Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

In Memoriam

John Bernard Henry, MD

1928–2009

It was with a profound sense of sadness and loss that we learned of the passing of Dr. John Bernard Henry, editor of seven editions of this textbook from 1969 to 2001. Dr. Henry, who died in Skaneateles, New York, on April 10, 2009, was a superb academic physician who made immense contributions to medicine, especially to the development of the medical laboratory in both the diagnosis and treatment of human disease.

John grew up in Elmira, New York, where he graduated from Elmira Catholic High School. He enlisted in the United States Navy just after World War II where he served as a corpsman. He then attended Cornell University on a New York State Scholarship and graduated with a Bachelor of Arts degree in 1951. Using his GI Bill, John went on to the University of Rochester School of Medicine and Dentistry where he was elected to the Alpha Omega Alpha Medical Honor Society and received his Doctor of Medicine degree in 1955. Also while at Rochester, he married Georgette Boughton, his wife of 56 years.

John interned at Barnes Hospital in St. Louis, Missouri, and began his pathology training at Columbia Presbyterian Medical Center in New York City. He finished his residency at the New England Deaconess Hospital in Boston as a National Cancer Institute Trainee. While a resident, he also received training in forensic pathology at the City of New York Medical Examiner's Office and training in the clinical use of radioisotopes at the Cancer Research Institute of the New England Deaconess Hospital.

He joined the faculty of the University of Florida at Gainesville in 1960 as an assistant professor and rose to the rank of associate professor while directing the Blood Bank. In 1964, he relocated to Syracuse to become Professor of Pathology and the Director of Clinical Pathology in what was then the new University Hospital of the State University of New York (SUNY) Upstate Medical Center. There John started the Clinical Pathology Residency program and the Medical Technology School at a time when clinical pathology was a rapidly growing field.

Starting as an inspector for the National Committee on Inspection and Accreditation, John went on to serve as president (1970–1971) and member of the board of directors of the American Association of Blood Banks. He served as president (1976–1978) and trustee of the American Board of Pathology. He served as president (1980–1981) and member of the board of directors of the American Society of Clinical Pathologists. In addition, he served on the Scientific Advisory Board of the Armed Forces Institute of Pathology as well as the Pathology Advisory Council for the Veterans Administration.

For the College of American Pathologists, he served in numerous roles, including chairperson of the Future Technology Committee, the Section of Academic Pathology, the Committee on the Teaching of Pathology, and the Joint Policy Committee of the American Society of Clinical Pathology and College of American Pathologists, and as a member of the Board of Governors.

Awards given to Dr. Henry include the American Association for Clinical Chemistry's Gerald B. Lambert Award (1972) and its General Diagnostics Award in Clinical Chemistry (1982), the Royal Society of Medicine's S.C. Dyke Founder Award (1979), the Distinguished Service Award of the American Society of Clinical Pathologists (1979) and its H.P. Smith Memorial Award (1984), and the ASCP/CAP Joint Distinguished Service Award (1997). In 1997, the State University of New York Board of Trustees named him a Distinguished Service Professor.

Parallel with his career in pathology, Dr. Henry began a career as an executive in 1971 when he became the first dean of the SUNY Upstate Medical Center's College of Health Related Professions. He left Syracuse

to serve as the dean of the Georgetown University School of Medicine in Washington, DC, from 1979 to 1984. The seventeenth edition of this textbook adopted the blue and gray colors of Georgetown University during this period. Finally, John returned to Syracuse in 1985 as president of the Upstate Medical Center, which became the SUNY Health Science Center at Syracuse, and is now the SUNY Upstate Medical University. While president, he secured the construction of a new library, the Institute for Human Performance, and the first six floors of the east wing of the hospital. A state-of-the-art children's hospital has now been added to that east wing. A quote from John frequently heard by friends, family, and colleagues was, "Good decisions and a sustained focus in pursuit of excellence in patient care with goals and objectives will serve you well."

A man of tremendous energy, John also served as a captain in the U.S. Navy Reserves from 1979 until his retirement. In 1990, he was awarded the Navy Commendation Medal for Meritorious Achievement by the Secretary of the Navy. For much of this era, John could be found on his sailboat on Skaneateles Lake where he was a member of the Skaneateles Country Club and directed the Junior Sailing program for 13 years. He was also an avid skier, served on the Greek Peak Ski Patrol for 30 years, and taught skiing at the Skaneateles Ski Hill Ski Club for 13 years.

John was an inspirational leader and role model for generations of medical students, residents in training, and pathologists in practice. He was a strong advocate for promoting academic pathology, with special interests in the advancement and adoption of new technologies in the clinical laboratory. He had a particular interest in medical education and, upon stepping down from the presidency of SUNY Upstate Medical University, John became intensively involved with development of medical school course content emphasizing the spectrum of the understanding of diseases, from the molecular level to their manifestations as organ injury. He served on editorial boards of several journals in pathology and health care, and on numerous committees and advisory groups for universities, hospitals, government, and industry. His enthusiasm and determination to improve the teaching and practice of pathology were infectious to everyone around him. He will be remembered for always encouraging his colleagues to strive to achieve their best and to maintain the highest of professional standards, and particularly for advancing the careers of junior faculty members.

His work on this textbook began as co-editor with Israel Davisohn for the fourteenth edition in 1969; he then was the principal editor through the twentieth edition in 2001. Among John's contributions to this book were sections on the use of organ panels, automated instrumentation, laboratory management, and information systems. He had a knack for recruiting top authors in every field to prepare original chapters on topics such as histocompatibility, microbiology, molecular diagnostics, blood banking, hematology, clinical chemistry, and immunology. To honor John's consummate leadership of this book and his vision that shaped it for seven editions, it has been renamed *Henry's Clinical Diagnosis and Management by Laboratory Methods* beginning with the twenty-first edition.

John Bernard Henry will be missed by his wife, Georgette, and their six children: Maureen A. Mayer, Julie P. Henry, MD, William B. Henry, Paul B. Henry, John B. Henry Jr., and T. David Henry, SJ. He will also be missed by the countless pathologists and laboratory scientists whose lives he either shaped or touched.

PREFACE

Clinical laboratory measurements form the scientific basis upon which medical diagnosis and management of patients is established. These results constitute the largest section of the medical record of patients, and laboratory examinations will only continue to grow in number as new procedures are offered and well established ones are ordered more frequently in the future. The modern concept of an electronic health record encompasses information from a patient's birth through that individual's entire life, and laboratory testing is a significant component of that record from prenatal and newborn screening through childhood, adulthood, and geriatric years. Traditional areas of testing are well established in clinical chemistry, hematology, coagulation, microbiology, immunology, and transfusion medicine. Genetic testing for hereditary disease risk assessment is becoming a reality beginning with individual disease testing that is expected to be followed by whole genome screening for a multitude of conditions. The rapid pace in the introduction of new testing procedures demands that laboratory practitioners be expert in several divergent aspects of this profession. The environment of clinical laboratories is extremely well suited for translation of research procedures into diagnostic assays because of their traditional involvement in basic analysis, quality control, professional competencies, and cost-effective strategies of operation. All of these applications are made stronger for occurring under regulations of federal and state governments as well as the standards of accreditation of professional pathology organizations. Clinical laboratories excel in these tasks, and they are now responding to pressures for even greater accomplishments in areas of informatics, advanced analytic methods, interpretation of complex data, and communication of medical information in a meaningful way to physician colleagues. The most successful practitioners of laboratory medicine will incorporate all of these approaches into their daily lives and will be leaders in their institutions for developing initiatives to promote outstanding health care in a fiscally responsible endeavor. This textbook strives to provide the background knowledge by which trainees can be introduced to these practices and to serve as a resource for pathologists and other laboratory personnel to update their knowledge to solve problems they encounter daily.

This twenty-second edition marks more than 100 years since *A Manual of Clinical Diagnosis*, authored by James Campbell Todd, was introduced in 1908. In its current format as *Henry's Clinical Diagnosis and Management by Laboratory Methods*, this textbook remains the authoritative source of information for residents, students, and other trainees in the discipline of clinical pathology and laboratory medicine, and for physicians and laboratory practitioners. The current edition continues the tradition of partnership between laboratory examinations and the formulation and confirmation of clinical diagnoses followed by monitoring of body functions, therapeutic drug levels, and other results of medical treatments. Beginning with the twenty-first edition, color illustrations have been used throughout the book to accurately and realistically depict clinical laboratory test findings and their analysis. The overriding mission of this book is to incorporate new discoveries and their clinical diagnostic applications alongside the wealth of information that forms the core knowledge base of clinical pathology and laboratory medicine. Our contributing authors, who are experts in their specialties, present to the reader the essential basic and new information that is central to clinical laboratory practice.

Part 1, The Clinical Laboratory, covers the organization, purposes, and practices of analysis, interpretation of results, and management of the clinical laboratory from quality control through informatics and finances. The general structure of this section includes general management principles with emphasis on preanalytic, analytic, and postanalytic components of laboratory analysis as well as oversight functions. Administrative concepts for the laboratory are considered in Chapter 1, with optimization of workflow presented in Chapter 2. Preanalytic factors such as variations arising from specimen collection, transport, and handling and other variables are discussed in Chapter 3. The principles of analysis,

instrumentation, and automation are presented in Chapters 4 and 5. The growing arena of near-patient laboratory services beyond central hospital laboratories in the format of point-of-care testing is presented in Chapter 6 along with a new section on this application in the military. Postanalysis processes of result reporting, medical decision making, and interpretation of results are presented in Chapter 7, while selection of laboratory testing and interpretation for most cost-effective and efficient information gathering for medical problem solving by clinical laboratory testing is discussed in Chapter 8. A key component to all phases of laboratory processes, interpretation of results, and decision making is statistical analysis, which is introduced in Chapter 9. Explicit applications of statistics are in quality control (Chapter 10). Maintaining order for the complexities of laboratory test result ordering and reporting and the management of clinical information are possible only through sophisticated information systems that are essential to all clinical laboratories (Chapter 11). Management decisions in the clinical laboratory involve choice of analytic instrumentation, automation to process and deliver specimens to analytic stations, and computer systems to coordinate all of the preanalytic, analytic, and postanalytic processes to meet the mission of the institution. These choices determine the productivity that a laboratory can achieve (especially its ability to respond to increased volumes of testing and complexity of measurements and examinations as the standards of practice advance). Paramount is the manner in which the laboratory can muster its resources in equipment, personnel, reagent supplies, and ingenuity of its leadership to respond to the needs of health care providers and patients in terms of access, timeliness, cost, and quality of test results. New challenges continue to emerge for the laboratory to provide excellent quality services at fiscally responsible expense; the changing models of reimbursement for medical and laboratory services demand that pathologists and laboratory leaders develop and maintain a strong understanding of the principles of financial management and are well aware of mechanisms that laboratories can utilize for responding to these new approaches to reimbursement (Chapter 12). Laboratory organization should also include preparedness for threats to our security through bioterrorism and related activities (Chapter 13).

Part 2, Clinical Chemistry, is organized to present laboratory examinations according to organ systems and their disorders. Some of the most commonly ordered laboratory tests are directed at the evaluation of renal function, water, electrolytes, metabolic intermediates and nitrogenous wastes, and acid-base balance, all of which are critically important for monitoring acutely ill patients and in the management of patients with kidney and pulmonary disorders (Chapter 14). The important field of bone metabolism and bone diseases, stemming from the enormous public interest in osteoporosis of our aging population, is covered in Chapter 15. The significance of carbohydrate measurements with particular emphasis on diabetes mellitus, the overall hormonal regulation of glucose metabolism, and disorders of other sugars are reviewed in Chapter 16. Chapter 17 covers the extremely important topic of lipids and disorders in their metabolism and highlights the critical patterns in lipoprotein profiles that indicate disposition to cardiac malfunction, especially myocardial infarction. In Chapter 18, the serodiagnostic markers for cardiac injury evaluation and the related disorders of stroke are elaborated. The clinical significance of specific proteins and their analysis with emphasis on electrophoresis of blood and body fluids is covered in Chapter 19. The field of clinical enzymology with applications to assessment of organ injury is covered in Chapter 20. The principles of enzymology (e.g., transition state theory) have been used directly in the design of new effective drugs against specific diseases such as hypertension and AIDS. Therefore, these applications are now also discussed in this chapter. Laboratory assessment of liver function is presented in Chapter 21 and that of gastrointestinal and pancreatic disorders in Chapter 22. Toxicological analysis and therapeutic drug monitoring are covered in Chapter 23, with applications of both immunoassays and mass spectroscopy emerging in endocrinology (Chapter

24) and pregnancy and perinatal testing as well (Chapter 25). Nutritional analysis with examination of vitamins and trace metals is presented in Chapter 26. A new presentation on the chemical basis for analysis covers this topic, which is crucial to the understanding of virtually all laboratory measurements (Chapter 27).

Part 3, Urine and Other Body Fluids, reviews the utility and methods for examining fluids other than blood. Chapter 28 presents the basic examination of urine, with extensive discussions of both chemical testing and microscopic examination of urine sediment. A special area for consideration is body fluid analysis, which has received national attention recently in terms of standardizing the approach to testing of typical fluids and other alternative specimens (Chapter 29). A large range of specimen types is considered in this discussion.

Part 4, Hematology, Coagulation, and Transfusion Medicine, introduces techniques for the basic examination of blood and bone marrow (Chapter 30) and provides a wealth of background on the physiologic processes involved in hematopoiesis (Chapter 31). Erythrocytic disorders and leukocytic disorders and their diagnosis are covered in Chapters 32 and 33, respectively. Modern techniques for use of flow cytometry for diagnosis of hematopoietic neoplasias are presented in Chapter 34 to round out the approaches to diagnosis in this rapidly changing field. Immunohematology, which is so important for the understanding of erythrocyte antibodies and their impact on transfusion, is covered in Chapter 35. Blood component manufacture and utilization are covered in Chapter 36 along with transfusion reactions. Chapters 37 and 38 deal with the rapidly expanding areas of apheresis with its applications to therapy of multiple blood disorders as well as the collection, processing, and dispensing of hematopoietic progenitor cells (adult stem cells) from bone marrow, peripheral blood, and cord blood for treatment of both malignant and non-malignant diseases.

Part 5, Hemostasis and Thrombosis, was first introduced in the last edition of this textbook, and is based on the vast increase in our knowledge of the pathways involved in clotting and in fibrinolysis and the panoply of new testing and therapeutic modalities that have evolved as a result. This section continues to reflect the impact of our growing knowledge of coagulation and fibrinolysis (Chapter 39) plus that of platelet function disorders with emphasis on von Willebrand disease (Chapter 40). Advances in the diagnosis and monitoring of thrombotic disorders are covered extensively in Chapter 41, with particular interest in the prediction of thromboembolic risk. Along with our better understanding of thrombosis have come new drugs for treatment of patients with vascular occlusive disorders, particularly ischemic events in the heart or the brain. Principles of anti-thrombotic therapy and the laboratory's role in its monitoring is covered in Chapter 42. Also discussed in this section is the major advance in pharmacogenomics (fully discussed in Chapter 72) that now allows determination of the optimal anticoagulant therapies for individual patients.

Part 6, Immunology and Immunopathology, presents a framework both for classifying disorders of the immune system and for the role of laboratory testing in diagnosing those diseases (Chapter 43). Measurements based on immunoassays have long been the essential components of understanding a multitude of disorders; an excellent account of the principles of immunoassay and immunochemistry is included in Chapter 44. Evaluation of the cellular immune system is described in Chapter 45, which is newly updated. Humoral immunity and the examination of immunoglobulins in disease are covered in Chapter 46, with particular emphasis on the evaluation of monoclonal disorders in the blood. The material on complement and other mediators of inflammation (Chapter 47) is also newly updated and reorganized. Also brought up to date are Chapter 48 on the major histocompatibility complex (MHC), with its significant applications to organ transplantation, and Chapter 49, which looks at MHC and disease associations. The evaluation of immunodeficiency disorders includes many standard examinations for protein and cellular functions plus new genetic tests for specific abnormalities (Chapter 50). The assessment of autoimmune diseases is presented for the systemic rheumatic diseases (Chapter 51), the vasculitides (Chapter 52), and organ-specific diseases (Chapter 53). Allergic diseases, with their ever-increasing laboratory evaluations, are presented in Chapter 54.

Part 7, Medical Microbiology, covers an enormous spectrum of infectious diseases and related topics that includes viral infections (Chapter 55); chlamydial, rickettsial, and mycoplasmal infections (Chapter 56); classical medical bacteriology (Chapter 57); and susceptibility testing of antimicrobial agents (Chapter 58). Other major topics and infectious organisms of special note are spirochete infections (Chapter 59); mycobacteria (Chapter 60), with immense concern about emergence of resistant strains; mycotic diseases (Chapter 61), with a wide array of photographs of cultures and

photomicrographs; and medical parasitology (Chapter 62), with worldwide significance that is growing as large numbers of people move between countries and continents. In line with the importance of achieving maximum diagnostic benefit from the laboratory, specimen collection and handling for diagnosis of infectious disease are detailed in Chapter 63. Although the classic techniques in microbiology have consisted of culturing microbiology organisms with identification and antimicrobial susceptibility testing through functional bioassays, modern methods of nucleic acid amplification and detection are now becoming widespread for each type of microbiologic organism; these applications are described in each chapter about the various organisms.

Part 8, Molecular Pathology, covers some of the most rapidly changing and exciting areas of clinical laboratory testing. Chapter 64 provides an introduction to the role of molecular diagnostics, with an updated discussion of the principles and techniques of the field in Chapter 65. Similar updates are provided for the vital molecular diagnostic techniques of polymerase chain reaction and other amplification methods (Chapter 66) and newer approaches to nucleic acid hybridization (Chapter 67). The application of cytogenetics with modern methods of karyotyping, including fluorescent *in situ* hybridization and examination for chromosomal abnormalities, is covered in Chapter 68. Translation of research techniques to the molecular diagnostic laboratory is presented in Chapter 69, which also deals with procedures for establishing a molecular diagnostics laboratory that follows all the expectations for well-standardized testing and is fully compliant with regulations and good laboratory practices. This section is rounded out with excellent presentations on the application of molecular diagnostics to genetic diseases for which screening is becoming more important (Chapter 70) and to identity testing as used in parentage testing and forensic analysis (Chapter 71). Finally, an entirely new presentation on pharmacogenomics (Chapter 72) provides an understanding of how molecular analysis of selected genes crucial for response to therapeutic drugs or for the metabolism of drugs can be used to optimize individualized treatment plans, also known as *personalized medicine*.

Part 9, Clinical Pathology of Cancer, is a further outgrowth of this section that was new in the twenty-first edition. Because of the explosion of new diagnostic information as a result of the successful sequencing of the human genome, genetic profiles of different forms of cancers have now become available. Specific forms of cancer are beginning to be diagnosed using microchips containing gene arrays in which patterns of gene expression and mutation are evaluated. In addition, new methods of proteomics (i.e., determination of expression of multiple proteins in patients' body fluids and tissues) allow for cancer detection, monitoring, and treatment. Thus there has been a vast increase in information about the principles and applications of laboratory methods for diagnosis and monitoring of malignancies in just the past few years. Chapter 73 deals with the important protein markers for cancer in blood and tissues that are commonly used for the diagnosis and management of malignant diseases. Chapter 74 extends this discussion with exciting new applications of oncoproteins and growth factors and their receptors in the assessment of malignancies and modification of therapies. A broad spectrum of molecular and cytogenetic markers is now commonly used for the initial evaluation of hematopoietic neoplasms (Chapter 75) that could well become a model for assessment of most, if not all, malignancies. Because the methods in molecular pathology used in diagnosing cancer in body fluids are the same as in solid-tissue diagnosis, breaking down the barriers between anatomic and clinical pathology, we have now included a new chapter on the evaluation of solid tumors by these methods in Chapter 76.

The prospects for early detection, prognosis, and implementation of treatment regimens for cancer based on specific alterations in the genome have never been more apparent. These chapters in cancer diagnostics emphasize the genome-based approaches and other new methods such as proteomics, which has the potential to identify patterns of protein alterations that can be used both for discovery of new targets for examination and for direct detection of clinical abnormalities. Many of these technologies have been developed in the past few years and many more versions of them are sure to appear as the competitive advantage of rapid and inexpensive genomic analysis emerges. We think it is vital for pathologists to understand the bases of molecular diagnostics, the power of this type of analysis for clinical decision making, and the paths such testing is likely to take in the future. To this end, the final chapter (77) presents the diagnostic and prognostic impact of high-throughput genomic and proteomic technologies and the role they can play in the present and future practice of pathology.

The fundamental task for trainees in laboratory medicine is to achieve a sound understanding of analytic principles and the power and limitations

of laboratory examinations so that they can interpret whether abnormal results are due to a patient's physical condition or to other potential interferences such as altered physiologic state, drug interactions, or abnormalities introduced by specimen mishandling. Based on mastery of these technical aspects of test performance and interpretation, pathologists should be able to recommend strategies to provide the appropriate level of care for multiple purposes: to screen for disease, to confirm a diagnosis, to establish a prognosis, and to monitor the effects of treatment. National practice recommendations from the American Medical Association and the U.S. Department of Health and Human Services have led to the formulation of standardized panels of multiple individual tests that are targeted to several organ systems such as through the basic metabolic panel and comprehensive metabolic panel (Appendix 7). These panels consist of individual tests that are highly automated and can be conveniently and inexpensively delivered through most hospital laboratories. Such convenience was not always the case when these assays for basic constituents such as potassium, sodium, chloride, bicarbonate, calcium, bilirubin, and all the various metabolites, proteins, and enzyme activities were performed manually, as documented in previous editions of this textbook. Beyond those relatively simple tests, immunoassays, too, have undergone similar transformation: A mere 30 years ago the rapid assay for thyroid-stimulating hormone (TSH) required 2 days, whereas today a third-generation TSH measurement can be completed in 20 minutes or less. Conversion from highly complex and operator-interactive testing to immediately available and inexpensive assays will almost certainly occur with procedures that are now at the cutting edge of technology and require elaborate instrumentation and special expertise to perform. These include tandem mass spectrometry for small molecules such as hormones, vitamins, and drugs; whole genome sequencing for assessing risk of developing hereditary disorders and diagnosing malignancies; and proteomics for screening a wide array of proteins in blood, body fluids, and tissues for disease detection and evidence of progression. The configuration of these assays will consolidate multiple analyses onto miniature platforms such as chip technologies. Although these new technologies will likely be expensive to implement initially, the hope is that they will reduce costs in other parts of the health care system through initiating prevention or treatment

earlier than would be possible without such complex and intimate information about a patient's disease state or propensity to develop a disease.

Within this context, it is clear that the role of the clinical laboratory in the future will involve more than simply providing numeric results for physicians to glance at during rounds or after clinic duty. The complexity and the enormity of the test results that will be routinely available will require entirely new approaches to data presentation and interpretation to provide useful information for clinical diagnosis and management. The challenge to laboratories and clinicians alike is to develop "meaningful uses" in which electronic health records can store and present all of this information about a patient—from cradle through an entire life—in which several segments are integrated: genetic background, environmental factors, previous diagnostic and monitoring tests, and contemporaneous monitoring tests. All of these aspects of a patient's history have the potential to be meaningful in the most rigorous sense to provide personalized medical treatments.

