhat in size but are usually about 7 μm in diameter. If the specimen is not fresh when it is examined, erythrocytes may appear as faint, colorless circles or “shadow cells,” because the hemoglobin may dissolve out. They may become crenated in hypertonic urine and appear as small, rough cells with crinkled edges. In dilute urine, the cells will swell and rapidly lyse, releasing hemoglobin and leaving only empty cell membranes, referred to as **ghost cells**.

On occasion, erythrocytes may be confused with oil droplets or yeast cells. Oil droplets, however, exhibit greater variation in size and are highly refractile, and yeast cells usually show budding. If identification is difficult,

Figure 28-5 Dysmorphic erythrocytes ($\times 160$).

two preparations may be made and a few drops of acetic acid added to one. Erythrocytes are lysed in the acidified preparation.

Erythrocytes are found in small numbers (0–2 cells/hpf) in normal urine; more than 3 cells/hpf is considered abnormal. The presence of increased numbers of erythrocytes in the urine may indicate a variety of urinary tract and systemic conditions. These include (1) renal disease—glomerulonephritis, lupus nephritis, interstitial nephritis associated with drug reactions, calculus, tumor, acute infection, tuberculosis, infarction, renal vein thrombosis, trauma (including renal biopsy), hydronephrosis, polycystic kidney, and occasionally acute tubular necrosis and malignant nephrosclerosis; (2) lower urinary tract disease—acute and chronic infection, calculus, tumor, stricture, and hemorrhagic cystitis following cyclophosphamide therapy; (3) extrarenal disease—acute appendicitis, salpingitis, diverticulitis, acute febrile episodes, malaria, subacute bacterial endocarditis, polyarteritis nodosa, malignant hypertension, blood dyscrasias, scurvy, and tumors of the colon, rectum, and pelvis; (4) toxic reactions due to drugs, such as sulfonamides, salicylates, methenamine, and anticoagulant therapy; and (5) physiologic causes, including exercise. When increased numbers of erythrocytes are found in the urine in conjunction with erythrocyte casts, bleeding may be assumed to be renal in origin.

Dysmorphic Erythrocytes. Numerous studies have concentrated on the variable morphology of urinary erythrocytes, attempting to localize the site of origin of hematuria. Red blood cells with cellular protrusions or fragmentation are termed dysmorphic (Fig. 28-5), and some authors have suggested that their presence in urine samples is strongly suggestive of renal glomerular bleeding (Fracchia, 1995). Others have not found dysmorphic morphology reliable in predicting primary renal hematuria (Favaro, 1997; Ward, 1998). The so-called “G1 cell,” which has a doughnut shape with one or more membrane blebs, may be more specific than dysmorphic cells for diagnosing glomerular hematuria (Dinda, 1997). Another study describes immunocytochemical staining of urinary erythrocytes with Tamm-Horsfall protein in renal hematuria; this appears to be even more reliable than cellular morphology in terms of separating renal from nonrenal sources of erythrocytes (Fukuzaki, 1996). Normal persons may also have a mixture of distorted and undistorted erythrocytes in urine.

Leukocytes

Neutrophils. The polymorphonuclear leukocyte (neutrophil) is the predominant type of leukocyte (white blood cell [WBC]) that appears in the urine. Under high power, these cells appear as granular spheres about 12 μm in diameter with multilobated nuclei. Nuclear segments may sometimes appear as small, round, discrete nuclei. When cellular degeneration has begun, nuclear detail may be lost, and neutrophils may then become difficult to distinguish from renal tubular epithelial cells. Dilute acetic acid may enhance nuclear detail so that definition may still be possible (Fig. 28-6). Ultimately, however, with continued degeneration, neutrophilic nuclear segments fuse, making distinction from mononuclear cells difficult or impossible. Supravital staining may also be helpful in emphasizing nuclear detail. With crystal-violet safranin, neutrophilic nuclei appear reddish purple and cytoplasmic granules violet. The peroxidase cytochemical reaction is also useful in distinguishing neutrophils from tubular cells.

In dilute or hypotonic urine, neutrophils swell and their cytoplasmic granules exhibit brownian movement. Because of the refractivity of the moving granules, neutrophils in this setting are known as **glitter cells**. These cells stain poorly with supravital stains and will show loss of nuclear segmentation. The leukocyte esterase reagent strip is valuable in the confirmation of pyuria in hypotonic urine specimens.

Additionally, leukocytes are rapidly lysed in hypotonic or alkaline urine. Approximately 50% are lost following 2–3 hours of standing at room

Figure 28-6 Neutrophils with dilute acetic acid ($\times 100$).

Figure 28-7 Eosinophils ($\times 500$).

temperature. This necessitates prompt examination of the urinary sediment following collection.

Pyuria. Typically, fewer than 5 leukocytes/hpf are seen in normal urine, although females not uncommonly will have somewhat higher quantities present. Increased numbers of leukocytes (principally neutrophils) in the urine constitute pyuria and indicate the presence of infection or inflammation in the urinary tract. When accompanied by leukocyte casts or mixed leukocyte–epithelial cell casts, increased urinary leukocytes are considered to be renal in origin.

Infection, either bacterial or nonbacterial, may be centered in the renal parenchyma (pyelonephritis) or may be localized as cystitis, prostatitis, urethritis, or balanitis. In women, the acute urethral syndrome (dysuria-pyuria syndrome) is regularly associated with greater than 8 neutrophils/ μL in clean-catch urine specimens; however, bacterial colony counts are lower than expected. *Chlamydia trachomatis*, staphylococci, and coliforms are causative agents. Urinary neutrophil counts greater than 30 cells/hpf suggest acute infection, and repeated sterile cultures in this setting may indicate tuberculosis or a nephritis. Gross pyuria may reflect rupture of a renal or urinary tract abscess. It should be noted that the common finding of leukocytes in urine is not as reliable an indication of urinary tract infection as the detection of bacteriuria by Gram stain or culture of a fresh midstream specimen.

Increased leukocytes may be found in a variety of other urinary tract diseases, including glomerulonephritis, systemic lupus erythematosus (SLE), and interstitial nephritis. Calculous disease at any level may give rise to increased numbers of urinary leukocytes caused by stasis-induced ascending infection or localized mucosal inflammatory response. Bladder tumors, as well as a variety of acute or chronic localized inflammatory processes, may also cause leukocytes to be increased in the urine. Urine leukocytes may be transiently increased during fevers and following strenuous exercise.

Eosinophils. These cells are not normally seen in urine, and the finding of more than 1% eosinophils among the leukocyte population present is considered significant (Fig. 28-7). Evaluation of a concentrated stained urine is necessary for proper evaluation of urine for the presence of eosinophils. A cytocentrifuge preparation with Wright's, Diff-Quik, or Papanicolaou stain is commonly used, and the Hansel secretion stain (methylene blue and eosin-Y in methanol, Libe Labs, Florissant, MO) has been shown to be an excellent stain for recognition of eosinophiluria. Appropriately stained, bilobed eosinophils may be noted in patients with tubulointerstitial disease associated with hypersensitivity to drugs such as penicillin and its analogs. The cellular pattern in allergic interstitial nephritis typically includes many erythrocytes and some renal tubular epithelial cells. Eosinophiluria is also seen in other acute disorders of the genitourinary tract, with small numbers seen in urinary tract infections and renal transplant rejections.

Lymphocytes and Mononuclear Leukocytes. Small lymphocytes are normally present in urine and, along with histiocytes, are easily

Figure 28-8 Squamous epithelial cell. Pyridium stained ($\times 200$).

Figure 28-9 Transitional epithelial cells. Papanicolaou stained ($\times 430$).

Figure 28-10 Renal tubular epithelial cells ($\times 200$).

differentiated in stained smears. When mononuclear cells (histiocytes, lymphocytes, or plasma cells) constitute 30% or more of a differential count, chronic inflammation is indicated. Many small lymphocytes may be found in urine during renal transplant rejection. Plasma cells and atypical lymphocytes should be noted when present, and further investigation is warranted.

Epithelial Cells

Squamous Epithelial Cells. These cells are the most frequent epithelial cells seen in normal urine and the least significant. The distal one third of the urethra is lined by squamous epithelial cells, and in the urine, these cells are large and flat, with abundant cytoplasm and small round central nuclei (Fig. 28-8). Their margins are often folded. When stained with crystal-violet safranin, nuclei are purple and cytoplasm pink to violet. Many of the squamous cells present in female urine may be derived from the vagina or vulva.

Transitional (Urothelial) Epithelial Cells. Transitional epithelial cells line the urinary tract from the renal pelvis to the lower third of the urethra. These cells are smaller than squamous cells, their size ranging from 40–200 μm . They are round or pear shaped, with a round, centrally located nucleus. Occasional binucleate forms may be seen. When stained, transitional cells have dark blue nuclei with variable amounts of pale blue cytoplasm (Fig. 28-9). Another helpful clue to the proper identification of transitional cells is a characteristic **endo-ecto cytoplasmic rim**.

A few urothelial cells are present in normal urine, reflecting normal desquamation; similar to squamous cells, they are rarely of pathologic significance. The exception is the presence of large clumps or sheets of transitional cells in the absence of instrumentation (i.e., catheterization). This situation necessitates cytologic examination with the Papanicolaou stain to evaluate for possible transitional cell carcinoma.

Renal Tubular Epithelial Cells. These are the most significant types of epithelial cells found in urine because the finding of an increased number indicates tubular damage (Figs. 28-10 and 28-11). Small numbers of tubular cells may be seen in normal urine, reflecting the normal sloughing of aging cells. They may be present in somewhat larger numbers in the urine of normal newborns.

Figure 28-11 Renal tubular epithelial cells and neutrophils. Papanicolaou stained (×430).

Figure 28-12 Oval fat body (×160).

The Papanicolaou stain has been shown to be especially useful in distinguishing renal tubular cells from other mononuclear cells in urine. Renal epithelial cells from the proximal and distal convoluted tubules occur singly and are large (14–60 μm), oblong cells with characteristic coarsely granular eosinophilic cytoplasm. Nuclei may be multiple but are small with dense chromatin and rare nucleoli. Increased numbers of proximal and distal convoluted renal epithelial cells are seen in cases of acute tubular necrosis and with certain drug or heavy metal toxicities.

Epithelial cells from the collecting ducts measure 12–20 μm and are identified by their characteristic cuboidal or polygonal shape and large, usually slightly eccentric nucleus. Cytoplasmic properties include a basophilic endo-ecto cytoplasmic rim commonly found in transitional epithelial cells. Increased numbers of collecting duct epithelial cells are found in renal transplant rejection, acute tubular necrosis (diuretic phase), and other ischemic injuries to the kidney. They may also be found in increased numbers in malignant nephrosclerosis, as well as in cases of acute glomerulonephritis accompanied by tubular damage. Ingestion of various drugs and chemicals may cause significant tubular desquamation. Collecting duct tubular cells are easily found in the urine following salicylate intoxication.

Renal epithelial fragments of collecting duct origin have been described. Three or more renal cells of collecting duct origin constitute a renal epithelial fragment and indicate a more severe form of renal tubular injury with basement membrane disruption. Renal epithelial fragments are indicative of ischemic necrosis and are usually found accompanying varying degrees of renal tubular injury and pathologic casts. Proximal and distal convoluted tubular cells are not found in fragment form. Proper identification of renal epithelial fragments is essential, not only in diagnosing a more severe form of renal tubular injury, but also in avoiding a false-positive diagnosis of low-grade transitional cell carcinoma.

Lipids in Renal Tubular Epithelial Cells. Oval fat bodies are tubular cells that have absorbed lipoproteins with cholesterol and triglycerides leaked from nephrotic glomeruli (Fig. 28-12). Oval fat bodies therefore constitute one form of lipiduria. Lipids may also appear in the urine as free fatty droplets, or within histiocytes as ingested material. The presence of any or all of these lipid forms accompanied by marked proteinuria is characteristic of the nephrotic syndrome.

Positive identification of lipid is required before lipiduria is reported. When free or incorporated droplets contain large amounts of cholesterol, they exhibit Maltese cross formation under polarized light (Figs. 28-13 and 28-14). When they contain large quantities of triglycerides, fat stains (Oil Red O or Sudan III) are required for positive lipid identification.

Pigment in Renal Tubular Epithelial Cells. With hemoglobinuria or myoglobinuria, heme pigment is absorbed into the cells and is converted to hemosiderin. The iron-laden cells are desquamated and found in the urine sediment. The cytoplasmic granules appear yellow-brown and stain for iron with Prussian blue. These cells may also be incorporated into casts (see Figs. 28-1 and 28-2).

Figure 28-13 Oval fat body with attached fat droplets. Bright-field (×160).

Figure 28-14 Oval fat body with attached fat droplets. Polarized (×160).

Melanin granules are absorbed into the tubular cells in rare cases of melanuria. The desquamated pigmented cells may be demonstrated in the sediment. Pigmented tumor cells are also found in cases of melanoma metastasis to the bladder.

Bilirubin pigment colors all of the elements of the sediment, including renal tubular epithelial cells and casts. Note that urobilin does not color cells and casts.

Casts

Casts are the only formed elements of urine that have the kidney as their sole site of origin. Tamm-Horsfall protein is the glycoprotein secreted by the thick part of the ascending loop of Henle (and possibly the distal tubule), which constitutes about one third of the total urinary protein in normal individuals. It is generally held that Tamm-Horsfall protein forms the matrix of all casts. The protein forms a meshwork of fibrils that can potentially trap any elements present in the tubular filtrate, including cells, cell fragments, or granular material.

Casts can be quite variable in their appearance, size, shape, and stability. Perhaps this variability is one factor in the apparent low precision of cast identification in some laboratories (Yoo, 1995; Rasoulpour, 1996). The width of a cast depends on the size of the tubule in which it was formed. Broad casts are seen in dilated tubules or with stasis in collecting ducts. Thin casts occur in tubules compressed by swollen interstitial tissue or as the result of disintegration. Casts may be short and stubby, or long and convoluted. The latter variety appears when diuresis occurs after urinary stasis. Casts typically have parallel sides and blunt ends, but with age they may begin to disintegrate and show thinning and irregularities. Fibrils may separate, causing a frayed appearance. Tails and tapering ends can be seen, and these disintegrating forms are referred to as **cylindroids**.

In the normal person, very few casts are seen in the urinary sediment. In kidney diseases, they may appear in large numbers and in many forms. Increased numbers of casts usually indicate that kidney disease is widespread, and that many nephrons are involved. Large numbers of casts may also be seen in healthy persons after strenuous exercise accompanied by proteinuria.

Cast formation increases with lower pH or increased ionic concentration and with stasis or obstruction of the nephron by cells or cell debris. It is increased when larger than normal quantities of plasma proteins enter the tubules. Usually the protein in excess is albumin, but globulins such as the Bence Jones immunoglobulin cause cast formation, as do hemoglobin and myoglobin. The plasma proteins possibly react or combine with Tamm-Horsfall protein to form less translucent casts and granular casts.

Casts may be classified according to their matrix, inclusions, pigments, and cells present, as shown in Table 28-11. A detailed discussion, including clinical significance, follows.

Cast Matrix

Hyaline Casts. These are the most frequently observed casts, consisting almost entirely of Tamm-Horsfall protein; zero to two hyaline casts per

Figure 28-15 Waxy cast (x200).

Figure 28-16 Fine granular cast becoming waxy (x200).

TABLE 28-11

Classification of Casts

Matrix	Pigments
Hyaline—variable size	Hemoglobin, myoglobin, bilirubin, drugs
Waxy—often broad in use	
Inclusions	Cells
Granules—proteins, cell debris	Erythrocytes and red blood cell remnants
Fat globules—triglycerides, cholesterol esters	Leukocytes—neutrophils, lymphocytes, monocytes, and histiocytes
Hemosiderin granules	Renal tubular epithelial cells
Crystals—uncommon	Mixed cells—erythrocytes, neutrophils, and renal tubular cells
Melanin granules—rare	Bacteria

low-power field (lpf) is considered normal. Hyaline casts are translucent with bright-field microscopy and pink with supravital staining, and are more easily visualized with phase-contrast microscopy (see Fig. 28-4, *A* and *B*). Increased numbers are seen with renal diseases and transiently with exercise, heat exposure, dehydration, fever, congestive heart failure, and diuretic therapy.

Waxy Casts. With chronic renal diseases, some casts become denser in appearance and are known as waxy. These differ from hyaline casts in that they are easily visualized because of their high refractive index. With bright-field microscopy, waxy casts are homogeneously smooth in appearance with sharp margins, blunted ends, and cracks or convolutions frequently seen along the lateral margins, indicating a measure of brittleness (Fig. 28-15).

Waxy casts are commonly associated with tubular inflammation and degeneration. They are observed most frequently in patients with chronic renal failure and are found during acute and chronic renal allograft rejection. Early waxy casts are believed by some investigators to reflect the final phase of dissolution of the fine granules of granular casts (Fig. 28-16). Because time is required for granules to undergo lysis, waxy casts imply localized nephron obstruction and oliguria. When waxy casts are unusually broad, they are known as **renal failure casts**. These casts imply advanced tubular atrophy and/or dilation, in turn reflecting end-stage renal disease and extreme stasis of urine flow.

Cellular Casts

Erythrocyte (Red Blood Cell) Casts. Finding these casts in the urine is significant because they are an indication of bleeding within the nephron. Glomerular damage allows erythrocytes to escape into the tubule; if there is concomitant proteinuria, and if conditions are optimal for cast formation, red cell casts form in the distal nephron. In urine, these casts appear yellow under low-power objectives. A prerequisite for the identification of an erythrocyte cast is that red blood cell outlines should be sharply defined in at least part of the cast (Fig. 28-17). The amount of matrix material that

Figure 28-17 Erythrocyte cast (x200).

Figure 28-18 Leukocyte cast. IRIS urinalysis stain (x200).

Figure 28-19 Cellular cast (x200).

may be visible ranges from scant to a prominent delicate hyaline matrix with only one or two visible red cells. These casts are better visualized with phase-contrast microscopy or with supravital staining, in which case the erythrocytes are colorless or lavender in a pink matrix. With prolonged stasis, red cell casts may degenerate and appear in the urine as reddish brown, coarsely granular hemoglobin (blood) casts.

Pathologic disorders in which erythrocyte casts appear in the sediment include many acute glomerulonephritides, IgA nephropathy, lupus nephritis, subacute bacterial endocarditis, and renal infarction. Rarely, tubulointerstitial disease may allow transtubular entry of erythrocytes with subsequent incorporation into a cast. This may occur in severe pyelonephritis. Additionally, the appearance of erythrocyte and leukocyte casts has been found to coincide with renal relapse in patients with SLE (Herbert, 1995).

Leukocyte (WBC) Casts. WBC casts are refractile and exhibit granules; frequently, multilobated nuclei will be visible (Fig. 28-18), unless disintegration has begun. Phase-contrast microscopy may be helpful in delineating nuclear segmentation. Supravital stains also enhance visualization.

Leukocytes usually enter tubular lumina from the interstitium, and for the most part, leukocyte casts (Fig. 28-19) reflect tubulointerstitial disease with neutrophilic exudates and interstitial inflammation. The most common disease of this category is pyelonephritis. Leukocyte casts may be present in glomerular disease owing to the chemotactic effect of complement. They are also seen in interstitial nephritis, lupus nephritis, and even the nephrotic syndrome.

Renal Tubular Epithelial Cell Casts. Renal tubular epithelial cell casts may be difficult to distinguish from leukocyte casts, particularly in unstained preparations viewed with bright-field microscopy. Supravital

Figure 28-20 Renal tubular epithelial cell cast. Papanicolaou stained (×430).

Figure 28-21 Mixed (leukocyte and renal epithelial tubular cell) cast (×200).

Figure 28-22 Cellular cast (×200).

Figure 28-23 Granular cast (×200).

staining, phase-contrast microscopy, and Papanicolaou staining (see Figs. 28-19 and 28-20) are helpful in delineating between these two cast types. The most reliable distinguishing characteristic of renal tubular cells is their singular round nuclei.

Renal tubular epithelial cell casts are seen in urine with acute tubular necrosis, viral disease (e.g., cytomegalovirus disease), or exposure to a variety of drugs. Heavy metal poisoning and ethylene glycol and salicylate intoxication may cause tubular cells and casts to appear in the urine. In transplant units, these cells and casts constitute some of the more reliable criteria for detecting acute allograft rejection after the third postoperative day.

Mixed Cellular Casts. Not infrequently, two distinct cell types may be present within a single cast. This has been referred to as a **mixed cast**, and examples might include leukocyte/renal, erythrocyte/leukocyte, and eosinophil/renal (Fig. 28-21). When cell types cannot be established with certainty, the resulting cast is known as a **cellular cast** (Fig. 28-22). Some inferences as to cell type may be drawn from the dominant population of free cells in the surrounding sediment.

Inclusion Casts

Granular Casts. Granular casts are fairly common and may appear in both pathologic and nonpathologic conditions (Fig. 28-23). Granules may be small or large and may originate from plasma protein aggregates that

Figure 28-24 Fatty cast. Bright-field, nonpolarized (×160).

Figure 28-25 Fatty cast. Positive Oil Red O (×200).

Figure 28-26 Hemoglobin cast (×200).

pass into the tubules from damaged glomeruli, as well as from cellular remnants of leukocytes, erythrocytes, or damaged renal tubular cells. Fine salt precipitates and lysosomes may also be granular components. Protein aggregates include fibrinogen, immune complexes, and globulins. With prolonged stasis, large granules in casts may become smaller, and there appears to be no advantage to separating types of granular casts.

Granular casts appear with glomerular and tubular diseases but are also a feature of tubulointerstitial disease and renal allograft rejection. They may accompany pyelonephritis, viral infections, and chronic lead poisoning. Coarsely granular casts occur, with hematuria, in cases of renal papillary necrosis. It is possible that some fine granules represent calcium phosphate precipitants in hyperparathyroidism. Granular casts may also be seen following periods of extreme stress or strenuous exercise.

Fatty Casts. Fatty material is incorporated into the cast matrix from lipid-laden renal tubular cells. These are commonly seen when heavy proteinuria is present and are a feature of nephrotic syndrome (Figs. 28-24 and 28-25).

Crystal Casts. Casts containing urates, calcium oxalate, and sulfonamides (sulfamethoxazole) are occasionally seen. A matrix is visible in a true crystal cast, and the crystals may polarize. These casts indicate deposition of crystals in the tubule or collecting duct. Hematuria, possibly related to tubular damage, regularly accompanies crystal casts. These casts should be carefully distinguished from clumps of crystals forming at room or refrigerator temperatures.

Pigmented Casts

Hemoglobin (Blood) Casts. Hemoglobin casts typically appear yellow to red, although sometimes the color is pale (Fig. 28-26). Most often, hemoglobin casts, also known as blood casts, are seen with erythrocyte casts and glomerular disease. Less commonly, they are seen with tubular bleeding and rarely with hemoglobinuria.

Hemosiderin Casts. Hemosiderin granules in casts derive from pigment-laden renal tubular cells.

Myoglobin Casts. These casts are red-brown in color and occur with myoglobinuria following acute muscle damage. They may be associated with acute renal failure.

Figure 28-27 Acid urates ($\times 160$).

Bilirubin and Other Drug Casts. Bilirubin is seen in urine when obstructive jaundice is present, and will color casts a deep yellow brown. Drugs such as phenazopyridine (Pyridium) cause a bright yellow to orange color in acid urine and color casts and cells as well.

Broad Casts. Broad casts are defined as those with a diameter two to six times that of normal casts. They indicate tubular dilation and/or stasis in the distal collecting duct. All types of casts may occur in broad forms, and they are typically seen in individuals with chronic renal failure. They portend a poor prognosis.

Other Miscellaneous Casts or Cast-like Structures. Bacteria may become embedded in cast matrices; on supravital staining, they appear dark purple with a pale pink matrix. Mucous threads are commonly confused with casts. However, these are larger, long, and ribbon-like, with poorly defined edges and pointed or split ends, in contradistinction to casts, which tend to have well-defined edges and blunt ends.

Telescoped Sediment. This term is used to describe the simultaneous occurrence of elements of glomerulonephritis and those of nephrotic syndrome in the same urine specimen. A telescoped sediment might therefore include red cells, red cell casts, cellular casts, broad waxy casts, lipid droplets, oval fat bodies, and fatty casts. Such sediment may be found in collagen vascular disease (notably lupus nephritis) and subacute bacterial endocarditis.

Crystals

Crystals form by the precipitation of urinary salts when alterations in multiple factors affect their solubilities. These include changes in pH, temperature, and concentration. Precipitates can appear in the urine in the form of true crystals or amorphous material. Most crystal formation takes place in refrigerated specimens and those allowed to sit at room temperature for several hours. Increased solute concentration is typically responsible for crystal formation.

Although most crystals in the urine are of limited clinical significance, proper identification is essential, so as not to miss the relatively few abnormal crystals that are associated with various pathologic conditions. Knowledge of urine pH is a valuable aid in crystal identification because it is the pH that determines which chemical will precipitate. Many of the commonly seen crystals have characteristic morphologies; however, variability does exist, sometimes leading to confusion between pathologic and non-pathologic crystal structures. For the purpose of separating abnormal from more commonly occurring **nuisance crystals**, a summary of crystal morphology is presented (Table 28-12).

Crystals Found in Normal Acid Urine

Amorphous Urates (Calcium, Magnesium, Sodium, and Potassium Urates). Amorphous urates will precipitate upon standing in concentrated urine of a slightly acid pH. When large quantities are present, the urine sediment may appear pink-orange to reddish brown on macroscopic examination; this appearance has been referred to as **brick dust**. Microscopically, this amorphous material appears as yellow-brown small granules that can form clumps and adhere to fibers and mucous threads. Amorphous urates will convert to uric acid crystals with acidification with acetic acid, and will dissolve with heat (60°C) and with dilute alkali.

Crystalline Urates (Sodium, Potassium, and Ammonium). These biurates and acid urates form small brown spheres (Fig. 28-27) or colorless needles in slightly acid urine. The spheres may cluster in pairs and triplets. Similar to amorphous urates, these crystalline forms will slowly revert to uric acid plates on acidification with acetic acid.

Crystalline Uric Acid. Uric acid crystals occur at low pH (5–5.5) and are seen in a variety of shapes, including rhombic or four-sided flat plates,

Figure 28-28 Uric acid crystals ($\times 160$).

Figure 28-29 Large uric acid plate, laminated ($\times 160$).

Figure 28-30 Hexagonal uric acid crystals. Bright-field ($\times 50$).

Figure 28-31 Hexagonal uric acid crystals. Polarized ($\times 50$).

prisms, oval forms with pointed ends (lemon-shaped), wedges, rosettes, and irregular plates (Figs. 28-28 and 28-29). Most are colored, typically yellow or reddish brown. Rarely, they are colorless and hexagonal, resembling cystine (Fig. 28-30). Unlike cystine, they show birefringence with polarized light (Fig. 28-31).

Large numbers of uric acid crystals and urates may reflect increased nucleoprotein turnover, especially during chemotherapy of leukemia or lymphoma. Increased quantities may be seen with Lesch-Nyhan syndrome and may provide circumstantial evidence of the nature of small stones lodged in the ureters, especially when radiolucent and found in conjunction with raised serum uric acid levels. They may also herald the urate nephropathy of gout.

Calcium Oxalates. Dihydrates may appear at pH 6 or in neutral urine. Their classic form is that of a small, colorless octahedron that resembles an envelope (Fig. 28-32). Dumbbell shapes and ovoid forms may occur (Fig. 28-33). Longer forms occur in calcium oxalate monohydrate. Oxalate crystals are insoluble in acetic acid.

Oxalate crystals in large numbers may reflect severe chronic renal disease or ethylene glycol or methoxyflurane toxicity. Oxaluria has come into prominence as a reflection of the increased absorption of oxalates from food following small bowel disease and resection, notably for Crohn's disease. Oxaluria may also be present in genetically susceptible persons following large doses of ascorbic acid.

TABLE 28-12

Characteristics of Amorphous and Crystalline Urinary Sediments

Substance	Description	URINE pH WHERE FOUND			Solubility characteristics and comments
		Acid	Neutral	Alkaline	
Ampicillin	Uncommon—from high dose; colorless; long prisms that form clusters, sheaves	+	–	–	
Bilirubin	Reddish brown; amorphous needles, rhombic plates, or cubes; may color uric acid crystals	+	–	–	Soluble in alkali, acid, acetone, and chloroform
Cholesterol	Rare; colorless; flat plate with corner notch; accompanies fatty casts and oval fat bodies	+	+	–	Very soluble in chloroform, ether, and hot alcohol
Calcium carbonate	Colorless; small granules in pairs, fours; spheres; rarely needles	–	+	+	Soluble in acetic acid with effervescence
Calcium oxalate	Dihydrate—common; colorless; small refractile octahedron Monohydrate—uncommon; dumbbell and ovoid rectangle	+	+	–	Soluble in dilute HCl
Cystine	Colorless; hexagonal plates, often laminated; rapidly destroyed by bacteria; may be confused with uric acid, but cystine is soluble in dilute hydrochloric acid	+	–	–	Soluble in alkali (especially ammonia) and dilute HCl; insoluble in boiling water, acetic acid, alcohol, ether; apply cyanide–nitroprusside reaction
Hematin	Small, biconvex “whetstone” seen with hemoglobinuria	+	–	–	
Hemosiderin	Golden brown; granules in clumps, in cells, casts	+	+	–	Blue with Prussian blue
Hippuric acid	Rare; colorless, needles, rhombic plates and four-sided prisms; distinguish from phosphates	+	+	+	Soluble with hot water and alkali; insoluble in acetic acid
Indigotin	Rare; blue; amorphous or small crystals; colors other crystals	+	+	+	Very soluble in chloroform; soluble in ether; insoluble in acetone
Phosphates					
Amorphous phosphate (magnesium, calcium)	Colorless; fine, granular precipitate	–	+	+	Insoluble with heat; soluble with acetic acid, dilute HCl
Calcium hydrogen phosphate	Less common; colorless, star-shaped or long, thin prisms or needles; form rosettes	sl	+	sl	Slightly soluble in dilute acetic acid, soluble in dilute HCl
Triple phosphate (ammonium, magnesium)	Common form: colorless; three- to six-sided prisms, “coffin lids” Less often: Flat, fern leaf form, sheets, flakes	–	+	+	Soluble in dilute acetic acid
Radiographic media (meglumine diatrizoate)	Intravenous: Colorless; thin, rhombic plates, some with notch, resemble cholesterol plates; elongated crystals Retrograde: Colorless; long, pointed crystals	+	–	–	Soluble in 10% NaOH; Insoluble in ether and chloroform; high specific gravity in urine: polarizes with interference colors
Sulfonamides					
Acetylsulfadiazine	Wheat sheaves with eccentric binding	+	–	–	
Acetylsulfamethoxazole	Brown; dense spheres or irregular divided spheres	+	–	–	
Sulfadiazine	Brown; dense globules	+	–	–	Soluble in acetone
Tyrosine	Rare; colorless or yellow, appears black with focusing; fine silky needles in sheaves or rosettes	+	–	–	Soluble in alkali, dilute mineral acid, relatively heat soluble; insoluble in alcohol, ether
Urates					
Amorphous (calcium, magnesium, sodium, potassium)	Common; colorless to yellow-brown; amorphous, granular precipitate	+	+	–	Soluble in dilute alkali; soluble at 60° C or lower; change to uric acid crystal with concentrated HCl or acetic acid
Monosodium urate	Colorless; needles or amorphous precipitate	+	–	–	
Urates (sodium, potassium, ammonium)	Brown; small, spherical; clusters resemble biurates	sl	+	–	Soluble at 60° C; change to uric acid with glacial acetic acid
Ammonium biurate	Common in “old” urine; dark yellow or brown; spheres or “thorn apples” (spheres with horns)	–	+	+	Soluble at 60° C with acetic acid; soluble strong alkali; change to uric acid with concentrated hydrochloric or acetic acid
Uric acid	Common; yellow, red-brown, brown; large variety of shapes—rhombic, four-sided plates, rosettes, “whetstones” lemon shapes; rarely, colorless hexagonals	+	–	–	Soluble in alkali; Insoluble in alcohol and acids; polarizes with interference colors
Xanthine	Rare; colorless; small, rhombic plates	+	+	–	Soluble in alkali; soluble with heat; insoluble in acetic acid

sl, Slight.

Crystals Found in Normal Alkaline Urine

Amorphous Phosphates (Calcium and Magnesium). Similar to amorphous urates, amorphous phosphates have a granular appearance microscopically; unlike the former, they tend to be colorless and will produce a fine or lacy white precipitate macroscopically. Clumps or masses can often be seen by light microscopy (Fig. 28-34). Large amounts of this material may precipitate out upon prolonged standing at room temperature or in a refrigerator.

Calcium and magnesium monohydrogen phosphates are the least soluble in alkaline urine, although the dihydrogen phosphates may be soluble at a similar pH. Phosphates, in general, will dissolve in acids such as dilute hydrochloric and nitric acids and vary in solubility in acetic acid. They do not dissolve in dilute sodium hydroxide solutions or alcohol.

Crystalline Phosphates. Triple phosphate (ammonium magnesium phosphate) crystals are one of the most easily identified urine crystals, although they commonly show variation in size. They are colorless, three- to six-sided prisms with oblique ends referred to as **coffin lids** (Fig. 28-35). They may form colorless sheets or flakes (Fig. 28-36). Magnesium phosphate forms colorless rhomboids, some with notched ends or corners. These are seldom recognized. Dicalcium hydrogen phosphate crystals, on the other hand, may be seen in neutral or slightly acidic urine, and are long, three-sided prisms with pointed ends. They may form clusters or

Figure 28-36 Calcium phosphate (fine sheaves) ($\times 160$).

Figure 28-37 Ammonium biurate ($\times 160$).

Figure 28-38 Cystine (hexagonal, laminated) ($\times 200$).

rosettes. Overall, phosphate crystals have little if any clinical significance. They are often seen in infected urine of alkaline pH.

Calcium Carbonate. These uncommon crystals are small and colorless, with dumbbell or spherical shapes. They may form pairs, fours, or clumps. They are distinguished from other crystals/amorphous material by their production of carbon dioxide in the presence of acetic acid.

Ammonium Biurate. Similar to typical urate crystals, ammonium biurate crystals have a yellow-brown color and appear as spheres with radial or concentric striations and irregular projections or thorns (Fig. 28-37). Referred to as **thorn apples**, they may also be seen in neutral and occasionally in slightly acid urine. They dissolve with heat at 60°C and with acetic acid, reappearing as typical uric acid crystals after about 20 minutes.

Crystals Found in Abnormal Urine

Cystine. Cystine crystals are colorless, refractile, hexagonal plates (Fig. 28-38), which appear in acid urine. They are soluble in water at pH less than 2 or greater than 8, and they may be confused with hexagonal forms of uric acid (see Fig. 28-30). Whereas uric acid crystals polarize (see Fig. 28-31), thin cystine crystals do not, although thick laminated forms may polarize. Furthermore, both cystine and uric acid are soluble in ammonia water, but cystine will also dissolve in dilute hydrochloric acid, and uric acid will not.

Cystine crystals are among the most important crystals identified in urine sediment. They occur in patients with cystinuria and may be associated with cystine calculi. Confirmatory testing consists of the cyanide-nitroprusside reaction (see later under Cystinuria).

Tyrosine. In acidic urine, tyrosine forms fine silky needles that may be arranged in sheaves or clumps, especially after refrigeration. These may be colorless or yellow, appearing black as the microscope is focused (Fig. 28-39). They are soluble in alkali (ammonia and potassium hydroxide) and in dilute hydrochloric acid; they are not soluble in alcohol or ether.

These crystals, which are uncommon, are less soluble than leucine, and therefore are more often precipitated in urine (see later under Tyrosinuria). Tyrosine and leucine crystals are occasionally seen in the urine of patients with severe liver disease (see later under Urinary Screening for Inherited Metabolic Diseases).

Figure 28-39 Tyrosine crystals (×160).

Figure 28-40 Leucine crystals (×160).

Figure 28-41 Sulfadiazine (×160).

Figure 28-42 Ampicillin (×160).

Leucine. These crystals are also rare, occurring as yellow, oily-appearing spheres with radial and concentric striations (Fig. 28-40). They are soluble in both acids and alkalis. Leucine and tyrosine crystals may occur together; leucine may be precipitated with tyrosine crystals if alcohol is added to the urine.

Sulfonamide (Sulfadiazine) Crystals. These crystals may be seen in urine of acid pH and may take on various morphologies, depending on the form of drug involved. They may be seen as yellow-brown sheaves of wheat with central bindings, striated sheaves with eccentric bindings (Fig. 28-41), rosettes, arrowheads, petals, needles, and round forms with radial striations. They are occasionally colorless. Confirmatory testing is by the diazo reaction. High-performance liquid chromatographic and colorimetric methods have also been described (Simo-Alfonso, 1995; Mount, 1996).

With the advent of soluble sulfonamides, sulfa crystals are not as frequently found in urine, especially when urine is examined at 37° C. Before this development, these crystals could be seen in the urine of patients on sulfonamide therapy who were inadequately hydrated. This could result in renal tubular damage if crystal formation occurred within the nephron. Currently, sulfamethoxazole (Bactrim, Septra) is seen with some regularity.

Ampicillin (High Dosage). Ampicillin may crystallize in the urine under conditions of high dosage. These crystals appear in urine of acid pH as long, fine, colorless structures (Fig. 28-42). They may form coarse sheaves after refrigeration.

Figure 28-43 Renografin (meglumine diatrizoate). Bright-field (×160).

Figure 28-44 Renografin (meglumine diatrizoate). Polarized (×160).

Radiographic Media (Meglumine Diatrizoate). Urinary crystals form after radiographic examinations using diatrizoate dyes. They may be found in urine of acid pH shortly after intravenous radiographic studies (particularly if the patient has not been well hydrated), appearing as flat, clear, colorless, notched rhombic plates, or longer, slender rectangles. They are easily polarized, showing interference colors (Figs. 28-43 and 28-44). They may also be seen after retrograde cystograms as long, colorless needles, forming clusters after refrigeration. The presence of radiographic crystals should correlate with a high specific gravity (>1.040).

Other Drugs. One must always remember to check the patient's drug therapy when unusual crystals are found in the urine. Several drugs have been reported to cause crystalluria when administered in high-dosage schedules or following overdose. Examples include high-dosage 6-mercaptopurine therapy, primidone overdose, and dihydroxyadenine from massive blood transfusion.

Abnormal Cells and Other Formed Elements

Tumor Cells. Malignant tumor cells exfoliated from the renal pelvis, ureter, bladder wall, and urethra are best identified using cytologic techniques. Myeloma cells have also been noted in urine, both with and without apparent renal involvement. For a comprehensive discussion of disease types and cytologic morphologies, the reader is directed to standard urinary cytology references (Bibbo, 1997).

Viral Inclusion Cells. Epithelial cells containing inclusion bodies may be found in the urine sediment in various viral infections involving the urinary tract. Syncytial giant cells containing eosinophilic, intranuclear inclusions are seen in patients during herpetic infections. In children or immunosuppressed patients with cytomegalovirus infection, affected cells are enlarged and contain basophilic intranuclear inclusions and/or cytoplasmic bodies. Polyomavirus (e.g., BK virus)-infected cells contain dense, basophilic, homogeneous intranuclear inclusions that often completely fill the nucleus. Cytologic techniques are far more sensitive in detecting all of the aforementioned viral cytopathic effects.

Platelets. These have been demonstrated in urine. Up to 30,000/μL have been demonstrated by phase-contrast microscopy and confirmed by electron microscopy in the urine of patients with hemolytic-uremic syndrome.

Bacteria. Finding bacteria in urine may or may not be significant, depending on the method of urine collection and how soon after collection of the specimen the examination takes place. If bacteria are identified with Gram stain in an uncentrifuged urine specimen under an oil-immersion lens, this suggests that more than 100,000 organisms/mL are present (i.e., significant bacteriuria). Most commonly, rod-shaped bacteria are seen because the enteric organisms are the causative agents in the majority of urinary tract infections (Fig. 28-45). Leukocytes will usually be seen in the sediment as well.

Acid-fast bacilli may be seen in urine sediment, but because the urethral flora may contain nonpathogenic acid-fast organisms, the presence of tuberculosis in urine must be substantiated by culture and/or polymerase chain reaction methods.

Figure 28-45 Bacteria and leukocytes ($\times 600$).

Figure 28-46 *Candida*. Budding yeasts ($\times 200$).

Figure 28-47 *Candida*. Pseudohyphae ($\times 160$).

Figure 28-48 Muscle fiber ($\times 200$).

Fungi. Yeasts (most commonly *Candida* species) may be causative agents in urinary tract infection (e.g., in diabetes mellitus), but yeasts are also common contaminants from the skin, the female genital tract, and the air. On microscopic examination, they may be confused with erythrocytes; the presence of budding helps to identify them as yeast cells (Fig. 28-46). Pseudohyphae of *Candida* are occasionally found (Fig. 28-47).

Parasites. Parasites and parasitic ova may be seen in urine sediments as a result of fecal or vaginal contamination. When noted, repeat examination should be performed on a fresh, clean-voided urine specimen. Although *Trichomonas vaginalis* may be present in urine as a result of vaginal contamination, urethral or bladder infection can occur; when suspected, the protozoa should be searched for immediately in a wet preparation of the sediment. Motility of the organism is helpful in making the appropriate identification. In patients with schistosomiasis due to *Schistosoma haematobium*, typical ova are shed directly into the urine accompanied by erythrocytes from the urinary bladder. Amebae are rarely seen in the urine; they may reach the bladder from lymphatics or more likely from fecal contamination of the urethra. The pathogenic *Entamoeba histolytica* is usually accompanied by erythrocytes and leukocytes.

Contaminants and Artifacts. Partially digested muscle fibers or vegetable cells may be found when fecal contamination occurs (Fig. 28-48). Spermatozoa are occasionally present, and pollen grains contaminate

Figure 28-49 Pollen grain ($\times 160$).

Figure 28-50 Starch granule ($\times 160$).

specimens seasonally (Fig. 28-49). Fibers from many different sources may be seen, including cotton, hair, wood fibers from applicator sticks, and synthetic fibers from disposable diapers. Unlike casts, these fibers polarize brightly.

Starch granules from surgical gloves are the most common contaminants of urine and other body fluids. Microscopically, they appear bright and faintly striated with an irregular outline and a central depression (Fig. 28-50). With crossed polarizing filters, starch granules exhibit a typical Maltese cross pattern, and because of their large size (several times larger than an erythrocyte), they are not likely to be confused with cholesterol droplets. Oil droplets from catheter lubricants may be confused with cells, especially red cells. Lipid material from vaginal creams also forms droplets in urine and may form large amorphous aggregates.

METHODS FOR URINALYSIS

BASIC (ROUTINE) URINALYSIS PROCEDURE

1. Pour 10–15 mL of a well-mixed urine specimen into a graduated disposable centrifuge tube. Perform physical examination and reagent strip chemical evaluations. Centrifuge at 450 g for 5 minutes.
2. Carefully remove and save the supernatant. The final volume used to resuspend the sediment may vary with the standardized system used but should remain constant within any given laboratory. Use a disposable pipet, specialized tube, or pipet system to concentrate the sediment.
3. Gently resuspend the sediment in the remaining supernatant, and add one drop of supravital stain if desired. Using an appropriate pipet, load/charge the examination chamber of a standardized slide. Allow the urine to settle for 30–60 seconds.
4. Examine with low- and high-power objectives. Subdued light or phase-contrast illumination will be required to detect sediment entities with a low refractive index. The fine focus should be varied continuously while scanning. Systematically progress around the entire examination chamber, being careful to examine along the edges for casts.
5. Count the number of casts in at least 10 lpf, average, and report the number of casts per lpf. A reasonable range may be used in reporting (e.g., 0–2, 2–5, 5–10). Use high power to identify casts by type. Casts will not be missed if phase-contrast microscopy is used (see Fig. 28-4, A and B).
6. Identify and count erythrocytes, leukocytes, and renal epithelial cells using the high-power objective. Count at least 10 hpf, average, and report as cells/hpf. A reasonable range may be used for reporting.

7. Comment on the following:
 - a. Squamous and transitional cells if present in large numbers or as fragments (transitional cells).
 - b. Bacteria, yeast, and microorganisms. Bacteriuria detectable on low power should be reported as at least 2+.
 - c. Crystals (quantitated under low power). The presence of abnormal crystals should be confirmed chemically and correlated with the patient history.
 - d. Large amounts of mucus.
8. The authors recommend confirming the following results with cytopathologic examination or specific chemical tests (crystals):
 - a. More than two renal epithelial cells/hpf.
 - b. Pathologic casts.
 - c. Atypical mononuclear cells, particularly urothelial cells.
 - d. Tissue fragments.
 - e. Pathologic crystals.

Review the entire report, including physical, chemical, and microscopic data, and correlate with available clinical information. Discrepancies should be resolved before the report is released. Normal values for the procedure include the following: 0–10 RBCs/hpf, 0–10 WBCs/hpf, and 0–2 hyaline casts/lpf. Values will vary, depending on the standardized system used.

Routine urinalysis is a helpful diagnostic tool in the workup and follow-up of various urinary system disorders. Table 28-13 summarizes the macroscopic, reagent strip, and microscopic findings typical for the most commonly encountered entities.

AUTOMATED URINALYSIS

Several instruments have been developed to partially or completely automate routine urinalysis. In addition to enhancing workflow, automation can standardize some aspects of manual urinalysis. Most of these instruments can be interfaced with laboratory information systems, facilitating reporting and result retrieval.

Several instruments are available to automate the macroscopic/chemical analysis or the microscopic portions of the routine urinalysis. For example, fully automated urine chemistry reagent strip analyzers from several manufacturers are equipped to perform automatic pipetting or test strip dipping, as well as carry out photometric measurements of the reagent strip fields.

The IRIS Urinalysis workstations (now iQ200 series Automated Urinalysis System, Iris Diagnostics, Chatsworth, Calif.) (van den Broek, 2008) combine several automated subsystems to perform a complete urinalysis through a combination of dipstick chemistries and flow imaging technology. Specific gravity is measured by a mass gravity meter, urine chemistries are measured by a standard reflectance spectrophotometer, and microscopic analysis is facilitated with an automated intelligent microscopy system. No centrifugation is involved, and handling of the specimen is minimal. A touch-sensitive video screen eliminates keyboard entry. In the analysis, the urine specimen is poured into the instrument's entry port over a urine chemistry reagent strip. This reagent strip is then placed in the reflectance photometer reader platform. The urine chemistries are automatically timed, read, and collated by the internal computer. A portion of the specimen is diverted to the harmonic oscillator mass gravity meter for specific gravity determination; the rest of the specimen is then stained and passed into a laminar flow chamber, where the formed elements are detected and imaged by a video camera mounted to a microscope and a stroboscopic lamp that allows stop-motion images. Images of cells, casts, crystals, yeast, and bacteria found in the sediment are then sorted by size and presented to the operator on the touch-sensitive screen for identification. Because the volume of the laminar flow chamber is known, the images can be counted and related to a volume of urine with a precision that exceeds that which can be obtained with a centrifuged specimen, glass slide, and coverslip. The system can remove the need for microscopic analysis in most cases (Hughes, 2003). The computer then consolidates the report for printing or transmission to the laboratory information system.

The IRIS system bases its analysis on cell image analysis. Another way to analyze urinary cells and casts is by flow cytometry. These analyzers typically stain the DNA and membranes of the formed elements in native urine, pass the sample as a laminar flow through a laser beam, and measure the light scatter, fluorescence, and impedance. The UF-100 (Sysmex Corporation, Kobe, Japan) analyzes urine by flow cytometry and gives quantitative results for red and white blood cells, epithelial cells, casts, and bacteria (Fig. 28-51). It can detect yeast, crystals, dysmorphic red blood cells, and pathologic casts (Fig. 28-52) in the urine (Ben-Ezra, 1998;

Ottinger, 2003). This technology may be useful in decreasing the number of urine specimens requiring routine microscopy (Fenili, 1998). Normal values are fewer than 20 RBCs/ μ L, fewer than 25 WBCs/ μ L, and fewer than 2000 bacteria/ μ L. Similar to the microscopic examination of urine on unspun specimens, the automated systems are not prone to the artifacts that characterize examination of spun urine sediment. A second generation of this machine, the UF-1000, provides better enumeration of bacteria with fewer artifacts due to interfering debris.

Although these automated sediment analysis machines are very useful in standardizing workflow and eliminating the need to perform a manual examination of the urine sediment in the routine clinical laboratory, they may not be that useful in a population with a high incidence of renal pathology (e.g., patients in a nephrology clinic) (Gai, 2003).

Automated urine sediment analyzers have the potential to add more quantitative information to the monitoring of abnormalities such as urinary tract infections by providing very exact counts of bacteria and cells in serial specimens while patients are under treatment. The clinical utility of this accurate information is yet to be determined. Its application would require a more comprehensive understanding of such counts by practicing physicians as opposed to the semiquantitative estimates now commonly in use.

SPECIAL TESTING AND MONITORING TECHNIQUES

URINARY CALCULI

Nephrolithiasis is a common condition, affecting nearly 5 in 1000 persons. It is a heterogeneous disorder, with stones developing from a wide variety of metabolic or environmental disturbances. Although most studies have concentrated on nonorganic components, many stones have been found to be associated with an organic matrix containing lipids and protein, suggesting the involvement of cellular membranes in the nucleation of crystals (Khan, 1996). One study showed that antisera raised against these stone matrix proteins had cross-reactivity between proteins isolated from different stones, irrespective of their mineral composition (Siddiqui, 1998). Many stone patients have been found to show elevation of interleukin-6, which may in the future be useful as a potential marker for stone disease (Rhee, 1998).

Upper (renal) stones are common in Western industrialized countries, whereas bladder stones are uncommon. The passage of stones down the ureter produces renal colic, which is characterized by severe pain in the flank radiating to the groin. Hematuria frequently accompanies stone passage. If stones obstruct the pelvis of the kidney or ureter, hydronephrosis can result, and infection is a common consequence. Recurrences are frequent, but with appropriate identification of the stones and the risk factors associated with them, stone formation may be greatly reduced.

Calcium oxalate or a mixture of oxalate and calcium phosphate is often found in stones ($\approx 80\%$). Mixed calcium phosphate, magnesium ammonium phosphate, and uric acid are the next most common constituents (3%–10% each), and these are followed by cystine stones (1%–2%). Carbonate, which is frequently detected in chemical analysis, probably results from adsorption of carbon dioxide to the calcium phosphate crystal. Males are more often affected with calcium stones than females, and children are not often affected with calcium stones.

Calcium oxalate precipitates at an acid or neutral pH, and calcium phosphate—hydroxyapatite $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ —forms calculi at the normal urinary pH of 6.0–6.5. Uric acid, which is not very soluble, will crystallize at a low pH (5.3) and form stones. Magnesium ammonium phosphate (struvite) forms stones at alkaline pH, where the ammonium level is high. These tend to form in the pelvis of the kidney but apparently are not attached to papillae, as are the calcium stones. They may, however, develop on preexisting nuclei when infection from organisms such as *Proteus* causes alkalization of the urine. Struvite stones may become large, forming casts of the kidney pelvis and showing staghorns. Mixed stones may form when calcium or uric acid crystals (or stones) cause obstruction followed by infection and the subsequent deposition of ammonium salts.

Hypercalciuria and Calcium Stones

Calcium homeostasis is maintained by parathyroid hormone (PTH) and 1,25-dihydroxycholecalciferol ($1,25(\text{OH})_2\text{D}$). Both affect bone resorption by osteoclasts. PTH causes a diminution of phosphorus reabsorption and an increase in calcium reabsorption by renal tubular cells. It also causes increased synthesis of $1,25(\text{OH})_2\text{D}$, which acts upon the small intestinal

TABLE 28-13

Various Urinary System Diseases and Corresponding Urinalysis Abnormalities

Diseases	Macroscopic urinalysis	Microscopic urinalysis
Acute glomerulonephritis	Gross hematuria "Smoky" turbidity Proteinuria	Erythrocyte and blood casts Epithelial casts Hyaline and granular casts Waxy casts Neutrophils Erythrocytes
Chronic glomerulonephritis	Hematuria Proteinuria	Granular and waxy casts Occasional blood casts Erythrocytes Leukocytes Epithelial casts Lipid droplets
Acute pyelonephritis	Turbid Occasional odor Occasional proteinuria	Numerous neutrophils (many in clumps) Few lymphocytes and histiocytes Leukocyte casts Epithelial casts Renal epithelial cells Erythrocytes Granular and waxy casts Bacteria
Chronic pyelonephritis	Occasional proteinuria	Leukocytes Broad waxy casts Granular and epithelial casts Occasional leukocyte casts Bacteria Erythrocytes
Nephrotic syndrome	Proteinuria Fat droplets	Fatty and waxy casts Cellular and granular casts Oval fat bodies and/or vacuolated renal epithelial cells occurring singly or as cellular clusters
Acute tubular necrosis	Hematuria Occasional proteinuria	Necrotic or degenerated renal epithelial cells Neutrophils and erythrocytes Granular and epithelial casts Waxy casts Broad casts Epithelial tissue fragments
Cystitis	Hematuria	Numerous leukocytes Erythrocytes Transitional epithelial cells occurring singly or as fragments Histiocytes and giant cells Bacteria Absence of casts
Dysuria-pyuria syndrome	Slightly turbid	Numerous leukocytes, bacteria Erythrocytes No casts
Acute renal allograft rejection (lower nephrosis)	Hematuria Occasional proteinuria	Renal epithelial cells Lymphocytes and plasma cells Neutrophils Renal epithelial casts Renal epithelial fragments Granular, bloody, and waxy casts
Urinary tract neoplasia	Hematuria	Atypical mononuclear cells with enlarged, irregular hyperchromatic nuclei and sometimes containing prominent nucleoli that occur singly or as tissue fragments
Diseases	Macroscopic urinalysis	Microscopic urinalysis Neutrophils Erythrocytes Transitional epithelial cells
Viral infection	Hematuria Occasional proteinuria	Enlarged mononuclear cells and/or multinucleated cells with prominent intranuclear and/or cytoplasmic inclusions Neutrophils Lymphocytes and plasma cells Erythrocytes

mucosa, causing increased absorption of calcium and phosphorus. Low serum ionized calcium levels cause increased PTH secretion, and low serum phosphorus stimulates 1,25(OH)₂D synthesis.

About 40% of patients with calcium stones will have hypercalciuria, defined as a daily urinary excretion of calcium in excess of 0.1 mmol/kg (Houillier, 1998). Increased calcium in urine may result from an increase in intestinal calcium absorption, lack of appropriate renal tubular

reabsorption of calcium, resorption or loss of calcium from bone, or a combination of these factors. In a few instances of hypercalciuria, an underlying disease process can be identified. In most cases, however, it is primary, or idiopathic hypercalciuria (IH). Although the exact mechanism of hypercalciuria is still unknown in this disorder, it most likely includes a combination of factors, including those listed previously. Three hypotheses to account for IH pathophysiology have been proposed. These include

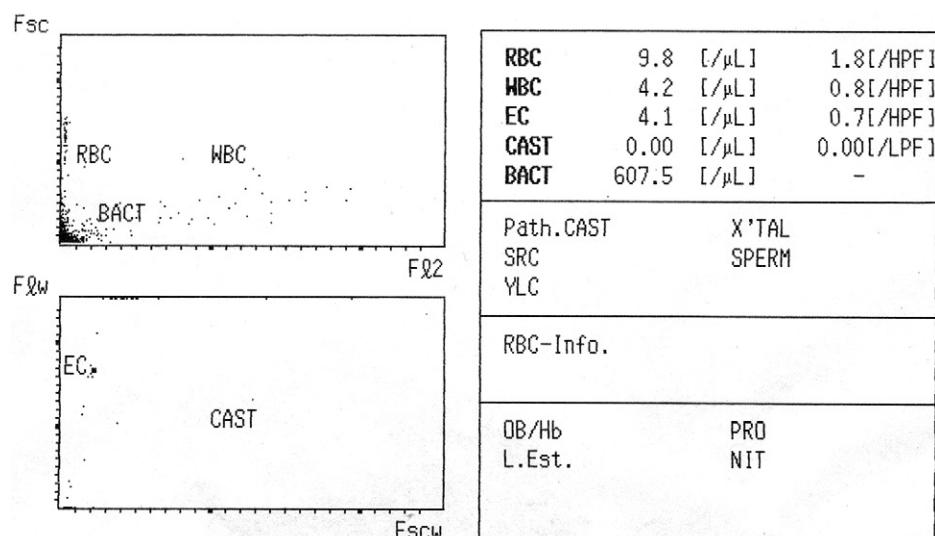

Figure 28-51 Printout from UF-100 automated urine analyzer, showing normal urine. Note the lack of RBCs, WBCs, bacteria, and casts. RBCs, Red blood cells; WBCs, white blood cells.

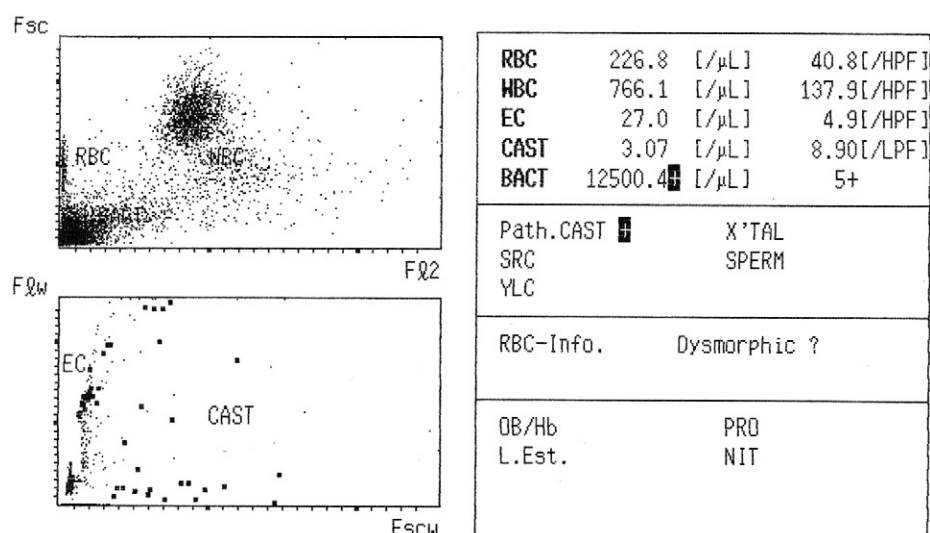

Figure 28-52 Printout from UF-100 automated urine analyzer, showing abnormal urine. Compare with Figure 28-51. Note the sizable numbers of RBCs, WBCs, bacteria, and casts. ECs, Squamous epithelial cells; NIT, nitrite; PRO, protein; RBCs, red blood cells; SRC, small round cells; WBCs, white blood cells; X'TAL, crystals; YLC, yeast-like cells.

possible defects in the fatty acid content of cell membranes, increased expression of the vitamin D or calcium receptors of the 25-hydroxyvitamin D₁ α -hydroxylase, or a disease of monocytes (Bataille, 1998).

Excess loss of calcium in urine and the possibility of stone formation may occur secondary to a variety of other conditions. For instance, hypercalciuria may result from increased absorption of calcium from the gut. This may occur following excessive loss of phosphorus from the kidney and low serum phosphorus levels, or when increased serum 1,25(OH)₂D is seen with normal serum phosphorus levels. Increased resorption of bone may occur with immobilization of the skeleton, rapidly progressive bone disease, thyrotoxicosis, and Cushing's disease, leading to hypercalciuria. Calcium may be lost from bone as a result of osteolytic tumors, as well as in the presence of renal disease such as distal renal tubular acidosis and medullary sponge kidney. Sarcoidosis, vitamin D excess, and furosemide may also cause renal hypercalciuria.

About 5%–10% of calcium stones are associated with primary hyperparathyroidism. In this disorder, increased mineral turnover in bone and hypercalcemia are important causes of hypercalciuria. Affected patients often present with stone symptoms, and calcium phosphate deposits may be found in the renal tissue, cornea, and other organs.

Dietary hypercalciuria is an uncommon cause of calcium stones; it is associated with a large calcium intake, on the order of 3–4 g/day, together

with a high protein intake. About 800 mg/day is the normal recommended adult intake.

As stated previously, calcium oxalate stones are the most common. They may form with excess oxalate and uric acid in the urine, the latter sometimes providing a nidus for stone formation. Newly formed calcium oxalate aggregates are about 20–25 μ m in diameter, much smaller than the outlet of the collecting ducts. Adherence to the epithelial surface apparently allows stones to continue growth rather than be excreted. Calcium phosphate stone formation is favored by a less acid urine, as is seen in renal tubular acidosis, with infection, and in persons consuming large amounts of alkali. These stones are also seen in primary hyperparathyroidism, although the urine is in the normal pH range. In a patient exposed to heat and dehydration, these may contribute to a rise in urinary solute levels, followed by crystallization and stone formation.

Hyperoxaluria

A majority of calcium stones (70%–80%) contain oxalate. Some of the oxalate in urine is dietary in origin from beverages (tea, cocoa, coffee, cola), vegetables (beans, rhubarb, spinach), nuts, berries, and citrus fruits. Oxalate is also derived from ascorbic acid.

The gastrointestinal system plays an important role in oxalate homeostasis. Oxalate absorption increases when calcium and magnesium intake

decreases. Disorders of the small bowel such as Crohn's disease, ileal resection, and intestinal bypass surgery may result in excessive oxalate absorption, with subsequent excretion in the urine. Malabsorption with steatorrhea causes loss of calcium as soaps, and malabsorption with increased bile salts remaining in the gut is thought to promote oxalate absorption in the colon. Additionally, absence of *Oxalobacter formigenes* from the intestinal tract of patients with cystic fibrosis appears to lead to increased absorption of oxalate, thereby increasing the risk of hyperoxaluria (Sidhu, 1998).

Other causes of hyperoxaluria include pyridoxine deficiency and primary hyperoxaluria. The latter is a rare inherited autosomal recessive disease with oxoglutarate carboxylase deficiency. Systemic oxalosis and renal failure may be seen in young adulthood. Renal transplantation and large doses of pyridoxine or nicotinamide have been tried for the treatment of these patients.

Hyperuricuria

Excessive excretion of uric acid may be due to excessive dietary intake of purines (liver, dried beans, some fish, meat) or various disease processes. Endogenous uric acid production is increased in gout, glycogen storage diseases, Lesch-Nyhan syndrome, many leukemias, and treated tumors with associated cell necrosis. Chemotherapy and irradiation can lead to increased breakdown of tumor cells (nucleotide/purine forms uric acid), which may cause acute renal failure secondary to tubular and ureteral obstruction by masses of uric acid crystals.

In gout, about 20% of patients form stones, most of which are pure uric acid or mixed uric acid and calcium. Heat, dehydration, and unusually acid urine contribute to stone formation. Gouty nephropathy occurs with sodium urate deposits in the medulla, even when stones are not present, and masses of crystals may cause obstruction of terminal collecting ducts in the kidney. Uricosuric drugs cause potential problems with massive uric acid output in the first 3–4 days of treatment.

Normally, about one third of the uric acid formed is degraded by bacteria in the colon. Absence of bacteria or intestinal diversion may cause increased absorption of uric acid from the gut. Because ileostomy patients lose large amounts of alkaline fluid from the intestine, they excrete concentrated acidic urine and are likely to produce uric acid stones.

The average uric acid excretion by adults is 500–600 mg/24 hours. Solute concentration as well as pH appears to be important in the solubility of uric acid and urate. Uric acid, a weak acid, forms free, insoluble, undissociated uric acid and a urate (which is more soluble with some sodium and potassium present) at pH 5.5. The amount of free uric acid present in urine will decrease as the pH rises, and at pH 7, uric acid is more soluble as urate. With high salt concentrations, the urate becomes less soluble. If urine volume is low, the solubility of uric acid at acid pH will be exceeded.

Whereas large quantities of uric acid crystals are regularly seen in urinary sediment, uric acid stone formation is not common. Uric acid crystals form a sludge that may obstruct the nephron without forming a stone. On the other hand, uric acid and sodium acid urate crystals are found as nuclei for calcium stones. Most normal persons with a pH of 6 have urine saturated with uric acid but do not form stones. Further acidity or dehydration is apparently required to engender stone formation.

Cystine Stones

Cystine stones form in patients with an inherited amino acid transport disorder (see later under Cystinuria). Cystine, ornithine, lysine, and arginine are subsequently excreted in large amounts in the urine. Of these, only cystine forms crystals and stones. Cystine does not become soluble until the urine pH is 7.4, and stones form over a range of normal urinary pH values. Heterozygous carriers for the disease will have increased amounts of cystine in urine but do not form stones; homozygotes are stone formers. A 24-hour quantitative urine cystine measurement is needed to detect potential stone formers; this should always be done when cystine crystals are found in random specimens.

Rare Calculi

Calculi containing sulfonamides have been described, and silica calculi have been reported in patients ingesting silica gel over a long period of time. Triamterene (Dyazide, Dyrenium), a relatively insoluble diuretic, may contribute to stone formation. It can form 1- to 2-mm mustard-colored stones, giving a bright blue fluorescence when dissolved in butanol and with exposure to ultraviolet light. Rare adenine stones have been described in children with an inherited enzyme deficiency disorder and hyperuricemia. Xanthine stones are uncommon and may be associated with a genetic disorder with an absence of xanthine oxidase.

LABORATORY TESTS USED TO INVESTIGATE STONE FORMERS

Urine Examinations

1. Routine urinalysis, qualitative test for cystine, and urine culture. Hematuria is a constant finding when stones are present, even when they are asymptomatic. Proteinuria is usually not a feature of calculous disease, but with renal tubular damage, excretion of low molecular weight plasma proteins such as β_2 -microglobulin, and some albumin, may be increased. Erythrocyte casts usually are not found, and other casts are unusual. Leukocytes are increased when infection is present, and the reagent strip nitrite and leukocyte esterase may be elevated. Multiple clusters of nonmalignant transitional cells may be found in urine of patients with calculous disease and may be helpful in the diagnosis of unsuspected calculi.
2. Twenty-four-hour urine specimen: Sodium, calcium, phosphorus, uric acid, oxalate, and creatinine clearance. Supersaturation values from 24-hour urine collections have been shown to accurately reflect stone composition (Asplin, 1998). Some authors suggest that spot urine samples are sufficient for the metabolic evaluation of stone formers, although because of day-to-day variation, three samples should be obtained to overcome the doubtful significance of a single result (Strohmaier, 1997).
3. Urine pH determination on a fresh specimen is important in determining the types of crystals likely to be precipitated, for example, uric acid with low pH (5–5.5), and triple phosphate with alkaline urine.

Serum Chemistry

Appropriate tests include calcium, phosphorus, uric acid, and electrolytes.

Stone Analysis

Calculi may be of various sizes, commonly described as sand, gravel, or stone. The physical characteristics of the various calculi rarely will suffice for their identification, but a few points are worth noting. Uric acid and urate stones are typically yellow to brownish red and are moderately hard. Phosphate stones are usually pale and friable. Calcium oxalate stones are very hard, often of a dark color, and typically have a rough surface. Cystine stones are yellow-brown and feel somewhat greasy.

Several methods are available for the analysis of calculi, such as optical crystallography, radiograph diffraction, and infrared spectroscopy. Electron beam analysis and mass spectroscopy are also used. A simplified method for analysis of renal calculi is presented by Farrington (1980). A quantitative method for five of eight frequently measured substances using available clinical chemistry methods has been described: calcium, phosphorus, magnesium, ammonium, and uric acid. Cystine, oxalate, and carbonate are detected by qualitative means and are interpreted with the quantitative results to characterize the stones. Most laboratories send calculi specimens out to more specialized laboratories for chemical analysis, where both chemical and specialized tests should be used to determine the composition of the stones.

Method for Gross Examination of Calculi

1. Wash the stone(s) free of blood, mucus, preservation solution, and so forth. Place stones in a beaker, cover with several thicknesses of gauze held firmly in place with rubber bands, and wash under cold running water. Drain, remove gauze carefully, and dry beaker and stones in an oven. Rinse tiny stones with water from a squeeze bottle (not running water).
2. Record the dimension of the stone.
3. Describe briefly the color and texture of the stone's exterior surface. The stone may be photographed for record purposes.
4. Cut, saw, or break the stone so as to examine the interior. Note whether a foreign body may have acted as a nucleus for its formation. Describe the color and texture of the interior and layers, if present.
5. Reduce small stones to a fine powder by pulverizing with a mortar and pestle.
6. If possible, when a stone is very large, it may be advisable to make separate analyses of layers that appear to have different constituents.

Because most small calculi consist of calcium oxalate, the best way to analyze them is to put all available powder in one test tube. (If the stone

is very tiny, it may be placed directly in the test tube and crushed with a spatula.) Reagents used for the chemical determination of rare stones may be found in an earlier edition of this book (Henry, 1996). It is important to have known positive material to test the reagents.

Radiologic Examination

Asymptomatic stones are sometimes found. Most stones are radiopaque, except for pure uric acid and the rare xanthine; cystine stones are opaque because of their sulfur content.

URINARY SCREENING FOR INHERITED METABOLIC DISEASES

Urine has been used for many years to screen for metabolic diseases, particularly those resulting from a genetic predisposition. In many of these diseases, an abnormal metabolite or a larger than normal amount of a normal metabolite is excreted in the urine. Because these conditions are uncommon and their symptoms often nonspecific, and because some may be treatable if early diagnosis is confirmed, blood and urine should be analyzed using techniques that are highly selective and sensitive. Numerous inborn errors of metabolism have been identified, and this section will describe some of the more common disease entities.

Aminoacidurias

Excretion of one or more amino acids in the urine may be due to a block in a major metabolic pathway (overflow type) or a deficiency in renal tubular function (renal type). Phenylketonuria is an example of overflow aminoaciduria in which an enzyme substrate and other metabolites in the pathway accumulate, causing increased body fluid levels and increased substrate excretion in urine. Unlike the overflow-type diseases, renal-type aminoacidurias do not have high levels of the amino acid in the blood because the primary defect is in the renal tubular reabsorption mechanism. An example of renal transport aminoaciduria is cystinuria.

Phenylketonuria. Phenylketonuria is an autosomal recessive inherited disorder in which there is absence of the enzyme phenylalanine hydroxylase. Both sexes are affected equally, with an incidence of about 1 in 11,000. Allelic heterogeneity can be extensive, particularly in the United States (Guldberg, 1996). Mental retardation is the major clinical finding, and dietary restriction of phenylalanine has proven efficacious in these patients.

Because they are not converted to tyrosine in this disorder, phenylalanine and other normal metabolites accumulate in abnormal amounts. Plasma phenylalanine and phenylpyruvic acid levels are elevated; urinary phenylpyruvic acid (highest), phenylacetic acid, and phenylalanine are increased. Urinary indoleacetic acid and other indoles arising from altered tryptophan metabolism and indican (an indole) are also increased. The excretion of 5-hydroxyindoleacetic acid is diminished, paralleling the low level of serum 5-hydroxytryptamine. The urine and sweat of these patients have a characteristic mousy/musty odor due to phenylacetic acid.