This textbook provides grounding in the practice of modern laboratory medicine, and it points the way to new disciplines that will contribute to the evolution of strategies for creating, analyzing, and presenting medical information in the future. We hope that the discussions in this textbook will stimulate our colleagues at all levels to embrace new diagnostic laboratory technologies, in addition to those that are now standard, and to retain the most valuable from each into practices of the future. The legacy of this book over the past century has been to provide a clear and useful account of laboratory tests that generate the solid scientific information upon which medical decisions are based. Building on that foundation, we enthusiastically anticipate new diagnostic capabilities, and we hope that this textbook will be a stimulus to their development.

It is a privilege and an honor to serve as editors for this twenty-second edition.

Matthew R. Pincus, MD, PhD

April 2011

ACKNOWLEDGMENTS

We gratefully acknowledge the outstanding contributions made by our expert colleagues and collaborators who served as associate editors: Jay L. Bock, MD, PhD; Martin H. Bluth, MD, PhD; Robert E. Hutchison, MD; H. Davis Massey, MD, PhD; Jonathan L. Miller, MD, PhD; Gregory A. Threatte, MD; Katherine I. Schexneider, MD; Elizabeth R. Unger, MD, PhD; and Gail L. Woods, MD. They all have made extensive contributions to the quality of this book both through development of textual matter and through the exercise of practiced review of the chapters under their guidance. We deeply appreciate their efforts in this edition.

We gratefully acknowledge the participation in previous editions of Robert P. DeCresce, MD, MBA, MPH; D. Robert Dufour, MD; Timothy Hilbert, MD, PhD, JD; Mark L. Jaros, MBA, MT(ASCP), SM(AAM); Irina Lutinger, MPH, DLM(ASCP); Herb Miller, PhD, MT(ASCP), CLS (NCA); Robert A. Webster, PhD; and Edmond J. Yunis, MD. We also acknowledge our gratitude to them for the opportunity to revise their prior chapters from the twenty-first edition for this, the twenty-second one.

It is with sadness that we note the passing of Robert M. Nakamura, MD, an outstanding immunologist, who co-authored three chapters in this edition and served as author and associate editor in other editions. We will greatly miss his leadership, expertise, and strength of character in the pursuit of academic excellence.

All of our students, residents, and colleagues have for decades contributed enormously to the development of our knowledge in human disease and in the use of laboratories for diagnosis and patient management. We are grateful for all their questions and the stimulus they have provided to our professional growth. We are especially grateful for the mentorship and encouragement provided in our careers by Alfred Zettner, MD; Cecil Hougie, MD; Abraham Braude, MD; Charles Davis, MD; James A. Rose, MD; Robert P. Carty, PhD; Donald West King, MD; George Teebor, MD; Phillip Prose, MD; Fred Davey, MD; and Gerald Gordon, MD. We will remember them always and the standards for excellence they set.

The development of this edition, with its myriad details, would not have been possible without the outstanding professional efforts of our editors at Elsevier: William R. Schmitt, Kathryn DeFrancesco, and Louise King, each of whom added tremendously to this enterprise. We are sincerely grateful to them and to all the staff of Elsevier. They have made this endeavor a happy one. We also send very special thanks to Anne Erickson, who has drawn many of the illustrations in both the twenty-first and twenty-second editions with a fine eye to beauty in presentation and ease of comprehension.

We are grateful to all the authors for accepting the challenge to participate in the education of future and present laboratorians and physicians in all fields of medicine by distilling the essential information from each of their fields of expertise and creating readable and authoritative text for our audience. Special thanks to the authors, who have created wholly new chapters on molecular pathology and cancer diagnostics for this edition.

We also remember with perpetual gratitude the inspiration provided to us by John Bernard Henry, MD. He provided leadership for seven editions of this book. Moreover, he encouraged us, guided us, and demanded excellence from us in our profession.

Upon the completion of this twenty-second edition, we humbly thank all the individuals who have played roles in making it possible. It is not possible to name all of the individuals who have contributed to this textbook. To those mentioned here and to those not explicitly named, we thank you for your prodigious efforts and support.

KEY POINTS

- Effective laboratory management requires leaders to provide direction and managers to get things done. Strategic planning, marketing, human resource management, and quality management are all key elements of a laboratory organization.
- Most laboratory errors occur in the preanalytic and postanalytic stages. Six Sigma and Lean are tools that can be used to reduce laboratory errors and increase productivity.
- Laboratory services are provided in many different ways and can be thought of as placed on a continuum from point-of-care tests producing immediate answers to highly complex laboratory tests that require sophisticated technology and skilled staff.
- Clinical laboratories are highly regulated; many laboratory practices are the direct result of federal or state/local legislation. At the federal level, laboratory activities are regulated through the Clinical Laboratory Improvement Acts of 1988.
- Biological, chemical, ergonomic, and fire hazards cannot be completely eliminated from the laboratory, but can be minimized through the use of engineering controls (i.e., safety features built into the overall design of equipment and supplies), personal protective equipment, and work practice controls (such as hand washing).

The laboratory plays a central role in health care. How critical is the laboratory? By one estimate, 70% of all medical decisions are based on laboratory results (Silverstein, 2003), although laboratory costs account for only 2.3% of total health care dollars (Terry, 2009). The laboratory is a \$55.1 billion industry that offers high clinical value at relatively low cost.

The purpose of the laboratory is to provide physicians and other health care professionals with information to: (1) detect disease or predisposition to disease; (2) confirm or reject a diagnosis; (3) establish prognosis; (4) guide patient management; and (5) monitor efficacy of therapy (Kurec, 2000). The laboratory also plays a leading role in education and research, information technology design and implementation, and quality improvement. To successfully achieve its goal, a laboratory must use (1) medical, scientific, and technical expertise; (2) resources such as personnel, laboratory and data processing equipment, supplies, and facilities; and (3) organization, management, and communication skills. The goal of this chapter is to provide a fundamental understanding of general administrative concepts and issues that are the basis of sound laboratory practices. Crucial to a well-managed laboratory that generates accurate and timely laboratory reports is sound leadership with skills to guide staff in performing their daily tasks. A more detailed discussion of these topics is available elsewhere (Nigon, 2000; Snyder, 1998).

LEADERSHIP AND MANAGEMENT

An organization is only as good as its people, and people are guided by leaders and managers. The terms leadership and management are

often used interchangeably but represent different qualities (Table 1-1). Leadership provides the direction of where one (or an organization) is going, whereas management provides the “road” to get there. The adage, “If you don’t know where you are going, any road will get you there,” illustrates why leadership must be visionary and must set clear goals with strategic objectives. Effective management uses certain talents to work with people to get things done. It requires an optimal mix of skilled personnel, dedicated people, and task-oriented leaders to achieve these goals. These skills fall under four primary management functions: (1) planning and prompt decision-making, (2) organizing, (3) leading, and (4) controlling.

Leadership is a pattern of behaviors used to engage others to complete tasks in a timely and productive manner. One model of leadership describes four key leadership styles: supporting, directing, delegating, and coaching. A supportive leader provides physical and personal resources so that an individual can accomplish his or her duties. A directive leader presents rules, orders, or other defined instructions to the individual. The former approach offers flexibility and encourages creative problem-solving, whereas the latter approach offers concise and detailed instructions on how to complete a task. Other styles are also defined by these qualities: A delegating leader provides low support and direction, whereas a coaching leader provides high support and direction. A leader may adopt any behavior style periodically to suit a situation, but in general, one style usually dominates.

Good management uses, in the most efficient and effective manner, the human, financial, physical, and information resources available to an organization. Some basic managerial responsibilities are listed in Table 1-2. Managers can be stratified as first-line managers (supervisors, team leaders, chief technologists), middle managers (operations managers, division heads), and top managers (laboratory directors, chief executive officers [CEOs], chief financial officers [CFOs], chief information officers [CIOs]). Each managerial level dictates the daily activities and skill sets required for that position. Top-level managers concentrate on strategizing and planning for the next 1–5 years, while first-line managers are more concerned about completing the day’s work. A top-level manager may or may not possess technical skills that a first-line manager uses every day. Middle managers may straddle both areas to some degree by engaging in a variety of activities that may be strategic as well as tactical.

STRATEGIC PLANNING

Technology has moved the science of laboratory medicine from using numerous manual methods to applying highly automated ones. This has leveled the playing field of laboratory science to a point where testing can be done in the clinic, in the physician’s office, and even in the home by nontraditional laboratorians. This makes the laboratory a commodity that must engage in competitive business practices. To survive and even thrive in a competitive environment, a laboratory must constantly reevaluate its goals and services and adapt to market forces (e.g., fewer qualified laboratory personnel, reduced budgets, stricter regulatory mandates, lower reimbursements, new sophisticated technologies). This requires a leader to

TABLE 1-1

Leader versus Manager Traits

Leader	Manager
Administrator	Implementer
Organizer and developer	Maintains control
Risk taker	Thinks short term
Inspiration	Asks how and when
Thinks long term	Watches bottom line
Asks what and why	Accepts status quo
Challenges status quo	Is a good soldier
Does the right thing	Does things right

carefully make strategic decisions that can have an impact on the laboratory for years.

The process by which high level decisions are made is called strategic planning and can be defined as (1) deciding on the objectives of the organization and the need to modify existing objectives if appropriate; (2) allocating resources to attain these objectives; and (3) establishing policies that govern the acquisition, use, and disposition of these resources (Lifshitz, 1996). Strategic planning is usually based on long-term projections and a global view that can have an impact on all levels of a laboratory's operations. It is different from tactical planning, which consists of the detailed, day-to-day operations needed to meet the immediate needs of the

TABLE 1-3

SWOT Analysis for a New Hospital Outreach Program

Strengths

1. Use current technology/instrumentation
2. Have excess technical capacity
3. Increased test volume will decrease cost per test
4. Strong leadership support
5. Financial resources available

Opportunities

1. Opening of a new physician health care facility
2. Department of Health mandates lead testing on all children younger than 2 years old
3. Have access to hospital marketing department
4. Hospital X is bankrupt; laboratory will close

Weaknesses

1. Staffing shortage
2. Morale issues
3. Inadequate courier system
4. Need to hire additional pathologist
5. Limited experience in providing multihospital/client LIS services
6. Turnaround times are marginal

Threats

1. Competition from other local hospital laboratories
2. Competition from national reference laboratories
3. Reimbursement decreasing
4. Three local hospitals have consolidated their services, including laboratory
5. Several new patient service centers (phlebotomy stations) already opened

LIS, Laboratory information system.

laboratory and works toward meeting the long-term strategic goals that have been set. For example, a global strategy to develop an outreach business may prompt addressing issues such as bringing more reference work in-house; the need for additional instrumentation and/or automation; enhancing information technology tools; and adequate staffing to satisfy service expectations. Risk can be involved in initiating a specific strategy. A wrong decision may burden a laboratory with unnecessary costs, unused equipment, and/or overstaffing, making it that much harder to change course in response to future market forces or new organizational strategies. Yet not taking a risk may result in loss of opportunities to grow business and/or improve services.

Strategic planning generally is not the result of a single individual's creation but rather is derived from a committee. Managers spend a significant amount of time in meetings that often are nonproductive if not organized efficiently. A variety of techniques can be used to facilitate the strategic planning process; these include histograms/graphs/scattergrams, brainstorming, fishbone diagrams, storyboarding, Pareto analyses, and Delphi analyses (Kurec, 2004a). Another way to evaluate the risks associated with new strategies is the Strengths, Weaknesses, Opportunities, and Threats (SWOT) analysis. Generally, environmental factors internal to the laboratory are classified as strengths and weaknesses, and external environmental factors are opportunities and threats. This process is a particularly useful tool for guiding a marketing strategy (Table 1-3) and can be used in developing such a program (Table 1-4). Successful strategic planning requires preplanning, organization, well-defined goals, communication, and a firm belief in what is to be accomplished.

QUALITY SYSTEMS MANAGEMENT

A key management goal is to ensure that quality laboratory services are provided. To accomplish this, every laboratory should strive to obtain modern equipment, to hire well-trained staff, to ensure a well-designed and safe physical environment, and to create a good management team. A key study from 1999 by the IOM (Institute of Medicine, 2000) is often referred to when quality health care issues and medical error rates are addressed. This study concluded that 44,000 to as many as 98,000 Americans die each year because of medical errors (Silverstein, 2003; Kohn, 1999). Among those errors, 50% were failure to use appropriate tests, and of those, 32% were failure to act on test findings and 55% were due to

LIS, Laboratory information system.

avoidable delays in rendering a diagnosis. The frequency of laboratory error varies across the vast number of laboratory tests performed annually. In one study, error rates were reported to range from 0.05%–0.61%; and the distribution of errors among the testing stages was similar, with most (32%–75%) occurring in the preanalytic stage and far fewer (13%–32%) in the analytic stage (Bonini, 2002). Preanalytic errors included hemolyzed, clotted, or insufficient samples; incorrectly identified or unlabeled samples; and wrong collection tube drawn and improper specimen storage. Analytic errors included calibration error and instrument malfunction. Postanalytic errors included reports sent to the wrong physician, long turnaround time, and missing reports. Concerted efforts by various governmental regulatory agencies and professional associations have resulted in mandated programs that focus on ways to identify errors and to prevent them.

Total quality management (TQM) and *continuous quality improvement (CQI)* have been standard approaches to quality leadership and management for over 30 years (Juran, 1988; Deming, 1986). TQM is a systems approach that focuses on teams, processes, statistics, and delivery of services/products that meet or exceed customer expectations (Brue, 2002). CQI is an element of TQM that strives to continually improve practices and not just meet established quality standards. Table 1-5 compares traditional quality thinking versus TQM. TQM thinking strives to continually look for ways to reduce errors (“defect prevention”) by empowering employees to assist in solving problems and getting them to understand their integral role within the greater system (“universal responsibility”).

Two other quality tools often used are Six Sigma and Lean. Six Sigma is a process improvement program that is a hands-on process with the

TABLE 1-5

Quality Management: Traditional Versus TQM Thinking

Traditional thinking	TQM thinking
Acceptable quality	Error-free quality
Department focused	Organization focused
Quality as expense	Quality as means to lower costs
Defects by workers	Defects by system
Management-controlled worker	Empowered worker
Status quo	Continuous quality improvement
Manage by intuition	Manage by fact
Intangible quality	Quality defined
We versus they relationship	Us relationship
End-process focus	System process
Reactive systems	Proactive systems

single mantra of “improvement”: improved performance, improved quality, improved bottom line, improved customer satisfaction, and improved employee satisfaction. Six Sigma is a structured process that is based on statistics and quantitative measurements. Through this process, the number of defects per million opportunities (DPMO) is measured. A defect is anything that does not meet customer requirements, for example,

TABLE 1-6

Six Sigma Steps

Six Sigma step	Example
Define project goal or other deliverable that is critical to quality.	Emergency department results in less than 30 minutes from order
Measure baseline performance and related variables.	Baseline performance: 50% of time results are within 30 minutes, 70% within 1 hour, 80% within 2 hours, etc. Variables: Staffing on each shift, order-to-laboratory receipt time, receipt-to-result time, etc.
Analyze data using statistics and graphs to identify and quantify root cause.	Order-to-receipt time is highly variable because samples are not placed in sample transport system immediately and samples delivered to laboratory are not clearly flagged as emergency.
Improve performance by developing and implementing a solution.	Samples from emergency department are uniquely colored to make them easier to spot among routine samples.
Control factors related to the improvement, verify impact, validate benefits, and monitor over time.	New performance: Results available 90% of time within 30 minutes

a laboratory result error, a delay in reporting, or a quality control problem. So, if a laboratory sends out 1000 reports and finds that 10 are reported late, it has a 1% defect rate; this is equivalent to 10,000 DPMO. The goal of Six Sigma is to reduce the number of defects to near zero. The sigma (σ), or standard deviation, expresses how much variability exists in products or services. By reducing variability, one also reduces defects. Thus, one sigma represents 691,463 DPMO, or a yield (i.e., percentage of products without defects) of only 30.854%, whereas the goal of Six Sigma is to reach 3.4 DPMO, or a 99.9997% yield (Brue, 2002). Most organizations operate at or near four sigma (6210 DPMO). To put this in perspective, per Clinical Laboratory Improvement Act (CLIA) '88 guidelines, most proficiency testing (PT) requires an 80% accuracy rate. This translates to 200,000 defects per million tests, or 2.4 sigma. The reported PT accuracy rate for CLIA participating laboratories was 97%, or 3.4 sigma (Garber, 2004). Six Sigma practices can be applied to patient care and safety, providing a tool for meeting process improvement needs (Riebling, 2008). Examples, based on College of American Pathologists (CAP) Q-Probes and Q-Tracks programs, show the outcomes of applying Six Sigma to some common performance quality indicators. In these studies, the median variance (50th percentile) for test order accuracy was 2.3%, or 23,000 DPMO; patient wristband error was 3.13%, or 31,000 DPMO; blood culture contamination was 2.83%, or 28,300 DPMO; and the pathology discrepancy rate was 5.1%, or 51,000 DPMO (Berte, 2004). By lowering defects, quality of care is improved and cost savings are realized by eliminating waste (e.g., supplies and materials for reruns), unnecessary steps, and/or staff time (Sunyog, 2004). By some estimates, the cost of doing business is reduced by 25%–40% in moving from 3 sigma to 6 sigma performance. An example of the Six Sigma process is provided in Table 1-6.

The Lean process, first implemented in Japan by Toyota, was ultimately designed to reduce waste (“nonvalued activities”) (Blaha and White, 2009). The intent of Lean is to reduce costs by identifying daily work activities that do not directly add to the delivery of laboratory services in the most efficient or cost-effective ways. A Lean laboratory utilizes fewer resources, reduces costs, enhances productivity, promotes staff morale, and improves the quality of patient care. Lean directly addresses the age-old concept of “that’s the way we always did it” and looks for ways to improve the process. Lean practices can be very broad in nature or unique to a single laboratory work area by focusing on work flow actions in performing specific tasks, procedures, or other activities accomplished by critically reviewing each step in the process to determine where inefficiencies can be eliminated. Some changes require minimal resources and can be accomplished relatively quickly. Examples include relocating analytic equipment to an area that would require fewer steps, thus improving turnaround time; consolidating test menus to fewer instruments, eliminating the expense of maintaining multiple instruments and supplies; placing pipettes, culture plates, etc., in easy to access areas; and reallocating staff to maximize use and minimize wasteful downtime.

CLSI, Clinical and Laboratory Standards Institute.

Many laboratories are taking a more focused and stringent approach to quality system management. In a cooperative effort, the International Organization for Standardization (ISO) established guidelines that reflect the highest level of quality. The ISO 15189:2007 has been adopted by CAP in an effort to improve patient care through quality laboratory practices. A laboratory that meets or exceeds these guidelines can be CAP-certified, indicating a high level of confidence in the quality of services provided by that laboratory. In a similar fashion, the CLSI has created 12 Quality System Essentials (Table 1-7) based on ISO standards. Each of these 12 areas serves as a starting point in establishing a quality system that covers pretesting, testing, and posttesting operations. Quality Systems Management ultimately dispels the concept of “good enough” and promotes one of “it can always be done better.”

HUMAN RESOURCE (HR) MANAGEMENT

Recruiting, hiring, training, and retaining qualified personnel have become major challenges for today’s manager. Over the past 20–30 years, almost 70% of accredited Medical Technology programs have closed, resulting in a 22% reduction in the number of graduating students. In a recent survey, the average vacancy rate for staff medical technologists was 10% (Bennett, 2009) with an anticipated employment growth rate of 14% (U.S. Bureau of Labor Statistics, 2009). The need to compete with other professions has necessitated implementation of more creative recruitment incentives such as offering competitive salaries and comprehensive benefits and ensuring a nonhostile work environment. Today’s job market is volatile and draws from around the world; thus a greater understanding of cultural, ethnic, and gender-related traits is necessary to properly evaluate and attract a pool of competent employees who will meet the needs of the laboratory and contribute to accomplishing anticipated goals (Kurec, 2004b).

Labor accounts for 50%–70% of a laboratory’s costs; thus any new or replacement position must be justified. It is appropriate to review the authority level, experience and education required, and responsibilities of a position and compare them with any related changes in technology, required skills, or other factors. To ensure that the position is still necessary and covers responsibilities at an appropriate level, ask the question, “If the position remained unfilled or downgraded, how would that impact the department or the hospital?” For example, could a particular position be refilled by an entry-level technologist or a laboratory aide without compromising patient care or creating other staffing hardships?

Once the justification review is complete, a criterion-based job description should be developed (Kurec, 2004b). The criterion-based job description should focus on roles and not on specific tasks, as the latter may require frequent changes depending on operations. A criterion-based job description includes title, grade, and qualifications (including certification or licensure) and clearly identifies responsibilities, accountability, and internal and external organizational relationships. This provides a clear guide to expectations for both employee and employer.

The recruiting and hiring process requires understanding current and potential future needs of the laboratory, finding a qualified individual, and being aware of current local and federal hiring guidelines. During the interview process, an employer must restrict questions to what can be legally asked, yet still be able to gain insight as to whether the position is the right fit for both parties. Also important is developing a sensitivity

toward gender and generational or cultural differences that may be misinterpreted or misunderstood during the selection process (Kurec, 2005).

LABORATORY DESIGN AND SERVICE MODELS

Laboratory services are provided in many different ways and can be thought of as a continuum from point-of-care tests producing immediate answers to highly sophisticated laboratory tests that may take days to complete. Ease of Internet access has added a level of transparency to how health care is provided to the public and, in particular, provides a better understanding of laboratory testing through websites such as www.webmd.com and www.labtestsonline.org. This has increased awareness of what tests are available and what they mean, and has increased the expectancy that laboratories will provide high quality and timely services. To meet this demand, laboratories have been redesigned for efficiency, accessibility, safety, and reliability. Laboratories have changed their internal design from a very compartmentalized environment to a more centralized one, where traditional laboratory sections have been consolidated. When appropriate, regionalized laboratories have been developed to perform specialty or complex testing, thus capitalizing on expertise, equipment, and materials. In many institutions, laboratory testing has been pushed out to point-of-care testing (POCT) to shorten turnaround time for critical results and enhance convenience for both patients and caregivers. These internal and external organizational changes have fostered a greater awareness of the importance of laboratory services and how they contribute to the continuum of care.

The *functional design of a laboratory* and its relationship to other testing sites within a facility have evolved from one with discrete hematology, chemistry, microbiology, and blood bank sections to one where boundaries have been obscured. In an effort to lower costs and respond more rapidly to clinical needs, laboratories have employed both highly automated “core” facilities and distributed testing at peripheral stat laboratories and/or POCT sites. Based on current technology, tests that once were performed in separate laboratory sections are now performed on a single testing platform (single analyzer), on a workcell (two or more linked instruments), or with the use of total laboratory automation (workcell with preanalytic and postanalytic processing). In conjunction with improved preanalytic sample handling (e.g., bar coding, automated centrifuges, decapper), use of highly accurate analyzers and timely postanalytic activities (e.g., reporting laboratory results via networked computer systems, the Internet, auto-faxing) further contributes to enhancing the quality of services provided. These configurations will be discussed further in Chapters 2 and 5.

Regionalization is a consolidation process on a grand scale. In the “hub and spoke” model, a single, core laboratory serves as the hub, providing high volume, routine testing. One or more other laboratories act as the spokes, thus consolidating certain functions into one highly specialized laboratory. For example, a single laboratory may focus on providing just microbiology, virology, parasitology, mycology, or other related services. In constructing such a unique site, the redundancy of procuring technical expertise, expensive biohazard hoods, negative pressure rooms, clinical and molecular testing equipment, and other materials can be minimized. Similar opportunities may exist for other laboratory sections such as cytogenetics, molecular diagnostics, cytology, or histocompatibility. Establishing regionalized laboratory systems can require significant up-front resources, appropriate space requirements, and commitment from senior personnel from all institutions involved to make this work. In hospital settings, a Stat or rapid-response laboratory would be necessary to handle urgent test requests. Challenges to consider in implementing and succeeding with this model include timely specimen transportation, resistance to change, personnel issues, morale issues, “lost identity” of the laboratory, and union problems.

The design of facilities is important regardless of the type of laboratory and may best be accomplished by implementing Six Sigma/Lean techniques to ensure the highest level of productivity. Location of the specimen processing area, patient registration and data entry, specimen testing workflow, short- and long-term storage, and laboratory information system (LIS) connectivity requirements must be considered. Spatial requirements in relationship to other hospital services (proximity to emergency department, intensive care units, and surgical operating suite) should be viewed as a multidisciplinary process. Robotics, pneumatic tubes, computers, hand-held devices, and facsimile machines are the new tools used in modern laboratories and must be accounted for in the design plans. Electrical power, temperature/humidity controls, access to water (distilled/

TABLE 1-8

Laboratory Physical Design Considerations

- In developing a needs assessment, identify space for offices, personal facilities, storage, conference/library area, and students.
- Routinely review all floor plans and elevations for appropriate usage, and ensure space and function are related; handicapped accessibility may be required.
- Develop and use a project scheduler to ensure on-time progress.
- Fume hoods and biological safety cabinets must be located away from high traffic areas and doorways that might cause unwanted air current drafts.
- Modular furniture allows for flexibility in moving or reconfiguration of the laboratory according to current and anticipated needs; conventional laboratory fixtures may be considered in building depreciation, whereas modular furniture may not.
- Consider HVAC requirements to ensure proper temperature (68° F–76° F), humidity (20%–60%), air flow (12 air exchanges/hour); extremes in any one area can adversely affect patients, staff, and equipment.
- Base cabinets (under laboratory counters) provide 20%–30% more storage space than suspended cabinets.
- Noise control in open laboratories may be obtained by installing a drop ceiling. Installation of utilities above a drop ceiling adds to flexibility in their placement.
- In general, space requirements are 150–200 net square feet (excludes hallways, walls, custodial closets, etc.) per FTE, or 27–40 net square feet per hospital bed.
- Rooms larger than 100 square feet must have two exits; corridors used for patients must be 8 feet wide, and those not used for patients must be 3 feet 8 inches wide.
- An eyewash unit must be within 100 feet of work areas; hands-free units are preferred.
- Suggested standard dimensions in planning and designing a laboratory:
 - Laboratory counter width: 2 feet 6 inches
 - Laboratory counter-to-wall clearance: 4 feet
 - Laboratory counter-to-counter clearance: 7 feet
 - Desk height: 30 inches
 - Keyboard drawer height: 25–27 inches
 - Human body standing: 4 square feet
 - Human body sitting: 6 square feet
 - Desk space: 3 square feet

Painter, 1993; Mortland, 1997.

FTE, Full-time equivalent; HVAC, heating, ventilating, and air conditioning.

deionized), drainage sources, and air circulation/ventilation issues must be considered for access and adequate quantity. Regulatory compliance codes must be reviewed carefully and implemented appropriately to ensure that safety, ergonomic, and comfort needs are met (Table 1-8). Recently, concerns of reducing environmental impact have come into play (Kurec, 2009). Many municipalities and hospitals offer strong incentives, or even mandates, to “go green” by purchasing alternative, nontoxic chemicals, recycling used electronic products, integrating paperless reporting, and generally raising staff awareness of energy-wasting practices. To ensure that one meets local, state, and federal codes, a qualified architect who has had experience in designing clinical laboratories should be consulted at the beginning of relocation or renovation designs. This minimizes costly change orders and maximizes on-time start-up of the new facility.

REGULATION, ACCREDITATION, AND LEGISLATION

Clinical laboratories are among the most highly regulated health care entities (Table 1-9). Understanding these laws is necessary to avoid legal or administrative repercussions that may limit a laboratory’s operations or shut it down completely. To operate (and receive reimbursement for services), laboratories must be licensed and often accredited under federal and/or state requirements. Although all pathologists must be state-licensed physicians, 13 states currently require laboratory personnel licensure—a key consideration when attempting to hire technical staff (Table 1-10).

At the federal level, laboratory activities are regulated through CLIA ’88 (*Federal Register* 55, 1990; *Federal Register* 57, 1992; <http://www.fda.gov/cclia/>).

TABLE 1-9

Laboratory Regulations and Their Significance

1983	Prospective Payment System for Medicare patients established payment based on diagnosis-related groups (DRGs). Hospitals are paid a fixed amount per DRG, regardless of actual cost, thereby creating an incentive to discharge patients as soon as medically possible. For inpatients, laboratories become cost centers instead of revenue centers (Social Security Amendments P.L. 98-21).
1984	Deficit Reduction Act (P.L. 93-369): Established outpatient laboratory fee schedule to control costs; froze Part B fee schedule.
1988	Clinical Laboratory Improvement Act of 1988 (CLIA '88) (amended 1990, 1992): Established that all laboratories must be certified by the federal government with mandated quality assurance, personnel, and proficiency testing standards based on test complexity. Until this time, the federal government regulated only the few laboratories conducting interstate commerce or independent or hospital laboratories that wanted Medicare reimbursement. CLIA applies to all sites where testing is done, including physician's offices and clinics.
1989	Physician Self-referral Ban (Stark I; PL 101-239): Prevents physicians from referring Medicare patients to self-owned laboratories.
1990	Ergonomic Safety and Health Program Management Guidelines: Establish OSHA guidelines for employee safety.
1990	Three-Day Rule initiated by CMS: Payment for any laboratory testing done 3 calendar days before admission as an inpatient is not reimbursed because testing is considered to be part of the hospital stay (Omnibus Reconciliation Act); directs HHS to develop an outpatient DRG system.
1992	Occupational Exposure to Hazardous Chemicals in Laboratories: Establishes OSHA guidelines to limit unnecessary exposure to hazardous chemicals.
1992	Occupational Exposure to Blood-Borne Pathogens: Establishes OSHA guidelines to limit unnecessary exposure to biological hazards.
1996	Health Insurance Portability and Accountability Act: Directs how health care information is managed. This law protects patients from inappropriate dispersion (oral, written, or electronic) of personal information and is the basis for many of the privacy standards currently in place.
1997	OIG Compliance Guidelines for clinical laboratories: Help laboratories develop programs that promote high ethical and lawful conduct, especially regarding billing practices and fraud and abuse.
2001	CMS National Coverage Determinations: Replaced most local medical review policies used to determine whether certain laboratory tests are medically necessary and therefore reimbursable. Before this, each Medicare intermediary had its own medical necessity guidelines.
2003	Hazardous Material Regulations: Deal with shipment of blood and other potentially biohazardous products (DOT).

CMS, Centers for Medicare and Medicaid Services; DOT, U.S. Department of Transportation; HHS, U.S. Department of Health and Human Services; OIG, Office of Inspector General; OSHA, Occupational Safety and Health Administration.

www.cms.hhs.gov/clia/). Before CLIA '88, no consistent federal regulatory standards had been provided for most laboratories, only sporadic state initiatives that carried various levels of authority and oversight of laboratory activities. CLIA '88 was enacted in response to concerns about the lack of national laboratory quality standards. Minimum standards are enforced by the federal government or by their designees that have received "deemed status," reflecting standards equivalent to or stricter than those put forth by CLIA '88. Most of the clinical laboratories in the United States are CLIA-certified to perform testing on human samples, indicating that the laboratory meets personnel, operational, safety, and quality standards based on test complexity (Table 1-11). Detailed, current guidelines may be found at <http://wwwn.cdc.gov/clia/regs/toc.aspx>.

The Laboratory Compliance Program was mandated by Congress (*Federal Register* 63[163], Aug 24, 1998) in response to concerns from the Centers for Medicare and Medicaid Services (CMS) about fraud and abuse of payments. This program requires that laboratories that receive payment for services from any federal agency must have policies addressing the medical necessity for tests ordered, ensuring accurate billing for testing, and promoting a standard of conduct to be adopted by laboratory employees. Failure to have an active program could cause a laboratory to be excluded from participating with CMS and could lead to significant financial and legal penalties. Consider, for example, the patient mix that may be encountered over the next decade or so. The largest population segment at this time will be the baby boomer generation (about 78 million). It has been estimated that those 65 years and older will utilize five times as many laboratory tests per year as are currently used (Terry, 2009). This will have an impact not only on test volume requirements, but also on the kind of testing appropriate for this age set. Physicians must now select the most

TABLE 1-11

CLIA Categories Included and Excluded

Test categories (based on analyst/operator and complexity to run test)
• Waived (e.g., blood glucose, urine pregnancy)
• Moderate complexity
• High complexity
Not categorized (because they do not produce a result)
• Quality control materials
• Calibrators
• Collection kits (for HIV, drugs of abuse, etc.)
Not currently regulated (by CLIA)
• Noninvasive testing (e.g., bilirubin)
• Breath tests (e.g., alcohol, <i>Helicobacter pylori</i>)
• Drugs of abuse testing in the workplace
• Continuous monitoring/infusion devices (e.g., glucose/insulin)

CLIA, Clinical Laboratory Improvement Act; HIV, human immunodeficiency virus.

appropriate tests and avoid the "shotgun" approach to test ordering practices. Ordering the right tests must be justified as medically necessary and must meet evidence-based medicine protocols (Wians, 2009).

The Health Insurance Portability and Accountability Act (HIPAA) was enacted in 1996, providing standards that protect the confidentiality of health information while allowing interchange of information in appropriate circumstances (*Federal Register* 63, 1998). Various rules have been implemented that have a direct impact on the laboratory and include the use and disclosure of protected health information (PHI). PHI includes any oral, written, electronic, or recorded information such as date of birth, social security number, address, phone number, or other patient identifier. Access to this information is restricted on a "need-to-know" basis as described within an employee's job description/title. Failure to adhere to these rules can result in significant fines, and in blatant cases of abuse, prison time.

A variety of other government agencies and nongovernment organizations directly or indirectly influence laboratory operations. These agencies address laboratory issues and other business practices and provide

TABLE 1-12

Laboratory-Related Governmental Agencies

CDC	Centers for Disease Control and Prevention is under the U.S. Department of Health and Human Services (HHS) and provides oversight of public health and safety, including the laboratory (www.cdc.gov).
CMS	Centers for Medicare and Medicaid Services (formerly known as HCFA) oversees the largest health care program in the United States, processing more than 1 billion claims per year. Medicare (see Chapter 12) provides coverage to approximately 40 million Americans over the age of 65, some people with disabilities, and patients with end-stage renal disease, with a budget of \$309 billion (2004). Medicaid provides coverage to approximately 50 million low-income individuals through a state–federal partnership that costs \$277 billion (2004). CMS sets quality standards and reimbursement rates that apply to the laboratory and are often used by other third-party payers (www.cms.hhs.gov).
DOT	U.S. Department of Transportation has the responsibility of regulating biohazardous materials that include blood and other human products. Laboratory specimens sent to reference laboratories must be packaged per guidelines set by this agency (www.dot.gov).
EPA	Environmental Protection Agency sets and enforces standards for disposal of hazardous laboratory materials, such as formalin, xylene, and other potential carcinogens (www.epa.gov).
EEOC	Equal Employment Opportunity Commission oversees and enforces Title VIII dealing with fair employment practices related to the Civil Rights Act of 1964 and the Equal Employment Opportunity Act of 1972. Hiring of laboratory staff falls under the same rules as most businesses (www.eeoc.gov).
FDA	U.S. Food and Drug Administration is part of HHS and regulates the manufacture of biologics (such as blood donor testing and component preparation) and medical devices (such as laboratory analyzers) and test kits through its Office of In-Vitro Diagnostic Device Evaluation and Safety. FDA inspects blood donor and/or component manufacturing facilities irrespective of other regulatory agencies and/or accrediting organizations (www.fda.gov).
HHS	U.S. Department of Health and Human Services oversees CMS, OIG, and FDA.
NARA	National Archives and Records Administration provides a number of databases, including access to the <i>Federal Register</i> , where laboratory and other regulations are published (www.gpoaccess.gov/fr/index.html).
NRC	Nuclear Regulatory Commission develops and enforces federal guidelines that ensure the proper use and operation of nonmilitary nuclear facilities. Laboratory tests that use radioactive materials (like radioimmunoassays) must adhere to guidelines set by this agency (www.nrc.gov).
NIDA	National Institute on Drug Abuse regulates standards for performing and maintaining appropriate quality control for drugs of abuse testing (www.nida.nih.gov).
NIOSH	National Institute of Occupational Safety and Health is a part of HHS and provides research, information, education, and training in the field of occupational safety and health. NIOSH makes recommendations regarding safety hazards but has no authority to enforce them (www.cdc.gov/niosh/homepage.html).
NIH	National Institutes of Health is an agency of HHS and is a world leader in medical research. It publishes a variety of clinical practice guidelines, some of which are applicable to the laboratory, such as those for diabetes and lipid testing (www.nih.gov).
NIST	National Institute of Standards and Technology is a branch of the Commerce Department and has contributed to the development of many health care products. In addition, it has developed standards for calibration, weights and measures, and the International System of Units (www.nist.gov).
OIG	Office of the Inspector General is part of HHS and is responsible for auditing, inspecting, and identifying fraud and abuse in CMS programs such as laboratory testing. The focus of OIG is usually noncompliance with reimbursement regulations such as medical necessity (www.oig.hhs.gov).
OSHA	Occupational Safety and Health Administration is part of the U.S. Department of Labor and develops and enforces workplace standards to protect employees' safety and health. Recommendations from OSHA include guidelines addressing blood-borne pathogens, chemical safety, phlebotomies, latex gloves, ergonomics, and any other potentially hazardous situation that may be found in the workplace (www.osha.gov).
State Department of Health	State Departments of Health vary in the extent to which they regulate laboratories. Some states, like New York, license all laboratories and oversee mandatory proficiency testing and laboratory inspection programs; others do neither. New York and Washington have Clinical Laboratory Improvement Act "deemed status."

regulations concerning human resource practices, transportation of specimens, environmental protection, and interstate commerce, to name just a few (Tables 1-12 and 1-13). The responsibilities assumed by these agencies represent federal, state, and professional guidelines that are designed to protect the public and employees from shoddy laboratory testing practices or unnecessary exposure to biological, chemical, or radioactive hazards. These guidelines also ensure the availability of quality blood products, access to laboratory testing as needed, and a safe work environment for employees. Professional associations play an important part in establishing guidelines and often lobby for their acceptance as standard of care practice by governmental agencies. For example, Table 1-14 provides suggested time limits for record and specimen retention based on CAP guidelines.

SAFETY

The clinical laboratory exposes staff, and potentially the public, to a variety of hazards, including infectious patients, infectious patient specimens, and potentially hazardous chemicals and equipment. All health care facilities should have policies that address routine job-related exposures to biological, chemical, and radiation hazards, as well as ergonomic/environmental

hazards, fire safety, act-of-God occurrences (tornadoes, hurricanes, floods, etc.), and epidemic emergency preparedness plans. Laboratories are obligated to identify hazards, implement safety strategies to contain the hazards, and continually audit existing practices to determine whether new ones are needed. Situations such as the H1N1 flu outbreak of 2009 required plans to meet staffing shortages and to manage the infected patient population (Satyadi, 2009). Frequent safety reviews and disaster drills and general employee awareness help maintain a safe work environment.

Good safety practices benefit patients and employees and the bottom line of the laboratory. Injuries and harmful exposures can negatively affect the laboratory financially, by reputation due to bad press, and through potential lawsuits, lost workdays and wages, damage to equipment, and poor staff morale. An injured person may be absent for an indefinite period and often cannot work at peak efficiency upon return. During this time off, the workload has to be absorbed by existing staff or through additional temporary services. Careful planning and compliance with the laws will minimize undesired outcomes. Although inexperience may be a cause for some accidents, others result from ignoring known risks, pressure to do more, carelessness, fatigue, or mental preoccupation (failure to focus

TABLE 1-13

Laboratory-Related, Nongovernmental Organizations

AABB	Formerly known as American Association of Blood Banks, AABB is a peer professional group that offers a blood bank accreditation program that can substitute for (but coordinate with) a CAP inspection. It has CLIA deemed status (www.aabb.org).
ASCP	American Society for Clinical Pathology is the largest organization for laboratory professionals and offers certification for various specialties (www.ascp.org).
CAP	College of American Pathologists offers the largest proficiency survey program in the United States and has a peer-surveyed laboratory accreditation program that has CLIA deemed status. CAP accreditation is recognized by The Joint Commission as meeting its laboratory standards (www.cap.org).
CLSI	Clinical and Laboratory Standards Institute (formerly NCCLS) is a peer professional group that develops standardized criteria regarding laboratory practices; accrediting and licensing entities often adopt these as standards (e.g., procedure manual format) (www.clsi.org).
COLA	COLA (originally the Commission on Office Laboratory Accreditation) is a nonprofit organization sponsored by the American Academy of Family Physicians, the American College of Physicians, the American Medical Association, the American Osteopathic Association, and CAP. It has CLIA deemed status, and its accreditation is recognized by The Joint Commission. It was originally organized to provide assistance to physician office laboratories (POLs), but has recently expanded its product line to other services (www.cola.org).
TJC	The Joint Commission (formerly known as Joint Commission on Accreditation of Healthcare Organizations) is an independent, not-for-profit entity that accredits nearly 17,000 health care organizations and programs in the United States based on a comprehensive set of quality standards. It has CLIA deemed status and may substitute for federal Medicare and Medicaid surveys; it also fulfills licensure requirements in some states and general requirements of many insurers. TJC usually surveys the laboratory as part of an overall health care facility survey (www.jointcommission.org/).

CLIA, Clinical Laboratory Improvement Act.

attention or to concentrate on what is at hand). A number of strategies may be used to contain hazards, including the use of work practice controls, engineering controls, and personal protective equipment (Table 1-15). The most effective safety programs use all three strategies.

BIOLOGICAL HAZARDS

Biological hazards expose an unprotected individual to bacteria, viruses, parasites, or other biological entities that can result in injury. Exposure occurs from ingestion, inoculation, tactile contamination, or inhalation of infectious material from patients or their body fluids/tissues, supplies or materials they have been in contact with, or contaminated needles, or by aerosol dispersion. The potential also exists for inadvertent exposure to the public through direct contact with aerosolized infectious materials, improperly processed blood products, and inappropriately disposed of waste products.

The spread of hepatitis B virus (HBV), hepatitis C virus (HCV), human immunodeficiency virus (HIV), and tuberculosis (TB) has focused the responsibility on each health care organization to protect its employees, patients, and the general public from infection. The Centers for Disease Control and Prevention (CDC) and the Occupational Safety and Health Administration (OSHA) have provided guidelines (Universal Precautions) that recommend precautions in handling body fluids and human tissues for all patients regardless of their blood-borne infection status (CDC Recommendations and Reports, 1989). OSHA defines occupational exposure as "reasonably anticipated skin, eye, mucous membrane, or percutaneous contact with blood or other potentially infectious materials that may result from the performance of an employee's duties" (*Federal Register* 29CFR, 1910.1030, 1992). Blood, all other body fluids, and any

*College of American Pathologists, Northfield, Ill. (March 2009) and/or CLIA '88 guidelines (*Federal Register* 55, 1990; 57, 1992); check with other organizations (like AABB) or local regulatory agencies for current requirements that may differ from those above.

unfixed tissue samples are considered potentially infectious for various blood-borne pathogens. In the laboratory, individuals should avoid mouth pipetting; consumption of food; smoking; applying cosmetics; potential needlestick situations; and leaving unprotected any skin, membranes, or open cuts. Aerosol contamination may be due to inoculating loops (flaming a loop), spills on laboratory counters, expelling a spray from needles, and centrifugation of infected fluids.

Although many laboratories require wearing of gloves when performing phlebotomies, OSHA strongly recommends that gloves be used routinely as a barrier protection, especially when the health care worker has cuts or other open wounds on the skin, anticipates hand contamination (biological or chemical), performs skin punctures; or during phlebotomy training (OSHA, 1991). All other phlebotomy access procedures may require use of gloves as determined by local or institutional policy. Employees must wash their hands after removal of gloves, after any contact with blood or body fluids, and between patients. Gloves should not be washed and reused because microorganisms that adhere to gloves are difficult to remove (Doebbeling, 1988). Masks, protective eyewear, or face shields must be worn to prevent exposure from splashes to the mouth, eyes, or nose. All protective equipment that has the potential for coming into contact with infectious material, including laboratory coats, must be removed before leaving the laboratory area and must never be taken home or outside the laboratory (such as during lunch or personal breaks). Laboratory coats must be cleaned onsite or by a professional. It is helpful for all employees to know what areas (offices, conference rooms, lounges, etc.) and equipment (telephones, keyboards, copy machines, etc.) are designated as laboratory work areas because they can be potentially contaminated. Avoid contamination by not wearing soiled gloves when in these areas or when using nonlaboratory equipment. Use of medical safety devices will help reduce the 600,000 to 800,000 needlestick injuries each year (Sharma, 2009; NIOSH; The Needlestick Safety and Prevention Act of 2000, Pub. L. 106-430, 2000; Bloodborne Pathogens Standard, *Federal Register* 29CFR 1910.1030, 1992). Table 1-16 outlines some common materials that may be used for decontamination (CLSI M29-A3, 2005).

CHEMICAL HAZARDS

All clinical laboratories are mandated by OSHA to develop and actively follow plans that protect laboratory workers from potential exposure to

Chemical Hazard Communications Plan

1. Develop written hazard communication program.
2. Maintain inventory of all chemicals with chemical and common names, if appropriate.
3. Manufacturer must assess and supply information about chemical or physical hazards (flammability, explosive, aerosol, flashpoint, etc.).
4. Employers must maintain Material Safety Data Sheets (MSDS) in English.
5. MSDS must list all ingredients of a substance greater than 1%, except for known carcinogens if greater than 0.1%.
6. Employers must make MSDS available to employees upon request.
7. Employers must ensure that labels are not defaced or removed and must post appropriate warnings.
8. Employers must provide information and training (“right-to-know”).
9. Employers must adhere to Occupational Safety and Health Administration permissible exposure limit, threshold limit, or other exposure limit value.
10. Designate responsible person(s) for the program.

hazardous chemicals. To minimize the incidence of chemically related occupational illnesses and injuries in the workplace, OSHA published its “Hazard Communication Standard” (*Federal Register* 29CFR 1910.1200; 1983) and “Chemical Hygiene Plan” (*Federal Register* 29CFR 1910.1450; 1993), requiring the manufacturers of chemicals to evaluate the hazards of the chemicals they produce and to develop hazard communication programs for employees and other users who are exposed to hazardous chemicals (Table 1-17). These OSHA standards are based on the premise that employees have the right to know what chemical hazards they are potentially exposed to and what protective measures the employer needs to take to minimize hazardous exposure. Many states have developed individual guidelines and regulations mandating that employers develop and implement safety and toxic chemical information programs for their workers that are reviewed with all employees each year (e.g., the Right-to-Know Law in New York State [Chap. 551, Art. 48, 12 NYCRR Part 820]).