Methods. Phenistix reagent strips contain ferric ammonium sulfate, magnesium sulfate, and cyclohexylsulfamic acid. At 30 seconds following immersion into urine, the color of the test area is compared with the color chart provided. A positive test result shows a gray to gray-green color. The test detects 5–10 mg/dL. Salicylates and metabolites of phenothiazine derivatives may cause a pink to purple color. Ion-exchange high-performance liquid chromatography has been found suitable for quantitative confirmatory testing of abnormal specimens (Reilly, 1998).

Alkaptonuria. Normally, phenylalanine and tyrosine are metabolized to homogentisic acid (dihydroxyphenylacetic acid), which is then oxidized to maleylacetoacetic acid. In alkaptonuria, the enzyme homogentisic acid oxidase is deficient, and homogentisic acid is excreted in urine in large quantities. The urine characteristically turns brown-black on standing or with alkaline pH. Patients with alkaptonuria develop dark blue to black pigmentation in cartilage and connective tissue; frequently, the disease is not diagnosed until arthritis has already developed.

Methods. Screening methods include ferric chloride and silver nitrate tests. A transient, dark blue color appears as two drops of 10% ferric chloride solution are added to about 2 mL urine containing homogentisic acid. The silver nitrate test involves adding 4 mL of 3% silver nitrate to 0.5 mL urine, mixing, and then adding several drops of 10% NH_4OH . Homogentisic acid will cause a black color to develop. Confirmatory methods include paper or thin-layer chromatography, as well as capillary

electrophoresis. These methods should distinguish homogentisic acid from gentisic acid, an aspirin metabolite.

Tyrosinuria. Tyrosinemia with tyrosinuria occurs when the metabolism of tyrosine derived from the diet or from phenylalanine is abnormal. This may be part of a generalized amino acid disorder associated with liver disease, or it may represent one of the various genetic disorders involving tyrosine metabolism. Tyrosine crystals may appear in the urine as fine, silky crystals scattered singly or aggregated to form sheaves. They appear brown to black, precipitate at an acid pH, and are soluble in alkali. Small quantities of tyrosine may appear in the urine of normal individuals.

Transitory hypertyrosinemia may occur in low-birthweight and premature infants as a benign condition. Typically, these infants are asymptomatic, and no liver or renal disease is present. The elevated tyrosine levels may on occasion be accompanied by transiently elevated phenylalanine levels. Tyrosine and the phenolic acids *p*-hydroxyphenyllactic and *p*-hydroxyphenylpyruvic acids are excreted in larger than normal amounts in the urine. The nature of the enzymatic defect has not been well characterized, and the tyrosine level of these patients usually returns to normal within a few weeks to months.

Type I hereditary tyrosinemia (tyrosinosis) is an autosomal recessive disorder characterized by defects in fumarylacetoacetate hydrolase and maleylacetoacetate hydrolase. Succinylacetoacetone and succinylacetone accumulate and inhibit renal function, various hepatic enzymes, and porphobilinogen synthetase. Patients may experience liver failure, renal dysfunction, rickets, and acute intermittent porphyria-like symptoms. Hepatoma is a late complication. Generalized aminoaciduria, phosphaturia, glycosuria, and uricosuria may occur. A low-tyrosine/phenylalanine diet is the mainstay of therapy.

Type II tyrosinemia (Richner-Hanhart syndrome) is an autosomal recessive inherited deficiency of tyrosine aminotransferase. Patients will have tyrosinemia, tyrosinuria, and increased urinary phenolic acids. The metabolism of other amino acids, renal function, and hepatic function are otherwise normal. Erosions of the cornea, soles, and palms are common, and mental retardation sometimes occurs. Therapy centers on a low-tyrosine/phenylalanine diet.

Methods. The nitrosonaphthol test for tyrosine is a nonspecific screening method and should be confirmed by chromatography or quantitative serum assay of tyrosine. Tyrosine and tyramine form soluble red complexes with nitrosonaphthol.

Maple Syrup Urine Disease. MSUD is one of a group of diseases associated with abnormal branched-chain amino acid metabolism. These include hypervalinemia, isovaleric acidemia causing "sweaty feet" odor, and other rare diseases. Several different clinical forms of MSUD have been described, together with various sites of biochemical derangement. The classic type of MSUD, inherited as an autosomal recessive trait, is marked by severe neonatal vomiting, seizures, stupor, irregular respirations, and often hypoglycemia. Left untreated, patients become rapidly comatose and die. Leucine, isoleucine, valine, and their corresponding keto acids are elevated in the plasma and excreted in the urine. Deficient decarboxylases and other enzymes are thought to prevent the conversion of keto acids to fatty acids. Intermittent, intermediate, thiamine-responsive, and dihydrolipoyl dehydrogenase (E3) deficiency forms of MSUD have been described (Holmes, 1997).

The urine of patients with MSUD has an odor resembling maple syrup, caramelized sugar, or curry, the source of which is not certain. The urinary keto acids are demonstrable by the first week of life.

Methods. The dinitrophenylhydrazine screening test indicates the presence of α -keto acids in the urine. Insoluble hydrazones are formed from the reaction of carbonyl groups with dinitrophenylhydrazine. A positive result is seen with MSUD and possibly in phenylketonuria (phenylpyruvic acid), histidinemia (imidazole pyruvic acid), and methionine malabsorption (oasthouse syndrome). The test is positive with ketonuria due to other inherited diseases and other causes. A preliminary screening test for ketones should be performed.

Procedure

1. Reagent and control (ketoglutaric acid, 25 mg in 100 mL normal urine) should be at room temperature.
2. Add 10 drops of reagent (100 mg of 2,4-dinitrophenylhydrazine in 100 mL of 2N HCl) to 1 mL of clear urine.
3. Within 10 minutes, a yellow or chalky white precipitate indicates a positive reaction. It should be the same as or greater than the control precipitate.

Gas or thin-layer chromatographic analysis and nuclear magnetic resonance spectroscopy of the urine may be used as confirmatory methods (Holmes, 1997).

Cystinuria. Cystinuria is a common amino acid disorder that occurs equally in both sexes, with an incidence estimated at about 1 per 10,000 (homozygous) (larger numbers for heterozygotes). In mass screening programs for infants, the homozygous form is detected at about the same rate as phenylketonuria. Defective transport of cystine by the epithelial cells of the renal tubules and gut is transmitted as an autosomal recessive trait. The basic defect is not known. Although large amounts of the dibasic acids ornithine, lysine, and arginine are also excreted in this disease, cystine is the only one that crystallizes out, with stone formation as a clinical manifestation.

Cystinosis, a recessively inherited disorder of unknown cause, is characterized by intracellular cystine crystal deposition within lysosomes. Crystals may accumulate in the kidney, eye, bone marrow, and spleen. The severe form of this disorder is characterized by photophobia, renal failure, rickets, and growth failure. With renal tubular involvement, Fanconi's syndrome develops with generalized aminoaciduria and glucosuria. Benign and intermediate varieties of cystinosis have been described. Unlike in cystinuria, the cystine loss in cystinosis parallels the loss of other amino acids in the urine.

Urinary cystine is sometimes detected in patients with various renal tubular diseases. Cystine is excreted with other amino acids in Wilson's disease, in Lowe's disease, and with the aminoaciduria of Hartnup's disease.

Methods. Examine a first morning urine specimen for colorless, hexagonal crystals of cystine. Cystine may not always crystallize in a concentrated urine, although it may be present in large amounts.

The cyanide-nitroprusside test used for the qualitative determination of urine cystine is Brand's modification of the Legal nitroprusside reaction. Cystine is reduced to cysteine by sodium cyanide, and the free sulfhydryl groups then react with nitroprusside to produce a red-purple color. Cysteine, cystine, homocystine, and ketones (dark red) all will give positive reactions. The qualitative test separates normal, heterozygote, and homozygote ranges of excretion. The lower limit of the test was 35–60 μmol of cystine per mole of creatinine, and this corresponded to the heterozygote range. Homozygous stone formers usually excrete more than 300 mg/g creatinine and are also detected by this test.

Procedure

1. Place 3–5 mL urine in a test tube and add 2.0 mL sodium cyanide solution (5 g/dL water); allow to stand for 10 minutes. Timing is important. Treat a control solution in the same way. For a positive control, use 5 mg cystine dissolved in 10 mL 0.1N HCl, diluted to 100 mL with normal urine.

2. Add fresh, aqueous sodium nitroprusside solution (5 g/dL) dropwise (about five drops), and mix.
3. Read immediately as positive or negative. A stable red-purple color will develop with cystine. "Trace" results may also be reported. A concentrated normal specimen could give a weakly positive "trace" result.

Further identification and quantification of cystine may be accomplished by thin-layer or quantitative ion-exchange chromatography, or high-voltage electrophoresis.

Homocystinuria. The classic form of homocystinuria is due to deficiency of cystathionine β -synthase, which catalyzes the formation of cystathionine from homocystine and serine in the methionine pathway. Homocystine is rapidly oxidized to homocystine, which accumulates along with methionine and is excreted in the urine. Children with this disease may have seizures, thromboses, mental retardation, arachnodactyly, and kyphoscoliosis. Connective tissue manifestations are thought to result from accumulation of the intermediate homocystine, which interferes with collagen cross-linking.

Urine for testing must be fresh because homocystine is labile. The cyanide-nitroprusside test, described earlier, is positive. Quantitative chemical analysis reveals high levels of homocystine, methionine, and cysteine-homocystine disulfide. Urine levels are monitored to follow the effects of the methionine-restricted diet used to treat this disease.

ADDITIONAL URINE TESTING MODALITIES

A latex agglutination nephelometric immunoassay has been developed to measure urinary basic fetoprotein (BFP). Levels of this substance may be elevated with ureter stones, infection, and prostate and bladder cancers, making BFP a nonspecific marker of inflammation or tumor (Itoh, 1998).

The urine Trinder spot test, performed by emergency room physicians, is a sensitive screen for salicylates.

Rendl (1998) described a semiquantitative rapid urinary iodide test, suitable for epidemiologic surveys of iodine deficiency, particularly in developing countries.

Lastly, a monoclonal antibody assay for the detection of free urinary pyridinium cross-links can help to identify bone resorption in patients with osteoporosis, hyperthyroidism, hyperparathyroidism, and Paget's disease of bone (Gomez, 1996).

Cytopathologic examination of the urine is commonly performed to detect malignancies. Enzyme-linked immunosorbent assay and fluorescence in situ hybridization tests can be used to detect carcinoma of the urinary bladder. These tests are discussed in greater detail in Chapter 74.

CHEMICAL MEASUREMENTS IN BODY FLUIDS, 506

SELECTED REFERENCES, 506

KEY POINTS

- Determining the etiologic cause of fluid accumulation in various body cavities (i.e., joints, chest, abdomen) is critical for proper treatment of these disorders.
- Appropriate laboratory examination of these fluids is therefore critical for the diagnosis of numerous diseases (i.e., bacterial, viral and fungal infections; distinction between various arthritides; primary [i.e., mesothelioma] and metastatic malignancies; among others).

- Accurate test interpretation depends on appropriate specimen collection, turnaround time, physician/laboratory communication, and reliable reference values.

CEREBROSPINAL FLUID

In adults, approximately 500 mL of cerebrospinal fluid (CSF) is produced each day (0.3–0.4 mL/min). The total adult volume varies from

90–150 mL, about 25 mL of which is in the ventricles and the remainder in the subarachnoid space. In neonates, the volume varies from 10–60 mL. Thus, the total CSF volume is replaced every 5–7 hours (Wood, 1980). An estimated 70% of CSF is derived by ultrafiltration and secretion through the choroid plexuses. The ventricular ependymal lining and the cerebral subarachnoid space account for the remainder. CSF leaves the ventricular system through the medial and lateral foramina, flowing over the brain and spinal cord surfaces within the subarachnoid space. CSF resorption occurs at the arachnoid villi, predominantly along the superior sagittal sinus.

The CSF has several major functions: (1) It provides physical support because the 1500-g brain weighs about 50 g when suspended in CSF; (2) it confers a protective effect against sudden changes in acute venous (respiratory and postural) and arterial blood pressure or impact pressure; (3) it provides an excretory waste function because the brain has no lymphatic system; (4) it is the pathway whereby hypothalamus releasing factors are transported to the cells of the median eminence; and (5) it maintains central nervous system ionic homeostasis.

The concept of the blood-brain barrier (BBB) is derived from dye-exclusion (trypan blue) studies. It consists of two morphologically distinct components: A unique capillary endothelium held together by intercellular tight junctions; and the choroid plexus, where a single layer of specialized choroidal ependymal cells connected by tight junctions overlies fenestrated capillaries. The CSF ionic components (e.g., H^+ , K^+ , Ca^{++} , Mg^{++} , bicarbonate) are tightly regulated by specific transport systems, whereas glucose, urea, and creatinine diffuse freely but require 2 or more hours to equilibrate. Proteins cross by passive diffusion at a rate dependent on the plasma-to-CSF concentration gradient and inversely proportional to their molecular weight and hydrodynamic volume (Fishman, 1992). Thus, the BBB maintains the relative homeostasis of the central nervous system environment during acute perturbations of plasma components.

SPECIMEN COLLECTION AND OPENING PRESSURE

Cerebrospinal fluid may be obtained by lumbar, cisternal, or lateral cervical puncture or through ventricular cannulas or shunts. Details of the performance of lumbar puncture are described elsewhere (Herndon, 1989; Ward, 1992). Respiratory compromise may occur in infants if the head is flexed (Ward, 1992).

A manometer should be attached before fluid removal to record the opening pressure. CSF pressure varies with postural changes, blood pressure, venous return, Valsalva maneuvers, and factors that alter cerebral blood flow. The normal opening adult pressure is 90–180 mm of water in the lateral decubitus position with the legs and neck in a neutral position. It may be slightly higher if the patient is sitting up and varies up to 10 mm with respiration. However, the pressure may be as high as 250 mm of water in obese patients. In infants and young children, the normal range is 10–100 mm of water, with the adult range attained by age 6–8 years (Fishman, 1992). Opening pressures above 250 mm H_2O are diagnostic of intracranial hypertension, which may be due to meningitis, intracranial hemorrhage, and tumors (Seehusen, 2003). If the opening pressure is greater than 200 mm H_2O in a relaxed patient, no more than 2.0 mL should be withdrawn.

Idiopathic intracranial hypertension is most commonly seen in obese women during their childbearing years. When an elevated opening pressure is noted, CSF must be removed slowly and the pressure carefully monitored. Additional CSF should not be removed if the pressure reaches 50% of the opening pressure (Conly, 1983).

Elevated pressures may be present in patients who are tense or straining and in those with congestive heart failure, meningitis, superior vena cava syndrome, thrombosis of the venous sinuses, cerebral edema, mass lesions, hyposmolality, or conditions inhibiting CSF absorption. Opening pressure elevation may be the only abnormality in cryptococcal meningitis and pseudotumor cerebri (Hayward, 1987). Decreased CSF pressure may be present in spinal-subarachnoid block, dehydration, circulatory collapse, and CSF leakage. A significant pressure drop after removal of 1–2 mL suggests herniation or spinal block above the puncture site, and no further fluid should be withdrawn.

Up to 20 mL of CSF may normally be removed. However, the clinician not only should be aware of the quantity of CSF required for the requested tests to ensure that a sufficient sample is submitted, but should also provide an appropriate clinical history to the laboratory. The sample site (i.e., lumbar, cisternal, etc.) should be noted because cytologic and chemical

*Sensitivity is the ability of a test to detect disease when it is present; specificity is the ability of a test to exclude disease when it is not present.

parameters vary at different sites. The necessity for a simultaneous serum glucose should also be considered. This is best obtained 2–4 hours before lumbar puncture because of the delay in serum-CSF equilibrium.

The CSF specimen is usually divided into three serially collected sterile tubes: Tube 1 for chemistry and immunology studies; tube 2 for microbiological examination; and tube 3 for cell count and differential. An additional tube may be inserted in the No. 3 position for cytology if a malignancy is suspected. However, under certain conditions, some variations are critical. For example, if tube 1 is hemorrhagic because of a traumatic puncture, it should not be used when protein studies are the most important aspect of the analysis (i.e., suspected multiple sclerosis). Indeed, tube 3 should be examined for the major purpose of CSF collection. Perhaps the only definite statement one can make is that tube 1 should never be used for microbiology because it may be contaminated with skin bacteria. If questions arise, communication between the laboratory and the clinician before CSF analysis is critical.

Glass tubes should be avoided because cell adhesion to glass affects the cell count and differential. Specimens should be delivered to the laboratory and processed quickly to minimize cellular degradation, which begins within 1 hour of collection. Refrigeration is contraindicated for culture specimens because fastidious organisms (e.g., *Haemophilus influenza*, *Neisseria meningitidis*) will not survive.

INDICATIONS AND RECOMMENDED TESTS

Indications for lumbar puncture can be divided into four major disease categories: meningeal infection, subarachnoid hemorrhage, primary or metastatic malignancy, and demyelinating diseases (American College of Physicians, 1986). Identification of infectious meningitis, particularly bacterial, is the most important indication for CSF examination (Table 29-1). Recommended laboratory tests are directed toward identification of these disorders (Table 29-2). CSF examination for other diseases is generally less helpful but often provides supportive evidence of a clinical diagnosis or helps to rule out other diseases (Irani, 2009). Limited routine studies followed by reflexive ordering of more focused tests (as needed) on the stored specimen have been advocated as a way of improving test efficiency (Albright, 1988).

GROSS EXAMINATION

Normal CSF is crystal clear and colorless and has a viscosity similar to that of water. Abnormal CSF may appear cloudy, frankly purulent, or pigment tinged. Turbidity or cloudiness begins to appear with leukocyte (white blood cell [WBC]) counts over 200 cells/ μ L or red blood cell (RBC) counts of 400/ μ L. However, grossly bloody fluids have RBC counts greater than 6000/ μ L. Microorganisms (bacteria, fungi, amebas), radiographic contrast material, aspirated epidural fat, and a protein level greater than 150 mg/dL (1.5 g/L) may also produce varying degrees of cloudiness. Experienced observers may be able to detect cell counts of less than 50 cells/ μ L with the unaided eye by observing for Tyndall's effect (Simon, 1978). Here,

direct sunlight directed on the tube at a 90-degree angle from the observer will impart a “sparkling” or “snowy” appearance as suspended particles scatter the light.

Clot formation may be present in patients with traumatic taps, complete spinal block (Froin's syndrome), or suppurative or tuberculous meningitis. It is not seen in patients with subarachnoid hemorrhage. Fine surface pellicles may be observed after refrigeration for 12–24 hours. Clots may interfere with cell count accuracy by entrapping inflammatory cells.

Viscous CSF may be encountered in patients with metastatic mucin-producing adenocarcinomas, cryptococcal meningitis due to capsular polysaccharide, or liquid nucleus pulposus resulting from needle injury to the annulus fibrosus.

Pink-red CSF usually indicates the presence of blood and is grossly bloody when the RBC count exceeds 6000/ μ L. It may originate from a subarachnoid hemorrhage, intracerebral hemorrhage, or cerebral infarct, or from a traumatic spinal tap.

Xanthochromia

Xanthochromia commonly refers to a pale pink to yellow color in the supernatant of centrifuged CSF, although other colors may be present (Table 29-3). To detect xanthochromia, the CSF should be centrifuged and the supernatant fluid compared with a tube of distilled water. Xanthochromic CSF is pink, orange, or yellow owing to RBC lysis and hemoglobin breakdown. Pale pink to orange xanthochromia from released oxyhemoglobin is usually detected by lumbar puncture performed 2–4 hours after the onset of subarachnoid hemorrhage, although it may take as long as 12 hours. Peak intensity occurs in about 24–36 hours and then gradually disappears over the next 4–8 days. Yellow xanthochromia is derived from bilirubin. It develops about 12 hours after a subarachnoid bleed and peaks at 2–4 days, but may persist for 2–4 weeks.

Visible CSF xanthochromia may also be due to the following: (1) oxyhemoglobin resulting from artifactual red cell lysis caused by detergent contamination of the needle or collecting tube, or a delay of longer than 1 hour without refrigeration before examination; (2) bilirubin (bilirubin) in jaundiced patients; (3) CSF protein levels over 150 mg/dL, which are also present in bloody traumatic taps (>100,000 RBCs/ μ L) or in pathologic states such as complete spinal block, polyneuritis, and meningitis; (4) merthiolate disinfectant contamination; (5) carotenoids (orange) in people with dietary hypercarotenemia (i.e., hypervitaminosis A); (6) melanin (brownish) from meningeal metastatic melanoma; and (7) rifampin therapy (red-orange).

Although spectral absorbance scans provide an objective record of xanthochromia, careful gross CSF inspection has comparable sensitivity (Britton, 1983). Spectrophotometry can also help to differentiate hemoglobin-derived substances from other xanthochromic pigments with different maximal absorption peaks.

TABLE 29-3

Xanthochromia and Associated Diseases/Disorders

CSF supernatant color	Associated diseases/disorders
Pink	RBC lysis/hemoglobin breakdown products
Yellow	RBC lysis/hemoglobin breakdown products Hyperbilirubinemia CSF protein >150 mg/dL (1.5 g/L)
Orange	RBC lysis/hemoglobin breakdown products Hypervitaminosis A (carotenoids)
Yellow-green	Hyperbilirubinemia (biliverdin)
Brown	Meningeal metastatic melanoma

CSF, Cerebrospinal fluid; RBC, red blood cell.

Differential Diagnosis of Bloody CSF

A traumatic tap occurs in about 20% of lumbar punctures. Distinction of a traumatic puncture from a pathologic hemorrhage is, therefore, of vital importance. Although the presence of crenated RBCs is not useful, the following observations may be helpful in distinguishing the two forms of bleeding.

1. In a traumatic tap, the hemorrhagic fluid usually clears between the first and third collected tubes but remains relatively uniform in subarachnoid hemorrhage.
2. Xanthochromia, microscopic evidence of erythrophagocytosis, or hemosiderin-laden macrophages indicate a subarachnoid bleed in the absence of a prior traumatic tap. RBC lysis begins as early as 1–2 hours after a traumatic tap. Thus, rapid evaluation is necessary to avoid false-positive results.
3. A commercially available latex agglutination immunoassay test for cross-linked fibrin derivative D-dimer is specific for fibrin degradation and is negative in traumatic taps (Lang, 1990). However, false-positive results might be expected in disseminated intravascular coagulation, fibrinolysis, or trauma from repeated lumbar punctures.

MICROSCOPIC EXAMINATION

Total Cell Count

Although the traditional manual method for cell counting in CSF samples, using undiluted CSF in a manual counting chamber, continues to be a useful approach, because of the low cell counts frequently encountered in CSF, the precision of manual counting in these samples is inherently limited (Barnes, 2004). For example, using 18 large squares (1 mm² each) in a Fuchs-Rosenthal-type chamber with a depth of 0.2 mm, a total volume of 3.6 μ L (18 \times 0.2 μ L/square) is examined. With 5 cells/ μ L, a total of 18 cells is counted. The coefficient of variation (CV), defined as 100 divided by the square root of the number of cells counted, is 24%; \pm 2 CV is about 48%. A Neubauer hemocytometer with nine 1-mm² squares with a depth of 0.1 mm has a CV of 45% (+90% for 2 CV) with the same cell concentration. Improvements in the hardware and software in flow cytometers now allow reliable use of these instruments in performing automated total WBC counts and WBC differential counts (Hoffman, 2002; Aune, 2004), and even in detecting bacteria (Nanos, 2008) in CSF samples; however, the low clinical decision levels for total WBC count and enumeration of some WBC types in CSF and limitations in detecting small numbers of RBCs continue to represent challenges in the use of these instruments with CSF (Hoffman, 2002; Andrews, 2005; Glasser, 2009; Kleine, 2009). Because of these limitations, laboratories should exercise caution in utilizing automated cell counters with CSF samples and should carefully follow manufacturer and Clinical and Laboratory Standards Institute guidelines (CLSI Approved Guideline H56-A, 2006) when implementing these automated methods.

The normal leukocyte cell count in adults is 0–5 cells/ μ L. It is higher in neonates, ranging from 0–30 cells/ μ L, with the upper limit of normal decreasing to adult values by adolescence. No RBCs should be present in normal CSF. If numerous (except a traumatic tap), a pathologic process is probable (e.g., trauma, malignancy, infarct, hemorrhage). Although red cell counts have limited diagnostic value, they may give a useful approximation of the true CSF WBC or total protein in the presence of a traumatic puncture by correcting for leukocytes or protein introduced by the traumatic puncture. To be valid, all measurements (WBC, RBC, protein)

TABLE 29-4

CSF Reference Values for Differential Cytocentrifuge Counts

Cell type	Adults, %	Neonates, %
Lymphocytes	62 ± 34	20 ± 18
Monocytes	36 ± 20	72 ± 22

Ependymal cells	Rare	Rare
Eosinophils	Rare	Rare

CSF, Cerebrospinal fluid.

must be performed on the same tube. This procedure also assumes that the blood is derived exclusively from the traumatic tap. The corrected WBC count is as follows:

$$WBC_{\text{corr}} = WBC_{\text{obs}} - WBC_{\text{added}}$$

where

$$WBC_{\text{added}} = WBC_{\text{BLD}} \times RBC_{\text{CSF}} / RBC_{\text{BLD}}$$

and

$$WBC_{\text{obs}} = \text{CSF leukocyte count}$$

$$WBC_{\text{added}} = \text{leukocytes added to CSF by traumatic tap}$$

$$WBC_{\text{BLD}} = \text{peripheral blood leukocyte count}$$

$$RBC_{\text{CSF}} = \text{CSF erythrocyte count}$$

$$RBC_{\text{BLD}} = \text{peripheral blood erythrocyte count.}$$

An analogous formula may be used to correct for **added total protein** (TP):

$$TP_{\text{added}} = [TP_{\text{serum}} \times (1 - HCT)] \times RBC_{\text{CSF}} / RBC_{\text{BLD}}$$

In the presence of a normal peripheral blood RBC count and serum protein, these corrections amount to about 1 WBC for every 700 RBCs and 8 mg/dL protein for every 10,000 RBCs/ μL . This latter RBC correction factor is reasonably accurate as long as the peripheral WBC count is not extremely high or low. Moreover, the accuracy of these corrections is limited by the precision of the CSF RBC count, which can significantly limit its value.

An observed/expected (added) WBC count ratio greater than 10 has a sensitivity of 88% and a specificity of 90% for bacterial meningitis. When the predicted WBC is below the observed count, the probability of bacterial meningitis appears to be low (Mayefsky, 1987; Bonadio, 1990).

Differential Cell Count

Suggested differential count reference ranges are presented in Table 29-4. A differential performed in a counting chamber is unsatisfactory because the low cell numbers give rise to poor precision, and identifying the cell type beyond granulocytes and “mononuclears” is difficult in a wet preparation. Direct smears of the centrifuged CSF sediment are also subject to significant error from cellular distortion and fragmentation.

The **cytocentrifuge method** is rapid, requires minimal training, and allows Wright's staining of air-dried cytopins. Indeed, it is the recommended method for differential cell counts in all body fluids (Rabinovitch, 1994). Cell yield and preservation are better than with simple centrifugation. From 30–50 cells can be concentrated from 0.5 mL of “normal” CSF. Variable artifactual distortions may be seen, but they are minimized when the specimen is fresh, albumin is added to the specimen (2 drops of 22% bovine serum albumin), and the cell concentration is adjusted to about 300 WBCs/L prior to centrifugation (Kjeldsberg, 1993). Manual differential cell counting on a cytocentrifuge preparation of CSF continues to be the most reliable method, even with low cell numbers. Although automated differential counts may be safely performed on CSF samples using flow cytometers (Hoffman, 2002; Aulesa, 2003), confirmation of the automated differential count by manual examination of a cytocentrifuged smear is recommended with some instruments (Aune, 2004) and is a requirement with specimens at risk of containing neoplastic cells.

Filtration and sedimentation methods are too cumbersome for routine use. Filtration does, however, allow concentration of large volumes of CSF for cytologic examination or culture, while retaining the fluid filtrate for additional studies.

In adults, normal CSF contains small numbers of **lymphocytes** and **monocytes** in an approximate 70:30 ratio (Fig. 29-1). A higher proportion of monocytes is present in young children, in whom up to 80% may be

Figure 29-1 Cerebrospinal fluid cytology (lymphocyte to monocyte distribution ratio 70:30).

Figure 29-2 Choroid plexus cells in cerebrospinal fluid.

Figure 29-3 Cluster of blast-like cells in cerebrospinal fluid from premature newborn. (From Kjeldsberg CR, Knight JA. *Body fluids: laboratory examination of amniotic, cerebrospinal, seminal, serous and synovial fluids*. 3rd ed. Chicago: © American Society for Clinical Pathology; 1993, with permission.)

normal (Pappu, 1982). Erythrocytes due to minor traumatic bleeding are commonly seen, especially in infants. Small numbers of neutrophils (PMNs) may also be seen in “normal” CSF specimens, most likely as a result of minor hemorrhage (Hayward, 1988) and improved cell concentration methods. No general consensus regarding an upper limit of normal for PMNs has been established. We accept up to 7% neutrophils with a normal WBC count. Over 60% neutrophils has been reported in high-risk neonates without meningitis (Rodriguez, 1990). The number of PMNs may be decreased by as much as 68% within the first 2 hours after lumbar puncture owing to cell lysis (Steele, 1986).

Traumatic puncture may result in the presence of bone marrow cells, cartilage cells, squamous cells, ganglion cells, and soft tissue elements. In addition, ependymal and choroid plexus cells may rarely be seen (Fig. 29-2). Moreover, blast-like primitive cell clusters, most likely of germinal matrix origin, are sometimes found in premature infants with intraventricular hemorrhage (Fig. 29-3).

Increased CSF **neutrophils** occur in numerous conditions (Table 29-5). In early bacterial meningitis, the proportion of PMNs usually exceeds 60%. However, in about one quarter of cases of early viral meningitis, the proportion of PMNs also exceeds 60%. Viral-induced neutrophilia usually changes to a lymphocytic pleocytosis within 2–3 days. A total PMN count of over 1180 cells/ μL (or more than 2000 WBCs/ μL) has a 99% predictive value for bacterial meningitis (Spanos, 1989). Persistent neutrophilic meningitis (over 1 week) may be noninfectious or due to less common pathogens such as *Nocardia*, *Actinomyces*, *Aspergillus*, and the zygomycetes (Peacock, 1984).

• Parasitic CNS infestations	• Tuberculous meningitis

CNS, Central nervous system; CSF, cerebrospinal fluid.

Increased CSF *lymphocytes* have been reported in various diseases/disorders (Table 29-6). Lymphocytosis (>50%) may occur in early acute bacterial meningitis when the CSF leukocyte count is under 1000/ μ L (Powers, 1985). Reactive lymphoplasmacytoid and immunoblastic variants may be present, particularly with viral meningoencephalitis. Blast-like lymphocytes may be seen admixed with small and large lymphocytes in the CSF of neonates.

Plasma cells, not normally present in CSF, may appear in a variety of inflammatory and infectious conditions (Table 29-7), along with large and small lymphocytes, and in association with malignant brain tumors

TABLE 29-8

Causes of CSF Eosinophilic Pleocytosis

Modified with permission from Kjeldsberg CR, Knight JA. Body fluids: laboratory examination of amniotic, cerebrospinal, seminal, serous and synovial fluids. 3rd ed. Chicago: © American Society for Clinical Pathology; 1993. CNS, Central nervous system; CSF, cerebrospinal fluid.

Figure 29-4 Eosinophils in cerebrospinal fluid from a child with malfunctioning ventricular shunt.

Figure 29-5 Hemosiderin-laden macrophages (siderophages) from the cerebrospinal fluid of a patient with subarachnoid hemorrhage. Hemosiderin crystals (golden-yellow) are also present. (From Kjeldsberg CR, Knight JA. Body fluids: laboratory examination of amniotic, cerebrospinal, seminal, serous and synovial fluids. 3rd ed. Chicago: © American Society for Clinical Pathology; 1993, with permission.)

(Fishman, 1992). Multiple myeloma may also rarely involve the meninges (Oda, 1991).

Although **eosinophils** are rarely present in normal CSF, they may be increased in a variety of central nervous system (CNS) conditions (Table 29-8). For example, eosinophilia is frequently mild (1%–4%) in a general inflammatory response, but in children with malfunctioning ventricular shunts, it may be marked (Fig. 29-4). A suggested criterion for eosinophilic meningitis is 10% eosinophils (Kuberski, 1981); parasitic invasion of the CNS is the most common cause worldwide. *Coccidioides immitis* is a significant cause of CSF eosinophilia in endemic regions of the United States (Ragland, 1993).

Increased CSF **monocytes** lack diagnostic specificity and are usually part of a “mixed cell reaction” that includes neutrophils, lymphocytes, and plasma cells. This pattern is seen in tuberculous and fungal meningitis, chronic bacterial meningitis (i.e., *Listeria monocytogenes* and others), leptospiral meningitis, ruptured brain abscess, *Toxoplasma* meningitis, and amebic encephalomyelitis. A mixed cell pattern without neutrophils is characteristic of viral and syphilitic meningoencephalitis. **Macrophages** with phagocytosed erythrocytes (**erythrophages**) appear from 12–48 hours following a subarachnoid hemorrhage or traumatic tap. Hemosiderin-laden macrophages (**siderophages**) appear after about 48 hours and may persist for weeks (Fig. 29-5). Brownish yellow or red hematoidin crystals may form after a few days.

(From Kjeldsberg CR, Knight JA. *Body fluids: laboratory examination of amniotic, cerebrospinal, seminal, serous and synovial fluids*. 3rd ed. Chicago: © American Society for Clinical Pathology; 1993, with permission.)

Morphologic cerebrospinal fluid examination for tumor cells has moderate sensitivity and high specificity (97%–98%) (Marton, 1986). Sensitivity depends on the type of neoplasm. CSF examination of leukemic patients has the highest sensitivity (about 70%), followed by metastatic carcinoma (20%–60%) and primary CNS malignancies (30%). Sensitivity may be optimized by using filtration methods with larger fluid volumes or by performing serial punctures in patients in whom a neoplasm is strongly suspected. Processing of CSF samples using liquid-based thin-layer methods also increases sensitivity in the detection of neoplastic cells and enhances preservation of these cells for potential immunocytochemical analysis (Sioutopoulou, 2008). These liquid-based methods are now commonly used for cytopathologic examination of CSF and other body cavity fluid specimens.

Leukemic involvement of the meninges is more frequent in patients with acute lymphoblastic leukemia (Fig. 29-6) than in those with acute myeloid leukemia (Fig. 29-7); both are significantly more common than CNS involvement in the chronic leukemias. A leukocyte count over 5 cells/ μ L with unequivocal lymphoblasts in cytocentrifuged preparations is commonly accepted as evidence of CSF involvement. The incidence of CNS relapse in children with lymphoblasts but cell counts lower than 6 cells/ μ L appears to be low and is not significantly different from cases in which no blasts are identified (Odom, 1990; Gilchrist, 1994; Tubergen, 1994).

Non-Hodgkin lymphomas involving the leptomeninges are usually high-grade tumors (lymphoblastic, large cell immunoblastic, and Burkitt's lymphomas) (Fig. 29-8); low-grade lymphomas and Hodgkin lymphoma

TABLE 29-9

Adult Lumbar CSF Reference Values

Analyte	Conventional units	SI units
Protein	15–45 mg/dL	0.15–0.45 g/L
Prealbumin	2%–7%	
Albumin	56%–76%	
α_1 -Globulin	2%–7%	
α_2 -Globulin	4%–12%	
β -Globulin	8%–18%	
γ -Globulin	3%–12%	
Electrolytes		
Osmolality	280–300 mOsm/L	280–300 mmol/L
Sodium	135–150 mEq/L	135–150 mmol/L
Potassium	2.6–3.0 mEq/L	2.6–3.0 mmol/L
Chloride	115–130 mEq/L	115–130 mmol/L
Carbon dioxide	20–25 mEq/L	20–25 mmol/L
Calcium	2.0–2.8 mEq/L	1.0–1.4 mmol/L
Magnesium	2.4–3.0 mEq/L	1.2–1.5 mmol/L
Lactate	10–22 mg/dL	1.1–2.4 mmol/L
pH		
Lumbar fluid	7.28–7.32	
Cisternal fluid	7.32–7.34	
pCO₂		
Lumbar fluid	44–50 mm Hg	
Cisternal fluid	40–46 mm Hg	
pO ₂	40–44 mm Hg	
Other Constituents		
Ammonia	10–35 μ g/dL	6–20 μ mol/L
Glutamine	5–20 mg/dL	0.3–1.4 mmol/L
Creatinine	0.6–1.2 mg/dL	45–92 μ mol/L
Glucose	50–80 mg/dL	2.8–4.4 mmol/L
Iron	1–2 μ g/dL	0.2–0.4 μ mol/L
Phosphorus	1.2–2.0 mg/dL	0.4–0.7 mmol/L
Total lipid	1–2 mg/dL	0.01–0.02 g/L
Urea	6–16 mg/dL	2.0–5.7 mmol/L
Urate	0.5–3.0 mg/dL	30–180 μ mol/L
Zinc	2–6 μ g/dL	0.3–0.9 μ mol/L

CSF, cerebrospinal fluid; pCO₂, partial pressure of carbon dioxide; pO₂, partial pressure of oxygen.

are significantly less common (Bigner, 1992; Walts, 1992). T cells predominate in normal and inflammatory conditions, whereas most lymphomas, especially those occurring in immunocompromised hosts, are of B cell lineage. Lymphoblastic lymphoma, the most common T cell lymphoma, can be detected by terminal deoxynucleotidyl transferase stain.

Multiparameter flow cytometric immunophenotypic studies and/or molecular DNA analysis may significantly improve diagnostic sensitivity and specificity in CSF samples involved by leukemic or lymphoma cells (Rhodes, 1996; Finn, 1998; Scrideli, 2004; Bromberg, 2007; Quijano, 2009), and these are used increasingly as part of a complete evaluation in patients being worked up for these conditions.

Amebae, fungi (especially *Cryptococcus neoformans*), and *Toxoplasma gondii* organisms may be present on cytocentrifuge specimens but may be difficult to recognize without confirmatory stains.

CHEMICAL ANALYSIS

Reference values for lumbar cerebrospinal fluid in adults are listed in Table 29-9.

Proteins

Total Protein

More than 80% of the CSF protein content is derived from blood plasma, in concentrations of less than 1% of the plasma level (Table 29-10).

TABLE 29-10

Mean Concentrations of Plasma and CSF Proteins

Protein	CSF, mg/L	Plasma/CSF ratio
Prealbumin	17.3	14
Albumin	155.0	236
Transferrin	14.4	142
Ceruloplasmin	1.0	366
Immunoglobulin (Ig)G	12.3	802
IgA	1.3	1346
α_2 -Microglobulin	2.0	1111
Fibrinogen	0.6	4940
IgM	0.6	1167
β -Lipoprotein	0.6	6213

CSF, Cerebrospinal fluid.

Prealbumin (transthyretin), transferrin, and small quantities of nerve tissue-specific proteins are the major qualitative differences that normally exist between CSF and plasma proteins. Although some authors have argued against routine measurement of total protein (American College of Physicians, 1986), it is the most common abnormality found in CSF. Thus, an increased CSF protein serves as a useful, albeit nonspecific, indicator of meningeal or CNS disease.

Reference Values. CSF total protein reference values vary considerably between laboratories owing to differences in methods, instrumentation, and type of reference standard used (College of American Pathologists CSF Chemistry Survey, Set M-B, 1991*; Gerbaut, 1986). CSF protein levels of 15–45 mg/dL have long been accepted as the “normal” reference range (Silverman, 1994). Using the classic Lowry method, the reported adult range was 24.1–48.5 mg/dL (Tibbling, 1977). Others reported a reference range of 14–49 mg/dL using a trichloroacetic acid–Ponceau S method (Breebaart, 1978), and of 22.3–50.3 mg/dL with a biuret method (Ahonen, 1978). Reference levels were also compared using three different methods: (1) A modified biuret technique; (2) a Dupont aca method in which protein was precipitated and then reacted with trichloroacetic acid; and (3) a Kodak Ektachem colorimetric slide technique (Lott, 1989). All three methods gave similar, although significantly higher, levels than those previously reported (i.e., 14–62 mg/dL, 16–61 mg/dL, and 12–60 mg/dL, respectively).

Although discrepancies in gender and in those over the age of 60 years have been reported, the differences are probably not significant. However, infants have significantly higher CSF protein levels than older children and adults. Thus, mean levels of 90 mg/dL for term infants and 115 mg/dL for preterm infants were reported; the upper levels were 150 mg/dL and 170 mg/dL, respectively (Sarff, 1976). Similarly, others recently noted that the CSF protein concentration fell rapidly from birth to 6 months of age (mean levels, 108 mg/dL–40 mg/dL), plateaued between 3 and 10 years (mean, 32 mg/dL), and then rose slightly from 10–16 years (mean, 41 mg/dL) (Biou, 2000).

Elevated CSF protein levels may be caused by increased permeability of the blood-brain barrier, decreased resorption at the arachnoid villi, mechanical obstruction of CSF flow due to spinal block above the puncture site, or an increase in intrathecal immunoglobulin (Ig) synthesis. Common conditions associated with elevated lumbar CSF protein values (>65 mg/dL) are summarized in Table 29-11.

Low lumbar CSF total protein levels (<20 mg/dL) normally occur in some young children between 6 months and 2 years of age and in patients with conditions associated with increased CSF turnover. These include the following: (1) Removal of large CSF volumes; (2) CSF leaks induced by trauma or lumbar puncture; (3) increased intracranial pressure, probably due to an increased rate of protein resorption by the arachnoid villi; and (4) hyperthyroidism (Fishman, 1992).

Protein electrophoresis of concentrated normal CSF reveals two distinct differences from serum: A prominent transthyretin (prealbumin) band and two transferrin bands. Transthyretin is relatively high because of its dual synthesis by the liver and the choroid plexus. The second transferrin band, referred to as β_2 -transferrin, migrates more slowly than its

TABLE 29-11

Conditions Associated With Increased CSF Total Protein

Traumatic spinal puncture
Increased blood–CSF permeability
Arachnoiditis (e.g., following methotrexate therapy)
Meningitis (bacterial, viral, fungal, tuberculous)
Hemorrhage (subarachnoid, intracerebral)
Endocrine/metabolic disorders
Milk–alkali syndrome with hypercalcemia
Diabetic neuropathy
Hereditary neuropathies and myelopathies
Decreased endocrine function (thyroid, parathyroid)
Other disorders (uremia, dehydration)
Drug toxicity
Ethanol, phenothiazines, phenytoin
CSF circulation defects
Mechanical obstruction (tumor, abscess, herniated disk)
Loculated CSF effusion
Increased immunoglobulin (Ig)G synthesis
Multiple sclerosis
Neurosyphilis
Subacute sclerosing panencephalitis
Increased IgG synthesis and blood–CSF permeability
Guillain-Barré syndrome
Collagen vascular diseases (e.g., lupus, periarteritis)
Chronic inflammatory demyelinating polyradiculopathy

CSF, Cerebrospinal fluid.

serum equivalent owing to cerebral neuraminidase digestion of sialic acid residues.

Methods. Turbidimetric methods, commonly based on trichloroacetic acid (TCA) or sulfosalicylic acid and sodium sulfate for protein precipitation, are popular because they are simple and rapid, and require no special instrumentation. However, they are temperature sensitive and require much larger specimen volumes (about 0.5 mL). Moreover, some methods are prone to significant variation from changes in the albumin/globulin ratio (Schriever, 1965). A false protein elevation may be observed using TCA methods in the presence of methotrexate (Kasper, 1988). Benzethonium chloride and benzalkonium chloride have been used as precipitating agents in automated methods and micromethods (Luxton, 1989; Shephard, 1992).

Colorimetric methods include the Lowry method, dye-binding, methods using Coomassie brilliant blue (CBB) or Ponceau S, and the modified Biuret method. The CBB method is rapid and highly sensitive, and can be used with small sample sizes. Immunologic methods measure specific proteins, require only 25–50 μ L of CSF, and are relatively simple to perform once conditions and reagents have been standardized. Automated methods are also commonly used and usually show good correlation with standard methods (Lott, 1989).

Albumin and IgG Measurements

The permeability of the blood-brain barrier may be assessed by immunochemical quantification of the CSF albumin/serum albumin ratio in grams per deciliter (g/dL). The normal ratio of 1:230 (Tourtellotte, 1985) yields an unwieldy decimal of 0.004, which prompted the use of the **CSF/serum albumin index**, which is arbitrarily calculated as follows:

$$\text{CSF/Serum albumin index} = \frac{\text{CSF albumin (mg/dL)}}{\text{Serum albumin (g/dL)}} \quad (29-1)$$

An index value less than 9 is consistent with an intact barrier. Slight impairment is considered with index values of 9–14, moderate impairment with values of 14–30, and severe impairment with values greater than 30 (Silverman, 1994). The index is slightly elevated in infants up to 6 months of age, reflecting the immaturity of the blood-brain barrier, and increases gradually after age 40 years. A traumatic tap invalidates the index calculation.

Increased intrathecal IgG synthesis is reflected by an increase in the CSF/serum IgG ratio:

$$\text{CSF/Serum IgG ratio} = \frac{\text{CSF IgG (mg/dL)}}{\text{Serum IgG (g/dL)}} \quad (29-2)$$

*College of American Pathologists, 325 Waukegan Road, Northfield, Ill.

The normal ratio is 1/390 or 0.003 (Tourtellotte, 1985). Similar to the albumin index, the CSF/serum IgG index may be obtained by using milligrams per deciliter for the CSF IgG value. The CSF/serum IgG index normal range is 3.0–8.7.

The **CSF/serum IgG index** can be elevated by intrathecal IgG synthesis or increased plasma IgG crossover from breakdown of the blood-brain barrier. Ig derived from plasma crossover may be corrected by dividing the CSF/serum IgG index by the CSF/albumin index to yield the CSF IgG index.

$$\text{CSF IgG index} = \frac{\text{CSF IgG (mg/dL) / Serum IgG (g/dL)}}{\text{CSF albumin (mg/dL) / Serum albumin (g/dL)}} \quad (29-3)$$

or

$$\text{CSF IgG index} = \frac{\text{CSF IgG (mg/dL)} \times \text{Serum albumin (g/dL)}}{\text{Serum IgG (g/dL)} \times \text{CSF albumin (mg/dL)}} \quad (29-4)$$

The normal reference range for the IgG index varies, reflecting variations in determination of the four index components. A reasonable normal upper limit is 0.8 (Souverein, 1989). However, each laboratory should determine its own critical ratio.

The **IgG synthesis rate** is calculated by an empirical formula (Tourtellotte, 1985):

$$\begin{aligned} \text{IgG synthesis rate (mg/day)} = & [(\text{CSF IgG} - \text{Serum IgG}/369) - \\ & (\text{CSF albumin} - \text{Serum albumin}/230) \times \\ & (\text{Serum IgG}/\text{Serum albumin}) \times 0.43 \times 5 \text{ dL/day}] \end{aligned} \quad (29-5)$$

All protein concentrations are expressed in milligrams per deciliter. The first bracketed term represents the difference between measured CSF IgG and the IgG expected from diffusion across a normal blood-brain barrier; 369 is the normal serum/CSF ratio. The second bracketed term represents the difference between measured CSF albumin and expected albumin if the blood-brain barrier is intact; 230 is the normal serum/CSF albumin ratio. The CSF albumin excess is multiplied by the IgG/albumin ratio and the molecular weight ratio of IgG to albumin (0.43) to correct for changes in CSF IgG due to increased barrier permeability. The number 5 converts the result from a concentration to a daily amount, assuming an average daily CSF production of 500 mL (i.e., 5 dL). The formula does not consider variations in CSF production or Ig consumption. It assumes that the IgG/albumin ratio remains constant over various degrees of blood-brain barrier impairment—a concept that may lead to variable error (Lefvert, 1985). The normal reference interval for the synthesis rate is –9.9 to +3.3 mg/day. Values greater than 8.0 mg/day indicate an increased rate (Silverman, 1994).

CSF IgG is normally 3%–5% of total CSF protein, but in multiple sclerosis (MS), the concentration approaches that of plasma (15%–18%) (Hersey, 1980). The CSF IgG index and the IgG synthesis rate have a sensitivity of 90% in patients with definite MS, but the sensitivity is lower in patients with possible MS, in whom accuracy is most needed (Marton, 1986). In addition, the specificity for MS is only moderate because increased intrathecal IgG synthesis occurs in many other inflammatory neurologic diseases.

The Ig index and synthesis rate calculations may also be applied to IgM, IgA, Ig light chains, and specific antibodies to infectious microorganisms. For example, increased synthesis of IgM and free κ light chains have been suggested as markers for MS (Rudick, 1989; Lolli, 1991).

Electrophoretic Techniques. Although the diagnosis of MS is ultimately a clinical one, significant advances have been made in laboratory testing for this disorder. CSF total protein is increased in less than 50% of patients with MS. Indeed, if the CSF protein exceeds 100 mg/dL, the patient probably does not have MS. However, the γ -globulin fraction, as determined by CSF electrophoresis, is often increased in MS. Thus, the CSF total protein/ γ -globulin ratio exceeds 0.12 in about 65% of cases (Johnson, 1977). Using **electroimmunodiffusion**, a CSF IgG/albumin ratio greater than 0.25 is present in about 75% of cases (Tourtellotte, 1971). Furthermore, levels greater than the mean CSF IgG index + 3SD are present in 80%–85% of MS cases. However, this upper reference level varies significantly between laboratories, and 0.58, 0.66, and 0.77 have been reported as cutoff values (Olsson, 1976; Tibbling, 1977; Markowitz, 1983, respectively). Therefore, laboratories should establish their own reference values.

High-resolution agarose gel electrophoresis of concentrated CSF from patients with MS often shows discrete populations of IgG, the **oligoclonal bands**. Although these discrete IgG populations are normally absent, two or more bands are necessary to support the diagnosis of MS; a single band is not considered a positive result. Using this technique, oligoclonal bands have been reported in 83%–94% of patients with definite MS, 40%–60% of those with probable MS, and 20%–30% of possible MS cases. However, they are also frequently present in patients with subacute sclerosing panencephalitis, various viral CNS infections, neurosyphilis, neuroborreliosis, cryptococcal meningitis, Guillain-Barré syndrome, transverse myelitis, meningeal carcinomatosis, glioblastoma multiforme, Burkitt's lymphoma, chronic relapsing polyneuropathy, Behçet's disease, cysticercosis, and trypanosomiasis, among others (Trotter, 1989; Chalmers, 1990; Fishman 1992; Hall, 1992). Subsequent studies indicate that agarose gel electrophoresis sensitivity for MS is less than previously reported (see later).

Oligoclonal light chains (both κ and λ) are present in about 90% of MS patients (Gallo, 1989; Sindie, 1991). They have also occasionally been identified in the CSF of those who are negative for IgG oligoclonal bands. However, because of their uncommon occurrence in the absence of IgG and cost-ineffectiveness, as well as the ready availability of magnetic resonance imaging, it is unlikely that this technique will become common.

Coomassie brilliant blue or paragon violet stains can resolve oligoclonal bands in only 5 μ g of IgG (Silverman, 1994). However, **silver staining** is 20–50 times more sensitive than CBB and can be used on unconcentrated CSF. It is important to note that these electrophoretic techniques must be simultaneously carried out on the patient's serum to be certain that a polyclonal gammopathy is not present (e.g., liver disease, systemic lupus, rheumatoid arthritis, chronic granulomatous disease) because these disorders may be accompanied by Ig diffusion into the CSF, yielding false-positive results.

Immunofixation electrophoresis (IFE) is more sensitive than agarose gel electrophoresis and does not require CSF concentration (Cawley, 1976). A subsequent study reported a sensitivity of 74% using this technique compared with 57% for agarose gel electrophoresis (Cavuoti, 1998). More recently, using a semiautomated immunofixation-peroxidase technique, the sensitivity was 83% and the specificity was 79% in patients with clinically definite MS (Richard, 2002). However, IFE provides fewer bands than **isoelectric focusing and IgG immunoblotting (IgG-IEF)**. Moreover, the bands obtained by IFE tend to be more diffuse.

IgG-IEF performed on paired CSF and serum samples is the most sensitive method for the detection of oligoclonal bands (Andersson, 1994). One study showed that IgG-IEF detected 100% of definite MS, but only about 50% were positive by agarose electrophoresis (Lunding, 2000). Others detected 91% of MS cases but only 68% with agarose (Seres, 1998). Similarly, a semiautomated IgG-IEF technique identified 90% of MS cases compared with 60% for agarose electrophoresis (Fortini, 2003). In 2005, an international consensus standard for the diagnosis of MS established IgG-IEF as the method of choice for qualitative detection of oligoclonal IgG bands as evidence of intrathecal synthesis of IgG (Freedman, 2005). This method is more sensitive and specific than quantitative methods.

In summary, the diagnosis of MS, as with many other neurologic disorders, is ultimately a clinical one based on neurologic history and physical examination. Nevertheless, advanced laboratory results in CSF, such as elevated IgG indices and particularly the detection of oligoclonal IgG bands, as well as neuroimaging techniques, have proved invaluable in the diagnosis of MS.

Other CSF Proteins

Approximately 300 different proteins have been identified in CSF using two-dimensional electrophoresis, the first dimension being isoelectric focusing and the second polyacrylamide gel in the presence of sodium dodecyl sulfate (Harrington, 1986). Using this technique, four abnormal proteins were identified in patients with Creutzfeldt-Jakob disease (CJD). Two of these proteins (molecular mass about 40 kilodaltons [kDa] each) were present in some, but not all, patients with herpes simplex encephalitis, Parkinson's disease, Guillain-Barré syndrome, and schizophrenia. They were not present in various other neurologic disorders, nor in 100 normal CSF control specimens. However, these and two other proteins (molecular masses about 26 and 29 kDa) were present in all cases of CJD and in 5 of 10 cases of herpes simplex encephalitis. Neither of these latter proteins was present in any other neurologic disease or in controls.

Increased concentrations of various specific CSF proteins have been associated with several CNS diseases (Table 29-12).

TABLE 29-12
CSF Proteins and Central Nervous System Diseases

Protein	Major diseases/disorders
α_2 -Macroglobulin	Subdural hemorrhage, bacterial meningitis
β -Amyloid and τ proteins	Alzheimer's disease
β_2 -Microglobulin	Leukemia/lymphoma, Behçet's syndrome
C-reactive protein	Bacterial and viral meningitis
Fibronectin	Lymphoblastic leukemia, AIDS, meningitis
Methemoglobin	Mild subarachnoid/subdural hemorrhage
Myelin basic protein	Multiple sclerosis, tumors, others
Protein 14-3-3	Creutzfeldt-Jakob disease
Transferrin	CSF leakage (otorrhea, rhinorrhea)

AIDS, Acquired immunodeficiency syndrome; CSF, cerebrospinal fluid.

Myelin Basic Protein. Myelin basic protein (MBP), a component of the myelin nerve sheath, is released during demyelination as a result of various neurologic disorders, especially MS. Thus, MBP has been shown to positively correlate with CSF leukocyte count, intrathecal IgG synthesis, and the CSF/serum albumin concentration quotient (Sellebjerg, 1998). These results support the use of MBP in CSF as a surrogate disease marker during acute MS exacerbations. Others have found that analysis of antibody against MBP in patients with a clinically isolated syndrome is a rapid and precise method for predicting early conversion to clinically definite MS (Berger, 2003). However, increased CSF levels have also been reported in Guillain-Barré syndrome, lupus erythematosus, subacute sclerosing panencephalitis, and various brain tumors, and following CNS irradiation and chemotherapy (Brooks, 1989; Mahoney, 1984). Measurement of CSF levels has also been proposed as a prognostic marker in patients with serious head injury (Noseworthy, 1985).

α_2 -Macroglobulin. Except for a small amount transported across the BBB in pinocytic vesicles, α_2 -macroglobulin (A2M) is normally excluded from the CSF because of its large size. The number of these vesicles is increased in certain polyneuropathies, resulting in an increased CSF A2M level. Significant elevation reflects subdural hemorrhage or breakdown of the BBB, as occurs in bacterial meningitis. A2M measurement alone, or in relationship to albumin and IgG, may assist in the evaluation of neurologic disorders and increased CSF protein, and in the rapid differentiation between bacterial and aseptic meningitis (Meucci, 1993; Kanoh, 1997).

β_2 -Microglobulin. This protein is part of the human leukocyte antigen class I molecule on the surfaces of all nucleated cells. CSF levels above 1.8 mg/L are associated with leptomeningeal leukemia and lymphoma but are not highly specific (Weller, 1992), in that they have a maximal positive predictive value of 78% in cases with a positive cytology (Jeffrey, 1990). β_2 -microglobulin (B2M) was also recently shown to be a marker for neuro-Behçet's syndrome (Kawai, 2000). Moreover, viral infections, including human immunodeficiency virus (HIV)-1, other inflammatory conditions, and various malignancies have also been associated with elevated levels. However, the measurement of B2M remains primarily investigational.

C-Reactive Protein. Early studies indicated that CSF C-reactive protein (CRP) is useful in differentiating viral (aseptic) meningitis from bacterial meningitis (Corral, 1981; Abramson, 1985; Stearman, 1994). Others have reported that CSF CRP is a more useful screening test for viral versus bacterial meningitis, especially in children (Sormunen, 1999). A meta-analysis of CRP studies since 1980 suggested that a normal CSF or serum CRP has a high probability of ruling out bacterial meningitis (i.e., negative predictive value about 97%) (Gerdes, 1998). Moreover, a recent study found not only that CSF CRP levels were increased in bacterial meningitis, but that these levels were significantly higher in patients with gram-negative bacterial meningitis than in those with gram-positive bacterial meningitis (Rajs, 2002).

Fibronectin. This large glycoprotein (molecular mass about 420 kDa) is normally present in essentially all tissues and body fluids. Its primary function is its role in cell adhesion and phagocytosis (Ruoslahti, 1981). Thus, cell adhesion allows leukocytes to adhere to and pass through the vascular endothelia and migrate to the inflammatory site.

In children with acute lymphoblastic leukemia, elevated CSF fibronectin levels are associated with a poor prognosis, presumably due to leukemic involvement of the CNS (Rautonen, 1989). Significant CSF elevations have also been reported in Burkitt's lymphoma (Rajantie, 1989), some metastatic solid tumors, astrocytomas, and bacterial meningitis (Weller, 1990; Torre, 1991). Decreased levels have been reported in viral meningitis and in the acquired immunodeficiency syndrome (AIDS)-dementia complex (Torre, 1991, 1993).

β -Amyloid Protein 42 and τ Protein. The diagnosis of Alzheimer's disease (AD) is based on the presence of dementia and a specific clinical profile (i.e., from medical history, clinical examination) suggestive of AD, together with the exclusion of other causes of dementia. Pathologically, the disease is characterized by the presence of neurofibrillary tangles and amyloid plaques.

Recent studies indicate that measurement of biochemical markers increases diagnostic accuracy, especially early in the course of the disease, when clinical symptoms are mild and vague and overlap with cognitive changes that accompany aging and ischemic dementia. Thus, increased CSF levels of microtubule-associated τ protein and decreased levels of β -amyloid protein ending at amino acid 42 have been shown to significantly increase the accuracy of AD diagnosis (Andreassen, 2001; Riemenschneider, 2002; Sunderland, 2003). Indeed, the predictive value for early AD is greater than 90% (Andreassen, 2001). Others have found that the calculated ratio of phosphorylated τ protein to β -amyloid peptide is superior to either measure alone (Maddalena, 2003). The results were as follows: Distinguishing patients with AD from healthy controls—sensitivity 96%, specificity 97%; patients with AD from those with non-AD dementia—sensitivity 80%, specificity 73%; and patients with AD from those with other neurologic disorders—sensitivity 80%, specificity 89%.

Protein 14-3-3. The transmissible spongiform encephalopathies constitute a group of uniformly fatal neurodegenerative diseases. Of these, CJD is the major spongiform disease in humans. Two proteins, designated 130 and 131, have been detected in low concentrations in CSF from CJD patients. These proteins have the same amino acid sequence as protein 14-3-3 (Hsich, 1996). Moreover, in patients with dementia, a positive immunoassay for the 14-3-3 protein in CSF strongly supports a diagnosis of CJD. In a subsequent study of patients with suspected CJD, the sensitivity of the 14-3-3 protein determined by immunoassay was 97%, and the specificity was 87% (Lemstra, 2000). False-positive results were seen primarily in patients with stroke and meningoencephalitis.

Others, using a modified Western blot technique, reported a 94.7% positive predictive value and a 92.4% negative predictive value for CJD (Zerr, 1998). False-positive results from a single CSF analysis were seen in patients with herpes simplex encephalitis, atypical encephalitis, metastatic lung cancer, and hypoxic brain damage.

Transferrin and CSF Leakage. Cerebrospinal fluid leakage usually presents as otorrhea or rhinorrhea following head trauma, in some cases beginning months to years after the injury. Recurrent meningitis is a serious complication, making accurate identification of the leaking fluid very important. In this regard, protein and glucose measurements are too nonspecific to be of value. Transferrin, an iron-binding glycoprotein with a molecular mass of about 77 kDa, is synthesized primarily in the liver. However, two transferrin isoforms are present in the CSF; the major isoform (β_1 -transferrin) is present in all body fluids. The second isoform (β_2 -transferrin), present only in the central nervous system, is produced in the central nervous system by the catalytic conversion of β_1 -transferrin by neuraminidase. Immunofixation electrophoresis readily identifies both isoforms.

Protein electrophoresis with transferrin immunofixation is a noninvasive, rapid, and inexpensive test of high sensitivity and specificity that requires as little as 0.1 mL of fluid (Ryall, 1992; Normansell, 1994). Several reports have demonstrated the value of this technique in the diagnosis of CSF otorrhea and rhinorrhea—conditions in which both isoforms are readily identified (Irjala, 1979; Rouah, 1987; Zaret, 1992). Others have stressed the importance of β_2 -transferrin identification in both CSF and inner ear perilymphatic leakage, as well as possible sources of error due to the presence of a transferrin allelic variant (Skedros, 1993a,b; Sloman, 1993).

Methemoglobin and Bilirubin. Although most cases of subarachnoid and intracerebral hemorrhage are readily identified by computed

tomography (CT), patients with mild subarachnoid hemorrhage, small subdural or cerebral hematomas, and blood seepage from an aneurysm or neoplasm and from small cerebral infarcts often are not identified by this technique. In these cases, CSF spectrophotometric analysis has been shown to detect methemoglobin in colorless CSF ($<0.3 \mu\text{mol/L}$) (Trbojevic-Cepe, 1992). However, an increase in CSF bilirubin is now recognized as the key finding supporting the diagnosis of subarachnoid hemorrhage (UK National External Quality Assessment Scheme for Immunochemistry Working Group, 2003). Thus, a single net bilirubin absorbance cutoff point of >0.007 absorbance units is recommended in the decision tree for interpretation and reporting of results.

Glucose

Derived from blood glucose, fasting CSF glucose levels are normally 50–80 mg/dL (2.8–4.4 mmol/L)—about 60% of plasma values. Results should be compared with plasma levels, ideally following a 4-hour fast, for adequate clinical interpretation. The normal CSF/plasma glucose ratio varies from 0.3–0.9, with fluctuations in blood levels caused by the lag in CSF glucose equilibration time.

CSF values below 40 mg/dL (2.2 mmol/L) or ratios below 0.3 are considered to be abnormal. Hypoglycorrhachia is a characteristic finding of bacterial, tuberculous, and fungal meningitis. However, sensitivity can be as low as 55% for bacterial meningitis (Hayward, 1987), so a normal level does not exclude these conditions. Some cases of viral meningoencephalitis also have low glucose levels, but generally not to the degree seen in bacterial meningitis. Meningeal involvement by a malignant tumor, sarcoidosis, cysticercosis, trichinosis, ameba (*Naegleria*), acute syphilitic meningitis, intrathecal administration of radioiodinated serum albumin, subarachnoid hemorrhage, symptomatic hypoglycemia, and rheumatoid meningitis may also produce low CSF glucose levels (Fishman, 1992).

Decreased CSF glucose results from increased anaerobic glycolysis in brain tissue and leukocytes and from impaired transport into the CSF. Bacteria are usually present in insufficient quantities to be a major contributor. CSF glucose levels normalize before protein levels and cell counts during recovery from meningitis, making it a useful parameter in assessing response to treatment.

Increased CSF glucose is of no clinical significance, reflecting increased blood glucose levels within 2 hours of lumbar puncture. A traumatic tap may also cause a spurious increase in CSF glucose.

Lactate

CSF and blood lactate levels are largely independent of each other. The reference interval for older children and adults is 9.0–26 mg/dL (1.0–2.9 mmol/L) (Knight, 1981). Newborns have higher levels, ranging from about 10–60 mg/dL (1.1–6.7 mmol/L) for the first 2 days, and from 10–40 mg/dL (1.1–4.4 mmol/L) for days 3 to 10 (McGuinness, 1983). Elevated CSF lactate levels reflect CNS anaerobic metabolism due to tissue hypoxia.

Lactate measurement has been used as an adjunctive test in differentiating viral meningitis from bacterial, mycoplasma, fungal, and tuberculous meningitis, in which routine parameters yield equivocal results. In patients with viral meningitis, lactate levels are usually below 25 mg/dL (2.8 mmol/L) and are almost always less than 35 mg/dL (3.9 mmol/L), whereas bacterial meningitis typically has levels above 35 mg/dL (Bailey, 1990; Cameron, 1993). Using 30–36 mg/dL as the cutoff value for bacterial meningitis, the sensitivity and specificity are about 80% and 90%, respectively. Viral meningitis, partially treated bacterial meningitis, and tuberculous meningitis often have intermediate lactate levels that overlap each other, limiting the use of lactate measurements in this differential diagnosis.

Persistently elevated ventricular CSF lactate levels are associated with a poor prognosis in patients with severe head injury (DeSalles, 1986).

F2-Isoprostanes

F2-isoprostanes are increased in diseased regions of the brain in patients with AD (Pratico, 1998). Compared with age-matched controls, CSF F2-isoprostanes are also elevated in patients with probable AD (Montine, 1999). Therefore, in conjunction with CSF τ and β -amyloid protein, the measurement of CSF F2-isoprostanes appears to enhance the accuracy of the laboratory diagnosis of AD (Montine, 2001).

Enzymes

A wide variety of enzymes derived from brain tissue, blood, or cellular elements have been described in the CSF. Although CSF enzyme assays are not commonly used in the diagnosis of CNS diseases, there are diseases/disorders in which they may prove useful.

Adenosine Deaminase

Adenosine deaminase (ADA) catalyzes the irreversible hydrolytic deamination of adenosine to produce inosine. Because ADA is particularly abundant in T lymphocytes, which are increased in tuberculosis, its measurement has been recommended in the diagnosis of pleural, peritoneal, and meningeal tuberculosis. Higher ADA levels are present in tuberculous infections than in viral, bacterial, and malignant diseases (Blake, 1982; Mann, 1982; Choi, 2002), although the degree of increase indicative of tuberculous infection varies depending on the specific assay used. ADA appears to have limited utility in HIV-associated neurologic disorders (Corral, 2004).

Creatine Kinase

Brain tissue is rich in creatine kinase (CK) because it participates in maintaining an adequate supply of adenosine triphosphate. Increased CSF CK activity has been reported in numerous CNS disorders, including hydrocephalus, cerebral infarction, various primary brain tumors, and subarachnoid hemorrhage, among others (Savory, 1979). In patients with head trauma, CSF CK levels correlate directly with the severity of the concussion (Florez, 1976).

CSF CK-MM and CK-MB are not normally present; when identified, they are due to blood contamination (CK-MM) and an equilibrium between CK-BB and CK-MM to produce CK-MB. Because the CK-BB isoenzyme accounts for about 90% of brain CK activity and mitochondrial CK (CKmt) the other 10%, CK isoenzyme measurements are more specific than total CK for CNS disorders (Chandler, 1984).

CSF CK-BB is increased about 6 hours following an ischemic or anoxic insult. Global brain ischemia following respiratory or cardiac arrest results in diffuse cerebral injury with peak CK-BB levels in about 48 hours (Chandler, 1986). Here, CSF CK-BB activity less than 5 U/L (upper normal level) indicates minimal neurologic damage; 5–20 U/L indicates mild to moderate CNS injury; and levels between 21 and 50 U/L are commonly correlated with death. Death occurs in essentially all patients with levels above 50 U/L.

Increased CSF CK-BB levels are also associated with the outcome following a subarachnoid hemorrhage (Coplin, 1999). Here, a CK-BB level greater than 40 U/L increased the chance of an unfavorable early or late outcome to 100%. The death rate was 13% when the CSF CK-BB level was less than 40 U/L.

Lactate Dehydrogenase

Lactate dehydrogenase (LD) activity is high in brain tissue, with a predominance of the electrophoretically fast-moving isoenzyme fractions LD₁ and LD₂. Total LD activity of 40 U/L is a reasonable upper limit of normal for adults and 70 U/L for neonates (Donald, 1986; Engelke, 1986). LD is useful in differentiating a traumatic tap from intracranial hemorrhage because a current traumatic tap with intact RBCs does not significantly elevate the LD level (Engelke, 1986). Sensitivity and specificity are about 70%–85% depending on the cutoff value. As with lactate, LD activity is significantly higher in bacterial meningitis than in aseptic meningitis (Donald, 1986; Engelke, 1986). Using a cutoff of 40 U/L, the sensitivity is about 86% and the specificity about 93%.

Total CSF LD levels are also increased in patients with CNS leukemia, lymphoma, metastatic carcinoma, bacterial meningitis, and subarachnoid hemorrhage (Kjeldsberg, 1993). CSF LD isoenzymes have been shown to add considerable specificity in the evaluation of various metastatic brain tumors (Fleisher, 1981). Thus, the LD₃/total LD ratio is increased (i.e., above 10%–15%) in patients with leptomeningeal metastases from carcinoma of the breast and lung and malignant melanoma. Isoenzyme analysis also shows a distinct pattern in young children with infantile spasms (Nussinovitch, 2003a) and febrile convulsions (Nussinovitch, 2003b). Compared with controls, both disorders are characterized by decreased LD₁, increased LD₂ and LD₃, and no changes in LD₄ and LD₅.

CT is of limited value in estimating recovery potential and neurologic outcome during the early stages of ischemic brain injury. However, compared with controls (mean LD, 11.2 U/L), patients with an early stroke had a mean level of 40.9 U/L, and those with a transient ischemic attack (TIA) had a mean value of 11.8 U/L (Lampl, 1990). Moreover, in patients with hypoxic brain injury, an increased LD level 72 hours following resuscitation indicates a poor prognosis (Karkela, 1992).

Lysozyme

Lysozyme (muramidase) catalyzes the depolymerization of mucopolysaccharides. Because the enzyme is particularly rich in neutrophil and macrophage lysosomes, its activity is very low in normal CSF. However, CSF lysozyme activity is significantly increased in patients with both bacterial

and tuberculous meningitis. Thus, discriminant analysis demonstrated that 97% of patients with bacterial meningitis had increased lysozyme levels (Ribeiro, 1992). Others found that patients with tuberculous meningitis had significantly higher CSF lysozyme levels than those with bacterial meningitis, partially treated bacterial meningitis, and controls (Mishra, 2003). The diagnostic sensitivity and specificity for tuberculous meningitis were 93.7% and 84.1%, respectively. Increased levels are also present in cerebral atrophy, various CNS tumors, multiple sclerosis, intracranial hemorrhage, and epilepsy (Kjeldsberg, 1993).