ERGONOMIC HAZARDS

OSHA presented guidelines (*Federal Register* 54, 29CFR 1910, 1989) to address ergonomic hazards in the workplace and to assist employers in developing a program to prevent work-related problems that primarily include cumulative trauma disorders. This is a collective group of injuries involving the musculoskeletal and/or nervous system in response to

long-term repetitive twisting, bending, lifting, or assuming static postures for an extended period of time. These injuries may evolve from environmental factors such as constant or excessive repetitive actions, mechanical pressure, vibrations, or compressive forces on the arms, hands, wrists, neck, or back. Human error may also be a causative factor when individuals push themselves beyond their limits, or when productivity limits are set too high.

Among laboratory personnel, cumulative trauma disorders are usually related to repetitive pipetting, keyboard use, or resting their wrists/arms on sharp edges, such as a laboratory counter. These actions can cause carpal tunnel syndrome (compression and entrapment of nerve from wrist to hand), tendonitis (inflammation of tendon), or tenosynovitis (inflammation or injury to synovial sheath) (Gile, 2004). Awareness and prevention are essential in managing these disorders. Work practice and engineering controls, in addition to various hand, arm, leg, back, and neck exercises, may reduce these problems (Prinz-Lubbert, 1996). The costs of implementing programs to help employees understand and avoid ergonomic hazards can be financially justified. Back injuries are the second most common cause for employee absenteeism after the common cold and can cost employers up to \$16,000 per episode (Prinz-Lubbert, 1996).

SELECTED REFERENCES, 23

KEY POINTS

- An effective testing process requires integration of preanalytic, analytic, and postanalytic steps.
- An understanding of workflow is a fundamental prerequisite to any performance optimization strategy.
- A variety of techniques should be used to collect workflow data. These include sample and test mapping, tube analysis, workstation analysis, staff interviews, and task (process) mapping.
- Though technology is a critical component of every laboratory, it is only a tool to reach a goal. Technology alone does not improve performance and workflow; its success or failure depends on how it is implemented and whether it was truly needed.
- Consolidation, standardization, and integration are key strategies that can optimize workflow using concepts such as Six Sigma to achieve Lean processes. Managing test utilization may also change overall operational needs and workflow patterns.
- Assessment of excess capacity is useful in establishing the feasibility of increasing testing workload, especially in outreach programs.

The clinical laboratory is a complex operation that must smoothly integrate all three phases of the testing process: preanalysis, analysis, and postanalysis. Preanalysis refers to all the activities that take place before testing, such as test ordering and sample collection. The analysis stage consists of the laboratory activities that actually produce a result, such as running a sample on an automated analyzer. Postanalysis comprises patient reporting and result interpretation. Collectively, all of the interrelated laboratory steps in the testing process describe its workflow; this, in turn, occurs within the overall design of a laboratory operation as described in its policies and procedures.

The steps in the testing process can be generally categorized according to testing phase, role (responsibility), or laboratory technology (Fig. 2-1). Note that the testing process and the grouping of steps vary somewhat from one facility to another. Depending on the laboratory service model and technology used, some steps may fall into one category or another. For example, centrifugation may be performed in a physician office (pre-analysis) or in the laboratory as part of a total automation workcell (analysis). Depending on the technology selected, a laboratory may automate some or many of the steps identified in Figure 2-1. Information technology is the essential “glue” that binds these steps. A more detailed discussion of each testing phase is presented in Chapters 3–8. This chapter will explore the interrelationship of laboratory workflow, technology, and performance.

UNDERSTANDING WORKFLOW

To fully understand a laboratory’s workflow, one must audit all phases of the testing process. Only then can one determine how to optimize performance and to what degree technologic or nontechnologic solutions are needed. Table 2-1 provides some of the issues to consider.

Data are of paramount importance in any workflow analysis. Although laboratory data are rather easy to produce because they are readily available from automated analyzers and information systems, they may not be complete, valid, or in the format required. Because laboratory data play a central role in laboratory decision-making (e.g., determining which analyzer to acquire), they have to be accurate; otherwise, one may make wrong downstream decisions that can have a negative impact on operations. One must understand how data are collected by each of these systems and whether they are valid. For instance, do the test statistics pulled from an analyzer provide information on how many patient reportable tests are done, or do they count how many total tests are done (with quality control, repeats, etc.)? Are panel constituents counted individually, is only the panel counted, or are both counted? Are the “collect” times accurate on turnaround time reports that measure “collect to result”? Or are samples indicated as “collected” on a patient floor before they are actually collected, thereby making the turnaround time appear longer than actual? Ultimately, there is no substitute for carefully reviewing data to determine whether they make sense. Sometimes, this requires manually verifying data collected electronically or directly observing a work area. For example, it may be necessary to observe when samples arrive in the laboratory to determine how long a delay exists before staff assign a receipt time in the computer. By doing so, one can determine the accuracy of the sample receipt time.

DATA COLLECTION TECHNIQUES

Many types of data can be used to assess workflow. Although some of the fundamental data analysis techniques are described in this chapter, they may have to be supplemented with additional data collection to analyze unique characteristics of a laboratory’s operation. It is always useful (some would say imperative) to check that the data collected reflect actual laboratory experience rather than anomalies created by unusual workflow patterns or laboratory information system (LIS) programs or definitions.

Sample and Test Mapping

One fundamental data collection technique is to analyze the distribution of samples and tests over time (Fig. 2-2). Depending on what is mapped, the time interval can be a day (e.g., hour increments for frequently ordered tests like those in general chemistry) or a week (e.g., daily increments for tests batched several times a week). The goal is to identify overall workload patterns to assess whether resources are appropriately matched to needs, and whether turnaround time or other performance indicators can be

TABLE 2-1

Issues to Consider When Auditing Operations

Test ordering	Where are orders placed—in the laboratory, patient unit, or office? Are inpatient orders handled differently than outpatient ones? Is there a paper or electronic requisition?
Sample collection	Who collects the samples—laboratory or physician? When are they collected—all hours or just in the AM? Are samples bar coded at the site of collection or in the laboratory? How are the labels generated? Is there a positive patient ID system? Does the label contain all the information needed to process the sample?
Transportation	How are samples delivered—by messenger, automatic carrier transport, or a combination? Do all laboratories participate? Are all patient care areas served? How are stats handled? What is their impact? Is there a separate system for emergency department and intensive care units?
Sample receipt	Is there a central receiving area? How are samples distributed to each laboratory? Does physical layout promote efficient sample flow? How are stat samples distinguished from routine ones? How are problem samples handled? Are samples sorted by workstation or department?
Sample processing	Are samples centrifuged centrally or in distributed locations? Are stats handled differently? Are samples aliquoted? If so, where? Is a separate sample drawn for each workstation?
Testing	How many workstations are used? How does capacity relate to need? How are samples stored and retrieved? How long are samples kept? When and why are samples repeated? Are repeat criteria appropriate?
Reporting	How are results reported? Electronically? By remote printer? How are stat and critical values reported, and are criteria appropriate? How many calls for reports does the laboratory receive, and why? How are point-of-care tests reported?

improved. It is important that the workload measured reflects actual experience. For example, if phlebotomists remotely mark specimens “received” or the laboratory actually orders tests in the LIS, the measured workload distribution may not accurately reflect the underlying processes. As part of the exercise, it is also important to map routine samples versus stat ones and to map locations that may have special needs such as the emergency department. In addition to sample mapping, one should map key tests and the number or “density” of tests per sample. This is of special interest in the chemistry section. Outpatient samples typically have greater test density than inpatient ones, so an equal number of inpatient and outpatient samples may be associated with different inpatient and outpatient workloads. In automated chemistry, sample mapping more closely reflects staffing needs in that much of the labor is associated with handling and processing tubes rather than actually performing the assays. In contrast, test mapping more closely reflects instrument needs (i.e., the test throughput it needs to complete its workload in a timely manner). By mapping samples and tests and relating them to turnaround time and staffing, a laboratory can identify production bottlenecks and alter workflow to

achieve better outcomes. Very frequently, laboratories discover that delays are less the result of instrument issues per se, and are more the result of workflow patterns that are not matched to instrument capabilities.

Tube Analysis

Part of the laboratory’s daily work is related to processing collection tubes or containers. “Tube labor” includes sorting and centrifuging; aliquoting; racking, unracking, loading, and unloading samples on analyzers; retrieving tubes for add-on tests; performing manual dilutions or reruns (depending on instrument); and storing tubes. Although the time needed to perform a tube task may seem insignificant, it has to be repeated many times per day, and this can add up to a substantial amount of time. For example, at an average of 10 seconds per tube, it will take a laboratory 3.3 hours to sort 1200 tubes per day. Automation can often reduce this labor, but redesigning the workflow may be a less expensive and more efficient alternative. To the extent that a laboratory reduces the number of tubes and/or the number of tasks associated with each tube, it can reduce tube labor and positively influence workflow and staffing needs.

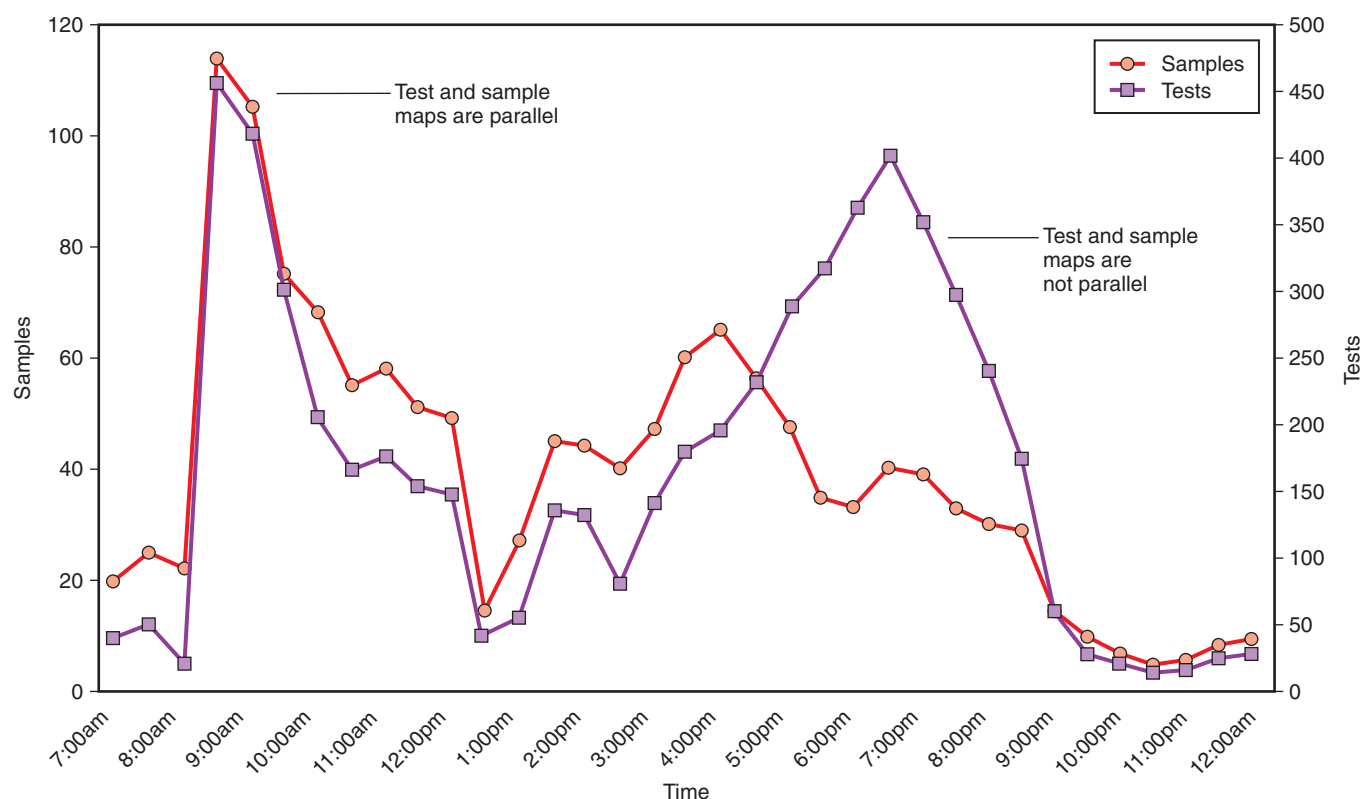

Figure 2-2 Sample and test mapping. Note that the morning volume peak is due to inpatients, and the density is roughly four tests per sample. The evening peak is largely due to outpatients and density is far greater, about 10 tests per sample. Test density fluctuates during the day; thus both sample mapping and test mapping are necessary to accurately evaluate workload.

TABLE 2-2

Chemistry Tube Analysis

	Analyzer A	Analyzer B
Total tubes run	500	500
Mechanical error	13	15
Dilution	7	20
Clot/low volume	20	30
Total instrument-related reruns	40 (32% of total reruns)	65 (65% of total reruns)
Delta check	62	21
Panic value	23	14
Total laboratory criteria-related reruns	85 (68% of total reruns)	35 (35% of total reruns)
Total reruns	125	100
% reruns	25%	20%

Chemistry “reruns” are caused by different factors and can be a source of nonproductive technologist time and/or turnaround time delays. Most Analyzer A reruns are related to overly tight limits for delta checks and panic values that flag too many test results for technologist review and rerun. Most Analyzer B reruns are related to instrument flags caused by a narrow linear range for many methods and a large sample volume requirement per test. A nontechnologic solution (i.e., altering laboratory rerun/review criteria to reduce the number of tubes flagged for rerun) benefits Analyzer A; however, only a technologic solution (i.e., a new analyzer) can lower the number of reruns in Analyzer B.

Reducing tube labor is one of the main goals of consolidating chemistry and immunodiagnostic tests into a single analyzer or workcell. Sample mapping provides information about how many containers are received within a specified interval; tube analysis helps to analyze how many additional “tube-related” tasks have to be done. Tube analysis includes the number of containers other than tubes (e.g., fingerstick collections that may require special processing or aliquoting) and the number of reruns (i.e., repeats) needed as the result of instrument flags and/or laboratory policies (Table 2-2).

Workstation Analysis

A typical laboratory is divided into stations for allocating work and scheduling staff. Some workstations consist of a variety of tasks or tests that are grouped together for purposes of organizing work for one or more staff. For example, all manual or semiautomated chemistry tests may be grouped into a workstation, even though testing might actually be performed at different sites or using different equipment around the laboratory. More typically, a workstation is one physical location (e.g., a fully automated analyzer or group of analyzers such as hematology cell counters or a chemistry workcell). Regardless of how a laboratory is organized, it is important to understand where, when, and how the work is performed. This is the goal of a workstation analysis.

Instrument Audit

A key component of any workstation is equipment. By performing an instrument audit (Table 2-3), one can better understand how each analyzer is used, its associated costs, and what potential opportunities might exist to improve performance. The operating characteristics of each instrument should be detailed as part of this process. Examples include the maximum number of samples that can be processed per hour, the number of samples that can be loaded at a single time, and the numbers of reagent containers and assays that can be stored onboard. Instrument throughput (tests/hour) should also be studied by conducting timing studies and reviewing various statistical reports that can be extracted from the instrument and the LIS. Most chemistry analyzers are test-based systems, that is, they perform a specific number of tests per hour, irrespective of how many tests are ordered on each sample. On the other hand, some of these systems are affected by test mix (e.g., the relative proportion of electrolytes, general chemistries, and immunoassays), and this is the major reason that actual throughput experienced in the laboratory may be lower than what is claimed by the vendor. The latter may assume an ideal test mix that cannot be achieved in a given laboratory. It is important to understand how test mix affects an analyzer’s throughput, and whether work can be redistributed in a way that enhances throughput. An instrument that was well suited for the laboratory’s test mix and volume when initially acquired may no longer provide adequate throughput given a change in test mix. It is important to ensure that a vendor’s throughput analysis is based on the laboratory’s actual test mix, and not on a standard used by the vendor.

TABLE 2-3

Number of staff trained
Operating mode
Batch versus continuous
Primary system versus backup

It may turn out that the number of instruments proposed may not meet the laboratory's needs.

It is equally important to receive a clear and concise definition of up-time from the vendor for the instrument(s). This definition should be simple. If the laboratory cannot report patient results, the instrument is down. Some vendors consider an instrument down only if the vendor is called for service. This may mean the percent of up-time by the vendor may be valued higher than the actual up-time experienced by the laboratory. It is important to include this definition in a contract if a laboratory expects a vendor to uphold desired operational performance levels necessary to consistently maintain patient care support.

Last, labor considerations should not be ignored. Must the instrument be attended at all times, or does it have walkaway capability? This information can be very useful in identifying processing bottlenecks and redesigning workflow.

Test Menu

A careful review of the laboratory's test offerings should be done during a workstation analysis. Are the tests performed appropriate for the facility, given the volume and frequency of test analysis? Just because a laboratory can perform a test does not mean that it should. For example, if a test is performed only once a week but requires considerable equipment, training, or labor input, it may make more sense to send it to a reference laboratory where it is performed more frequently. Sometimes the best way to improve turnaround time and lower the cost of a test is not to perform it. Unfortunately, this option can be easily overlooked if one focuses only on how to improve the way existing tests are performed, instead of analyzing how to best meet clinician needs.

Processing Mode and Load Balancing. These can affect both the cost and the timeliness of testing. Samples can be processed in batches or run continuously as they arrive in the laboratory. When grouped into batches, samples are run at specific intervals (e.g., once a shift, once a day, every other day) or whenever the batch grows to a certain size (e.g., every 20 samples). Batch processing is often less expensive than continuous processing because the setup costs (quality control, labor, etc.) are spread over many specimens (see Table 12-2); however, batch processing produces less timely results. Sometimes batch processing is a limitation of the instrument that is used. A batch analyzer cannot be interrupted during operation; thus, a newly arrived sample cannot be processed immediately if the instrument is already in use. Most currently available general chemistry and immunoassay analyzers are random access analyzers that continuously process samples. These analyzers can randomly access sample and reagents and can accommodate an emergency sample at any time. The characteristics of these analyzers are discussed more fully in Chapter 5. Continuous processing is facilitated by load balancing, a technique of spreading testing

over a longer period to better match instrumentation throughput. For example, outpatient work, which does not require a rapid turnaround time, can be sequenced into the workflow during off hours. This improves testing efficiency, reduces the labor content of individual tests, and reduces throughput requirements (and capital cost) of instruments. In addition, if significant outreach testing (which does not typically require a rapid turnaround) is performed, some or all of this volume can be shifted to times that the laboratory is not as busy. The feasibility of load balancing can be evaluated only if accurate test mapping and tube analysis are performed.

Interviews

Data collection is not complete without interviewing staff. This exercise provides an opportunity for staff to participate in analyzing workflow and improving performance. It also identifies issues that would not be readily apparent from data collection alone. For example, many hospitals require electronic order entry on patient care units. Although this practice may eliminate paper requisitions, laboratory staff members may still be placing orders for "add-on" tests that are called into the laboratory (or added electronically), processing special requests, and troubleshooting incorrect orders, unacceptable samples, or misaligned bar code labels applied by nonlaboratory staff during sample collection. This residual work is likely to be transparent because it probably will not appear on reports, logs, or computer printouts. Thus, "computer-generated orders" may still be associated with considerable manual laboratory labor that may be identified only through interviews.

Interviews are particularly valuable in understanding what occurs outside the laboratory. Test ordering patterns or habits can have a significant impact on a laboratory's ability to meet clinician needs. Visits to patient care units and discussions with nursing unit staff can identify pre-processing improvements that cost little to implement but save considerable money downstream.

Early patient discharge can be a challenging task for hospitals trying to shorten length of stay. A full understanding of the discharge process requires interviewing all related staff. One issue that sometimes emerges is the sample collection time for patients awaiting discharge pending a laboratory result. To avoid delays in providing results for discharge patients, some facilities develop elaborate "stat" systems to collect, identify, and process these samples, as well as report results, during the busiest time of the day—the early morning. Sometimes, dedicated (stat instrument) or new technology (point-of-care device) is used for this purpose. However, one can ensure that results are available in the chart during early morning clinical rounds by simply collecting laboratory samples from patients on the evening before discharge. Thus, not all solutions require technology. A careful mix of workflow restructuring and appropriate technology is usually the correct approach and the most cost-effective solution.

Task Mapping

No workflow study is complete without mapping of the tasks or processes involved in performing a test (Middleton, 1996). A rigorous review will detail every specimen-handling step, each decision point, and redundant activities. Task mapping can be applied to any segment of a laboratory's workflow, whether technical or clerical. A full understanding of the tasks involved usually requires thorough staff interviews, as discussed previously. Task mapping should be an ongoing activity and should also be undertaken whenever one contemplates adding a workstation, test, new technology, or any significant change to a laboratory process. When implementing change, it is important to avoid unnecessary or additional steps that are inadvertently added in the name of "efficiency"; task mapping helps identify these steps. Mapping also helps compare processes before and after change (Fig. 2-3, *A* and *B*).

WORKFLOW ANALYSIS

Workflow analysis assimilates all of the previously discussed data and transforms them into valuable information. This step can be done manually or, as will be described later, using commercially available software for part of the analysis. A comprehensive workstation analysis should identify bottlenecks and highlight areas where improvements are necessary.

How is this done? The easiest way, and one that does not require computer support, is to follow the path of a specimen or group of specimens through the entire process. This should begin at or near the bedside to see how physicians are ordering tests and should proceed to specimen acquisition and delivery to the laboratory. A flow sheet, which follows the sample from initial order to arrival in the laboratory, should be created.

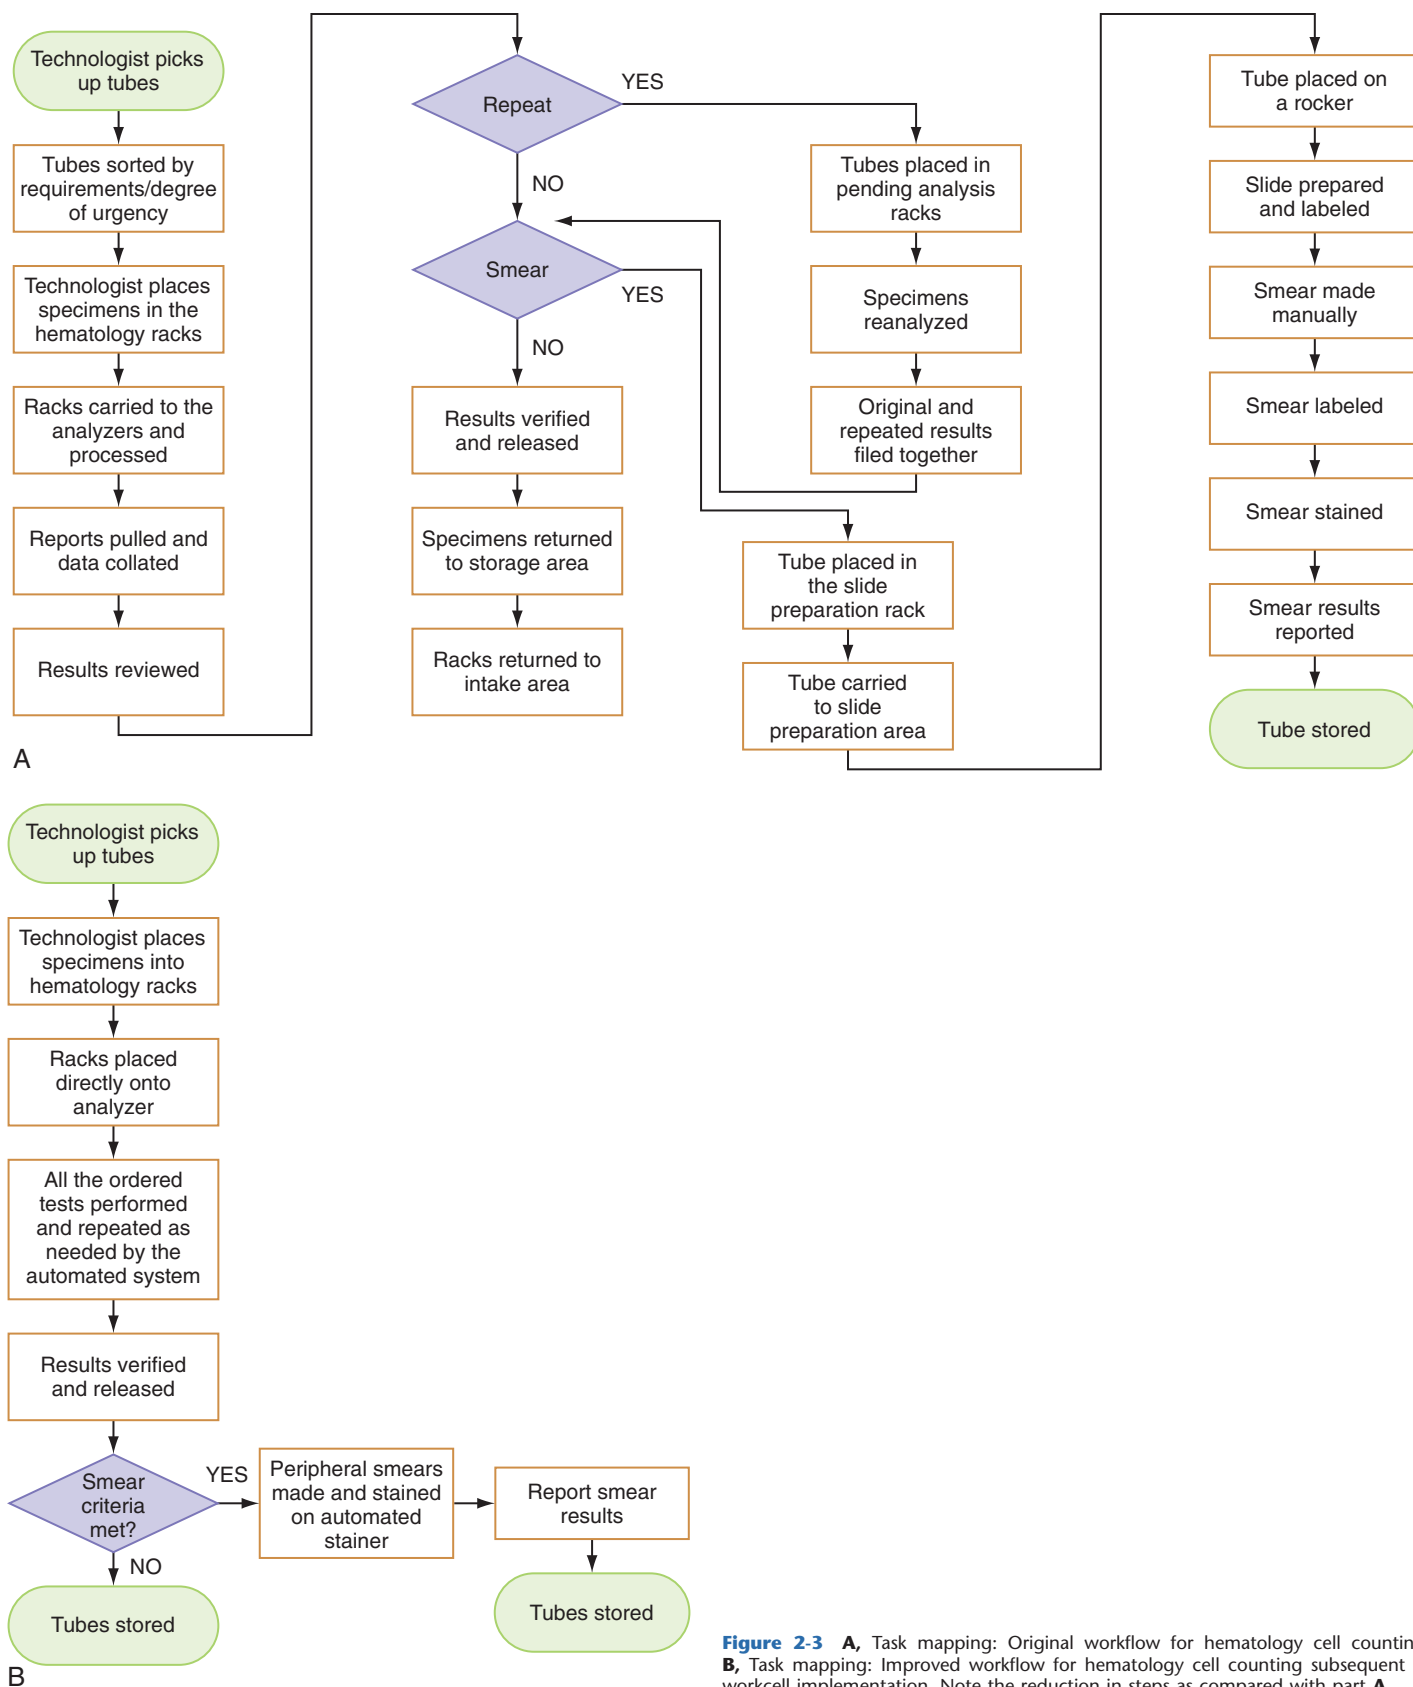

Figure 2-3 **A**, Task mapping: Original workflow for hematology cell counting. **B**, Task mapping: Improved workflow for hematology cell counting subsequent to workcell implementation. Note the reduction in steps as compared with part **A**.

A separate task force is usually assigned to the prelaboratory phase because multiple departments and staff are usually involved; the laboratory often has little or no direct control over this critical portion of workflow, especially when nonlaboratory staff collect samples.

Specimen transit through the laboratory should then be documented, noting areas where batch processing occurs. For example, one should

identify minimum and maximum centrifugation times for applicable specimens (such as those that have to be aliquoted). If specimens require 10 minutes for loading and spinning, this should not be assumed to be the average time because a sample queue may form during peak periods. Using the sample arrival mapping done in data collection, an average time can be assigned by time of day. If this is done manually, it is best to select a

number of key times and average them, if possible. Similarly, one should note whether loading specimens on the analyzer is delayed. Many other examples of physical bottlenecks need to be identified and quantified. It is not always possible to completely eliminate bottlenecks; however, it is possible to mitigate their impact through new technology, alternative processing modes (e.g., random access vs. batch processing), and workflow redesign.

Nonphysical bottlenecks should also be identified and quantified. A classic example is the mode of result verification. Batching results for a technologist to review and accept is every bit as much a bottleneck as is waiting for a centrifuge to process a sample. In contrast, LIS autoverification (where results are automatically released on the basis of preset criteria) can reduce test turnaround time without requiring a major reorganization of the laboratory. However, the degree to which autoverification enhances workflow depends on the manner in which it is implemented and the algorithms defined to qualify a result for this feature. This, in turn, may depend on the LIS used. These issues are discussed further in Chapter 11.

Many vendors who want to sell automated equipment systems to the laboratory will provide free workflow analysis. They usually have experienced technical staff who do this, and the information can be very helpful. The laboratory will need to provide the necessary data or access to the laboratory for data collection. Together the vendor and laboratory leadership need to analyze the workflow to identify opportunities to improve operations, which may well involve the vendor's automated system.

Workflow Modeling

Although the analyses discussed earlier are critical to understanding current and proposed workflow designs, they usually provide a somewhat static picture (i.e., each describes a single data element and often how it changes over time). In practice, however, workflow consists of many interrelated variables, and it is difficult to understand (or to evaluate in the laboratory) how a change in one variable affects another. Further, although workflow studies can be very beneficial, they consume resources that may not be available in every laboratory. To address this need, technology vendors have developed workflow simulations. By using sophisticated workflow modeling software, one can analyze these complex interrelationships to better predict the outcome of a given workflow design (Table 2-4). Workflow modeling can help identify bottlenecks and the impact of staffing changes or different equipment configurations on cost and turnaround time. It can also be used to gain a better understanding of how a given analyzer responds to changes in test volume and test mix. For example, one can simulate the impact of increasing routine test volume on an instrument's turnaround time for stat samples (Mohammad, 2004). As with all workflow analyses, however, software modeling must be based on accurate data collection techniques.

Because most simulation programs are proprietary products, they may not allow modeling of all available instruments. Workflow simulation is still a powerful tool, and inferences can be drawn about more efficient processing and testing regardless of the model instrument involved. More important, these programs readily highlight deficiencies in a laboratory's current operations and can point to specific areas where the greatest improvements are achievable.

Pneumatic Tube Transport of Specimens

Many laboratories, especially those in large hospital facilities, use pneumatic tube systems for specimen transport to the laboratory. They can greatly decrease transport time and thus total turnaround time for test

results. Some of these systems can be extensive, especially the branching systems that can reach most parts of a hospital. Once a laboratory has a tube system, it becomes very dependent on it, requiring a good service and support system to maintain it. Usually the plant operations or engineering department of the hospital maintains the system on a daily basis. In addition, enough specimen carriers must be available to supply all areas of the hospital in need of specimen transport to the laboratory. It is important to monitor the number of carriers in the system and to order new carriers when existing supplies wear out or “disappear” (it is not uncommon for locations to “stockpile” carriers, at the expense of other locations, to ensure their availability).

UNDERSTANDING TECHNOLOGY

No discussion of workflow is complete without examining the role of technology (De Cresce, 1988). Laboratory technology refers largely to three functional areas: testing equipment (i.e., analyzers), preanalytic processors, and information technology (IT). Although the former two areas are specific to the laboratory, IT is not, and its design and role are often determined by factors outside the laboratory. For example, the manner in which a laboratory information system is used for data retrieval and reporting (i.e., whether or not physicians directly access the LIS to view results) depends on whether a hospital information system is available to serve this purpose (see Chapter 11). In the latter case, laboratory data are accessed and reported through a secondary system. Also, the laboratory system may be part of a broader approach or a single IT vendor solution within the health care center and not a standalone product to be selected by the laboratory. Under these circumstances, the technology selected, although optimal for the general institution, may not be optimal for the laboratory. Changes in hospital-wide systems are rarely made to accommodate efficiencies in ancillary services like the laboratory. These systems are primarily geared toward easy access to clinical information by caregivers and accurate billing by the hospital finance department.

THE ROLE OF TECHNOLOGY: PRINCIPLES AND PITFALLS

Technology has radically changed the clinical laboratory over the past 30 years and continues to be the driving force behind many new developments. Periodically, a breakthrough technology is introduced that revolutionizes laboratory medicine (Table 2-5). Examples include the random access chemistry analyzer, the automated immunodiagnostics system, the chemistry and immunodiagnostics integrated workcell, and molecular diagnostics. Each change profoundly alters how a laboratory functions and the type of information it provides clinicians. Although breakthrough technologies offer a large potential benefit, they cost more. Over time, a breakthrough technology is adopted by multiple vendors, competition develops, prices fall, and its use becomes widespread among laboratories; in other words, it becomes a current or derivative technology. Early adopters of breakthrough technology often pay more and receive less benefit than those who wait until it becomes a current technology. By thoroughly understanding the role of technology one can determine how to best use it in the clinical laboratory. The following issues should be considered when evaluating technology.

Is technology needed? Technology is an integral part of a modern laboratory; however, it is not the solution to every problem. Often a non-technologic solution provides a faster, better, and less expensive workflow approach than a technologic one. Knowing when to introduce a nontechnologic solution instead of a technologic one can mean the difference between a targeted, cost-effective solution and an expensive one that does

Figure 2-4 Test demand versus instrument capacity. Note that demand exceeds capacity during peak periods, thereby creating backlogs. In many facilities, short backlogs are acceptable. If they are not clinically acceptable, the laboratory should explore ways to more evenly match capacity and demand, for example, by altering blood collection schedules or introducing new work from additional clients. New technology should be the last approach that is considered.

not fully address the initial problem, provides unnecessary functionality, or provides necessary functionality but at an unnecessary cost. For example, a laboratory may experience a sharp morning spike in samples, thereby creating workflow backlogs (Fig. 2-4). Instead of purchasing more equipment to provide additional capacity during peak periods, the laboratory should look for ways to distribute work more evenly during the shift. The key is to avoid delivering large sample batches to the laboratory. Outreach samples can be more evenly distributed because the turnaround time is usually not critical. One approach might be to rearrange phlebotomy draw schedules so that blood draws begin earlier and are spread out over a longer period (Sunyog, 2004). Another approach is to have phlebotomists send samples to the laboratory after every few patients instead of waiting to collect a large batch from an entire floor. One consideration is to have the inpatient nursing unit staff perform specimen collection. This may control the number of inappropriate stat orders because nursing units are more familiar than a laboratory phlebotomist with the status of the patient. This requires consistent phlebotomy training for all nursing unit staff that collect specimens to prevent specimen integrity problems. Thus one should analyze and reengineer processes to the greatest possible degree before embarking on a technology solution; this approach may yield an inexpensive solution that is quicker and easier to implement. Sometimes, nontechnologic solutions, although preferable, are out of the direct control of the laboratory staff and consequently do not receive the attention they deserve. Thus, a technology solution is selected because it can be implemented without the support of other departments.

Technology is a means to an end, not an end. Technology alone does not improve performance and workflow; it is only a tool to reach a goal. Ultimately, new technology succeeds or fails according to how it is implemented. This, in turn, depends on people and their ability to clearly analyze how technology and workflow can be optimally integrated into their setting. What works for one location may not work for another. Sometimes this means changing long-standing practices or staff schedules. For example, if four chemistry analyzers are consolidated into two, staff need to be reallocated to take into account fewer workstations and/or peak testing needs. Similarly, batching certain tests on a new high throughput analyzer does not take full advantage of its continuous processing capabilities and in some instances may yield a lower throughput than the analyzer it replaces. Last, manually transcribing physician orders from paper requisitions into a hospital or laboratory information system provides far less functionality and error reduction capability than is provided by direct electronic order entry by physicians. Because technology has to be “customized” for each site, laboratories implement the same technology in different ways and experience different outcomes. It should never be assumed that improvements and results seen at another facility will automatically occur in one’s own facility. The most successful implementations require a total workflow reassessment to evaluate how best to integrate technology. By critically evaluating existing practices, one can avoid perpetuating inefficient processes even with new equipment.

Overbuying—the cardinal sin. More than anything else, overbuying increases costs that burden an operation over the life of the technology.

Although it is tempting to overbuy “just in case” capacity needs grow (such as with new outreach work), these needs may not materialize or may occur slowly over time, allowing for an incremental and more cost-effective approach. A new instrument in the laboratory rarely, if ever, directly translates into new testing volume. The market demand for testing is generally independent of the laboratory’s capacity to test, although greater capacity may allow the laboratory to more aggressively market services. Different types of overbuying may occur. For example, one may buy three analyzers instead of two or an analyzer that performs 1000 tests per hour instead of a device that runs 500 tests per hour. Alternatively, a total laboratory automation solution may be implemented instead of one based on several smaller workcells or standalone analyzers. In all instances, overbuying increases costs. All of the previous examples increase depreciation costs, require more service and maintenance, and can lead to ineffective labor utilization and suboptimal workflow. Buying more analyzers than necessary can also increase reagent costs in that each instrument has to be calibrated, controlled, and cross-correlated with other devices running the same test. Reagent waste (due to outdated) may also increase if low volume tests are set up on all of the analyzers.

Overbuying should not be confused with excess capacity that is sometimes unavoidable when necessary backup systems are implemented. Ultimately, it is the laboratory service model that determines whether backup is needed. For some tests (e.g., cardiac markers), the laboratory may need a backup system; for others (e.g., tumor markers), it may not. Also, a stat laboratory’s backup needs will differ from those of a reference laboratory. A well-designed workflow can balance a laboratory’s need for some backup without unnecessary overbuying. For a laboratory that needs a 1000 test/hour capacity, this may mean selecting two 500 test/hour analyzers instead of two running 1000 tests/hour. Alternatively, it may mean selecting one 1000 test/hour analyzer and using a laboratory nearby (that is interfaced to the first laboratory’s information system) for backup. Last, it may mean selecting two 1000 test/hour analyzers but running one at a time. This last solution is rarely successful because it duplicates expensive technology and increases maintenance costs. A simple analogy to the family car is often instructive—people rarely buy two automobiles to do what one can do most of the time. Instead, they rely on alternative sources such as renting, public transportation, or taxis to fill occasional needs. One must be sure not to underbuy as well. Many times the number of analyzers is dependent not only on volume throughput but also on stability (up time). If instrumentation is down a significant amount of time, and the effort to bring it back online will take hours or days, a backup instrument is critical for continued testing support. Many large laboratory operations have extensive automation in chemistry and hematology that require constant availability of service support by the vendor to make sure the instrumentation is always in working order. In some cases, a vendor will actually have a service engineer routinely present onsite during weekday hours to maintain the automation system and to help train staff to do the same. Because of staffing shortages on a national level, automation has helped laboratories do more with less, but only if the automation stays consistently functional. Ultimately, the goal is to “right buy,” that is, to avoid overbuying or underbuying technology.

Do you understand what you are buying? There is a difference between “buying” technology and being “sold” technology by vendors. The former approach requires an analysis by the laboratory to identify what it needs and a thorough understanding of the technology under consideration, whereas the latter relies more heavily on the vendor to provide a solution to the laboratory. The risk of being “sold” a technology is that it might not be the optimal solution. Most instruments work and do what they are advertised to do. Unfortunately, “what they do” may not be what one needs.

The type of technology is also important. Current technology is generally easier to understand and offers a less risky strategy than breakthrough technology, although it might also provide less reward. Breakthrough technology is, by definition, a new technology, and it may be difficult to fully understand whether it is appropriate in a given laboratory setting, how best to implement it, or how significant a financial impact it will make.

Other issues to consider relate to the technology itself and whether it currently offers all the features required by a laboratory. A vendor may promote certain enhancements or capabilities scheduled for the future, especially when marketing analyzers. These may include tests in development, instrument or computer hardware improvements, new versions of software, or automatic upgrades to a next-generation system. Although

TABLE 2-6

Workflow Metric Examples

Metric	Comments
Turnaround Time (TAT) Studies	
Collection to receipt	Is collection time correct? How long does it take for samples to reach laboratory? Is tube transport system functioning properly? Are messenger pickups reliable?
Receipt to result	How long does testing take once the laboratory receives a sample? Is it held in a central receiving area before it is brought to the technologist?
Order (or collection) to result	This is what the physician perceives as total turnaround time. Is it accurate? How long does it take for a released laboratory result to appear in the hospital information system? Do networking issues external to the laboratory delay the appearance of results?
Stat and routine TAT by hour	Is stat TAT longer in AM when routine samples from morning collection arrive? What is the difference in TAT for routine and stats? Are some tests affected more than others?
Monthly Volume Statistics	
"Billable" tests	How many orderable tests are performed? What is the trend? Has total volume or a specific test's volume changed enough to warrant a reevaluation of workflow or testing capacity? Should any tests be sent to a reference laboratory rather than performed in-house?
"Exploded" tests	Exploding chemistry panels into individual components provides a more accurate assessment of general testing "load" on analyzers and reagent usage than orderable tests alone. Has volume changed? Is it related to a specific location or a new service?
By location	Has testing volume changed in specific nursing units or outpatient settings? Has the volume of inpatient and outpatient testing changed?
Reference laboratory tests	Are certain tests increasing in volume; if so, why and at what cost? Are total monthly costs changing? (Tests with the highest cost/year are not always the highest volume ones.) Should certain tests be screened for appropriateness? Does it make sense to perform any of these tests in-house ("buy versus make" decision)?
Sample and Test Mapping	
Tubes per hour	Tube handling in chemistry has a direct impact on staff and includes centrifugation, aliquoting, and storage.
Tests per hour by department or workstation	This is needed to compare "testing demand" versus "instrument capacity" and can help determine optimal instrument configuration.

these future enhancements may seem attractive, they may not materialize, so they should not be a primary reason for choosing technology. A better approach is to delay purchasing the system until it can offer the laboratory the capabilities it needs. Another potential mistake is overestimating a technology's lifetime or usefulness because this will underestimate its true cost. In the end, the question each laboratorian should ask is not "Does this technology work?" but rather "Does this technology work for me?"

OPTIMIZING PERFORMANCE

Optimizing performance refers to the process by which workflow (including laboratory design) and technology are integrated to yield an operation that best meets the clinical needs and financial goals of the organization: high quality at low cost. In practice, there are times when workflow changes improve service levels and reduce cost. For example, consolidating chemistry systems may lower capital and operating costs and may improve turnaround time. At other times, there is a tradeoff between cost and quality. For example, a phlebotomy staff reduction, while lowering costs, may lengthen the time necessary to complete morning blood collection. This, in turn, may delay when test results become available, but this may not be significant if results are not needed until later in the day. On the other hand, if a patient's discharge is contingent on reviewing the result in the morning, a testing delay could increase length of stay. Ultimately, these decisions need to be analyzed within the framework of the overall institution, taking into account the downstream impact of these actions and their effects on other departments.

Optimizing performance is an ongoing process that requires one to constantly assess and reassess workflow and needs. This requires periodic data collection and analysis. Table 2-6 provides examples of workflow metrics that are useful to monitor. Ultimately, the degree to which any of these reports is useful depends on the accuracy of the data. Many different approaches may be taken to optimizing performance; some of the more common ones are discussed here and in Table 2-7.

Consolidation, integration, and standardization are three key interrelated strategies that have assumed increasing importance in recent years as laboratories have become affiliated with one another through large health care networks. These concepts are also relevant to a single facility.

Consolidation. Testing can be consolidated from multiple sites or workstations in a single facility, or selected tests from many facilities can be centralized in one or more locations. Consolidation creates larger sample batches or runs; this improves testing efficiency in that fixed quality control and calibration costs are distributed over more samples. This, in turn, lowers per unit costs. Consolidation may yield larger reference laboratory test volume. A "make versus buy" analysis can determine whether it is economically feasible to insource tests previously sent to a reference laboratory (Kisner, 2003). Consolidation may also improve turnaround time by making it cost-effective to perform tests more frequently or to use a more automated technology. Some tests may not be appropriate to consolidate. For example, blood gases and other point-of-care tests may have to be performed at multiple sites in a hospital to provide the necessary turnaround time demanded by clinicians. Similarly, little benefit may be derived from performing routine hospital complete blood counts (CBCs) at a central off-site location instead of at the main hospital rapid response laboratory. In contrast, it may be beneficial to consolidate across facilities those tests that are less time-sensitive (e.g., tumor markers) or that require special skills and/or dedicated equipment at each site (e.g., microbiology services). To successfully consolidate tests from multiple facilities, a central site must control new costs (by minimizing additional staff or equipment to perform the tests) and provide better or comparable quality and service to what had been provided (Carter, 2004). It must also foster a collaborative approach to ensure that all of the sending facility's needs are met, including common physician concerns such as longer turnaround time and limited ability to access information or interact with a remote laboratory. A successful consolidation should be transparent to the clinician.