Ammonia, Amines, and Amino Acids

CSF ammonia levels vary from 30%–50% of blood values. Elevated levels are generally proportional to the degree of existing hepatic encephalopathy but are difficult to quantify. Moreover, because hepatic encephalopathy generally correlates with blood ammonia levels, the measurement of CSF ammonia has little, if any, clinical value. However, cerebral glutamine, synthesized from ammonia and glutamic acid, serves as the means for CNS ammonia removal. Thus, CSF glutamine levels reflect the concentration of brain ammonia. Glutamine reference intervals are method dependent; the upper reference level is about 20 mg/dL. Values over 35 mg/dL are usually associated with hepatic encephalopathy (Fishman, 1992). Elevated CSF glutamine levels have also been reported in patients with encephalopathy secondary to hypercapnia and sepsis (Mizock, 1989).

A major etiologic theory of schizophrenia involves dopamine. The cornerstone for this theory is the fact that neuroleptic drugs that block dopamine receptors are effective in the treatment of this disorder. Thus, it has been reported that CSF levels of homovanillic acid (HVA), a metabolite of the biogenic amines, are related to the severity of schizophrenic psychosis (Maas, 1997). However, HVA concentration varied as a function of psychosis rather than being related to the diagnosis of schizophrenia per se. Others reported decreased CSF levels of 5-hydroxyindoleacetic acid, a metabolite of serotonin, in schizophrenic patients with suicidal behavior (Cooper, 1992). This report adds support for a possible relationship between suicide and CNS serotonin metabolism.

Although free CSF amino acids are relatively high in infants younger than 30 days of age, their concentration is further increased in those with febrile convulsions and bacterial meningitis. γ -Aminobutyric acid (GABA), a major inhibitory brain transmitter, is significantly decreased in basal ganglia neurons, and is very low or undetectable in the CSF of patients with Alzheimer's disease and Huntington's disease (Achar, 1976; Dubowitz, 1992). In addition, CSF GABA was detected in all patients with migraine attacks, but not in those with tension headaches or in the control group without headaches (Welch, 1975). Conversely, infants with startle disease, a rare inherited autosomal dominant disorder characterized by seizures or the so-called **stiff baby syndrome**, have significantly decreased CSF GABA levels (Dubowitz, 1992; Berthier, 1994).

Electrolytes and Acid-Base Balance

There are no clinically useful indications for the measurement of CSF sodium, potassium, chloride, calcium, or magnesium. Measurements of CSF pH, partial pressure of carbon dioxide ($p\text{CO}_2$), and bicarbonate are also not practical for patient care (Fishman, 1992).

Tumor Markers

Numerous studies have shown that various tumor markers are increased in the CSF of patients with both primary and metastatic tumors. However,

the value of most of these tests in routine clinical practice has not been established.

Carcinoembryonic Antigen

Carcinoembryonic antigen (CEA) is an oncofetal protein produced by a variety of carcinomas. An early study found increased CEA levels in 44% of patients with metastatic brain tumors (Suzuki, 1980). Others reported that CSF levels of CEA have a sensitivity of only about 31%, although the specificity is about 90% for detecting metastatic carcinoma of the leptomeninges (Klee, 1986; Twijnstra, 1986). Recently, CSF levels of CEA in patients with benign, primary malignant, and metastatic brain tumors were 0.31 ng/mL, 0.92 ng/mL, and 6.3 ng/mL, respectively (Batabyal, 2003).

Other oncofetal proteins include **human chorionic gonadotropin** (hCG), produced by choriocarcinoma and malignant germ cell tumors with a trophoblastic component, and **α -fetoprotein**, a glycoprotein produced by yolk sac elements of germ cell tumors. Results of a recent study revealed that both β -hCG and α -fetoprotein may be useful in the diagnosis and monitoring of the response to therapy in patients with CNS germ cell tumors (Seregni, 2002).

Elevation of CSF **ferritin** is a sensitive indicator of CNS malignancy but has very low specificity because it is also increased in patients with inflammatory neurologic diseases (Zandman-Goddard, 1986).

MICROBIOLOGICAL EXAMINATION

A thorough and prompt examination of cerebrospinal fluid is essential for the diagnosis of CNS infection because an inaccurate or delayed report may result in significant mortality or morbidity. Although changes in opening pressure, total cell and differential counts, total protein, and glucose suggest an infectious origin (Table 29-13), Gram stain and culture are critical for a definitive diagnosis.

Bacterial Meningitis

The most common agents of bacterial meningitis are group B streptococcus (neonates), *Neisseria meningitidis* (3 months and older) (Fig. 29-9), *Streptococcus pneumoniae* (3 months and older), *Escherichia coli* and other gram-negative bacilli (newborn–1 month), *Haemophilus influenzae* (3 months–18 years), and *Listeria monocytogenes* (neonates, elderly, alcoholics, and immunosuppressed) (Graves, 1989; Wenger, 1990). *H. influenzae*, once

TABLE 29-13

Typical Lumbar CSF Findings in Meningitis

Test	Bacterial	Viral	Fungal	Tuberculous
Opening pressure	Elevated	Usually normal	Variable	Variable
Leukocyte count	$\geq 1000/\mu\text{L}$	$< 100/\mu\text{L}$	Variable	Variable
Cell differential	Mainly neutrophils*	Mainly lymphocytes†	Mainly lymphocytes	Mainly lymphocytes
Protein	Mild–marked increase	Normal–mild increase	Increased	Increased
Glucose	Usually ≤ 40 mg/dL	Normal	Decreased	Decreased: may be < 45 mg/dL
CSF/serum glucose ratio	Normal–marked decrease	Usually normal	Low	Low
Lactic acid	Mild–marked increase	Normal–mild increase	Mild–moderate increase	Mild–moderate increase

Data from Body, 1987; Tang, 1988; Arevalo, 1989; Fishman, 1992; Wubbel, 1998; Zunt, 1999.
CSF, Cerebrospinal fluid.

*Lymphocytosis present in about 10% of cases.

†Neutrophils may predominate early in disease.

the most common bacterial cause of meningitis in young children, has decreased dramatically from widespread use of *H. influenzae* type b vaccine. Cerebrospinal fluid shunts, head trauma, and neurosurgery place patients at risk for CNS infections from *Staphylococcus* species, gram-negative bacilli, and *Propionibacterium* species.

The Gram stain remains an accurate, rapid method by which to diagnose CNS infection. All specimens should be concentrated by centrifugation before Gram stain and culture. Depending upon the type of infecting microorganism and its concentration in the cerebrospinal fluid, Gram stain sensitivity ranges from 60%–90%, with the greatest sensitivity corresponding to higher concentrations of bacteria (about 10^5 colony-forming units/mL). For example, the sensitivity of the Gram stain for detecting *Listeria monocytogenes* and gram-negative bacilli is 50% or less (Greenlee, 1990). For patients with many polymorphonuclear leukocytes but no organisms seen on Gram stain, the more sensitive acridine orange stain may be helpful. Cultures have a sensitivity of 80%–90%, but are about 30% less sensitive in partially treated cases (Greenlee, 1990).

Although standard culture-based methods remain the mainstay for diagnosis, the BinaxNOW *Streptococcus pneumoniae* antigen test, an immunochromatographic membrane assay that detects the presence of the C polysaccharide cell wall antigen common to all pneumococcal serotypes, has proved to be a valuable tool for the rapid diagnosis of pneumococcal meningitis from CSF. Latex agglutination bacterial antigen tests performed on CSF to detect *H. influenzae*, *N. meningitidis*, *S. pneumoniae*, and β -hemolytic group B streptococci historically were used as adjuncts to Gram stain and culture; however, the sensitivity is approximately the same as the Gram stain, and a negative test does not rule out the diagnosis of bacterial meningitis. Perhaps the best application of latex agglutination antigen tests is seen in partially treated, community-acquired meningitis that is negative for microorganisms by Gram stain (Perkins, 1995; Wilson, 1997).

The polymerase chain reaction (PCR) and sequencing of 16S ribosomal RNA in CSF have been shown to be very useful in the diagnosis of bacterial meningitis (Schuurman, 2004). Compared with bacterial culture, the assay shows a sensitivity of 86%, a specificity of 97%, a positive predictive value of 80%, and a negative predictive value of 98%. Nucleic acid amplification tests may also be helpful in patients already receiving antimicrobial therapy and in detecting more fastidious pathogens such as *N. meningitidis* (Porritt, 2000; Seward, 2000; Baethgen, 2003).

Spirochetal Meningitis

The incidence of neurosyphilis has increased in recent years, primarily in patients with HIV infection. In one report, 44% of patients with neurosyphilis had AIDS (Flood, 1998). Unfortunately, the remaining patients, who may have had HIV infection without AIDS, were not studied. The diagnosis of CNS infection in patients with syphilis relies primarily on CSF parameters and serologic testing, although molecular DNA testing may now represent a new approach. Abnormalities in CSF protein and cell counts are common in syphilitic meningitis, but are nonspecific. CSF serologic testing to diagnose neurosyphilis is difficult. The standard nontreponemal test performed on CSF is the Venereal Disease Research Laboratory (VDRL). If few erythrocytes are contaminating the CSF, the VDRL specificity is high, but its sensitivity is only 50%–60% (Davis, 1989). Treponemal tests, such as the treponemal antibody absorption (FTA-ABS), are both sensitive and specific for syphilis; however, their use in CSF for neurosyphilis is controversial. The CSF FTA-ABS is highly sensitive, but false-positive results may occur. Moreover, in the absence of CSF abnormalities or clinical suspicion, it should not be used as a screening test. Thus, the following generalizations have been proposed (Davis, 1989): (1) A nonreactive serum FTA-ABS test rules out neurosyphilis; (2) a reactive serum FTA-ABS test with a nonreactive CSF FTA-ABS test essentially rules out neurosyphilis; (3) a reactive CSF VDRL test makes a diagnosis of neurosyphilis likely; and (4) a reactive CSF FTA-ABS test may indicate active neurosyphilis, asymptomatic neurosyphilis, treated neurosyphilis, or a false-positive reaction. Recent studies have demonstrated the potential utility of a PCR-based assay as a sensitive and specific means of diagnosing neurosyphilis (Leslie, 2007).

Diagnosis of Lyme meningitis represents another challenge for the laboratory. The mainstay of diagnosis remains serologic analysis performed on a serum specimen, using an enzyme-linked immunosorbent assay (ELISA)-based screening assay followed by confirmation with Western blot. PCR-based analysis may be performed on CSF specimens; however, the sensitivity of this approach is low, particularly in patients with chronic neuroborreliosis (Steere, 2010).

Viral Meningitis

Enteroviruses (echoviruses, coxsackieviruses, polioviruses) and arboviruses are responsible for the majority of meningitis cases; a seasonal peak in spring to autumn has been noted for these agents. As an example, echoviruses 9 (E9) and 30 (E30) were found to be mainly responsible for an increase in cases of aseptic meningitis (Morbidity and Mortality Weekly Report, 2003). Most patients present with a CSF pleocytosis, and although neutrophils may be observed early in the infection, patients soon develop a predominance of lymphocytes.

Before molecular diagnostic testing, viral meningitis was a diagnosis of exclusion because the sensitivity of viral cultures can be low. Thus, in an early study, a specific etiologic diagnosis by viral cultures varied from 72% for enteroviruses to 5% for herpes simplex virus (HSV) (Marton, 1986).

Reverse transcriptase polymerase chain reaction (RT-PCR) is significantly more sensitive than cell culture (Dumler, 1999; Hausfater, 2004). Arguably, it has evolved as the “gold standard” for the diagnosis of viral meningitis secondary to enterovirus, herpes simplex virus, cytomegalovirus, varicella zoster, and JC virus. The use of RT-PCR may result in significant cost savings by shortening hospital stays and eliminating unnecessary diagnostic and therapeutic interventions (Ramers, 2000). For patients with arbovirus-associated meningitis, acute and convalescent serologic testing in serum remains the cornerstone for diagnosis, with CSF testing a possible adjunct. Presumptive diagnosis of West Nile viral meningitis may be made on a CSF specimen using an IgM antibody-capture ELISA assay. PCR testing for West Nile virus and other arboviruses may also be done on CSF specimens; however, these assays have low sensitivity because of the short-lived nature of the viremia in these diseases and are not recommended for routine use (Vaughn, 2010).

PCR amplification of HSV DNA has revolutionized the testing for HSV infection in CSF and has replaced brain biopsy as the primary method used in the early diagnosis of HSV meningoencephalitis (Tunkel, 2008). False negatives might occur in very early infections and with bloody taps, necessitating analysis of a second CSF specimen (Tyler, 2004).

Human Immunodeficiency Virus

A wide variety of CSF abnormalities may be found in HIV-positive patients with or without neurologic disease, including lymphocytic pleocytosis, elevated IgG indexes, and oligoclonal bands (Chalmers, 1990; Hall, 1992). Identifying opportunistic infection is the most important indication for examining the CSF. Serious fungal infections may exist in the presence of few or no CSF parameter abnormalities.

Fungal Meningitis

Cryptococcus neoformans is the most frequently isolated fungal pathogen from CSF. India ink or nigrosin stains for cryptococcus capsular halos have a sensitivity of about 25%, increasing to 53% with multiple lumbar punctures, and to greater than 90% in untreated HIV-infected patients (Marton, 1986). Detection of cryptococcal antigen from sera or CSF using latex agglutination has higher sensitivity, ranging from 60%–95%. False-negatives due to a prozone effect or low concentration of polysaccharide antigen may occur. Early disease, intraparenchymal infection, infection with nonencapsulated *C. neoformans* variants, and immune complexes (corrected with pronase treatment) may also produce false-negatives. Conversely, sera or CSF from patients with rheumatoid factor or *Trichosporon asahii* infection may be falsely positive. If clinical suspicion for dimorphic or filamentous fungi is high, large volumes of CSF (approximately 15–20 mL) are optimal for culture to improve the recovery of fungal organisms.

Tuberculous Meningitis

Abnormal CSF with elevated protein and lymphocytic predominance are the hallmark features of tuberculous meningitis. The sensitivity of CSF acid-fast stains for the diagnosis of tuberculous meningitis is highly variable, ranging from 10%–12% (Greenlee, 1990) to greater than 50% (Thwaites, 2004). Large volumes of CSF, often obtained from multiple lumbar punctures with the use of concentration techniques, are recommended to improve the sensitivity of both acid-fast stain and culture (Marton, 1986).

PCR nucleic acid amplification for detecting *Mycobacterium tuberculosis* DNA-specific sequences shows great promise in the rapid and accurate diagnosis of tuberculous meningitis (Lin, 1995; Desai, 2002). However, a negative PCR result does not exclude the diagnosis of tuberculous

meningitis. Indeed, if high clinical suspicion remains, empirical therapy should be initiated.

DOT ELISA has been standardized to detect tuberculosis antigens and antibodies against *M. tuberculosis* in CSF. Using this technique, a positive reaction was present in 86% of cases with suspected tuberculous meningitis (Kashyap, 2003). Only 5% of patients with other disorders, mainly pyogenic meningitis, were positive.

Other tests have been shown to be useful in some cases of tuberculous meningitis. ADA levels are significantly higher in tuberculous meningitis than in other types of meningitis and CNS disorders (Pettersson, 1991; Choi, 2002), although the degree of increase indicative of tuberculous infection varies depending on the specific assay used.

Primary Amebic Meningoencephalitis

This rare disease is caused by the free-living ameba *Naegleria fowleri*, *Acanthamoeba* species, and *Balamuthia mandrillaris*. *Naegleria* and *Balamuthia* are more likely to cause an acute inflammatory response with a neutrophilic pleocytosis, a decreased glucose level, an elevated protein concentration, and the presence of erythrocytes. Gram stain is always negative. *Acanthamoeba* more often produces a granulomatous meningitis. Motile *Naegleria* trophozoites may be visualized by light or phase-contrast microscopy in direct wet mounts, allowing rapid diagnosis. Intact and degenerating organisms may be identified on Wright's- or Giemsa-stained cytospins but must be distinguished from macrophages (dos Santos, 1970; Benson, 1985). Acridine orange stain is useful in differentiating ameba (brick red) from leukocytes (bright green).

SYNOVIAL FLUID

Synovium refers to the tissue lining synovial tendon sheaths, bursae, and diarthrodial joints, except for the articular surface. It is composed of one to three cell layers that form a discontinuous surface overlying fatty, fibrous, or periosteal joint tissue.

Synovial fluid (synovia, SF) is an imperfect ultrafiltrate of blood plasma combined with hyaluronic acid produced by the synovial cells. Small ions and molecules (e.g., Na^+ , K^+ , glucose, urea) readily pass into the joint space and therefore are similar in concentration to plasma; large molecules are absent or present in trace amounts. Resorption of synovial fluid is by the lymphatics and is not size dependent. SF acts as a lubricant and adhesive and provides nutrients for the avascular articular cartilage.

Examination of the synovial fluid is essential to distinguish infectious from noninfectious arthritis. Results from gross and microscopic examination of synovial fluid have traditionally been divided into "reaction types," as depicted in Table 29-14. These groupings are largely descriptive, and considerable overlap between them is evident. Except for Gram stain, culture, and crystal examination, synovial fluid parameters can be nonspecific and must be integrated into the clinical context.

Noninflammatory effusions (Group I) typically have leukocyte counts less than 3000/ μL , with a minority of neutrophils. Osteoarthritis, traumatic arthritis, neuropathic osteoarthropathy, pigmented villonodular synovitis, and early rheumatic fever usually present with little inflammatory response. Early rheumatoid arthritis, early bacterial infection, and viral arthritis may also present as noninflammatory effusions.

Inflammatory effusions (Group II) have leukocyte counts between 3000 and 75,000, with neutrophils accounting for more than 50% of the population. Rheumatoid arthritis, systemic lupus erythematosus (SLE), Reiter's syndrome, rheumatic fever, acute crystal-induced arthritis, arthritis associated with inflammatory bowel disease, psoriatic arthritis, and fat droplet synovitis are examples of this reaction group.

Purulent (infectious) effusions (Group III) typically have leukocyte counts greater than 50,000, of which 90% or more are neutrophils. Bacterial, fungal, and tuberculous joint infections constitute this group.

Hemorrhagic effusions (Group IV) may be seen in association with traumatic arthritis, pigmented villonodular synovitis, synovial hemangioma, neuropathic osteoarthropathy, joint prostheses, and hematologic disorders (hemophilia, thrombocytopenia, anticoagulant therapy, sickle cell disease or trait, myeloproliferative syndrome).

SPECIMEN COLLECTION

Joint fluid aspiration (arthrocentesis) should be confined to patients with an undiagnosed effusion or a significant clinical change related to a known effusion (Pal, 1999). It should be performed by an experienced operator using good sterile technique. Caution is necessary to avoid aspirating a sterile joint in someone with bacteremia or through a cutaneous or peri-articular soft tissue infection into a sterile joint. Large joints such as the knee normally contain no more than 4.0 mL of synovial fluid, so small sample size is common unless an effusion is present.

Synovial fluid must be collected with sterile, disposable needles and plastic syringes to avoid contamination by birefringent particulates. The syringe may be heparinized with 25 U of sodium heparin/mL of SF in routine arthrocentesis. Oxalate, lithium heparin, and powdered ethylenediaminetetraacetic acid (EDTA) anticoagulants should be avoided because they form crystal artifacts that may be misleading during the microscopic examination. Before aspiration, turn or manipulate the joint to ensure mixing of its contents.

Ideally, the specimen should be separated into three parts: 3–10 mL into a sterile heparinized tube or syringe for microbiological studies; 2–5 mL in an anticoagulant tube (sodium heparin or liquid EDTA) for microscopic examination; and about 5 mL into a plain (no anticoagulant) tube for chemical analysis (normal synovial fluid does not clot because fibrinogen is absent). Heparin concentrations greater than 125 U/mL have an inhibitory effect on some pathogenic bacteria (Rosett, 1980). Specimens for culture, therefore, should be at least 1–2 mL in volume if they are submitted in green-top heparin tubes (Becton Dickinson, Rutherford, N.J.) containing 143 U/tube of heparin, or submitted in recapped syringes after removal of the needle and excess air.

Dry taps may still have fluid within the needle, which may be sufficient for the most critical tests. Such specimens should be submitted with the needle still on the syringe and its tip stuck into a sterile cork. Good communication with the laboratory is crucial to the appropriate processing of such specimens.

RECOMMENDED TESTS

Laboratory examination of synovial fluid is of major importance in the differential diagnosis of joint disease, especially in crystal-induced

TABLE 29-14

Synovial Fluid Findings by Disease Category

Finding	Normal	CATEGORY			
		Group I noninflammatory	Group II inflammatory	Group III infectious	Group IV hemorrhagic
Clarity	Transparent	Transparent	Transparent/opaque	Opaque	Opaque
Color	Clear to pale yellow	Xanthochromic	Xanthochromic to white/bloody	White	Red-brown or xanthochromic
WBCs/mL	0–150	<3000	3000–75,000	50,000–200,000	50–10,000
PMNs, %	<25	<30	>50	>90	<50
RBCs	No	No	No	Yes	Yes
Glucose (blood/SF difference, mg/dL)	0–10 (0–0.56 mmol/L)	0–10 (0–0.56 mmol/L)	0–40 (0–2.2 mmol/L)	20–100 (1.11–5.5 mmol/L)	0–20 (0–1.11 mmol/L)

TABLE 29-15

Recommended Synovial Fluid Tests

Routine tests

- Gross examination (color, clarity)
- Total and differential leukocyte counts
- Gram stain and bacterial culture (aerobic and anaerobic)
- Crystal examination with polarizing microscope and compensator

Useful tests in certain circumstances

- Fungal and acid-fast stains and cultures
- PCR for bacterial and mycobacterial DNA
- Serum–synovial fluid glucose differential
- Lactate and other organic acids
- Complement
- Enzymes
- Uric acid

Modified from Kjeldsberg CR, Knight JA. Body fluids: laboratory examination of amniotic, cerebrospinal, seminal, serous and synovial fluids. 3rd ed. Chicago: © American Society for Clinical Pathology; 1993, with permission.
DNA, Deoxyribonucleic acid; PCR, polymerase chain reaction.

and infectious arthritis. When either is suspected, arthrocentesis and a systematic examination of the synovial fluid are imperative, and when examination is carried out properly, it is usually diagnostic. In other joint diseases, a specific diagnosis may not be possible. Nevertheless, fluid examination is still important, if only to rule out infectious arthritis, which is a critical diagnosis to make in that a joint may be irreversibly damaged within a couple of days if not properly treated. This is especially true when *Staphylococcus aureus* is the infectious organism. Therefore, routine tests should be directed toward the diagnosis of these two disorders (Table 29-15). Although other tests are not of practical value for routine use, they may provide important diagnostic information under certain circumstances.

It is critical that these tests be performed well because they can provide highly specific diagnostic information. However, a major problem in the laboratory examination of synovial fluid is that, in contrast to CSF and amniotic fluid, in most laboratories no consensus exists as to what constitutes a “routine” analysis (Hasselbacher, 1987). Moreover, quality performance is not consistent, in part because of the fact that the average laboratory examines only one to two synovial fluids each month (Hasselbacher, 1987; Rabinovitch, 1994).

GROSS EXAMINATION

Total volume should be recorded at the bedside, especially if the sample is to be divided for submission to different laboratory sections.

Color should be evaluated in a clear glass tube against a white background. Normal SF is colorless but is often pale yellow because of diapedesis of a few RBCs associated with even mild trauma. Noninflammatory and inflammatory disorders are usually seen as straw- to yellow-colored (xanthochromia). Septic fluid may be yellow, brown, or green depending on the chromogens produced by the offending organism and the host response, including the presence of WBCs and RBCs.

A **traumatic tap** produces an uneven distribution of blood during arthrocentesis or streaking in the syringe. Although pale yellow xanthochromia is difficult to distinguish from normal, a red-brown color following centrifugation is good evidence of pathologic hemarthrosis.

Clarity relates to the number and type of particles within the synovia. Because normal SF is transparent, newsprint is easily read through the tube. Although translucent fluid obscures details, black and white areas can be distinguished, but opaque fluid completely obscures the background.

Leukocytes are most commonly responsible for changes in clarity. However, very large numbers of crystals may produce an opaque, milky opalescent fluid without leukocytes. A shimmering, oily-appearing specimen suggests an abundance of cholesterol crystals, which may grossly resemble pus.

Increased turbidity is less often due to concentrations of fibrin, free-floating **rice bodies** (fragments of degenerating proliferative synovial cells or microinfarcted synovium), metal and plastic particles from patients with joint prostheses, or cartilage fragments in osteoarthritis. A **ground pepper** appearance from pigmented cartilage fragments may be the result of a metabolic disorder (i.e., ochronosis).

Figure 29-10 Lupus erythematosus cell in the synovial fluid from a patient with systemic lupus erythematosus.

MICROSCOPIC EXAMINATION

Total Cell Count

Total leukocyte counts should be performed promptly to avoid degenerative cell loss, which begins as soon as 1 hour following arthrocentesis. Tubes must be inverted before sampling to ensure uniform mixing. Cell counts are usually performed in a standard hemocytometer. Automated cell counters may be used, but their use risks clogging the machine aperture or obtaining spuriously high cell counts from non-WBC particles (e.g., crystals, fat globules), especially in multichannel machines. Pretreatment of highly viscous synovial fluid samples with hyaluronidase improves automated cell counting in these samples (Aulesa, 2003). A wet-prep slide count of 0–2 leukocytes per high-power field (hpf) (averaged over 10 fields) predicts fewer than 1300 WBCs by cell count (Clayburne, 1992). Leukocyte counts over 50,000/ μ L require dilution, which should be done with saline, not acetic acid, to avoid mucin clot formation and cell clumping.

Leukocyte counts greater than 10,000/ μ L, and often greater than 50,000/ μ L, are characteristic of crystal-induced arthritis (e.g., gout, pseudogout), chronic inflammatory arthritis (e.g., rheumatoid arthritis, systemic lupus erythematosus, ankylosing spondylitis), and septic arthritis (Kjeldsberg, 1993). Osteoarthritis, osteochondritis dissecans, trauma, and synovialoma usually have total WBC counts less than 10,000/ μ L.

Erythrocytes should be routinely counted unless it is an obvious traumatic tap. If a large number of red cells interferes with the leukocyte count, they may be lysed by dilution with 0.3 normal saline or 1% saponin in saline.

The upper reference level for SF leukocytes is 150–200/ μ L (Kjeldsberg, 1993). Elevated cell counts are used to help divide findings into different disease categories but are nonspecific for any particular disease because of extensive overlap.

Differential Leukocyte Count

Cytospin preparations are preferred over smears from centrifuged SF because the cell morphology is significantly better preserved. Treatment with hyaluronidase may be necessary to produce thin smears in viscous specimens. Automated leukocyte differential counts utilizing flow cytometers may also be reliably performed on synovial fluid samples (Aulesa, 2003); however, morphologic examination is still essential for identification of crystals, lipid droplets, etc.

Neutrophils normally account for about 20% of SF leukocytes. Neutrophils generally exceed 50% in urate gout, pseudogout, and rheumatoid arthritis (RA); they most often exceed 75% in acute bacterial arthritis. When 75% is used as a cutoff, the sensitivity for an inflammatory process is about 75% and the specificity is 92% (Shmerling, 1990). These cells frequently exhibit degenerative changes and may contain bacteria, crystals, lipid droplets, vacuoles, or dark blue to black granular inclusions (ragocytes, RA cells), which are similar to the toxic granulation occasionally seen in peripheral blood smears. The presence of ragocytes in patients with RA may indicate a poorer outcome (Davis, 1988).

Lupus erythematosus (LE) cells, not uncommonly present in patients with lupus arthritis, are most often neutrophils that have phagocytosed the nuclei of degenerating cells (Fig. 29-10). However, LE cells are not pathognomonic for SLE because they have also been identified in the synovial fluid of RA patients (Hunder, 1970).

Lymphocytes, normally constituting about 15% of SF cells, are prominent in early RA and other collagen disorders, as well as in chronic infections. Reactive forms, including immunoblasts, are occasionally present.

Monocytes and **macrophages** are the most common cells present in normal SF, accounting for approximately 65% of the cell count.

Figure 29-11 Reiter's cells in the synovial fluid from a patient with Reiter's syndrome.

Monocytosis may be self-limited in viral arthritis or serum sickness, or more chronic in SLE or undifferentiated connective tissue disorders. Reiter's cells, originally believed to be specific for Reiter's syndrome, are macrophages containing degenerating neutrophils (Fig. 29-11).

Eosinophilia, defined as more than 2% of the leukocyte count, has been reported in rheumatoid arthritis, rheumatic fever, metastatic carcinoma, Lyme disease, parasitic infection, chronic urticaria, and angioedema, and following arthrography (allergic reaction to dye) and irradiation (Podell, 1980; Kay, 1988).

Synovial cells have no pathologic significance. They appear similar to mesothelial cells and may be difficult to distinguish from monocytes and macrophages.

Lipid bodies are associated with trauma, aseptic necrosis, and RA. These droplets often form Maltese crosses under polarized light, can be associated with a leukocyte response, and may cause spurious elevations of the automated WBC count (Wise, 1987).

Crystal Examination

Crystals in synovial fluid lead to acute inflammation with increased WBC counts and a neutrophil-predominant infiltrate. Crystal identification, especially if intracellularly in neutrophils or macrophages, is pathognomonic for a crystal-induced arthritis (Judkins, 1997).

Gout refers to the process of crystal deposition in articular tissue. Common usage typically implies urate gout, and an inflammatory response to crystal deposition is referred to as gouty arthritis. The most common types of endogenous crystals responsible for gouty arthritis are **monosodium urate monohydrate** (urate gout), **calcium pyrophosphate dihydrate** (pyrophosphate gout, chondrocalcinosis, or "pseudogout"), apatite and other **basic calcium phosphates** (BCP; apatite gout), **calcium oxalate** (oxalate gout), and **lipids** (lipid gout).

Except for BCP, all of the above crystals can be detected by polarized light microscopy. A high-quality polarizing microscope with a first-order red plate compensator should be used. The **polarizer** filter is placed directly above the light source. The **analyzer** (another polarizing filter) is placed between the specimen slide and the microscope oculars, oriented 90 degrees from the polarizer to produce a dark background. The **compensator** is placed between the polarizer and the analyzer, usually oriented 45 degrees (halfway) between the planes of the two polarizing filters.

Initial examination should be performed on a wet preparation using polarized light. Phase-contrast microscopy enhances crystal detection. The slide and coverslip must be cleaned and carefully dried immediately before use to avoid birefringent dust particulate artifacts. The coverslip edges are sealed with nail polish, which retards but does not prevent evaporation. The coverslip edge is used to find the proper plane of focus. However, crystals in this location should be ignored because they are most likely artifacts. Most crystals are scanned with a 10× objective and are evaluated with at least a 40× objective, concentrating especially on cellular areas. Complete examination requires 100× oil immersion, however, because apparently negative fluids on scanning may contain a large population of small crystals (Gatter, 1991). Aligning the crystals' orientation to the compensator by rotating the microscope stage or the compensator facilitates recognition and identification. Crystal morphology, the extinction angle, strength, and signs of any birefringence (i.e., the ability to refract light and split the incident light into two rays: a fast ray and a slow ray) are noted. Nevertheless, the sensitivity and specificity of polarized microscopy for crystals are only 78% and 79%, respectively, for monosodium urate (Hasselbacher, 1987), and 12% and 67% for calcium pyrophosphate dihydrate (McGill, 1991). However, repeat examination following

Figure 29-12 Monosodium urate crystals under polarized light from a patient with urate gout.

Figure 29-13 Monosodium urate crystals in synovial fluid. Compensated polarized light. (From Kjeldsberg CR, Knight JA. *Body fluids: laboratory examination of amniotic, cerebrospinal, seminal, serous and synovial fluids*. 3rd ed. Chicago: © American Society for Clinical Pathology; 1993, with permission.)

24 hours of refrigeration at 4° C may result in a significant increase in the number of crystal-positive fluids (Yuan, 2003).

The Diff-Quik staining method may be a reliable alternative to polarized microscopy. Overall specificity, sensitivity, and accuracy were, respectively, 87.5%, 94.4%, and 91.9%. The overall positive predictive value was 92.7%; the negative predictive value was 90.3% (Selvi, 2001). Moreover, other more sophisticated and reliable methods, such as X-ray crystallography and Fourier transform infrared spectroscopy, have been described for identifying and characterizing crystals in biological specimens (Rosenthal, 2001).

Monosodium urate (MSU) crystals appear as needle-shaped rods 5–20 µm long, but they may be only 1–2 µm in length or, rarely, may appear as rounded spherulites. They are strongly birefringent (Fig. 29-12): Yellow when oriented parallel to the compensator and blue with perpendicular orientation (negative birefringence or elongation) (Fig. 29-13). A control slide of MSU crystals should always be used for comparison. Alternatively, betamethasone, a steroid that appears as a strongly negative birefringent rod, can be used to prepare a reference slide for the polarizing microscope (Judkins, 1997).

MSU crystals are found in 90% of acute urate gout and in about 75% of patients between attacks. Intracellular MSU crystals are characteristic of acute urate gout. They may occasionally be observed as a result of inflammation in septic arthritis (McCarty, 1988).

Calcium pyrophosphate dihydrate (CPPD) crystals are found in a group of conditions collectively known as CPPD crystal deposition disease. These crystals appear as rhomboids, rods, or rectangles 1–20 µm in length. CPPD crystals are weakly birefringent with positive elongation (blue when aligned with the compensator axis; Fig. 29-14). Many are too small to polarize the light, making them difficult to detect without phase-contrast microscopy. Extinction is incomplete and occurs between 20 and 30 degrees from the angle of the polarizer and analyzer (oblique or inclined extinction).

CPPD crystals are associated with degenerative arthritis and are seen in arthritides associated with hypomagnesemia, hemochromatosis, hyperparathyroidism, and hypothyroidism (Jones, 1992).

Calcium hydroxyapatite and the other BCP crystals are typically too small and nonbirefringent (isotropic) to see with light microscopy, unless they are clumped into 1- to 50-µm spherical microaggregates. **Alizarin red S dye** may be used to stain these and other calcium-containing crystals (Lazcano, 1993). At present, identification of BCP crystals is not important for diagnosis or prognosis, or as a guide in treatment.

Figure 29-14 Calcium pyrophosphate dihydrate crystals in synovial fluid from a patient with pseudogout. Compensated polarized light. (From Kjeldsberg CR, Knight JA. *Body fluids: laboratory examination of amniotic, cerebrospinal, seminal, serous and synovial fluids*. 3rd ed. Chicago: © American Society for Clinical Pathology; 1993, with permission.)

Figure 29-15 Cholesterol crystals in synovial fluid. Polarized light.

Calcium oxalate dihydrate crystals are 5- to 30- μ m bipyramidal octahedral “envelopes” with variable birefringence and positive elongation. They are seen in arthropathy associated with chronic renal dialysis and primary oxalosis, a rare inborn error of metabolism. The monohydrate form is birefringent but nondescript in shape.

Lipid crystals are 1- to 20- μ m spheres with a Maltese cross appearance and positive birefringence under compensated polarized light. They have been implicated as a cause of acute arthritis (McCarty, 1988).

Crystalline corticosteroids from intraarticular injection may have an appearance similar to MSU or CPPD crystals and persist up to a month following injection. Most often, they have blunt, jagged edges without clear crystal structure because they are prepared by grinding up larger crystalline forms. Triamcinolone hexacetonide is negatively birefringent, but most others show positive birefringence.

Cholesterol crystals typically appear as irregular birefringent plates, often with notched corners (Fig. 29-15). In chronic effusions (e.g., tuberculous arthritis, RA, SLE), needle- or rhomboid-shaped crystals similar to MSU or CPPD may be present (Ettlinger, 1979). Very small (1–5 microns) irregular, rod- and needle-shaped cholesterol crystals have been identified by X-ray diffraction analysis and by ultrastructural studies in osteoarthritis effusions (Fam, 1981). Cholesterol crystals are ethanol and ether soluble and are not phagocytosed by leukocytes. Moreover, if the crystals are cholesterol, quantitative analysis should show that the SF cholesterol level exceeds the plasma level.

Glove powder introduced during joint surgery appears as round, strongly birefringent particles 5–30 μ m in diameter with a Maltese cross appearance when polarized.

A variety of other crystals or particulates may be present in synovial fluid. These include monoclonal Ig crystals or cryoglobulins, Charcot-Leyden crystals, amyloid fragments, cartilage fragments, collagen fibrils and fibrin strands, hematoxin crystals from prior hemorrhage, crystals from certain anticoagulants, nail polish, prosthetic fragments, and dust particles (Gatter, 1991).

CHEMICAL ANALYSIS

Chemical analyses of SF generally offer only supportive information to the routine tests. High viscosity may be remedied by dilution with normal saline, sonication, or hyaluronidase treatment. Reference intervals for the more important chemical analytes are shown in Table 29-16.

TABLE 29-16

Reference Intervals for Synovial Fluid Constituents

Constituent	Synovial fluid	Plasma
Total protein	1–3 g/dL	6–8 g/dL
Albumin	55%–70%	50%–65%
α_1 -Globulin	6%–8%	3%–5%
α_2 -Globulin	5%–7%	7%–13%
β -Globulin	8%–10%	8%–14%
γ -Globulin	10%–14%	12%–22%
Hyaluronic acid	0.3–0.4 g/dL	
Glucose	70–110 mg/dL	70–110 mg/dL
Uric acid	2–8 mg/dL	2–8 mg/dL
Lactate	9–29 mg/dL	9–29 mg/dL

Modified from Kjeldsberg CR, Knight JA. *Body fluids: laboratory examination of amniotic, cerebrospinal, seminal, serous and synovial fluids*. 3rd ed. Chicago: © American Society for Clinical Pathology; 1993, with permission.

Mucin Clot Test

Addition of acetic acid to SF precipitates hyaluronate into a mucin clot, which may be graded as good, fair, or poor. A fair to poor mucin clot test reflects dilution and depolymerization of hyaluronic acid—a nonspecific finding of several inflammatory arthritides. Although of historic interest, the mucin clot test has minimal clinical utility (Baker, 1991).

Glucose

Proper interpretation of SF glucose values requires comparison with serum levels, ideally preceded by a fast of 8 hours to allow glucose to equilibrate across the synovial membrane. The serum–synovia differential is less than 10 mg/dL in normal and many noninflammatory conditions. In septic arthritis, this difference ranges from 20–60 mg/dL but overlaps significantly with other inflammatory conditions, thereby limiting its clinical usefulness. When a cutoff value of 75 mg/dL is used, the sensitivity of low glucose for detecting an inflammatory joint disease is only 20%; the specificity is 84% (Shmerling, 1990).

In vitro glycolysis by large numbers of leukocytes may falsely reduce SF glucose values unless testing is performed within 1 hour of collection. However, tubes containing sodium fluoride, an inhibitor of glycolysis, prevent the loss of glucose.

Protein

The mean normal protein concentration is 1.38 g/dL in living volunteers (Weinburger, 1989) and 1.88 g/dL in cadavers. This difference most likely represents method variations. A reliable reference interval is 1.0–3.0 g/dL. With increasing inflammation, larger proteins (e.g., fibrinogen) enter the synovial space. Spontaneous clot formation may be detected in non-anticoagulated specimen tubes (fibrin clot test). Measurement of SF protein is highly nonspecific; the sensitivity is about 52% and the specificity 56% for inflammatory disorders. The total protein level generally is not useful in patient diagnosis, treatment, or outcome (Shmerling, 1990).

Enzymes

Numerous enzymes have been studied in SF, including lactate dehydrogenase, aspartate aminotransferase, adenosine deaminase, acid and alkaline phosphatase, and lysozyme, among others (Kjeldsberg, 1993). **Lactate dehydrogenase** is elevated in RA, gout, failed arthroplasties, and infectious arthritis. This increase most likely reflects the neutrophil infiltrate. Elevated **acid phosphatase** may have negative prognostic value in RA but is not specific (Luukkainen, 1989). Although enzyme analysis of SF is currently not clinically relevant, the measurement of various hydrolases may have significant predictive value in joint prognosis, especially RA.

Organic Acids

When compared with nonseptic monoarticular arthritis, SF **lactic acid** levels are usually increased in patients with septic arthritis (Kjeldsberg, 1993). Levels significantly greater than 30 mg/dL (3.7 mmol/L) are commonly associated with septic arthritis due to gram-positive cocci and gram-negative bacilli. Thus, the measurement of SF lactate may provide rapid provisional evidence for infection in specimens with negative Gram stains—a common occurrence, especially with gram-negative bacilli.

However, normal or intermediate levels neither rule in nor rule out infection. Moreover, gonococcal arthritis is notorious for having normal SF lactate levels (Curtis, 1983).

When gas-liquid chromatography is used, the presence of other organic acids not normally present in SF (e.g., **n-valeric**, **n-hexanoic**, and **succinic acids**) may be very helpful in differentiating septic from non-septic arthritis (Brook, 1980; Borenstein, 1982).

Uric Acid

Synovial fluid uric acid levels generally, albeit not always, parallel serum levels in gout and noninflammatory arthropathies. An exception is inflammatory joint disorders other than gout, where SF urate levels may be significantly lower than in the paired serum (Beutler, 1996). It provides little clinical value in synovial fluid analysis except in some cases where gout is suspected but crystals are not identified (Reeves, 1965). Increased SF uric acid levels in these cases support a diagnosis of gout.

Lipids

In contrast to plasma, normal synovial fluid contains extremely low concentrations of lipids. Synovial fluid lipid abnormalities include (1) rare cholesterol-rich pseudochylous effusions typically associated with chronic RA; (2) lipid droplets, usually the result of trauma; and (3) extremely rare chylous effusions seen in association with RA, SLE, filariasis, pancreatitis, and trauma (Wise, 1987). These diseases can usually be differentiated clinically and by gross and microscopic examination; quantification of lipids currently has no clinical value in joint fluid analysis, except in cases where cholesterol crystals may resemble MSU or CPPD. In these cases, a cholesterol level that exceeds the plasma level supports the presence of cholesterol crystals.

IMMUNOLOGIC STUDIES

Rheumatoid factor (RF) is found in the synovia of about 60% of RA patients, usually at a titer equal to or slightly lower than the serum titer. **Antinuclear antibodies** (ANA) are found in the SF of about 70% of patients with SLE and 20% of patients with RA. Neither is specific enough for practical use. SF **complement** levels, normally about 10% of serum levels, increase to 40%–70% of serum activity with inflammation, proportional to the increase in protein exudation. Complement consumption in SLE and RA, in particular, results in levels less than 30% of serum complement. Complement is also decreased in some cases of bacterial and crystal-induced arthritis, so measurement is impractical for routine diagnosis.

MICROBIOLOGICAL EXAMINATION

Immediate transportation of joint fluid and good communication of clinical suspicions to the laboratory are extremely important in the rapid identification of an infectious agent.

Septic arthritis may be acute or chronic, and Gram stain and culture should be performed as part of the routine synovial fluid evaluation. Gram stain sensitivity varies from about 75% for staphylococcal infections and 50% for most gram-negative organisms, to less than 25% for gonococcal infections (Goldenberg, 1985). Concentration methods, including cytocentrifugation, may increase the sensitivity of the Gram stain.

Culture sensitivity ranges from 75%–95% for nongonococcal joint infections in patients who have not received antibiotics. For patients with gonorrhea, the sensitivity is only 10%–50% (Shmerling, 1994). In partially treated patients, the use of resin-containing blood culture bottles for culturing synovial fluid may improve isolation and identification of the responsible organism.

Although not yet in routine practice, the use of polymerase chain reaction with universal primers to detect bacterial DNA is helpful, particularly for the more fastidious, uncultivable pathogens (e.g., *Borrelia burgdorferi*, *Chlamydia* spp., *Mycoplasma* spp.) (Nocton, 1994; Li, 1996). Viruses are often associated with acute infectious arthritis, and, depending on the putative virus, serology, viral culture, and detection of viral DNA by nucleic acid amplification should be performed.

Depending on the clinical history, infectious arthritis may be associated with particular exposures and their associated pathogens. Arthritis develops in approximately 60% of patients with Lyme disease resulting from exposure to ticks infected with *Borrelia burgdorferi* (Golightly, 1993). The PCR test for detecting *B. burgdorferi* DNA in synovial fluid is positive in 96% of untreated cases (Nocton, 1994; Exner, 2003).

In patients with a travel history or outdoor occupations, synovial fluid/tissue should be examined for fungal pathogens by KOH/calcofluor white stain and cultured on selective fungal media. For example, a patient with a recent travel history to Arizona may present with a monoarticular arthritis secondary to *Coccidioides immitis*. Patients with chronic arthritis and risk factors for *Mycobacterium tuberculosis* or nontuberculous infections should undergo a synovial biopsy.

Ziehl-Neelsen or Kinyoun stains for acid-fast organisms have a sensitivity of about 20%. Cultures for *M. tuberculosis* are positive in about 80% of proven cases. Because conventional culture methods for *M. tuberculosis* are often very time consuming, applying PCR for the detection of *M. tuberculosis* is a novel and promising technique for more rapid diagnosis. Synovial biopsy is recommended for suspected tuberculous arthritis to provide a more rapid diagnosis (Verettas, 2003; Titov, 2004).

PLEURAL FLUID

The pleural cavity is a potential space lined by mesothelium of the visceral and parietal pleurae. The pleural cavity normally contains a small amount of fluid that facilitates movement of the two membranes against each other. This fluid is a plasma filtrate derived from capillaries of the parietal pleura. It is produced continuously at a rate dependent on capillary hydrostatic pressure, plasma oncotic pressure, and capillary permeability. Pleural fluid is reabsorbed through the lymphatics and venules of the visceral pleura.

An accumulation of fluid, called an **effusion**, results from an imbalance of fluid production and reabsorption. This fluid accumulation in the pleural, pericardial, and peritoneal cavities is known as a **serous effusion**.

SPECIMEN COLLECTION

Thoracentesis is indicated for any undiagnosed pleural effusion or for therapeutic purposes in patients with massive symptomatic effusions; however, pleural fluid samples are frequently collected, handled, and/or analyzed in a less than satisfactory manner. Indeed, improper collection/handling and undertesting or inappropriate testing are more common than with other body fluids. The laboratory often receives a large syringe or vacuum bottle, which must be circulated through the various laboratory sections. Moreover, a large blood or fibrin clot may be present as the result of inadequate anticoagulation or mixing.

Except for an EDTA tube for total and differential cell counts, the specimen should be collected in heparinized tubes to avoid clotting. Aliquots for aerobic and anaerobic bacterial cultures are best inoculated into blood culture media at the bedside. If malignancy, fungal infection, or mycobacterial infection is suspected, all remaining fluid (≥ 100 mL) should be submitted to maximize the yield of stains and culture. Because serous effusions are more forgiving than CSF in maintaining cellular integrity, fresh specimens for cytology may be stored up to 48 hours in the refrigerator with satisfactory results. For pH measurements, the fluid should be collected anaerobically in a heparinized syringe and submitted to the laboratory on ice. Grossly purulent specimens do not require pH measurement and may clog the analyzer.

TRANSUDATES AND EXUDATES

It has long been recognized that the initial classification of a pleural fluid as a **transudate** or an **exudate** greatly simplifies the process of arriving at a correct final diagnosis. Moreover, it determines whether further testing is needed.

Transudates are usually bilateral owing to systemic conditions leading to increased capillary hydrostatic pressure or decreased plasma oncotic pressure (Table 29-17). Malignant effusions may infrequently be transudative as the result of a simultaneous confounding clinical condition such as congestive heart failure (Ashchi, 1998). Exudates are more often unilateral, associated with localized disorders that increase vascular permeability or interfere with lymphatic resorption (see Table 29-17).

RECOMMENDED TESTS

The evaluation of serous body fluids (pleural, pericardial, peritoneal) is directed first toward differentiating transudative from exudative effusions. Transudates generally require no further workup. However, the fluid should be retained for 7–10 days in case further testing is needed. To separate the two, several chemical parameters have been proposed, although none is 100% accurate (Table 29-18).

TABLE 29-17

Classification of Pleural Effusions

Transudates: Increased Hydrostatic Pressure or Decreased Plasma Oncotic Pressure

Congestive heart failure
Hepatic cirrhosis
Hypoproteinemia (e.g., nephrotic syndrome)

Exudates: Increased Capillary Permeability or Decreased Lymphatic Resorption**Infections**

Bacterial pneumonia
Tuberculosis, other granulomatous diseases (e.g., sarcoidosis, histoplasmosis)
Viral or mycoplasma pneumonia

Neoplasms

Bronchogenic carcinoma
Metastatic carcinoma
Lymphoma
Mesothelioma (increased hyaluronate content of effusion fluid)

Noninfectious inflammatory disease involving pleura

Rheumatoid disease (low pleural fluid glucose in most cases)
Systemic lupus erythematosus (LE cells are occasionally present)

Pulmonary infarct (may be associated with hemorrhagic effusion)**Fluid From Extrapleural Sources**

Pancreatitis (elevated amylase activity in effusion fluid)
Ruptured esophagus (elevated amylase activity and low pH)
Urinothorax (elevated creatinine and low pH)

LE, Lupus erythematosus.

TABLE 29-18

Laboratory Criteria for Pleural Fluid Exudate

Pleural fluid/serum protein ratio	≥ 0.50
Pleural fluid/serum LD ratio	≥ 0.60
Pleural fluid LD	$\geq \frac{2}{3}$ upper limit of normal serum LD
Pleural fluid cholesterol	>45 mg/dL
Pleural fluid/serum cholesterol ratio	≥ 0.30
Serum–pleural fluid albumin gradient	≤ 1.2 g/dL
Pleural fluid/serum bilirubin ratio	≥ 0.60

LD, Lactate dehydrogenase.

Classical teaching stressed that exudates and transudates can be distinguished on the basis of total protein concentrations above (exudates) or below (transudates) 3.0 g/dL. However, using total protein alone misclassifies both exudates and transudates by about 30% (Melsom, 1979). It is now well accepted that test combinations increase sensitivity (any positive parameter indicates an exudate), improve accuracy, and serve as the basis for the well-established Light criteria (Light, 1972). Accordingly, an exudate meets one or more of the following criteria: (1) Pleural fluid/serum protein ratio greater than 0.5; (2) pleural fluid/serum LD ratio greater than 0.6; and (3) pleural fluid LD level greater than two thirds of the serum upper limit of normal. The sensitivity and specificity are about 98% and 80%, respectively.

Several subsequent reports support Light's criteria as the most reliable method to differentiate transudates from exudates (Peterman, 1984; Burgess, 1995; Assi, 1998; Gazquez, 1998).

Several alternative measurements have been proposed to differentiate exudates from transudates. Testing for total cholesterol, the albumin gradient, or a combination of LD and total cholesterol may discriminate effusions with equivocal Light's criteria results. For example, the albumin gradient is recommended to confirm a clinical transudate misclassified as an exudate by Light's criteria (Light, 1997), that is, a serum albumin level greater than 1.2 g/dL higher than the pleural fluid level indicates that the fluid is a transudate (Burgess, 1995). In many such cases, the patient is being diuresed. Other test combinations have equaled but not surpassed the performance of Light's criteria. A recent study indicated that in most cases the same categorization of pleural fluids as exudates or transudates

TABLE 29-19

Pleural Effusion: Recommended Tests

Routine tests

ADA, Adenosine deaminase; LD, lactate dehydrogenase; LE, lupus erythematosus.

was achieved using measurements of protein and LD alone without comparison with a blood sample, as was accomplished with application of Light's criteria (Murphy, 2008).

Some tests, such as the combination of pleural fluid LD and cholesterol, may be more convenient and cost-effective by avoiding the need for simultaneous blood tests (Costa, 1995). Bilirubin measurement is not a strong discriminator of effusions (Heffner, 1997).

Further analysis of exudates is directed toward ruling out malignancy and infection. Cytology and appropriate bacterial stains and cultures are the most useful tests in this regard. Moreover, given that pleural fluid DNA levels are significantly increased in exudates, quantitative analysis may be an effective new method to evaluate the causes of serous effusion (Chan, 2003). Recommended tests for the evaluation of pleural effusions are summarized in Table 29-19. The types of tests ordered and the interpretation of test results should always be correlated with clinical findings and differential diagnosis. Total leukocyte, differential, and red cell counts are of limited use in the evaluation of serous effusions.

GROSS EXAMINATION

Transudates are typically clear, pale yellow to straw-colored, and odorless, and do not clot. Approximately 15% of transudates are blood tinged. A bloody pleural effusion (hematocrit $>1\%$) suggests trauma, malignancy, or pulmonary infarction (Jay, 1986). A traumatic tap is suggested by uneven blood distribution, fluid clearing with continued aspiration, or formation of small blood clots. A pleural fluid hematocrit greater than 50% of the blood hematocrit is good evidence for a hemothorax (Light, 1995).

Exudates may grossly resemble transudates, but most show variable degrees of cloudiness or turbidity, and they often clot if not heparinized. A feculent odor may be detected in anaerobic infections. Turbid, milky, and/or bloody specimens should be centrifuged and the supernatant examined. If the supernatant is clear, the turbidity is most likely due to cellular elements or debris. If the turbidity persists after centrifugation, a chylous or pseudochylous effusion is likely.

True chylous effusions are produced by leakage from the thoracic duct resulting from obstruction by lymphoma, carcinoma, or traumatic disruption. A creamy top layer of chylomicrons may form in the specimen on standing. Idiopathic congenital chylothorax is the most common form of pleural effusion in the newborn.

Pseudochylous or chyloform effusions may have a milky, greenish, or "gold paint" appearance. They accumulate gradually through the breakdown of cellular lipids in long-standing effusions such as rheumatoid pleuritis, tuberculosis, or myxedema. Features that distinguish true chylous from pseudochylous effusions are summarized in Table 29-20.

TABLE 29-20 Characteristic Features of Chylous and Pseudochylous Effusions		
Feature	Chylous	Pseudochylous
Onset	Sudden	Gradual
Appearance	Milky-white, or yellow to bloody	Milky or greenish, metallic sheen
Microscopic examination	Lymphocytosis	Mixed cellular reaction, cholesterol crystals
Triglycerides*†	≥110 mg/dL (≥1.24 mmol/L)	<50 mg/dL (<0.56 mol/L)
Lipoprotein electrophoresis	Chylomicrons present	Chylomicrons absent

Modified from Kjeldsberg CR, Knight JA. Body fluids: laboratory examination of amniotic, cerebrospinal, seminal, serous and synovial fluids. 3rd ed. Chicago: © American Society for Clinical Pathology; 1993, with permission.
 *Values in parentheses are SI units.
 †Triglyceride levels between 50 mg/dL and 110 mg/dL are equivocal and require electrophoresis to confirm chylothorax.

MICROSCOPIC EXAMINATION

Cell Counts

Total cell counts may be performed using manual hemocytometer methods; however, automated cell counts are increasingly used with pleural fluid specimens (Conner, 2003). Leukocyte counts have limited utility in separating transudates (<1000/μL) from exudates (>1000/μL). Although red cell counts above 100,000/μL are highly suggestive of malignancy, trauma, or pulmonary infarction, they are not specific for these conditions.

Differential Leukocyte Count and Cytology

Examination is commonly performed on a stained smear, preferably prepared by cytocentrifugation and with the air-dried smear stained with a Romanowski stain. Indeed, examination by the hematology laboratory can be highly effective in the detection of malignant cells, especially hematologic malignancies (Kendall, 1997). Filtration or automated concentration methods with Papanicolaou stain may also be used, especially if cell loss is a matter of concern. Automated WBC differential counts may be done on pleural fluid samples; however, some variation in results from those of manual methods may be seen (Conner, 2003). Liquid-based thin-layer methods are increasingly used to prepare pleural and other serous fluid specimens for cytopathologic examination and show good performance in the detection of malignant cells (Moriarty, 2008).

Cytologic analysis will establish the diagnosis of metastatic carcinoma in 70% or more of cases when both smears and cell blocks are examined (Light, 2002). However, the sensitivity is significantly less efficient if the patient has mesothelioma (10%), squamous cell carcinoma (20%), lymphoma (25%–50%), or sarcoma (25%). Preparation of cell blocks is unnecessary, except for effusions in which malignancy is an important consideration (Jonasson, 1990).

Mesothelial cells are common in pleural fluids from inflammatory processes (Fig. 29-16). They are, however, conspicuously scarce in patients with tuberculous pleurisy, empyema, and rheumatoid pleuritis, and in patients who have had pleurodesis. Fibrin deposition and fibrosis occurring in these conditions prevent mesothelial cell exfoliation. Well-differentiated carcinoma cells may be easily recognized (Fig. 29-17) or may be highly

undifferentiated (Fig. 29-18). A panel of immunocytochemical stains may be necessary for confirmation, and these studies are enhanced by the use of liquid-based preparation methods (Sioutopoulou, 2008).
Neutrophils predominate in pleural fluid from patients with pleural inflammation (Table 29-21). More than 10% of transudates will also have a predominance of neutrophils, but this has limited clinical significance.
Lymphocytes predominate in the disorders summarized in Table 29-21. Most are small, but medium, large, and reactive (transformed)

Figure 29-19 Pleural effusion in patient with non-Hodgkin lymphoma, small lymphocytic type. The cells are small round forms, difficult to distinguish from benign lymphocytes. (From Kjeldsberg CR, Knight JA. *Body fluids: laboratory examination of amniotic, cerebrospinal, seminal, serous and synovial fluids*. 3rd ed. Chicago: © American Society for Clinical Pathology; 1993, with permission.)

variants may be seen. Nucleoli and nuclear cleaving are more prominent in effusions than in the peripheral blood, and these features may be particularly prominent in cytocentrifuge preparations. **Plasma cells** may also be observed. Lymphocytosis associated with transudates is of limited clinical significance.

Low-grade non-Hodgkin lymphoma and chronic lymphocytic leukemia (CLL) may be difficult to distinguish from benign lymphocyte-rich serous effusion (Fig. 29-19).

Immunophenotyping by flow cytometry or immunocytochemistry, in conjunction with cellular morphology, is usually helpful in making a correct diagnosis. The relative proportions of T and B cells are, by themselves, not definitive for separating benign from malignant exudates (Ibrahim, 1989); however, the pattern of expression of Ig light chains and/or other distinctive cell marker combinations may allow specific diagnosis of lymphoproliferative disorders. Molecular DNA analysis may be another useful adjunct to morphologic analysis. An unusual form of high-grade B cell non-Hodgkin lymphoma, called **primary effusion lymphoma**, may be seen in pleural, peritoneal, and/or pericardial fluid specimens, typically from immunocompromised patients, with a characteristic highly anaplastic and immunoblastic morphologic appearance and without expression of most B cell-associated antigens (Karcher, 1997). The diagnosis is usually confirmed by demonstrating in the neoplastic cells the presence of human herpesvirus-8 (HHV-8)-associated antigens and/or DNA by immunophenotypic and/or molecular analysis.

An eosinophilic effusion is one that has 10% or more **eosinophils**. The most common causes are related to the presence of air or blood in the pleural cavity (see Table 29-21). Most of these are exudates; however, in about 35% of patients, the cause is unknown (Adelman, 1984). Although not of much assistance in diagnosing the cause of an effusion, eosinophilia appears to be independently associated with longer survival (Rubins, 1996). A small number of **mast cells** or **basophils** often accompany eosinophils. Eosinophil-derived **Charcot-Leyden crystals** may also be seen.

CHEMICAL ANALYSIS

Protein

The measurement of pleural fluid total protein or albumin has little clinical value except when combined with other parameters to differentiate exudates from transudates. Protein electrophoresis shows a pattern similar to serum, except for a higher proportion of albumin; it has little value for differential diagnosis (Light, 1995).

Glucose

The glucose level of normal pleural fluid, transudates, and most exudates is similar to serum levels. Decreased pleural fluid glucose, accepted as a level below 60 mg/dL (3.33 mmol/L) or a pleural fluid/serum glucose ratio less than 0.5, is most consistent and dramatic in rheumatoid pleuritis and grossly purulent parapneumonic exudates (Sahn, 1982). Low pleural fluid glucose may also be present in malignancy, tuberculosis, nonpurulent bacterial infection, lupus pleuritis, and esophageal rupture.

Lactate

Pleural fluid lactate levels can be a useful adjunct in the rapid diagnosis of infectious pleuritis. Levels are significantly higher in bacterial and tuberculous pleural infections than in other pleural effusions. Moderate

elevations are generally observed in malignant effusions (Brook, 1980). Values greater than 90 mg/dL (10 mmol/L) have a positive predictive value for infectious pleuritis of 94% and a negative predictive value of 100% (Gastrin, 1988).

Enzymes

Amylase elevations above the serum level (usually 1.5–2.0 or more times greater) indicate the presence of pancreatitis, esophageal rupture, or malignant effusion (Light, 1973). Elevated amylase derived from esophageal rupture or malignancy is the salivary isoform, which differentiates it from pancreatic amylase (Kramer, 1989).

Pleural fluid LD levels rise in proportion to the degree of inflammation. In addition to their use in separating exudates from transudates, declining LD levels during the course of an effusion indicate that the inflammatory process is resolving. Conversely, increasing levels indicate a worsening condition requiring aggressive workup or treatment. LD isoenzyme analysis may be helpful in diagnosing problematic exudates but is not routinely recommended (Lossos, 1997).

ADA, which is particularly rich in T lymphocytes, is significantly increased in tuberculous pleuritis. At a level of 50 U/L, the sensitivity, specificity, positive predictive value, negative predictive value, and efficiency for tuberculosis are 91%, 81%, 84%, 89%, and 86%, respectively (Burgess, 1996). When the lymphocyte/neutrophil ratio is 0.75 or greater, the percentages are 88%, 95%, 95%, 88%, and 92%, respectively. ADA levels of 40 U/L or greater are present in about 99.6% of patients with verified tuberculous pleuritis (Lee, 2001). However, in patients with lymphocyte-rich pleural fluids from nontuberculous causes, ADA levels less than 40 U/L are present in 97.1% of cases.

Interferon- γ

Pleural fluid interferon (IFN)- γ levels are significantly increased in the pleural fluid of patients with tuberculous pleuritis. The sensitivity of levels of 3.7 IU/L or greater is 99%, and the specificity is 98% (Villena, 1996a). Test sensitivity does not differ in HIV-positive and HIV-negative patients. Only about 20% of patients with effusions due to hematologic malignancies have IFN- γ levels slightly above 3.7 IU/L (Villena, 2003a).

pH

Pleural fluid pH measurement has the highest diagnostic accuracy in assessing the prognosis of parapneumonic (pneumonia-related) effusions (Heffner, 1995). A parapneumonic exudate with a pH greater than 7.30 generally resolves with medical therapy alone. A pH less than 7.20 indicates a complicated parapneumonic effusion (loculated or associated with empyema), requiring surgical drainage.

Patients with borderline complicated exudates (pH 7.20–7.30) may be closely watched with repeat measurements. A concomitant pleural glucose level below 60 mg/dL (3.33 mmol/L), however, strongly suggests impending empyema. Rheumatoid pleuritis and malignant effusions with a poor response to pleurodesis also have pH values below 7.20 and a low glucose level (Rodríguez-Panadero, 1989). A pH below 6.0 is characteristic of **esophageal rupture**, although the pH in severe empyema may be 6.0 or less (Good, 1980).

Urin thorax, a collection of urine presumably produced by lymphatic drainage of perirenal accumulations into the pleural cavity, is also associated with a pleural fluid pH less than 7.30. These effusions are transudative because of their low protein content and smell of urine, and they have a creatinine level greater than in simultaneously drawn serum (Miller, 1988).

Lipids

Some serous effusions appear to be chylous (i.e., a milky appearance) but are not (pseudochylous), whereas others may not look chylous but are. Although pseudochylous fluids may be partially due to increased leukocytes and necrotic debris, they are primarily due to the presence of increased lecithin-globulin complexes. A true chylous effusion has chylomicrons at the origin on lipoprotein electrophoresis. Lipid measurements are also helpful in identifying chylous effusions (Staats, 1980). Thus, pleural fluid triglyceride levels above 110 mg/dL indicate a chylous effusion; values from 60–110 mg/dL (0.68–1.24 mmol/L) are less certain and require lipoprotein electrophoresis to confirm a chylothorax. Nonchylous and pseudochylous effusions generally have triglyceride levels below 50 mg/dL (0.56 mmol/L) and no chylomicrons on electrophoresis (see Table 29-20).

Cholesterol measurements may be useful in separating transudates from exudates, especially when there is a question regarding Light's

criteria. A total cholesterol value of 54 mg/dL or more and a pleural fluid/serum cholesterol ratio of 0.32 or higher have sensitivity and specificity values similar to Light's criteria (Suay, 1995). Elevated levels and the presence of cholesterol crystals may be seen with pleural effusions that have been present for several years.

C-Reactive Protein

Pleural fluid CRP is often a clinically useful screening test for organ disease, index of disease activity, and measure of response to therapy (Castano, 1992). Pleural fluid CRP levels >30 mg/L reportedly have a sensitivity of 93.7%, a specificity of 76.5%, and a positive predictive value of 98.4% in parapneumonic infections (Turay, 2000). Mean CRP values are about 90 mg/L in parapneumonic infections compared with 26 mg/L and 23 mg/L for tuberculous and malignant effusions, respectively.

Tuberculostearic Acid (10-Methyloctadecanoic Acid)

Tuberculostearic acid (TSA) was first isolated from the bacillus *Mycobacterium tuberculosis*. This fatty acid is a structural component of mycobacteria and is not normally present in human tissue. Using gas chromatography/mass spectroscopy, TSA was measured in sputum, bronchial washings, and pleural fluid from patients with pulmonary tuberculosis (Muranishi, 1990). Here, pleural fluid TSA was identified in 24 of 32 (75%) patients with active tuberculosis; bronchial washings were positive for TSA in 15 of 22 cases. In patients with other pulmonary disorders, only 4 of 46 pleural fluids and 3 of 69 bronchial washings had detectable levels. A later smaller study reported the following for pleural fluid TSA: Sensitivity 54%, specificity 80%, positive predictive value 75%, negative predictive value 61%, and efficacy 66% (Yorgancioglu, 1996).

Tumor Markers

Although not recommended as a routine test, various tumor markers are often a useful adjunct in enigmatic noninflammatory exudates with negative cytology. Several tumor markers, especially CEA, CA 15-3, CA 549, CA 72-4, and CYFRA 21-1, among others, have been studied in pleural fluids. CEA is probably the most useful single marker for adenocarcinomas, but reported cutoff values vary considerably. The sensitivity of CEA for malignant effusions varies depending on tumor origin and is about 50% overall. Although complicated parapneumonic effusions may result in elevated CEA levels (Garcia-Pachon, 1997), they are usually not a problem to distinguish clinically.

A combination of tumor markers increases the accuracy of diagnosis. Thus, a combination of CEA, CA 15-3, and CA 72-4 had an accuracy of 90% with 78% sensitivity, 95% specificity, 88% positive predictive value, and 91% negative predictive value (Villena, 1996b). Similarly, CA 15-3 and CEA combined had an accuracy of 87% (Romero, 1996); a combination of CA 549, CEA, and CA 15-3 had a sensitivity of 65%, specificity 99%, and accuracy 85% (Villena, 2003b). The use of the cytokeratin 19 fragment (CYFRA 21-1) may also be useful in combination with other tumor markers.

Other tumor markers may also be useful in the diagnosis of unexplained effusions. For example, a marked increase in pleural fluid prostate-specific antigen (PSA) led to the correct diagnosis of a patient with metastatic prostate cancer who presented with severe anemia, peripheral edema, and pleural and pericardial effusions that were negative by cytologic examination (Chin, 1999).

IMMUNOLOGIC STUDIES

Approximately 5% of patients with RA and 50% with SLE develop pleural effusions sometime during the course of their disease.

RF is commonly present in pleural effusions associated with seropositive RA. Although a pleural fluid titer of 1:320 or greater in a patient with known RA is reasonable evidence of rheumatic pleuritis (Halla, 1980), elevated RF titers up to 1:1280 have been identified in 41% of patients with bacterial pneumonia, 20% of patients with malignant effusions, and 14% of patients with tuberculosis, making a routine test for RF of little value (Levine, 1968).

ANA titers may be useful in the diagnosis of effusion due to lupus pleuritis; the sensitivity is about 85% when a cutoff titer of 1:160 is used (Good, 1983). The specificity is not high, however, because elevated ANA titers also occur in various other conditions. Thus, pleural fluid ANA titers are not clinically useful.

Decreased **complement** levels (CH50 <10 U/mL or C4 level below 10×10^{-5} U/g protein) are present in most patients with rheumatoid or

TABLE 29-22
Causes of Pericardial Effusions

Procainamide	Radiation therapy
Phenytoin	

AIDS, Acquired immunodeficiency syndrome.

lupus pleuritis (Hunder, 1972; Halla, 1980). However, complement measurements are not highly specific and are of little value for routine diagnosis, although they may be helpful in the diagnosis of otherwise enigmatic effusions.

MICROBIOLOGICAL EXAMINATION

Bacteria most commonly associated with parapneumonic effusions are *Staphylococcus aureus*, *Streptococcus pneumoniae*, β -hemolytic group A streptococci, enterococci, and some gram-negative bacilli. Anaerobic bacteria are isolated in a significant proportion of cases, so both anaerobic and aerobic cultures should be performed. The sensitivity of the Gram stain is approximately 50% (Ferrer, 1999), and concentration methods, such as cytocentrifugation, may increase the sensitivity. Use of resin-containing blood culture bottles may improve the isolation of certain bacteria in partially treated patients.

For patients with suspected *M. tuberculosis*, direct staining of tuberculous effusions for acid-fast bacteria has a sensitivity of 20%–30%, and positive cultures are found in 50%–70% of cases (Baer, 2001). Pleural biopsy yields the highest culture sensitivity (50%–75%) and may provide a rapid presumptive diagnosis of tuberculosis by histopathologic demonstration of granulomas or acid-fast bacteria. Combining culture and acid-fast stains with pleural biopsy increases the sensitivity to about 95% (Jay, 1986).

ADA can provide rapid chemical evidence for tuberculous effusions independent of HIV status (Burgess, 1996; Riantawan, 1999; Lee, 2001). Although the ADA-2 isoenzyme form is elaborated by activated lymphocytes in tuberculosis, only mild elevations occur in lymphocyte-rich pleural effusions from nontuberculous causes. However, the relatively low prevalence of tuberculous pleurisy in North America anticipates a lower positive predictive value rate compared with the excellent results reported in the Asian and European literature, where tuberculosis is more common. Moreover, the colorimetric Giusti method by which most ADA data were derived is, unfortunately, not widely available in the United States (Roth, 1999).

Pleural fluid interferon- γ is significantly increased in tuberculous pleuritis and may be helpful in some cases because it is independent of HIV status and is only modestly increased in about 20% of hematologic malignancies (Villena, 2003a).