Standardization. Standardized policies, methods, and equipment benefit laboratories in several ways. Direct benefits, like lower costs, can be realized when the laboratory aggressively negotiates with one vendor to supply all chemistry or hematology equipment and reagents. Indirect benefits are due to the simplified operations that result from standardization and make it easier to cross-train staff or implement policies and procedures. Standardization is a gradual process that can take several years to complete. Rapid transition usually is not possible because of vendor contract lock-ins; a buyout of an existing contract is usually too expensive and can partially

TABLE 2-7

Strategies to Optimize Performance

Strategy	Example
Consolidate	One facility: Run stat and routine samples together on the same analyzer; run routine and specialty tests on the same platform; collapse number of analyzers and workstations and use workcell, if applicable. Consolidation can reduce “tube labor.” Multiple facilities: Centralize selected low volume, high cost tests/services at a single location (e.g., molecular diagnostics [HIV viral load], blood donor collection).
Standardize	Equipment: All equipment purchased from one vendor yields larger volume discounts and lower costs for reagents and analyzers, especially in chemistry and immunodiagnostics. Method: Uniform reference range for all laboratories promotes seamless testing environment for inpatients and outpatients with data comparability and trending results across laboratories; it also provides system backup without excess redundancy. Policies: Simplify procedure manuals and compliance documents so they can be shared. Staff: Standardized operations make it easier to share staff among facilities. LIS: Database management is simplified.
Integrate	Computer: Network LIS system with other data systems to promote seamless flow (e.g., sending point-of-care results into the LIS). Courier: Use single service to deliver samples among multiple sites.
Strategic sourcing	Long-term strategy: Competitively bid equipment, supplies, reference laboratory services, etc., taking into account payment terms, delivery charges, value-added services, and product costs.
Rapid repricing “Make versus buy”	Short-term strategy: Renegotiate pricing with existing vendors. Review all send-out tests and low volume in-house tests to identify which tests to “buy” (i.e., send out or outsource) and which to “make” (i.e., do in-house) based on cost and turnaround time. Also, review services such as couriers.
Review laboratory policies and tasks	Critically review laboratory policies and procedures to determine their relevance and appropriateness: Can delta check limits be narrowed or eliminated to reduce the numbers of test repeats and verifications without compromising quality? Are critical call values clinically appropriate, or do they generate unnecessary calls to physicians? Can nonurgent expensive tests be batched twice weekly instead of every day? Do clinicians need certain tests daily that are available only several times a week? Are quality control and maintenance procedures excessive?
Make maximum use of simple and/or existing IT solutions	Rule-based autoverification process eliminates need for technologist to manually release each result (Crolla, 2003); sample racking storage system eliminates most of the time spent looking for samples.
Cross-train staff	Train technologists to perform automated chemistry and hematology tests instead of chemistry or hematology alone.
Adjust skill mix	Adjust skill level (and compensation) of staff to match task performed: Use laboratory helpers instead of technologists to centrifuge samples or load samples on analyzers.
Adjust staff scheduling	Use part-time phlebotomists to supplement peak blood collection periods instead of full-time phlebotomists who are underutilized once morning collection is finished.
Change laboratory layout	Design open laboratory that allows all automated testing to run in the same location and promotes cross-training of staff.
Manage utilization	Require pathologist or director approval to order select costly reference laboratory tests, and/or restrict usage of various tests to specialists.

HIV, Human immunodeficiency virus; IT, information technology; LIS, laboratory information system.

or completely offset any intended savings from a new contract. Sometimes, the unique needs of a location may preclude standardization with other laboratories, or a single vendor may not offer a product line that is suitable for each facility. In these instances, it is still possible to significantly lower costs and/or improve performance albeit using a more varied or limited approach.

Integration. Integration is the process by which services at one location are coordinated, shared, and/or connected to those at another to provide a seamless operation. Although integration is often a byproduct of consolidation and standardization, the latter two strategies are not a prerequisite to successful integration. For example, consider a laboratory information system that links several facilities. Although a single seamless operation can be created with a single vendor's system, it is also possible to network systems from different vendors, albeit with greater difficulty and possibly less functionality. Other integration examples include cross-training staff among different laboratory sections or facilities and interfacing point-of-care laboratory data to the main laboratory system.

Six Sigma and Lean. Six Sigma is a management concept that was first introduced by Motorola in 1979 (Gras, 2007). The ultimate goal is to reduce defects to fewer than 3.4 per million procedures. Lean is a management concept that reduces waste and streamlines an operation (Sunnyog, 2004). It was used to describe the automaker Toyota's business process in the 1980s. (See Chapter 1 for a complete discussion of Six Sigma and Lean).

Managing Utilization. Thus far, strategies to optimize performance have focused on ways to do work better and at lower cost. Although this is important, it does not address the most basic question—Is the work, that is, the test, necessary? After all, the least expensive test is the test that is not done. Lowering test volume may change overall operational needs and workflow patterns. Keep in mind that inpatient laboratory work generally is not reimbursed (see Chapter 12), so each laboratory test is an added cost for the hospital. Thus, lowering inpatient utilization has a direct impact on costs. In contrast, outpatient testing generally is reimbursed by a third-party payer or by the patient. Despite this, the amount reimbursed may not be sufficient to cover the cost of the test. This is especially true for expensive new reference laboratory tests for which the laboratory may receive only \$0.20–\$0.30 for each dollar spent. So, selectively controlling outpatient utilization can be financially beneficial. Appropriate utilization of tests does not only mean lowering utilization. In some instances, tests that should be ordered may not be ordered; this could potentially have an impact on patient care and could lengthen stay.

A laboratory may use different strategies to manage utilization depending on the type of test (Lewandrowski, 2003). Over the years, laboratories have realized large cost savings through productivity improvements. As a result, it is far easier and less costly to run a \$0.10 test than to determine whether each one is appropriate. Although this is true for many high-volume tests (like CBCs and basic metabolic panels) it is not true for many new, complex, and costly reference laboratory tests such as cancer diagnostics and viral genotyping. Thus, a different strategy is needed to

manage utilization of costly reference laboratory tests than to manage CBCs. For example, reference laboratory utilization can be managed by reviewing each order (for certain tests) and its cost with the clinician according to guidelines developed with the clinical services. This cost avoidance strategy not only ensures that clinical indications are met; it also educates physicians about the costs and challenges each one to evaluate the cost-benefit of using it. In contrast, high-volume tests such as a CBC require a broader strategy that restricts or guides ordering frequency electronically through various clinical pathways or guideline-based decision support systems (van Wijk, 2002). For example, a comprehensive or basic metabolic panel might be limited to one order per admission if the patient is stable. Little can be saved by eliminating one low-cost laboratory test from a panel of five other tests. The most significant cost savings is realized when a phlebotomy is eliminated. This usually requires rethinking the frequency of laboratory orders across all clinical services and changing practice patterns to reduce the number of times a patient's blood is collected. Test repetition is a common component of overall test utilization and is costly (van Walraven, 2003).

A laboratory-based diagnostic algorithm can assist with medical decision-making and reduce test utilization. With this approach, a physician requests the laboratory to perform a diagnostic workup (e.g., thyroid function evaluation) instead of ordering specific tests. Thus, the laboratory determines the appropriate tests to run and in what order (Yang, 1996).

EVALUATING EXCESS CAPACITY

Multiple factors are involved in the assessment of whether a laboratory has excess capacity that will allow it to accept additional specimens for testing (Table 2-8).

Philosophy and Mission. Before embarking on a program of expansion in testing, it is essential to establish whether additional work brought into a laboratory is consistent with the role of that laboratory and its parent institution. A privately constituted laboratory without direct affiliation to a medical center might look at the situation simply as a business decision with a potential for profit. In contrast, a laboratory that is part of a hospital would have to consider whether additional testing efforts such as outreach specimens from external clients might interfere with delivery of laboratory services to patients being cared for by that health system. Once a statement of purpose has laid out the overall expectations consistent with the philosophy and mission of the organization, a business plan can be developed to decide the resources needed to achieve expansion of laboratory testing.

TABLE 2-8

Factors for Assessing Excess Capacity

Philosophy and mission of laboratory/health system
Maintained service level for existing patients
Revenue enhancement
Business plan
Physical resources
Instrument testing capacity
Periods of peak and slack activity each day
Measurement of actual throughput
Information system enhancements to connect with new clients
Personnel and activities
Preanalytic phase (usually greatly expanded over existing activities within a medical center)
Specimen transport by couriers
Client service representatives/sales persons
Collection of billing and insurance information
Analytic phase
Time and effort study for available time
Specimen receiving, processing, testing, storing, retrieval
Postanalytic phase
Reporting of results by paper, facsimile, computer interface
Economy of scale
Fixed costs of reagents and labor spread over larger number of test specimens
Incremental cost of additional testing

Physical Resource Assessment. Strictly speaking, there would be no sense in growing business by bringing in more specimens for testing if the analytic capability of available laboratory instruments is not sufficient to perform it. In practice, most laboratories have slack periods every day when relatively low numbers of specimens arrive, thereby lending credibility to the idea of excess testing capacity. In addition, it is a generally accepted principle that redundancy of essential analyzers should be maintained, further increasing excess capacity.

Most automated instruments have a product claim of numbers of specimens tested per hour; however, this number could actually be lower than claimed, depending on how many different tests of varying complexity are ordered on each specimen. In addition, it is necessary to take into account both scheduled and actual downtimes for daily and periodic preventive maintenance, for quality control and proficiency specimens, for repeat testing of problem specimens, and for general troubleshooting of unanticipated problems. A review of turnaround times and numbers of specimens tested at peak hours of specimen arrival could yield a reasonable estimate of throughput capacity at greatest efficiency with all instruments fully functional and with a steady supply of specimens to test. Other factors such as speed of delivery of specimens manually or on an automated track system, capacity to process specimens by batching for centrifugation, and time for each batch to be readied for analysis must also be taken into account. Of course, an assessment that comes up short on analytic capacity might be justification for acquisition of additional analyzers to handle increased test volumes.

A particular concern with accepting testing from new clients is the connectivity of information systems and what might need to be done to facilitate direct interface between physician office computers and the computer of a laboratory in a hospital for purposes of ordering and reporting of results and correct billing and insurance information. The costs of computers, interface devices, and software must be taken into account for new client sites.

Personnel. A key question on expansion of testing is whether existing personnel will be sufficient to perform not only additional analytic tasks but also other activities associated with the acquisition and handling of specimens from other sites. A time and effort study can reveal how much time each employee spends receiving, processing, testing, and storing specimens, and retrieving specimens for tests added later. The effort involved in other tasks must also be accounted for; these include instrument calibrations, quality control, proficiency testing, troubleshooting, review of results for repeat testing, proportion of repeat testing, preventive maintenance, and interactions with other personnel both within and outside the laboratory. Factors for vacation and sick leave as well as work breaks and lunch must be included. This type of analysis can measure the amount of time available to perform more testing without increasing the number of employees.

In reality, increasing the number of specimens from new sources and sites such as physician offices will require new tasks to be performed, such as specimen transport and delivery by couriers, account acquisition and maintenance by client service representatives/sales personnel, entry of correct billing and insurance information, and reporting of test results by various means such as paper copy, facsimile transmission, computer interface between laboratory and physician office information systems, and even telephoning of critical results.

Expansion and Economy of Scale. The simplest way to estimate the costs of reagents and other consumable supplies for increased testing volumes is to use the existing rate of such expenses for existing volumes. In fact, whenever an increase in volume can be managed without performing additional calibrations or quality control testing, then this economy of scale allows the additional work to be done at an incremental cost consisting of only the additional reagents and consumables. This economy of scale also extends to labor costs whenever excess capacity exists and no additional personnel are needed to perform more tests. Thus fixed costs become a smaller percentage of operating expenses as the volume of test specimens increases.

Most laboratories at some point will have the need to assess the feasibility of adding testing to enhance revenues. For this reason and also simply to be prepared for expansion of testing requirements from existing clients, it is good practice to periodically update the laboratory's capacity to expand delivery of services.

SELECTED REFERENCES, 36**KEY POINTS**

- Errors and variables in the preanalysis stage can affect test results.
- Patient variables include physical activity, diet, age, sex, circadian variations, posture, stress, obesity, smoking, and medication.
- Strict adherence to proper technique and site selection can minimize collection variables such as hemolysis, hemoconcentration, clots, and other causes for sample rejection or erroneous results.
- Blood collection containers are color-coded based on additive or preservative, and each is suitable only for specific tests. Failure to use the proper tubes or filling tubes in the wrong sequence can produce erroneous results.
- Blood collection staff must be adequately trained in safety and confidentiality issues.
- Blood, urine, and other body fluid constituents can change during transport and storage. The extent of these changes varies by analyte.
- The most common reasons for specimen rejection are clotted blood for hematology or coagulation tests; insufficient volume in a tube for coagulation tests; and hemolysis, icterus, and lipemia in serum or plasma that can cause interferences in chemistry testing.

Preanalysis refers to all the complex steps that must take place before a sample can be analyzed. Over the years, a series of studies identified that 32%–75% of all testing errors occur in the preanalytic phase (Bonini, 2002; Hofgartner, 1999; Lapworth, 1994; Plebani, 2010; Stahl, 1998), and technologic advances and quality assurance procedures have significantly reduced the number of analytic-based errors. This has exposed the preanalysis stage as a major source of residual “error” and/or variables that can affect test results. Preanalytic factors include patient-related variables (diet, age, sex, etc.), specimen collection and labeling techniques, specimen preservatives and anticoagulants, specimen transport, and processing and storage. Potential sources of error or failure in this process include improperly ordered tests, sample misidentification, improper timing, improper fasting, improper anticoagulant/blood ratio, improper mixing, incorrect

order of draw, and hemolyzed or lipemic specimens. The most frequent preanalytic errors include improperly filling the sample tube, placing specimens in the wrong containers or preservatives, and selecting the incorrect test (Plebani, 2010). Table 3-1 lists 10 of the most common errors associated with specimen collection.

Errors in the preanalytic stage create rework or additional investigation that may cause unnecessary procedures for patients and costs to the health care system (Stankovic, 2010). Preanalytic issues have downstream impact on the use of laboratory resources, hospital costs, and overall quality of care. By some estimates, specimen collection errors cost the average 400-bed hospital about \$200,000/year in re-collection costs. Proper collection technique is also essential to minimize injury to the phlebotomist and the patient. Treatment for an injury related to a traumatic needlestick can cost \$500–\$3000, and poor technique can result in patient injury such as nerve and arterial damage, subcutaneous hemorrhage, infection, and even death. The Centers for Disease Control and Prevention (CDC) estimates that 385,000 needlestick injuries occur per year (CDC, 2008). Many go unreported. This chapter discusses the preanalytic process with special emphasis on the clinical impact of variables and sources of failure.

PRECOLLECTION VARIABLES

In preparing a patient for phlebotomy, care should be taken to minimize physiologic factors related to activities that might influence laboratory determinations. These include diurnal variation, exercise, fasting, diet, ethanol consumption, tobacco smoking, drug ingestion, and posture.

PHYSIOLOGIC FACTORS

Diurnal variation. This may be encountered when testing for hormones, iron, acid phosphatase, and urinary excretion of most electrolytes such as sodium, potassium, and phosphate (Dufour, 2003). Table 3-2 presents several tests affected by diurnal variations, posture, and stress.

Exercise. Physical activity has transient and long-term effects on laboratory determinations. Transient changes may include an initial decrease

TABLE 3-1

Ten Common Errors in Specimen Collection

1. Misidentification of patient
2. Mislabeling of specimen
3. Short draws/wrong anticoagulant/blood ratio
4. Mixing problems/clots
5. Wrong tubes/wrong anticoagulant
6. Hemolysis/lipemia
7. Hemoconcentration from prolonged tourniquet time
8. Exposure to light/extreme temperatures
9. Improperly timed specimens/delayed delivery to laboratory
10. Processing errors: Incomplete centrifugation, incorrect log-in, improper storage

followed by an increase in free fatty acids, and lactate may increase by as much as 300%. Exercise may elevate creatine phosphokinase (CK), aspartate aminotransferase (AST), and lactate dehydrogenase (LD), and may activate coagulation, fibrinolysis, and platelets (Garza, 1989). These changes are related to increased metabolic activities for energy purposes and usually return to preexercise levels soon after exercise cessation. Long-term effects of exercise may increase CK, aldolase, AST, and LD values. Chronic aerobic exercise is associated with lesser increases in plasma concentration of muscle enzymes such as CK, AST, alanine aminotransferase (ALT), and LD. Decreased levels of serum gonadotropin and sex steroid concentrations are seen in long-distance athletes while prolactin levels are elevated (Dufour, 2003).

Diet. An individual's diet can greatly affect laboratory test results. The effect is transient and is easily controlled. Glucose and triglycerides, absorbed from food, increase after eating (Dufour, 2003). After 48 hours of fasting, serum bilirubin concentrations may increase. Fasting for 72 hours decreases plasma glucose levels in healthy women to 45 mg/dL (2.5 mmol/L), while men show an increase in plasma triglycerides, glycerol, and free fatty acids, with no significant change in plasma cholesterol. When determining blood constituents such as glucose, triglycerides, cholesterol, and electrolytes, collection should be done in the basal state (Garza, 1989). Eating a meal, depending on fat content, may elevate plasma potassium, triglycerides, alkaline phosphatase, and 5-hydroxyindoleacetic acid (5-HIAA). Stool occult blood tests, which detect heme, are affected by the intake of meat, fish, iron, and horseradish, a source of peroxidase, causing a false-positive occult blood reaction (Dufour, 2003). Physiologic changes may include hyperchylomicronemia, thus increasing turbidity of the serum or plasma and potentially interfering with instrument readings.

Certain foods or diet regimens may affect serum or urine constituents. Long-time vegetarian diets are reported to cause decreased concentrations of low-density lipoproteins (LDLs), very-low-density lipoproteins (VLDLs), total lipids, phospholipids, cholesterol, and triglycerides. Vitamin B₁₂ deficiency can also occur, unless supplements are taken (Young, 2001). A high meat or other protein-rich diet may increase serum urea, ammonia, and urate levels. High protein, low carbohydrate diets, such as the Atkins diet, greatly increase ketones in the urine and increase the serum blood urea nitrogen (BUN). Foods with a high unsaturated-to-saturated fatty acid ratio may show decreased serum cholesterol, while a diet rich in purines will show an increased urate value. Foods such as bananas, pineapples, tomatoes, and avocados are rich in serotonin. When ingested, elevated urine excretion of 5-HIAA may be observed. Beverages rich in caffeine elevate plasma free fatty acids and cause catecholamine release from the adrenal medulla and brain tissue. Ethanol ingestion increases plasma lactate, urate, and triglyceride concentrations. Elevated high-density lipoprotein (HDL) cholesterol, γ -glutamyl transferase (GGT), urate, and mean corpuscular volume (MCV) have been associated with chronic alcohol abuse.

Serum concentrations of cholesterol, triglycerides, and apoB lipoproteins are correlated with obesity. Serum LD activity, cortisol production, and glucose increase in obesity. Plasma insulin concentration is also increased, but glucose tolerance is impaired. In obese men, testosterone concentration is reduced (Young, 2001).

Stress. Mental and physical stresses induce the production of adrenocorticotropic hormone (ACTH), cortisol, and catecholamines. Total cholesterol has been reported to increase with mild stress, and HDL cholesterol

TABLE 3-2

Tests Affected by Diurnal Variation, Posture, and Stress

Cortisol	Peaks 4–6 AM; lowest 8 PM–12 AM; 50% lower at 8 PM than at 8 AM; increased with stress
Adrenocorticotrophic hormone	Lower at night; increased with stress
Plasma renin activity	Lower at night; higher standing than supine
Aldosterone	Lower at night
Insulin	Lower at night
Growth hormone	Higher in afternoon and evening
Acid phosphatase	Higher in afternoon and evening
Thyroxine	Increases with exercise
Prolactin	Higher with stress; higher levels at 4 and 8 AM and at 8 and 10 PM
Iron	Peaks early to late morning; decreases up to 30% during the day
Calcium	4% decrease supine

to decrease by as much as 15% (Dufour, 2003). Hyperventilation affects acid-base balance and elevates leukocyte counts, serum lactate, or free fatty acids.

Posture. Posture of the patient during phlebotomy can have an effect on various laboratory results. An upright position increases hydrostatic pressure, causing a reduction of plasma volume and increased concentration of proteins. Albumin and calcium levels may become elevated as one changes position from supine to upright. Elements that are affected by postural changes are albumin, total protein, enzymes, calcium, bilirubin, cholesterol, triglycerides, and drugs bound to proteins. Incorrect application of the tourniquet and fist exercise can result in erroneous test results. Using a tourniquet to collect blood to determine lactate concentration may result in falsely increased values. Prolonged tourniquet application may also increase serum enzymes, proteins, and protein-bound substances, including cholesterol, calcium, and triglycerides, as the result of hemoconcentration when plasma water leaves the vein because of back pressure. After bed rest in the hospital, a patient's hemoglobin (Hb) can decrease from the original admitting value enough to falsely lead a physician to suspect internal hemorrhage or hemolysis (Dufour, 2003). This effect can be amplified by intravenous fluid administration. Patients should be advised to avoid changes in their diet, consumption of alcohol, and strenuous exercise 24 hours before having their blood drawn for laboratory testing.

Age. Age of the patient has an effect on serum constituents. Young defines four age groups: newborn, childhood to puberty, adult, and elderly adult (Young, 2001). In the newborn, much of the Hb is Hb F, not Hb A, as seen in the adult. Bilirubin concentration rises after birth and peaks at about 5 days. In cases of hemolytic disease of the fetus and newborn (HDFN), bilirubin levels continue to rise. This often causes difficulty in distinguishing between physiologic jaundice and HDFN. Infants have a lower glucose level than adults because of their low glycogen reserve. With skeletal growth and muscle development, serum alkaline phosphatase and creatinine levels, respectively, also increase. The high uric acid level seen in a newborn decreases for the first 10 years of life, then increases, especially in boys, until the age of 16 (Young, 2001). Most serum constituents remain constant during adult life until the onset of menopause in women and middle age in men. Increases of about 2 mg/dL (0.05 mmol/L) per year in total cholesterol and 2 mg/dL (0.02 mmol/L) per year in triglycerides until midlife have been reported. The increase in cholesterol seen in postmenopausal women has been attributed to a decrease in estrogen levels. Uric acid levels peak in men in their 20s but do not peak in women until middle age. The elderly secrete less triiodothyronine, parathyroid hormone, aldosterone, and cortisol. After age 50, men experience a decrease in secretion rate and concentration of testosterone and women have an increase in pituitary gonadotropins, especially follicle-stimulating hormone (FSH) (Young, 2001).

Gender. After puberty, men generally have higher alkaline phosphatase, aminotransferase, creatine kinase, and aldolase levels than women; this is due to the larger muscle mass of men. Women have lower levels of magnesium, calcium, albumin, Hb, serum iron, and ferritin. Menstrual blood loss contributes to the lower iron values (Young, 2001).