PERICARDIAL FLUID

From 10–50 mL of fluid is normally present in the pericardial space, produced by a transudative process similar to pleural fluid. Pericardial effusions are most often caused by viral infection, and enterovirus is the most common etiologic agent. They may develop as a result of bacterial, tuberculous, or fungal infection, or in association with autoimmune disorders, renal failure, myocardial infarction, mediastinal injury, or the effects of various drugs; they may be idiopathic (Table 29-22). HIV-infected patients commonly have asymptomatic pericardial effusions, which may become large in more advanced disease (Silva-Cardosa, 1999) and/or with

primary effusion lymphoma (Karcher, 1997). Many of the recommended laboratory tests described for pleural fluid also pertain to pericardial effusions (see Table 29-19).

SPECIMEN COLLECTION

Pericardial effusions of unknown origin or large effusions with signs of cardiac tamponade are generally submitted for laboratory examination. Fluid may be obtained by pericardiocentesis following limited thoracotomy, or by pericardiocentesis (sterile needle aspiration).

Normal pericardial fluid is pale yellow and clear. Large effusions (>350 mL) are most often caused by malignancy or uremia, or they may be idiopathic. In HIV-associated cardiac tamponade, 45% of cases are idiopathic, and tuberculous and bacterial effusions each account for about 20% of cases (Chen, 1999). Infection or malignancy typically produces turbid effusions, whereas effusions due to uremia are usually clear and straw-colored. These and several other disorders may produce hemorrhagic effusions.

Blood-like fluid obtained by pericardiocentesis might represent a hemorrhagic effusion or inadvertent aspiration of blood from the heart. Blood obtained from the heart chamber will have a hematocrit comparable with that of peripheral blood, and blood gas analysis yields results similar to venous or arterial blood. In contrast, the hematocrit of a hemorrhagic effusion is usually lower than that of peripheral blood. The pH and partial pressure of oxygen are lower and the $p\text{CO}_2$ is higher than in venous or arterial blood (Mann, 1978). Blood from a cardiac puncture clots, but a hemorrhagic effusion usually does not.

A milky appearance suggests the presence of a chylous or pseudochylous effusion. Identification and differentiation of these effusions are discussed under Pleural Fluid.

GROSS EXAMINATION

The **postpericardiotomy syndrome** is a fairly common but nonspecific complication of cardiac surgery (or other cardiac damage) that develops days to weeks following the initial injury. It is hallmarked by the development of fever, pleuritic chest pain, and other signs of pleural, pericardial, and, less often, lung inflammation. Exudative pleural effusions develop in more than 80% of cases. These are often serosanguineous to hemorrhagic and typically have a pH greater than 7.4 and a normal glucose level (Stelzner, 1983). No specific tests are available for diagnosing this syndrome. Diagnosis, therefore, remains one of clinical exclusion. Although the cause is uncertain, the time course, presence of antimyocardial antibodies, and response to antiinflammatory therapy suggest an immune-mediated process. Increased levels of antimyocardial antibodies relative to serum, decreased complement levels, and immune complexes have been documented in pleural fluid from a single patient with the syndrome (Kim, 1996).

EXUDATES AND TRANSUDATES

Until recently, the criteria for differentiating exudates from transudates had not been carefully studied in pericardial effusions. According to Light's criteria, a pleural exudate has one or more of the following: pleural fluid/serum protein ratio >0.5; pleural fluid/serum LD ratio >0.6; and pleural fluid LD level >200 U/L. Light's criteria for pericardial fluid have now been shown to be the most reliable diagnostic tool for identifying pericardial exudates and transudates (Burgess, 2002a).

Routine testing of pericardial effusions should probably be limited to cell count, glucose, total protein, LD, bacterial culture, and cytology (Meyers, 1997). Other, more specific tests are appropriate for diseases of high clinical suspicion.

MICROSCOPIC EXAMINATION

The hematocrit and red cell count document the presence of a hemorrhagic effusion, but are of limited value for differential diagnosis. Total leukocyte counts over 10,000/ μL suggest bacterial, tuberculous, or malignant pericarditis; however, low counts may be encountered in these conditions, limiting the value of this measurement (Agner, 1979). Although formal leukocyte differentials add little diagnostic information, a stained smear should always be examined.

Cytologic identification of malignant cells is usually not difficult. Metastatic carcinomas of the lung and breast are most frequently observed in

malignant pericardial effusion. Cytology has a sensitivity of 95% and a specificity of 100% (Meyers, 1997).

CHEMICAL ANALYSIS

Chemical parameters for the diagnosis of pericardial effusions have not been studied to the same extent as in other body fluids. Although pericardial effusions are very similar to pleural fluids, routine application of these tests requires additional studies to fully appreciate their diagnostic importance.

Protein

A value greater than 3.0 g/dL has a sensitivity of 97% for exudative effusions, but a specificity of only 22%, which significantly limits its usefulness. Thus, total protein has no discriminating power in pericardial diagnosis (Meyers, 1997).

Glucose

Pericardial glucose levels less than 60 mg/dL have a diagnostic accuracy of only 36% in identifying pericardial exudates (Meyers, 1997). Values less than 40 mg/dL (<2.22 mmol/L) are common in bacterial, tuberculous, rheumatic, or malignant effusions.

pH

Pericardial fluid pH may be markedly decreased (<7.10) in rheumatic or purulent pericarditis. Malignancy, uremia, tuberculosis, and idiopathic disorders may have moderate decreases in the range of 7.20–7.30 (Kindig, 1983).

Lipids

Separation of true chylous from pseudochylous effusions may be facilitated by triglyceride and cholesterol measurements, as well as by lipoprotein electrophoresis for chylomicrons (see Table 29-20). See **Lipids** section in Pleural Fluids for further details on the diagnosis of chylous effusions.

Enzymes

A pericardial fluid LD level greater than 200 U/L has been suggested as a cutoff for pericardial exudates (Burgess, 2002a). Moreover, the measurement of LD and creatine kinase in postmortem pericardial fluid within 48 hours of death may be useful in establishing acute myocardial injury in cases where such injury is suspected but cannot be established by the usual histologic methods (Luna, 1982; Stewart, 1984). Pericardial fluid levels of CK-MB, myoglobin, and troponin I in postmortem pericardial fluid are significantly increased in patients with myocardial injury (Perez-Carceles, 2004).

ADA activity is a useful adjunctive test for tuberculous pericarditis in suspicious cases with negative acid-fast stains. The median ADA level in tuberculous pericarditis is significantly higher than in other pathologic effusions (Burgess, 2002b). Using a cutoff of 30 U/L, the sensitivity was 94%, specificity 68%, and positive predictive value 80%. Using a cutoff of 40 U/L, the sensitivity and specificity were 93% and 97%, respectively (Koh, 1994).

Interferon- γ

Increased IFN- γ levels have been reported in tuberculous serous effusions, including tuberculous pericarditis (Burgess, 2002b). Here, the IFN- γ level was greater than 1000 pg/L, which was significantly higher than in effusions from other pathologic conditions. A cutoff value of 200 pg/L resulted in a sensitivity and specificity of 100% for the diagnosis of tuberculous pericarditis.

Polymerase Chain Reaction

PCR is a sensitive technique and may be more specific than adenosine deaminase in the diagnosis of tuberculous pericarditis (Lee, 2002). However, a negative test does not rule out tuberculous pericarditis because some pericardial fluids from patients with large tuberculous effusions may not contain *M. tuberculosis*.

IMMUNOLOGIC STUDIES

A negative ANA test makes the diagnosis of lupus serositis highly unlikely. Conversely, high ANA titers in pericardial effusions lack specificity, even when they are as high as 1:5120 (Leventhal, 1990; Wang, 2000). If a high ANA titer is unexplained, malignancy should be considered.

MICROBIOLOGICAL EXAMINATION

The sensitivity of the Gram stain and culture for bacterial pericarditis is similar to other serous body fluids (i.e., about 50% and 80%, respectively). Important aerobic bacteria include *S. aureus*, *S. pneumoniae*, *S. pyogenes*, and gram-negative bacilli. Although infectious pericarditis due to anaerobic bacteria may be encountered rarely, the bacteria sometimes are not recognized because of inconsistent methods used for their isolation and identification (Brook, 2002). For this reason, proper laboratory technique is of particular importance when infection with an anaerobic organism is suspected. The major anaerobic organisms are the *Bacteroides fragilis* group, anaerobic streptococci, *Clostridium* species, *Fusobacterium* species, and *Bifidobacterium* species.

Identification of a specific etiologic agent in viral pericarditis is difficult because the viruses (e.g., coxsackieviruses, influenza virus, mumps) are rarely isolated from pericardial fluid. Obtaining acute and convalescent sera for antibody response to suspected viral pathogens may help support the diagnosis (Bellinger, 1987). Viral infection probably accounts for most idiopathic HIV-associated pericardial effusions.

The sensitivity of acid-fast stains and culture for tuberculous pericarditis is about 50% (Agner, 1979). PCR is a sensitive technique and may be more specific than the use of adenosine deaminase in the diagnosis of tuberculous pericarditis (Lee, 2002). However, a negative test does not exclude the diagnosis of tuberculous pericarditis.

PERITONEAL FLUID

Ascites is the pathologic accumulation of excess fluid in the peritoneal cavity. Up to 50 mL of fluid is normally present in this mesothelial-lined space. As with pleural and pericardial fluids, it is produced as an ultrafiltrate of plasma dependent on vascular permeability and on hydrostatic and oncotic Starling forces.

TRANSUDATES AND EXUDATES

Common causes of peritoneal effusion are listed in Table 29-23. The laboratory criteria for classifying ascitic fluid as a transudate or an exudate are not as well defined as they are for pleural and pericardial fluids. For example, infected or malignancy-related samples are not uncommonly reported with protein concentrations in the transudative range (i.e., <3.0 g/dL), and many patients with cirrhotic or heart failure ascites have protein values in the exudative range (>3.0 g/dL) (Runyon, 1992).

TABLE 29-23

Causes of Peritoneal Effusions

Transudates: Increased Hydrostatic Pressure or Decreased Plasma Oncotic Pressure

Congestive heart failure
Hepatic cirrhosis
Hypoproteinemia (e.g., nephrotic syndrome)

Exudates: Increased Capillary Permeability or Decreased Lymphatic Resorption

Infections

Primary bacterial peritonitis
Secondary bacterial peritonitis (e.g., appendicitis, bowel rupture)
Tuberculosis

Neoplasms

Hepatoma
Lymphoma
Mesothelioma
Metastatic carcinoma
Ovarian carcinoma
Prostate cancer

Trauma

Pancreatitis
Bile peritonitis (e.g., ruptured gallbladder)

Chylous Effusion

Damage to or obstruction of thoracic duct (e.g., trauma, lymphoma, carcinoma, tuberculosis and other granulomas [e.g., sarcoidosis, histoplasmosis], parasitic infestation)

The **serum–ascites albumin gradient**, defined as the serum albumin concentration minus the ascitic fluid albumin concentration, is widely considered as the most reliable method to differentiate peritoneal transudates from exudates (Runyon, 1992). Ascites caused by portal hypertension has a gradient of at least 1.1 g/dL (>11 g/L; transudate), whereas ascites produced by other causes has a gradient less than 1.1 g/dL (exudate) (Runyon, 1992). Indeed, the diagnostic accuracy was 98% for the serum–ascites albumin gradient compared with only 52%–80% for four other markers: Ascitic fluid total protein; ascites/serum total protein ratio; ascitic fluid LD concentration; and ascites/serum LD ratio (Akriviadis, 1996).

An ascitic fluid/serum bilirubin ratio of 0.6 or greater is also significantly associated with exudates (Elis, 1998). Indeed, the accuracies of the bilirubin ratio, the serum–ascites albumin gradient, and Light's criteria were 81.5%, 84%, and 80.2%, respectively. Others suggested that if the ascitic fluid LD is >130 U/L and the ascitic fluid/serum total protein ratio is >0.4, the fluid should be regarded as an exudate (Paramothayan, 2002).

Although the serum–ascites albumin gradient is probably the best single method to differentiate an ascitic exudate from a transudate, other methods compare favorably. Nevertheless, no ideal biochemical markers allow complete discrimination between ascitic fluid exudates and transudates.

SPECIMEN COLLECTION

Paracentesis

Diagnostic paracentesis is performed in most patients with new ascites, or if there is a change in the clinical picture of a patient with ascites, such as rapid fluid accumulation or fever development. A minimum of 30 mL is needed for complete evaluation. If possible, at least 100 mL should be provided for cytologic examination. Samples for cell counts should be placed in an EDTA-anticoagulated venipuncture tube. Culture specimens should include blood culture bottles that have been inoculated at the bedside with ascitic fluid (10 mL per culture bottle).

Diagnostic Peritoneal Lavage

This procedure is no longer recommended as a routine technique for the evaluation of abdominal trauma. Concerns of oversensitivity and nonspecificity, and improvements in noninvasive diagnostic procedures such as computed tomography and ultrasound, have limited its common use to (1) rapid screening for significant abdominal hemorrhage, and (2) evaluation of hollow viscous injuries.

A catheter is placed through a small incision into the abdominal cavity. If less than 15 mL of gross blood can be aspirated, diagnostic peritoneal lavage (DPL) is performed by infusing 1.0 L of saline or Ringer's solution (20 mg/kg in children) and retrieving the fluid by gravity drainage. At least 600 mL should be recovered to avoid falsely low counts (Sullivan, 1997). The catheter is sometimes left in place so that DPL may be repeated in 2–3 hours if initial results are negative or indeterminate.

Commonly accepted criteria for DPL interpretation after trauma are shown in Table 29-24. The positive predictive value is only 23% for an isolated (no other abnormal criteria) leukocyte count of 500/μL or greater (Soyka, 1990).

The conventional DPL criteria may be unreliable in detecting hollow viscous injury when blood is present from a simultaneous solid organ injury not requiring surgical repair, resulting in unnecessary exploratory laparotomies. Suggested modifications of DPL criteria to adjust for this source of bleeding include either of the following: (1) WBC count greater than or equal to RBC count divided by 150, where RBC is $10 \times 10^3/\text{mm}^3$ or greater (Otomo, 1998); or (2) cell count ratio greater than 1.0 (Fang, 1998). The cell count ratio is defined as the ratio between WBC and RBC counts in the lavage fluid divided by the WBC/RBC ratio in the peripheral blood. These new criteria have a reported specificity of 97% for hollow organ injury, especially if DPL is performed at least 3 hours following injury.

Other applications of DPL include the evaluation of patients with suspected acute peritonitis or pancreatitis. For example, a WBC count in the lavage fluid of 200 cells/mm³ is associated with a 99% probability of acute peritonitis (Larson, 1992).

Peritoneal Dialysis

Dialysate fluid from renal patients undergoing chronic ambulatory peritoneal dialysis should be submitted to the laboratory to check for infection.

TABLE 29-24

Criteria for Evaluation of Peritoneal Lavage

Positive result

Aspiration of >15 mL gross blood on catheter placement
 Grossly bloody lavage fluid
 RBC >100,000/ μ L after blunt trauma
 RBC >50,000/ μ L after penetrating trauma
 WBC >500/ μ L
 Amylase >110 U/dL

Indeterminate result

Small amount of gross blood on catheter placement
 RBC 50,000–100,000/ μ L after blunt trauma
 RBC 1000–50,000/ μ L after penetrating trauma
 WBC 100–500/ μ L

Negative result

RBC <50,000/ μ L after blunt trauma
 RBC <1000/ μ L after penetrating trauma
 WBC <100/ μ L

Modified from Feied CF. Diagnostic peritoneal lavage. *Postgrad Med* 1989;85:40, with permission.

RBC, Red blood cells; WBC, white blood cells.

Peritoneal Washings

This procedure is performed intraoperatively to document early intraabdominal spread of gynecologic and gastric carcinomas. Samples are generally sent for cytologic examination only.

RECOMMENDED TESTS

The most important tests for the evaluation of ascitic fluid are listed in Table 29-25. Relative importance varies depending on the type of sample and the clinical findings. For example, RBC and WBC counts are more important than cytology or the serum–ascites albumin gradient in the evaluation of abdominal effects of trauma. Gross examination provides immediate information in the clinical and laboratory triage.

GROSS EXAMINATION

Whereas transudates are generally pale yellow and clear, exudates are cloudy or turbid because of the presence of leukocytes, tumor cells, or increased protein levels. The presence of food particles, foreign material, or green-yellow bile staining in a DPL specimen suggests perforation of the gastrointestinal or biliary tract. Acute pancreatitis and cholecystitis may also cause greenish discoloration.

Blood-tinged or grossly bloody fluid must be distinguished from a traumatic tap in which the blood usually clears with continued

Figure 29-20 Neutrophils in a patient with bacterial peritonitis.

paracentesis. As little as 15 mL of blood per liter of fluid produces a bright red opaque color such that newsprint cannot be read through the lavage tubing. In most cases, the ability to read newsprint through the tubing results in a negative DPL. Opaque specimens require cell counts because newsprint readability is lost well below the 100,000 RBCs/ μ L criterion for a positive DPL (Bellows, 1998). Bloody ascites is also seen in malignancy and tuberculosis.

Milky fluid that does not clear with centrifugation suggests a chylous or pseudochylous effusion. True chylous peritoneal effusions are significantly less common than chylous pleural fluids. They are caused by disruption or blockage of lymphatic flow by trauma, lymphoma, carcinoma, tuberculosis, other granulomatous diseases (e.g., sarcoidosis), hepatic cirrhosis, adhesions, or parasitic infestation. Differentiation of true chylous and pseudochylous effusions is discussed under Pleural Fluid, Gross Examination.

MICROSCOPIC EXAMINATION

The total leukocyte count is useful in distinguishing ascites due to uncomplicated cirrhosis from spontaneous bacterial peritonitis (SBP), which is caused by migration of bacteria from the intestine into the ascitic fluid. Approximately 90% of patients with SBP will have leukocyte counts greater than 500/ μ L, more than 50% of which are neutrophils (Fig. 29-20) (Runyon, 1984; Stewart, 1986).

The ascitic fluid total neutrophil count is the preferred method for the diagnosis of SBP. Cutoff values of 250 and 500 neutrophils/ μ L have been recommended, with a diagnostic accuracy of about 94% for 500 neutrophils/ μ L and about 90% for 250 neutrophils/ μ L (Stassen, 1986; Albillos, 1990).

Cell counts, total protein, and albumin gradient values vary with fluid shifts associated with ascites formation and resolution. For example, diuresis may cause the WBC count to increase from 300/ μ L–1000/ μ L or more. When obtained by DPL, a leukocyte count of 200/ μ L or more is reported to be associated with a 99% probability of acute peritonitis (Alverdy, 1988; Larson, 1992).

Eosinophilia (>10%) is most commonly associated with the chronic inflammatory process associated with chronic peritoneal dialysis. It has also been reported in congestive heart failure, vasculitis, lymphoma, and ruptured hydatid cyst.

Cytology has an overall sensitivity of 40%–65% for malignant ascites. Peritoneal carcinomatosis accounts for only about two thirds of malignant effusions; however, cytology has a sensitivity of over 95% when confined to these cases (Runyon, 1988). Liquid-based thin-layer preparations of peritoneal effusions and pelvic washings have been shown to be superior to standard cytologic preparations in the detection of carcinoma (Moriarty, 2008). Immunocytochemical stains are useful in characterizing atypical cells in equivocal cases.

CHEMICAL ANALYSIS

Protein

The serum–ascites albumin gradient is superior to total protein content in differentiating cirrhosis from other causes of peritoneal effusion (Runyon, 1992). Spontaneous bacterial peritonitis is commonly associated with low total protein (<3.0 g/dL) and a high serum–ascites albumin gradient (>1.1 g/dL), making total protein measurements of little value in this disorder. Extracellular fluid shifts associated with ascites formation and resorption also cause variations in protein content.

TABLE 29-25

Recommended Tests in Peritoneal Effusion

Useful in most patients

Gross examination
 Cytology
 Stains and culture for microorganisms
 Serum–ascites albumin concentration gradient

Useful in selected disorders

Total leukocyte and differential cell counts
 RBC count (lavage)
 Bilirubin
 Creatinine/urea nitrogen
 Enzymes (ADA, ALP, amylase, LD, telomerase)
 Lactate
 Cholesterol (malignant ascites)
 Fibronectin
 Tumor markers (CEA, PSA, CA 19-9, CA 15-3, CA-125)
 Immunocytology/flow cytometry
 Tuberculostearic acid

ADA, Adenosine deaminase; ALP, alkaline phosphatase; CEA, carcinoembryonic antigen; LD, lactate dehydrogenase; PSA, prostate-specific antigen; RBC, red blood cell.

Glucose

Early reports indicated that peritoneal fluid glucose levels of 50 mg/dL or less are present in 30%–60% of cases of tuberculous peritonitis and in about 50% of patients with abdominal carcinomatosis (Polak, 1973; Brown, 1976). However, a more recent study found decreased glucose levels in most cases of tuberculous ascites (Bansal, 1998). Nevertheless, glucose measurements are of little value because the sensitivity and specificity are generally too low to be of practical value.

Enzymes

Amylase activity in normal peritoneal fluid is similar to plasma levels. A level greater than three times the plasma value is good evidence of pancreas-related ascites, including acute pancreatitis and pancreatic pseudocyst (Runyon, 1987a). Amylase is not recommended in the routine evaluation of ascites, however, because the prevalence of pancreatic ascites is low. Retrospective amylase measurement on a stored specimen is indicated if initial studies are not diagnostic. However, amylase levels in peritoneal lavage fluid may be valuable in patients following blunt and penetrating abdominal trauma (McAnena, 1991). Here, amylase levels greater than or equal to 20 U/L had a sensitivity of 87%, a specificity of 75%, and a positive predictive value of 46% for significant intraabdominal injury. In these cases, laparotomy should be considered. Gastroduodenal perforation, acute mesenteric vein thrombosis, intestinal strangulation, or necrosis may also produce elevated amylase levels. Although various non-pancreatic malignancies may rarely produce amylase elevations, isoenzyme evaluation usually identifies the salivary isoform in these latter cases (Kosches, 1989).

Elevated **alkaline phosphatase** (ALP) levels greater than 10 U/L in diagnostic peritoneal lavage fluid are very useful in predicting hollow visceral injury in patients who would otherwise not undergo laparotomy (specificity 99.8%, sensitivity 94.7%) (Jaffin, 1993). Ascitic fluid ALP measurements may also be helpful in the differentiation of primary bacterial peritonitis from secondary bacterial peritonitis due to bowel perforation. Secondary peritonitis has significantly higher mean ALP levels than SBP. Thus, ALP levels >240 U/L were present in 92% of patients with secondary peritonitis versus 12% for SBP (Wu, 2001). The sensitivity and specificity for differentiating secondary peritonitis from SBP were 92% and 88%, respectively.

LD activity is often increased in malignant effusions (Gerbes, 1991). An ascitic fluid/serum LD ratio greater than 0.6 has a reported sensitivity of 80% (Boyer, 1978). Combined measurement of ascitic fluid LD and cholesterol totally discriminated peritoneal carcinomatosis from cirrhosis and hepatocarcinoma-related ascites (Castaldo, 1994; Halperin, 1999). Although both serum and peritoneal fluid LD levels are significantly higher in patients with ovarian cancer than in those with benign ovarian tumors or other gynecologic malignancies, peritoneal fluid LD has higher diagnostic sensitivity (87%) and diagnostic accuracy (90%) than serum LD (60% and 77%, respectively) (Schneider, 1997). LD has also been used for the early diagnosis of spontaneous bacterial peritonitis, in which it has a diagnostic accuracy of about 74% using an ascitic fluid/serum ratio cutoff of 0.4 (Lee, 1987).

The presence of **telomerase** is a specific discriminatory marker in malignant ascites (Tangkijvanich, 1999). Thus, telomerase activity was detected in 81% of malignant peritoneal effusions with a sensitivity of 76% and a specificity of 95.7%.

ADA is commonly used in endemic areas to identify patients with tuberculous peritonitis (Burgess, 2001). Using receiver operating characteristic curves and a cutoff value of 30 U/L, the sensitivity and specificity were 94% and 92%, respectively. Using a cutoff value of 33 U/L, the sensitivity, specificity, positive and negative predictive values, and overall diagnostic accuracy for diagnosing tuberculous peritonitis were 100%, 96.6%, 95%, 100%, and 98%, respectively (Dwivedi, 1990).

Fibronectin

Using a cutoff value of 85 µg/mL (85 mg/L), fibronectin was more reliable in differentiating malignant from sterile ascites (diagnostic accuracy, 79%) than were total protein, LD, γ-glutamyltransferase, pH, amylase, triglycerides, leukocyte count, and cytologic examination (Colli, 1986). In a subsequent study using a cutoff of 94.6 µg/mL, the sensitivity, specificity, positive accuracy, negative accuracy, and overall diagnostic accuracy in the diagnosis of malignant ascites were 100%, 95%, 93.8%, 100%, and 97.1%, respectively (Sood, 1997).

Lactate

Ascitic fluid lactate has been used with pH measurements to differentiate SBP from uncomplicated ascites. Sensitivity and specificity are approximately 90% using a cutoff of 40 mg/dL (4.44 mmol/L), with a positive predictive value of 62% (Stassen, 1986). Although not as accurate as leukocyte counts, the high specificity of lactate in hepatic ascites suggests that it has some value in the diagnosis of SBP in otherwise equivocal cases. Malignant and tuberculous ascites are also associated with elevated lactate levels.

Patients with hollow viscous perforation, gangrenous intestine, peritonitis, or intraabdominal abscess have a peritoneal fluid minus plasma lactate level of at least 13.5 mg/dL (1.5 mmol/L), which reportedly separates these patients completely from those with other conditions producing acute abdominal problems (DeLaurier, 1994). Additional studies are necessary to determine the utility of measuring ascitic fluid lactate in surgical decision making.

Creatinine and Urea

Measurement of creatinine and urea nitrogen is useful to differentiate between peritoneal fluid and urine. Elevated peritoneal fluid urea nitrogen and creatinine, in association with elevated serum urea but normal serum creatinine (due to back-diffusion of urea), suggest urinary bladder rupture.

Bilirubin

The mean (±SD) ascitic fluid bilirubin concentration in various types of ascites was reported as 0.7 ± 0.8 mg/dL, and the mean ascitic fluid/serum bilirubin ratio was 0.38 ± 0.44 (Runyon, 1987b). An ascitic fluid bilirubin greater than 6.0 mg/dL and an ascitic fluid/serum bilirubin ratio over 1.0 suggest choleperitoneum from a ruptured gallbladder. A ratio of 0.6 or greater has been advocated as an additional marker for an exudative process, although its accuracy is not as high as that of the serum–ascites albumin gradient (Elis, 1998).

pH

Ascitic fluid pH may be helpful in the diagnosis of SBP in patients with cirrhotic ascites, especially if it is used in conjunction with the leukocyte count (Attali, 1986; Stassen, 1986). A pH less than 7.32 or a blood–ascitic fluid pH difference of more than 0.1 has a reported sensitivity and specificity of about 90% for SBP, with the pH differential being slightly more accurate. Peritoneal fluid pH appears useless in detecting SBP, however, in the absence of neutrophils (Runyon, 1991). Patients with an ascitic fluid pH of less than 7.15 have a poor prognosis (Attali, 1986). Low pH is also found in patients with malignant and pancreatic ascites and tuberculous peritonitis.

Cholesterol

The ascitic fluid cholesterol level is a moderately useful index in separating malignant ascites (>45–48 mg/dL) from cirrhotic ascites (Mortensen, 1988; Castaldo, 1994). The sensitivity and specificity average just over 90% using a cutoff value of 45–48 mg/dL (1.2 mmol/L). Thus, using a cutoff value of 48 mg/dL, the sensitivity, specificity, positive and negative predictive value, and overall diagnostic accuracy for differentiating malignant from nonmalignant ascites were reported as 96.5%, 96.6%, 93.3%, 98.3%, and 96.6%, respectively (Garg, 1993).

Interleukin-8

Interleukin-8, a cytokine produced by a variety of cells in response to stimuli such as bacterial lipopolysaccharide, is significantly higher in spontaneous bacterial peritonitis compared with sterile ascites (Martinez-Bru, 1999). Using a cutoff value of 100 ng/L, the sensitivity and specificity were both 100% in cirrhotic patients.

Tuberculostearic Acid (10-Methyloctadecanoic Acid)

As noted in the **Pleural Fluid** section, TSA was detected in pleural fluid in 75% of patients with pulmonary tuberculosis using gas chromatography–mass spectroscopy (Muranishi, 1990). Using quantitative chemical ionization gas chromatography–mass spectrometry, the measurement of TSA is a valuable technique to identify tuberculous peritonitis, as well as tuberculous meningitis (spinal fluid) and pneumonia (pleural fluid) (Brooks, 1998).

Tumor Markers

Because of their reportedly low sensitivity and specificity, the measurement of tumor markers is generally considered to be of little value. They are often useful, however, in selected cases, such as in following a patient's response to therapy and in the early detection of tumor recurrence. They may also be very useful in cases where cytology is negative but suspicion of malignant ascites is high. Indeed, the poor sensitivity of cytologic examinations is disappointing. They were positive in only 40% (35 of 89 patients) of malignant cases, while tumor markers were positive in 80% (Cascinu, 1997). Moreover, excluding small cell lung and renal cancers, for which specific tumor markers are lacking, tumor markers (i.e., CEA, CA 19-9, CA 15-3, PSA) in ascitic fluid for other carcinomas were positive in 97% of cases. These tumor markers, as well as α -fetoprotein, were also found to be very specific (over 90%) for serous fluid malignancies, although their sensitivities were low (19%–38%) (Sari, 2001). The measurement of **PSA** may also be a valuable marker for the diagnosis of malignant effusions due to prostate cancer (Appalaneni, 2004).

CEA has a sensitivity of only 40%–50% and a specificity of about 90% using a cutoff value of 3.0 ng/mL (Mezger, 1988). Using a 5-mg/mL cutoff, the specificity is about 97% (Gulyas, 2001). Elevated CEA levels in peritoneal washings suggest a poor prognosis in gastric carcinoma (Irinoda, 1998).

Ascitic fluid **CA-125** is elevated to some degree in a variety of nonmalignant conditions. Indeed, cardiovascular and chronic liver disease may be the most frequent diagnoses in patients with increased CA-125 levels (Miralles, 2003), thereby supporting the general opinion that CA-125 lacks adequate specificity as a marker for malignancy. However, extremely high levels are more likely to be caused by epithelial carcinomas of the ovary, fallopian tubes, or endometrium.

The sensitivity for ovarian carcinoma depends on the tumor's stage (range, 40%–95%) and histologic subtype (mucinous adenocarcinomas have lower values) (Molina, 1998).

DNA ploidy analysis by flow cytometry or image analysis might provide useful complementary diagnostic information in cases with equivocal cytology results when the malignant cells carry an aneuploid karyotype. Image analysis appears to be more practical than flow cytometry when the tumor cells are scarce (Rijken, 1991).

MICROBIOLOGICAL EXAMINATION

Primary peritonitis occurs at any age and is seen in children with nephrotic syndrome and in adults with cirrhotic liver disease. Spontaneous bacterial peritonitis occurs in patients with ascites in the absence of recognized secondary causes such as bowel perforation or intraabdominal abscess. The bacteria in SBP are most often normal intestinal flora, and more than 92% are monomicrobial. Aerobic gram-negative bacilli (e.g., *E. coli*, *Klebsiella pneumoniae*) are responsible for two thirds or more of all cases (Gilbert, 1995), followed by *S. pneumoniae*, *Enterococcus* spp., and, rarely, anaerobes. The Gram stain has a sensitivity of 25% in SBP (Lee, 1987), and routine cultures are positive in only about 50% of cases (Castellote, 1990). Inoculation of blood culture bottles at the bedside and concentration of large volumes of fluid can improve sensitivity, but up to 35% of infected patients may still have negative ascitic fluid cultures (Marshall, 1988). Use of resin-containing blood culture bottles may improve the isolation of certain bacteria in partially treated patients.

Ascitic fluid total neutrophil count is the preferred method for the diagnosis of SBP (see under **Microscopic Examination**). However, as noted earlier, in difficult cases, several analytes may be useful in differentiating SBP from secondary bacterial or tuberculous peritonitis. More recently, PCR has been successfully used in the detection of bacterial DNA in culture-negative ascitic fluid (Such, 2002).

The sensitivity of acid-fast stains for *M. tuberculosis* is no more than 20%–30%, and cultures have a sensitivity of only 50%–70% (Reimer, 1985). Application of PCR to detect *M. tuberculosis* DNA has been studied, but a negative result does not exclude the diagnosis (Schwake, 2003). In a patient with a high clinical suspicion for tuberculous peritonitis, laparoscopic examination with biopsy may be indicated.

ALTERNATIVE SPECIMENS

SALIVA

Saliva is generally easily collected by noninvasive means, and so its acquisition is well accepted by patients. Because it is a filtrate of plasma, saliva

has concentrations of some small molecules that are in equilibrium with the free (unbound) active fractions of those substances in plasma. This property has been especially useful for measuring free cortisol, which is the physiologically important fraction that reflects the secretion rate of cortisol and so is important for diagnosis. Salivary cortisol measurements have been used to assess adrenal function in critically ill subjects (Arafah, 2007) and in those with Cushing's syndrome and adrenal insufficiency (Raff, 2009), with late-night (or midnight) salivary cortisol being an effective screening test for Cushing's syndrome (Raff, 1998). Unfortunately, salivary concentrations of several other steroid hormones are not reliable measures of plasma free levels because of rapid fluctuations in their salivary concentrations (e.g., estradiol, progesterone, testosterone, dehydroepiandrosterone, aldosterone) (Wood, 2009).

Saliva also contains some antibody molecules that apparently derive from plasma. Thus measurements are sometime performed on saliva to detect antibodies against infectious agents in circumstances where collection of saliva is much more convenient or acceptable to patients. Testing of saliva for antibodies against human immunodeficiency virus has been practiced widely in sexually transmitted disease clinics, although episodes of false-positive results have diminished confidence in these point-of-care tests (MMWR, 2008).

Genetic testing requires DNA from the patient that can be obtained conveniently from leukocytes in blood specimens, or even more conveniently from buccal cells in saliva or from swabs of the interior of the mouth.

Drug testing has also been done in saliva to provide evidence of ingestion of illicit substances. Although drugs such as amphetamines, cocaine, and opioids are present in oral fluid at concentrations similar to those in plasma, local absorption of these drugs in the mouth can increase their concentration in saliva after use (Drummer, 2006).

HAIR AND NAILS

Drug testing has time limitations of detection in blood for periods of minutes to hours after ingestion. The need to detect illicit drug use over longer periods of time has prompted analysis of other body sources. Concentrations of drugs in saliva follow the same time course as blood of minutes to hours after ingestion. Detection in urine can be as soon as minutes up to many days after drug use. Sweat concentrations also rise in minutes but may persist for weeks. True long-term detection is possible in hair and nails, where drugs of abuse can be detected days to even years after ingestion. Although numerous companies offer drug testing of hair or nail specimens, there has not been official adoption of this strategy by government agencies, largely because of issues of uncertainty as to whether the substances detected from hair or nail specimens were actually "in" the hair following ingestion and incorporation into that tissue, or whether the detected drug was simply "on" the surface of the specimen because of incidental contact that did not involve ingestion (Curtis, 2008).

TISSUE ASPIRATES

Breast nipple aspirate fluid can be obtained by noninvasive means such as massage or with automated collection devices to yield material suitable for cytologic examination for early detection of breast cancer. This new collection approach may lead to other effective applications of cancer detection using modalities such as proteomics or still to be discovered biomarkers (Alexander, 2004).

Fine-needle aspiration for cytologic examination is frequently used to evaluate head and neck masses. Rapid identification of a mass of parathyroid tissue has been done by measuring parathyroid hormone (PTH) in saline, into which the needle aspirate is flushed (Conrad, 2006). This method was shown to be 99% accurate for diagnosis of parathyroid tissue because the measured values of PTH are orders of magnitude higher in parathyroid aspirates than in those from other tissues such as thyroid, adipose, or lymphatic. This type of specimen is truly unusual and would not likely be included in any manufacturer's claims for assay performance; however, this practice is well recognized by endocrine surgeons who now consider it a standard of practice.

BILLING FOR TESTS IN NONSTANDARD SPECIMENS

Although considerations of medical necessity provide strong motivation for performing tests in unusual specimen types to provide unique

information that could not be obtained by other means, reporting of the results and subsequent billing may lead to confusion. Most laboratory computer systems have strictly defined specimen types, such as blood, serum, urine, and CSF. When dealing with an unusual specimen type that is not individually coded or recognized in a computer system, laboratories should take care not to enter these results as though they were serum or other commonly tested fluid. For both medical needs and reimbursement, some disclaimer should be included to indicate the specimen type, so that it is not confused with serum or other conventional fluid.

CHEMICAL MEASUREMENTS IN BODY FLUIDS

Plasma, serum, cerebrospinal fluid, and urine are standard fluids that are often submitted for chemical analysis. Manufacturers generally provide product claims for their assays in one or more of these body fluids, but they have not established assay behavior in other specimen types such as pleural fluid, peritoneal fluid, synovial fluid, and other accumulations of abnormal fluids such as drainage or lavage fluids. These types of fluids are not normally present in health but rather can form as the result of various pathologic processes, such as hemodynamic imbalance, infection, inflammation, malignancy, or other organ dysfunction. Consequently, the composition of these fluids can range widely, thereby leading to unpredictable effects on laboratory measurements. Matrix effects from variations in protein concentration can alter fluid surface tension, viscosity, and miscibility in a reaction mixture. All of these variations potentially might cause differences in measurements because of errors in pipetting fixed volumes or in speed and completeness of mixing with reagents in an assay. Other constituents present in these pathologic fluids (e.g., hyaluronic acid in synovial fluid) but not in serum also have the potential to alter measurements in assays intended for use in serum. This potential for erroneous measurements in body fluids due to matrix effects should be recognized when such requests for analysis are received.

A second issue concerning chemical measurements in pathologic fluids is what reference range to use for comparison in an interpretive report. Because abnormal fluid accumulations do not exist in a state of health, they cannot, of course, be collected from a normal healthy population to establish reference ranges.

These two issues of potential interferences and lack of reference ranges for analysis of body fluids fly in the face of Clinical Laboratory Improvement Act requirements for assay validation. In fact, the lack of manufacturers' claims for body fluid testing might actually place a greater burden on a laboratory to validate these assays than for use in serum for which manufacturer claims are typically cleared by the U.S. Food and Drug Administration. Without such validation, measuring chemical constituents in body fluids could be considered an off-label use of commercial assays.

In recognition of these difficulties faced by laboratories, the Clinical and Laboratory Standards Institute (CLSI) has developed the document

C49A, Analysis of Body Fluids in Clinical Chemistry, to provide guidance in this situation (CLSI, 2007). The specific recommendations from CLSI are as follows:

1. Review performance claims of the manufacturer for the possibility of extending a commercial assay to body fluids with special attention to accuracy, precision, analytic measurement range, reference interval (usually in comparison with simultaneous measurement in serum, in addition to the patient's body fluid), and interferences from substances in the body fluid.
2. Existing methods may be suitably modified for body fluid analysis when necessary to obtain medically relevant information. Matrix effects that could alter the accuracy of measurement must be recognized. Furthermore, lack of a reference range for the analyte in body fluids should be compensated for by interpretation of results in comparison with a simultaneously collected serum specimen.
3. The preconditions for using a routine assay for an alternate body fluid are that the measurement system in another specimen type (serum plasma, urine)
 - a. Has acceptable test characteristics.
 - b. Has a reference method by which to ascertain bias.
 - c. Has calibrators and controls.
 - d. External proficiency testing should be done whenever available.
4. Specimen collection of body fluid and its handling, processing, and storage should follow guidelines for specimens of plasma or serum collected for that measurement. Special attention should be directed to the possibility of interference from anticoagulants into which a body fluid might be collected (e.g., heparin, EDTA, citrate).
5. Unusual properties of a body fluid such as high viscosity should be given consideration if they have the potential to alter the analyte concentration in the final solution of the reaction mixture (e.g., inaccurate pipetting, inadequate mixing).
6. The presence of an interferer in a body fluid can be assessed by testing the fluid neat and at 1:2 and 1:4 dilutions. Recovery of similar concentrations suggests lack of interference. Low concentrations can be checked for interference by mixing with a routine (serum) sample with a high measurable value to measure recoverability.
7. Result reporting should include the measured value and the type of fluid analyzed plus a statement that accuracy might be affected by sample type, and that results should be interpreted in the clinical context. The laboratory is urged to contact ordering physicians to explain these limitations.

A key point is that to be useful clinically, measurements in body fluids need not necessarily be highly accurate but instead must be within a clinically acceptable range of the true value. This CLSI document provides an extensive list of applications of many different chemical analytes that may provide medically unique information about the source of a body fluid (e.g., creatinine in peritoneal fluid to evaluate urinary tract injury; amylase in peritoneal fluid to evaluate for pancreatitis; triglycerides in pleural fluid as an indicator of chylous effusion from lymphatic damage).

KEY POINTS

- Article I: Assessment of erythrocyte, leukocyte, and platelet counts from manual and automated particle counters is central to the diagnosis and management of hematologic disease.
- Article II: With few exceptions, manual methods have been replaced by automated hematology analyzers. The selection of analyzers is varied and voluminous enough to meet the needs of any hematology laboratory setting.
- Article III: Hematology automation combined with sophisticated algorithms for data interpretation has led to dramatic improvement in the utility of automated analyzers in patient care. Newer instrumentation has progressed far beyond the screening tool of the past.

- Article IV: Examination of peripheral blood with bone marrow smear/biopsy represents the cornerstone of hematologic diagnosis. The bone marrow examination provides a semiquantitative and qualitative assessment of the state of hematopoiesis, and aids in the diagnosis of several hereditary and acquired benign and malignant diseases.

Hematology includes the study of blood cells and coagulation. It encompasses analyses of the concentration, structure, and function of cells in blood; their precursors in the bone marrow; the chemical constituents of plasma or serum intimately linked with blood cell structure and function; and the function of platelets and proteins involved in blood coagulation. Advancement of molecular biological techniques and their increased use in hematology have led to detection of several genetic mutations

underlying the altered structure and function of cells and proteins that may result in hematologic disease.

HEMATOLOGY PRINCIPLES AND PROCEDURES

HEMOGLOBIN

Hemoglobin (Hb), the main component of the red blood cell (RBC), is a conjugated protein that serves as the vehicle for the transportation of oxygen (O_2) and carbon dioxide (CO_2). When fully saturated, each gram of Hb holds 1.34 mL of O_2 . The red cell mass of the adult contains approximately 600 g of Hb, capable of carrying 800 mL of O_2 . A molecule of Hb consists of two pairs of polypeptide chains ("globins") and four prosthetic heme groups, each containing one atom of ferrous iron. Each heme group is precisely located in a pocket or fold of one of the polypeptide chains. Located near the surface of the molecule, the heme reversibly combines with one molecule of O_2 or CO_2 . The main function of Hb is to transport O_2 from the lungs, where O_2 tension is high, to the tissues, where it is low. At an O_2 tension of 100 mm Hg in the pulmonary capillaries, 95%–98% of the Hb is combined with O_2 . In the tissues, where O_2 tension may be as low as 20 mm Hg, the O_2 readily dissociates from Hb; in this instance, less than 30% of the O_2 would remain combined with Hb.

Reduced Hb is Hb with iron unassociated with O_2 . When each heme group is associated with one molecule of O_2 , the Hb is referred to as oxyhemoglobin (HbO_2). In both Hb and HbO_2 , iron remains in the ferrous state. When iron is oxidized to the ferric state, methemoglobin (hemoglobin; Hi) is formed, and the molecule loses its capacity to carry O_2 or CO_2 .

Anemia is a decrease to below normal Hb concentration, erythrocyte count, or hematocrit (Hct). It is a very common condition and is frequently a complication of other diseases. Clinical diagnosis of anemia or of high Hb based on estimation of the color of the skin and of visible mucous membranes is highly unreliable. The correct estimation of Hb is important and is one of the routine tests performed on practically every patient.

Hemoglobin Derivatives

Hemoglobin (Methemoglobin)

Methemoglobin (Hi) is a derivative of Hb in which the ferrous iron is oxidized to the ferric state, resulting in the inability of Hi to combine reversibly with O_2 . The polypeptide chains are not altered. A normal individual has up to 1.5% methemoglobin. Methemoglobinemia will cause chocolate brown discoloration of blood, cyanosis, and functional "anemia" if present in high enough concentrations. Cyanosis becomes obvious at a concentration of about 1.5 g Hi/dL (i.e., 10% of Hb). Comparable degrees of cyanosis will be caused by 5 g Hb per deciliter of blood, 1.5 g Hi per deciliter of blood, and 0.5 g sulfhemoglobin (SHb) per deciliter of blood. The degree of cyanosis, however, is not necessarily correlated with the concentration of Hi. A small amount of Hi is always being formed but is reduced by enzyme systems within the erythrocyte. The most important is the NADH (reducing agent derived from nicotinamide adenine dinucleotide)-dependent methemoglobin reductase system (NADH-cytochrome-*b*₅ reductase). Others, which may function mainly as reserve systems, are ascorbic acid, reduced glutathione, and reduced nicotinamide adenine dinucleotide phosphate (NADPH)-methemoglobin reductase. The latter requires a natural cofactor or an auto-oxidizable dye such as methylene blue for activity.

Methemoglobinemia, an increased amount of Hi in the erythrocytes, may result from increased production of Hi or decreased NADH-cytochrome-*b*₅ reductase activity, and may be hereditary or acquired (Jaffé, 1989). The hereditary form is divided into two major categories. In the first, methemoglobinemia is due to a decrease in the capacity of the erythrocyte to reduce the Hi that is constantly being formed back to Hb. This is most often due to *NADH-cytochrome-*b*₅ reductase deficiency*, which is inherited as an autosomal recessive characteristic. The homozygote has methemoglobin levels of 10%–50% and is cyanotic. Only occasionally is polycythemia present as a compensating mechanism. Hi concentrations of 10%–25% may give no apparent symptoms; levels of 35%–50% result in mild symptoms, such as exertional dyspnea and headaches; and levels exceeding 70% are probably lethal. Therapy with ascorbic acid or methylthioninium chloride (methylene blue) in this form of hereditary methemoglobinemia will reduce the level of Hi, the latter apparently by activation of the NADPH-methemoglobin reductase system. Heterozygotes have

intermediate levels of NADH-cytochrome-*b*₅ reductase activity and normal blood levels of Hi. They may become cyanotic because of methemoglobinemia after exposure to oxidizing chemicals or drugs in amounts that will not affect normal individuals.

In the second major category of hereditary methemoglobinemia, the reducing systems within the erythrocyte are intact, but the structure of the Hb molecule itself is abnormal. A genetically determined alteration in the amino acid composition of α - or β -globin chains may form a Hb molecule that has an enhanced tendency toward oxidation and a decreased propensity of the methemoglobin formed to be reduced back to Hb. Their principal consequence is asymptomatic cyanosis as a result of methemoglobinemia; they are designated as various forms of *hemoglobin M (Hb M)*. In six of the seven Hb M variants, tyrosine is substituted for histidine in the heme pocket of the proximal or distal globin chain. Nagai (1995) showed by spectroscopy that a considerable proportion of the mutant subunits of Hb M Saskatoon and Hb M Boston stay in the fully reduced form under circulation conditions. They are inherited as autosomal dominant traits (Lukens, 2004). Methylthioninium chloride therapy in these individuals is without effect, and treatment is not necessary.

Most cases of methemoglobinemia are classified as secondary or acquired, due mainly to exposure to drugs and chemicals that cause increased formation of Hi. Chemicals or drugs that directly oxidize HbO_2 to Hi include nitrites, nitrates, chlorates, and quinones. Other substances, which are aromatic amino and nitro compounds, probably act indirectly through a metabolite because they do not cause Hi formation in vitro. These include acetanilid, phenacetin, sulfonamides, and aniline dyes. Ferrous sulfate may produce methemoglobinemia after ingestion of very large doses. Levels of drugs or chemicals that would not cause significant methemoglobinemia in a normal individual may do so in someone with a mild reduction in NADH-cytochrome-*b*₅ reductase activity that, under ordinary circumstances, is not cyanotic. Such individuals are newborn infants and persons heterozygous for NADH-cytochrome-*b*₅ reductase deficiency (Bunn, 1986). Hi is reduced back to Hb by the erythrocyte enzyme systems. It can also be reduced (slowly) by the administration of reducing agents, such as ascorbic acid or sulfhydryl compounds (glutathione, cysteine); these, as well as methylthioninium chloride, are of value in cases of hereditary NADH-cytochrome-*b*₅ reductase deficiency. In cases of acquired or toxic methemoglobinemia, methylthioninium chloride is of great value; its rapid action is based not on its own reduction capacity but on its acceleration of the normally slow NADPH-methemoglobin reductase pathway. Hi can combine reversibly with various chemicals (e.g., cyanides, sulfides, peroxides, fluorides, azides). Because of the strong affinity of Hi for cyanide, the therapy of cyanide poisoning is to administer nitrites to form Hi, which then combines with the cyanide. Thus, the free cyanide (which is extremely poisonous to the cellular respiratory enzymes) becomes less toxic when changed to $HiCN$.

Hi is quantitated by spectrophotometry. If Hi is elevated, drugs or toxic substances must first be eliminated as a cause. Congenital methemoglobinemia due to NADH-cytochrome-*b*₅ reductase deficiency is determined by assay of the enzyme. An abnormal hemoglobin (Hb M) may also be responsible for methemoglobinemia noted at birth or in the first few months of life.

Sulfhemoglobin

SHb is a mixture of oxidized, partially denatured forms of Hb that form during oxidative hemolysis (Jandl, 1996). During oxidation of Hb, sulfur (from some source, which may vary) is incorporated into heme rings of Hb, resulting in a green hemochrome. Further oxidation usually results in the denaturation and precipitation of Hb as Heinz bodies (Fig. 30-1). SHb cannot transport O_2 , but it can combine with carbon monoxide (CO) to form carboxysulfhemoglobin. Unlike methemoglobin, SHb cannot be reduced back to Hb, and it remains in the cells until they break down. The

Figure 30-1 Simplified concept of oxidation of hemoglobin (Hb) to methemoglobin (Hi), as proposed by Jandl (1996). Reversible binding and release of oxygen occur in lungs and tissues; oxidation of ferrous ions and formation of Hb are reversible in the red cell to a limited extent; continued oxidation leads to irreversible conformational changes and sulfhemoglobin; still further oxidation results in denaturation of the Hb and precipitation within the erythrocyte as Heinz bodies. *HbO₂*, Oxyhemoglobin; *NADH*, reduced nicotinamide adenine dinucleotide; *SHb*, sulfhemoglobin.

blood is mauve-lavender in sulfhemoglobinemia. SHb has been reported in patients receiving treatment with sulfonamides or aromatic amine drugs (phenacetin, acetanilid), as well as in patients with severe constipation, in cases of bacteremia due to *Clostridium perfringens*, and in a condition known as enterogenous cyanosis. The concentration of SHb in vivo normally is less than 1%, and in these conditions it seldom exceeds 10% of the total Hb. It results in cyanosis and is usually asymptomatic. The reason why some patients develop methemoglobinemia, some sulfhemoglobinemia, and others Heinz bodies and hemolysis is not well understood. SHb is quantitated by spectrophotometry.

Carboxyhemoglobin

Endogenous CO produced in the degradation of heme to bilirubin normally accounts for about 0.5% of carboxyhemoglobin (HbCO) in the blood, and is increased in hemolytic anemia. Hb has the capacity to combine with CO with an affinity 210 times greater than for O₂. CO will bind with Hb even if its concentration in the air is extremely low (e.g., 0.02%–0.04%). In those cases, HbCO will build up until typical symptoms of poisoning appear. HbCO cannot bind and carry O₂. Furthermore, increasing concentrations of HbCO shift the Hb–O₂ dissociation curve increasingly to the left, thus adding to the anoxia. If a patient poisoned with CO receives pure O₂, the conversion of HbCO to HbO₂ is greatly enhanced. HbCO is light sensitive and has a typical, brilliant, cherry red color.

Acute CO poisoning is well known. It produces tissue hypoxia as a result of decreased O₂ transport. Chronic poisoning, a result of prolonged exposure to small amounts of CO, is less well recognized but is of increasing importance. The chief sources of the gas are gasoline motors, illuminating gas, gas heaters, defective stoves, and the smoking of tobacco. Exposure to CO is thus one of the hazards of modern civilization. The gas has even been found in the air of busy streets of large cities in sufficient concentration to cause mild symptoms in persons such as traffic police officers, who are exposed to it over long periods of time. Chronic exposure through tobacco smoking may lead to chronic elevation of HbCO and an associated left shift in the Hb–O₂ dissociation curve; smokers tend to have higher Hcts than nonsmokers and may have polycythemia. Healthy persons exposed to various concentrations of the gas for an hour do not experience definite symptoms (headache, dizziness, muscular weakness, and nausea) unless the concentration of gas in the blood reaches 20%–30% of saturation; however, it appears that in chronic poisoning, especially in children, serious symptoms may occur with lower concentrations. HbCO may be quantitated by differential spectrophotometry or by gas chromatography.

Measurement of Hb Concentration

The cyanmethemoglobin (hemiglobincyanide; HiCN) method has the advantages of convenience and a readily available, stable standard solution.

Hemiglobincyanide Method

Principle. Blood is diluted in a solution of potassium ferricyanide and potassium cyanide. The potassium ferricyanide oxidizes Hb to Hi (methemoglobin), and potassium cyanide provides cyanide ions (CN[−]) to form HiCN, which has a broad absorption maximum at a wavelength of 540 nm (Fig. 30-2; Table 30-1). The absorbance of the solution is measured in a spectrophotometer at 540 nm and is compared with that of a standard HiCN solution.

Reagent. The diluent is detergent-modified Drabkin reagent:

0.20 g	Potassium ferricyanide (K ₃ Fe[CN] ₆)
0.05 g	Potassium cyanide (KCN)
0.14 g	Dihydrogen potassium phosphate (anhydrous) (KH ₂ PO ₄)
	Nonionic detergent, for example,
0.5 mL	Sterox S.E. (Harleco), or
1.0 mL	Triton X-100 (Rohm and Haas)
Distilled water to 1000 mL	

The solution should be clear and pale yellow, have a pH of 7.0–7.4, and give a reading of zero when measured in the photometer at 540 nm against a water blank.

Substituting dihydrogen potassium phosphate (KHP₂PO₄) in this reagent for sodium bicarbonate (NaHCO₃) in the original Drabkin reagent shortens the time needed for complete conversion of Hb to HiCN from 10 minutes to 3 minutes. The detergent enhances lysis of erythrocytes and decreases turbidity from protein precipitation.

Care must be taken with KCN in the preparation of the Drabkin solution, as salts or solutions of cyanide are poisonous. The diluent itself contains only 50 mg KCN per liter—less than the lethal dose for a 70-kg person. However, because hydrogen cyanide (HCN) is released by acidification, exposure of the diluent to acid must be avoided. Disposal of reagents and samples in running water in the sink is advised. The diluent keeps well in a dark bottle at room temperature but should be prepared fresh periodically.

Method. Twenty microliters of blood are added to 5.0 mL of diluent (1:251), mixed well, and allowed to stand at room temperature for at least 3 minutes (Dacie, 1991). The absorbance is measured against the reagent

Figure 30-2 Absorption spectra of oxyhemoglobin (HbO₂), deoxyhemoglobin (Hb), methemoglobin (hemoglobin [Hi]), and cyanmethemoglobin (hemiglobincyanide [HiCN]). (From Morris MW, Skrodzki Z, Nelson DA. Zeta sedimentation ratio [ZSR], a replacement for the erythrocyte sedimentation rate [ESR]. *Am J Clin Pathol* 1975;64:254–6. © 1975 American Society for Clinical Pathology.)

TABLE 30-1

Nomenclature and Absorption Maxima of Hemoglobins

Term	Symbol	Absorption peak 1		Absorption peak 2		Absorption peak 3	
		λ	ε	λ	ε	λ	ε
Hemoglobin	Hb	431	(140)	555	(13.04)		
Oxyhemoglobin	HbO ₂	415	(131)	542	(14.37)	577	(15.37)
Carboxyhemoglobin	HbCO	420	(192)	539	(14.36)	568.5	(14.31)
Hemoglobin (methemoglobin)	Hi	406	(162)	500	(9.04)	630	(3.70)
Hemiglobincyanide (cyanmet Hb)	HiCN	421	(122.5)	540	(10.99)		

Data from van Assendelft OW (1970).

The wavelength (λ) in nanometers for each maximum is followed by the extinction coefficient (ε) placed in parentheses.

blank in the photoelectric colorimeter at 540 nm or with an appropriate filter. A vial of HiCN standard is then opened and the absorbance measured, at room temperature, in the same instrument in a similar fashion. The test sample must be analyzed within a few hours of dilution. The standard must be kept in the dark when not in use and discarded at the end of the day.

$$\text{Hb (g/dL)} = \left[\frac{A^{540} \text{ test sample}}{A^{540} \text{ standard}} \right] \times \left[\frac{\text{Concentration of standard (mg/dL)}}{100 \text{ mg/g}} \right] \times 251$$

It is usually convenient to calibrate the photometer to be used for hemoglobinometry by preparing a standard curve or table that will relate absorbance to Hb concentration in grams per deciliter. The absorbance of fresh HiCN standard is measured against a reagent blank. Absorbance readings are made of fresh HiCN standard and of dilutions of this standard in the reagent (1 in 2, 1 in 3, and 1 in 4) against a reagent blank. Hb values in grams per deciliter are calculated for each solution as described previously. When the absorbance readings are plotted on linear graph paper as the ordinates against Hb concentration as the abscissa, the points should describe a straight line that passes through the origin. An advantage of the HiCN method is that most forms of hemoglobin (Hb, HbO₂, Hi, and HbCO, but not SHb) are measured.

The test sample can be directly compared with the HiCN standard, and the readings can be made at the convenience of the operator because of the stability of the diluted samples. Increased absorbance not due to Hb may be caused by turbidity due to abnormal plasma proteins, hyperlipemia, large numbers of leukocytes (counts >30 × 10⁹/L), or fatty droplets, any of which may lead to increased light scattering and apparent absorbance.

Errors in Hemoglobinometry

Sources of error may be those of the sample, the method, the equipment, or the operator.

Errors Inherent in the Sample. Improper venipuncture technique may introduce hemoconcentration, which will make Hb concentration and cell counts too high. Improper technique in fingerstick or capillary sampling can produce errors in either direction.

Errors Inherent in the Method. The HiCN method is the method of choice. Use of the HiCN standard for calibration of the instrument and for the test itself eliminates a major source of error. The broad absorption band of HiCN in the region of 540 nm makes it convenient to use both in filter-type photometers and in narrow-band spectrophotometers. With the exception of SHb, all other varieties of hemoglobin are converted to HiCN.

Errors Inherent in the Equipment. The accuracy of equipment is not uniform. A good grade of pipet with a guaranteed accuracy of greater than 99% is desirable. Calibration of pipets will lessen errors. Significant error can be introduced by the use of unmatched cuvettes; therefore, flow-through cuvettes are preferred. The wavelength settings, the filters, and the meter readings require checking. The photometer must be calibrated in the laboratory before its initial use and must be rechecked frequently to reduce the method's error to 2% (±CV).

Operator's Errors. Human errors can be reduced by good training, an understanding of the clinical significance of the test and the necessity for a dependable method, adherence to oral and written instructions, and familiarity with the equipment and with the sources of error. Errors increase with fatigue and tend to be greater near the end of the day. A technologist who is patient and critical by nature and by training and who is interested in the work is less prone to make errors.

The preceding discussion applies to manual techniques of hemoglobinometry. Automated equipment is widely used and eliminates most errors.

Spectrophotometric Identification of Hemoglobins

The various Hbs have characteristic absorption spectra, which can be determined easily with a spectrophotometer. Useful absorbance maxima are given in Table 30-1. The maxima for Hi vary considerably with pH. The maxima given in the two right-hand columns are useful for distinguishing among these forms of Hb. Absorbance between 405 and 435 nm

(the Soret band) is considerably greater and may be used when small concentrations of Hb are to be measured.

HEMATOCRIT (PACKED CELL VOLUME)

The Hct of a sample of blood is the ratio of the volume of erythrocytes to that of the whole blood. It may be expressed as a percentage (conventional) or as a decimal fraction (SI units). The units L/L are implied. Dried heparin and ethylenediaminetetraacetic acid (EDTA) are satisfactory anticoagulants. Before taking a sample from a tube of venous blood for a hematologic determination, it is important to mix the blood thoroughly. If the tube has been standing, this requires at least 60 inversions of the tube, or 2 minutes on a mechanical rotator; less than this leads to unacceptable deterioration in precision (Fairbanks, 1971). The number of inversions required to achieve homogeneity of a specimen depends on the dimensions of the container. Standard 10–14 × 75-mm tubes, containing 5 mL of blood and an air bubble that constitutes at least 20% of the tube volume, require at least eight inversions (NCCLS, 1993). The venous Hct agrees closely with the Hct obtained from a skin puncture; both are greater than the total body Hct. The Hct may be measured directly by centrifugation with macromethods or micromethods, or indirectly as the product of the mean corpuscular volume (MCV) times RBC count in automated instruments. In blood kept at room temperature, swelling of erythrocytes between 6 and 24 hours raises Hct and MCV. Cell counts and indices are stable for 24 hours at 4° C (Brittin, 1969).

The Wintrobe macromethod Hct employs centrifugation of blood in a thick-walled glass tube with a uniform internal bore and a flattened bottom. It is no longer used.

Gross Examination

Hct determination is performed by centrifugation. Inspection of the specimen after spinning may furnish valuable information. The relative heights of the red cell column, buffy coat, and plasma column should be noted. The buffy coat is the red-gray layer between the red cells and the plasma; it includes platelets and leukocytes.

An orange or green color of the plasma suggests increased bilirubin, and pink or red suggests hemoglobinemia. Poor technique in collecting the blood specimen is the most frequent cause of hemolysis. If specimens are not obtained within an hour or two after a fat-rich meal, cloudy plasma may point to nephrosis or certain abnormal hyperglobulinemias, especially cryoglobulinemia.

Hematocrit Measurement by Micromethod

Equipment

A capillary Hct tube about 7 cm long with a uniform bore of about 1 mm is used. For blood collection directly from a skin puncture, heparinized capillary tubes are available.

Procedure

The microhematocrit tube is filled by capillary attraction from a free-flowing puncture wound or a well-mixed venous sample. The capillary tube should be filled to at least 5 cm. The empty end is sealed with modeling clay. The filled tube is placed in the radial grooves of the microhematocrit centrifuge head with the sealed end away from the center. Place the bottom of the tube against the rubber gasket to prevent breakage. Centrifugation for 5 minutes at 10,000–12,000 g is satisfactory unless the Hct exceeds 50%; in that case, an additional 5 minutes' centrifugation should be employed to ensure minimal plasma trapping. The capillary tubes are not graduated. The length of the blood column, including the plasma, and of the red cell column alone must be measured in each case with a millimeter rule and a magnifying lens, or with one of several commercially available measuring devices. The instructions of the manufacturer must be followed.

Interpretation of Results

Typical reference values for adult males are 0.41–0.51, and for females, 0.36–0.45. A value below an individual's normal value or below the reference interval for age and sex indicates anemia, and a higher value, polycythemia. The Hct reflects the concentration of red cells—not the total red cell mass. The Hct is low in hydremia of pregnancy, but the total number of circulating red cells is not reduced. The Hct may be normal or even high in shock accompanied by hemoconcentration, although the total red cell mass may be decreased considerably owing to blood loss. The Hct is unreliable as an estimate of anemia immediately after loss of blood or immediately following transfusions.

Sources of Error

Centrifugation. Adequate duration and speed of centrifugation are essential for a correct Hct. The red cells must be packed so that additional centrifugation does not further reduce the packed cell volume. In the course of centrifugation, small proportions of the leukocytes, platelets, and plasma are trapped between the red cells. The error resulting from the former is, as a rule, quite insignificant. The amount of trapped plasma is larger in high Hcts than in low Hcts. Trapped plasma accounts for about 1%–3% of the red cell column in normal blood (about 0.014 in a Hct of 0.47), slightly more in macrocytic anemia, spherocytosis, and hypochromic anemia (Dacie, 1991). Even greater amounts of trapped plasma are noted in the Hcts of patients with sickle cell anemia; these vary depending on the degree of sickling and consequent rigidity of the cells. In using the microhematocrit as a reference method for calibrating automated instruments, correction for trapped plasma is recommended (International Committee for Standardization in Hematology [ICSH], 1980).

Sample. Posture, muscular activity, and prolonged tourniquet-stasis can cause the same order of changes in Hct and cell concentrations as they do in nonfilterable soluble constituents. Unique to the Hct is error due to excess EDTA (inadequate blood for a fixed amount of EDTA): The Hct will be falsely low as a result of cell shrinkage, but the Hb and cell counts will not be affected. There is no uniformity as to which EDTA salt is used for anticoagulation (O'Broin, 1997). The tripotassium (K_3 -EDTA) salt shrinks red cells about 2% and lowers packed cell volume compared with the dipotassium salt (K_2 -EDTA) (Koepke, 1989). Also, because K_3 -EDTA is a liquid, measured Hb and red and white cell counts are decreased by 1%–2%. Although the ICSH and the Clinical Laboratory Standards Institute recommend the K_2 -EDTA salt (powder), the K_3 -EDTA is more often used, perhaps because of its increased miscibility and fewer instances of specimen clotting (Geller, 1996).

Other Errors. Technical errors include failure to mix the blood adequately before sampling, improper reading of the levels of cells and plasma, and inclusion of the buffy coat as part of the erythrocyte volume. With good technique, the precision of the Hct, expressed as ± 2 CV (coefficient of variation), is $\pm 1\%$. With low Hct values, the CV is greater because of reading error.

ERYTHROCYTE INDICES

Wintrobe introduced calculations for determining the size, content, and Hb concentration of red cells; these erythrocyte indices have been useful in the morphologic characterization of anemias. They may be calculated from the red cell count, Hb concentration, and Hct.

Mean Cell Volume

The MCV, the average volume of red cells, is calculated from the Hct and the red cell count. $MCV = Hct \times 1000/RBC$ (in millions per μL), expressed in femtoliters or cubic micrometers. If the Hct = 0.45 and the red cell count = $5 \times 10^{12}/L$, 1 L will contain 5×10^{12} red cells, which occupy a volume of 0.45 L.

$$MCV = 0.45 L / 5 \times 10^{12} = 90 \times 10^{-15} L$$

$$\text{One femtoliter (fL)} = 10^{-15} L = 1 \text{ cubic micrometer } (\mu m^3).$$

Mean Cell Hemoglobin

The MCH is the content (weight) of Hb of the average red cell; it is calculated from the Hb concentration and the red cell count.

$$MCH = Hb \text{ (in g/L)} / RBC \text{ (in millions}/\mu L)$$

The value is expressed in picograms. If the Hb = 15 g/dL and the red cell count is $5 \times 10^{12}/L$, 1 L contains 150 g of Hb distributed in 5×10^{12} cells.

$$MCH = 150 / (5 \times 10^{12}) = 30 \times 10^{-12} \text{ (pg)}$$

$$\text{One picogram (pg)} = 10^{-12} \text{ g}$$

Mean Cell Hemoglobin Concentration

The mean cell hemoglobin concentration (MCHC) is the average concentration of Hb in a given volume of packed red cells. It is calculated from the Hb concentration and the Hct.

$$MCHC = Hb \text{ (in g/dL)} / Hct, \text{ expressed in g/dL}$$

$$\text{If the Hb} = 15 \text{ g/dL and the Hct} = 0.45, \text{ the}$$

$$MCHC = 15 \text{ g/dL} / 0.45 = 33.3 \text{ g/dL}$$

Indices are determined in the electrical impedance instruments somewhat differently. The MCV is derived from the mean height of the voltage pulses formed during the red cell count, and the Hb is measured by optical density of HiCN. The other three values are calculated as follows:

$$Hct = MCV \times RBC; MCH = Hb/RBC; MCHC = (Hb/Hct) \times 100$$

The reference values for the indices will depend on whether they are determined from the centrifuged Hct or the cell counters. The values in normal individuals will be similar if both are corrected for trapped plasma. However, because of increased trapped plasma in hypochromic anemias and sickle cell anemia, the MCHC calculated from the microhematocrit will be significantly lower than the MCHC derived from the electrical impedance counters.

The 95% reference intervals for normal adults are as follows: MCV = 80–96 fL; MCH = 27–33 pg; and MCHC = 33–36 g/dL (Ryan, 2001a). In a healthy person, there is very little variation—no more than ± 1 unit in any of the indices. Deviations from the reference value for an individual or outside the reference intervals for normal persons are useful, particularly in characterizing morphologic types of anemia.

In *microcytic anemias*, the indices may be as low as an MCV of 50 fL, an MCH of 15 pg, and an MCHC of 22 g/dL; rarely do any become lower.

In *macrocytic anemias*, the values may be as high as an MCV of 150 fL and an MCH of 50 pg, but the MCHC is normal or decreased (Dacie, 1991). The MCHC typically increases only in spherocytosis, and rarely is over 38 g/dL.

MANUAL BLOOD CELL COUNTS

Except for some platelet counts and low leukocyte counts, the hemocytometer is no longer used for routine blood cell counting. Yet it is still necessary for the technologist to be able to use this method effectively and to know its limitations. Any cell counting procedure includes three steps: dilution of the blood; sampling of the diluted suspension into a measured volume; and counting of the cells in that volume. Counts of erythrocytes, leukocytes, and platelets are each expressed as concentrations, that is, cells per unit volume of blood. The unit of volume was expressed as cubic millimeters (mm^3) because of the linear dimensions of the hemocytometer (cell counting) chamber.

$$1 \text{ mm}^3 = 1.00003 \mu L$$

Although there is no consistency in the literature in the use of traditional/conventional units versus Système International d'Unités (SI) units, the ICSH recommends that the unit of volume be the liter (SI units), as on the right in the following examples:

Erythrocytes:

$$5.00 \times 10^6 / mm^3 = 5.00 \times 10^6 / \mu L \text{ (conventional)} = 5.00 \times 10^{12} / L \text{ (SI units)}$$

Leukocytes:

$$7.0 \times 10^3 / mm^3 = 7.0 \times 10^3 / \mu L \text{ (conventional)} = 7.0 \times 10^9 / L \text{ (SI units)}$$

Platelets:

$$300 \times 10^3 / mm^3 = 300 \times 10^3 / \mu L \text{ (conventional)} = 300 \times 10^9 / L \text{ (SI units)}$$

Erythrocyte Counts: Manual

Combining a microcapillary tube with a plastic vial containing a premeasured volume of diluent, the Unopette (Becton-Dickinson, Franklin Lakes, N.J.) is a valuable system for manual dilutions. After the capillary tube is filled, it is pushed into the container, and the sample is washed out by squeezing the soft plastic vial. This system is especially convenient for microsampling. Unopettes are available with diluents for counts of RBCs, white blood cells (WBCs), platelets, eosinophils, and reticulocytes.

Semiautomated Methods

Instruments are available for precise and convenient diluting which both aspirate the sample and wash it out with the diluent. The dilutor should perform a 1:250 or a 1:500 dilution with a coefficient of variation of less than 1%.

Reticulocyte Count: Manual

Principle

Reticulocytes are immature nonnucleated red cells that contain ribonucleic acid (RNA) and continue to synthesize Hb after loss of the nucleus. When blood is briefly incubated in a solution of new methylene blue or brilliant cresyl blue, the RNA is precipitated as a dye-ribonucleoprotein complex. Microscopically, the complex appears as a dark blue network (reticulum or filamentous strand) or at least two dark blue granules that allow reticulocytes to be identified and enumerated (ICSH, 1998). A proposed reference method for reticulocyte counting based on determination of the reticulocyte/red cell ratio has been published (ICSH, 1998), expanding on the 1994 ICSH red cell count reference method.

Reagent. One percent new methylene blue in a diluent of citrate/saline (one part 30 g/L sodium citrate plus four parts 9 g/L sodium chloride).

Controls. Although commercial controls are available, Ebrahim (1996) describes a method requiring about 2 hours that produces a multilevel control that is stable for several months. Hypotonic dialysis of RBCs in the presence of RNA followed by a short period of hypertonic dialysis to reseal the pores of the RBC membrane results in about 20% of the RBCs as “synthetic reticulocytes” with various amounts of encapsulated RNA.

Procedure

Three drops each of reagent and blood are mixed in a test tube, incubated 15 minutes at room temperature, and remixed. Two wedge films are made on glass slides and air dried.

Viewed microscopically with an oil immersion lens, reticulocytes are pale blue and contain dark blue reticular or granular material, and red cells stain pale blue or blue-green. The percentage of reticulocytes is determined in at least 1000 red cells. A Miller disk inserted into the eyepiece allows rapid estimation of large numbers of red cells by imposing two squares (one square is nine times the area of the other) onto the field of view (Brecher, 1950). Reticulocytes are counted in the large square and red cells in the small square in successive microscopic fields until at least 300 red cells are counted. This provides an estimate of reticulocytes among at least 2700 red cells, as follows:

$$\text{Reticulocytes (percent)} = \left[\frac{\text{No. reticulocytes in large squares}}{(\text{No. red cells in small squares} \times 9)} \right] \times 100$$

The absolute reticulocyte count is determined by multiplying the reticulocyte percentage by the red cell count.

Reference Values

Normal adults have a reticulocyte count of 0.5%–1.5%, or $24\text{--}84 \times 10^9/\text{L}$. In newborn infants, the percentage is 2.5%–6.5%; this falls to the adult range by the end of the second week of life.

Interpretation

Because reticulocytes are immature red cells that lose their RNA a day or so after reaching the blood from the marrow, a reticulocyte count provides an estimate of the rate of red cell production. An absolute reticulocyte count or reticulocyte production index is more helpful than the percentage (see Chapter 31).

Sources of Variation

Because such a small number of actual reticulocytes are counted, the sampling error in the manual reticulocyte count is relatively large. The 95% confidence limits may be expressed as follows:

$$R \pm 2\sqrt{[R(100 - R)/N]}$$

where R is the reticulocyte count in percent, and N is the number of erythrocytes examined. This means that if only 1000 erythrocytes are evaluated, the 95% confidence limits for a 1% count are 0.4%–1.6%; for a 5% count, 3.6%–6.4%; and for a 10% count, 8.1%–11.9%.

Leukocyte Counts: Manual

Specimen Collection

EDTA should be used; heparin is unsatisfactory as an anticoagulant.

Hemocytometer Method

Although this method is used only occasionally in leukocyte counting, the technologist should be able to perform it

Figure 30-3 The upper figure is a diagram of the improved Neubauer ruling; this is etched on the surface of each side of the hemocytometer. The large corner squares, A, B, C, and D, are used for leukocyte counts. The five blue squares in the center are used for red cell counts or for platelet counts, and the 10 green plus blue squares for platelet counts. Actually, each of the 25 squares within the central 5 mm has within it 16 smaller squares for convenience in counting. The lower figure is a side view of the chamber with the cover glass in place.

1. As a check on the validity of electronic methods for calibration purposes
2. As a check on the validity of electronic counts in patients with profound leukopenia or thrombocytopenia
3. For blood specimens with platelet counting interference (i.e., very microcytic RBCs), and
4. As a backup method.

It is also commonly used as a method for counting cells in cerebrospinal fluid (CSF).

Counting Chamber. The hemocytometer is a thick glass slide with inscribed platforms of known area and precisely controlled depth under the coverslip. Counting chambers and cover glasses should be rinsed in lukewarm water immediately after use; wiped with a clean, lint-free cloth; and allowed to air dry. The surfaces must not be touched with gauze or linen because these materials may scratch the ruled areas.

Diluting Fluid. The diluting fluid lyses the erythrocytes so that they will not obscure the leukocytes. The fluid must be refrigerated and filtered frequently to remove yeasts and molds.

Procedure.

1. Well-mixed blood is diluted 1:20 in diluting fluid and the vial rotated for about 5 minutes. The chamber is loaded with just enough fluid to fill the space beneath the cover glass.
2. The cells are permitted to settle for several minutes, and the chamber is surveyed with the low-power objective to verify uniform cell distribution.
3. Counting is performed. The condenser diaphragm of the microscope is partially closed to make the leukocytes stand out clearly under a low-power (10 \times) objective lens. The leukocytes are counted in each of the four large (1 mm²) corner squares (A, B, C, and D in Fig. 30-3). A total of eight large corner squares from two sides of a chamber are counted.
4. Each large square encloses a volume of 1/10 mm³, and the dilution is 1:20. A general formula is as follows:

$$\text{Leukocyte count (cells/mm}^3\text{)} = (\alpha/lsc) \times d \times 10$$

where α is the total number of cells counted, d is the dilution factor, 10 is the factor transforming value over one large square (1/10 mm³) to the volume in mm³, and lsc is the number of large squares counted.

In leukopenia, with a total count below 2500, the blood is diluted 1:10. In leukocytosis, the dilution may be 1:100 or even 1:200.

Sources of Error. Errors may be due to the nature of the sample, to the operator's technique, and to inaccurate equipment. Errors that are inherent in the distribution of cells in the counting volume are called "field" errors and can be minimized only by counting more cells.

Hemocytometer leukocyte counts show a CV of about 6.5% for normal and increased counts, and about 15% in leukopenic blood. Utilizing electronic counters, on the other hand, results in CVs of approximately 1%–3%.

Errors Due to the Nature of the Sample. Partial coagulation of the venous blood causes changes in the distribution of the cells and/or decreases their number. Failure to mix the blood thoroughly and immediately before dilution introduces an error, which depends on the degree of sedimentation.

Operator's Errors. Errors caused by faulty technique may occur during dilution, when the chamber is loaded, and when the cells are counted.

Errors Due to Equipment. Equipment errors can be diminished by using pipets and hemocytometers certified by the U.S. Bureau of Standards.

Inherent or Field Errors. Even in a perfectly mixed sample, variation occurs in the numbers of suspended cells that are distributed in a given volume (i.e., come to rest over a given square). This "error of the field" is the minimal error. Another error is the "error of the chamber," which includes variations in separate fillings of a given chamber and in sizes of different chambers. Still another is the "error of the pipet," which includes variations in filling a given pipet and in the sizes of different pipets. In performing a WBC count, if 200 cells are counted using two chambers and one pipet, the CV = 9.1%, corresponding to 95% confidence limits of $\pm 18.2\%$ (twice the CV). Using four chambers and two pipets and counting twice as many cells reduces the 95% confidence limits to $\pm 12.8\%$. This relatively large percentage error is of little practical consequence because of the physiologic variation of the leukocyte count.

Nucleated Red Blood Cells. Nucleated red blood cells (NRBCs) will be counted and cannot be distinguished from leukocytes with the magnification used. If their number is high, as seen on the stained smear, a correction should be made according to the following formula:

$$\text{True leukocyte count} = (\text{Total count} \times 100) / (100 + \text{No. of NRBCs})$$

where the *No. of NRBCs* is the number of nucleated red cells that are counted during the enumeration of 100 leukocytes in the differential count.

Example. The blood smear shows 25 NRBCs per 100 leukocytes. The total nucleated cell count is 10,000.

$$\text{True leukocyte count} = 10,000 \times 100 / 125 = 8000/\mu\text{L} (8.0 \times 10^9/\text{L})$$

Reference Value. In the total leukocyte count, no distinction is made among the six normal cell types (neutrophils and bands, lymphocytes, monocytes, eosinophils, and basophils). The reference interval for adults is $4.5\text{--}11.0 \times 10^9/\text{L}$.

Platelet Counts

Platelets are thin disks, 2–4 μm in diameter and 5–7 fL in volume (in citrated blood). They function in hemostasis, in maintenance of vascular integrity, and in the process of blood coagulation.

In EDTA-blood, the mean platelet volume (MPV) increases with time up to 1 hour in vitro, is relatively stable between 1 and 3 hours, and then increases further with time. Change from a discoid to a spherical shape accounts for this increase in apparent volume in EDTA compared with citrate (Rowan, 1982). For reproducible results, platelet volume measurements obtained with multichannel instruments should be made between 1 and 3 hours after the blood is drawn. The frequency distribution of platelet volumes in an individual is log normal. However, a nonlinear, inverse relationship has been noted between the MPV and the platelet count within normal individuals (Fig. 30-4). Therefore, reference values for the MPV appear to vary with the platelet count (Bessman, 1981). The MPV is generally increased in hyperthyroidism (Ford, 1988) and myeloproliferative disease (Small, 1981). Platelets are more difficult to count because they are small (must be distinguished from debris) and have a tendency to adhere to glass, any foreign body, and particularly to one another. It is often possible to recognize a significant decrease in the number of platelets by careful inspection of stained films. With capillary blood, films must be made evenly and very quickly after the blood is obtained to avoid clumping and to minimize the decrease due to adhesion of platelets to the margins of the injured vessels. A better estimate is possible by examining stained films made from venous blood with EDTA as an anticoagulant (EDTA-blood), in which platelets are evenly distributed and where

Figure 30-4 Mean platelet volume (MPV) related to platelet count in 683 normal subjects. Each group is shown as mean (number) ± 2 SD (bar) of subjects grouped by platelet counts of 128–179, 180–199, 200–219, 220–239, 240–259, 260–279, 280–309, 310–319, 320–339, 340–359, 360–403, 404–462 $\times 10^9/\text{L}$. The number of the mean position is the number of subjects in the group (Bessman, 1981).

clumping normally does not occur. The visual method of choice employs the phase-contrast microscope. This is the reference method. Laboratories performing over five platelet counts per day can justify electronic platelet counting; both voltage pulse counting and electro-optical counting systems are satisfactory.

Hemocytometer Method—Phase-Contrast Microscope

Specimen. Venous blood is collected with EDTA as the anticoagulant. Blood from skin puncture wounds gives more variable results but is satisfactory if the blood is flowing freely and if only the first few drops are used.

Diluent Solution. One percent ammonium oxalate is mixed in distilled water. The stock bottle is kept in the refrigerator. The amount needed for the day is filtered before use and the unused portion discarded at end of day.

Procedure

1. Well-mixed blood is diluted 1:100 in diluting fluid, and the vial containing the suspension is rotated on a mechanical mixer for 10–15 minutes.
2. The hemocytometer is filled in the usual fashion, using a separate capillary tube for each side.
3. The chamber is covered with a Petri dish for 15 minutes to allow settling of the platelets in one optical plane. A piece of wet cotton or filter paper is left beneath the dish to prevent evaporation.
4. The platelets appear round or oval and frequently have one or more dendritic processes. Their internal granular structure and a purple sheen allow the platelets to be distinguished from debris, which is often refractile. Ghosts of red cells that have been lysed by the ammonium oxalate are seen in the background.
5. Platelets are counted in 10 small squares (the black squares in Fig. 30-3), five on each side of the chamber. If the total number of platelets counted is less than 100, more small squares are counted until at least 100 platelets have been recorded—10 squares per side (black plus shaded squares; see Fig. 30-3) or all 25 squares in the large central square on each side of the hemocytometer, if necessary. If the total number of platelets in all 50 of these small squares is less than 50, the count should be repeated with a 1:20 or a 1:10 dilution of blood.

Calculation. Each of the 25 small squares defines a volume of $1/250 \mu\text{L}$ ($1/25 \text{ mm}^2 \text{ area} \times 1/10 \text{ mm depth}$): Platelet count (per μL) = (Number of cells counted/Number of squares counted) \times Dilution $\times 250$.

By adjusting the number of squares so that at least 100 platelets are counted, the field error (the statistical error caused by counting a limited

number of platelets in the chamber) can be kept in the same range for low platelet counts as for high platelet counts. It has been shown that the CV due to combined field, pipet, and chamber errors is about 11% when at least 100 platelets are counted, and 15% when 40 platelets are counted.

Platelet counts tend to be the least reproducible of the blood cell counts, and the technologist must be vigilant to ensure their accuracy. This includes the readiness to confirm suspicious or abnormal results with a freshly drawn sample. Whenever the platelet count is in question, such as with an instrument flag, the blood film (prepared from EDTA-blood) must be checked to corroborate the count and to detect abnormalities in platelets or other blood elements that may give a false value. Further, because of the low number of platelets counted in the manual method and the high degree of imprecision with severe thrombocytopenia ($CV > 15\%$), 7×10^9 platelets/L is the lowest count that should be reported from manual quantitation (Hanseler, 1996).

Sources of Error. Blood in EDTA is satisfactory for 5 hours after collection at 20°C and for 24 hours at 4°C , provided that no difficulty was encountered in collection. Platelet clumps present in the chamber imply a maldistribution and negate the reliability of the count; a new sample of blood must be collected. The causes of platelet clumping are likely to be initiation of platelet aggregation and clotting before the blood reaches the anticoagulant; imperfect venipuncture; delay in the anticoagulant contacting the blood; or, in skin puncture technique, delay in sampling. Capillary blood gives similar mean values, but errors are about twice those with venous blood, probably because the platelet level varies in successive drops of blood from the skin puncture wound.

Falsely Elevated Counts. Fragments of leukocyte cytoplasm that are sometimes numerous in leukemias may falsely elevate the count. The phase-contrast hemocytometer method must be employed in these cases with a correction made based on the ratio of fragments to platelets determined from the blood film.

Falsely Low Counts. These can occur if platelets adhere to neutrophils (platelet satellitism) or if there is platelet clumping due to agglutinins (Lombarts, 1988), spontaneous aggregation, or incipient clotting due to faulty blood collection. The first two of these phenomena appear to depend on EDTA (Dacie, 1991). The reported incidence of EDTA-induced in vitro platelet clumping and pseudothrombocytopenia has ranged from 0.1% (Bartels, 1997) to 2% (Lippi, 1990). Alterations in platelet histograms or in quantitative cutoff measures derived from them should be used to screen for pseudothrombocytopenia (Bartels, 1997).

Variation In Automated Platelet Count

Standard guidelines with each instrument mandate performing manual platelet counts below and above the established reference ranges. For example, an automated platelet count below $30 \times 10^9/\text{L}$ using Technicon HP 81 (Technicon Instruments Corporation, Tarrytown, N.Y.) should be replaced by the manual procedure (Hanseler, 1996).

Upon comparing the ADVIA 120 (Siemens Healthcare Diagnostics, Deerfield, Ill.) to Coulter STKS (Coulter, Hialeah, Fla.), Stanworth (1999) showed that in some cases of thrombocytopenia due to peripheral consumption, the ADVIA gave higher platelet counts and the blood film showed some large platelets. Further study with platelet-specific monoclonal antibodies such as CD61 will likely determine which count is more correct. Cantero (1996) showed that visibly turbid plasma in blood specimens resulted in, on average, a 47% increase in platelet count with the Technicon HP 83.

Reference values for platelet counts are $150\text{--}450 \times 10^9/\text{L}$. Reference values for MPV are approximately 6.5–12 fL in adults.

Reticulated Platelets

Reticulated platelets are those newly released circulating platelets that have residual RNA. Reticulated platelet counts are an estimate of thrombopoiesis (Rapi, 1998), analogous to the use of reticulocyte count as an estimate of erythropoiesis. Matic (1998) describes an optimized flow cytometric analysis method after incubating whole blood with thiazole orange, which has a 3000-fold increase in fluorescence after binding to RNA. Phycoerythrin-labeled antibodies directed against GPIb on the surface of the platelet are also in the incubation mixture to distinguish platelets from other cells or debris. Recombinant human erythropoietin seems to improve platelet function in uremia not only by correcting the anemia, but also by increasing young platelets, detected as reticulated platelets (Tassies, 1998). Significantly lower median levels of reticulated platelets in frequent plateletpheresis donors than in new donors suggest that repeat platelet

donation might lead to relative exhaustion of thrombopoiesis (Stohlawetz, 1998). Depending on the conditions of the measurement, published normal values for reticulated platelets vary tremendously from 3%–20% (Matic, 1998).

Increased reticulated platelet values have been reported in idiopathic thrombocytopenic purpura (Koike, 1998; Saxton, 1998), and hyperthyroidism (Stiegler, 1998). In neonates younger than 30 weeks' gestation, the reticulated platelet count was about twice that seen in full-term infants (Peterec, 1996). Bone marrow recovery after chemotherapy for acute myeloid leukemia (AML) showed an increase in reticulated platelets after about day 20 (Stohlawetz, 1999). *Decreased* reticulated platelet values have been reported in association with aplasia and liver cirrhosis (Koike, 1998; Saxton, 1998).

Electronic Counting

Because of the relatively low cost, reduced time (for labor and results), and increased accuracy of the automated analyzers, semiautomated instruments are rarely used in clinical practice these days. Speed of performance, elimination of visual fatigue of the technician, and improved precision are decisive advantages of the electronic cell counter over the hemocytometer/manual methods of performing blood cell counts. Electronic counting instruments are discussed in more detail in the next section, Instrument Technology.

INSTRUMENT TECHNOLOGY

The multichannel instruments used in the modern laboratory for performing cell counts are based on the principles of electrical impedance, light scattering, radiofrequency conductivity, and/or cytochemistry (Ward, 2000). The principles of these techniques are discussed in the following section. Combining hematology instrumentation with laboratory automation allows for reduction in preanalytic and postanalytic variables and positive identification of samples for processing and analysis, storage, and retrieval.

Electrical Impedance

Cells passing through an aperture through which a current is flowing cause changes in electrical resistance that are counted as voltage pulses. This principle, illustrated in Figure 30-5, is used in instruments marketed by Coulter (LH series, GEN-S, HmX, A-T, etc.; Beckman Coulter Inc., Brea, Calif.), Sysmex (XE and XT series, etc.; Sysmex America Inc., Mundelein, Ill.), Abbott (Cell-Dyn, 3700, Ruby, Sapphire, etc.; Abbott Diagnostics, Santa Clara, Calif.), ABX (Micros 60, Pentra series, etc.; ABX Diagnostics Inc., Irvine, Calif.), and others. An accurately diluted suspension of blood (CS) is made in an isotonic conductive solution that preserves the cell shape. The instrument has a glass cylinder (GC) that can be filled with the

Figure 30-5 Schematic diagram of particle counter in which changes in electrical resistance are counted as voltage pulses. (Diagram adapted from Ackerman, 1972.) A, Aperture; CS, cell suspension; E1 and E2, platinum electrodes; EC1 and EC2, electrical contacts; GC, glass cylinder; M, mercury column; V, valve; VP, vacuum pump.

conducting fluid and has within it an electrode (E2) and an aperture (A) of 100 μm diameter in its wall. Just outside the glass cylinder is another electrode (E1). The cylinder is connected to a U-shaped glass tube that is partially filled with mercury (M), and that has two electrical contacts (EC1 and EC2). The glass cylinder is immersed in the suspension of cells to be counted (CS) and is filled with conductive solution and closed by a valve (V). A current now flows through the aperture between E1 and E2. As mercury moves up the tube, the cell suspension is drawn through the aperture into the cylinder. Each cell that passes through the aperture displaces an equal volume of conductive fluid, increasing the electrical resistance and creating a voltage pulse, because its resistance is much greater than that of the conductive solution. The pulses, which are proportional in height to the volume of the cells, are counted. This is the Coulter principle.

In the simplest system, the counting mechanism is started when the mercury contacts EC1 and stopped when it contacts EC2; during this time, the cells are counted in a volume of suspension exactly equal to the volume of the glass tubing between contact wires EC1 and EC2. If two or more cells enter the aperture simultaneously, they will be counted as one pulse; this produces a coincidence error for which corrections are now automatically made by analyzers. A threshold setting or pulse discriminator allows the exclusion of pulses below an adjustable height on certain counters. On others, a second threshold also excludes the counting of pulses above a certain height. One therefore counts only the cells in the "window" between the two settings. By systematically changing each threshold by given increments, one can determine a frequency distribution of relative cell volumes. Such cell size distributions can be automatically plotted and are valuable in the study of red cells, white cells, or platelets when two or more changing populations of cells are present. This is the basis for determination of the blood cell histograms, which are now routinely produced by the multichannel hematology analyzers.

Radiofrequency Conductivity

Conductivity is determined using a high-frequency electromagnetic probe that provides information on the cells' internal constituents (chemical composition, nuclear characteristics, and granular constituents) by permeating the lipid layer of a cell's membrane. Conductivity is especially helpful in differentiating between cells of like size such as small lymphocytes and basophils (Burns, 1992; Bentley, 1993). This principle is utilized in instruments marketed by Coulter (LH series, GENfi-S, HmX, A-T, etc.; Beckman Coulter Inc.) and Sysmex (XE-2100, XT 2000i, HST-N, etc.; Sysmex America Inc.).

Light Scattering

In the electro-optical analyzers (Fig. 30-6), a light-sensitive detector measures light scattering. All major multichannel analyzers now employ optical methods, at least to some extent. The size of the pulse detected is proportional to the size of the particle (WBC, RBC, or platelet). Although the precision of the instruments employing optical methods is equivalent to that of systems utilizing electrical impedance, some systems use a combination of the two methods to supply an internal comparison. Forward angle scatter of a laser-generated monochromatic light determines cell surface characteristics, morphology, and granulation. Measurement of light scatter at multiple angles allows enhanced differentiation of cell types. For example, in the Abbott Cell Dyn, four simultaneous light scattering measurements are made on each white cell. Zero-degree forward angle is primarily affected by and thus determines cell size. Ten-degree light scatter is an indicator of cell structure or complexity and is especially helpful in resolving basophils and separating all cell populations. Ninety-degree light scatter separates granulated cells and is termed **lobularity**. Depolarized

90-degree light scattering resolves eosinophils because of their large crystalline granularity. Abnormal cells can have distinctive locations in the size-versus-complexity scatterplot and help to determine WBC suspect flags (Cornbleet, 1992), such as for blasts, variant lymphs, bands, and immature granulocytes. Fluorescent deoxyribonucleic acid (DNA) dyes are used in the Abbott automated hematology systems to enumerate nucleated RBCs and identify populations of atypical lymphocytes and nonviable WBCs. Adaptive gating technology permits better separation of overlapping clusters of cell types. Suspect flags are generated when the distinction cannot be clearly delineated, as is often the case in the presence of abnormal WBC populations or interfering substances.

Cytochemistry

A method unique to the Siemens automated hematology series (Siemens Healthcare Diagnostics, Deerfield, Ill.) is the use of a cytochemical reaction to determine the peroxidase activity of white blood cells. The mean peroxidase index (MPXI), a measure of neutrophil-staining intensity, is determined for each specimen. The relative positivity seen in neutrophils, eosinophils, and monocytes is used in conjunction with data derived from light scatter to determine the WBC differential (Simson, 1986). ABX Diagnostics utilizes a cytochemical reagent that fixes the WBCs in their native state and subsequently stains their intracellular and plasmic membranes with chlorazol black E (Clinical Case Studies: Interpretation Guide for ABX 5-Part Diff Hematology Analyzers, ABX Horiba Diagnostics, Montpellier, France).

Reporting/Flagging

Each instrumentation system combines the data generated by these methods in their own configuration to provide a five- or six-part WBC differential along with RBC morphology and platelet parameters (Fig. 30-7). The principles of measurement specific to selected systems are detailed in Table 30-2. Data generated by the instrument that are not acceptable based on instrument- or user-defined criteria are flagged to alert the technologist that reporting the sample requires further investigation. Data management systems now include sophisticated programs that utilize user-defined criteria to determine reflex and repeat testing, including automated slide making and staining. Extreme care must be taken when defining these criteria, as the addition of each lessens the advantage provided by automating the process. The best configurations are developed with the patient population in mind. In addition, follow-up should be tailored to minimize the extended time necessary to derive the correct result.

Sources of Error

Table 30-3 lists various causes of erroneous results obtained from automated cell counters.

Automated Reticulocyte Counting

Many of the same principles applied in determination of the WBC differential may be utilized to determine reticulocyte counts, resulting in enhanced precision and increased accuracy in routine practice (Metzger, 1987). Depending on the specific model of analyzer, this process may be semiautomated or fully automated. All methods rely on the addition of a stain or dye to detect the RNA content of the RBC. Such stains include new methylene blue (NMB), oxazine, auramine O, polymethine, and thiazole orange. Methods of detection include impedance, light scatter, absorption, and fluorescence intensity. Reticulocyte fractions are separated based on RNA content, with the more immature cells containing the highest amount of reticulum. The immature reticulocyte fraction (IRF) quantitatively describes the youngest reticulocytes with the greatest staining intensity. This parameter allows early detection of an increased

Figure 30-6 Schematic diagram of the electro-optical cell counter. Light is focused on the flow cell. Only light scattered by a cell reaches the photomultiplier tube (PMT), which converts to an electrical pulse. (From Mansberg HP. *Adv Autom Anal* 1970;1:213, with permission. Coulter	x	x	x	
Sysmex	x	x	x	

erythropoietic response, important in determining the response of the bone marrow recovering from chemotherapy or transplant or the response to erythropoietin therapy. It may also be used in conjunction with the absolute reticulocyte count to classify anemias (Davis, 1994, 1996; d'Onofrio, 1996). The reticulocyte Hb content (CHr) provides a sensitive index by which to identify hypochromic RBCs. This can be used to detect iron deficiency and evaluate patient response to iron therapy (Goodnough, 2000).

PHYSIOLOGIC VARIATION

Physiologic Variation in Erythrocytes

Changes in red cell values are greatest during the first few weeks of life (Fig. 30-8). At the time of birth, as much as 100–125 mL of placental blood may be added to the newborn if tying the cord is postponed until its pulsation ceases. In a study of newborns whose cords had been clamped late, average capillary red cell counts were $0.4 \times 10^{12}/L$ higher 1 hour after and $0.8 \times 10^{12}/L$ higher 24 hours after birth compared with newborns whose cords had been clamped early. Capillary blood (obtained by skin puncture) gives higher RBC and Hb values than venous blood (cord). The differences may amount to about 0.5×10^{12} RBC/L and 3 g Hb/dL. Slowing of capillary circulation and the resulting loss of fluid may be the responsible factors. Examination of venous blood furnishes more consistent results than are obtained by examination of capillary blood.

TABLE 30-3

Potential Causes of Erroneous Results With Automated Cell Counters

Parameter	Causes of spurious increase	Causes of spurious decrease
WBC	Cryoglobulin, cryofibrinogen Heparin Monoclonal proteins Nucleated red cells Platelet clumping Unlysed red cells	Clotting Smudge cells Uremia plus immunosuppressants
RBC	Cryoglobulin, cryofibrinogen Giant platelets High WBC ($>50,000/mL$)	Autoagglutination Clotting Hemolysis (in vitro) Microcytic red cells
Hb	Carboxyhemoglobin ($>10\%$) Cryoglobulin, cryofibrinogen Hemolysis (in vitro) Heparin High WBC ($>50,000/\mu L$) Hyperbilirubinemia Lipemia Monoclonal proteins	Clotting Sulfhemoglobin
Hct (automated)	Cryoglobulin, cryofibrinogen Giant platelets High WBC ($>50,000/\mu L$) Hyperglycemia (>600 mg/dL)	Autoagglutination Clotting Hemolysis (in vitro) Microcytic red cells
Hct (microhematocrit)	Hyponatremia Plasma trapping	Excess EDTA Hemolysis (in vitro) Hypernatremia
MCV	Autoagglutination High WBC ($>50,000/\mu L$) Hyperglycemia Reduced red cell deformability	Cryoglobulin Cryofibrinogen Giant platelets Hemolysis (in vitro) Microcytic red cells Swollen red cells
MCH	High WBC ($>50,000/\mu L$) Spuriously high Hb Spuriously low RBC	Spuriously low Hb Spuriously high RBC
MCHC	Autoagglutination Clotting Hemolysis (in vitro) Hemolysis (in vivo) Spuriously high Hb Spuriously low Hct	High WBC ($>50,000/\mu L$) Spuriously low Hb Spuriously high Hct
Platelets	Cryoglobulin, cryofibrinogen Hemolysis (in vitro and in vivo) Microcytic red cells Red cell inclusions White cell fragments	Clotting Giant platelets Heparin Platelet clumping Platelet satellitosis

EDTA, Ethylenediaminetetraacetic acid; Hb, hemoglobin; Hct, hematocrit; MCH, mean cell hemoglobin; MCHC, mean cell hemoglobin concentration; MCV, mean corpuscular volume; RBC, red blood cell; WBC, white blood cell.

In the full-term infant, nucleated red cells average about $0.5 \times 10^9/L$. The normoblast count declines to about 200/ μL at 24 hours, 25/ μL at 48 hours, and less than 5/ μL at 72 hours. By 7 days, it is rare to find circulating normoblasts (Barone, 1999).

The normal reticulocyte count at birth ranges from 3%–7% during the first 48 hours, during which time it rises slightly. After the second day, it falls rather rapidly to 1%–3% by the seventh day of life. Hb concentration in capillary blood during the first day of life averages 19.0 g/dL, with 95% of normal values falling to between 14.6 and 23.4 g/dL. In cord blood the average is 16.8 g/dL, with 95% of normal between 13.5 and 20 g/dL. Frequently, an initial increase in the Hb level of venous blood is seen at

Figure 30-8 Values for hemoglobin (Hb), hematocrit (Hct; volume of packed red cells), and red cell count from birth to old age. Mean values are heavy lines. Reference interval for Hb is indicated by dotted lines, for red cell counts by dashed lines, and for Hct by dotted and dashed lines. The scales on the ordinate are similar, so that relative changes in Hb, red cell count, and Hct are apparent on inspection. The scale for age, however, is progressively altered (Wintrobe, 1974).

the end of 24 hours compared with that of cord blood. At the end of the first week, the level is about the same as in cord blood, and it does not begin to fall until after the second week. During the first 2 weeks, the lower limit of normal is 14.5 g/dL for capillary blood and 13.0 g/dL for venous blood. The Hct in capillary blood on the first day of life averages 0.61, with 95% of normal values between 0.46 and 0.76. In cord blood, the average is 0.53. Changes during the first few weeks parallel the Hb concentration. The Hb and Hct are highest at birth but fall rather steeply in the first days and weeks of life to a minimum at 2 months of age, at which time the lower limit of the 95% reference values and the mean value for the Hb are 9.4 and 11.2 g/dL, and for the Hct are 0.28 and 0.35, respectively. After the age of 4 months, the lower limit for the Hb is 11.2 g/dL and for the Hct is 0.32; these values rise gradually until about age 5 years, and somewhat more steeply in boys than in girls thereafter (Shannon, 2002). The normal MCV at birth ranges from 104–118 fL, compared with the adult reference interval of 80–96 fL. Because the RBC does not fall to the degree that the Hb and Hct do, the MCV decreases abruptly, then gradually, during the first few months of life. The lowest value is reached at about 1 year. In studies in which iron deficiency and thalassemia are excluded, the lower reference limit (95% reference values) for the MCV gradually rises between the ages of 1 year and 15 years—in boys from 70–76 fL, and in girls from 70–78 fL (Shannon, 1996). Reference intervals for RBC values in sexually mature adults are given in Table 30-4. The indices are similar in males and females, but the Hb is 1–2 g/dL higher in males, with commensurate increments in Hct and RBCs (see Fig. 30-8). This is believed to be mainly the effect of androgen in stimulating erythropoietin production and its effect on the marrow. In older men, the Hb tends to fall, and in older women, the Hb tends to fall to a lesser degree (in some studies) or even rise slightly (in other studies). In older individuals, therefore, the sex difference is less than 1 g Hb/dL (Dacie, 1991). Posture and muscular activity change the concentration of the formed elements. The Hb, Hct, and RBC increase by several percent when the change from recumbency to standing is made, and strenuous muscular activity causes a further increase, presumably owing primarily to loss of plasma water. Diurnal variation that is not related to exercise or to analytic variation also occurs. The Hb is highest in the morning, falls during the day, and is lowest in the evening, with a mean difference of 8%–9% (Dacie, 1991). In persons living at a higher altitude, the Hb, Hct, and RBC are elevated over what they would be at sea level. The difference is about 1 g Hb/dL at 2 km altitude and 2 g Hb/dL at 3 km. Increased erythropoiesis is secondary to anoxic stimulation of erythropoietin production. People who are smokers also tend to have a mild erythrocytosis.

Physiologic Variation in Leukocytes

The total white cell count at birth and during the first 24 hours varies within wide limits. Neutrophils are the predominant cell, varying from $6\text{--}28 \times 10^9/\text{L}$; about 15% of these are band forms (Altman, 1974), and a few myelocytes are present. Neutrophils drop to about $5 \times 10^9/\text{L}$ during

the first week and remain at about the same level thereafter. Lymphocytes are about $5.5 \times 10^9/\text{L}$ at birth and change little during the first week. They become the predominant cell, on average, after the first week of life and remain so until about age 7, when neutrophils again predominate. The upper limit of the 95% reference interval for lymphocytes at age 6 months is 13.5, at 1 year 10.5, at 2 years 9.5, at 6 years 7.0, and at 12 years $6.0 \times 10^9/\text{L}$. For neutrophils at the same ages, the values are 8.5, 8.5, 8.5, 8.0, and $8.0 \times 10^9/\text{L}$, respectively—all somewhat higher than those for adults (Table 30-5).

Diurnal variation has been recognized in the neutrophil count, with highest levels in the afternoon and lowest levels in the morning at rest. Exercise produces leukocytosis, which includes an increased neutrophil concentration as a result of a shift of cells from the marginal to the circulating granulocyte pool. Increased lymphocyte drainage into the blood also appears to contribute to the total increase. Both average and lower reference values for neutrophil concentration in the black population are lower than in the Caucasian population; this difference must be taken into account in assessing neutropenia. Cigarette smokers have higher average leukocyte counts than nonsmokers. The increase is greatest (about 30%) in heavy smokers who inhale and affects neutrophils, lymphocytes, and monocytes.

Mild changes occur during the menstrual cycle. Neutrophils and monocytes fall and eosinophils tend to rise during menstruation. Basophils have been reported to fall during ovulation. The availability of precise automated leukocyte analyzers provides the potential for investigating physiologic sources of variation that have been obscured by statistical errors in traditional microscopic differential counts (Statland, 1978).

Physiologic Variation in Platelets

The average platelet count is slightly lower at birth than in older children and adults, and may vary from $84\text{--}478 \times 10^9/\text{L}$ (Barone, 1999). After the first week of life, the reference intervals are those of the adult. In women, the platelet count may fall at the time of menstruation. Women have higher platelet (and WBC and neutrophil) counts than men, and Africans (and less so Afro-Caribbeans) have lower platelet, WBC, and neutrophil counts than Caucasians (Bain, 1996). Reported means (95% reference ranges) for platelet counts were 218 (143–332) for Caucasian men and 183 (115–290) for African men versus 246 (169–358) for Caucasian women and 207 (125–342) for African women. Among Australians west of Sydney and aged 49 or older, Tsang (1998) lists 247 (128–365) for mean platelet counts for men and 275 (147–403) for women.

ERYTHROCYTE SEDIMENTATION RATE

Erythrocyte sedimentation rate (ESR) is a useful but nonspecific marker of underlying inflammation. Recently, high-sensitivity C-reactive protein and other inflammatory markers have been used to detect or monitor disease, particularly cardiovascular disease and metabolic syndrome

TABLE 30-4

Typical Blood Cell Values in a Normal Population of Young Adults

	Men	Women
White cell count ($\times 10^9/\text{L}$ blood)		7.8 (4.4–11.3)
Red cell count ($\times 10^{12}/\text{L}$ blood)	5.21 (4.52–5.90)	4.60 (4.10–5.10)
Hemoglobin (g/dL blood)	15.7 (14.0–17.5)	13.8 (12.3–15.3)
Hematocrit (percent)	46 (41.5–50.4)	40.2 (35.9–44.6)
Mean cell volume (fL/red cell)		88.0 (80.0–96.1)
Mean cell hemoglobin (pg/red cell)		30.4 (27.5–33.2)
Mean cell hemoglobin concentration (g/dL RBC)		34.4 (33.4–35.5)
Red cell distribution width (CV, percent)		13.1 (11.6–14.6)
Platelet count ($\times 10^9/\text{L}$ blood)		311 (172–450)

The mean and reference intervals (normal range) are given. Because the distribution curves may be nongaussian, the reference interval is the nonparametric central 95% confidence interval. Results are based on 426 normal adult men and 212 normal adult women. Studies were performed on the Coulter model S-Plus IV (Morris, 1975). CV, Cell values; RBC, red blood cell.

TABLE 30-5

Normal Leukocyte Count, Differential Count, and Hemoglobin Concentration at Various Ages

LEUKOCYTES*									
Age	Total leukocytes	Total neutrophils	Band neutrophils	Segmented neutrophils	Eosinophils	Basophils	Lymphocytes	Monocytes	Hemoglobin (g/dL blood)
12 months	11.4 (6.0–17.5)	3.5 (1.5–8.5) 31	0.35 3.1	3.2 (1.0–8.5) 28	0.30 (0.05–0.70) 2.6	0.05 (0–0.20) 0.4	7.0 (4.0–10.5) 61	0.55 (0.05–1.1) 4.8	12.6 (11.1–14.1)

Source: For leukocyte and differential count, Altman (1961); for hemoglobin concentrations, Dalman (1987).

*Values are expressed as mean (95% reference) values. For leukocytes and differential count cell types, the units are cells $\times 10^9/\mu\text{L}$; the numbers in italic type are mean percentages.

(Pearson, 2003; Rifai, 2005). When well-mixed venous blood is placed in a vertical tube, erythrocytes will tend to fall toward the bottom. The length of fall of the top of the column of erythrocytes over a given interval of time is called the ESR. Several factors are involved.

Plasma Factors

An accelerated ESR is favored by elevated levels of fibrinogen and, to a lesser extent, α_2 -, β -, and γ -globulins. These asymmetric protein molecules have a greater effect than other proteins in decreasing the negative charge of erythrocytes (zeta potential) that tends to keep them apart. The decreased zeta potential promotes the formation of rouleaux, which sediment more rapidly than single cells. Removal of fibrinogen by defibrination lowers the ESR. No absolute correlation has been noted between the ESR and any of the plasma protein fractions. Albumin and lecithin retard sedimentation, and cholesterol accelerates the ESR.

Red Cell Factors

Anemia increases the ESR because the change in the erythrocyte/plasma ratio favors rouleaux formation, independently of changes in the concentrations of plasma proteins. By any method of measurement, ESR is most sensitive to altered plasma proteins in the Hct range of 0.30–0.40 (Bull, 1975). The sedimentation rate is directly proportional to the weight of the cell aggregate and inversely proportional to the surface area. Microcytes sediment slower than macrocytes, which have decreased surface area/volume ratios. Rouleaux also have a decreased surface area/volume ratio

and accelerate the ESR. Red cells with an abnormal or irregular shape, such as sickle cells or spherocytes, hinder rouleaux formation and lower the ESR.

Stages in the ESR

Three stages can be observed: (1) In the initial 10 minutes, little sedimentation occurs as rouleaux forms; (2) for about 40 minutes, settling occurs at a constant rate; and (3) sedimentation slows in the final 10 minutes as cells pack at the bottom of the tube.

Methods

Westergren Method

Westergren method is widely used, as the method is very simple. The ICSH (1993) has recommended it as the reference method when undiluted whole blood is used. The ICSH states that the patient's Hct should not exceed 35% because reproducibility of sedimentation may be poorer in narrow tubes. A formula to convert between diluted blood ESR and undiluted is as follows:

$$\text{Diluted blood ESR} = (\text{Undiluted ESR} \times 0.86) - 12$$

Equipment. The Westergren tube is a straight pipet 30 cm long, 2.55 mm in internal diameter, and calibrated in millimeters from 0–200. It holds about 1 mL. The Westergren rack is also used, with levelers as needed for a vertical tube position.

Reagent. A 0.105 molar solution (range, 0.10–0.136) of sodium citrate is used as the anticoagulant–diluent solution (31 g of $\text{Na}_3\text{C}_6\text{H}_5\text{O}_7 \cdot \text{H}_2\text{O}$ added to 1 L of distilled water in a sterile glass bottle). This is filtered and is kept refrigerated without preservatives.

Procedure

1. Two milliliters of whole blood are added to 0.5 mL of sodium citrate and mixed by inversion.
2. A Westergren pipet is filled to the 0 mark and is placed exactly vertical in the rack at room temperature without vibration or exposure to direct sunlight.
3. After exactly 60 minutes, the distance from the 0 mark to the top of the column of red cells is recorded in millimeters as the ESR value. If the demarcation between plasma and the red cell column is hazy, the level is taken where the full density is first apparent.

Modified Westergren Method

A modification of the Westergren method produces the same results but employs blood anticoagulated with EDTA rather than with citrate. This is more convenient because it allows the ESR to be performed from the same tube of blood as is used for other hematologic studies. Two milliliters of well-mixed EDTA-blood is diluted with 0.5 mL of 3.8% sodium citrate or with 0.5 mL of 0.85% sodium chloride. Undiluted blood anticoagulated with EDTA gives poor precision (ICSH, 1977). The ESR gradually increases with age. Westergren's original upper limits of normal (10 mm/hour for men and 20 mm/hour for women) appear to be too low. According to studies of Böttiger (1967) and Zaubler (1987), upper limits of reference values for the Westergren method should be as follows:

	Men	Women
Below age 50 years	15 mm/hour	20 mm/hour
Above age 50 years	20 mm/hour	30 mm/hour
Above age 85 years	30 mm/hour	42 mm/hour

Smith (1994) states that the rise in ESR with age likely reflects higher disease prevalence in the elderly; therefore for practical purposes, it may be advisable to use the standard normal range in elderly patients.

Sources of Error

If the concentration of the anticoagulant is higher than recommended, the ESR may be elevated. Sodium citrate or EDTA does not affect the rate of sedimentation if used in the proper concentration. Heparin, however, alters the membrane zeta potential and cannot be used as an anticoagulant. It can also increase the ESR when used as a medication in vivo (Penchas, 1978). Bubbles left in the tube when it is filled will affect the ESR. Hemolysis may modify the sedimentation. The cleanliness of the tube is important. Tilting the tube accelerates the ESR. The red cells aggregate along the lower side while the plasma rises along the upper side. Consequently, the retarding influence of the rising plasma is less effective. An angle of even 3 degrees from the vertical may accelerate the ESR by as much as 30%. Plastic ESR pipets have slightly higher (1–2 mm/hour) values than glass pipets (Schneiderka, 1997).

Temperature should be within the range of 20°–25° C. Lower or higher temperatures in some cases alter the ESR. If the blood has been kept refrigerated, it should be permitted to reach room temperature and be mixed by inversion a minimum of eight times before the test is performed. The test should be set up within 2 hours after the blood sample is obtained (or within 12 hours if EDTA is used as the anticoagulant and the blood is kept at 4° C); otherwise, some samples with elevated ESRs will be falsely low (Morris, 1975). On standing, erythrocytes tend to become spherical and less readily form rouleaux.

No effective method is known for correcting for anemia in the Westergren method, although this can be done with the Wintrobe method.

Alternative Methods and Technologies to Measure ESR

The **VES-MATIC 20** instrument is a bench top analyzer designed to measure the ESR in 20 blood samples (Plebani, 1998; Caswell, 1991). It is completely automated. The blood is collected in special cuvetts and is carefully mixed by the instrument; the samples are then left to sediment for a certain period. The 18-degree slant of the tubes with respect to the vertical axis causes acceleration of the sedimentation, allowing results comparable with those of Westergren at the first hour to be obtained in only

25 minutes; those comparable with Westergren at the second hour require only 45 minutes. The optoelectrical sensors automatically read the erythrocyte sedimentation level. The data are elaborated and then are printed or visualized on the display.

The **Micro-ESR method** has greater utility in pediatric patients. Barrett (1980) described a micro-ESR method using 0.2 mL blood to fill a plastic disposable tube 230 mm long with a 1-mm internal bore. Capillary blood values correlated well with venous blood micro-ESR and Westergren ESR values. Kumar (1994) refers to a micro-ESR (mESR) that utilizes whole blood to completely fill a 75-mm heparinized microhematocrit capillary tube.

Another instrument used to measure ESR is ESR STAT PLUS, which is a centrifugation-based method. The sample is placed in the centrifuge, and infrared laser tracks the erythrocyte-plasma interface and makes multiple measurements, from which the linear portion of the sedimentation curve is identified and is used by the software algorithm to determine the ESR result. This method requires smaller volumes of specimen than the Westergren method and is faster. The pitfall is correlation with the reference Westergren method, especially in the 0–20 mm/hour range. It can be also prone to human error because it requires a minimum of 15 mixing intervals, followed by a 5-minute limit before drawing into the capillary tube (Shelat, 2008).

Application

The ESR is one of the oldest laboratory tests still in use. Although some of its usefulness has decreased as more specific methods of evaluating disease (such as C-reactive protein [CRP]) have been developed (Zlonis, 1993), new clinical applications are being reported (Saadeh, 1998). Recently, the ESR has been reported to be of clinical significance in sickle cell disease (low value in the absence of painful crisis, moderately increased 1 week into the crisis), osteomyelitis (elevated, helpful in following therapy), stroke (ESR ≥ 28 mm/hour has poorer prognosis), prostate cancer (ESR ≥ 37 mm/hour has higher incidence of disease progression and death), and coronary artery disease (ESR > 22 mm/hour in white men had high risk of coronary artery disease [CAD]) (Saadeh, 1998). In pregnancy, the ESR increases moderately, beginning at the 10th to the 12th week, and returns to normal about 1 month postpartum. The ESR tends to be markedly elevated in monoclonal blood protein disorders such as multiple myeloma or macroglobulinemia, in severe polyclonal hyperglobulinemia due to inflammatory disease, and in hyperfibrinogenemia.

Moderate elevations are common in active inflammatory disease such as rheumatoid arthritis, chronic infection, collagen disease, and neoplastic disease. The ESR has little diagnostic value in these disorders but can be useful in monitoring disease activity. It is simpler than measurement of serum proteins, which has tended to replace ESR. Because the test is often normal in patients with neoplasm, connective tissue disease, and infection, a normal ESR cannot be used to exclude these diagnostic possibilities. In patients with known cancer, however, when the value exceeds 100 mm/hour, metastases are usually present (Sox, 1986). The ESR is of little value in screening asymptomatic patients for disease; history and physical examination will usually disclose the cause of an elevated ESR (Sox, 1986). The ESR is useful and is indicated in establishing the diagnosis and in monitoring polymyalgia rheumatica and temporal arteritis, where the rate typically exceeds 90 mm/hour (Zlonis, 1993). Emergency physicians continue to use the ESR in evaluating temporal arteritis, septic arthritis, pelvic inflammatory disease, and appendicitis (Olshaker, 1997). Freeman (1997) urges immediate quick ESR estimation if giant cell arteritis is clinically indicated, as a delay of even a few hours in starting steroid therapy may result in irreversible visual failure. Harrow (1999) concludes that an ESR of 5 mm or less at 30 minutes correctly identifies most patients with normal ESR without misclassifying elevated ESRs.

In Hodgkin's disease, the ESR may be a very useful prognostic blood measurement in the absence of systemic ("B") symptoms (fever, weight loss, night sweats). In one study (Vaughan Hudson, 1987), one third of asymptomatic patients had both an ESR of less than 10 mm/hour and an excellent survival rate, regardless of age, stage, or histopathology. Asymptomatic patients with an ESR of 60 mm/hour or greater had a survival rate as poor as those with systemic symptoms.

Iversen (1996) reported that 70% of renal cell carcinoma patients had an increased ESR, which had been significantly rising for up to 6 years before diagnosis. They argued for a systematic graphing and baseline determination of the ESR over time, which showed a marked elevation in ESR a year before diagnosis. Such a trend of increasing ESR should lead to further investigation, as with renal ultrasound, which may then lead to curative nephrectomy before metastases occur.

BLOOD FILM EXAMINATION

Microscopic examination of the blood spread on a glass slide or coverslip yields useful information regarding all formed elements of the blood. The process of making thin blood film causes mechanical trauma to the cells. Also the cells flatten on the glass during drying, and fixation and staining involve exposure to methanol and water. Some artifacts are inevitably introduced, but these can be minimized by good technique.

EXAMINATION OF WET PREPARATIONS

It is sometimes advantageous to examine fresh blood under the microscope to avoid artifacts of fixation or staining. This is readily accomplished by sealing a small drop of blood diluted with isotonic sodium chloride beneath a coverslip on a glass slide. Buffered glutaraldehyde will preserve the cells for reexamination at a later time. Petroleum jelly or xipamide (Aquaphor) may be used to seal the edges of the coverslip to the slide. Wet preparations are used to detect sickling, and spherocytes may be readily detected in this manner. Wet preparations may be examined to ensure that the erythrocyte abnormalities seen on fixed films are not artifacts of drying or staining.

MAKING AND STAINING BLOOD FILMS

Examination of the blood film is an important part of the hematologic evaluation. The reliability of the information obtained depends heavily on well-made and well-stained films that are systematically examined. Blood films should be prepared immediately if possible. Three methods of making films are described: the two-slide or wedge method, the cover glass method, and the spinner method.

Wedge Method

Place a drop of blood 2–3 mm in diameter about 1 cm from the end of a clean, dust-free slide that is on a flat surface. With the thumb and forefinger of the right hand, hold the end of a second (spreader) slide against the surface of the first slide at an angle of 30–45 degrees, and draw it back to contact the drop of blood. Allow the blood to spread and form the angle between the two slides. Push the “spreader slide” at a moderate speed forward until all the blood has been spread into a moderately thin film. The spreader slide should be clean, dry, and slightly narrower than the first slide, so that the edges can be easily examined with the microscope.

The slides should be rapidly air dried by waving the slides or using an electrical fan. The thickness of the film can be adjusted by changing the angle of the spreader slide or the speed of spreading, or by using a smaller or larger drop of blood. At a given speed, increasing the angle of the spreader slide will increase the thickness of the film. At a given angle, increasing the speed with which the spreader slide is pushed will also increase the thickness of the film. The film should not cover the entire surface of the slide. A good film includes a thick portion and a thin portion and a gradual transition from one to the other. The film should have a smooth, even appearance and be free from ridges, waves, or holes. The edge of the spreader must be absolutely smooth. If it is rough, the film has ragged tails containing many leukocytes. In films of optimal thickness, some overlap of red cells is seen in much of the film, but with even distribution and separation of red cells toward the thin tail. The faster the film is air dried, the better is the spreading of individual cells on the slide. Slow drying (e.g., in humid weather) results in contraction artifacts of the cells. The slide may be labeled with a lead pencil on the frosted end or directly on the thicker end of the blood film.

Cover Glass Method

No. 1 or 1½ cover glasses 22 mm square are recommended.

Touch a cover glass to the top of a small drop of blood without touching the skin, and place it, blood side down, crosswise on another cover glass, so that the corners appear as an eight-pointed star. If the drop is not too large and the cover glasses are perfectly clean, the blood will spread out evenly and quickly in a thin layer between the two surfaces. Just as it stops spreading, pull the cover glasses quickly but firmly apart on a plane parallel to their surfaces. The blood usually is much more evenly spread on one of the cover glasses than it is on the other. Cover glasses should be placed film side up on clean paper and allowed to dry in the air, or they may be inserted back to back in slits made in a cardboard box. Films from venous blood may be prepared similarly by placing a drop of blood on a coverslip and proceeding as described.

Spinner Method

Blood films that combine the advantages of easy handling of the wedge slide and uniform distribution of cells of the cover glass preparation may be made with special types of centrifuges known as **spinners** (Rogers, 1973). The spinner slide produces a uniform blood film, in which all cells are separated (a monolayer) and randomly distributed. White cells can be easily identified at any spot in the film. On a wedge smear, disproportions (1) of monocytes occur at the tip of the feather edge, (2) of neutrophils are seen just in from the feather edge, and (3) of both occur at the lateral edges of the film (Rogers, 1973). This is of little practical significance, but it does result in slightly lower monocyte counts in wedge films.

Blood Stains

The aniline dyes used in blood work are of two general classes: basic dyes, such as methylene blue; and acid dyes, such as eosin. Nuclei and certain other structures in the blood are stained by the basic dyes and, hence, are called **basophilic**. Structures that take up only acid dyes are called **acidophilic**, or **eosinophilic**. Other structures stained by a combination of the two are called **neutrophilic**.

Polychrome methylene blue and **eosin stains** are the outgrowth of the original time-consuming Romanowsky's method and are widely used. They stain differentially most normal and abnormal structures in the blood. The basic components of thiazine include methylene blue (tetramethylthionine) and, in varying proportions, its analogs produced by oxidative demethylation: azure B (trimethylthionine); azure A (asymmetrical dimethylthionine); symmetrical dimethylthionine; and azure C (monomethylthionine) (Lillie, 1977). The acidic component eosin is derived from a xanthene skeleton. Most Romanowsky's stains are dissolved in methyl alcohol and combine fixation with staining. Among the best known methods are Giemsa and Wright's stains.

Wright's Stain

This is a methyl alcoholic solution of eosin and a complex mixture of thiazines, including methylene blue (usually 50%–75%), azure B (10%–25%), and other derivatives (Lubrano, 1977). Wright's stain certified by the Biological Stain Commission is commercially available as a solution ready for use or as a powder. The buffer solution (pH 6.4) contains primary (monobasic) potassium phosphate (KH_2PO_4), anhydrous 6.63 g; secondary (dibasic) sodium phosphate (Na_2HPO_4), anhydrous 2.56 g; and distilled water to make 1 L. A more alkaline buffer (pH 6.7) may be prepared by using 5.13 g of the potassium salt and 4.12 g of the sodium salt.

Procedure

1. To prevent the plasma background of the film from staining blue, blood films should be stained within a few hours of preparation or fixed if they must be kept without staining.
2. Fixation and staining may be accomplished by immersing the slides in reagent-filled jars or by covering horizontally supported slides or coverslips with the reagents. With the latter method, covering the film with copious stain avoids evaporation, which leads to precipitation.
3. Fixation is provided for 1–2 minutes with absolute methanol.
4. The slide is next exposed to undiluted stain solution for 2 minutes. Then, without removing the stain from the horizontal slide, an equal amount of buffer is carefully added and is mixed by blowing gently.
5. The stain is flushed from the horizontal slide with water. Washing for longer than 30 seconds reduces the blue staining. The back of the slide is cleaned with gauze.
6. The slide is allowed to air dry in a tilted position.
7. Cover glasses are mounted film side down on a slide with Canada balsam or other mounting medium.

Films stained well with Wright's stain have a pink color when viewed with the naked eye. Under low power, the cells should be evenly distributed. The red cells are pink, not lemon yellow or red. There should be a minimum of precipitate. The color of the film should be uniform. The blood cells should be free from artifacts, such as vacuoles. The nuclei of leukocytes are purple, the chromatin and parachromatin clearly differentiated, and the cytoplasmic neutrophilic granules tan in color. The eosinophilic granules are red-orange, and each is distinctly discernible. The basophil has dark purple granules. Platelets have dark lilac granules. Bacteria (if present) are blue. The cytoplasm of lymphocytes is generally light blue; that of monocytes has a faint blue-gray tinge. Malarial parasites have sky-blue cytoplasm and red-purple chromatin. The colors are prone to

fade if the preparation is mounted in balsam of poor quality or is exposed to the light.

Staining Problems

Excessively Blue Stain. Thick films, prolonged staining time, inadequate washing, or too high an alkalinity of stain or diluent tends to cause excessive basophilia. In such films, the erythrocytes appear blue or green, the nuclear chromatin is deep blue to black, and the granules of the neutrophils are deeply overstained and appear large and prominent. The granules of the eosinophils are blue or gray. Staining for a shorter time or using less stain and more diluent may correct the problem. If these steps are ineffective, the buffer may be too alkaline, and a new one with a lower pH should be prepared.

Excessively Pink Stain. Insufficient staining, prolonged washing time, mounting the coverslips before they are dry, or too high an acidity of the stain or buffer may cause excessive acidophilia. In such films, the erythrocytes are bright red or orange, the nuclear chromatin is pale blue, and the granules of the eosinophils are sparkling brilliant red. One of the causes of the increased acidity is exposure of the stain or buffer to acid fumes. The problem may be a low pH of the buffer, or it may be the methyl alcohol, which is prone to develop formic acid as a result of oxidation on standing.

Other Staining Problems. Inadequately stained red cells, nuclei, or eosinophilic granules may be due to understaining or excessive washing. Prolonging the staining or reducing the washing may solve the problem.

Precipitate on the film may be due to unclean slides; drying during the period of staining; inadequate washing of the slide at the end of the staining period, especially failure to hold the slide horizontally during initial washing; inadequate filtration of the stain; or permitting dust to settle on the slide or smear.

Other Stains

Besides Wright's stain, Romanowsky-type stains include a number of others: Giemsa, Leishman's, Jenner's, May-Grünwald, MacNeal's, and various combinations. Some have been particularly recommended for certain purposes, such as Giemsa stain for excellence in staining malarial parasites and protozoa.

Reference Method

Studies have demonstrated the ability of the combination of just two dyes—azure B and eosin Y—to give the full range of colors provided by ideal Romanowsky's staining of blood and marrow cells. This is the reference method for Romanowsky's staining (ICSH, 1984a).

Automated Slide Stainer

Automated slide stainers are being used in several laboratories for routine hematology and microbiology slides. The stainer is a compact instrument with microprocessor control for flexibility in staining applications. Several slides can be stained uniformly in minutes. Typically, any automated stainer has several user-definable programs to choose from. Staining problems are encountered even with the use of automatic stainers and must be dealt with on an individual basis.

ERYTHROCYTES

The practicing pathologist may be called upon to review peripheral blood smears, to confirm or compare his/her assessment with that of the technologist, and to review the findings with clinical colleagues at the multi-head microscope. Although this is a daily task for the hematopathologist, the general pathologist examines the peripheral smear less frequently and the bone marrow preparation even less so. Following is a summary of the main features that he or she should evaluate. In the blood from a healthy person, the erythrocytes, when not crowded together, appear as circular, homogeneous disks of nearly uniform size, ranging from 6–8 μm in diameter (Fig. 30-9). However, even in normal blood, individual cells may be as small as 5.5 μm and as large as 9.5 μm . The center of each is somewhat paler than the periphery. In disease, erythrocytes vary in their Hb content, size, shape, staining properties, and structure.

Color

Hemoglobin Content

The depth of staining furnishes a rough guide to the amount of Hb in red cells, and the terms **normochromic**, **hypochromic**, and **hyperchromic** are used to describe this feature of red cells. Normochromic refers to

Figure 30-9 Normal peripheral smear. Erythrocytes appear as circular, homogeneous disks of nearly uniform size, ranging from 6–8 μm in diameter, with central pallor not exceeding more than one third of the cell. On average, the red cells are approximately the same size as the nucleus of a small lymphocyte (500 \times).

Figure 30-10 Microcytic hypochromic red cells in iron deficiency anemia. Red cells are hypochromic—the amount of hemoglobin per cell is decreased, and the central pale area becomes larger (more than one third) (500 \times).

Figure 30-11 Macrocytes. Red cells are larger and thicker, stain deeply, and lack central pallor (500 \times).

normal intensity of staining (see Fig. 30-9). When the amount of Hb is diminished, the central pale area becomes larger and paler. This is known as **hypochromia**. The MCH and MCHC are usually decreased (Fig. 30-10). In megaloblastic anemia, because the red cells are larger and hence thicker, many stain deeply and have less central pallor (Fig. 30-11). These cells are hyperchromic because they have an increased MCH, but the MCHC is normal. In hereditary spherocytosis (Fig. 30-12), the cells are also hyperchromic; although the MCH is normal, the MCHC is usually increased because of a reduced surface/volume ratio. The presence of hypochromic cells and normochromic cells in the same film is called **anisochromia** or, sometimes, a **dimorphic anemia** (Fig. 30-13). This is characteristic of sideroblastic anemias but also is found some weeks after iron therapy for iron deficiency anemia, or in a hypochromic anemia after transfusion with normal cells.

Polychromatophilia

A blue-gray tint to the red cells (polychromatophilia or polychromasia) is a combination of the affinity of Hb for acid stains and the affinity of RNA for basic stains. The presence of residual RNA in the red cell indicates that

Figure 30-12 Hereditary spherocytosis. Spherocytes are nearly perfectly round in shape, smaller than normal red cells, and lack central pallor (hyperchromic) (1000 \times).

Figure 30-13 Dimorphic anemia. Anisocytosis and anisochromia characterized by the presence of microcytic hypochromic cells, normocytic cells, and few macrocytes (1000 \times).

Figure 30-14 Polychromatophilia. Polychromatophilic red cells are young red cells, larger than mature red cells; they lack central pallor and appear slightly basophilic on Wright's stain. They are called reticulocytes when stained supravivally with brilliant cresyl blue (1000 \times).

it is a young red cell that has been in the blood for 1–2 days. These cells are larger than mature red cells and may lack central pallor (Fig. 30-14). Young cells with residual RNA are polychromatophilic red cells on air-dried films stained with Wright's stain but are reticulocytes when stained supravivally with brilliant cresyl blue. Therefore, increased polychromasia implies reticulocytosis; it is most marked in hemolysis and in acute blood loss.

Size

The red cells may be abnormally small, or microcytes (see Fig. 30-10), or abnormally large, or macrocytes (see Fig. 30-11), or they may show abnormal variation in size (anisocytosis) (see Fig. 30-13). Anisocytosis is a feature of most anemias; when it is marked in degree, both macrocytes and microcytes are usually present. In analyzing causes of anemia, the terms **microcytic** and **macrocytic** have greatest meaning when considered as cell volume rather than cell diameter. The mean cell volume is measured directly on a multichannel analyzer. We perceive the diameter directly from the blood film and infer volume (and the Hb content) from it. Thus, the red cells in Figure 30-10 are microcytic; because they are hypochromic,

Figure 30-15 Poikilocytosis. Variation in shape of red cells. Abnormally shaped cells include oval, pear-shaped, and other irregularly shaped cells (1000 \times).

Figure 30-16 Hereditary elliptocytosis. Most cells are elliptocytes. They are seen in a normal person's blood, but usually account for less than 10% of cells. They are also common in iron deficiency anemia, myelofibrosis, megaloblastic anemia, and sickle cell anemia (1000 \times).

they are thinner than normal and the diameter is not decreased proportionately to the volume. Also, the mean cell volume in the blood of the patient with spherocytosis (see Fig. 30-12) is in the normal range; although many of the cells have a small diameter, their volume is not decreased because they are thicker than normal.

Shape

Variation in shape is called **poikilocytosis**. Any abnormally shaped cell is a poikilocyte. Oval, pear-shaped, teardrop-shaped, saddle-shaped, helmet-shaped, and irregularly shaped cells may be seen in a single case of anemia such as megaloblastic anemia (Fig. 30-15).

Elliptocytes are most abundant in hereditary elliptocytosis (Fig. 30-16), in which most cells are elliptical; this is a dominant condition that is only occasionally associated with hemolytic anemia. Elliptocytes are seen in normal persons' blood but account for less than 10% of the cells. They are more common, however, in iron deficiency anemia (see Fig. 30-10), myelofibrosis with myeloid metaplasia, megaloblastic anemia, and sickle cell anemia.

Spherocytes are nearly spherical erythrocytes, in contradistinction to normal biconcave disks. Their diameter is smaller than normal. They lack the central pale area or have a smaller, often eccentric, pale area (because the cell is thicker and can come to rest somewhat tilted instead of perfectly flattened on the slide). They are found in hereditary spherocytosis (HS) (see Fig. 30-12), in some cases of autoimmune hemolytic anemia (AHA), and in some conditions in which a direct physical or chemical injury has occurred to the cells, such as from heat (Fig. 30-17). In each of these three instances, tiny bits of membrane (in excess of Hb) are removed from the adult red cells, leaving the cells with a decreased surface/volume ratio. In HS and AHA, this occurs in the reticuloendothelial system; in other instances (e.g., in the patient with body burns), this may occur intravascularly.

Target cells are erythrocytes that are thinner than normal (leptocytes) and when stained show a peripheral rim of Hb with a dark, central, Hb-containing area. They are found in obstructive jaundice (Fig. 30-18), in which there appears to be an augmentation of the cell surface membrane; in the postsplenectomy state, in which there is a lack of normal reduction of surface membrane as the cell ages; in any hypochromic anemia, especially thalassemia; and in Hb C disease.

Figure 30-17 Thermal injury. Tiny bits of membrane (in excess of hemoglobin) are removed from the red cell surface, leading to formation of spherocytes (1000 \times).

Figure 30-18 Target cells. Red cells with thin membrane, peripheral rim of hemoglobin (Hb), and dark, central, Hb-containing area. They are frequently seen in Hb C disease, in hypochromic anemia, and in liver disease (1000 \times).

Figure 30-19 Schistocytes. Presence of cell fragments is indicative of hemolysis. Schistocytes can be seen in several conditions, including microangiopathic hemolytic anemia, megaloblastic anemia, burns, and disseminated intravascular coagulation (500 \times).

Schistocytes (cell fragments) indicate the presence of hemolysis, whether in megaloblastic anemia, severe burns (see Fig. 30-17), or microangiopathic hemolytic anemia (Fig. 30-19). The latter process may be associated with small blood vessel disease or with fibrin in small blood vessels and results in intravascular fragmentation; particularly characteristic are helmet cells and triangular cells. Burr cells are irregularly contracted red cells with prominent spicules and are seen in the same process; however, this term is used differently by different hematologists and therefore leads to confusion.

Acanthocytes are irregularly spiculated red cells in which the ends of the spicules are bulbous and rounded (Fig. 30-20); they are seen in abetalipoproteinemia, hereditary or acquired, and in certain cases of liver disease. Crenated cells or echinocytes (Fig. 30-21) are regularly contracted cells that may commonly occur as an artifact during preparation of films, or they may be due to hyperosmolarity, or to the discocyte–echinocyte transformation. In vivo, the latter may be associated with decreased red cell adenosine triphosphate (ATP) resulting from any of several causes. Artifacts resembling crenated cells consisting of tiny pits or bubbles indenting the red cells (Fig. 30-22) may be caused by a small amount of

Figure 30-20 Acanthocytes. Irregularly spiculated cells with bulbous and rounded ends, frequently seen in abetalipoproteinemia or certain cases of liver disease (1000 \times).

Figure 30-21 Echinocytes. Regularly contracted cells with sharp ends; may occur as an artifact during film preparation or as the result of hyperosmolarity or decreased adenosine triphosphate due to several causes (1000 \times).

water contaminating the Wright's stain (or absolute methanol, if this is used first as a fixative).

Structure

Basophilic Stippling (Punctate Basophilia)

This is characterized by the presence, within the erythrocyte, of irregular basophilic granules, which vary from fine to coarse (Fig. 30-23). They stain deep blue with Wright's stain. The erythrocyte containing them may stain normally in other respects, or it may exhibit polychromatophilia. Fine stippling is commonly seen when there is increased polychromatophilia and, therefore, with increased production of red cells. Coarse stippling may be seen in lead poisoning or other diseases with impaired Hb synthesis, in megaloblastic anemia, and in other forms of severe anemia; it is attributed to an abnormal instability of the RNA in the young cell. Red cells with inorganic iron-containing granules (as demonstrated by stains for iron) are called **siderocytes**. Sometimes these granules stain with

Figure 30-23 Basophilic stippling. Presence of irregular basophilic granules, either fine or coarse; commonly seen in increased red cell production. Coarse stippling is usually seen in lead poisoning, or other anemias due to impaired hemoglobin synthesis, such as megaloblastic anemia (1000 \times).

Figure 30-24 Howell-Jolly bodies. Smooth round remnants of nuclear chromatin. Seen rarely in erythrocytes in pernicious anemia, lead poisoning, and after splenectomy. Multiple Howell-Jolly bodies in a single cell usually indicate megaloblastic anemia or some other form of abnormal erythropoiesis (1000 \times).

Wright's stain; if so, they are called **Pappenheimer bodies**. In contrast to basophilic stippling, Pappenheimer bodies are few in number in a given red cell and are rarely seen in the peripheral blood except after splenectomy.

Howell-Jolly Bodies

These particles are smooth, round remnants of nuclear chromatin. Single Howell-Jolly bodies may be seen in megaloblastic anemia (Fig. 30-24), in hemolytic anemia, and after splenectomy. Multiple Howell-Jolly bodies in a single cell usually indicate megaloblastic anemia or some other form of abnormal erythropoiesis.

Cabot Rings

These are ring-shaped, figure-of-eight, or loop-shaped structures. Occasionally, they are formed by double or several concentric lines. They are observed rarely in erythrocytes in pernicious anemia, lead poisoning, and certain other disorders of erythropoiesis. They stain red or reddish purple with Wright's stain and have no internal structure. The rings are probably microtubules remaining from a mitotic spindle (Bessis, 1977). They are interpreted as evidence of abnormal erythropoiesis.

Malarial Stippling

Fine granules may appear in erythrocytes that harbor *Plasmodium vivax*. With Wright's stain, the minute granules, "Schüffner's granules," stain purplish red. They are sometimes so numerous that they almost hide the parasites. These red cells are, as a rule, larger than normal.

Rouleaux Formation

This is the alignment of red cells one upon another so that they resemble stacks of coins. On air-dried films, rouleaux appear as in Figure 30-25. Elevated plasma fibrinogen or globulins cause rouleaux to form and also promote an increase in the erythrocyte sedimentation rate. Rouleaux formation is especially marked in paraproteinemia (monoclonal gammopathy). **Agglutination**, or clumping, of red cells is more surely separated from rouleaux in wet preparations, and on air-dried films tends to show more irregular and round clumps than linear rouleaux. Cold agglutinins are responsible for this appearance (Fig. 30-26).

Figure 30-25 Rouleaux formation. Alignment of red cells one upon another, so that they resemble a stack of coins. It is usually caused by elevated plasma fibrinogen or globulins (500 \times).

Figure 30-26 Agglutination. Clumping of red cells, which is more irregular than linear rouleaux formation. It is caused by cold agglutinins (500 \times).

Figure 30-27 Nucleated red cell/normoblasts. Precursors of mature red cells, normoblasts are usually present only in the bone marrow. Their presence in blood is usually associated with increased red cell production or infiltrative bone marrow disorders (1000 \times).