TABLE 3-3

Changes in Serum Concentration (or Activities) of Selected Constituents Due to Lysis of Erythrocytes (RBCs)

Constituent	Ratio of concentration (or activity) in RBC to concentration (or activity) in serum	Percent change of concentration (or activity) in serum after lysis of 1% RBC, assuming a hematocrit of 0.50
Lactate dehydrogenase	16:1	+272.0
Aspartate aminotransferase	4:1	+220.0
Potassium	23:1	+24.4
Alanine aminotransferase	6.7:1	+55.0
Glucose	0.82:1	−5.0
Inorganic phosphate	0.78:1	+9.1
Sodium	0.11:1	−1.0
Calcium	0.10:1	+2.9

Modified from Caraway WT, Kammeyer CW. Chemical interference by drug and other substances with clinical laboratory test procedures. Clin Chem Acta 1972; 41:395; and Laessig RH, Hassmer DJ, Paskay TA, et al. The effects of 0.1 and 1.0 percent erythrocytes and hemolysis on serum chemistry values. Am J Clin Pathol 1976; 66:639–644, with permission.

COMMON INTERFERENCES

In Vivo

Tobacco Smoking

Tobacco smokers have high blood carboxyhemoglobin levels, plasma catecholamines, and serum cortisol. Changes in these hormones often result in decreased numbers of eosinophils, while neutrophils, monocytes, and plasma fatty free acids increase. Chronic effects of smoking lead to increased Hb concentration, erythrocyte (RBC) count, MCV, and leukocyte (WBC) count. Increased plasma levels of lactate, insulin, epinephrine, and growth hormone and urinary secretion of 5-HIAA are also seen. Vitamin B₁₂ levels may be substantially decreased and have been reported to be inversely proportional to serum thiocyanate levels. Smoking also affects the body's immune response. Immunoglobulin (Ig)A, IgG, and IgM are lower in smokers, and IgE levels are higher. Decreased sperm counts and motility and increased abnormal morphology have been reported in male smokers when compared with nonsmokers (Young, 2001).

In Vitro

Collection-Associated Variables

On occasion, when there is a problem finding a vein for phlebotomy, the specimen may be hemolyzed as the result of sheer forces on the red blood cells. Hemolysis can also be caused by using a needle that is too small, pulling a syringe plunger back too fast, expelling the blood vigorously into a tube, shaking or mixing the tubes vigorously, or performing blood collection before the alcohol has dried at the collection site. Hemolysis is present when the serum or plasma layer is pink. Hemolysis can falsely increase blood constituents such as potassium, magnesium, iron, LD, phosphorus, ammonium, and total protein (Garza, 2002). Table 3-3 shows changes in serum concentrations (or activities) of selected constituents caused by lysis of RBCs.

Because of the extremely important role of potassium in cardiac excitation, elevations due to hemolysis can be problematic, especially for emergency room patients who are at risk of hemolysis during frantic blood collection. The relationship between level of hemolysis and potassium (as determined on a Siemens ADVIA 1650 chemistry analyzer [Siemens Healthcare Diagnostics, Deerfield, Ill.]) in serum and plasma specimens is shown in Figure 3-1. Even with no hemolysis, the range of potassium concentrations can be broad in a combination of healthy and sick individuals. Low levels of hemolysis cause only minor elevations, but very strong hemolysis can raise the potassium level by 2 to 3 mEq/L into a critical range.

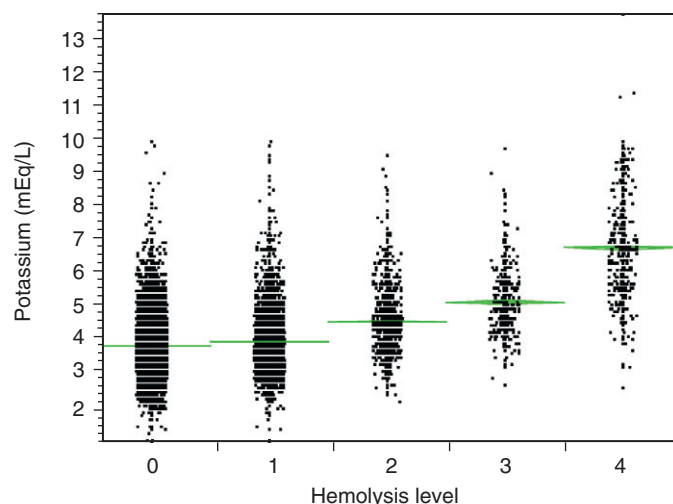

Figure 3-1 Relationship between hemolysis and potassium in 60,989 serum and plasma specimens grouped according to level of hemolysis. The mean values of potassium were 4.12, 4.23, 4.80, 5.36, and 6.93 mEq/L for levels of hemolysis from 0 through 4, respectively.

Another special case where pseudohyperkalemia can occur is in patients with extremely high blast counts in acute or accelerated phase leukemias. Those blasts can be fragile and may lyse during standard phlebotomy, releasing potassium. In contrast, specimens with very high WBC counts that are collected gently can show pseudohypokalemia when potassium is taken up by highly metabolically active leukemic cells along with glucose; such specimens can be transported on ice to slow this enzymatically mediated uptake.

Normally platelets release potassium during clotting, so serum has a slightly higher value of potassium than plasma from the same individual; this difference is accentuated when the platelet count is extremely elevated.

To avoid problems with hemoconcentration and hemodilution, the patient should be seated in a supine position for 15 to 20 minutes before the blood is drawn (Young, 2001). Extended application of the tourniquet can cause hemoconcentration, which increases the concentrations of analytes and cellular components. When blood collection tubes that contain various anticoagulants/additives are used, it is important to follow the proper order of draw and to thoroughly mix an anticoagulated tube of blood after it has been filled. Failure to mix a tube containing an anticoagulant will result in failure to anticoagulate the entire blood specimen, and small clots may be formed. Erroneous cell counts can result. If a clot is present, it may also occlude or otherwise interfere with an automated analyzer. It is very important that the proper anticoagulant be used for the test ordered. Using the wrong anticoagulant will greatly affect the test results.

Each collection tube containing an anticoagulant has a specific manufacturer's color code. Icteric or lipemic serum provides additional challenges in laboratory analysis. When serum bilirubin approaches 430 mmol/L (25 mg/L), interference may be observed in assays for albumin (4-hydroxyazobenzene-2-carboxylic acid [HABA] procedure), cholesterol (using ferric chloride reagents), and total protein (Biuret procedure). Artificially induced values in some laboratory determinations result when triglyceride levels are elevated (turbidity) on the basis of absorbance of light of various lipid particles. Lipemia occurs when serum triglyceride levels exceed 4.6 mmol/L (400 mg/dL). Inhibition of assays for amylase, urate, urea, CK, bilirubin, and total protein may be observed. To correct for artifactual absorbance readings, "blanking" procedures (the blank contains serum, but lacks a crucial element to complete the assay) or dual-wavelength methods may be used. A blanking process may not be effective in some cases of turbidity, and ultracentrifugation may be necessary to clear the serum or plasma of chylomicrons.

SPECIMEN COLLECTION

THE TEST ORDER

One of the most frequent preanalytic errors involves selecting the wrong laboratory test or panel of tests, leading to inappropriate interpretation of results (Bonini, 2002). Laboratory tests are usually ordered electronically

(e.g., computer) or in writing (e.g., paper requisition). This information is conveyed through written or computer order entry. Online computer input is the most error-free means of requesting laboratory tests. The clinician initiates the request for a laboratory measurement or examination by completing a written order for desired laboratory measurements or examinations in the patient's medical record or chart. Verbal requests are made in emergency situations and should be documented on a standard form; after the blood is drawn, an official laboratory request or computerized order should be placed (Garza, 2002). Physician direct order entry and result acquisition through user-friendly networked computers are realistic approaches to providing prompt and accurate patient care. Patient demographics include the patient's name, sex, age, date of birth (DOB), date of admission, date on which measurement or examination was ordered, hospital number, room number, physician, and physician's pharmacy code number. Computerized laboratory information systems (LISs), common in today's laboratories, are used to generate requisitions and specimen labels. Some systems also generate requisitions with the number of tubes and the types of tubes required for collection.

Most laboratories facilitate test ordering by providing a written or computerized medical information system, which lists available tests, types of specimens required, collection methods, color of blood collection tubes used, amounts of blood/body fluid required, turnaround time, reference intervals, test codes, costs, diagnostic information, etc. All specimens must be clearly labeled. Preprinted bar code labels applied after proper patient identification, and after the specimen is collected, avoid preanalytic transcription errors. Frequently, the laboratory receives requests for "add-ons." These are additional tests requested to be performed on a specimen that has previously been collected. Problems are encountered when the specimen is not the proper type for the add-on requested test, the residual volume is not sufficient to perform the test, or storage conditions result in deterioration of the analyte (e.g., bicarbonate). This is usually due to the presence or absence of a particular anticoagulant or additive. All add-on requests must be documented.

Medicolegal concerns include proper identification of the patient, proper labeling of the specimen, patient consent issues, patient privacy issues, and chain of custody. Laboratories should have clearly written policies for these issues. In addition, policies should describe what to do when a patient refuses to have blood drawn, what to do if the patient was unable to be drawn, what to do if a patient is unavailable, and how to deal with a combative patient, as well as emergency measures for patients who become ill or faint during phlebotomy. The Health Insurance Portability and Accountability Act (HIPAA) ensures the security and privacy of health data and protects the confidentiality of all patient record information, including all laboratory data. Employees must be trained to comply with HIPAA.

TIME OF COLLECTION

Sometimes, samples have to be collected at a specific time. Failure to follow the planned time schedule can lead to erroneous results and misinterpretation of a patient's condition. The most common tests in this category are the ASAP and stat collections. ASAP means "as soon as possible" and stat is an American medical term meaning "immediately" (from the Latin "statim"). The exact definitions of these terms vary from one laboratory to another. Stat specimens are collected and analyzed immediately. They are given the highest priority and are usually ordered from the emergency department and critical care units (Strasinger, 2003). Timed specimens are ordered for a variety of reasons, usually to monitor changes in a patient's condition, to determine the level of a medication, or to measure how well a substance is metabolized. For example, a physician may want to monitor a cardiac marker to determine if it is rising or decreasing. In therapeutic drug monitoring, trough and peak levels of a drug may be ordered. Trough specimens reflect the lowest level in the blood and are generally drawn 30 minutes before the drug is administered. The peak specimen is drawn shortly after the medication is given; the actual collection time varies by medication. Drug manufacturers specify the length of time that must pass between trough and peak collection times. Measuring how well the body metabolizes glucose involves a 2-hour postprandial specimen and/or a glucose tolerance test. Two-hour postprandial specimens are drawn 2 hours after the patient eats a meal. Results are compared with those of the fasting level. In a glucose tolerance test, multiple samples are drawn over time—one sample before and one or more after the administration of a standardized glucose solution. This test is used to diagnose diabetes mellitus by determining how well the body metabolizes glucose over a given time period.

TABLE 3-4

Reasons for Specimen Rejection

Hemolysis/lipemia
Clots present in an anticoagulated specimen
Nonfasting specimen when test requires fasting
Improper blood collection tube
Short draws, wrong volume
Improper transport conditions (ice for blood gases)
Discrepancies between requisition and specimen label
Unlabeled or mislabeled specimen
Contaminated specimen/leaking container

SPECIMEN REJECTION

All specimens must be collected, labeled, transported, and processed according to established procedures that include sample volume, special handling needs, and container type. Failure to follow specific procedures can result in specimen rejection. Inappropriate specimen type, wrong preservative, hemolysis, lipemia, clots, etc., are reasons for rejection. Not only is specimen rejection costly and time-consuming, it may cause harm to the patient, especially when the blood sample in the tube is mislabeled. The first goal of The Joint Commission 2008 National Patient Safety Goals for Laboratories is to improve "the accuracy of patient identification" (www.jointcommission.org/PatientSafety/NationalPatientSafetyGoals). Misidentification of patients during sample collection for transfusion or at the time of transfusion can be a life-threatening medical error. The incidence of patient misidentification at the time of specimen collection is approximately 1 in 1000, and 1 in 12,000 patients receives a unit of blood that was not intended for that individual (Dzik, 2003; Linden, 2000). As a result, the College of American Pathologists requires laboratories to have a plan to reduce the risk of mistransfusion and suggests as options collecting two samples at separate phlebotomy events, or utilizing an electronic identification verification system such as an electronic bar code reader for patient identification wrist bands (CAP TRM.30575). It is therefore essential to thoroughly train all medical staff in all aspects of patient identification, specimen collection, transportation, and processing. Table 3-4 lists various reasons for specimen rejection.

BLOOD COLLECTION OVERVIEW

Venipuncture is accomplished using a needle/adaptor assembly attached to an evacuated glass/plastic test tube with a rubber/plastic stopper. Blood may also be collected in a syringe and transferred to the appropriate specimen container (evacuated tube system). A syringe may be helpful when procuring a specimen from the hand or ankle, or from small children. In addition, patients with small or poor veins may experience collapse of veins with use of an evacuated tube system. AccuVein (AccuVein LLC, Huntington, N.Y.) is a newly marketed hand-held medical device that helps medical staff visualize veins before phlebotomy. The device emits infrared light and is held about 7 inches over the potential phlebotomy site. Hb in the blood absorbs infrared light and projects an image map of the veins onto the patient's overlying skin. The device is able to distinguish between Hb in the veins and surrounding tissue. This device assists the phlebotomist in determining the best site for needle placement, especially for challenging patients such as the elderly, the obese, burn victims, oncology patients, and patients with other chronic diseases requiring many diagnostic or therapeutic procedures (<http://www.accuvein.com>).

Blood collection tubes have color-coded stoppers that distinguish the presence of a specific anticoagulant or additive, how the tube is chemically cleaned (e.g., for lead or iron determinations), or if the tube does not contain any additives. Table 3-5 lists the most frequently used anticoagulants/additives based on color-coded tube stoppers. Tubes also come in various sizes for adult and pediatric patient populations. Draw volume is determined by the internal vacuum within the sealed tubes (e.g., 3.5, 4.0, 4.5, or 8.5 mL). The use of anticoagulants allows for analysis of whole blood specimens or plasma constituents obtained by centrifugation and separation of the plasma. Plasma contains fibrinogen, which is missing from serum. Many laboratories have converted from glass to plastic collection tubes to minimize exposure to biohazardous material (e.g., blood) and broken glass; to lower biohazard waste disposal costs; and to comply with Occupational Safety and Health Administration (OSHA) guidelines.

TABLE 3-5

Tube Color and Anticoagulant/Additive

Stopper color	Anticoagulant/additive	Specimen type/use	Mechanism of action
Red (glass)	None	Serum/chemistry and serology	N/A
Red (plastic/Hemogard)	Clot activator	Serum/chemistry and serology	Silica clot activator
Lavender (glass)	K ₃ EDTA in liquid form	Whole blood/hematology	Chelates (binds) calcium
Lavender (plastic)	K ₂ EDTA/spray-dried	Whole blood/hematology	Chelates (binds) calcium
Pink	Spray-dried K ₂ EDTA	Whole blood/blood bank and molecular diagnostics	Chelates (binds) calcium
White	EDTA and gel	Plasma/molecular diagnostics	Chelates (binds) calcium
Light blue	Sodium citrate	Plasma/coagulation	Chelates (binds) calcium
Light blue	Thrombin and soybean trypsin inhibitor	Plasma/coagulation	Fibrin degradation products
Black	Sodium citrate	Plasma/sed rates—hematology	Chelates (binds) calcium
Light green/black	Lithium heparin and gel	Plasma/chemistry	Inhibits thrombin formation
Green	Sodium heparin, lithium heparin	Plasma/chemistry	Inhibits thrombin formation
Royal blue	Sodium heparin, K ₂ EDTA	Plasma/chemistry/toxicology	Heparin inhibits thrombin formation Na ₂ EDTA binds calcium
Gray	Sodium fluoride/potassium oxalate	Plasma/glucose testing	Inhibits glycolysis
Yellow	Sterile containing sodium polyanetholesulfonate	Serum/microbiology culture	Aids in bacterial recovery by inhibiting complement, phagocytes, and certain antibiotics
Yellow	Acid citrate dextrose	Plasma/blood bank, HLA phenotyping, and paternity testing	WBC preservative
Tan (glass)	Sodium heparin	Plasma/lead testing	Inhibits thrombin formation
Tan (plastic)	K ₂ EDTA	Plasma/lead testing	Chelates (binds) calcium
Yellow/gray and orange	Thrombin	Serum/chemistry	Clot activator
Red/gray and gold	Clot activator separation gel	Serum/chemistry	Silica clot activator

EDTA, Ethylenediaminetetraacetic acid; HLA, human leukocyte antigen; K₂EDTA, dipotassium form of EDTA; K₃EDTA, tripotassium form of EDTA; N/A, not applicable; Na₂EDTA, disodium EDTA; WBC, white blood cell.

TABLE 3-6

Order of Draw: Evacuated Tube and Syringe

1. Blood-culture tubes (yellow)
2. Coagulation sodium citrate tube (blue stopper)
3. Serum tubes with or without clot activator or gel separator
4. Heparin tubes with or without gel (green stopper)
5. Ethylenediaminetetraacetic acid tubes (lavender stopper)
6. Glycolytic inhibitor tubes (gray stopper)

mandating substitution. This change from glass to plastic has required a modification in the order of draw. Glass or plastic tubes with additives, including gel tubes, are drawn after the citrate tube (blue top) to avoid interference with coagulation measurements (Table 3-6). Glass or plastic serum tubes, without a clot activator or gel separator, may be drawn before the coagulation tubes are drawn, consistent with National Committee on Clinical Laboratory Standards (NCCLS) guidelines (H3-A6) (Ernst, 2004).

ANTICOAGULANTS AND ADDITIVES

Ethylenediaminetetraacetic acid (EDTA) is the anticoagulant of choice for hematology cell counts and cell morphology. It is available in lavender-top tubes as a liquid or is spray-dried in the dipotassium or tripotassium salt form (K₂EDTA in plastic, spray-dried, and K₃EDTA in liquid form in glass tubes). K₃EDTA is a liquid and will dilute the sample $\approx 1\%$ – 2% . K₂EDTA is spray-dried on the walls of the tube and will not dilute the sample. Pink-top tubes also contain EDTA. The EDTA is spray-dried K₂EDTA. Pink tubes are used in immunohematology for ABO grouping, Rh typing, and antibody screening. These tubes have a special cross-match label for information required by the American Association of Blood Banks (AABB) and approved by the U.S. Food and Drug Administration (FDA) for blood bank collections. White-top tubes also contain EDTA and gel. They are used most often for molecular diagnostic testing of plasma. For coagulation testing, a light blue-top tube containing 0.105 M or 0.129 M (3.2% and 3.8%) sodium citrate is commonly used because it preserves the labile coagulation factors. Black-top tubes also contain buffered sodium

citrate and are generally used for Westergren sedimentation rates, as are lavender-top tubes. They differ from light blue-top tubes in that the ratio of blood to anticoagulant is 4:1 in the black-top tubes and 9:1 in the light blue-top tubes.

Heparin, a mucopolysulfuric acid, is an effective anticoagulant in small quantities without significant effect on many determinations. Heparin was originally isolated from liver cells by scientists looking for an anticoagulant that could work safely in humans. Heparin is available as lithium heparin (LiHep) and sodium heparin (NaHep) in green-top tubes. Heparin accelerates the action of antithrombin III, neutralizing thrombin and preventing the formation of fibrin. Heparin has an advantage over EDTA as an anticoagulant, as it does not affect levels of ions such as calcium. However, heparin can interfere with some immunoassays. Heparin should not be used for coagulation or hematology testing. Heparinized plasma is preferred for potassium measurements to avoid an elevation due to the release of potassium from platelets as the blood clots (Garza, 2002). Lithium heparin may be used for most chemistry tests except for lithium and folate levels; for lithium, a serum specimen can be used instead. Sodium heparin cannot be used for assays measuring sodium levels, but it is recommended for trace elements, leads, and toxicology. Sodium heparin is the injectable form used for anticoagulant therapy.

Gray-top tubes are generally used for glucose measurements because they contain a preservative or antiglycolytic agent, such as sodium fluoride, which prevents glycolysis for 3 days (Strasinger, 2003). In bacterial septicemia, fluoride inhibition of glycolysis is neither adequate nor effective in preserving glucose concentration. Red-top tubes have no additive, so blood collected in these tubes clots.

Red-top tubes are used for most chemistry, blood bank, and immunology assays. Integrated serum separator tubes are available for isolating serum from whole blood. During centrifugation, blood is forced into a thixotropic gel material located at the base of the tube. The gel undergoes a temporary change in viscosity during centrifugation and lodges between the packed cells and the top serum layer (Strasinger, 2003). Pediatric-sized tubes are also available. Advantages of serum separator tubes include (1) ease of use, (2) shorter processing time through clot activation, (3) higher serum yield, (4) minimal liberation of potentially hazardous aerosols, (5) only one centrifugation step, (6) use of single tube (same one as patient specimen), and (7) ease of a single label. A unique advantage is that centrifuged specimens can be transported without disturbing the separation.

TABLE 3-7

Anticoagulant/Additive Effect on Blood Tests

Additive	Test	Effect
EDTA	Alkaline phosphatase	Inhibits
	Creatine kinase	Inhibits
	Leucine aminopeptidase	Inhibits
	Calcium and iron	Decrease
	PT and PTT	Increase
	Sodium and potassium	Increase
	Platelet aggregation	Prevents
Oxalate	Acid phosphatase	Inhibits
	Alkaline phosphatase	Inhibits
	Amylase	Inhibits
	LD	Inhibits
	Calcium	Decreases
	Sodium and potassium	Increase
	Cell morphology	Distorts
Citrate	ALT and AST	Inhibit
	Alkaline phosphatase	Inhibits
	Acid phosphatase	Stimulates
	Amylase	Decreases
	Calcium	Decreases
	Sodium and potassium	Increase
	Labile coagulation factors	Preserve
Heparin	Triiodothyronine	Increases
	Thyroxine	Increases
	PT and PTT	Increase
	Wright's stain	Causes blue background
	Lithium (LiHep tubes only)	Increases
	Sodium (NaHep tubes only)	Increases
Fluorides	Acid phosphatase	Decreases
	Alkaline phosphatase	Decreases
	Amylase	Decreases
	Creatine kinase	Decreases
	ALT and AST	Decrease
	Cell morphology	Distorts

ALT, Alanine aminotransferase; AST, aspartate aminotransferase; EDTA, ethylenediaminetetraacetic acid; LD, lactate dehydrogenase; LiHep, lithium heparin; NaHep, sodium heparin; PT, prothrombin time; PTT, partial thromboplastin time.

Some silica gel serum separation tubes may give rise to minute particles that can cause flow problems during analysis. Filtering the serum solves the problem.