Nucleated Red Cells

In contrast to erythrocytes of lower vertebrates and to most mammalian cells, the mammalian erythrocyte lacks a nucleus. Nucleated red cells (normoblasts; Figs. 30-27 and 30-48) are precursors of nonnucleated mature red cells in the blood. In the human, normoblasts are normally present only in the bone marrow. Stages in their production (see Chapter 31) from the earliest to the latest include pronormoblast, basophilic normoblast, polychromatophilic normoblast, and orthochromatic normoblast. In general, nucleated red cells that might appear in the blood in disease are polychromatic normoblasts. In some, however, the cytoplasm is so basophilic that it is difficult to recognize the cell as erythroid except by the character of the nucleus, intensely staining chromatin, and sharp separation of chromatin from parachromatin. Such erythroid cells are often mistaken for lymphocytes—an error that usually can be prevented by careful observation of the nucleus. The megaloblast (Fig. 30-28) is a distinct, nucleated erythroid cell—not merely a larger normoblast. It is characterized by large size and an abnormal "open" nuclear chromatin pattern. Cells of this series are not found in normal marrow but are

Figure 30-28 Megaloblast. Large nucleated red cell with abnormal “open” nuclear chromatin. They are frequently seen in the bone marrow in myelodysplastic syndrome or other megaloblastic anemia. Occasionally, these can also be seen in the peripheral blood (1000 \times).

Figure 30-29 Leukemoid reaction. Left-shifted neutrophilic series with neutrophils, bands, and myelocytes. The neutrophils also show coarse toxic granulation (1000 \times).

characteristically present in the marrow and sometimes in the blood of patients with pernicious anemia or other megaloblastic anemias.

Significance of Nucleated Red Cells

Normoblasts are present normally only in the blood of the fetus and of very young infants. In the healthy adult, they are confined to the bone marrow and appear in the circulating blood only in disease, in which their presence usually denotes an extreme demand made on the marrow, extramedullary hematopoiesis, or marrow replacement. Large numbers of circulating nucleated red cells are found particularly in hemolytic disease of the newborn (erythroblastosis fetalis) and thalassemia major.

Leukoerythroblastic Reaction

The presence of normoblasts and immature cells of the neutrophilic series in the blood is known as a **leukoerythroblastic reaction** (Fig. 30-29). This often indicates space-occupying disturbances of the marrow, such as myelofibrosis with myeloid metaplasia, metastatic carcinoma, leukemias, multiple myeloma, Gaucher disease, and others. Nonetheless, in the study of Weick (1974), more than a third of patients with a leukoerythroblastic reaction did not have malignant or potentially malignant disease (Table 30-6). In patients with metastatic malignancy, a leukoerythroblastic reaction is good evidence for marrow involvement by tumor.

LEUKOCYTES ON PERIPHERAL BLOOD SMEAR EXAMINATION

Before evaluating leukocytes on the Romanowsky's-stained blood film, one should first determine that the film is well made, the distribution of the cells is uniform, and the staining of the cells is satisfactory. One first scans the counting area of the slide and, in wedge films, the lateral and feather edges, where monocytes, neutrophils, and large abnormal cells (if present) tend to be disproportionately represented. With coverslip preparations, this uneven distribution is less likely to occur. Suspicious cells are detected at 100 \times magnification and are confirmed at high power. Because nucleated red cells, macrophages, immature granulocytes, immature lymphoid cells, megakaryocytes, and abnormal cells are not normally found in blood, they should be recorded if present.

Figure 30-30 Neutrophil and band form. Neutrophil and band form depicting separation of nuclear lobes in the mature neutrophil vs. horseshoe-shaped nucleus in the band form. A giant platelet is also seen (1000 \times).

TABLE 30-6

Conditions Associated With Leukoerythroblastosis

0.63	0.26	Solid tumors and lymphomas
	0.24	Myeloproliferative disorders, including chronic myeloid leukemia (CML)
	0.13	Acute leukemias
0.37	0.03	Benign hematologic conditions
	0.08	Hemolysis
	0.26	Miscellaneous, including blood loss

Data are from Weick JK, Hagedorn AB, Linman JW. Leukoerythroblastosis: diagnostic and prognostic significance. *Mayo Clin Proc* 1974;49:110.

Proportions are based on a series of 215 cases discovered in a study of 50,277 blood film examinations in a 6-month period—a proportion of 0.004.

While scanning under low power, it is advisable to estimate the leukocyte count from the film. Even though it is a crude approximation, it sometimes enables one to detect errors in total count. One then proceeds to determine the percentage distribution of the different types of leukocytes, which is known as the differential leukocyte count. In patients with leukopenia, it may be necessary to concentrate the leukocytes by centrifuging blood anticoagulated with EDTA and preparing films from the top layer of the packed cells. This buffy coat contains primarily leukocytes and platelets. In the crenellation technique of counting, the field of view is moved from side to side across the width of the slide in the **counting area**, just behind the feather edge, where the red cells are separated from one another and are free of artifacts. As each leukocyte is encountered, it is classified, until 100, 200, 500, or 1000 leukocytes have been counted. The greater the number of cells counted, the greater is the precision, but for practical reasons, 100-cell counts are usually made. A record of the count may be kept by using a mechanical or electronic tabulator. Leukocytes that cannot be classified should be placed together in an unidentified group. In some conditions, notably leukemia, many of these unidentified leukocytes may be present. During the differential leukocyte counting procedure, the morphology of erythrocytes and platelets is examined, and the number of platelets is estimated. The absolute concentration of each variety of leukocyte is its percentage times the total leukocyte count. An increase in absolute concentration is an absolute increase; an increase in percentage only is a relative increase. Reference intervals are more useful if given as absolute concentrations rather than percentages (see Table 30-5).

Leukocytes Normally Present in Blood

Neutrophil (Polymorphonuclear Neutrophilic Leukocyte; Segmented Neutrophilic Granulocyte)

Neutrophils average 12 μ m in diameter; they are smaller than monocytes and eosinophils and slightly larger than basophils. The nucleus stains deeply; it is irregular and often assumes shapes comparable to such letters as E, Z, and S. What appear to be separate nuclei normally are segments of nuclear material connected by delicate filaments.

A filament has length but no breadth as one focuses up and down. A **segmented neutrophil** (Figs. 30-30 and 30-49) has at least two of its lobes separated by a filament. A **band neutrophil** (see Figs. 30-30 and 30-49)

Figure 30-31 Neutrophilic granules. Cytoplasmic granules in myelocytes and mature neutrophils (1000 \times).

Figure 30-32 Basophil (below), eosinophil (above). Eosinophilic granules are coarser and bigger and often do not overlie the nucleus, unlike the basophil, which has large, deeply basophilic granules, often obscuring nuclear details (1000 \times).

Figure 30-33 Basophil (center), neutrophilic myelocyte and band (left). The granules in the basophil are much bigger and coarser compared with the fine azurophilic granules of the neutrophil and precursors (1000 \times).

Figure 30-34 Monocyte. Among the normal blood cells, the monocyte is the largest and has the most delicate nuclear chromatin pattern. A moderate amount of light gray cytoplasm with fine granularity and vacuolation is noted (500 \times).

has either a strand of nuclear material thicker than a filament connecting the lobes, or a U-shaped nucleus of uniform thickness. The nucleus in both types of neutrophils has coarse blocks of chromatin and rather sharply defined parachromatin spaces. If, because of overlapping of nuclear material, it is not possible to be certain whether a filament is present, the cell should be placed in the segmented category (Mathy, 1974). The number of lobes in normal neutrophils ranges from two to five, with a median of three. The cytoplasm itself is colorless and has tiny granules (0.2–0.3 μm) that stain tan to pink with Wright's stain. About two thirds of these are specific granules, and one third azurophil granules. With light microscopy, the two types of granules often cannot be distinguished in the mature cell (Fig. 30-31). Segmented neutrophils average 56% of leukocytes; reference intervals are $1.8\text{--}7.0 \times 10^9/\text{L}$ in Caucasian adults but have a lower limit of about $1.1 \times 10^9/\text{L}$ in black adults. Band neutrophils average 3% of leukocytes; the upper reference value is about $0.7 \times 10^9/\text{L}$ in Caucasian people and slightly lower in black people (using the preceding definition and counting 100 cells in the differential) (see Table 30-5).

Normally, about 10%–30% of segmented neutrophils have two lobes, 40%–50% have three lobes, and 10%–20% four; no more than 5% have five lobes. A “shift to the left” occurs when increased bands and less mature neutrophils are present in the blood, along with a lower average number of lobes in segmented cells (see Figs. 30-29 and 30-31).

Neutrophil production and physiology are discussed in subsequent chapters. Neutrophilia or neutrophilic leukocytosis is an increase in the absolute count, and neutropenia is a decrease.

Eosinophil (Eosinophilic Granulocyte)

Eosinophils average 13 μm in diameter. The structure of these cells is similar to that of polymorphonuclear neutrophils, with the striking difference that, instead of neutrophilic granules, their cytoplasm contains larger round or oval granules that have a strong affinity for acid stains (Fig. 30-32). They are easily recognized by the size and color of the granules, which stain bright red with eosin. The cytoplasm is colorless. The nucleus stains somewhat less deeply than that of the neutrophils and usually has two connected segments (lobes), rarely more than three. Eosinophils average 3% of the leukocytes in adults, and the upper reference value is $0.6 \times 10^9/\text{L}$ when calculated from the differential count. If allergic individuals are excluded, the upper limit is probably $0.35 \times 10^9/\text{L}$ or 350/ μL .

The lower reference value is probably 40/ μL ; a decrease in eosinophils (eosinopenia) can be detected only by counting large numbers of cells as in direct hemocytometer counts (Dacie, 1991), or with a flow cytometer automated differential counter.

Basophil (Basophilic Granulocyte)

In general, basophils resemble neutrophils, except that the nucleus is less segmented (usually merely indented or partially lobulated), and granules are larger and have a strong affinity for basic stains (Figs. 30-32 and 30-33). In some basophils, most of the granules may be missing because they are soluble in water, leaving vacuoles or openings in the cytoplasm. The granules then are a mauve color. In a well-stained film, the granules are deep purple and the nucleus is somewhat paler and is often nearly hidden by the granules, so that its form is difficult to distinguish. Unevenly stained granules of basophils may be ring shaped and resemble *Histoplasma capsulatum* or protozoa.

Basophils are the least numerous of the leukocytes in normal blood and average 0.5%. The 95% reference values for adults are $0\text{--}0.2 \times 10^9/\text{L}$ when derived from the differential count.

Monocyte

The monocyte is the largest cell of normal blood (Fig. 30-34). It generally has about two to three times the diameter of an erythrocyte (14–20 μm), although smaller monocytes sometimes are encountered. It contains a single nucleus, which is partially lobulated, deeply indented, or horseshoe shaped. Occasionally, the nucleus of a monocyte may appear round or oval. The cytoplasm is abundant. The nuclear chromatin often appears to be in fine, parallel strands separated by sharply defined parachromatin. The nucleus stains less densely than that of other leukocytes. The cytoplasm is blue-gray and has a ground-glass appearance and often contains fine red to purple granules that are less distinct and smaller than the granules of neutrophils. Occasionally, blue granules may be seen. When the monocyte transforms into a macrophage, it becomes larger (20–40 μm); the nucleus may become oval and the chromatin more reticular or dispersed, so that nucleoli may be visible. A perinuclear clear zone (Golgi) may be evident. The fine red or azurophil granules are variable in number or may have disappeared. The more abundant cytoplasm tends to be irregular at the cell margins and to contain vacuoles. These are phagocytic vacuoles, which

Figure 30-35 Lymphocyte. This is a benign reactive lymphocyte with moderately abundant pale gray cytoplasm hugging the surrounding red cells and distinct separation of chromatin/parachromatin (1000 \times).

Figure 30-36 Reactive large lymphocyte with moderately abundant gray-blue cytoplasm (1000 \times).

may contain ingested red cells, debris, pigment, or bacteria. Evidence of phagocytosis in monocytes or the presence of macrophages in directly made blood films is pathologic and often indicates the presence of active infection.

Monocytes average 4% of leukocytes, and the reference interval for adults is approximately $0\text{--}0.8 \times 10^9/\text{L}$, depending on the method used to perform the differential count (see Table 30-5).

Lymphocyte

Lymphocytes are mononuclear cells without specific cytoplasmic granules. Small lymphocytes are about the size of an erythrocyte or slightly larger (6–10 μm) (see Fig. 30-9). The typical lymphocyte has a single, sharply defined nucleus containing heavy blocks of chromatin. The chromatin stains dark blue with Wright's stain, whereas the parachromatin stands out as lighter-stained streaks; at the periphery of the nucleus, the chromatin is condensed. Characteristically, a gradual transition or smudging is seen between the chromatin and the parachromatin. The nucleus is generally round but is sometimes indented at one side. The cytoplasm stains pale blue except for a clear perinuclear zone. Larger lymphocytes (Figs. 30-35 and 30-36), 12–15 μm in diameter, with less densely staining nuclei and more abundant cytoplasm, are frequently found, especially in the blood of children, and may be difficult to distinguish from monocytes. The misshapen, indented cytoplasmic margins of lymphocytes are due to pressure of neighboring cells. In the cytoplasm of about one third of large lymphocytes, a few round, red-purple granules are present. They are larger than the granules of neutrophilic leukocytes. There is a continuous spectrum of sizes between small and large lymphocytes and, indeed, there can be a transition from small to large to blast forms, as well as the reverse. It is not meaningful to classify small lymphocytes and large lymphocytes separately. The presence of significant proportions of atypical lymphocytes and blast forms (nonleukemic lymphoblasts, reticular lymphocytes) must be noted; these indicate transformation of lymphoid cells as a response to antigenic stimulation. Plasma cells have abundant blue cytoplasm, often with light streaks or vacuoles, an eccentric round nucleus, and a well-defined clear (Golgi) zone adjacent to the nucleus (Fig. 30-37). The nucleus of the plasma cell has heavily clumped chromatin, which is sharply defined from the parachromatin and is often arranged in a radial or wheel-like pattern. Plasma cells are not present normally in blood.

Figure 30-37 Plasma cell. Eccentric round nucleus with clumped nuclear chromatin and moderate amount of basophilic cytoplasm with prominent nuclear hof, or clear zone (1000 \times).

Figure 30-38 Broken cell. A broken cell of the myeloid series with ruptured cell membrane and disintegration of cytoplasmic contents (1000 \times).

Figure 30-39 Ruptured cell. Ruptured/disintegrating leukocyte (1000 \times).

Lymphocytes average 34% of all leukocytes and range from $1.5\text{--}4 \times 10^9/\text{L}$ in adults. The lymphocytes and their derivatives, the plasma cells, operate in the immune defenses of the body.

Artifacts

Broken Cells

Damaged or broken leukocytes (Figs. 30-38 and 30-39) constitute a small proportion of the nucleated cells in normal blood. Bare nuclei from ruptured cells (Figs. 30-40 and 30-41) vary from fairly well-preserved nuclei without cytoplasm to smudged nuclear material, sometimes with strands arranged in a coarse network, the so-called basket cells. They probably represent fragile cells, usually lymphocytes that have been broken in preparing the film. They are apt to be numerous when there is an atypical lymphocytosis, in chronic lymphocytic leukemia, and in acute leukemias.

Degenerative Changes

As EDTA-blood ages in the test tube, changes in leukocyte morphology begin to take place (Sacker, 1975). The degree of change varies among cells and in different individuals. Within a half hour, the nuclei of neutrophils may begin to swell, with some loss of chromatin structure. Cytoplasmic vacuoles appear, especially in monocytes and neutrophils. Nuclear

Figure 30-40 Smudge cell. Nuclear remnant from a damaged/broken white cell (1000 \times).

Figure 30-41 Basket cells (1000 \times).

lobulation appears in mononuclear cells; deep clefts may cause the nucleus to resemble a cloverleaf (radial segmentation of the nuclei; Rieder cells). Finally, loss of the cytoplasm and a smudged nucleus may be all that remains of the cell (see Fig. 30-40). Degenerative changes occur more rapidly in oxalated blood than in EDTA-blood. They arise more rapidly with increasing concentrations of EDTA, such as occur when evacuated blood collection tubes are incompletely filled.

Contracted Cells

In the thicker part of wedge films, drying is slow. Obvious changes in the film include rouleaux of the erythrocytes and shrinkage of the leukocytes. Because the leukocytes are contracted and heavily stained, mononuclear cells are difficult to distinguish. Optimal cell identification is usually impossible in these areas.

Endothelial Cells

Endothelial cells from the lining of the blood vessel may appear in the first drop of blood from a fingerstick specimen or, rarely, in venous blood. They have an immature reticular chromatin pattern and may be mistaken for histiocytes or for tumor cells.

Radial Segmentation of the Nuclei

Use of oxalated blood results in the appearance of abnormal segmentation of the nuclei of leukocytes on the blood film. This segmentation differs from that of the granulocytes in that the lobes appear to radiate from a single point, giving a cloverleaf or a cartwheel picture. Extensive changes can occur within an hour or two in oxalated blood. Less extensive changes occur with other anticoagulants, including EDTA.

Vacuolation

Vacuoles may develop in the nucleus and cytoplasm of leukocytes, especially monocytes and neutrophils from blood anticoagulated with EDTA. Vacuoles may be associated with swelling of the nuclei and loss of granules from the cytoplasm.

"Pseudophagocytosis"

Occasionally, a small lymphocyte, or more often an erythrocyte, will lie atop a granulocyte or a monocyte and thus will appear to have been ingested. The true positions of such cells can be suspected because they will come into sharp focus in a plane above that of the larger cell.

TABLE 30-7

Ninety-Five Percent Confidence Limits for Various Percentages of Blood Cells of a Given Type as Determined by Differential Counts*

a	n = 100	n = 200	n = 500	n = 1000	n = 10,000

*n is the number of cells counted; a, the observed percentage of cells of the given type. The limits for n = 100, 200, 500, and 1000 are exact; for n = 10,000, they have been determined with Freeman and Tukey's approximation, as described in the Geigy tables.

Sources of Error in the Differential Leukocyte Count

Even in perfectly made blood films, the differential count is subject to the same errors of random distribution. For interpretation of day-to-day or slide-to-slide differences in the same patient, it is helpful to know how much of the variation is ascribable to chance alone. Table 30-7 gives 95% confidence limits for different percentages of cells in differential counts performed, classifying a total of 100–10,000 leukocytes. In comparing the percentages from two separate counts, if one number lies outside the confidence limits of the other, it is probable that the difference is significant (i.e., not due to chance). Thus, on the basis of a 100-cell differential count, if the monocytes were 5% one day and 10% the next, it is probable that the difference is due solely to sampling error. Although the difference could be real, one cannot be sure of this because of the small number of cells counted. If, on the other hand, the differential count totaled 500 cells, the difference between 5% and 10% is significant; one can be reasonably certain (with a 5% chance of being wrong) that the difference is a real one and is not due to chance alone. Of course, this is a minimal estimate of

the error involved in differential counts because it does not include mechanical errors (due to variations in collecting blood samples, inadequate mixing, irregularities in distribution depending on the type and quality of the blood films, and poor staining) or errors in cell identification, which depend on the judgment and experience of the observer. Meticulous technique, as well as accurate and consistent cell classification, is therefore required. The physician who interprets the results must be aware of possible sources of error, especially error due to chance in the distribution of cells. Table 30-5 shows the distribution of the various types of leukocytes in the blood of normal persons. Absolute concentrations are given, as these have considerably greater significance than percentages alone.

Automated Differential Leukocyte Counting

Because the differential leukocyte count is nonspecific, nonprecise, error-prone, usually labor intensive, expensive to perform, and of limited clinical significance as a screening test, some investigators have suggested that it may be prudent to discontinue use of the differential count as an inpatient screening test for adults (Connelly, 1982). Automation of the differential count eliminates some of the detractors. Ideally, requirements for the automated differential leukocyte counting system should include the following:

1. The distribution of cells analyzed should be identical to that in the blood.
2. All leukocytes usually found in blood diseases should be accurately identified, or detected and “flagged” in some way.
3. The speed of the process should enable a large number of cells to be counted to minimize statistical error.
4. The instrument should be cost-effective (Bentley, 1977).

Impedance counters and flow cytometer systems and their differential counts were discussed earlier under Instrument Technology.

The automated systems have the advantage of rapidly analyzing larger numbers of cells and significantly reducing the statistical error of counting.

Disadvantages include that the categories of cells are not completely consonant with those with which we are familiar on Romanowsky’s-stained films. An “unclassified” category is difficult to interpret. When an abnormal result occurs, a film must be made and examined. Because of concern regarding the instrument flags, each laboratory should devise a policy for blood film examination and visual counting when indicated. Camden (1993) provides guiding questions to be asked in selecting a new hematology analyzer for your laboratory. The ICSH (1984b) also published a protocol for evaluation of automated blood cell counters.

Digital Image Processing

A uniformly made and stained blood film is placed on a motor-driven microscope stage. A computer controls scanning the slide and stopping it when leukocyte(s) are in the field. The optical details (e.g., nuclear and cytoplasmic size, density, shape, color) are recorded by a television camera, analyzed by computer, and converted to digital form; these characteristics are compared with a memory bank of such characteristics for the different cell types. If the pattern fits that of a normal cell type, it is identified as such; otherwise, the cell is classified as other or unknown. The coordinates of the unknown cells are kept by the instrument and relocated at the end of the count, so that the technologist can classify them (Lapen, 1982; Parthenis, 1992; Mukherjee, 2004).

PLATELETS ON PERIPHERAL BLOOD SMEAR EXAMINATION

In films made from EDTA-blood and stained with Romanowsky’s stains, platelets are round or oval, 2–4 μm in diameter, and separated from one another (Fig. 30-42). The platelet count may be estimated from such films. On average, if the platelet count is normal, about one platelet is found per 10–30 red cells. At 1000 \times magnification, this is equivalent to about 7–20 platelets per oil immersion field in the areas where red cell morphology is optimal (Fig. 30-43). Platelets contain fine purple granules that usually fill the cytoplasm. Occasionally, granules are concentrated in the center (the “granulomere”) and surrounded by a pale cytoplasm (the “hyalomere”); these are probably activated platelets, the appearance resulting from contraction of the microtubular band. A few platelets may have decreased concentrations of granules (hypogranular platelets). In EDTA-blood from normal individuals, the fraction of platelets that exceed 3 μm in diameter and the fraction of platelets that are hypogranular are both less than 5% if the films are made at 10 minutes or 60 minutes after the blood is drawn.

Figure 30-42 Platelet. Platelets are round to oval, 2–4 μm in diameter, and separated from one another (1000 \times).

Figure 30-43 Platelet/giant platelet. Platelets show fine granularity; an occasional larger (giant) form is noted (1000 \times).

If films are made immediately or at 3 hours after blood drawing, the fraction of large platelets and the fraction of hypogranular or activated platelets are increased (Zeigler, 1978). These artifacts make it necessary to standardize time of film preparation when evaluating platelet size from films. In patients with immune thrombocytopenia, large platelets/giant platelets (see Fig. 30-30) are increased in number. They are also increased in patients with the rare Bernard-Soulier syndrome and in those with myelophthisis or myeloproliferative syndrome; in the latter, the platelets are frequently hypogranular or have a distinct granulomere and hyalomere. In blood films made from skin puncture wounds, platelets assume irregular shapes with sharp projections and tend to clump together.

BONE MARROW EXAMINATION

The bone marrow examination provides a semiquantitative and qualitative assessment of the state of hematopoiesis and aids in the diagnosis of several hereditary and acquired benign and malignant diseases. Marrow aspiration and biopsy can be carried out as an office procedure on ambulatory patients with minimal risk. It compares favorably with ordinary venipuncture and is less traumatizing than a lumbar puncture. As for any other special procedure, however, the clinical indications for marrow examination should be clear. In each instance, the physician should have in mind some reasonable prediction of its result and consequent benefit to the patient. Without exception, the peripheral blood should be examined carefully first. It is a relatively uncommon circumstance to find hematologic disease in the bone marrow without evidence of it in the peripheral blood. It is estimated that the weight of the marrow in the adult is 1300–1500 g. The marrow can undergo complete transformation in a few days and occasionally even in a few hours. As a rule, this rapid transformation involves the whole organ, as evidenced by the fact that a small sample represented by a biopsy or aspiration is usually fairly representative of the whole marrow. This conclusion is in accord with results of studies of biopsy samples simultaneously removed from several sites. According to these observations, the various sites chosen for removal of marrow for studies are in most instances equally good. Consequently, the difficulty of access, the risks involved, the ease of obtaining a good biopsy specimen, and discomfort to the patient are the main reasons for selection of a site in the particular patient. Within a given site, the cellular distribution may vary in apparently hyperplastic or hypoplastic areas. This is particularly the case immediately below the cortex.

Occasionally, failure to obtain quantitatively or qualitatively adequate material in one site may be followed by success in another location. Also, the need for repeated aspirations or biopsies may indicate the use of several different sites. We regard the posterior iliac crest as the preferred site. The large marrow space allows both aspiration and biopsy to be performed with ease at one time. The techniques of marrow aspiration and biopsy have been adequately reviewed (Hyun, 1988).

PREPARATION OF THE ASPIRATE AND BIOPSY SECTION

Marrow Films

Delay, no matter how brief, is undesirable. Films can be made in a manner similar to that used for ordinary blood counts. Gray particles of marrow are visible with the naked eye. They are the best material for the preparation of good films and serve as landmarks for the microscopic examination of stained smears.

Direct Films

A drop of marrow is placed on a slide a short distance away from one end. A film 3–5 cm long is made with a spreader, not wider than 2 cm, dragging the particles behind but not squashing them. A trail of cells is left behind each particle.

Imprints

Marrow particles can also be used for preparation of imprints. One or more visible particles are picked up with a capillary pipet, the broken end of a wooden applicator, or a toothpick, and are transferred immediately to a slide and made to stick to it by a gentle smearing motion. The slide is air dried rapidly by waving, and then it is stained.

Crush Preparations

Marrow particles in a small drop of aspirate may be placed on a slide near one end. Another slide is carefully placed over the first. Slight pressure is exerted to crush the particles, and the slides are separated by pulling them apart in a direction parallel to their surfaces. All films should be dried rapidly by whipping them through the air or by exposing them to a fan. As the aspirated material is being spread, the appearance of fat as irregular holes in the films gives assurance that marrow and not just blood has been obtained.

Special Studies

A sterile anticoagulated sample containing viable unfixed cells in single cell suspension is the best substrate for nearly all special studies that are likely to be required on a marrow sample. Specifically, flow cytometry is best performed on an EDTA or heparin anticoagulated aspirate specimen, which is stable for at least 24 hours at room temperature. For cytogenetic or cell culture analysis, anticoagulated marrow should be added to tissue culture medium and analyzed as soon as possible to maintain optimal cell viability. Cytogenetic specimens are generally not adversely affected by overnight incubation. DNA is relatively stable and can be extracted and analyzed from paraffin-embedded tissue sections. However, reverse transcriptase polymerase chain reaction (RT-PCR) assays, involving amplification of complementary DNA (cDNA) prepared from cellular messenger RNA (mRNA), are often needed for molecular diagnosis of translocations associated with leukemia and lymphoma. Messenger RNA has a variable half-life in an intact cell and is degraded rapidly (on the order of seconds to minutes) in a cell lysate by ubiquitous RNases. For maximal mRNA recovery, cell suspensions, mostly buffy coat or mononuclear cell preparations, should be lysed in an appropriate RNase inhibitor containing buffer as soon as possible after sampling. EDTA is the preferred anticoagulant, as heparin can interfere with some molecular assays (Ryan, 2001b).

Histologic Sections

The needle biopsy and clotted marrow particles (fragments) are fixed in Zenker's acetic solution (5% glacial acetic acid; 95% Zenker's) for 6–18 hours, or in B-5 fixative for 1–2 hours (Hyun, 1988). Excessive time in either fixative makes the tissue brittle. Although these fixatives, particularly B-5, provide the best histology, they contain toxic mercuric chloride and are gradually being replaced by fixatives such as zinc formalin and other preparations. The tissue is processed routinely for embedding in paraffin, cut at 4 μ m, and stained routinely with hematoxylin and eosin (H&E). Giemsa and periodic acid–Schiff (PAS) stains are frequently useful. Embedding the tissue in plastic material allows thinner sections to be examined

Figure 30-44 Normal sideroblast. Single iron granule seen in the cytoplasm of a maturing normoblast. Identification requires high magnification and bright illumination, while focusing up and down (1000 \times).

and better survival of protein structure, so that enzyme histochemistry and immunocytochemistry are practical for identification of cell lineages.

Sections provide the best estimate of cellularity and a picture of marrow architecture but are somewhat inferior for the study of cytologic details. Another disadvantage is that particles adequate for histologic sections are not always obtained, especially in conditions in which the diagnosis depends on marrow evidence (e.g., myelofibrosis, metastatic cancer).

STAINING MARROW PREPARATIONS

Romanowsky's Stain

Marrow films should be stained with Romanowsky's stain (e.g., Wright-Giemsa) in a manner similar to that used for blood films. A longer staining time may be necessary for marrows with greater cellularity. Several special stains may be performed on peripheral blood smears, bone marrow aspirate, and touch imprint smears and bone marrow biopsy sections, besides the usual Romanowsky's and H&E stains. These include cytochemical stains (myeloperoxidase, Sudan black B, naphthol As-D chloroacetate esterase, nonspecific esterases, acid phosphatases, leukocyte alkaline phosphatase, periodic acid–Schiff stain, toluidine blue, and iron stain) and immunocytochemical stains, depending on the disease and the preliminary morphologic examination of the smear and/or section (Perkins, 2004). The procedure for the iron stain is discussed in the next section. The relevance of other stains is mentioned in subsequent chapters, along with the respective diseases.

Perls' Test for Iron

Procedure

One film containing marrow particles is fixed for 10 minutes in formalin vapor, immersed for 10 minutes in a freshly prepared solution that contains 0.5% potassium ferrocyanide and 0.75% hydrochloric acid, rinsed, dried, and counterstained with Nuclear Fast Red.

Interpretation

The Prussian blue reaction is produced when hemosiderin or ferritin is present; iron in Hb is not stained. It is reported as negative or 1+ to 5+. Storage iron, which is contained in macrophages, can be evaluated only in marrow particles on the film. In adults, 2+ is normal, 3+ slightly increased, 4+ moderately increased, and 5+ markedly increased. Storage iron in the marrow is located in macrophages. Normally, a small number of blue granules are seen. In iron deficiency, blue-staining granules are absent or extremely rare. Storage iron is increased in most other anemias, infections, hemochromatosis, hemosiderosis, hepatic cirrhosis, uremia, and cancer, and after repeated transfusions. Sideroblasts (Fig. 30-44) are normoblasts that contain one or more particles of stainable iron. Normally, from 20%–60% of late normoblasts are sideroblasts; in the remainder, no blue granules can be detected. The percentage of sideroblasts is decreased in iron deficiency anemia (in which storage iron is decreased) and also in the common anemias associated with infection, rheumatoid arthritis, and neoplastic disease (in which storage iron is normal or increased). The number of sideroblasts is increased when erythropoiesis is impaired for other reasons; it is roughly proportional to the degree of saturation of transferrin. The Prussian blue reaction can also be performed on slides previously stained with a Romanowsky's stain to identify sideroblasts or to determine

Figure 30-45 Ring sideroblast. Siderotic granules form a perinuclear ring spanning more than half of the nuclear diameter (Prussian blue stain, 1000 \times).

Figure 30-47 Marrow biopsy (1470 \times). Cellularity here is between 60% and 70%, which is normal for an adult. Three megakaryocytes are present, which is normal for this size of field. Granulocyte maturation appears normal, with all stages present. Very few normoblasts are noted. (Normoblasts have intensely staining nuclei and tend to occur in clusters.) The myeloid/erythroid (M/E) ratio is higher than 4:1, indicating erythroid hypoplasia. No other abnormalities are noted.

Figure 30-46 Marrow cellularity in hematologically normal individuals. Percent cellularity on the ordinate versus age, grouped by decade, on the abscissa. (From Hartsoc RJ, Smith EB, Petty CS. *Am J Clin Pathol* 1965;43:326, with permission.)

whether iron is present in other cells of interest. Further, iron stain is used to evaluate for the presence of abnormal sideroblasts and ring sideroblasts (Fig. 30-45), as seen in various hematologic diseases.

Sections

Routine H&E stains are satisfactory for most purposes. Romanowsky's stains can be used to good advantage with fixed material. Iron stains are best performed on films that contain particulate marrow tissue. They are less sensitive in sections of marrow because some iron is lost in processing, and a lesser thickness of tissue is examined in sections.

EXAMINATION OF MARROW

It is desirable to establish a routine procedure to obtain maximum information from examination of the marrow.

Peripheral Blood

The complete blood cell count, including platelet count and reticulocyte count, should be performed on the day of the marrow study, and the results incorporated in the report. The pathologist or hematologist who examines the marrow should also carefully examine the blood film as previously described and should incorporate the observations in the marrow report.

Cellularity of the Marrow

Marrow cellularity is expressed as the ratio of the volume of hematopoietic cells to the total volume of the marrow space (cells plus fat and other stromal elements). Cellularity varies with the age of the subject and the site. For example, at age 50 years, the average cellularity in the vertebrae is 75%; sternum, 60%; iliac crest, 50%; and rib, 30%. Normal cellularity of the iliac bone at different ages has been well defined by Hartsoc (1965), as summarized in Figure 30-46. If the percentage is increased for the patient's age, the marrow is hypercellular, or hyperplastic; if decreased, the marrow is hypocellular, or hypoplastic. Marrow cellularity is best judged by histologic sections of biopsy or aspirated particles (Fig. 30-47) but

should also be estimated from the particles present in marrow films. This is done by comparing the areas occupied by fat spaces and by nucleated cells in the particles, as well as the density of nucleated cells in the "tail" or fallout of the particles. Comparison of films and sections on each marrow specimen will enable the observer to estimate cellularity reasonably well from films—a skill that is useful in the instances when sectioned material is unavailable.

Distribution of Cells

Distribution of various cell types can be ascertained in two ways. First, one scans several slides under low, then high, magnification; on the basis of previous experience, one then estimates the number and distribution of cells. Second, one actually makes a differential count of 300–1000 cells and calculates the percentage of each type of cell. A combination of both methods is preferred. The second of these methods, careful differential counting, is an essential part of training in this work, without which accuracy in the first method may be difficult to achieve. The differential count also affords an objective record from which future changes may be measured.

One first scans the marrow film under low power (100 \times or 200 \times magnification) while looking for irregularities in cell distribution, numbers of megakaryocytes, and the presence of abnormal cells. Then one selects areas on the film where marrow cells are both undiluted with blood cells and separated and spread out sufficiently to allow optimal identification. These areas are usually just behind marrow particles on direct films, or near the particles on crushed films. The differential count is performed at 400 \times or 1000 \times magnification. Examples of reference intervals for differential counts of marrow at selected different ages are given in Table 30-8.

Changes in the marrow cell distribution are most dramatic in the first month of life, during which a predominance of granulocytic cells at birth changes to a predominance of lymphocytes. This predominance of lymphocytes characterizes the bone marrow during infancy. A small proportion of "immature" or transitional lymphoid cells (fine nuclear chromatin, high nuclear/cytoplasmic ratio, small to intermediate cell size) is normally present; it may be that these cells include stem cells and progenitor cells. These cells probably include cells designated as "hematogones"; they may be increased in iron deficiency anemia, immune thrombocytopenic purpura, and other disorders, especially in infancy. Normoblasts fall after birth; rise to a maximum at 2 months; then fall to a stable, relatively low level by 4 months, and remain there during most of infancy. The myeloid/erythroid (M/E) ratio is the ratio of total granulocytes to total normoblasts. In newborns and infants, it is somewhat higher than in older children or adults (see Table 30-8). In adults, the range is broad, varying from about 1.2:1 to 4:1. Both the differential count and the M/E ratio are relative values and must be interpreted with respect to cellularity, or with respect to other evidence that one of the systems is normal. An **increased** M/E ratio (e.g., 6:1) may be found in infection, chronic myelogenous leukemia, or erythroid hypoplasia. A **decreased** M/E ratio (i.e., <1.2:1) may mean a depression of leukopoiesis or a normoblastic hyperplasia, depending on the marrow cellularity. The number of megakaryocytes is estimated more reliably in sections than in marrow films. In scanning areas of films with good cellularity under low power (100 \times), an average of one to three megakaryocytes should be found in each field in normal marrow.

TABLE 30-8
Differential Cell Counts of Bone Marrow in Percent of Total Nucleated Cells

Cell types	ROSSE (1977)			MAUER (1969)	JANDL (1987)
	Birth (mean, SD)	1 month (mean, SD)	18 months (mean, SD)	Childhood (mean, range)	Adult (mean, range)
Normoblasts, total	14.48 ± 7.24	8.04 ± 5.00	8.21 ± 3.71	23.1	21.5 (14.2–30.4)
Pronormoblasts	0.02 ± 0.06	0.10 ± 0.14	0.08 ± 0.13	0.5 (0.0–1.5)	0.6 (0.2–1.4)
Basophilic n.	0.24 ± 0.25	0.34 ± 0.33	0.50 ± 0.34	1.7 (0.2–4.8)	2.0 (0.7–3.7)
polychromatophilic n.	13.06 ± 6.78	6.90 ± 4.45	6.97 ± 3.56	18.2 (4.8–34.0)	12.4 (12.2–24.2)
Orthochromatic n.	0.69 ± 0.73	0.54 ± 1.88	0.44 ± 0.49	2.7 (0.0–7.8)	6.5 (2.0–22.7)
Neutrophils, total	60.37 ± 8.66	32.35 ± 7.68	36.06 ± 7.40	57.1	56.0 (45.1–66.5)
Myeloblasts	0.31 ± 0.31	0.62 ± 0.50	0.06 ± 0.08	1.2 (0.0–3.2)	1.0 (0.5–1.8)
Promyelocytes	0.79 ± 0.91	0.76 ± 0.65	0.64 ± 0.59	1.4 (0.0–4.0)	3.4 (2.6–4.6)
Myelocytes	3.95 ± 2.93	2.50 ± 1.48	2.49 ± 1.39	18.3 (8.5–29.7)	11.9 (8.1–16.9)
Metamyelocytes	19.37 ± 4.84	11.30 ± 3.59	12.42 ± 4.15	23.3 (14.0–34.2)	18.0 (9.8–25.3)
Bands	28.89 ± 7.56	14.10 ± 4.63	14.20 ± 5.23		11.0 (8.5–20.8)
Segmented	7.37 ± 4.64	3.64 ± 2.97	6.31 ± 3.91	12.9 (4.5–29.0)	10.7 (8.0–16.0)
Eosinophils	2.70 ± 1.27	2.61 ± 1.40	2.70 ± 2.16	3.6 (1.0–9.0)	3.2 (1.2–6.2)
Basophils	0.12 ± 0.20	0.07 ± 0.16	0.10 ± 0.12	0.06 (0.0–0.8)	<0.1 (0.0–0.2)
Lymphocytes, total	15.6	49.0	45.5	16.0 (4.8–35.8)	15.8 (10.8–22.7)
Transitional	1.18 ± 1.13	1.95 ± 0.94	1.99 ± 1.00		
Small	14.42 ± 5.54	47.05 ± 9.24	43.55 ± 8.56		
Plasma cells	0.00 ± 0.02	0.02 ± 0.06	0.06 ± 0.08	0.4 (0.2–0.6)	1.8 (0.2–2.2)
Monocytes	0.88 ± 0.85	1.01 ± 0.89	2.12 ± 1.59		1.8 (0.2–2.8)
Megakaryocytes	0.06 ± 0.15	0.05 ± 0.09	0.07 ± 0.12		<1.0 (0.0–0.2)
Reticulum cells					0.3 (0.0–0.5)
M/E ratio	4.2	4.0	4.4	2.9 (1.2–5.2)	2.5 (1.2–5.0)

Data are from Rosse (1977), Mauer (1969), and Jandl (1987).

Figure 30-48 Normal erythroid maturation. Various stages of normoblastic erythroid maturation (1000×).

Figure 30-49 Normal myeloid (neutrophilic) maturation. Various stages of normal myeloid maturation from the blast to the mature neutrophil.

Maturation

While examining cells during the differential count, one should evaluate whether maturation is normal (Figs. 30-48 and 30-49), that is, whether nuclear and cytoplasmic development is in balance. Impaired cytoplasmic maturation in normoblasts, for example, occurs when Hb synthesis is impaired; impaired nuclear maturation occurs in megaloblastic anemias. Bizarre or dysplastic maturation occurs as a result of certain drugs, in some leukemias, and in dysmyelopoietic syndromes.

Presence of Rare Cell Types or Abnormal Cells

In scanning the marrow, one looks for the presence of rare or unexpected cell types.

Tissue mast cells (Fig. 30-50) are normally very infrequent. They are increased in number in aplastic or refractory anemias and in lymphoproliferative disorders.

Osteoblasts (Fig. 30-51) are cells that synthesize the collagen matrix of bone. **Osteoclasts** are cells that resorb bone and are thought to result from the fusion of histiocytes. Both cell types are normally present in small numbers in the aspirates of infants and children. They are uncommonly seen in adult marrow, except when bone destruction or repair is occurring,

Figure 30-50 Tissue mast cell. Mast cells contain numerous dense dark-purple cytoplasmic granules that can completely cover the round nucleus (1000×).

as in hyperparathyroidism, Paget's disease, metastatic tumor, or a recent biopsy at the same site.

Osteoblasts are large cells with a single eccentric nucleus that has reticular chromatin and a prominent nucleolus. The cytoplasm is moderately basophilic; a large pale Golgi zone is separated from the nucleus,

Figure 30-51 Osteoblast. Frequently found in pediatric patients, osteoblasts line the bone trabeculae. In smears, they appear as cells with eccentrically placed nuclei, resembling plasma cells, but the cytoplasmic clearing is more centrally located and is not found in the Golgi area, as in plasma cells (1000×).

Figure 30-52 Metastatic tumor. Bone marrow biopsy with islands of metastatic gastric adenocarcinoma (1000×).

rather than abutting it as in plasma cells. Osteoblasts are often present in clusters and may be confused with immature plasma cells or myeloma cells. Osteoclasts are large, multinucleated cells up to 100 µm diameter that may be mistaken for megakaryocytes. They have multiple nuclei that are separate (not joined as in megakaryocytes). The chromatin is reticular, and a prominent nucleolus is usually present. The cytoplasm may be basophilic but usually has pink-purple granules that resemble megakaryocyte granules. Coarse fragments of purple-staining material are often present. Clusters of **metastatic neoplastic cells** (Fig. 30-52) may be found in one or more marrow films of patients with metastatic tumor in the bone sampled; they may be found in biopsy sections and not in films, in both, or, less commonly, in one or more films and not in the biopsy. Some metastatic neoplastic cells resemble myeloblasts or other primitive blasts. The clue to recognizing them is that they almost always appear in clusters or clumps of cells; this is not true of hematopoietic blast cells.

Evaluation of the Biopsy Specimen

Histologic sections allow better estimates of marrow cellularity and of the number of megakaryocytes than do marrow films (see Fig. 30-47). Normally, immature myeloid precursors lie along bone trabeculae, erythroid

precursors are in discrete interstitial islands, and megakaryocytes are scattered in the interstitium. In good histologic preparations, cell distribution and maturation abnormalities can be quite reliably determined. In addition to more reliable detection of the presence of lymphomas or metastatic tumor, the histologic pattern can often be diagnostic of the type of neoplasm. Other focal lesions not found in films include granulomas, abscesses, and vascular lesions. In some conditions, such as myelofibrosis and hairy cell leukemia, the bone marrow cannot be aspirated, and biopsy is necessary to establish a diagnosis. Trabeculae should always be examined to detect bone abnormalities. Osteosclerosis with thickened bone trabeculae may accompany myelofibrosis or may be congenital. In osteoporosis, the bone trabeculae are thin. Osteomalacia is characterized by a recognizable osteoid seam. Osteitis fibrosa occurs in hyperparathyroidism and is characterized by irregular osteoclastic bone resorption, endosteal fibrosis, and some osteoblastic activity in areas of bone regeneration. Irregularly widened trabeculae with a “mosaic” pattern are typical findings in Paget’s disease of bone.

Interpretation

The summary of the marrow report includes an estimate of cellularity, an estimate of the number of megakaryocytes, the M/E ratio, statements about any cytologic or maturation abnormalities, an estimate of the storage iron and proportion of sideroblasts, and statements about any other abnormal findings present. Abnormalities in blood cell counts and morphology are also summarized. An interpretation of observed findings is made, which of course includes a diagnosis if this is possible. In making such an **interpretation**, one should include an integration of marrow and blood observations with clinical findings and other laboratory data. Alterations in blood and marrow cells are discussed, with reference to the diseases and disorders considered in subsequent chapters.

INDICATIONS FOR MARROW STUDY

In microcytic anemia, evaluation of iron stores and sideroblasts allows categorization of the anemia (i.e., iron deficiency, anemia of chronic disease, sideroblastic).

In macrocytic anemia, marrow examination will confirm whether the process is megaloblastic or not; in some cases, changes in the blood are minimal, yet the marrow is megaloblastic. In normocytic anemia (or macrocytic anemia) without an increased reticulocyte production index, the marrow is evaluated for quantitative or qualitative abnormalities in erythropoiesis (e.g., pure red cell aplasia, myelodysplasia).

In neutropenia, thrombocytopenia, or pancytopenia, marrow study is helpful in assessing the presence and normality of the precursor cells in each series. This enables one to assess the probability of decreased production, impaired maturation, or increased destruction as the mechanism of the disorder. In cytopenias, marrow examination sometimes will reveal the presence of leukemia or another hematologic neoplasia.

In immunoglobulin abnormalities, the diagnosis of plasma cell myeloma or macroglobulinemia may be confirmed if infiltrations of abnormal plasma cells or lymphocytes are present. Marrow examination is essential for the diagnosis and classification of acute leukemia. It is frequently performed to assist in the diagnosis and staging of other neoplasms, including lymphomas and metastatic tumors, and to assess response to therapy for hematologic disorders. If the marrow cannot be aspirated (“dry tap”), biopsy is essential. Marrow biopsy should also be performed if blood changes suggest myelofibrosis with myeloid metaplasia, or if granulomatous disease or metastatic tumor is suspected.

KEY POINTS

- Hematopoietic tissue arises in the bone marrow from stem cells that differentiate into granulocytes, monocytes, lymphocytes, megakaryocytes, and erythroid cells.
- Differentiation and maturation of hematopoietic cells are influenced by soluble factors, including growth factors and cytokines, by interaction with the bone marrow stroma, and are mediated in part through interaction of adhesion molecules.
- The primary function of erythrocytes is delivery of oxygen from lungs to tissues. This is dependent on the particular properties and adequate production of hemoglobin and is regulated by oxygen tension in the kidneys, where erythropoietin is produced.
- Inherited or acquired abnormalities of heme biosynthesis, known as porphyrias because of abnormal accumulation of porphyrins and metabolites, primarily affect the nervous system.
- Neutrophils and monocytes are derived from a common progenitor cell under the influence of growth factors, and are the major phagocytic cells. They and the other granulocytic cells (eosinophils, basophils, and mast cells) respond to soluble factors, eliminate microorganisms, and modulate immunity.
- Megakaryocytes, stimulated by thrombopoietin, give rise to platelets and thus effect primary hemostasis.

- Lymphocytes arise in thymus and peripheral lymphoid tissue, as well as in bone marrow. They are made up of complex populations of genetically distinct individual B cells, T cells, natural killer (NK) cells, and related subtypes. These interact with other cells, secrete soluble factors including principally cytokines and immunoglobulins, and effect both humoral and cellular immunity.

STEM CELLS

In postnatal life in humans, erythrocytes, granulocytes, monocytes, and platelets are normally produced only in the bone marrow. Lymphocytes are produced in the secondary lymphoid organs, as well as in the bone marrow and thymus gland.

Most bone marrow cells are morphologically recognizable precursors of granulocytes or erythrocytes with smaller numbers of platelet precursors (megakaryocytes), lymphocytes, monocytes, macrophages, stromal cells (endothelial cells, fibroblasts, osteoblasts, and osteoclasts), eosinophils, plasma cells, basophils, mast cells, and blasts. The latter include hematopoietic stem cells (HSCs), which are capable of self-renewal and differentiation; and progenitors, which differentiate along a specific pathway.

They consist of acidic glycoproteins, which are functionally diverse but structurally conserved (Kaushansky, 1993). They regulate the proliferation and differentiation of hematopoietic precursor cells and facilitate the function of mature blood cells. Hematopoietic growth factors may act locally near the site at which they are produced, or they may circulate in the blood. They act at low concentrations, are produced by many different types of cells, and usually affect more than one lineage (Quesenberry, 2001). They often act synergistically with other growth factors and may act on neoplastic cells as well as normal cells. Growth factors also tend to enhance membrane integrity and prevent apoptosis.

Genes associated with hematopoietic growth factors have been identified, cloned, and sequenced. Their products have been generated by recombinant deoxyribonucleic acid (DNA) methods. Molecular structures are frequently predicted using computer models from sequence data as well as analyzed directly by crystallography and magnetic resonance spectroscopy. Pure molecules are utilized experimentally, and several are now used therapeutically as drugs. The rapid growth in knowledge of hematopoietic growth factors and the complexity of their activities defies simple summation. Factors chiefly involved in hematopoiesis are briefly noted here.

Granulocyte/macrophage colony-stimulating factor (GM-CSF) is a pan-myeloid growth factor, stimulating erythroid, granulocyte, monocyte, megakaryocyte, and eosinophil progenitors, resulting primarily in increases of neutrophils, monocytes, and eosinophils, and in activation of phagocytic function. It is a 14- to 35-kDa glycoprotein encoded on the long arm of chromosome 5. GM-CSF is utilized clinically to combat neutropenia in patients receiving chemotherapy and in those undergoing bone marrow transplantation (Mertelsmann, 1993). Myeloid hyperplasia may result in bone marrow in these settings.

Granulocyte colony-stimulating factor (G-CSF) stimulates granulocyte production and functional activation. It is an 18-kDa protein encoded on the long arm of chromosome 17 (Bagby, 1991). G-CSF is frequently used to treat neutropenia and may induce less toxicity than GM-CSF (Root, 1999). It is also the growth factor most commonly used to mobilize CD34+ stem cells in the peripheral blood (Hübel, 2003).

Monocyte/macrophage colony-stimulating factor (M-CSF) (also known as colony-stimulating factor-1 [CSF-1]) stimulates monocyte-macrophage production and activity. It consists of two species of glycoprotein (40–50 and 70–90 kDa) that are encoded on the long arm of chromosome 5 (Bagby, 1991). CSF-1 induces macrophage production of interleukin (IL)-1. The CSF-1 receptor is the product of the FMS gene and acts as a tyrosine kinase to mediate cell activation.

Erythropoietin (EPO) stimulates proliferation, growth, and differentiation of erythroid precursors, resulting in increased erythrocyte counts, and may have a minor effect on megakaryocytes. EPO has a dominant effect on CFU-E, pronormoblasts, and basophilic normoblasts. Maximal BFU-E stimulation requires other growth factors such as IL-3 and GM-CSF. EPO, an 18-kDa protein (34–39 kDa when glycosylated) encoded on the long arm of chromosome 7, is primarily produced in the kidney in adult life and is induced by hypoxia (Bagby, 1991). Recombinant EPO is utilized clinically to treat anemia, particularly that associated with renal failure, chemotherapy, or bone marrow infiltration by cancer (Mertelsmann, 1993).

Thrombopoietin (TPO) is a 35-kDa polypeptide that is a ligand for the product of the proto-oncogene *c-mpl* (Kaushansky, 1994) and is the primary regulator of platelet production. It is produced by the liver, kidney, marrow stroma, and other tissues and stimulates both the production and differentiation of megakaryocytic precursor cells (Kaushansky, 2003). It is essential for the full maturation of megakaryocytes and enhances platelet production. TPO-mimetic drugs have been developed to speed the recovery of blood platelets after cytoreductive therapies.

IL-3 is a multipotential colony-stimulating factor that has activities analogous to GM-CSF but occurs at an earlier level. The 14- to 28-kDa protein is encoded near the GM-CSF gene on the long arm of chromosome 5, and is closely linked to the genes for GM-CSF, IL-4, and IL-5. IL-3 is produced by T cells, endothelial cells, fibroblasts, macrophages, and mast cells. It activates indirectly by stimulating other cytokines (Bagby, 1991).

IL-5 activates cytotoxic T cells, induces immunoglobulin (Ig) secretion, and stimulates eosinophils. It is a 50- to 60-kDa product of the long arm of chromosome 5 that is produced by activated T cells (Jandl, 1996).

IL-6 is a broad activating factor that appears to exert its influences indirectly through synergy with other factors. IL-6 facilitates B cell differentiation, promotes Ig secretion, and acts as a growth factor for

malignant plasma cells (Teoh, 1997). It functions along with IL-3 to increase replication of myeloid precursors, synergizes with IL-2 and IL-4, and stimulates platelet production. It is a 26-kDa product of the short arm of chromosome 7 (Jandl, 1996) and is secreted by T cells, macrophages, and fibroblasts.

IL-9 is a T cell growth factor and mast cell-activating factor that also has effects in stimulating erythroid and myeloid proliferation. It is a 30- to 40-kDa glycoprotein encoded on chromosome 5 (Quesniaux, 1992).

IL-11 promotes formation of antigen-specific Ig-secreting B cells and synergizes with IL-3 to stimulate megakaryocyte production and pluripotent stem cell proliferation. IL-11 synergizes with IL-4 to promote stem cell proliferation. It is a 23-kDa glycoprotein encoded on the long arm of chromosome 19 (Quesniaux, 1992). It is used to speed recovery of blood platelets after cytoreductive therapies.

Stem cell factor (SCF) is the ligand for the tyrosine kinase receptor *c-kit* and is also referred to as kit ligand. It synergizes with most other growth factors, including GM-CSF and IL-3, to stimulate myeloid, erythroid, and lymphoid progenitors (Quesniaux, 1992). The SCF receptor is encoded on chromosome 4, whereas SCF is mapped to chromosome 12 (Broudy, 1997). SCF stimulates the growth, viability, and adhesion of primitive progenitor cells, erythroid precursors (BFU-E, CFU-E), myeloid precursors (CFU-GM), megakaryocytic precursors (CFU-Meg), and mast cells. It also stimulates the growth of B cells, T cells, NK cells, and dendritic cells.

Flt-3 ligand (FL) stimulates primitive progenitor cells, often in synergy with SCF. Similarly to the SCF receptor, the FL receptor is a tyrosine kinase. It acts synergistically with other growth factors to stimulate T cells, B cells, NK cells, and dendritic cells. In contrast to SCF, FL does not stimulate mast cells (Lyman, 1998).

Other regulators of HSCs include tumor necrosis factor (TNF)- α and transforming growth factor (TGF)- β . HSCs express receptors of the notch and Wnt families; these cytokine pathways are also likely important in self-renewal and differentiation (Ohishi, 2003; Sauvageau, 2004).

HSCs and the earliest myeloid progenitors (CFU-GEMM) require SCF, FL, IL-3, and IL-6 for duplication and differentiation into committed progenitors. Further development of myeloid progenitors (CFU-G and CFU-M) requires G-CSF and M-CSF, in addition to GM-CSF and IL-3. G-CSF is primarily responsible for neutrophil differentiation, M-CSF for monocyte/macrophage differentiation, IL-5 for eosinophil differentiation, IL-3 and SCF for basophil differentiation, and SCF for mast cell differentiation. Development of the earliest erythroid progenitor (BFU-E) is independent of EPO, but subsequent differentiation into CFU-E needs EPO, in addition to other growth factors such as GM-CSF, IL-3, and SCF. EPO is solely responsible for further maturation of the erythroid lineage. Megakaryocyte development is dependent on TPO, in concert with IL-3, IL-6, IL-11, and SCF.

In addition to growth factors, other families of cell surface molecules are involved in directional migration of developing hematopoietic cells. Adhesion molecules are required to modulate many interactions between hematopoietic cells and growth factors, stromal cells, endothelium, and extracellular matrix. These cell surface molecules influence induction, differentiation, and function of hematopoietic cells. They are also responsible for the retention and release of hematopoietic cells in the bone marrow (Verfaillie, 1998). Several major families of adhesion molecules exist, including the Ig supergene family, the integrins, and the selectins (Long, 1992).

Many extracellular matrix components interact with receptors on hematopoietic cells. These include fibronectin, thrombospondin, hyaluronic acid, hemonection, laminin, and heparin sulfate. Receptors for some of these are known. CD44, receptor for hyaluronic acid, is an antigenically related group of inducible cell surface proteins variably expressed on all leukocytes. It is required for early granulopoiesis, as well as for trafficking of mature lymphocytes.

Another class of compounds, the chemokines, are important in regulating blood cell trafficking and homing. The chemokine SDF-1 is expressed by bone marrow stromal cells and microvascular endothelium. HSCs express CXCR4, the receptor for SDF-1. The interaction of SDF-1 and CXCR4 is involved in HSC engraftment. G-CSF-induced mobilization of HSCs is likely due to disruption of the interaction between SDF-1 and CXCR4 (Campbell, 2003; Papayannopoulou, 2008).

Laboratory assays are available for most hematopoietic growth factors and cytokines and are helpful in the diagnostic workup of a wide variety of diseases. Disease states caused by selective deficiency of a growth factor, such as anemia of renal failure due to low EPO levels, can be treated by administration of recombinant protein.

HEMATOPOIETIC TISSUES

EMBRYONIC AND FETAL HEMATOPOIESIS

Beginning in the first month of prenatal life, primitive hematopoiesis starts outside the embryo in the mesenchyme of the yolk sac as **blood islands**. These contain predominantly **primitive erythroblasts**, which are large and megaloblastic, are formed intravascularly, and retain their nuclei. Definitive hematopoiesis in mammals takes place in the aorta-gonad-mesonephros (AGM) region of the embryo, from which hematopoietic cells migrate to the liver and spleen. At the sixth week, hematopoiesis begins in the liver, and this becomes the major hematopoietic organ of early and midfetal life. **Definitive erythroblasts**, which become non-nucleated red cells, are formed extravascularly in the liver, and granulopoiesis and megakaryocytes are present to a lesser degree. In the middle part of fetal life, the spleen and to a lesser extent lymph nodes have a minor role in hematopoiesis, but the liver continues to dominate. In the latter half of fetal life, the bone marrow becomes progressively more important as a site of blood cell production. As this occurs, the liver's role diminishes.

POSTNATAL HEMATOPOIESIS

Shortly after birth, hematopoiesis in the liver ceases, and the marrow is the only site for the production of erythrocytes, granulocytes, and platelets. Hematopoietic stem cells and committed progenitor cells are maintained in the marrow. Lymphocytes (of the B cell type) continue to be produced in the marrow, as well as in the secondary lymphoid organs, whereas T lymphocytes are produced in the thymus and also in the secondary lymphoid organs (see **Lymphocytes**).

At birth, the total marrow space is occupied by active hematopoietic (red) marrow. As body growth progresses and marrow space increases during infancy, only part of that space is needed for hematopoiesis; the remaining space is occupied by fat cells. Later in childhood, only the flat bones (the skull, vertebrae, thoracic cage, shoulder, and pelvis) and the proximal parts of the long bones of the upper and lower limbs are sites of blood cell formation. The remaining marrow space is fatty or yellow marrow that can be replaced by hematopoietic cells if continuous, intensive stimulation exists.

The marrow circulation is closed, that is, arterioles deriving from central longitudinal arteries (i.e., in long bones) connect directly with broad venous sinuses that anastomose and eventually empty into central longitudinal veins. The flattened endothelium of the sinuses is partially covered by adventitial reticular cells, a form of fibroblast that elaborates argentophilic reticulin fibers. These reticular cells and fibers form the supporting meshwork of the marrow stroma, where the hematopoietic cells reside. The reticular cells are but minimally phagocytic; they may swell and take up water, may become fat cells, and may induce hematopoietic stem cells to become committed progenitor cells. After proliferation and maturation have occurred in the marrow stroma, blood cells gain entrance to the blood through or between the endothelial cells of the sinus wall. This requires displacement of adventitial cells. Stromal mesenchymal cells and sinusoidal endothelial cells produce a variety of cytokines and chemokines involved in hematopoiesis.

ERYTHROCYTE PRODUCTION

The erythrocyte is a vehicle for the transport of hemoglobin, which is produced in precursor cells of the erythrocytes, the normoblasts. The function of hemoglobin is the transport of oxygen and carbon dioxide. The erythrocyte is also metabolically capable of keeping hemoglobin in a functional state.

NORMOBLASTIC MATURATION

The earliest recognizable erythroid precursor is the **pronormoblast** (Fig. 31-2). At about 20 μm diameter, it is the largest of the erythroid precursors. The nucleus has a fine, uniform chromatin pattern that is somewhat more distinct and more intensely stained than that of the myeloblast. The nuclear membrane is prominent. One or more prominent nucleoli are present. The cytoplasm has a heterogeneous quality and is moderate in amount and basophilia; no granules are present. The pronormoblast undergoes mitosis and forms two basophilic normoblasts.

The **basophilic normoblast** (Fig. 31-3) is somewhat smaller and has slightly coarser chromatin that stains intensely; the chromatin may be

Figure 31-2 Pronormoblast with a large round nucleus, fine chromatin, and basophilic cytoplasm (Wright-Giemsa, 1000 \times).

Figure 31-3 Basophilic normoblasts with chromatin condensation and deeply basophilic cytoplasm (Wright-Giemsa, 1000 \times).

partially clumped, and the pattern may suggest a wheel with broad spokes. The parachromatin (the nonchromatin part of the nucleus) is distinct and stains pink. Nucleoli are present but are not often visible. The nuclear/cytoplasmic (N/C) ratio is moderate; about one fourth of the total cell area appears to be cytoplasm. The cytoplasm is deeply basophilic, owing to the abundance of RNA; much of this is evident as polyribosomes on electron micrographs. The cell borders of early normoblasts frequently appear irregular owing to the presence of pseudopodia.

After mitosis of the basophilic normoblast, evidence of continuing hemoglobin production becomes visible in the cytoplasm of the two daughter cells as polychromasia, that is, mixtures of the red-staining of hemoglobin with the blue of RNA in varying shades of gray. This cell is the **polychromatophilic normoblast** (Fig. 31-4), which is slightly smaller than the basophilic normoblast. The nucleus occupies about half of the area of the cell, stains intensely, and has moderately condensed chromatin that is sharply distinct from the pink parachromatin. The polychromatophilic normoblast undergoes one or two mitotic divisions.

After the last mitosis, the nucleus becomes small and dense (pyknotic), and the **orthochromatic normoblast** stage is reached (Fig. 31-5). Mitosis is no longer possible. The cell is smaller than the polychromatophilic normoblast and has a lower N/C ratio. The cytoplasm contains more abundant hemoglobin and fewer polyribosomes and remains slightly polychromatophilic.

Finally, accompanied by cytoplasmic contractions and undulations, the nucleus and a small rim of cytoplasm are ejected from the orthochromatic normoblast, forming the **reticulocyte** (Fig. 31-6). On air-dried films with Romanowsky-type stains, the reticulocyte is polychromatophilic as a result of the retention of RNA.

In the marrow, developing erythroid cells are usually in contact with macrophages in what are termed **erythroblastic islands** (Fig. 31-7). These erythroblastic islands are usually broken up when aspirated marrow is

Figure 31-4 Polychromatophilic normoblast with light blue cytoplasm due to accumulation of hemoglobin (Wright-Giemsa, 1000×).

Figure 31-5 Orthochromatic normoblast with pyknotic nucleus and pink-gray cytoplasm (Wright-Giemsa, 1000×).

Figure 31-6 Reticulocyte (polychromatophilic erythrocyte) with pink-gray cytoplasm due to residual RNA (Wright-Giemsa, 1000×). RNA, Ribonucleic acid.

spread on slides, but fragments of macrophage cytoplasm may sometimes be seen attached to the separated normoblasts, especially on Prussian blue-stained films.

During proliferation and maturation, iron is transferred from plasma transferrin into the cells in the normoblastic series. The pronormoblast and the basophilic normoblast have the highest content of RNA, which begins to decline in the polychromatophilic normoblasts as hemoglobin increases in amount. Synthesis of RNA gradually decreases in each stage through the orthochromatic normoblasts. When the nucleus is no longer present (in the reticulocyte), RNA synthesis ceases, yet the RNA already present remains for a few days, and protein and heme synthesis continue in the reticulocyte until the cell loses its RNA and mitochondria.

During this maturation process, three or four mitotic divisions occur in a period of 3 days, resulting in the potential production of 16 reticulocytes from each pronormoblast. The reticulocytes are larger than mature red cells and remain in the marrow stroma for 1–2 days before being released into the blood.

In the marrow, the reticulocytes are about equal in number to the nucleated erythrocytes and slightly greater in number than the reticulocytes in the circulating blood. If sufficiently severe hypoxia is present, this marrow pool of reticulocytes can be released. This approximately doubles the number of circulating reticulocytes.

Normally, reticulocytes remain as such, slowly synthesizing hemoglobin, for 2–3 days in the marrow and for 1 day in the blood. Residual ribosomes, mitochondria, and other organelles are then removed, and the mature erythrocytes circulate for about 120 days. During this time, they gradually age, certain enzymatic activities diminish, and they are finally destroyed within phagocytic cells of the mononuclear phagocyte system (reticuloendothelial system).

MEGALOBLASTIC MATURATION

Abnormal maturation of erythroid precursors that occurs in vitamin B₁₂ deficiency or folic acid deficiency is known as megaloblastic maturation, and the abnormal erythroid cells are called **megaloblasts**. Because of impaired ability of the cells to synthesize DNA, the intermitotic and mitotic phases are prolonged. This results in enlarged cells, with nuclear maturation lagging behind cytoplasmic maturation (nuclear–cytoplasmic dissociation). The nuclear chromatin pattern is more delicate and more “open,” with prominent parachromatin. Karyorrhexis, or breaking up of the nucleus, and Howell-Jolly bodies are frequently noted. Megaloblastic development parallels normoblastic maturation; the stages of promegaloblast, basophilic megaloblast, polychromatophilic megaloblast, and orthochromatic megaloblast may be recognized.

REGULATION OF ERYTHROCYTE PRODUCTION

The number of erythrocytes in the blood may be regulated by changing the rate of production. The rate of erythrocyte destruction does not vary appreciably in normal individuals. Increased production of erythrocytes occurs when oxygen transport to the tissues is impaired, as in anemia, in cardiac or pulmonary disorders, and in the low oxygen tension of high altitudes. Erythrocyte production decreases when an individual is hypertransfused or exposed to high oxygen tension.

Oxygen affinity of hemoglobin is modulated by the concentration of phosphates, in particular 2,3-diphosphoglycerate (2,3-DPG) in the red cell. These phosphates combine with the β -chains of reduced hemoglobin

Figure 31-8 Oxygen dissociation curves of hemoglobin at different concentrations of 2,3-DPG. The curve is sigmoidal and shifts to the right with increasing concentrations of 2,3-DPG; this results in decreased affinity of hemoglobin for oxygen and increased delivery of oxygen to the tissues. (Reprinted from Duhm J. *Oxygen affinity of hemoglobin and red cell acid base status*, p. 583, Copyright 1972, with permission from Elsevier.) DPG, diphosphoglycerate.

and diminish its affinity for oxygen (Fig. 31-8). In areas of tissue hypoxia, as oxygen moves from hemoglobin into the tissues, the amount of reduced hemoglobin in the red cells increases, binding more 2,3-DPG, further reducing its oxygen affinity so that more oxygen can be delivered to the tissues. If hypoxia persists, depletion of free 2,3-DPG leads to increased glycolysis, production of more 2,3-DPG, and a persistently lower oxygen affinity of the hemoglobin.

Tissue hypoxia induces formation of EPO via production of the transcriptional factor, hypoxia-inducible factor-1 (HIF-1). HIF-1 is a heterodimer consisting of α - and β -subunits, of which the α -subunit is regulated by hypoxia. Under conditions of normal oxygen tension, HIF-1 α undergoes proteosomal degradation, but it is stable under hypoxic conditions. EPO effects the production of more red cells in the bone marrow. It acts by inducing committed progenitor cells (CFU-E and BFU-E) in the marrow to proliferate and differentiate into pronormoblasts by shortening the generation time of normoblasts, and by promoting early release of reticulocytes into the blood. The result is increased numbers of marrow normoblasts in a normal ratio of cell types, a condition known as normoblastic hyperplasia. Increased cellular expression of HIF-1 α can result from a 598C→T mutation in the von Hippel-Lindau gene (the von Hippel-Lindau protein is involved in HIF-1 α degradation). This results in elevation of EPO levels and an autosomal recessive form of hereditary polycythemia known as Chuvash polycythemia (Gordeuk, 2004).

Measurement of EPO is accomplished by in vitro immunologic methods utilizing serum or plasma, with ethylenediaminetetraacetic acid (EDTA) plasma providing greater sensitivity (Lindstedt, 1998). Elevated levels are detected in patients with secondary polycythemia and in those with aplastic anemia. Decreased levels below the normal range are found in normal individuals after transfusion and in those with primary polycythemia (polycythemia vera). However, considerable overlap exists, and normal EPO levels may be found in both primary and secondary polycythemia (Spivak, 2002). Anti-EPO antibodies have been described in pure red cell aplasia and systemic lupus erythematosus (Casadevall, 1996; Schett, 2001); these may interfere with immunoassays for EPO and may contribute to anemia.

SYNTHESIS OF HEMOGLOBIN

Heme Synthesis

Heme synthesis occurs in most cells of the body, except the mature erythrocytes, but most abundantly in the erythroid precursors. Succinylcoenzyme A condenses with glycine to form the unstable intermediate α -amino β -ketoadipic acid, which is readily decarboxylated to δ -aminolevulinic acid (ALA) (Fig. 31-9). This condensation requires pyridoxal phosphate (vitamin B₆) and occurs in mitochondria.

ALA is excreted normally in small amounts in the urine, but in certain abnormalities of heme synthesis (e.g., lead poisoning), excretion is

increased. Two molecules of ALA condense to form the monopyrrole porphobilinogen, catalyzed by the enzyme ALA-dehydrase. Porphobilinogen is also normally excreted in small amounts in the urine. Markedly elevated amounts appear in the urine in acute intermittent porphyria, and are easily detected by a color reaction with Ehrlich's aldehyde reagent.

Four molecules of porphobilinogen react to form uroporphyrinogen III or I (Fig. 31-10). The type III isomer is converted, by way of coproporphyrinogen III and protoporphyrinogen, to protoporphyrin. In certain diseases when this pathway is partially blocked, the type I isomers of uroporphyrinogen and coproporphyrinogen are formed, and their oxidized excretion products, uroporphyrin I and coproporphyrin I, are increased in amount.

Protoporphyrin is normally found in mature erythrocytes. In lead poisoning and in iron deficiency, levels of free erythrocyte protoporphyrin (FEP) are increased. Iron is inserted into protoporphyrin by the mitochondrial enzyme ferrochelatase to form the finished heme moiety.

Other abnormalities of heme synthesis (the porphyrias) are discussed later in this chapter.

Globin Synthesis

Globin synthesis occurs in the cytoplasm of the normoblast and reticulocyte. The polypeptide chains are manufactured on the ribosomes. Specific small soluble RNA (sRNA) molecules determine the placement of each amino acid according to the code in the messenger RNA (mRNA). Progressive growth of the polypeptide chain begins at the amino end. This process of protein synthesis occurs on ribosomes clustered into polyribosomes, which are held together by the mRNA. Because the reticulocyte can synthesize hemoglobin for at least 2 days after loss of its nucleus, it appears that the mRNA for hemoglobin is quite stable. The polypeptide chains released from the ribosomes are folded into their three-dimensional configurations spontaneously.

Control of hemoglobin synthesis is exerted primarily through the action of heme. Increased heme inhibits further heme synthesis by inhibiting the activity and synthesis of ALA synthase. Heme also promotes globin synthesis, mainly at the site of chain initiation, and the interaction of ribosomes with mRNA.

STRUCTURE AND FUNCTION OF HEMOGLOBIN

In each hemoglobin (Hb) molecule, one heme group is inserted into a hydrophobic pocket of one folded polypeptide chain (Bunn, 1986). Normal adult HbA consists of four heme groups and four polypeptide chains (two α -chains and two β -chains), which form a roughly globular hemoglobin molecule (Fig. 31-11). The ferrous iron atoms have six coordination bonds: four to the pyrrole nitrogens of heme, one to the imidazole nitrogen of histidine of the globin chain (87- α or 92- β), and one that is reversibly bound to oxygen. As the oxygen partial pressure increases, each of the four heme groups sequentially binds one molecule of oxygen. In the process, a change in the overall configuration of the hemoglobin molecule occurs, which favors the additional binding of oxygen.

The sigmoid-shaped oxygen dissociation curve of hemoglobin reflects this increasing affinity for oxygen with increasing partial pressure of oxygen in the lungs (see Fig. 31-8). In the tissues, conversion of oxygenated Hb to Hb, decreasing pH, and increasing temperature produced by metabolic processes, as well as the binding of more 2,3-DPG to Hb, result in a shift of the Hb-oxygen dissociation curve to the right, favoring the release of oxygen from hemoglobin.

Carbon dioxide (CO₂) is transported in erythrocytes as well as in plasma. A small part of red cell CO₂ is dissolved and is bound to amino groups of hemoglobin as carbamino-CO₂, but most is in the bicarbonate form. The enzyme carbonic anhydrase catalyzes the transformation of carbon dioxide to bicarbonate in the red cell while in the tissue capillary bed and catalyzes the reverse reaction (the release of carbon dioxide from bicarbonate) in the erythrocyte when it is in the capillary bed of the lungs.

ERYTHROCYTE DESTRUCTION

The erythrocyte gradually undergoes metabolic changes over the course of its 120-day life span, at which time the less viable senescent cell is removed from the circulation. Certain glycolytic enzymes diminish in activity as the cell ages. Older red cells have a smaller surface area and an increased mean cell hemoglobin concentration (MCHC) compared with younger cells. Furthermore, aged red cells lose sialic acid from their

Figure 31-9 Formation of porphobilinogen from succinylcoenzyme A and glycine. (From Leavell BS. *Fundamentals of clinical hematology*. 4th ed. Philadelphia: WB Saunders; 1976, with permission.)

Figure 31-10 Formation of heme from porphobilinogen. (From Leavell BS. *Fundamentals of clinical hematology*. 4th ed. Philadelphia: WB Saunders; 1976, with permission.)

Figure 31-11 The hemoglobin molecule (tetramer, molecular weight 64,500 Da). The heme group for each monomeric polypeptide chain is depicted as a black disk, connected to an imidazole group of histidine and located near the surface of the molecule in a “pocket” formed by the polypeptide chain. The letters *A* and *H* designate α -helix segments of each polypeptide chain: *A* is the amino-terminal segment, and *H* is the carboxy-terminal segment. The four monomers are separated in this drawing but actually make contact along a relatively large area ($\alpha_1\beta_1$), which is thought to be the relatively fixed or stabilizing contact area, and a smaller ($\alpha_1\beta_2$) area thought to be the functional contact area, where movement occurs during oxygenation and deoxygenation, changing the molecular configuration. (Redrawn from White JM, Dacie JV. *Prog Hematol* 1971;7:69, with permission.)

membranes, exposing an asialoglycophorin. This senescent antigen is recognized and an autoantibody is synthesized by the host. After binding of the autoantibody, the senescent cell is removed from the circulation by the mononuclear phagocyte system, primarily within the spleen. About 3 million cells are normally removed from the blood per second with no demonstrable histologic evidence of erythrophagocytosis.

In some pathologic states, the mononuclear phagocyte system removes younger sensitized or abnormal red cells at a rapid rate. Subsequently, erythrophagocytosis is often evident. In autoimmune hemolytic anemia, the mononuclear phagocyte system removes red cells following the binding of autoantibodies or complement to reticulocytes and young red cells. In other pathologic states, red cells are removed because of structural defects that interfere with their normal passage through the microcirculation of the mononuclear phagocyte system.

DEGRADATION OF HEMOGLOBIN

After removal of the red cell from the circulation, hemoglobin is broken down within the macrophages of the mononuclear phagocyte system into its three constituents: iron, protoporphyrin, and globin. The iron goes into storage and may be completely reutilized. The globin may be degraded and returned to the amino acid pool of the body. In contrast, the protoporphyrin ring is split, converted to bilirubin, and excreted from the body.

In the macrophage, the protoporphyrin ring is cleaved by a heme oxidase enzyme at the α -methene bridge, yielding 1 mol of carbon monoxide (CO) and 1 mol of biliverdin. The CO appears in the blood as HbCO and is eventually exhaled. Biliverdin is reduced to bilirubin in the macrophage, and bilirubin is transported to the liver by plasma albumin. It is removed from the plasma by the liver cell, conjugated mainly with glucuronide, and excreted in the bile. In the intestine, reduction by bacteria occurs, and bilirubin is transformed into urobilinogen, mesobilirubinogen, and stercobilinogen, compounds that are collectively designated urobilinogens.

Estimation of exhaled CO, HbCO, or fecal urobilinogen can be used as a measure of hemoglobin breakdown. When production of red cells is diminished and the level of circulating hemoglobin is low, as in aplastic anemia, urobilinogen excretion is reduced. When destruction of erythrocytes is increased, as in hemolytic anemia, all three are increased in amount.

In normal humans, about 80%–90% of the excreted bile pigment measured as fecal urobilinogen is derived from breakdown of senescent erythrocytes that have lived 100–120 days. However, about 10%–20% of the pigment is excreted within the first few days. This early labeled bile pigment comes from nonhemoglobin heme formed in the liver, as well as from the breakdown of newly formed hemoglobin in the bone marrow. Much of the latter may represent hemoglobin from the pieces of cytoplasm of the orthochromatic normoblast that are lost during the process of nuclear extrusion.

In certain hematologic diseases, notably thalassemia, megaloblastic anemia, myelodysplasia, and erythropoietic porphyria, this early labeled bile pigment fraction may be markedly increased. This intramedullary destruction of hemoglobin, which never appears in circulating erythrocytes, is known as **ineffective erythropoiesis**.

ERYTHROKINETICS

The balance between delivery of erythrocytes to the blood and removal of erythrocytes from the blood results in a relatively constant hemoglobin mass in the circulation. Anemia occurs when removal of erythrocytes from the blood is increased and cannot be compensated for by increased production, or when delivery of erythrocytes to the blood is decreased, or when both processes exist together.

When anemia develops, tissue hypoxia leads to elevated levels of erythropoietin in the plasma. Resultant normoblastic hyperplasia produces more erythrocytes for delivery to the circulation. The marrow in a normal individual is capable of six to eight times the normal output of erythrocytes with extreme stimulation. This capacity must be compared with the output actually attained when one is evaluating the marrow response of a given patient.

Measurements that assess **effective erythropoiesis** (production and delivery of erythrocytes to the circulation), **ineffective erythropoiesis**, and destruction of erythrocytes may be necessary to determine the mechanism and the cause of anemia.

MEASUREMENTS OF TOTAL PRODUCTION OF ERYTHROCYTES OR HEMOGLOBIN

The **total mass of erythropoietic cells** in the body cannot be easily measured. An estimate is made by examining a sample of bone marrow from a normally active site and determining the cellularity and the percentage of total nucleated cells that are erythropoietic (see Bone Marrow Examination, Chapter 29). When marrow activity increases, usually the additional hematopoietic cells replace the fat in the red marrow sites before extension occurs into the yellow marrow of the long bones. One assumes that the sample is representative of the marrow as a whole—an assumption that usually is valid.

The **plasma iron turnover** is calculated from the serum iron level and the rate of removal of injected radioactive iron from the plasma. About 25%–30% of the iron is not used in erythropoiesis and is primarily taken up by the liver. The remaining 70%–75% is taken up by erythropoietic cells and is therefore a measure of total erythropoiesis, both effective and ineffective.

MEASUREMENTS OF TOTAL DESTRUCTION OF ERYTHROCYTES OR HEMOGLOBIN

Determination of **fecal urobilinogen** is an estimate of the total excretion of bile pigments—the breakdown products of heme. This measurement includes pigment derived from hemoglobin formed and destroyed in the marrow without ever reaching the circulating erythrocytes. Limitations include diminished conversion of bilirubin to urobilinogen caused by oral administration of broad-spectrum antibiotics, and failure of pigment to reach the intestine in obstructive jaundice.

A portion (up to 50%) of the excreted urobilinogen is reabsorbed into the portal circulation and is reexcreted into the bile, without conjugation, by the liver. Only a small amount is normally excreted in the urine. Increased urinary urobilinogen is seen with severe liver disease, as well as with conditions associated with increased heme catabolism that overwhelm the metabolic capacity of the liver. Thus, hepatocellular damage, cirrhosis, hepatic congestion due to congestive heart failure, obstructive liver disease, cholangitis, hemolytic anemia, and ineffective erythropoiesis are all associated with elevation of urinary urobilinogen.

MEASUREMENTS OF EFFECTIVE PRODUCTION OF ERYTHROCYTES

Reticulocyte Count

Because the RNA of the reticulocyte disappears about a day after its entry into the blood, enumeration of reticulocytes will be a measure of the number of cells being delivered by the marrow to the blood each day, that is, a measure of effective erythropoiesis. The absolute reticulocyte count is calculated by multiplying the reticulocyte percentage by the erythrocyte count. To give a meaningful expression of erythropoiesis, the absolute reticulocyte count, or some estimate of it, and not simply the percentage, must be used. The normal absolute reticulocyte count is approximately $50 \times 10^9/L$, or 1% of circulating erythrocytes. Because the normal maturation time for reticulocytes in the blood is 1 day, production of reticulocytes is $50 \times 10^9/L/day$.

A second consideration is an adjustment for increased maturation time of reticulocytes in the blood as a result of accelerated release from the marrow, an effect of erythropoietin. The need for this is recognized by the presence of large, polychromatic cells or nucleated red cells in the blood film, indicating a shift of excessively immature reticulocytes from the marrow into the blood. To avoid an overestimate of daily erythrocyte production, a correction factor is used that is based on estimated maturation time of reticulocytes in the blood. This varies inversely with hematocrit as follows (Hillman, 1996):

Hematocrit, %	Reticulocyte maturation time, days
45	1.0
35	1.5
25	2.0
15	2.5

If a patient has a Hct of 0.25, a red count of $2.89 \times 10^{12}/L$, and a reticulocyte count of 7%, he will have an absolute reticulocyte count of $202 \times 10^9/L$. Because the average normal absolute reticulocyte count is $50 \times 10^9/L$, the patient has

$$(202 \times 10^9/L) / (50 \times 10^9/L)$$

or four times as many reticulocytes as normal. However, this must be corrected for the increased maturation time: $4 \times \frac{1}{2} = 2$. Therefore, two times as many reticulocytes are entering the blood per day as in a normal individual, that is, red cell production is two times normal.

If only the hematocrit is available, the same correction can be made as follows:

Correction for anemia:

$$\text{Patient's reticulocyte count (7\%)} / \text{Normal reticulocyte count (1\%)} \times$$

$$\text{Patient's Hct (0.25)} / \text{Normal Hct (0.45)} = 4$$

Correction for shift:

$$\text{Corrected reticulocyte index (4)} \times 1 / \text{Maturation time (2)} = 2$$

These corrections are necessary to assess the degree of red cell production in response to anemia.

A normal individual with a normal supply of iron can increase red cell production by two times normal within a week if the hematocrit drops to 0.35, or by three times normal if the hematocrit drops to 0.25. Only if there is a parenteral supply of iron (such as in hemolysis) can the maximal red cell production of six to eight times normal be achieved.

If an appropriate marrow response to anemia has not been reached in 1–2 weeks, some impairment of red cell production exists.

The **erythrocyte utilization of iron** is a measure of the amount of an injected dose of iron that appears in the hemoglobin of circulating erythrocytes. It is derived from the plasma iron turnover and the percentage of radioactive iron that has been injected and that appears in the circulating erythrocytes after 2 weeks, assuming that none of the newly formed cells have been destroyed in that time interval. This, too, is a measure of effective erythropoiesis.

MEASUREMENTS OF EFFECTIVE SURVIVAL OF ERYTHROCYTES IN BLOOD

The **erythrocyte survival** can be determined by removing a sample of blood, labeling the erythrocytes with chromium-51 (^{51}Cr), inactivating the excess ^{51}Cr remaining in the plasma, and reinjecting the labeled erythrocytes into the patient. The ^{51}Cr is bound to the β -chain of the hemoglobin

molecule and for the most part is not released until the red cell is removed from the circulation and the hemoglobin is degraded. Measurements of radioactivity in the red cells are made at 2 hours or 24 hours (the zero time, or 100% level) and at 1- to 3-day intervals until over 50% of the activity has disappeared. The results are usually expressed as the ^{51}Cr half-survival time. The normal range is 28–38 days. (The reason it is not 60 days is that ^{51}Cr is eluted from the hemoglobin at the rate of about 1% per day.) If production of erythrocytes equals destruction (i.e., if a steady state exists), the erythrocyte survival is also a measure of effective production of erythrocytes.

SUMMARY

Total erythropoiesis refers to the total production of hemoglobin or red cells; effective erythropoiesis refers to production of hemoglobin or red cells that reach the circulation; and ineffective erythropoiesis refers to production of hemoglobin or red cells that never reach the circulating blood. These concepts of the **erythrokinetic** approach to the study of anemia are useful, especially in anemias that defy easy classification.

THE PORPHYRIAS

PHYSIOLOGY

Heme biosynthesis is an essential pathway that occurs in all metabolically active cells containing mitochondria and is most prominent in bone marrow and liver. The erythroid marrow is the major heme-forming tissue in the body, producing 85% of the daily heme requirement. Heme complexed with globin is preserved in circulating red blood cells for approximately 120 days, whereas heme produced in liver for cytochromes and enzymes is subject to much more rapid turnover, measurable in hours. A brief sequence of the heme biosynthesis pathway, with the disease states associated with specific enzyme deficiencies along the pathway, is shown in Figure 31-12.

Porphyrias are compounds composed of four pyrrole rings connected by methene bridges, differentiated by substituents found in the eight peripheral positions. The arrangement of four nitrogen atoms in the center of the porphyrin ring enables porphyrins to chelate various metal ions, such as iron, or in disease states, zinc. The biosynthetic intermediates between porphobilinogen (PBG) and protoporphyrin are not porphyrins, but rather their reduced, precursor forms: the porphyrinogens. Porphyrins that leak out of capillaries into the skin are the cause of photosensitivity, and the precursor substances have been linked to the neurovisceral manifestations. δ -Aminolevulinic acid seems to be the chief offender here (Sassa, 2006).

CLINICAL PORPHYRIAS AND THEIR BIOCHEMICAL BASIS

The porphyrias make up a group of inherited and acquired disorders of heme biosynthesis caused by a deficiency of a specific enzyme in the biosynthetic pathway, culminating in the excess production and increased excretion of precursors formed in the steps before the enzyme defect. The porphyrias can be classified by their clinical presentation, and this scheme may be a helpful starting point for the consulting pathologist, as clinicians will call with information about their patients' signs and symptoms, and then will ask for help with ordering laboratory studies (Tables 31-2 and 31-3).

Neurovisceral Symptoms in Isolation

Acute Intermittent Porphyria (AIP)

AIP is the most common acute and probably the most common inherited porphyria (Chemmanur, 2004). It is inherited in an autosomal dominant fashion with incomplete penetrance, making family studies more challenging. PBG deaminase deficiency has been demonstrated in all examined tissues, at levels of about 50% during attacks and quiescent periods. Diagnosis may be made most easily with demonstration of elevated levels of ALA and PBG in urine during acute attacks (with PBG greater in amount than ALA), but the PBG enzyme assay can be performed at any time on RBCs. Frequently, patients have urine metabolite levels at or near the

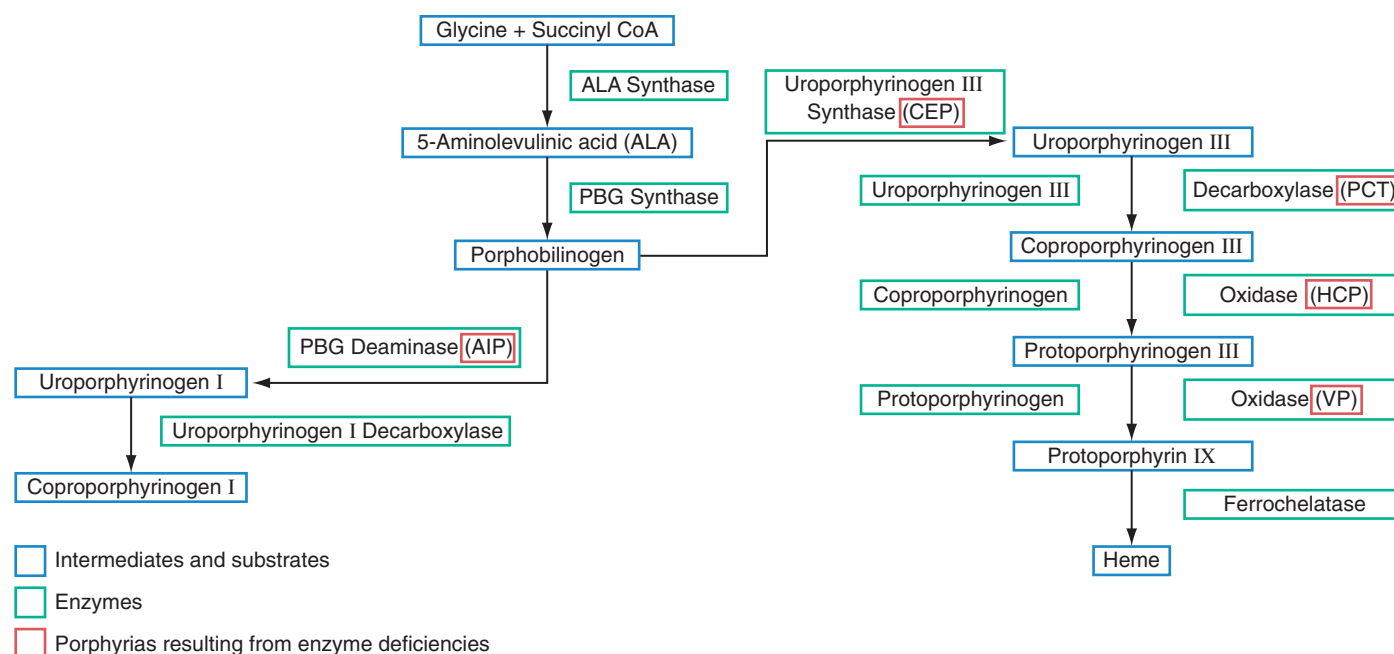

Figure 31-12 Biosynthetic pathway of heme and pathogenesis of the porphyrias.

TABLE 31-2

Key Features of the Major Porphyrias

Porphyria	Inheritance	Enzyme deficiency	Excess metabolites	Clinical features	Exacerbating factors
Acute intermittent porphyria	Autosomal dominant	PBG deaminase	PBG (U) ALA (U) Darkened urine on standing	Abdominal pain; psychiatric symptoms	Steroid hormones
Congenital erythropoietic porphyria	Autosomal recessive	Uroporphyrinogen I synthase and/or UPG III cosynthase	UP (U) CP (U) UP (E) Red, fluorescent pigment in urine	Photosensitivity; red urine, teeth; hemolysis	Sunlight
Hereditary coproporphyria	Autosomal dominant	Coproporphyrinogen oxidase	CP III (F, U) PBG (U) ALA (U) Red, fluorescent pigment in urine	Photosensitivity	Stress
Variegate porphyria	Autosomal dominant	Protoporphyrinogen oxidase	PBG (U) ALA (U) UP (U, F) CP (U, F) Red, fluorescent pigment in urine	Photosensitivity	Stress
Porphyria cutanea tarda	Autosomal dominant Acquired	Uroporphyrinogen decarboxylase	UP I (U) UP III (U) Acid induces pink fluorescence	Photosensitivity	Alcohol, hepatic injury, iron overload

ALA, Aminolevulinic acid; CP, coproporphyrin; E, erythrocyte; F, feces; PBG, porphobilinogen; U, urine; UP, uroporphyrin; UPG, uroporphyrinogen.

reference range during quiescent periods, although this is not always the case. Characteristically, the urine of AIP patients turns dark red upon exposure to air and light, as PBG is oxidized to a porphyrin spontaneously. It is interesting to note that the patient is often hyponatremic during acute attacks. The acute patient typically presents with colicky abdominal pain, nausea and vomiting, mental confusion, tachycardia, and, in half, a motor neuropathy (Chemmanur, 2004). Symptoms typically begin at the time of puberty, reflecting the influence of steroid hormones on the disease. Prevention is the mainstay of management, with avoidance of particular drugs (barbiturates and sulfonamides among many others), hormonal changes, and fasting. Specifically, a low-carbohydrate diet may trigger an attack. At a time when such diets are popular with the general public, clinicians may wish to caution all acute porphyria patients on the risks that these diets carry. A recent case series discussed the possible benefit of liver transplant in patients with severe AIP (Seth, 2007).

Aminolevulinic Acid Dehydratase Deficiency Porphyria (ADP)

ADP is the rarest of the porphyrias, with just six reported cases (Sassa, 2006). Clinically indistinguishable from AIP, it may be differentiated in the laboratory by the presence of excess ALA alone in the urine (Sassa suggests that it may indeed be ALA that is the chief offender causing neurovisceral symptoms) and decreased D-aminolevulinic acid dehydratase in the red blood cells of affected patients. Of note, this type of porphyria must be distinguished from tyrosinemia and heavy metal intoxication.

Neurovisceral Symptoms Plus Photosensitivity Variegate Porphyria (VP)

Similar to AIP and HCP, VP is inherited as an autosomal dominant disorder with low penetrance. It is sometimes referred to as South African

TABLE 31-3

Test Results for the Porphyrrias

Porphyria	Urine	RBC	Feces
Acute intermittent porphyria	↑ PBG, ALA	↓ PBGD activity	Noncontributory
ALA dehydratase deficiency porphyria	↑ porphyrins (ALA alone is increased) Note: Rule out organic acids and heavy metals in urine.	↓ D-aminolevulinic acid dehydratase activity	Noncontributory
Variegate porphyria	↑ porphyrins, PBG	Noncontributory	↑ coproporphyrin III/I ratio (<10)
Hereditary coproporphyria	↑ porphyrins, PBG	Noncontributory	↑ coproporphyrin III/I ratio (>10)
Porphyria cutanea tarda	↑ porphyrins	↓ UROD in Type II, UROD WNL in Types I, III	Noncontributory
Congenital erythropoietic porphyria	↑ porphyrins	↓ UPG III cosynthase	Noncontributory
Erythropoietic protoporphyria	Noncontributory	↑ free protoporphyrin	Noncontributory

ALA, Aminolevulinic acid; PBG, porphobilinogen; PBGD, porphobilinogen deaminase; UPG, uroporphyrinogen; UROD, uroporphyrinogen decarboxylase; WNL, within normal limits.

porphyria because of its prevalence in the Caucasian population in this region. It is called **variegate** because of the spectrum of patient presentations. Some have only the cutaneous manifestations, others just the neurovisceral, others both features. Thus, the clinician need not check both boxes to entertain this diagnosis, especially in patients of Afrikaner descent. Patients have approximately 50% activity of protoporphyrinogen oxidase. Thus, they excrete fecal protoporphyrins and coproporphyrins and urine ALA, PBG, and coproporphyrins. Induction of hepatic ALA synthase I by precipitating factors, such as barbiturates, oral contraceptives, or a low-carbohydrate diet, specifically results in increased ALA and PBG during acute attacks (Chemmanur, 2004). Cutaneous manifestations in the form of erosions or bullae following trauma to sun-exposed skin are seen at a younger age than is observed with porphyria cutanea tarda. Diagnosis is made by conventional measurements of metabolites, family history, and DNA analysis. Avoidance of triggering factors remains the major approach to patient care.

Hereditary Coproporphyria (HCP)

Also inherited in an autosomal dominant fashion with incomplete penetrance, HCP is less common than AIP. It is due to a deficiency of coproporphyrinogen oxidase. Clinically, HCP resembles a milder form of AIP with its neurovisceral attacks, but cutaneous manifestations are seen in roughly a third of patients (Chemmanur, 2004). Fecal coproporphyrinogen III is excreted both during and between attacks, and ALA and PBG are seen in urine during an acute crisis. ALA excretion usually exceeds that of PBG, and this, coupled with the cutaneous findings (if present) helps to differentiate HCP from AIP. Prevention, including sunscreen, is central to management.

Photosensitivity Plus Hemolytic Anemia

Porphyria Cutanea Tarda (PCT)

PCT is the most common of the porphyrias in the United States. Three types have been identified: I is sporadic; II and III are inherited in dominant fashion. The deficient enzyme is uroporphyrinogen decarboxylase (UROD), and researchers have postulated the presence of an inhibitor of UROD, possibly secondary to iron and metabolites of uroporphyrinogen. In Type I, only hepatic UROD is decreased; erythrocyte activity is within the reference range. In Type II, levels of both hepatic and erythrocyte UROD activity are decreased. In Type III, hepatic UROD activity is low, but family studies may aid in distinguishing this subgroup from Type I. It is interesting to note that patients with hemochromatosis are at increased risk for acquired PCT (Chemmanur, 2004). Patients present with cutaneous findings alone, and these are due to mild trauma to sun-exposed areas, not simple photosensitivity. Diagnostic laboratory findings include increased uroporphyrins with smaller increases in urine coproporphyrins. Exacerbating factors, such as alcohol, an inducer of hepatic ALA synthase I, and estrogens, should be avoided. Additional management strategies involve phlebotomy to reduce the hepatic iron load, chloroquine to complex porphyrins for urinary excretion, and the use of sunscreen (Chemmanur, 2004).

Congenital Erythropoietic Porphyria (CEP)

CEP is distinct from the other porphyrias discussed earlier in both its inheritance (it is a recessive disorder) and its severity. Patients present

shortly after birth with red-pigmented urine, hemolytic anemia, and severe cutaneous photosensitivity. Erythrodontia is striking and may be a useful clue if the diagnosis has not already been made. The deficient enzyme is uroporphyrinogen III synthase, and ALA synthase activity is increased. Coproporphyrin I and uroporphyrin I are present in urine. The prognosis for CEP is significantly worse than for the other porphyrias, with death occurring at an early age in many cases.

Hepatoerythropoietic Porphyria (HEP)

HEP is a rare form of porphyria that causes hemolysis and photosensitivity. It is not discussed further in this text.

Photosensitivity in Isolation

Erythropoietic Protoporphyria (EPP)

EPP is due to a partial deficiency of the enzyme ferrochelatase, the final enzyme in the heme biosynthetic pathway. The molecular basis of this disorder is complex. Some cases are autosomal recessive, but others involve two different genetic aberrations. Clinical symptoms begin in childhood, earlier than in other porphyrias (which have their onset at puberty) and painful, itching erythema occurs within a short time (minutes) of sun exposure. Neuropsychiatric symptoms are absent, but a recent case series described a child who was sent for psychiatric care after screaming in pain when outside (Wahlin, 2006). This article makes a useful point regarding the emotional sequelae of painful skin lesions: Emotional distress follows many diseases and must be carefully distinguished from the specific, although myriad, neurovisceral symptoms that characterize other porphyrias. Uniquely among the porphyrias, EPP has a normal urine profile, and RBC testing must be performed to render a diagnosis.

ANALYTIC TECHNIQUES

Testing of urine, red blood cells, and feces for various porphyrins, which are typically increased in the porphyrias, and for specific enzymes of the heme biosynthetic pathway, which may be decreased, takes place in reference laboratories. The pathologist should select a laboratory that is well familiar with the porphyrias, and that follows a logical algorithm, so that disease, if present, can be properly classified. Neither the ordering clinician nor the general pathologist needs to attempt classification of the porphyria by selecting one or two specific assays. The algorithmic approach is the rational one and begins with a quantitative evaluation of porphyrins: PBG and ALA in the urine, and porphyrins and PBGD (porphobilinogen deaminase) measurement in the erythrocytes. Although the Watson-Schwartz test has provided an adequate screening tool for decades, it does not offer the expected sensitivity of today's medical practice and is not even available at some of the reference laboratories that conduct porphyria workups. High-performance liquid chromatography (HPLC) and fluorometry are the mainstays of analytic technique. HPLC can separate individual porphyrins; this, combined with measurement of total fecal porphyrins, reliably distinguishes between AIP and HCP (Deacon, 2001). VP may be diagnosed by measurement of fecal and urine metabolites, and also by the fluorescence emission peak of 624–627 nm, which is unique among the porphyrias (Poh-Fitzpatrick, 1980). DNA testing for specific mutations should be restricted to patients with an established diagnosis based on clinical signs and urine/RBC/feces analysis, and to kindreds. Recall that

Figure 31-13 Myeloblast with high nuclear/cytoplasmic ratio, fine chromatin, visible nucleoli, and basophilic cytoplasm (Wright–Giemsa, 1000 \times).

the porphyrias are characterized by incomplete penetrance. Thus, a patient's signs and symptoms *may* be due to one of the porphyrias, or they may not. It is possible that the patient carries the genetic mutation but has another reason for his complaints. If the manifestations *are* due to porphyria, then urine and RBC tests will bear that out. Only then should one turn to DNA testing for the patient and his kindreds. The proper samples to submit for testing are urine (a 24-hour sample is strongly preferred, with the appropriate preservative dictated by the reference laboratory) and blood. A stool sample should be provided if VP or HCP is being considered but is less critical for the other porphyrias. Finally, testing is optimally performed during an attack to diagnose the acute porphyrias (AIP, ADP, VP, HCP). Thus, a negative test that was performed during quiescence may be repeated when the patient is again symptomatic.

NEUTROPHILS

The common progenitor cell for neutrophils and monocytes (CFU-GM) divides and gives rise to the progenitor cells for granulocytes (CFU-G) and for monocytes (CFU-M). CFU-G and CFU-M cells give rise to myeloblasts and monoblasts, respectively, under stimulation of colony-stimulating factors for granulocytes and monocytes (see Fig. 31-1).

MORPHOLOGY OF NEUTROPHIL PRECURSORS

The **myeloblast** (Fig. 31-13) is a cell about 15 μm in diameter with a moderately high N/C ratio; a large oval to quadrangular nucleus; a very fine, uniform chromatin pattern; a delicate nuclear membrane; and two to five nucleoli. The cytoplasm is pale, clear blue, and without granules. The appearance of azurophilic (primary) granules ($\approx 0.5\text{-}\mu\text{m}$ diameter) heralds the earliest promyelocyte (Fig. 31-14) and indicates that the cell is to be a neutrophil. The **promyelocyte** stage encompasses the entire period of production of azurophilic granules. The promyelocyte is slightly larger than the myeloblast. The nuclear chromatin begins to condense, and the nucleoli are less obvious. The cytoplasm is basophilic and is filled by more and more azurophilic granules. The **neutrophil myelocyte** stage begins with the appearance of specific neutrophil (secondary) granules, at first only in the Golgi region; as more specific granules develop, they spread throughout the cytoplasm (Fig. 31-15). With successive mitoses, the number of azurophilic granules (whose production has ceased at the end of the promyelocyte stage) is diminished. The early neutrophil myelocyte, therefore, has a rather fine, dispersed nuclear chromatin pattern, many azurophilic granules, and few specific granules. The late neutrophil myelocyte has a somewhat more condensed chromatin pattern, a cytoplasm well filled with specific granules, and rather few azurophilic granules. The myelocyte is the latest stage capable of cell division. The next stage, the **neutrophil metamyelocyte**, is distinguished by an indented, kidney-shaped nucleus with more condensed chromatin (Fig. 31-16). From this stage on, changes in the cytoplasm are insignificant. In the **band neutrophil** (stab form), the nucleus has more condensed chromatin and a rather uniform elongated shape (Fig. 31-17). Partial constriction of the nucleus

Figure 31-14 Promyelocyte (center) with azurophilic granules in the cytoplasm; the nuclear chromatin is still fine (Wright–Giemsa, 1000 \times).

Figure 31-15 Myelocytes have secondary granules in the cytoplasm and show condensation of nuclear chromatin. Persistent primary granules are seen in early myelocytes (center-right) and are lost as myelocytes mature. A band neutrophil and an orthochromatic normoblast are also seen (Wright–Giemsa, 1000 \times).

Figure 31-16 Metamyelocytes show nuclear indentation and increased chromatin clumping (Wright–Giemsa, 1000 \times).

occurs in the band stage, until a fine filament (length but no breadth) is formed between two of the lobes, at which point the cell is classified as a **segmented neutrophil** (Fig. 31-18).

During development and maturation, neutrophilic precursors express various cell surface markers that can be used for immunophenotypic recognition. Myeloblasts express the HSC marker CD34, as well as HLA-DR

Figure 31-17 Band neutrophil with mature nucleus with clumped chromatin but without segmentation (Wright–Giemsa, 1000 \times).

Figure 31-18 Segmented neutrophil with multiple nuclear lobes joined by fine chromatin filaments (Wright–Giemsa, 1000 \times).

and myeloid lineage specific markers CD13, CD33, CD15, and CD117. Mature neutrophils express CD13, CD15, CD16, and CD11b, but lose HLA-DR and CD33.

The mature human neutrophil has twice as many specific granules as azurophilic granules (Table 31-4). The azurophilic granules (formed in the promyelocyte stage) contain lysosomal enzymes (e.g., acid hydrolases: acid phosphatase, β -glucuronidase), myeloperoxidase, elastase, arylsulfatase,

and cationic antibacterial proteins, along with other enzymes and proteins. The specific granules (formed in the myelocyte stage) contain lysozyme, lactoferrin, collagenase, plasminogen activator, aminopeptidase, and vitamin B₁₂-binding protein, as well as other enzymes and proteins. Tertiary granules, similar in size to the specific granules, contain gelatinase. Alkaline phosphatase is located in yet another type of cytoplasmic organelle lighter in density than specific granules. These organelles first appear during the late myelocyte stage.

DISTRIBUTION AND KINETICS

For each neutrophil in the blood vessels, about 16 precursors are present in the marrow. From the time of differentiation into a myeloblast, through about five mitotic divisions (three of which occur at the myelocyte stage), it takes about 14 days until the progeny of that cell reach the blood. The last 6–7 days are spent in the maturation and storage pool. When a neutrophil enters the blood, it moves readily between a circulating granulocyte pool, which is sampled in the leukocyte count, and a marginal granulocyte pool, which is not, but is either margined along vessel walls or sequestered in capillary beds. In less than a day after it arrives, the neutrophil emigrates from the circulation in a random manner and enters the tissues. Migration into tissues is dependent on adhesion molecules of the selectin family (and their corresponding ligands) expressed on neutrophils and endothelial cells. From there, if not utilized in an inflammatory exudate, neutrophils leave the body within a few days via secretions in bronchi, saliva, gastrointestinal tract, and urine, or they are destroyed by the mononuclear phagocyte system.

FUNCTION

Neutrophils are able to move in a zigzag manner, but their motion changes to a straight line path if a chemotactic attractant or factor (e.g., a bacterium coated with certain components of complement) is within a certain distance. Neutrophils express chemokine receptors CXCR1 and CXCR2, which are responsible for neutrophil migration in response to chemokines. Neutrophils also have receptors for the Fc portion of IgG, as well as for complement (C3) and bind and phagocytose the coated particle. Phagocytosis occurs with the formation of a phagocytic vacuole that contains the ingested particle; accompanying this process is an increase in metabolic activity and energy production. Specific granules, followed shortly by azurophilic granules, empty their contents into the phagocytic vacuoles—a process known as degranulation. Bactericidal activity occurs within the vacuole, mediated by H₂O₂, superoxide anion (O₂⁻), myeloperoxidase, and a halide ion generating free halogen, or by other enzymatic activity. Other substances can act as chemotactic factors too. The C5a fragment is a chemotactic factor and is also an anaphylatoxin that causes smooth muscle contraction. Substances liberated by bacteria and metabolic products of arachidonic acid may also act as chemotactic factors for neutrophils. Neutrophils are thus important in defense against infectious disease. If their enzymes are activated and released outside the cell, neutrophils can cause tissue necrosis, tissue injury, and inflammation.

EOSINOPHILS

Eosinophils are produced in the bone marrow. In vitro culture studies show that there is a separate eosinophilic committed progenitor cell (CFU-Eo) in the marrow that is distinct from CFU-GM, CFU-G, and CFU-M. Three growth factors (GM-CSF, IL-3, IL-5) produced by T lymphocytes influence eosinophil development. IL-5 promotes terminal maturation, functional activation, and prevention of apoptosis of eosinophils.

MORPHOLOGY OF EOSINOPHIL PRECURSORS

The cell that is the precursor for the earliest recognizable eosinophil, the eosinophil myelocyte, is presumably a distinctive myeloblast. However, it is morphologically indistinguishable from that which gives rise to neutrophils and monocytes or to basophils (see Figs. 31-1 and 31-13). In the early eosinophil myelocyte, the granules are large and take the basophilic stain. As the cell matures, the granules appear olive-green, and finally the characteristic red-orange color (Figs. 31-19 and 31-20). Nuclear maturation is similar to that of the neutrophil. Eosinophils are slightly larger than neutrophils and have fewer nuclear lobes. Mature eosinophils express CD16 and CD32.

Figure 31-19 Eosinophil myelocyte with ovoid nucleus and eosinophilic secondary granules in the cytoplasm (Wright-Giemsa, 1000 \times).

Figure 31-20 Mature eosinophil with bilobed nucleus and large eosinophilic cytoplasmic granules (Wright-Giemsa, 1000 \times).

Electron micrographs of eosinophils show characteristic granules that have a dense crystalloid core in a less dense matrix. Immature granules, appearing in the myelocyte, at first have no crystalloids but develop them as maturation proceeds. Mature granules are of two types: a larger granule (0.5–1.5 μm in largest diameter) with a dense crystalloid, and a smaller granule (0.1–0.5 μm diameter) without a crystalloid. The smaller granules appear later during maturation, after the myelocyte stage.

Eosinophil-specific granules (Table 31-5) contain major basic protein (MBP) in the crystalloid core; MBP is toxic to parasites and cells, neutralizes heparin, and induces histamine release from basophils. Granule constituents in the matrix include acid hydrolases, peroxidase, phospholipase, and cathepsin. The specific granules also contain eosinophil cationic protein (ECP), eosinophil-derived neurotoxin (EDN), and eosinophil peroxidase (EPO). ECP shortens coagulation time and alters fibrinolysis; it also inhibits lymphocyte proliferation and is a potent neurotoxin. EDN is a strong neurotoxin (Gleich, 1986). The smaller granules contain arylsulfatase; both granule types contain peroxidase and acid phosphatase. Eosinophil peroxidase is different from the type of peroxidase present in neutrophils and monocytes; also, eosinophils contain no alkaline phosphatase or muramidase. Eosinophils secrete IL-1, IL-3, IL-6, IL-8, TNF- α , and GM-CSF. TNF- α appears to be the cause of fibrosis in Hodgkin's disease (Roberts, 1999).

DISTRIBUTION AND KINETICS

The kinetics of eosinophils are similar to those of neutrophils. They are stored in the bone marrow for several days after going through various maturational stages. The half-life in the blood is approximately 18 hours before entering the tissues, where they survive for at least 6 days. Eosinophils in the tissues, however, are at least 100 times as numerous as the total number of eosinophils in the blood; they are located primarily in skin,

TABLE 31-5

Eosinophil Constituents and Functions

- Phagocytosis
- Allergic response
- Dampen inflammatory reactions

lung, and gastrointestinal tract (i.e., the epithelial barriers to the outside world).

FUNCTION

Eosinophils act as phagocytes and modulate inflammatory responses (see Table 31-5). Eosinophils leave the blood when adrenal corticosteroid hormones increase. They proliferate in response to immunologic stimuli, and this proliferative response is mediated, at least with some antigens, by T lymphocytes, monocytes, and mast cells. Eosinophils destroy helminths by generating potent oxidants and releasing cationic proteins. Eosinophils participate in some inflammatory conditions, particularly allergic reactions, asthma, and certain myocardial diseases (Gleich, 1986). Although eosinophils phagocytose foreign particles and antigen-antibody complexes, this is not their only activity. Another major function of eosinophils is to dampen hypersensitivity and inflammatory reactions. Evidence indicates that eosinophils modulate reactions that occur when tissue mast cells and basophils degranulate. Eosinophils express the chemokine receptor CCR3. Among the chemotactic factors that attract eosinophils, eosinophil chemotactic factor of anaphylaxis (ECF-A) is present in basophils and mast cells; also, eosinophils contain substances that inactivate factors released by mast cells and basophils, such as histamine, slow-reacting substances of anaphylaxis, and platelet-activating factor (PAF).

When an intense or prolonged eosinophilic inflammatory reaction occurs, there is often the formation of Charcot-Leyden crystals. These hexagonal bipyramidal crystals are composed of lysophospholipase localized in the cytoplasm of eosinophils (Jandl, 1996).

BASOPHILS AND MAST CELLS

Basophils and mast cells are derived from hematopoietic precursors and probably share a common precursor with other granulocytes and monocytes.

MORPHOLOGY

Basophils develop from a cell resembling a myeloblast. The first recognizable stage is a **basophil myelocyte**, with the appearance of specific basophil granules. These granules (about 0.2–1 μm in diameter) are larger than the azurophilic granules of the promyelocyte and often are irregular in shape. As the cell matures, the granules become more metachromatic (red-purple) because of increasing acid mucopolysaccharide (heparin) content. During maturation, cytoplasmic RNA decreases, and the nucleus partially segments. Because of incomplete nuclear segmentation, stages analogous to the neutrophil are not readily identified. In mature basophils, the nucleus has condensed but smudged chromatin, and the background cytoplasm lacks basophilia (residual RNA) (Fig. 31-21). Mature basophils express CD32.

In contrast, **tissue mast cells** are connective tissue cells of mesenchymal origin that contain metachromatic cytoplasmic granules. They are

Figure 31-21 Mature basophil with large dark red-purple basophilic granules that partially obscure the nucleus (Wright-Giemsa, 1000 \times).

Figure 31-22 Bone marrow mast cell shows numerous uniform purple granules in the cytoplasm that partially obscure the nucleus (Wright-Giemsa, 1000 \times).

widely distributed throughout the body, including bone marrow, thymus, and spleen, but they do not normally appear in blood. On Romanowsky-stained films (Fig. 31-22), they are usually larger than basophils and have a low N/C ratio and a round or oval reticular nucleus that is usually obscured by abundant red-purple granules. The granules are smaller, more round and regular, and less soluble than basophil granules. The cytoplasmic granules are often spindle-shaped rather than round.

DISTRIBUTION AND KINETICS

Basophils have a life span similar to eosinophils. The maturation time in the marrow is approximately 7 days. Basophils circulate in the blood and are not normally found in tissues, in contrast to mast cells, which can spend 9–18 months in connective tissue (Jandl, 1996). GM-CSF, IL-3, and IL-5 influence basophil production. However, IL-3 is the principal growth factor for basophilic growth, whereas *c-kit* ligand enhances the number and activation state of mast cells (Lyman, 1998).

FUNCTION

With regard to circulating numbers, basophils respond to adrenal corticosteroids in similar fashion to eosinophils. Basophil granules contain histamine, heparin, and peroxidase (Table 31-6). Basophils synthesize and store histamine and ECF-A. They synthesize and release slow-reacting substance of anaphylaxis (SRS-A) and probably PAF at the time of stimulation but do not store them. Basophils lack hydrolytic enzymes such as alkaline and acid phosphatase, at least in cytochemically demonstrable amounts. Glycogen is abundant outside the granules. Although ultrastructurally different, mast cells have similar cytochemical characteristics, except for the presence of proteolytic enzymes and serotonin, which basophils lack. In tissues, the two cell types appear to function in a similar manner.

Basophils (as well as mast cells) appear to be involved in immediate hypersensitivity reactions, such as allergic asthma. IgE binds readily to basophil and mast cell membranes. When a specific antigen reacts with the membrane-bound IgE, degranulation occurs with the release of

Figure 31-23 Promonocytes have fine nuclear chromatin, often with visible folds and basophilic cytoplasm that may contain vacuoles (Wright-Giemsa, 1000 \times).

mediators of immediate hypersensitivity (e.g., histamine, SRS-A, PAF, heparin, ECF-A). The latter leads to the accumulation of eosinophils, which contain substances that tend to counteract these mediators. Basophils are also involved in some delayed hypersensitivity reactions, or **cutaneous basophil hypersensitivity**, such as contact allergies, in which they appear to undergo a different type of degranulation response.

MONOCYTES AND MACROPHAGES

Monocytes share the same committed progenitor cell as neutrophils, the CFU-GM (see Fig. 31-1).

MORPHOLOGY

In normal marrow, it is not possible morphologically to distinguish the “monoblast” from the myeloblast. The earliest recognizable cell in this series is the **promonocyte**, which is 15–20 μm in diameter—somewhat larger than the myeloblast. The N/C ratio is moderate, and the nucleus may be oval or indented with a fine uniform or slightly streaked chromatin pattern and two to five nucleoli. The cytoplasm is basophilic with a ground-glass appearance and a variable number of fine azurophilic granules (Fig. 31-23). The **monocyte**, which is present in both blood and marrow, is only slightly smaller; it has a moderate to low N/C ratio and an indented or lobed nucleus with a finely-streaked, only slightly condensed, delicate chromatin pattern. Nucleoli are indistinct or obscured. The cytoplasm is opaque, more gray than blue, and contains an abundance of fine azurophilic granules (Fig. 31-24).

Macrophages, the tissue component of the monocyte system, arise from emigrated blood monocytes. Macrophages are larger than monocytes and measure 15–80 μm in diameter. They have irregular cell membranes, often with blebs and pseudopodia. The N/C ratio is high with an oblong and/or indented nucleus. Although macrophages are located in virtually all tissues of the body, the greatest numbers are found in the bowel, liver, bone marrow, and spleen.

In promonocytes, monocytes, and macrophages, the granules (Table 31-7) contain acid hydrolase, arylsulfatase, nonspecific esterase, and

Figure 31-24 Mature monocyte with an indented nucleus, delicate chromatin, basophilic cytoplasm, and fine azurophilic granules (Wright-Giemsa, 1000 \times).

peroxidase. More than one type of granule may be present. As the cell matures, peroxidase activity diminishes, and acid phosphatase, arylsulfatase, and nonspecific esterase activity increases. The enzyme activity occurs in the rough endoplasmic reticulum, Golgi zone, coated vesicles, and digestive vacuoles, suggesting that in the macrophages the coated vesicles are a second form of primary lysosome that shuttles hydrolytic enzymes from the Golgi to the digestive vacuoles.

In addition to these enzymes, monocytes and macrophages possess numerous surface receptors and surface antigens. Monocytes and macrophages possess class I (HLA-A, B, C) antigens and class II (HLA-DR, DP, DQ) gene complex molecules. The CD4 T cell antigen (molecule) not only is present on T-helper cells but is also present on monocytes and macrophages. Because the CD4 molecule acts as a receptor for the human immunodeficiency virus type-1 (HIV-1), the virus infects monocytes and macrophages along with T-helper cells. Monocytes and macrophages express CD11 (CD11a, b, c) antigens, markers that define surface adhesion glycoproteins. CD14, CD64, and CD68 antigens are also present on monocytes and macrophages. These surface molecules are often used to identify the lineage of mononuclear cells in hematologic malignancies.

DISTRIBUTION AND KINETICS

After promonocytes are formed, they respond to M-CSF and undergo two or three mitotic divisions in a period of about 50–60 hours before being released into the blood. Under conditions of increased demand, the cycle time can shorten, with earlier release of more immature cells into the blood. Blood monocytes are distributed in a circulating monocyte pool and a marginal monocyte pool, in a ratio of 1:3.5. Once monocytes enter the blood, they leave randomly with a half-time of 8.4 hours; this time period is shortened in splenomegaly or acute infection and may be prolonged in monocytosis. After monocytes leave the blood, they spend several months, perhaps longer, as tissue macrophages.

FUNCTION

The monocyte is formed in the marrow and transported by the blood; it migrates into the tissues, where it transforms into a histiocyte or a

macrophage to spend most of its life span. Blood monocytes and tissue macrophages make up a mononuclear phagocyte system (reticuloendothelial system).

The mononuclear phagocyte system has an important role in defense against microorganisms, including mycobacteria, fungi, bacteria, protozoa, and viruses (see Table 31-7). The cells are motile and respond to chemotactic factors (complement components, as well as lymphokines and γ -interferon from activated T lymphocytes); they become immobilized by migration-inhibition factor from activated lymphocytes. They engage in phagocytosis, a process that is enhanced if the particle is coated by IgG or complement for which the macrophages have membrane receptors. After phagocytosis, they kill ingested microorganisms.

These mononuclear phagocytes are an integral part of both humoral and cell-mediated immunity. They handle or process antigens, providing contact of the antigen (or antigenic information) with lymphocytes. They also respond to various lymphokines and monokines and act as effector (e.g., cytotoxic) cells in the cell-mediated immune response. Monocytes and macrophages function in antibody-dependent cellular cytotoxicity. They have the ability to kill a variety of malignant cells (Weinberg, 2004) by promoting both cytostasis and cytolysis. Some of the ability of macrophages to destroy malignant cells may be attributed to the production of hydrogen peroxide (H_2O_2), nitrous oxide (NO), and reactive oxygen intermediates.

Macrophages remove and process senescent cells and debris through phagocytosis and digestion, for example, erythrocytes, leukocytes, and megakaryocyte nuclei are removed by macrophages in the marrow; inhaled particulate material is removed by alveolar macrophages in the lungs.

Macrophages may be activated by specific factors (e.g., cytophilic antibody) or nonspecific factors (e.g., in response to phagocytosed material). Activation results in enlargement of the cell and enhanced metabolism, phagocytosis, microbicidal activity, cytotoxicity, secretion of cytolytic proteins (including TNF- α), and the like.

Macrophages synthesize and secrete a large number of biologically active molecules, including enzymes, complement components, binding proteins, coagulation factors, cytokines and growth factors, chemotactic factors, angiogenesis factors, and bioactive lipids. This system, therefore, has multiple functions that include host defense, control of hematopoiesis, and policing of the environment within the body (Johnston, 1988).

MEGAKARYOCYTES

Platelets originate from polyploid megakaryocytes, the largest of all hematopoietic cells, which account for less than 1% of the total nucleated marrow cells. Megakaryocytes arise from the multipotential hematopoietic stem cell, and then from a committed progenitor cell, the CFU-Meg (see Fig. 31-1). Megakaryocyte proliferation is largely regulated by thrombopoietin. Additional growth factors, including kit-ligand, IL-3, IL-6, and IL-11, support megakaryocytic development in the presence of thrombopoietin (Kaushansky, 1995). Serum thrombopoietin levels are generally inversely proportional to platelet count; however, levels are elevated in liver disease and inflammatory states, probably through hepatocyte or marrow stromal cell responses (Kaushansky, 2003).

MORPHOLOGY

Committed progenitor cells are not morphologically distinguishable from lymphocytes. Megakaryocyte development is characterized by **endomitosis**, nuclear division without cytoplasmic division, which results in ploidies varying from 2N to 64N. Most are 8N and 16N, with smaller numbers on either side. Nuclear lobes do not correlate precisely with ploidy. Nuclear chromatin is intensely staining, rather dispersed early, more compact and dense later. Nucleoli are small at all stages of megakaryocyte development.

The earliest recognizable **megakaryoblast** has overlapping nuclear lobes and a small amount of basophilic cytoplasm. During the course of maturation, nuclear lobes increase and spread out, and red-pink granules become visible, first in the center of the cell. In the **mature megakaryocyte**, the nucleus is more compact, basophilia has disappeared, and the granules are clustered into small aggregates (Fig. 31-25).

The formation of individual platelets is a complex process. Megakaryocytes develop invaginated surface membranes (demarcation membranes) that provide a membrane reserve for proplatelet formation (Italiano, 2003). Proplatelets are pseudopodial extensions of megakaryocytes that progressively branch and thin out. Microtubular action is important in the formation of proplatelets and in bringing granule and organelle constituents into

Figure 31-25 Megakaryocyte with a large, lobated nucleus and abundant granular cytoplasm (Wright–Giemsa, 1000 \times).

Figure 31-26 Dwarf megakaryocyte with bilobed nucleus and scant granular cytoplasm; a few giant platelets are also seen. These cells are most often associated with myeloproliferative neoplasms or myelodysplastic syndromes (Wright–Giemsa, 1000 \times).

the proplatelets. Platelets are formed at the ends of proplatelets and are released by microtubular action (Hartwig, 2003).

MEGAKARYOCYTES IN BLOOD

Whole megakaryocytes or fragments may occasionally be found in normal blood films. If buffy coat films are examined, they are consistently present. Megakaryocyte fragments in blood films may be as small as lymphocytes and are recognized by the deeply stained chromatin (with a sharper chromatin–parachromatin separation than in lymphocyte nuclei) and by fragments of attached megakaryocyte cytoplasm. They are found more frequently than normal in myeloproliferative processes and myeloproliferative neoplasms, or after stress or injury to the marrow.

Dwarf or micromegakaryocytes (Fig. 31-26) show evidence of abnormal megakaryopoiesis: agranular cytoplasm with hyaloplasmic zones or pseudopods, and association with large atypical platelets having similar cytoplasmic characteristics. These abnormal dwarf megakaryocytes are rarely found in any condition except myeloproliferative neoplasms or myelodysplastic syndromes.

DISTRIBUTION AND KINETICS

The maturation time for megakaryocytes in the marrow is about 5 days in humans. Platelets are released into the marrow sinuses over a period of several hours (Hartwig, 2003), and the megakaryocyte nuclei are phagocytosed by macrophages. Newly released platelets appear larger, more active metabolically, and more effective hemostatically. Platelets circulate at a stable concentration that averages $275 \times 10^9/L$. At any one time, about two thirds of the total platelets are in the circulation, and the remaining third are present in the spleen. In asplenic individuals, all platelets are circulating. In diseases characterized by splenic enlargement, 80%–90% of platelets may be sequestered in the spleen, resulting in decreased concentrations of circulating platelets (thrombocytopenia).

Platelets survive for 8–11 days in the circulation. Some platelets are utilized in maintaining vascular integrity and in plugging small vascular

TABLE 31-8

Key Cell Surface Markers in Lymphocyte Development

Cell name	CD markers
Progenitor B cell	CD19, TdT, CD79a, HLA-DR
Pre-B cell	CD19, TdT, CD10, CD20, cytoplasmic μ
Naive mature B cell	CD19, CD20, Bcl-2, surface IgM
Centroblasts	CD19, CD20, CD10, Bcl-6
Mature B cells (peripheral blood)	CD19, CD20, CD21, CD22, CD24, CD38
Plasma cells	CD38, CD138, cytoplasmic Ig

injuries (random loss); others are removed by the mononuclear phagocytic system when they become senescent.

FUNCTION

Platelets normally function in (1) maintaining the integrity of blood vessels, and (2) forming hemostatic plugs to stop blood loss from injured vessels and, in the process, promoting coagulation of plasma factors.

LYMPHOCYTES

PRIMARY LYMPHOID TISSUE

During fetal life, lymphocyte precursors originate in the bone marrow and undergo antigen-independent lineage commitment. Maturation and selection of T cells occur primarily in the thymus, and of B cells, in the marrow and peripheral lymphoid organs. The T cell population is largely self-renewable following thymic involution. B cells are capable of only limited self-renewal. They are dependent on recruitment from marrow stem cells to replenish programmed B cells and plasma cells that are incapable of self-renewal (Jandl, 1996). NK cells are derived from CD34 $^{+}$ HSCs, but details of development and maturation are not completely understood.

B Cell Development: Bone Marrow (Table 31-8)

A distinct organ, the bursa of Fabricius, is present in birds and serves as the primary site of B cell development. In the human, B cells develop in the bone marrow after the hematopoietic stem cells have populated that organ. During adult life, generation of B cells occurs in the bone marrow.

B cell differentiation can be divided conveniently into two stages. The initial stage of B cell differentiation involves the antigen-independent generation of diversity through rearrangement of the Ig heavy and light chain genes. The second stage is regulated by antigen triggering, T cell interaction, macrophages, and various growth factors (Fig. 31-27). This stage occurs predominantly in the secondary lymphoid organs (LeBien, 2008).

A progenitor cell gives rise to the first recognizable B cell in man and mammals. This cell in humans is the pro-B (progenitor) cell that is characterized by receptor CD19 and terminal deoxynucleotidyl transferase (TdT) but contains no cytoplasmic or surface bound Ig (Hagman, 1994). Differentiation of pro-B cells requires Ig gene rearrangement. The pre-B cell is characterized by the presence of intracytoplasmic μ heavy chains with no surface-bound immunoglobulin (sIg $^{-}$ cu $^{+}$). It also contains HLA-DR antigens, CD19, CD79a, and other surface markers. Humoral proteins influence pre-B cell differentiation.

In becoming a pre-B cell, a lymphoid stem cell undergoes *D γ* and *VD γ* gene segment rearrangement to form a functional *V* gene for the μ heavy chain (Fig. 31-28). A productive heavy chain gene rearrangement is then followed by a rearrangement of the *V γ* gene segment of the light chain. Rearrangement of the κ light chain gene on chromosome 2 occurs first. If the κ rearrangements at both loci are nonproductive, rearrangement of the λ light chain gene on chromosome 22 follows. The controls exerted during pre-B cell development allow only one productive *VH* and *VL* gene to emerge, limiting each B cell to one unique antibody structure (Bertoli, 1988). The combination of the μ heavy chain and the κ or λ light chain allows the pre-B cell to generate an intact Ig molecule and express surface IgM. Isotype switching (changing from IgM/IgD to IgG1, etc.) and constant heavy gene deletions occur in pre-B cells and more differentiated B cells. The switching of μ cells to γ 1 or α 2 cells occurs by the formation of a DNA loop in which all intervening constant heavy genes are deleted (Fig. 31-29). IgD can be coexpressed with IgM through alternative RNA processing.

Figure 31-27 Differentiation of pre-B cells into B cells occurs independently of antigen, whereas proliferation and terminal differentiation of B cells are antigen driven. Hematopoietic stem cells with stromal cell help give rise to pre-B cells. These proliferate (open arrow denotes cell cycling), rearrange *DJ* and *VDJ* gene segments, then express μ chains in the cytoplasm ($c\mu^+$). A small, resting pre-B cell (not shown) with rearranged *VJk* gene assembles a complete IgMk molecule, becoming an immature B cell and leaving the bone marrow. Expression of *slgD* marks entry of the cell into the mature, resting phase (or G_0) characteristic of most blood and mantle zone B cells. Switching to an alternative isotype (IgG in this case) may occur before an encounter with antigen or afterward. Antigen triggers the resting B cell to enlarge (in G_1 phase of the cell cycle) and present processed antigen and DR to the antigen-specific T cell receptor-CD3 complex. T-helper cells (T_H) secrete growth factors that bind to newly expressed receptor, further enhancing proliferation (S and M phases) in germinal centers. The activated B cell can be induced to differentiate into plasma cells, which secrete their abundant cytoplasmic IgG. Alternatively, it can become a memory B cell with refined specificity poised to deliver an anamnestic immune response on its next encounter with antigen. (From Bertoli LF, Burrows PD. Normal B-lineage cells: their differentiation and identification. Clin Lab Med 1988;8:15, with permission.) IgG, Immunoglobulin G.

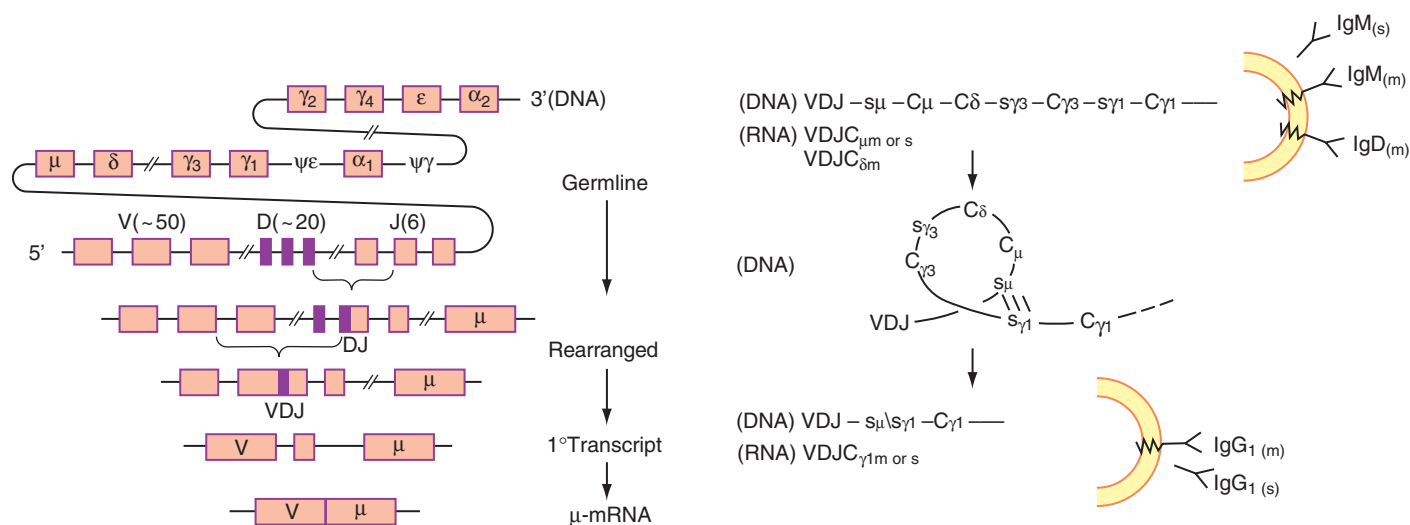

Figure 31-28 Generation of a functional Ig gene requires DNA rearrangement. In the germline and in somatic nonlymphoid cells, *V*, *D*, and *J* gene segments are widely separated in the DNA of chromosome 14. A cell committed to the B lineage first undergoes *D* to *J* rearrangement, juxtaposing the *D* and *J* segments and deleting intervening DNA sequences. This is followed by *V* to *DJ* rearrangement, generating a complete *VDJ* exon. The primary RNA transcript is processed to yield a contiguous *V* (*VDJ*) mRNA. (From Bertoli LF, Burrows PD. Normal B-lineage cells: their differentiation and identification. Clin Lab Med, 1988;8:15, with permission.) DNA, Deoxyribonucleic acid; Ig, immunoglobulin.

Figure 31-29 Alternative strategies for expression of non-IgM isotypes. IgD can be coexpressed with IgM, by alternative processing of a primary RNA transcript of *VDJ-Cμ-Cδ*, to yield μ membrane (m), μ secretory (s), and δm RNAs. The production of IgG, IgA, or IgE isotypes involves DNA rearrangement. During the switch from IgM to IgG, for example, intrachromosomal recombination between homologous switch (s) regions results in deletions of *Cμ*, *Cδ*, and *Cγ3*, so that *Cγ1* is now the first C gene 3' of the *VDJ* exon. Thus, the same variable region is expressed with a different constant region. (From Bertoli LF, Burrows PD. Normal B-lineage cells: their differentiation and identification. Clin Lab Med 1988;8:15, with permission.) Ig, Immunoglobulin; RNA, ribonucleic acid.

Pre-B cells give rise to naive mature B cells that characteristically express surface-bound Ig. These cells are present in primary lymphoid follicles, in follicular mantle zones, and in the circulation. In addition to IgD and IgM, these cells often express CD5 and are positive for Bcl-2.

In the second stage of differentiation, naive B cells interact with antigen and undergo transformation in the presence of T cells and macrophages. This process occurs in the germinal center. The B cells transform into blastic cells (centroblasts) that express Bcl-6 and CD10. Rapid division and expansion of B cell clones occur in an attempt to identify cells with Ig that provides the best fit for the stimulating antigen. Antigenic specificity is further refined through the process of somatic hypermutation in the variable region gene. Centroblasts give rise to centrocytes, which are cleaved follicle center cells. These cells express the modified Ig (following somatic hypermutation). Cells with lower affinity for the antigen are destroyed through apoptosis (cells in the germinal center do not express Bcl-2; therefore, they can undergo apoptosis). Surviving centrocytes differentiate into plasma cells that produce circulating Ig, or memory B cells that provide rapid humoral response the next time the same antigen is encountered. Memory B cells are present in the marginal zone of the follicle.

The state of Ig genes is, therefore, a good indicator of the developmental stage of B cells. The presence of Ig gene rearrangement identifies primitive B cells. Somatic hypermutation resulting in variable region sequences that are different from germline sequences identifies a B cell that has been stimulated by antigen. Germinal center B cells can be distinguished from post-germinal center B cells by the presence of intraclonal diversity in the former due to ongoing somatic hypermutation.

In the peripheral blood, approximately 6%–15% of B cells express surface-bound IgM (90% of these coexpress IgD), 1%–3% IgG, and 0.5%–2% IgA. Mature B cells express receptors for Fc portions of Ig isotypes, C3b and C3d fragments of complement, interferon, and IL-4. Mature B cells also express CD19, CD20, CD21, CD22, CD24, and CD38.

Plasma cells are characterized by abundant cytoplasmic Ig, reflecting the Ig commitment of the activated B cell. At this stage, Fc and C3 receptors, HLA-DR antigen, and surface-bound Ig are greatly reduced, but the cells express CD38 and CD138. Thus, the lymphocytes bearing sIg give rise to cells committed to the synthesis of IgM, IgG, and IgA.

T Cell Development: Thymus (Table 31-9)

The microenvironment of the thymus is necessary for the differentiation of T cells. The human thymus has two parts: the cortex and the medulla. The cortex is subdivided into two portions—the subcapsular cortex and the inner cortex—and is populated predominantly by small lymphocytes with a few scattered epithelial cells. Fibrous septa extend from the capsule to the medullary region. The medulla is composed mostly of

epithelial cells with a small component of lymphocytes. In the medulla, Hassall's corpuscles, small islands of partially hyalinized epithelial cells, are present.

Pro-T cells from the bone marrow or fetal liver migrate to the thymus, where they undergo T cell receptor (TCR) gene rearrangement and are processed into functionally mature T cells for circulation in the blood and to the peripheral or secondary lymphoid tissues. TCR genes are organized in a similar manner to Ig genes. They possess V, D, J, and C regions and undergo rearrangement during early T cell maturation. In addition to the heterodimeric glycoproteins (α/β or γ/δ), the TCR/CD3 complex consists of the following subunits: CD3- ϵ , $-\xi$, and $-\eta$ (Blumberg, 1990). The TCR recognizes foreign peptides held in an association with self-MHC molecules. In early T cell development, the γ - and β -chain genes rearrange simultaneously, with TCR commitment dependent on expression of surrogate α -chain and development of a pre-TCR (Haks, 1998; Kang, 2001). Successful passage of thymocytes with β -chain-containing pre-TCR through a developmental checkpoint is followed by rearrangement of the TCR α -chain and formation of α/β T cells. During this process, developing T cells first coexpress both CD4 and CD8 (double positive cells), with subsequent downregulation of one or the other. In the thymic medulla, pre-T cells lose the ability to make TdT as they convert to mature T cells (third stage) and then circulate in the blood and peripheral lymphoid tissues.

The earliest T cells in the thymus express CD2 and CD44 (Schattner, 2001). Subsequently, these cells express CD25 and CD3. The TCRs of CD4+ α/β T cells recognize nonself peptides held in the groove of class II MHC molecules, and TCRs of CD8+ α/β T cells recognize nonself polypeptides bound to the class I molecules (MacLennan, 1999).

The maturation of T cells is complex, however; at least three stages with multiple intermediate substages have been defined (Paraskevas, 2009b). In the first stage, pro-T cells migrate from the bone marrow or the fetal liver to the cortex of the thymus. In the second stage, pro-T cells migrate from the subcapsular cortex to the inner cortex and then to the thymic medulla (see Table 31-9). During this time, T cells with the ability to recognize foreign antigens are retained, and T cells with the ability to recognize self-antigens are eliminated.

Thymic function decreases with age, although it persists throughout life. Thymic function and T cell reconstitution can be assessed by measuring newly generated T cells utilizing a PCR assay for extrachromosomal DNA circles called **TCR rearrangement excision circles (TRECs)** (Kong, 1998).

A majority of postthymic (peripheral) T cells express α/β TCR; a small minority do not, but rather express γ/δ chains. NK cells express only ϵ chains with cytoplasmic CD3. Mature T cells are of at least three types. CD4 (helper) T cells possess α/β TCR chains and express CD2, CD3, CD4, CD5, and CD7 cell markers. CD8 (suppressor or cytolytic) T cells have α/β TCR chains and express CD2, CD3, CD5, CD7, and CD8 cell markers. Mature T cells with γ/δ TCR chains exhibit CD2, CD3, and CD7, lack CD4 and CD8, and seem to function as another population of cytotoxic cells (Paraskevas, 2009b).

CD4 T cells can develop into at least four subgroups with different functions (Zhu, 2008). Th1 cells produce interferon (IFN)- γ , TNF- β , and IL-2 and mediate immune response against intracellular pathogens. Th2 cells produce IL-4 and IL-5 and are important in defense against extracellular parasites. Th17 cells produce IL-17, IL-21, and IL-22 and mediate immune responses against extracellular bacteria and fungi. Induced regulatory T (iTreg) cells produce TGF- β , IL-10, and IL-35 and are involved in maintaining self-tolerance and regulating immune responses. Antigen-independent development of T cells is controlled by interaction with thymic epithelial cells and thymic fibroblasts, as well as by the influences of cytokines, growth factors, and thymic hormones. IL-1, IL-2, IL-3, IL-4, IL-7, and SCF are critical in the growth and differentiation of thymic lymphocytes. Thymic hormones produced by thymic epithelial cells also induce T cell function.

In the T-zone area of the peripheral lymphoid system, the T cell antigen-dependent pathway occurs through the binding of the TCRs to antigen peptides associated with appropriate MHC I and MHC II molecules on macrophages or interdigitating dendritic cells (IDCs). This results in the release of IL-1 by the activated macrophages, which, in turn, leads to the formation of IL-2 receptors on T cells and the subsequent synthesis and release of IL-2 by these activated T cells. In this activation process, many other cytokines (including IL-4, IL-6, IL-10, TNF, and interferon) are released, and appropriate cytokine receptors are upregulated. These events result in the activation and maturation of T-helper cells, T-suppressor

TABLE 31-9

Summary of T Cell Maturation

Stage	Maturation events	Cell surface markers
Pro-T cell	Migration from marrow to thymic cortex	CD2, CD44
α/β Pre-T cell	Migration from thymic cortex to medulla, elimination of self-recognizing T cells, α/β TCR rearrangement (for T cells destined for the helper or suppressor subset)	TdT, CD1, CD2, CD3, CD4, CD5, CD7, CD8
γ/δ Pre-T cell	Migration from thymic cortex to medulla, elimination of self-recognizing T cells, γ/δ TCR rearrangement (for T cells destined for the cytotoxic subset)	TdT, CD1, CD2, CD3, CD7
Mature T cell	Loss of ability to make TdT, circulation in peripheral blood as helper, suppressor, or cytotoxic subset	Helper T: CD2, CD3, CD4, CD5, CD7 Suppressor T: CD2, CD3, CD5, CD7, CD8 Cytotoxic T: CD2, CD3, CD7

TCR, T cell receptor; TdT, terminal deoxynucleotidyl transferase.

cells, T-cytotoxic cells, and other immunoregulatory cells. This activation process not only increases the number of antigen-specific T cells, it also alters the immunophenotype and changes the expression of certain adhesion molecules on T cells. For example, LFA-1 (a heterodimer formed from CD11a and CD18) and VLA-4 (a heterodimer of CD29 and CD49d, CD44, and CD2) are upregulated, and L-selectin (CD62L) is downregulated (MacLennan, 1999). Changes in the expression of adhesion markers allow for the proper circulation of T cells in the body.

Natural Killer Cells: Bone Marrow

Immunophenotypic and functional data suggest that NK cells and T cells have a close developmental relationship. Expression of CD3 proteins has been found in human fetal NK cells. Thus, it is likely that NK cells and T cells have a common precursor cell. Although NK cells can develop in the thymus, the thymic environment is not required for NK cell differentiation. NK cells can develop in secondary lymphoid tissues and bone marrow (Caligiuri, 2008). Fetal NK cells possess CD3 γ , δ , ϵ , and CD28; adult NK cells express CD2, CD3 ξ , CD7, CD8 α , CD16, and CD56. SCF, IL-7, and IL-2 are critical in the development of NK cells (Spits, 1995). NK cells proliferate in the presence of IL-2, and their activity can be augmented by exposure to IFN- γ . NK cells appear to be targeted against virus-infected cells unable to signal cytotoxic T cells (usually as a result of low expression of class I MHC molecules). Because NK cells possess the Fc portion of IgG, they participate in antibody-dependent cell lysis (MacLennan, 1999).

SECONDARY LYMPHOID TISSUE

In late fetal and postnatal life, lymphocytes are produced in the secondary lymphoid tissue: spleen, lymph nodes, and intestine. Lymphocytes of the secondary lymphoid organs are progeny from stem cells that have been influenced by primary lymphoid organs. The secondary lymphoid organs are thus composed of a mixture of B cells and T cells. Lymphopoiesis in secondary lymphoid organs depends solely on antigenic stimulation. B cells and T cells tend to localize in anatomically distinct parts of the lymphoid tissues, where proliferation can take place.

LYMPHOCYTE FUNCTION AND PHYSIOLOGY

T cells and their progeny function in cell-mediated immunity, which includes delayed hypersensitivity, graft rejection, graft-versus-host reactions, defense against intracellular organisms (such as tubercle bacillus and *Brucella*), and defense against neoplasms. B cells and their progeny perform in humoral immunity, or in the production of antibodies, either as a lymphocyte or after transformation into a plasma cell.

A majority of circulating lymphocytes are T cells that have a life span of months to years. The B cells are a minor population (10%–20% of the lymphocytes), probably have a short life span measured in days (with the exception of memory B cells), and are distinguished by the presence of considerable Ig on their surface membranes.

Lymphocytes circulate in the blood and home to appropriate lymphoid organs. During fetal development, lymphocytes migrate from fetal liver to bone marrow or thymus. Later, pro-T cells migrate from the bone marrow to the thymus and immature B cells home to secondary lymphoid tissues. After thymic processing, virgin T cells also home to specific areas in the peripheral lymphoid tissues. The circulation of lymphocytes is regulated by multiple cell surface adhesion molecules and chemokines, including integrins, selectins, and leukocyte (L) selectin. The circulation and homing of lymphocytes is a very complex, multistep phenomenon, reviewed elsewhere (Springer, 1994; Paraskevas, 2009a). However, in the postcapillary venule of lymphoid tissue, the lymphocyte travels from the blood through the endothelium and into the lymphoid tissue, where it may stay or percolate through and return to the blood via the thoracic duct lymph. Small lymphocytes (Fig. 31-30) have little cytoplasm and, in electron micrographs, few organelles and relatively little RNA. After antigenic stimulation, small lymphocytes (B cells or T cells, depending on the nature of the antigen) become activated, increase their RNA synthesis, and undergo blast transformation. On Romanowsky-stained films, these blasts are large cells (15–25 μm) with abundant, rather deep blue cytoplasm, a large reticular nucleus with uniform chromatin, and prominent nucleoli. This cell is called the **reticular lymphocyte** (nonleukemic lymphoblast; **immunoblast**). If the blasts are derived from B cells, the new lymphocytes function

in the production of antibodies (B cells, plasma cells); if the blasts are derived from T cells, the progeny act in the cellular immune response. The latter is mediated by several soluble factors produced by the activated T cell, including IL-2, which induces the proliferation of T cells; IL-3, which is a multipotential colony-stimulating factor; IL-4, which promotes the proliferation of B cells; IL-5, which enhances the proliferation of eosinophils as well as B cells; IL-6, which promotes differentiation of B cells; lymphotoxin, which is directly toxic to cells; and migratory inhibitory factor, which promotes adherence of macrophages and keeps them at the site. Atypical lymphocytes (Fig. 31-31) are seen in certain viral infections such as infectious mononucleosis. These cells have large nuclei with fine chromatin and more abundant cytoplasm that often scallops around adjacent red blood cells. Large granular lymphocytes (Fig. 31-32) contain azurophilic granules in their cytoplasm; these cells most often represent cytotoxic T cells or natural killer cells.

Plasma cells have abundant blue cytoplasm, often with light streaks or vacuoles, an eccentric round nucleus, and a well-defined clear (Golgi) zone adjacent to the nucleus. The nucleus of the plasma cell has heavily clumped chromatin, which is sharply defined from the parachromatin and is often arranged in a radial or wheel-like pattern (Fig. 31-33).

SELECTED REFERENCES, 600**KEY POINTS**

- Anemia may result from decreased marrow production or shortened red cell survival.
- Nonmarrow diseases, such as endocrine, renal, and inflammatory disorders, significantly influence bone marrow function.
- Stem cell disorders, such as inherited and acquired aplastic anemias, and paroxysmal nocturnal hemoglobinuria usually affect more than one cell line.
- Hemolytic anemia may be caused by extrinsic factors, usually acquired, such as chemical agents or antibodies, or intrinsic factors, usually inherited, such as disorders of the red cell membrane or enzymes, or hemoglobinopathy.
- Polycythemia is defined by laboratory parameters and may be absolute with an increase in total red cell mass as a result of increased erythropoietin production, or relative as a result of a decrease in plasma volume.

ANEMIAS**GENERAL MANIFESTATIONS**

Anemia is considered to be present if the hemoglobin (Hb) concentration or the hematocrit (Hct) is below the lower limit of the 95% reference interval for the individual's age, sex, and geographic location (altitude) (Table 32-1). This means that 2.5% of normal individuals will be classified as anemic. Conversely, an individual whose Hb falls within the reference intervals for age and sex yet significantly below his or her own reference values should be considered anemic.

Anemia may be absolute, when red blood cell mass is decreased, or relative, when associated with a higher plasma volume. Causes of absolute anemia fall into two major pathophysiologic categories: impaired red cell production and increased erythrocyte destruction or loss in excess of the ability of the marrow to replace these losses. Several authors have included posthemorrhagic anemia in the latter category (Hillman, 1996; Erslev, 2001b). The presence of anemia may be a sign of an underlying disorder

Hb, Hemoglobin.

whose cause should be identified because correction may be very important to the individual. Relative anemia may occur with pregnancy, with macroglobulinemia, and in postflight astronauts. However, recent studies suggest that prolonged exposure to weightlessness and return to sea level after a period of high altitude acclimatization are associated with selective loss of young red cells, also known as neocytes, as a result of erythropoietin (EPO) withdrawal (Risso, 2007).

Anemia may be classified by red cell morphology as macrocytic, normocytic, or microcytic—an approach that is useful in differential diagnosis (see later discussion). Both pathophysiologic and morphologic classifications should be understood. Some anemias (e.g., blood loss anemia) have more than one pathogenetic mechanism and go through more than one morphologic stage.

Clinical signs and symptoms result from diminished delivery of oxygen (O₂) to the tissues and, therefore, are related to the lowered Hb concentration and blood volume, and are dependent on the rate of these changes. Modifying factors include compensatory adjustments in cardiac output, respiratory rate, and O₂ affinity of Hb. When anemia develops slowly in a patient who is not otherwise severely ill, Hb concentrations as low as 6 g/dL may develop without producing any discomfort or physical signs, as long as the patient is at rest.

In general, the anemic patient complains of easy fatigability and dyspnea on exertion, and often of faintness, vertigo, palpitations, and headache. The more common physical findings are pallor, a rapid bounding pulse, low blood pressure, slight fever, some dependent edema, and systolic murmurs. In addition to these general signs and symptoms, certain clinical findings are characteristic of the specific type of anemia.

IMPAIRED PRODUCTION—IRON DEFICIENCY ANEMIA

Iron Metabolism

(Andrews, 2009).

Iron is an essential component of Hb, of myoglobin (in muscle cells), and of certain enzymes (in most body cells). The major “pools” of iron in the body are illustrated in Figure 32-1. Two thirds or more of the body’s total iron is in the erythron (normoblasts and erythrocytes); each milliliter of red cells contains about 1 mg of iron. Storage iron is present in macrophages of the reticuloendothelial system in two forms: ferritin and hemosiderin. Ferritin is a water-soluble complex of ferric salt and a protein, apoferritin. Apoferritin has a molecular weight of approximately 450,000 Da and consists of 24 subunits with a variable ratio of H (heavy) and L (light) types. Apoferritin forms a shell around a crystalline core of predominately ferric oxyhydroxide (FeOOH). The genes for the H and L subunits have been located on chromosomes 11 and 19, respectively. Hemosiderin is water insoluble and consists mostly of aggregates of ferric oxyhydroxide core crystals with partially or completely degraded protein shells. Protein degradation usually occurs in lysosomes. The iron in hemosiderin is much more difficult to release than that of ferritin. Most of the iron utilized in Hb synthesis is that recently released from degraded Hb in macrophages and transported to the normoblasts by plasma transferrin

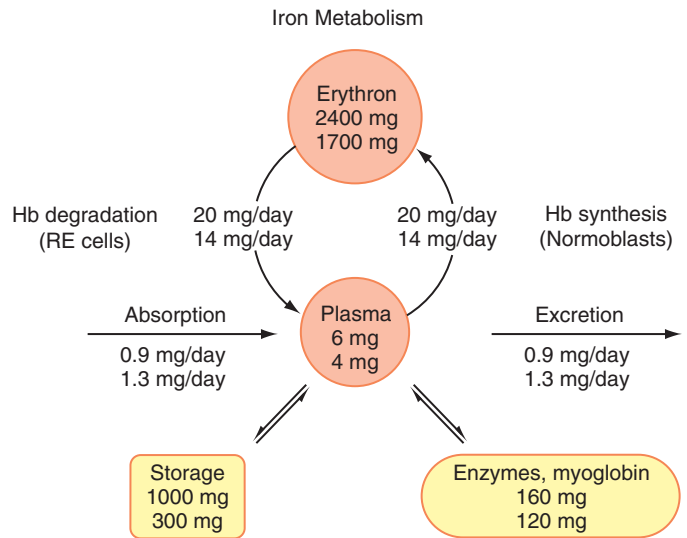

Figure 32-1 Scheme of iron metabolism. The upper figure in each position is average for an 80-kg man; the lower figure is for a 65-kg woman. (Data from Hillman and Finch, 1974.) The plasma iron, bound largely to transferrin, is central in this scheme. It completely turns over several times a day in supplying iron for heme synthesis. Each day, about $\frac{1}{200}$ of total circulating red cells are destroyed, and the same number of new red cells is delivered to the blood. That proportion of the total erythron iron enters the plasma from the site of hemoglobin (Hb) degradation, the macrophages of the reticuloendothelial (RE) system, and travels (bound to transferrin) to the normoblasts in the marrow. Storage iron largely resides also in the macrophages of the RE system. Absorbed iron enters the plasma pool, bound to transferrin. Iron is largely excreted by loss of cells.

(a β -globulin, molecular weight 80,000 Da, gene located on chromosome 3). Each molecule of apotransferrin binds two atoms of ferric iron. Subsequently, transferrin binds to transferrin receptors (TfRs) (CD71) on the cell membrane of erythroid precursors, reticulocytes, and most body cells. The transferrin–transferrin receptor complex is rapidly internalized, iron is released, and apotransferrin returns to the circulation and binds more iron. In addition to transferrin receptors, hepatocytes express a related molecule designated as transferrin receptor 2. Although its physiologic function is not clearly understood, mutations in the transferrin receptor 2 gene have been associated with hemochromatosis.

Very little iron is lost from the body; this small iron loss occurs mainly as loss of cells from the gastrointestinal (GI) tract and to a lesser extent from the skin and through the urine. The iron excreted in women averages more than that excreted in men because of menstrual blood loss. About 1 mg is lost each day, except in menstruating females, whose iron loss averages about 2 mg/day. Iron balance is maintained by control of absorption. In the United States, dietary iron averages 15 mg/day with 7% absorption in men, and 11 mg/day with 13% absorption in women. Absorption can be increased in iron deficiency, but only to about 20% of ingested iron in meat-containing diets, and less in vegetarian diets (Hillman, 1996). Absorption takes place largely in the small intestine, most efficiently in the duodenum and upper jejunum, with heme iron absorbed more efficiently than inorganic iron. Iron absorption is facilitated by ascorbate and citrate and is inhibited by phytates and tannins. Acid production by the stomach lowers the pH in the duodenum, thus enhancing the solubility and uptake of nonheme ferric iron. Although the mechanism of iron entry into mucosal cells of the upper GI tract remains largely unknown, more than one pathway seems to be in place, including an independent mechanism for heme absorption.

Recent studies suggest the presence of an iron transport channel called the divalent metal transporter (DMT), which is regulated by iron regulatory proteins 1 and 2. DMT-1 regulates iron transport from intestinal surface to inside the cell. This process is aided by the recently discovered duodenal cytochrome *b*-like ferredoxin, which reduces iron to the ferrous form. The export of iron from enterocytes, macrophages, and hepatocytes to plasma involves another transport system, which includes ferroportin-1 and hephaestin (Fleming, 2008). Ferroportin-1 is located at the basolateral membrane of apical enterocytes and functions as a transport protein delivering iron to the plasma. Hephastin, named after the Greek god **Hephaestus**, who forged iron, has a ferroxidase activity that contributes to iron transport by transforming iron to the ferric form to enable its uptake by circulating apotransferrin. Ceruloplasmin also has ferroxidase activity and is involved as well in the release of iron from the cells. Because

both ceruloplasmin and hephaestin are copper-containing ferroxidases, copper deficiency affects iron release and can produce iron deficiency anemia. Another recently identified 25-amino-acid antimicrobial peptide, hepcidin, has been shown to play a major role in iron homeostasis, possibly through a hormonal effect. Hepcidin is produced by the liver, is filtered by the kidney, and accumulates in urine. Hepcidin negatively controls the release of iron from cells, such as intestinal epithelium and macrophages, to the plasma. Hepcidin combines with ferroportin-1, leading to internalization and lysosomal degradation of both proteins; thus it limits the release of intracellular iron into the plasma (Fleming, 2008). Several proteins play a role in the regulation of hepcidin expression, which proved to be an intricate process that is still under study. These include a glycosylphosphatidyl inositol (GPI)-membrane-linked protein called hemojuvelin, TFRs 1 and 2, and human hemochromatosis protein, in addition to other groups of mediator proteins (Anderson, 2009).

In the plasma, total iron averages 110 $\mu\text{g/dL}$ (19.7 $\mu\text{mol/L}$). The great majority of this is bound to the transferrin, which has a capacity to bind 330 μg of iron per deciliter (or 59.1 $\mu\text{mol/L}$) and therefore is about one-third saturated. A very small amount of iron in plasma is in ferritin. Plasma (or serum) ferritin averages about 100 $\mu\text{g/L}$ in men (less in women—about 50 $\mu\text{g/L}$).

Iron Deficiency Anemia

When iron loss exceeds iron intake for a time long enough to deplete the body's iron stores, insufficient iron is available for normal Hb production. When well developed, iron deficiency is characterized by a hypochromic microcytic anemia.

Iron deficiency typically results when the need for iron is increased (e.g., during rapid growth in infancy and childhood, during pregnancy) or when excessive loss of blood has reduced the body's reserves of iron (e.g., following repeated hemorrhages, excessive menstruation, or multiple pregnancies).

Iron deficiency is probably the most common cause of anemia on the planet, affecting at least one third of the world's population (Brittenham, 2009). Children between the ages of 6 and 24 months are particularly susceptible. It is caused by insufficient dietary iron to meet the needs of rapid growth. After the first 4–6 months of life, the iron stores present from birth have been exhausted, and the infant depends on dietary iron. An infant maintained on milk and carbohydrates without supplements of iron-containing foods is likely to develop iron deficiency anemia—one component of the “milk anemia” of infancy. This anemia is also frequently related to intestinal blood loss due to cow's milk protein intolerance in young children when cow's milk is introduced too early. In a study in the United States, iron deficiency anemia was reported in 3% of toddlers aged 1–2 years and in 2%–5% of adolescent girls and women of childbearing age, with iron deficiency (absent anemia) noted in higher (>9%) proportions (Looker, 1997). Defective absorption of iron and eventual iron deficiency anemia occur after total gastrectomy or even subtotal gastrectomy. Prolonged treatment of peptic ulcer and acid reflux by H_2 blockers and acid pump blockers may cause defective iron absorption. Except for the sprue syndrome, causes of malabsorption of iron are extremely rare. Because iron deficiency increases the rate of absorption of both iron and lead, lead intoxication may accompany iron deficiency.

If an adult male had absolutely no iron intake or absorption (which would be extremely unlikely), his body iron stores of 1000 mg would last for 3–4 years before he would even begin to become iron deficient. Therefore, almost all cases of iron deficiency anemia in adult males are due to chronic blood loss. Hemorrhagic lesions, such as benign and malignant tumors, chronic ingestion of some medications, and helminthic infections are common causes of iron deficiency in males and postmenopausal females.

The sequence of events in developing iron deficiency anemia is usually as follows (Hillman, 1996): When blood loss exceeds absorption, a negative iron balance exists. Iron is mobilized from stores, storage iron decreases, plasma ferritin decreases, iron absorption increases, and plasma iron-binding capacity (transferrin) increases. This stage is known as **iron depletion**. After iron stores are depleted, the plasma iron concentration falls, saturation of transferrin falls below 15%, and the percentage of sideroblasts decreases in the marrow. As a result of lack of iron for heme synthesis, red cell protoporphyrin increases. This second stage is **iron-deficient erythropoiesis**; anemia may not yet be present. The third stage is **iron deficiency anemia**; in addition to the abnormalities just discussed, anemia is detectable. The anemia at first is normochromic and normocytic, gradually becomes microcytic, and finally becomes microcytic and hypochromic.

Figure 32-2 Iron deficiency anemia, post transfusion. The cells are pale with an enlarged central pallor, in sharp contrast to the transfused normochromic cells.

Clinical Features

Clinical findings may be due to the underlying cause of the blood loss itself, to the general manifestations of anemia (see previous discussion), or to iron deficiency. Those that are probably attributable to lack of tissue iron include paresthesias, such as numbness and tingling; atrophy of epithelium of the tongue with burning or soreness; fissures or ulcers at the corners of the mouth (angular stomatitis); chronic gastritis, which leads to decreased gastric secretions but few symptoms; “pica,” which is the craving to eat unusual substances such as dirt or ice; concave or spoon-shaped nails (koilonychia); and difficulty swallowing due to “webs” of tissue or partial strictures at the junction of the esophagus and hypopharynx. The latter two findings are relatively uncommon. The combination of glossitis, sore mouth, dysphagia, and iron deficiency is called Plummer-Vinson syndrome. Splenomegaly may occur in iron deficiency but is uncommon. A high prevalence of iron deficiency with or without anemia has been reported in patients with restless legs syndrome (Brittenham 2009).

Laboratory Features

Blood. In early iron deficiency anemia, the stained blood film often shows normochromic normocytic erythrocytes (Hillman, 1996). In later stages, the picture is one of microcytosis, anisocytosis, poikilocytosis (including elliptical and elongated cells), and varying degrees of hypochromia. The plasma membranes of iron-deficient cells are abnormally stiff, and this abnormality contributes to the development of poikilocytes, particularly elongated hypochromic elliptocytes (pencil cells). Anisocytosis may be identified by automated blood counters as increased red cell distribution width (RDW). This finding, however, is not specific for iron deficiency anemia. Reticulocytes are usually decreased in absolute numbers, except following iron therapy. The mean corpuscular volume (MCV) is low, and Hb and Hct are relatively lower than the erythrocyte count. Osmotic fragility may be decreased because the red cells are thinner than normal (see Figs. 30-10 and 32-2).

The leukocyte count is normal or slightly lowered. Granulocytopenia and a small number of hypersegmented neutrophils may be present. Megaloblastic changes in severe iron deficiency may be related to decreased activity of the enzyme ribonucleotide reductase, which contains an essential nonheme iron atom (Beck, 1991). However, the detection of hypersegmented neutrophils should raise suspicion for a mild folate deficiency, which may become more overt after iron therapy (Dallman, 1993). Platelets may be increased, whether the lack of iron is due to blood loss or dietary deficiency, but tend to be decreased in severe anemia.

Marrow. Normoblastic hyperplasia occurs early, but in later stages the limiting effect of severe iron deficiency restricts erythropoiesis to the basal level. The normoblasts are smaller than normal, deficient in the amount of Hb in the cytoplasm, and irregular in shape with frayed margins (Fig. 32-3). Giant neutrophil bands or metamyelocytes, if present, are rarely due to iron deficiency *per se*; usually, they indicate an associated cobalamin or folate deficiency (see later under Megaloblastic Anemia). Iron stains should be performed routinely (Figs. 32-4 and 32-5). **Storage iron** is absent, unless iron has recently been administered in some form. The proportion of normoblasts that are **sideroblasts** is decreased (<20%); this proportion is usually about the same as the percent saturation of transferrin (or total iron-binding capacity [TIBC]) and is a measure of iron delivery to the normoblasts.

Figure 32-3 Marrow film, iron deficiency anemia. The three normoblasts have irregular margins and irregular clear spaces, reflecting lack of hemoglobin synthesis (i.e., defective cytoplasmic maturation).

Figure 32-4 Marrow film, Prussian blue reaction. Depleted iron stores: No blue-green staining iron is visible. On a scale of 0–5+, the iron is normal from 1+ to 3+ for women and from 2+ to 3+ for men.

Figure 32-5 Marrow film, Prussian blue reaction. On a scale of 0–5+, the amount of storage iron is judged at 5+, which is markedly increased.

Serum Iron. The reference interval is 50–160 $\mu\text{g/dL}$ (9–29 $\mu\text{mol/L}$) in adults. The level is lower in iron deficiency and in infection and anemia of chronic disease.

Serum (Total) Iron-Binding Capacity. The reference interval for adults is 250–400 $\mu\text{g/dL}$ (45–72 $\mu\text{mol/L}$). In iron deficiency anemia, the serum TIBC is increased. It is normal or decreased in the anemia of chronic disease. If chronic infection coexists with chronic blood loss, the TIBC may not be increased, even though the patient is iron deficient.

Percent Saturation of TIBC. The ratio of serum iron to TIBC is the percent saturation of the TIBC. Normally, this is 20%–55%; values below 15% indicate iron-deficient erythropoiesis.

A marked diurnal variation in serum iron by as much as 30% normally occurs, with highest values in the morning and lowest values late in the day. Consequently, fasting morning blood specimens are preferred for the diagnosis of iron deficiency. The TIBC remains relatively constant in a normal individual. Pregnancy and oral contraceptives increase TIBC.

Serum iron is usually higher in the first 90 days of life; then it dips to somewhat lower reference intervals for the second month of life, and the value gradually increases with age, until it reaches the adult range approximately at the age of 15 years (Ritchie, 2002b; Soldin, 2004). On the other hand, the TIBC gradually rises with age until it reaches values that are comparable to those of adults at the age of 15 years (Soldin, 2004). Similarly, percent saturation in children is less than in adults; it reaches the adult value between the ages of 15 and 18 years (Ritchie, 2002b).

Serum Ferritin. In adults, the reference values are 12–300 $\mu\text{g/L}$, with higher values in men than in women. Serum ferritin appears to be in equilibrium with tissue ferritin and is a good reflection of storage iron in normal subjects and in most disorders. The equivalence of 1 $\mu\text{g/L}$ of serum ferritin with 8–10 mg storage iron has been suggested. In patients with some hepatocellular diseases, malignancies, and inflammatory diseases, serum ferritin is a disproportionately high estimate of storage iron because serum ferritin is an acute phase reactant. In such disorders, iron deficiency anemia may exist with a normal serum ferritin concentration. In the presence of inflammation, persons with a serum ferritin level of less than 50–60 $\mu\text{g/L}$ are likely to respond to iron therapy. On the other hand, hypothyroidism and ascorbate deficiency may lower plasma ferritin levels independent of iron stores (Brittenham, 2009).

In infancy and childhood, between the ages of 6 months and 15 years, the reference interval for serum ferritin is somewhat lower than in early infancy or adult life (Soldin, 2004). In men, serum ferritin gradually rises between the ages of 18 and 30 years, whereas in women, it does not. However, postmenopausal women have a much higher ferritin level than premenopausal women, and it is comparable with that of men (Van den Bosch, 2001). Serum ferritin levels do not display diurnal variation.

Erythrocyte Porphyrins. Because heme is formed by insertion of iron into protoporphyrin IX, the latter is increased in iron-deficient erythropoiesis, whether owing to iron deficiency or to anemia of chronic disease. It is also increased in lead poisoning and in some cases of sideroblastic anemia but is normal in thalassemia. Zinc usually becomes attached to protoporphyrin, forming zinc protoporphyrin (ZPP). A relatively simple micromethod measuring ZPP in whole blood has been shown to be useful in distinguishing microcytosis due to iron deficiency from that due to β -thalassemia minor (Labbé, 2004). The normal reference interval was 10–99 $\mu\text{g/dL}$ of erythrocytes; in iron deficiency, erythrocyte porphyrins became elevated before the development of anemia, and this may be one of the earliest indicators of iron deficiency (Labbé, 2004).

Serum Transferrin Receptors. TfRs also exist in a soluble form in the circulation. Serum TfRs (STfRs) are produced by shedding of membrane TfRs during erythrocyte maturation. STfRs vary with the rate of erythropoiesis. Patients with aplastic anemia (AA) have lower than normal levels of STfRs, and patients with autoimmune hemolytic anemia have higher values. Iron deficiency anemia is associated with increased serum levels of TfRs, probably as a result of increased membrane TfR synthesis and expression secondary to iron starvation. Unlike serum ferritin, STfRs are usually not affected by inflammation (Clark 2009).

Serum Transferrin Receptor-to-Serum Ferritin Ratio. The serum transferrin receptor-to-serum ferritin (TfR/F) ratio has been suggested as a new approach to estimate total body iron stores. However, it appears to have limited value in identifying anemia of chronic disease (ACD). The TfR/F ratio may be better utilized in identifying iron deficiency anemia coexisting with ACD (Clark, 2009).

Reticulocyte Hemoglobin Content. Some automated hematology analyzers offer an assay of Hb content within reticulocytes (CHr; in pg/cell). By measuring CHr, the status of erythropoiesis in the previous 3–4 days may be assessed using reticulocytes as a guide (Clark, 2009).

Hepcidin Level. Measuring plasma hepcidin may serve as a valuable tool in the study of abnormalities of iron metabolism and iron deficiency. Hepcidin level measurement is currently undergoing numerous studies.

Differential Diagnosis

Anemia due to iron deficiency usually needs to be distinguished from other causes of microcytosis with or without anemia. These include the thalassemia traits, long-standing ACD, and the sideroblastic anemias (see later

Figure 32-6 Blood film, megaloblastic anemia. Macrocytosis and a circulating megaloblast with abnormal, binucleated nucleus and open chromatin.

Figure 32-7 Hypercellular marrow in megaloblastic anemia. Cellularity is over 95%.

discussions of these entities). Bone marrow storage iron and serum ferritin will be decreased in iron deficiency and normal or elevated in all others. In **thalassemia trait**, the ZPP is normal, serum iron is normal, and the condition is present in family members. In β -thalassemia trait, Hb A₂ and sometimes fetal hemoglobin (Hb F) are increased. Yet, Hb A₂ is often decreased in iron deficiency. In **ACD** (chronic infection, rheumatoid arthritis, or neoplastic disease), although the serum iron is low, as in iron deficiency, the TIBC is low or normal. In the **sideroblastic anemias**, which include chronic lead poisoning, the serum iron and percent TIBC saturation are increased, and pathologic “ring” sideroblasts are present in the marrow.

Management

The first principle in therapy of iron deficiency anemia is that the underlying cause can be identified and corrected. Ferrous iron is given orally—at about 200 mg/day—in three doses between meals. This will provide 40–60 mg of absorbed iron per day, which, with the iron produced by turnover of senescent red cells, will be sufficient to increase production to two or three times normal (Hillman, 1996). The reticulocyte count will reach a maximum at 5–10 days, then will gradually decrease toward normal. Monitoring the Hb is best; Hb should increase by 0.1–0.2 g/dL/day after the fifth day, and by at least 2 g/dL for each of the subsequent 3 weeks. After the Hb has returned to normal, iron therapy should be continued for at least 2 months to replenish storage iron. Patients refractory to treatment need to be investigated for continued underlying diseases, particularly chronic gastritis and *Helicobacter pylori* gastritis (Clark, 2009).

IMPAIRED PRODUCTION—MEGALOBlastic ANEMIA

Macrocytosis With Normoblastic Marrow

Macrocytic anemias that are not megaloblastic may be due to early release of erythrocytes from the marrow, so-called shift reticulocytes. This may occur in response to acute blood loss, hemolysis, bone marrow infiltration, and high levels of EPO associated with bone marrow failure diseases such as aplastic anemia, refractory anemia, and Diamond-Blackfan anemia. Nonmegaloblastic macrocytosis is also found in hypothyroidism, in individuals with excessive alcohol intake, and in liver disease (Hillman, 1996).

Megaloblastic Anemia

Blood

Macrocytic anemias associated with megaloblastosis differ from nonmegaloblastic macrocytic anemia in that macroovalocytes and giant hypersegmented neutrophils are present in the blood (Figs. 30-11, 30-15, and 32-6). Pancytopenia is the rule. The anemia is macrocytic with an elevated MCV and is characterized by macroovalocytes and often extreme degrees of anisocytosis and poikilocytosis. Microcytes and dacryocytes are common. Basophilic stippling, multiple Howell-Jolly bodies, nucleated red cells with karyorrhexis, and even megaloblasts may be seen. Leukopenia is present. Granulocytes have increased numbers of lobes, presumably as a result of abnormal nuclear maturation. Five lobes in more than 5% of the neutrophils constitute hypersegmentation (Herbert, 1985), as do any neutrophils with six or more lobes. Thrombocytopenia is usually encountered and on rare occasions is sufficiently severe to be responsible for bleeding. It is

worth noting that significant morphologic changes may occur in the blood in the absence of anemia, and that neurologic symptoms may be present in the absence of anemia.

Marrow. Megaloblastic anemia is characterized by enlargement of all rapidly proliferating cells of the body, including marrow cells. The major abnormality is the diminished capacity for deoxyribonucleic acid (DNA) synthesis. In cobalamin or folate deficiency, marked reduction in intracellular 5,10-methylene tetrahydrofolate occurs and is required to transform deoxyuridine monophosphate to deoxythymidine monophosphate. This reaction is mediated by thymidylate synthase and is essential to maintain the normal rate of DNA synthesis (Antony, 2009). With such deficiency, the cells have both a prolonged intermitotic resting phase and a block early in mitosis. The number of mitotic figures is increased. Ribonucleic acid (RNA) synthesis is less impeded than DNA synthesis; hence, cytoplasmic maturation and growth continue, accounting for enlargement of the cells. The delicate chromatin and the prominent parachromatin result in a distinctly more “open” chromatin pattern than is seen in the erythroid precursors (Figs. 30-28 and 32-6). The nuclei undergo karyorrhexis readily, and multiple Howell-Jolly bodies may be present. Usually more cells analogous to the pronormoblast and the basophilic normoblast are noted (i.e., promegaloblast and basophilic megaloblast) than are seen in normal erythropoiesis. This has sometimes been termed **maturation arrest**, or nuclear-cytoplasmic asynchrony. Giant polychromatic megaloblasts are especially distinctive. The same general features are seen in the other cell lines. In the granulocytic series, the cells are larger, with retarded nuclear maturation and large cytoplasmic mass; often the specific granules themselves are distinctly larger. The chromatin pattern is less condensed (more “open”), and as a result the nucleus appears to stain poorly. Abnormally contorted nuclear configurations are common. The giant metamyelocyte is the most characteristic of the abnormal granulocytes. Megakaryocytes, too, are large and have separated nuclear lobes or nuclear fragments.

The bone marrow is hyperplastic (Fig. 32-7). The fat is replaced, and red marrow extends into the long bones. The number of erythroid precursors (megaloblasts) is increased, and the myeloid/erythroid ratio is decreased. If the megaloblastic process is incompletely developed, or if the patient has been inadequately treated, the findings may be only partial. Because they persist longer, granulocytic alterations are especially helpful in assessing recently treated megaloblastic anemia. Marrow findings result from the effects of impaired nucleic acid synthesis, leading to megaloblastosis and hypoxic stress, giving rise to increased numbers of erythroid cells. If the patient is transfused with packed red cells, the number of erythroid precursors diminishes, but the cytologic abnormalities persist.

Erythrokinetics. In megaloblastic anemias, the mass of erythroid tissue is increased, plasma iron turnover is rapid, and urine and fecal urobilinogen are increased. These measures indicate an **increase in total erythropoiesis** that may be up to three times normal. The decreased rate of appearance of iron in the Hb of circulating erythrocytes and reticulocytopenia indicate **ineffective erythropoiesis**. In addition to increased destruction of defective erythroid precursors in the marrow, survival of circulating erythrocytes is short, indicating hemolysis. Indirect serum bilirubin is increased, serum iron is increased, endogenous carbon monoxide (CO) production is increased, and serum lactate dehydrogenase is usually greatly elevated. Serum muramidase may be elevated, implying ineffective granulocytopoiesis.

Megaloblastic anemia is nearly always due to cobalamin or folic acid deficiency. The aforementioned findings are similar for either.

Cobalamin (Vitamin B₁₂) Metabolism

Vitamin B₁₂ (cyanocobalamin) has a molecular weight of 1355 Da. The molecule's two major parts are (1) a **planar group** (the corrin nucleus), a ring structure surrounding a cobalt atom; and (2) a **nucleotide group**, which consists of the base, 5,6-dimethylbenzimidazole, and a phosphorylated ribose esterified with 1-amino,2-propanol. A cyanide group is in coordinate linkage with the trivalent cobalt. Different forms of vitamin B₁₂ result from replacement of the cyanide by hydroxy, adenosyl, or methyl groups; generically, these are termed **cobalamins**.

Cobalamin is the only vitamin exclusively synthesized by microorganisms. It is found in practically all animal tissues and is stored primarily in the liver in the form of adenosylcobalamin. The human liver contains approximately 1 µg/g of liver. Cobalamin is initially bound to R binders (cobalamin-binding proteins with Rapid electrophoretic mobility) present in saliva or food, is released by peptic digestion, and is then bound by other R binders at the acid pH of the stomach. On entering the duodenum, cobalamin is released by pancreatic enzymes to finally bind to gastric intrinsic factor (IF), a 44-kDa glycoprotein produced in the parietal cells of the stomach. The gene for IF is located on chromosome 11. This cobalamin-IF complex, which is highly resistant to digestion, then adheres to specific receptor sites on the epithelial cells of the ileum, at which site the cobalamin is absorbed. A recent study indicates that the cobalamin-IF receptor is a combination of two proteins: a 460-kDa protein called cubilin, and a 45–50-kDa protein called amnionless. Both proteins are also present in renal tubules. Mutation of any of the two genes can produce megaloblastic anemia with proteinuria, also known as Imerslund-Gräsbeck syndrome (Fyfe, 2004). The concentration of the receptor in the ileum increases progressively until it reaches its maximum near the terminal ileum. The cobalamin-IF complex is taken into the cell, where cobalamin is released and the IF is destroyed. The receptor recycles to the surface of the cell (Babior, 2001).

Cobalamin is transported in the plasma as methylcobalamin, while bound to a group of proteins named transcobalamin II (TC II) and haptocorrins (variously called TC I, TC III, R binder, cobalophilin [*vide infra*]). Ninety percent of newly absorbed cobalamin is bound to TC II, which serves as the chief transport protein, rapidly delivering the vitamin to the liver, hematopoietic cells, and other dividing cells. Some cobalamin binds to haptocorrins—a step that prevents its loss from the plasma; this cobalamin is a passive reservoir in equilibrium with body stores in the liver but not taken up by other body cells. The reference values for plasma cobalamin depend on the method of assay, but they commonly are 200–900 ng/L (150–670 pmol/L). One third of the binding sites on transcobalamins are normally occupied: 70%–90% of plasma cobalamin is bound to haptocorrins, mostly TC I; this is very slowly cleared from the plasma. The remainder is bound to TC II, which remains only about 5% saturated; much of newly absorbed cobalamin bound to TC II is removed from the plasma during the first few hours, but a small fraction remains bound for several weeks.

The relative importance of the transcobalamins is illustrated by the clinical effects of congenital deficiency. Lack of TC II results in severe megaloblastic anemia in infancy; yet the serum cobalamin level is normal. Lack of TC I is not accompanied by anemia or megaloblastosis; yet the serum cobalamin level is decreased (Antony, 2009).

TC I and III are R-type proteins. TC III is probably an isoprotein of TC I, which is unsaturated with cobalamin and thus less charged. Much of the serum TC III is released from granulocytes during blood clotting in vitro; TC III does not appear to bind significant amounts of plasma cobalamin under normal conditions. Haptocorrins (TC I and III) may arise from granulocytes, salivary glands, and liver, as well as from other tissues. Elevation of TC I and III accounts for the elevation of total cobalamin-binding proteins in myeloproliferative neoplasms. TC II is also synthesized by a variety of cells, including renal cells, enterocytes, and hepatocytes. TC II acts as an acute phase reactant; its levels are increased in inflammatory and infectious conditions (Carmel, 1999).

The daily requirement for cobalamin is in the range of 2–5 µg/day. The body's stores of 2–5 mg will last for several years if intake is cut off, as is the case when total gastrectomy is performed (Beck, 1991).

Cobalamin Deficiency

Although the true prevalence of cobalamin deficiency in the general population is unknown, it increases with age. Approximately 15% of adults older

than 65 years have laboratory findings of vitamin B₁₂ deficiency. This prevalence may be attributed to the high frequency of hypochlorhydria of 25%–50%, which has been reported in the elderly population (Antony, 2009). The widespread use of proton pump inhibitors to control gastric secretion is becoming a contributing factor (Oh, 2003). Cobalamin deficiency is produced by any of several mechanisms which are not always exclusive of each other and involve inadequate intake and reduced absorption.

Inadequate Intake

A dietary deficiency is an *extremely rare* cause of megaloblastic anemia in the United States and is seen only in persons who completely abstain from animal food, including milk and eggs. Only strict vegetarians are known to develop this form of cobalamin deficiency.

Defective Production of Intrinsic Factor

This is the most common cause of cobalamin deficiency.

Pernicious Anemia

Pernicious anemia (PA) is a “conditioned” nutritional deficiency of cobalamin that is caused by failure of the gastric mucosa to secrete intrinsic factor. This abnormality is genetically determined but usually is not manifested until late in life; less than 10% of cases occur in persons younger than age 40. The annual incidence of PA is approximately 25 new cases per 100,000 individuals over the age of 40 years. Positive family history is obtained in approximately 30% of patients (Antony, 2009). Modern surveys indicate that PA is as common in blacks as in Caucasians (Carmel, 1999).

Clinical Features

The disorder is equally common in males and females. Symptoms of **anemia** and the combination of skin pallor and jaundice giving a lemon-yellow appearance to the skin are often present. The tongue may be sore, smooth, and pale (atrophic glossitis) or red and raw (acute glossitis). **GI symptoms** may be prominent and include episodic abdominal pain, constipation, and diarrhea. Diffuse and irregular degeneration of the white matter of the **central nervous system (CNS)** characteristically involves the posterior and lateral columns of the spinal cord (subacute combined degeneration) and sometimes other sites. Symmetrical sensations of “pins and needles” of the distal extremities, numbness and tingling, loss of position sensation (difficulty with balance and gait), and loss of vibratory sensation (perhaps the most constant sign) are indicative of peripheral neuropathy and posterior column lesions. Lateral column involvement gives rise to weakness, spasticity, and increased deep tendon reflexes. Sometimes, the brain may be affected, and the patient shows irritability, emotional instability, or a change in personality. Neuropsychiatric disorders may be associated with cobalamin deficiency even without accompanying hematologic manifestations (Lindenbaum, 1988). Recent studies suggest that cobalamin is essential for the maintenance of certain levels of cytokines and growth factors in the CNS. Cobalamin deficiency has been reported to cause an increase in CSF levels of myelinotoxic cytokines, such as tumor necrosis factor- α , while decreasing myelinotrophic cytokines, such as interleukin (IL)-6 (Scalabrino, 2009).

Gastric Findings

Atrophic gastritis of varying degrees is found in most adults with PA, and gastric atrophy involving all coats of the wall in the remainder. IF and hydrochloric acid (HCl) are secreted by gastric parietal cells in the human; in adult PA, IF secretion is absent, and almost always histamine-refractory achylia and achlorhydria—decreased volume of gastric juice and lack of HCl secretion—are present.

Immune Abnormalities

Autoantibodies have been found in the serum of patients with pernicious anemia (Antony, 2009). **Anti-parietal cell antibodies** react with gastric parietal cells and are present in more than 90% of patients. These anti-parietal cell antibodies are also present in patients with chronic gastritis, such as that associated with iron deficiency, and in some patients with thyroiditis and myxedema; they are seen in 4%–5% of age-matched healthy individuals. When these antibodies are chronically injected into rats, they decrease gastric HCl, IF, and pepsin secretion and produce gastric atrophy. The major antigen to which these antibodies are produced is the acid-producing enzyme H⁺,K⁺-ATPase, a 92-kDa protein present on the luminal membrane of parietal cells, which is the target of proton pump inhibitors. A recent study suggests that antibodies to *H. pylori* are common

in PA, particularly in young patients. Infection may be the first step toward initiation of an autoimmune response (Hershko, 2007).

Another type of autoantibody is directed against intrinsic factor. **Anti-intrinsic factor antibodies** occur in the serum, saliva, and gastric juice of about 75% of patients with PA. Two types of anti-IF antibodies occur: “blocking” antibodies, which block the binding of cobalamin to IF; and “binding” antibodies, which bind to the cobalamin-IF complex and prevent the complex from binding to receptors in the ileum. Although these antibodies can cause some functional impairment in vivo, it is not clear whether the antibodies are the cause or an effect of the disease. IF antibodies in the absence of PA occur in a small percentage of individuals with hyperthyroidism (Graves’ disease), and similarly in persons with insulin-dependent diabetes. Therefore, IF antibodies are considered highly specific and confirmatory for PA, although their absence does not exclude the diagnosis (Antony, 2009).

Family studies in patients with pernicious anemia have shown an increased incidence of the disease in relatives, and many relatives have achlorhydria and partial defects of cobalamin absorption. Relatives of patients with pernicious anemia also have a higher incidence of gastric parietal cell antibodies and of thyroid antibodies than normal individuals.

It is possible that adult pernicious anemia is a genetically determined autoimmune gastritis. However, the relationship of the gastric lesion to the antibodies remains unclear.

Pernicious Anemia in Children

Two forms of PA are known to occur in children. **Congenital pernicious anemia** usually appears early in the second year of life. IF secretion may be lacking, or the secreted IF may be functionally defective, but acid secretion and the appearance of the gastric mucosa are normal. Antibodies to parietal cells and to IF are absent. **Juvenile pernicious anemia** occurs usually in older children and is like that of adults, with gastric atrophy, achlorhydria, and serum antibody to IF and parietal cells, although the latter may be absent in a subset of patients (Rosenblatt, 1999).

Gastrectomy

Surgical removal of the stomach (total or even subtotal occasionally) will remove the source of intrinsic factor. This will lead to megaloblastic anemia after the body’s stores of cobalamin have been exhausted—in 3 to 6 years—if cobalamin therapy has not been given. Frequently, the anemia is due in part to iron deficiency.

Defective Absorption of Cobalamin

Malabsorption Syndromes. Celiac disease, tropical sprue, resection of the small bowel, or inflammatory disease of the small bowel may be associated with multiple defects of absorption, including other vitamins. Folic acid deficiency (absorbed principally in the upper small bowel) is more commonly seen than cobalamin deficiency (absorbed principally in the lower small bowel) in diseases leading to malabsorption. The reason for this is probably the lesser time necessary for depletion of body stores of folic acid.

The Imerslund-Gräsbeck syndrome is an autosomally recessive inherited defect in the intestinal absorption of cobalamin that occurs in the presence of normal intrinsic factor. In many patients, proteinuria of the tubular type is also found. As mentioned earlier, the syndrome is caused by a defect in the cubilin/amnionless receptor (Fyfe, 2004).

Lack of Availability of Cobalamin. In certain countries, infestation with the fish tapeworm *Diphyllobothrium latum* is common enough that cobalamin deficiency may occur occasionally when it is present. The worm successfully competes with the host for the ingested cobalamin. Most common in Finland, it is rarely seen in the United States.

Bacteria in a blind loop of intestine may also preferentially utilize ingested cobalamin to the detriment of the host.

Vitamin B₁₂ or folate deficiency may exert indirect cardiovascular effects. Both deficiencies are associated with hyperhomocystinemia, which is an independent factor for atherosclerosis and vascular thrombosis (Oh, 2003).

Diagnosis of Cobalamin Deficiency

Recognition of megaloblastic anemia indicates the likelihood of cobalamin deficiency or folic acid deficiency. In addition, evidence of neurologic involvement favors cobalamin deficiency. This diagnosis can be established by one of four methods.

Therapeutic Trial. With the patient on a diet low in cobalamin and folate, a parenteral physiologic dose of cobalamin (10 µg/day) is given. Optimal hematologic response indicates deficiency and consists of reticulocytosis beginning on the third or fourth day, reaching a peak on the seventh day. Erythropoiesis becomes normoblastic by 2 days, and leukopoiesis becomes normal by 12 to 14 days. Within a week, leukocyte and platelet counts have returned to normal, and the Hb concentration begins to rise.

Serum Cobalamin Assay. This is the usual method of detecting a cobalamin-deficient state. The original microbiological assay of serum cobalamin employed an organism (e.g., *Euglena gracilis*) that requires cobalamin for growth. Although the microbiological method is precise and reliable, it requires at least 48 hours of incubation and is subject to the inhibitory effects of antibiotics. Radioisotopic dilution and chemiluminescence assays are more rapid and widely used and give results comparable with those of the *Euglena* assay, provided that the binding protein is specific for biologically active cobalamin; a standardized intrinsic factor preparation is most satisfactory. However, these methods may produce false-normal values in approximately 10% of patients with cobalamin deficiency (Zittoun, 1999).

Reference values are 200–900 ng/L. In megaloblastic anemia due to cobalamin deficiency, serum cobalamin is usually less than 100 ng/L. Individuals with folate deficiency and mild cobalamin deficiency and who are pregnant have borderline values between 100 and 200 ng/L. Patients with human immunodeficiency virus (HIV) infection or multiple myeloma and those receiving megadose vitamin C therapy often have low serum cobalamin levels in the absence of clinical manifestations (Ward, 2002; Antony, 2009). Spuriously normal cobalamin levels have been recorded in patients with cobalamin deficiency associated with overgrowth of intestinal bacteria, which produce biochemically inert B₁₂ analogs, and in patients with autoimmune disorders, myeloproliferative neoplasms, and active liver disease (Ward, 2002; Antony, 2009). Measurement of TC II-bound cobalamin (holotranscobalamin II) may provide additional information, in that its levels fall below the normal range long before total serum cobalamin does and probably represent a state of negative cobalamin balance (Zittoun, 1999). However, its clinical utility has been limited (Ward, 2002).

Methylmalonic Acid and Homocysteine Assays. Because a cobalamin coenzyme is essential for the isomerization of methylmalonate to succinate, urine excretion of increased amounts of methylmalonate is found in cobalamin deficiency. Provided that the rare inborn error of metabolism, methylmalonic aciduria, is not present, this is a sensitive test for cobalamin deficiency, but it is not usually necessary for the diagnosis. In addition, plasma levels of methylmalonic acid and homocysteine are increased. However, plasma levels of methylmalonate are normal in folate deficiency in the absence of cobalamin deficiency (Antony, 2009). Following several weeks of therapy, their plasma concentration returns to normal. Plasma levels of these metabolites should be interpreted with caution in patients with chronic renal failure because of the tendency of these metabolites to accumulate (Zittoun, 1999).

Deoxyuridine Suppression Test. This measures the ability of marrow cells in vitro to utilize deoxyuridine in DNA synthesis. Normally, in marrow cells, the major source of thymidine for DNA is de novo synthesis from deoxyuridine, which requires intact cobalamin and folate enzymes; therefore, less than 10% of added tritium-labeled thymidine (³H-Tdr) is incorporated into DNA. In megaloblastic marrows due to cobalamin or folate deficiency, deoxyuridine cannot be efficiently converted to thymidine, and more ³H-Tdr is taken up into DNA. An abnormal deoxyuridine suppression test indicates cobalamin or folate deficiency. This test is very sensitive and produces abnormal results before anemia or macrocytosis is observed (Zittoun, 1999). A lymphocyte microdeoxyuridine suppression test (Herbert, 1985) requires only 1 mL of blood, making this diagnostic modality available to infants and children.

Detecting the Cause of Cobalamin Deficiency

Clinical history is useful in suggesting whether cobalamin or folate deficiency is the cause of megaloblastic anemia. Clinical associations of pernicious anemia include a family history of PA in one third of patients, along with certain endocrine deficiencies (thyroid disease, diabetes mellitus, hypothyroidism, and Addison’s disease) and immune disorders (immune thrombocytopenic purpura, autoimmune hemolytic anemia, and acquired

hypogammaglobulinemia). Cobalamin deficiency is likely to occur in strict vegetarians and in patients with paresthesias, neuropathy, or a previous gastrectomy.

In cobalamin-deficient patients, it is important to determine whether IF is lacking. To do so, the ability of the patient to absorb an oral dose of radioactive cobalamin may be measured. The usual method is the Schilling test, which measures radioactivity in a 24-hour sample of urine. Two hours after oral administration of 0.5–2.0 µg of radioactive cobalamin, a large “flushing” dose of nonlabeled cobalamin is given parenterally. Normal individuals will excrete more than 7% of a 1-µg dose of ingested cobalamin in the urine in 24 hours, whereas patients lacking IF will excrete less. If excretion is low, the test must be repeated using the same procedure, except that hog IF is given orally, along with labeled cobalamin. If 24-hour excretion is normal, the low value in the first part was due to IF deficiency. If excretion remains abnormal in the second part of the procedure, an explanation for malabsorption of cobalamin on the basis of intestinal disease must be sought. The test may be repeated after 7–10 days of antibiotic administration if bacterial overgrowth is suspected, and pancreatic extracts may be added to investigate the possibility of pancreatic dysfunction (Antony, 2009). The validity of the results depends on good renal function and accurate urine collection. The Schilling test will be abnormal in PA even after the patient is treated with cobalamin and is in remission. Some patients may absorb vitamin B₁₂ in water (as given in the original Schilling test) but fail to absorb vitamin B₁₂ bound to protein in food. A modification of the Schilling test is being introduced to include protein-bound B₁₂ using egg yolk or chicken serum (Zittoun, 1999).

Other tests that will establish the diagnosis of PA include direct assay of IF in gastric juice. The combination of megaloblastic anemia, decreased serum cobalamin, and serum antibodies to IF is essentially diagnostic of PA, obviating the need for the Schilling test (Lindenbaum, 1983).

Folic Acid Metabolism

Folic acid or pteroylmonoglutamic acid contains three parts: pteridine, *p*-aminobenzoate, and L-glutamic acid (Beck, 1991). In nature, folic acid occurs mainly as less soluble polyglutamates, with multiple glutamic acid residues attached to one another. Folic acid is present in a wide variety of foods, such as eggs, milk, leafy vegetables, yeast, liver, and fruits, and is formed by intestinal bacteria as well. Folates are extremely thermolabile, and prolonged cooking (>15 minutes) in large quantities of water in the absence of reducing agents destroys folate.

Polyglutamates are hydrolyzed to monoglutamate by folate hydrolase, which is present in the brush border of proximal jejunum and has maximal exopeptidase activity at pH 5.5 (Antony, 2009; Hamid, 2009). Folates are transported across the intestinal membrane by a variety of carriers, including reduced folate carrier and proton-coupled folate transporter (Hamid, 2009). Another transport system carries folate across the basolateral membrane of the cell. In the plasma, one third of the folate is free, and two thirds is nonspecifically and loosely bound to serum proteins. A small amount of folate is specifically bound to folate-binding proteins, the physiologic significance of which is unclear (Antony, 2009). Folate is rapidly removed from plasma to cells and tissues for utilization. The principal form of folate in serum, erythrocytes, and liver is 5-methyltetrahydrofolate (5-methyl-FH₄); the liver is the chief storage site. Intracellular folates exist primarily as polyglutamates. A significant enterohepatic circulation is present, and bile contains 2–10 times the folate concentration of normal serum. Moreover, folates that are filtered in the renal glomeruli are extensively reabsorbed back into the renal circulation (Hamid, 2009). The minimal daily requirement is about 50 µg of pteroylmonoglutamate or 400 µg of total folate; a typical reference interval for serum folate is 5–21 µg/L (11–48 nmol/L), and for red cell folate, 150–600 µg/L (340–1360 nmol/L) of red blood cells.

The Folate–Cobalamin Relationship

Anemia of cobalamin deficiency is partially corrected by folate even in the absence of cobalamin supplementation, but the reverse is not true. Therefore, some of the megaloblastic manifestations in cobalamin deficiency are actually caused by abnormalities in folate metabolism (Antony, 2009). The most accepted theory for their interrelationship is the methylfolate trap theory. This theory is based on the observation that the methyl form of tetrahydrofolate (FH₄) would leak out of cells unless conjugated to form polyglutamates. Methyl FH₄ is a poor substrate for the conjugating enzyme. Cobalamin is essential for the process of conversion of methyl FH₄ to FH₄. Accumulation of methyl FH₄ is followed by its leakage out of the cells (Babior, 2001).

Folic Acid Deficiency

(Antony, 2009).

Inadequate Intake of Folate

Evolution of Laboratory Abnormalities. Herbert delineated the sequence of events in the onset of folate-deficient megaloblastic anemia. After a folate-deficient diet was initiated, various abnormalities were established as follows: 3 weeks, low serum folate; 5 weeks, hypersegmented neutrophils in bone marrow; 7 weeks, hypersegmented neutrophils in peripheral blood, with bone marrow showing increased and abnormal mitoses and basophilic intermediate megaloblasts; 10 weeks, bone marrow showing some large metamyelocytes and polychromatophilic intermediate megaloblasts; 13 weeks, high excretion of formiminoglutamic acid (FIGLU) in urine; 17 weeks, low erythrocyte folate; 18 weeks, macrovalocytosis of erythrocytes with many large metamyelocytes in bone marrow; 19 weeks, overtly megaloblastic bone marrow; and 20 weeks, anemia (Herbert, 1985).

At this time, changes in the intestinal epithelium have not yet appeared. Therefore, in the human, with no dietary intake of folic acid, anemia will appear in 3 to 6 months. The peripheral blood and bone marrow features of megaloblastic anemia due to folic acid deficiency are similar to those of cobalamin deficiency; however, leukopenia and thrombocytopenia are less constant. Folic acid deficiency has usually been found in association with some complicating factor.

Nutritional Folate Deficiency. Megaloblastic anemia due to lack of folate is most commonly associated with insufficient dietary intake. The usual diet does not contain much above the minimal requirements, and body stores in the adult are sufficient for only about 3 months' needs. Dietary folate deficiency is especially common in the tropics and in India, and even in those locations, it is usually associated with increased demand for folate in pregnancy, rapid growth in infancy, infection, or hemolytic anemia. Elderly persons on inadequate diets in the United States may develop folate-deficient megaloblastic anemia.

Folate deficiency in infancy is uncommon in the United States. Human milk or fresh cow's milk contains sufficient folate, but heated milk, powdered milk, and goat's milk do not. If the infant's milk lacks folate, if the diet is low in ascorbic acid, or if infection or diarrhea is a problem, megaloblastic anemia may occur.

Megaloblastic anemia in pregnancy is not uncommon because of the fetal requirements for folate. The mother's plasma folate level gradually falls during pregnancy, and at birth the plasma level in the newborn averages five times that of the mother. Megaloblastic anemia is more frequent in multipara, may be precipitated by infection, and is usually due to folate deficiency rather than cobalamin deficiency. Pregnant women should receive, in addition to iron, folic acid supplements. Recent studies indicate that folate supplementation for pregnant women reduces the risk of giving birth to babies with neural tube defects, with anencephaly and spina bifida being the most common defects.

Liver Disease. Liver disease associated with alcoholism may lead to folate-deficient megaloblastic anemia because of the grossly inadequate diet of the alcoholic, and because the liver is the major site for folate storage and metabolism (Zittoun, 1999). With adequate dietary folic acid intake, however, the anemia that is found with liver disease is macrocytic and normoblastic—not megaloblastic.

Defective Absorption of Folate

Defective absorption of folic acid occurs in association with malabsorption syndromes discussed previously and in the blind loop syndrome, in which bacteria preferentially utilize folate.

Nontropical sprue, or adult celiac disease, is an important cause of malabsorption in adults or children that is related to dietary gluten (wheat protein). Included among the signs of malabsorption may be megaloblastic anemia due to folic acid deficiency (Beck, 1991). Jejunal biopsy shows villous atrophy. The folate deficiency, as well as the malabsorption, responds to a gluten-free diet. Folic acid therapy (parenteral) corrects the folate deficiency, but not the general malabsorption.

Tropical sprue is a poorly understood malabsorptive disorder that is common in the Caribbean, India, and Southeast Asia. Evidence of malabsorption includes megaloblastic anemia due to folate deficiency. Treatment with folic acid brings considerable improvement in general malabsorption, as well as in the anemia, but additional antimicrobial treatment is recommended.

Megaloblastic anemia or decreased serum and red cell folate without anemia has been associated with the long-term use of anticonvulsant

drugs such as phenytoin, phenobarbital, and primidone. The problem appears to be a drug-induced malabsorption of pteroylpolyglutamate. Oral contraceptives cause malabsorption of folate in a small proportion of women, owing to impaired deconjugation of pteroylpolyglutamate (Beck, 1991).

Increased Requirement for Folate

The increased need in pregnancy and in infants has been mentioned. Increased cell turnover that occurs in neoplasia and in the markedly stimulated hematopoiesis of hemolytic anemias may result in megaloblastic erythropoiesis. The basis for this is the increase in need for a marginal supply of folate.

Inadequate Utilization of Folate

Inadequate utilization of folic acid is relatively rare. Folic acid antagonists such as methotrexate block folic acid metabolism and because of this are used in therapy of some malignant neoplasms. In addition to inhibiting growth of the tumor, they induce megaloblastic hematopoiesis.

In addition to the previously mentioned nutritional problem in alcoholics, **alcohol** may exert a direct effect in suppressing hematopoiesis by blocking the metabolism of folate. In addition, alcohol can interfere with folate absorption and folate enterohepatic circulation, usually resulting in increased loss of folate in urine (Hamid, 2009). Plasma homocysteine is usually elevated in alcoholics (Zittoun, 1999).

Diagnosis of Folate Deficiency

Folic acid deficiency or cobalamin deficiency is suspected when the blood and bone marrow show findings characteristic of megaloblastic anemia; usually, serum folate and cobalamin levels are then determined.

Serum and Red Cell Folate. A microbiological assay for folic acid activity employing *Lactobacillus casei* is a reliable method for definitive diagnosis (Beck, 1991). Radioisotopic and chemiluminescence methods employing different folate binders are widely used because of their rapidity and greater convenience. Although correlation with the microbiological assay is generally good, discrepancies seem to be frequent and, on the basis of other data, tend to be resolved in favor of the microbiological assay. False-normal red cell folate levels have been reported in 16%–40% of patients identified by microbiological assays (Zittoun, 1999). Unlike serum folate (which is entirely 5-methyltetrahydrofolate), red cell folates are a heterogeneous mixture of different forms with varying polyglutamate chain lengths, which pose challenges to nonmicrobiological assays.

The serum folate level is decreased (<3 µg/L) in megaloblastic anemia due to folate deficiency but is usually normal or increased in cobalamin deficiency. A low serum folate level precedes a decrease in red cell or tissue folate; it indicates a negative folate balance but does not by itself indicate tissue folate deficiency. Serum folate is highly sensitive to folate intake and may normalize after a single adequate meal, despite the presence of true underlying deficiency (Antony, 2009). In cobalamin deficiency, serum folate is decreased in 10% of cases, increased in 20%, and normal in the remainder (Tietz, 1990).

The red cell folate is a better test of body folate stores and is decreased in megaloblastic anemia due to folate deficiency. In cobalamin deficiency, however, red cell folate is low in almost two thirds of cases, so this needs to be excluded before a low red cell folate is taken as proof of severe folate deficiency. Therefore, three measurements are often useful in distinguishing between deficiencies of folic acid and cobalamin (Table 32-2).

Physiologic doses of folic acid (parenteral, 50–200 µg/day) will allow an adequate reticulocyte response in patients with folic acid deficiency, but not with cobalamin deficiency. On the other hand, the usual therapeutic doses of folic acid (5–15 mg/day) or larger doses of cobalamin (500–1000 µg) may induce a partial response in a patient with megaloblastic anemia due to the other deficiency. Treatment of cobalamin deficiency with folic acid is hazardous in that although a reticulocyte response may occur, neurologic damage will progress.

Urinary Formiminoglutamic Acid

Folic acid coenzymes are required for the conversion of FIGLU to glutamic acid in the catabolism of histidine. When oral histidine is given, FIGLU will appear in increased amounts in the urine if folate deficiency is present. The test is useful in patients with megaloblastic anemia due to antifolate drugs; these patients have normal serum folate levels but greatly decreased tissue coenzyme levels (Beck, 1991).

Deoxyuridine Suppression Test. See earlier discussion.

TABLE 32-2

Correlation of Vitamin B₁₂ and Folate Levels With Clinical Status: Three Laboratory Tests Needed to Separate Four Clinical Situations

Clinical situation	Serum vitamin B ₁₂ , pg/mL	Serum folate, ng/mL	Red cell folate, ng/mL
Normal*	Normal (200–900)	Normal (5–16), indeterminate (3–5), or low (<3)	Normal (>150)
Vitamin B ₁₂ deficiency	Low (<100)	Normal (5–16) or high (>16)	Low (<150)
Folic acid deficiency	Normal	Low	Low
Deficiency of both	Low	Low	Low

From Herbert V. Megaloblastic anemias. Lab Invest 1985;52:3–19.

*Normal includes transient states of negative folate balance.

Plasma Homocysteine Assay. As with cobalamin deficiency, total plasma homocysteine is increased in approximately 75% of patients with folate deficiency. The level of methylmalonic acid is normal (Zittoun, 1999).

Acute Megaloblastic Anemia

Acute megaloblastic anemia may develop over the course of only a few days. The most common cause has been related to nitrous oxide (N₂O) anesthesia. N₂O rapidly destroys methylcobalamin, causing a rapidly progressive megaloblastic anemia. Acute folate deficiency may occur in some patients in intensive care units because of a combination of factors (decreased intake, total parenteral nutrition, dialysis, surgery, sepsis, medications). Serum folate may be normal (Antony, 2009).

Therapy for Megaloblastic Anemia

Although it may be necessary to treat severely anemic patients with both vitamins, it is usually possible to determine which deficiency is the cause, and treat only for it.

The maximal reticulocyte response occurs in 5 to 7 days. Within 4 to 6 hours after the initial therapy (if parenteral), the marrow shows decreased early megaloblasts and the appearance of pronormoblasts. Within 2–4 days, the marrow is predominantly normoblastic. Granulocytic abnormalities return to normal more slowly, and hypersegmented neutrophils disappear from the blood only after 12–14 days.

PA is treated parenterally with 1000 µg of cyanocobalamin daily for 1 week, twice weekly for the second week, once weekly for 4 weeks, then monthly for the lifetime of the patient (Antony, 2009). High concentrations of oral cobalamin (e.g., 1000 µg per day) force absorption of some cobalamin through an alternate system. Some reports recommend the use of oral cobalamin therapy instead of injections (Oh, 2003).

In folate deficiency, oral therapy is generally used at a dosage of 1–2 mg/day. Cobalamin deficiency must be excluded and corrected if present, to avoid the occurrence of neuropathies of cobalamin deficiency. Supplemental dietary folic acid during pregnancy is reported to reduce the incidence of neural tube defects in the baby.

Other Defects of Nucleoprotein Synthesis

Other defects of nucleoprotein synthesis may lead to megaloblastic anemias that do not respond to cobalamin or folic acid.

Congenital Defects

Orotic aciduria is a very rare autosomal recessive condition in which certain enzymes required for pyrimidine synthesis are absent. Findings include excessive urinary excretion of orotic acid, failure of normal growth and development, and megaloblastic anemia that is refractory to cobalamin and folate but that responds to uridine.

Inborn defects in enzymes involved in folate metabolism, including methyltetrahydrofolate reductase and glutamate formiminotransferase deficiencies, have also been described.

Synthetic Inhibitors

Synthetic inhibitors of purine synthesis (6-mercaptopurine, thioguanine, azathioprine), of pyrimidine synthesis (5-fluorouracil), or of deoxyribonucleotide synthesis (cytosine arabinoside or hydroxyurea) are used

in chemotherapy for neoplasia and may concomitantly produce megaloblastosis.

Refractory Anemias

Anemias that are megaloblastic and that fail to respond to cobalamin or folic acid are considered with the myelodysplastic syndromes (see Chapter 33). The megaloblastic changes are usually atypical and do not include the characteristic granulocytic features, but other dysplastic changes are present.

IMPAIRED PRODUCTION—OTHER

Anemia of Chronic Disease

(Means, 2003).

ACD designates an anemia syndrome typically found in patients with chronic infections or inflammatory or neoplastic disorders; it is characterized by reduced reticulocyte response accompanied by low serum iron, despite adequate iron stores. It is also termed anemia of chronic disorder, inflammation, or cytokine response. ACD occurs in approximately 50% of hospitalized patients, as identified by laboratory studies. The frequency is higher in the elderly population. ACDs have also been observed in acute trauma and critical care patients.

Erythrocytes are usually normocytic and normochromic, although in 20%–50% of patients, the anemia is microcytic and hypochromic. Anisocytosis and poikilocytosis are slight. The reticulocyte count usually is not elevated. Leukocytes and platelets are not distinctively altered, except by the causative disease.

The marrow is normocellular or minimally hypocellular or hypercellular, and the cell distribution is not greatly disturbed. The normoblasts may have frayed hypochromic cytoplasm, and the appearance of Hb in the cells may be delayed (as in iron deficiency anemia). Sideroblasts are decreased, but storage of iron is normal or increased.

The serum iron concentration is characteristically decreased, the TIBC is decreased or normal (in contrast to iron deficiency anemia, in which the TIBC is elevated), and the percent saturation is decreased. Erythrocyte protoporphyrin and serum ferritin are elevated.

The most important pathogenetic mechanism of ACD is the presence of high levels of cytokines, which may result in decreased red cell survival, altered iron metabolism, direct inhibition of hematopoiesis, and decreased EPO secretion. Tumor necrosis factor- α (TNF- α) plays a significant role in inflammation and immune response. TNF- α levels are increased in patients with cancer, rheumatoid arthritis, infection, and the acquired immunodeficiency syndrome. In vitro inhibition of human erythroid colony formation, burst forming units-erythroid (BFU-E), and colony forming units-erythroid (CFU-E) by TNF- α has been reported. Similarly, an inhibitory action of IL-1 and interferon- γ (IFN- γ) on erythropoiesis has been implicated. Ceramide, a product of cytokine-induced enzymatic hydrolysis of cell membrane sphingomyelin, plays a role as a messenger in the inhibitory effects of IFN- γ (Means, 2003).

EPO levels, although above normal, have been disproportionate to the degree of anemia, indicating relative EPO deficiency in ACD. Inhibitory effects of cytokines on EPO synthesis sites such as renal and liver cells have been suggested. The relative deficiency of EPO induces neocytolysis (i.e., selective hemolysis of the youngest red blood cells). Thus, a mild hemolytic event usually accompanies ACD (Risso, 2007).

Recently, hepcidin has been shown to be elevated in ACD through induction by IL-6 and is considered an acute phase reactant. As mentioned earlier, hepcidin interferes with the release of intracellular iron. Recent evidence also suggests that hepcidin may exert an inhibitory effect on erythroid colony formation at certain levels of EPO, and thus may provide a bone marrow inhibitory effect (Dallaglio, 2006).

The anemia usually fails to respond to iron therapy. However, patients treated with EPO have shown improvement.

Anemia of Renal Insufficiency

A normocytic normochromic anemia is commonly encountered in patients with chronic renal failure (CRF). The correlation between severity of anemia and degree of elevation of blood urea nitrogen (BUN) is positive but not strictly linear. When creatinine clearance falls below 20 mL/min, the Hct is usually below 0.30 (Caro, 2006).

Several factors are often involved in the anemia of chronic renal failure. Decreased production of EPO by the damaged kidney is probably the important factor in most cases in which the BUN exceeds 100 mg/dL.

Both ineffective erythropoiesis and impaired ability of the marrow to respond to EPO appear to be present to some degree.

Inhibitors of erythropoiesis have been demonstrated in the plasma of patients with chronic renal failure. The nature of these inhibitory factors is not known; however, parathyroid hormone and spermine have been implicated as inhibitors of erythropoiesis. Recent studies indicate the presence of a high level of inflammatory cytokines, such as IL-1, IL-4, IL-6, and TNF- α , in patients with CRF. As discussed under Anemia of Chronic Disease, these cytokines exert a bone marrow suppressive effect and probably contribute to the development of anemia (Stenvinkel, 2003). The role of hepcidin in this type of anemia is also being investigated.