A few specialized tubes exist. Red/gray- and gold-top tubes contain a clot activator and a separation gel. These tubes are referred to as serum separator tubes (SSTs) and are used most often for chemistry tests. Therapeutic drug monitoring specimens should not be collected in tubes that contain gel separators, as some gels absorb certain drugs, causing a falsely lowered result. Significant decreases in phenytoin, phenobarbital, lidocaine, quinidine, and carbamazepine have been reported when stored in Vacutainer SST tubes (Becton, Dickinson, and Company [BD], Franklin Lakes, N.J.), while no changes were noted in theophylline and salicylate levels. Storage in standard red-top Vacutainer collection tubes without barrier gels did not affect measured levels of the above therapeutic drugs (Dasgupta, 1994). Studies indicate that this absorption is time dependent, and therefore speed in processing minimizes absorption. Acrylic-based gels do not exhibit the absorption problems associated with silicone and polyester gels (Garza, 2002).

Tubes containing gels are not used in the blood bank or for immunologic testing, as the gel may interfere with the immunologic reactions (Strasinger, 2003). Clotting time for tubes using gel separators is approximately 30 minutes, and tubes that have clot activators, such as thrombin, will clot in 5 minutes. Plain red-stoppered tubes with no additives take about 60 minutes to clot completely (Strasinger, 2003).

Anticoagulants may affect the transport of water between cell and plasma, thereby altering cell size and constituent plasma concentration. Oxalate anticoagulants may shrink red cells; thus blood anticoagulated with oxalate cannot be used to measure hematocrit. Combined ammonium/potassium oxalate does not have the same effect of shrinking cells.

EDTA, citrate, and oxalate chelate calcium, thereby lowering calcium levels. Fluoride, used for glucose determinations, prevents glycolysis by forming an ionic complex with Mg^{++} , thereby inhibiting the Mg^{++} -dependent enzyme, enolase (Young, 2001). Table 3-7 lists anticoagulants/additives and their effects on various blood tests.

BLOOD COLLECTION DEVICES

The most common blood collection system uses a vacuum to pull blood into a container; it consists of a color-coded evacuated collection tube, a double-headed needle, and an adapter/holder. Small tubes are available for pediatric and geriatric collections. The blood collection holder accommodates various sizes (gauge) of blood collection needles. Needles vary from large (16 gauge) to small (23 gauge). Several types of holders have been designed to eject the needle after use. Recent OSHA policies require that the adapters be discarded with the used needle (OSHA, Needlestick Safety Prevention Act, 2002). Pediatric inserts are available for adapters and accommodate the smaller-diameter pediatric blood collection tubes. Also available are a variety of safety needles that cover the needle after use, or retract the needle before it is discarded.

Winged infusion sets (butterfly needles) can be used when blood has to be collected from a very small vein. Butterfly needles come in 21, 23, and 25 gauge. These needles have plastic wings attached to the end of the needle that aid in insertion of the needle into the small vein. Tubing is attached to the back end of the needle, which terminates with an adapter for attachment to a syringe or evacuated collection holder. Every effort must be made to protect the phlebotomist from being stuck with a used needle when a butterfly infusion set is used.

Blood collected in a syringe can be transferred to an evacuated tube. Special syringe safety shield devices are available to avoid unnecessary contact with the blood sample. If blood requires anticoagulation, speed becomes an important factor, and the blood must be transferred before clot formation begins. Once the blood has been transferred, the anticoagulated tube must be thoroughly mixed to avoid small clot formation.

Several additional pieces of phlebotomy equipment are necessary. A tourniquet, usually a flat latex strip or piece of tubing, is wrapped around the arm to occlude the vein before blood collection and is discarded after each phlebotomy. OSHA guidelines state that gloves should be worn when performing phlebotomy and should be changed between patients. Gloves are available in various sizes and are made of various materials to avoid latex sensitivity as experienced by some individuals. Other supplies include gauze pads, alcohol or iodine wipes for disinfection of the puncture site, and a Band-Aid (Johnson & Johnson, New Brunswick, N.J.) to prevent bleeding after completion of the phlebotomy.

BLOOD STORAGE AND PRESERVATION

During storage, the concentration of a blood constituent in the specimen may change as a result of various processes, including adsorption to glass or plastic tubes, protein denaturation, evaporation of volatile compounds, water movement into cells resulting in hemoconcentration of serum and plasma, and continuing metabolic activities of leukocytes and erythrocytes. These changes occur, although to varying degrees, at ambient temperature and during refrigeration or freezing. Storage requirements vary widely by analyte.

Stability studies have shown that clinically significant analyte changes occur if serum or plasma remains in prolonged contact with blood cells. After separation from blood cells, analytes have the same stability in plasma and serum when stored under the same conditions. Glucose concentration in unseparated serum and plasma decreases rapidly in the first 24 hours and more slowly thereafter. This decrease is more pronounced in plasma. Two approaches have been used to minimize this effect. First, the serum or plasma may be rapidly separated from the red cells, or the specimen may be collected in a fluoride tube to inhibit glycolysis of the red blood cells, thereby stabilizing the glucose level during transport and storage. Fluoride has little effect on reducing glycolysis within the first hour of storage and may not reach complete inhibition until 4 hours of storage. One study has demonstrated a reduction in glucose concentration by 0.39 mmol/L in specimens collected in fluoride that are not immediately separated. These authors suggest that specimens collected in fluoride have a negative bias in blood glucose levels (Shi, 2009). Lactate levels increase, and a greater rise is seen in plasma than in serum. Chloride and total carbon dioxide (CO_2) show a steady decrease over 56 hours, with the degree of change more pronounced in plasma. K^+ is reported to be stable for up to 24 hours, after which a rapid increase takes place. The degree of change is slightly more pronounced in plasma. Unseparated serum and plasma yield clinically significant increases in total bilirubin, sodium, urea, nitrogen, albumin, calcium, magnesium, and total protein. These changes are attributed to movement of water into cells after 24 hours, resulting in hemoconcentration (Boyanton, 2002). Other studies found potassium, phosphorus, and glucose to be the analytes that were least stable in serum

not removed from the clot within 30 minutes. Albumin, bicarbonate, chloride, C-peptide, HDL-cholesterol, iron, LDL-cholesterol, and total protein were found to be unstable after 6 hours when the serum was not separated from the clot (Zhang, 1998).

When serum and plasma are not removed from the cells, lipids (such as cholesterol) and some enzymes increase over time, with the change more pronounced in plasma than in serum. LD activity continuously increases over 56 hours. AST, ALT, and CK were found to be stable over 56 hours. GGT activity in plasma, with and without prolonged contact with cells, was found to be 27% lower than in serum at 0.5 hours; however, plasma GGT activity steadily increases with prolonged exposure to cells. Creatinine can increase by 110% in plasma and by 60% in serum after 48 to 56 hours (Boyanton, 2002).

Serum and plasma may yield significantly different results for an analyte. For example, when serum and EDTA plasma results for parathyroid hormone (PTH) are compared from specimens frozen within 30 minutes of collection, EDTA plasma results are significantly higher (>19%) than those obtained from serum (Omar, 2001). The effect of freeze-thaw cycles on constituent stability is an important consideration. In plasma or serum specimens, the ice crystals formed cause shear effects that are disruptive to molecular structure(s), particularly to large protein molecules. Slow freezing allows larger crystals to form, causing more serious degradative effects. Thus, quick freezing is recommended for optimal stability.

IMPORTANCE OF POLICIES AND PROCEDURES

It is essential to establish institution-specific phlebotomy policies and procedures that include personnel standards with qualifications; dress code and evaluation procedures; safety protocols including immunization recommendations; universal precautions; needlestick and sharps information; personal protective equipment; test order procedures; patient identification; confidentiality and preparation; documentation of problems encountered during blood collection; needlestick site selection and areas to be avoided (mastectomy side, edematous area, burned/scarred areas, etc.); anticoagulants required and tube color; order of draw; special requirements for patient isolation units; and specimen transport. The laboratory should have available all CDC, College of American Pathologists (CAP), Clinical and Laboratory Standards Institute (CLSI), OSHA, and The Joint Commission (TJC) guidelines, as well as other government regulations pertaining to laboratory testing. All employees must be trained about safety procedures, and a written blood-borne pathogen exposure control plan must be available. See Chapter 1 for a more complete discussion of safety.

The OSHA Bloodborne Pathogens Standard concluded that the best practice for prevention of needlestick injury following phlebotomy is the use of a sharp with engineered sharps injury protection (SESIP) attached to the blood tube holder and immediate disposal of the entire unit after each patient's blood is drawn (OSHA, 2001). Information on exposure prevention can be found on the Exposure Prevention Information Network (EPINet), a database coordinated by the International Healthcare Worker Safety Center at the University of Virginia (<http://www.healthsystem.virginia.edu/internet/epinet/>). OSHA further mandates that employers make available closable, puncture-resistant, leak-proof sharps containers that are labeled and color-coded. The containers must have an opening that is large enough to accommodate disposal of the entire blood collection assembly (i.e., blood tube, holder, and needle). These containers must be easily accessible to employees in the immediate area of use, and if employees travel from one location to another (one patient room to another), they must be provided with a sharps container that is conveniently placed at each location/facility. Employers must maintain a sharps injury log to record percutaneous injuries from contaminated sharps while at the same time protecting the confidentiality of the injured employee.

BLOOD COLLECTION TECHNIQUES

Table 3-8 summarizes the technique for obtaining blood from a vein (CLSI H3-A6, 2007).

ARTERIAL PUNCTURE

Arterial punctures are technically more difficult to perform than venous punctures. Increased pressure in the arteries makes it more difficult to stop

TABLE 3-8

Venous Puncture Technique

1. Verify that computer-printed labels match requisitions. Check patient identification band against labels and requisition forms. Ask the patient for his or her full name, address, identification number, and/or date of birth.
2. If a fasting specimen or a dietary restriction is required, confirm patient has fasted or eliminated foods from diet as ordered by physician.
3. Position the patient properly. Assemble equipment and supplies.
4. Apply a tourniquet and ask the patient to make a fist without vigorous hand pumping. Select a suitable vein for puncture.
5. Put on gloves with consideration of latex allergy for the patient.
6. Cleanse the venipuncture site with 70% isopropyl alcohol. Allow the area to dry.
7. Anchor the vein firmly.
8. Enter the skin with the needle at approximately a 30-degree angle or less to the arm, with the bevel of the needle up:
 - a. Follow the geography of the vein with the needle.
 - b. Insert the needle smoothly and fairly rapidly to minimize patient discomfort.
 - c. If using a syringe, pull back on the barrel with a slow, even tension as blood flows into the syringe. Do not pull back too quickly to avoid hemolysis or collapsing the vein.
 - d. If using an evacuated system, as soon as the needle is in the vein, ease the tube forward in the holder as far as it will go, firmly securing the needle holder in place. When the tube has filled, remove it by grasping the end of the tube and pulling gently to withdraw, and gently invert tubes containing additives.
9. Release the tourniquet when blood begins to flow. Never withdraw the needle without removing the tourniquet.
10. Withdraw the needle, and then apply pressure to the site. Apply adhesive bandage strip over a cotton ball or gauze to adequately stop bleeding and to avoid a hematoma.
11. Mix and invert tubes with anticoagulant; do not shake the tubes. Check condition of the patient. Dispose of contaminated material in designated containers (sharps container) using Universal Precautions.
12. Label the tubes before leaving patient's side with:
 - a. patient's first and last name
 - b. identification number
 - c. date of collection
 - d. time of collection
 - e. identification of person collecting specimen
13. Deliver tubes of blood for testing to appropriate laboratory section or central receiving and processing area.

bleeding, with the undesired development of a hematoma. In order of preference, the radial, brachial, and femoral arteries can be selected.

Before blood is collected from the radial artery in the wrist, one should do a modified Allen test (Table 3-9) to determine whether the ulnar artery can provide collateral circulation to the hand after the radial artery puncture. The femoral artery is relatively large and easy to puncture, but one must be especially careful in older individuals because the femoral artery can bleed more than the radial or brachial. Because the bleeding site is hidden by bedcovers, it may not be noticed until bleeding is massive. The radial artery is more difficult to puncture, but complications occur less frequently. The major complications of arterial puncture include thrombosis, hemorrhage, and possible infection. When performed correctly, no significant complications are reported except for possible hematomas.

Unacceptable sites are those that are irritated, edematous, near a wound, or in an area of an arteriovenous (AV) shunt or fistula (McCall, 1993). Arterial spasm is a reflex constriction that restricts blood flow with possible severe consequences for circulation and tissue perfusion. Radial artery puncture can be painful and is associated with symptoms such as aching, throbbing, tenderness, sharp sensation, and cramping. At times, it may be impractical or impossible to obtain arterial blood from a patient for blood gas analysis. Under these circumstances, another source of blood can be used, with the recognition that arterial blood provides a more accurate result. Although venous blood is more readily obtained, it usually reflects the acid-base status of an extremity—not the body as a whole.

TABLE 3-9

Modified Allen Test

1. Have the patient make a fist and occlude both the ulnar (opposite the thumb side) and the radial arteries (closest to the thumb) by compressing with two fingers over each artery.
2. Have the patient open his or her fist, and observe if the patient's palm has become bleached of blood.
3. Release the pressure on the ulnar artery (farthest from the thumb) only, and note if blood return is present. The palm should become perfused with blood. Adequate perfusion is a positive test indicating that arterial blood may be drawn from the radial artery. Blood should not be taken if the test is negative. Serious consequences may occur if this procedure is not followed, which may result in loss of the hand or its function.

TABLE 3-10

Arterial Puncture Procedure

1. Prepare the arterial blood gas syringe according to established procedures. The needle (18–20 gauge for brachial artery) should pierce the skin at an angle of approximately 45–60 degrees (90 degrees for femoral artery) in a slow and deliberate manner. Some degree of dorsiflexion of the wrist is necessary with the radial artery, for which a 23–25 gauge needle is used. The pulsations of blood into the syringe confirm that it will fill by arterial pressure alone.
2. After the required blood is collected, place dry gauze over the puncture site while quickly withdrawing the needle and the collection device.
3. Compress the puncture site quickly, expel air from the syringe, and activate the needle safety feature; discard into sharps container.
4. Mix specimen thoroughly by gently rotating or inverting the syringe to ensure anticoagulation.
5. Place in ice water (or other coolant that will maintain a temperature of 1°–5° C) to minimize leukocyte consumption of oxygen.
6. Continue compression with a sterile gauze pad for a minimum of 3 to 5 minutes (timed). Apply an adhesive bandage.

Arterial Puncture Technique

The artery to be punctured is identified by its pulsations, and the overlying skin is cleansed with 70% aqueous isopropanol solution followed by iodine. A nonanesthetized arterial puncture provides an accurate measurement of resting pH and partial pressure of carbon dioxide ($p\text{CO}_2$) in spite of possible theoretical error caused by patient hyperventilation resulting from the pain of the arterial puncture. The use of butterfly infusion sets is not recommended. Using 19-gauge versus 25-gauge needles does not vary the $p\text{CO}_2$ or the partial pressure of oxygen ($p\text{O}_2$) by more than 1 mm Hg. The amount of anticoagulant should be 0.05 mL liquid heparin (1000 IU/mL) for each milliliter of blood. Using too much heparin is probably the most common preanalytic error in blood gas measurement (Garza, 2002). Table 3-10 lists the procedure for arterial puncture (CLSI H11-A4, 2004).

FINGER OR HEEL SKIN PUNCTURE

For routine assays requiring small amounts of blood, skin puncture is a simple method by which to collect blood samples in pediatric patients. In the neonate, skin puncture of the heel is the preferred site to collect a blood sample; in older children, the finger is the preferred site. The large amount of blood required for repeated venipunctures may cause iatrogenic anemia, especially in premature infants. Venipuncture of deep veins in pediatric patients may rarely cause (1) cardiac arrest, (2) hemorrhage, (3) venous thrombosis, (4) reflex arteriospasm followed by gangrene of an extremity, (5) damage to organs or tissues accidentally punctured, (6) infection, and (7) injury caused by restraining an infant or child during collection. Accessible veins in sick infants must be reserved exclusively for parenteral therapy. Skin puncture is useful in adults with (1) extreme obesity, (2) severe burns, and (3) thrombotic tendencies, with point-of-care testing or with patients performing tests at home (blood glucose). Skin puncture is often preferred in geriatric patients because the skin is thinner and less elastic; thus a hematoma is more likely to occur from a venipuncture.

In newborns, skin puncture of the heel is frequently used to collect a sample for bilirubin testing and for newborn screening tests for inherited

TABLE 3-11

Skin Puncture Technique

1. Select an appropriate puncture site.
 - a. For infants younger than 12 months old, this is most usually the lateral or medial plantar heel surface.
 - b. For infants older than 12 months, children, and adults, the palmar surface of the last digit of the second, third, or fourth finger may be used.
 - c. The thumb and fifth finger must not be used, and the site of puncture must not be edematous or a previous puncture site because of accumulated tissue fluid.
2. Warm the puncture site with a warm, moist towel no hotter than 42° C; this increases the blood flow through arterioles and capillaries and results in arterial-enriched blood.
3. Cleanse the puncture site with 70% aqueous isopropanol solution. Allow the area to dry. Do not touch the swabbed area with any nonsterile object.
4. Make the puncture with a sterile lancet or other skin-puncturing device, using a single deliberate motion nearly perpendicular to the skin surface. For a heel puncture, hold the heel with the forefinger at the arch and the thumb proximal to the puncture site at the ankle. If using a lancet, the blade should not be longer than 2 mm to avoid injury to the calcaneus (heel bone).
5. Discard the first drop of blood by wiping it away with a sterile pad. Regulate further blood flow by gentle thumb pressure. Do not milk the site, as this may cause hemolysis and introduce excess tissue fluid.
6. Collect the specimen in a suitable container by capillary action. Closed systems are available for collection of nonanticoagulated blood and with additives for whole blood analysis. Open-ended, narrow-bore disposable glass micropipets are most often used up to volumes of 200 μL . Both heparinized and nonheparinized micropipets are available. Use the appropriate anticoagulant for the test ordered. Mix the specimen as necessary.
7. Apply pressure and dispose of the puncture device.
8. Label the specimen container with date and time of collection and patient demographics.
9. Indicate in the report that test results are from skin puncture.

metabolic disorders. A deep heel prick is made at the distal edge of the calcaneal protuberance following a 5- to 10-minute exposure period to prewarmed water. The best method for blood gas collection in the newborn remains the indwelling umbilical artery catheter. Table 3-11 lists the steps for a skin puncture (CLSI H4-A6, 2008).

CENTRAL VENOUS ACCESS DEVICES

Central venous access devices (CVADs) provide ready access to the patient's circulation, eliminating multiple phlebotomies, and are especially useful in critical care and surgical situations. Indwelling catheters are surgically inserted into the cephalic vein, or into the internal jugular, subclavian, or femoral vein and can be used to draw blood, administer drugs or blood products, and provide total parenteral nutrition. Continuous, real-time, intraarterial monitoring of blood gases and acid-base status has been accomplished with fiberoptic channels containing fluorescent and absorbent chemical analytes (Smith, 1992).

CVA Collection Technique

Blood specimens drawn from catheters may be contaminated with whatever was administered or infused via the catheter. The solution (usually heparin) used to maintain patency of the vein must be cleared before blood for analysis is collected. Sufficient blood (minimum of 2–5 mL) must be withdrawn to clear the line, so laboratory data are reliable. Specialized training is therefore necessary before a catheter line is used to collect blood specimens. To obtain a blood specimen from the indwelling catheter, 5 mL of intravenous fluid is first drawn and discarded. In a separate syringe, the amount of blood required for the requested laboratory procedure(s) is then drawn. Strict aseptic technique must be followed to avoid site and/or catheter contamination. Coagulation measurements such as prothrombin time (PT), activated partial thromboplastin time (APTT), and thrombin time (TT) are extremely sensitive to heparin interference, so that even larger volumes of presample blood must be withdrawn before laboratory

TABLE 3-12

Order of Draw From Catheter Lines

1. Draw 3–5 mL in a syringe and discard.
2. Blood for blood culture
3. Blood for anticoagulated tubes (lavender, green, light blue, etc.)
4. Blood for clot tubes (red, SST, etc.)

SST, Serum separator tube.

results are acceptable for these tests. The appropriate volume to be discarded should be established by each laboratory.

The laboratory is sometimes asked to perform blood culture studies on blood drawn from indwelling catheters. Because the indwelling catheters are in place for a few days, this procedure is not recommended because organisms that grow on the walls of the catheter can contaminate the blood specimen. Lines, such as central venous pressure (CVP) lines, are specifically inserted and used for immediate blood product infusion and are less likely to become contaminated. Determination of catheter contamination requires special handling and careful analysis of multiple samples from the catheter and peripheral blood. Table 3-12 lists the order of draw from catheter lines.

URINE AND OTHER BODY FLUIDS COLLECTION

URINE

Collection and preservation of urine for analytic testing must follow a carefully prescribed procedure to ensure valid results. Laboratory testing of urine generally falls into three categories: chemical, bacteriologic, and microscopic examinations. Several kinds of collection are used for urine specimens: random, clean-catch, timed, 24 hour, and catheterized. Random specimens may be collected at any time, but a first-morning-voided aliquot is optimal for constituent concentration, as it is usually the most concentrated and has a lower pH caused by decreased respiration during sleep. Random urine specimens should be collected in a chemically clean receptacle, either glass or plastic. A clean-catch midstream specimen is most desirable for bacteriologic examinations. Proper collection of a clean-catch specimen requires that the patient first clean the external genitalia with an antiseptic wipe; the patient next begins urination, stops midstream, and discards this first portion of urine, then collects the remaining urine in a sterile container. The vessel is tightly sealed, is labeled with the patient's name and date of collection, and is submitted for analysis. A urine transfer straw kit for midstream specimens (BD Vacutainer) can be used to remove an aliquot from the sterile collection container, which then can be transported to the laboratory. The system consists of an adapter that attaches to a yellow evacuated sterile tube. The vacuum draws the urine into the sterile tube. The adapter assembly must be treated like a needle assembly system and be discarded into a biohazard container. A similar product is available for cultures; it uses a sterile, gray-top tube containing 6.7 mg/L of boric acid and 3.335 mg/L of sodium formate, along with the adapter device described previously (BD Vacutainer).

Timed specimens are obtained at designated intervals, starting from “time zero.” Collection time is noted on each subsequent container. Urine specimens for a 24-hour total volume collection are most difficult to obtain and require patient cooperation. Incomplete collection is the most frequent problem. In some instances, too much sample is collected. In-hospital collection is usually supervised by nurses and generally is more reliable than outpatient collection. Pediatric collections require special attention to avoid stool contamination. One can avoid problems in collecting 24-hour specimens by giving patients complete written and verbal instructions with a warning that the test can be invalidated by incorrect collection technique. The preferred container is unbreakable, measures 4 L (approximately), is plastic, and is chemically clean, with the correct preservative already added. One should remind the patient to discard the first morning specimen, record the time, and collect every subsequent voiding for the next 24 hours. An easy approach is to instruct the patient to start with an empty bladder and to end with an empty bladder. Overcollection occurs if the first morning specimen is included in this routine. The total volume collected is measured and recorded on the request form, the entire 24-hour specimen is thoroughly mixed, and a 40 mL aliquot is submitted for analysis.

It is difficult to determine whether a collection is complete. If results appear clinically invalid, this is cause for suspicion. Because creatinine

TABLE 3-13

Changes in Urine With Delayed Testing

Result	Reason
Changes in color	Breakdown or alteration of chromogen or other urine constituent (e.g., hemoglobin, melanin, homogentisic acid, porphyrins)
Changes in odor	Bacterial growth, decomposition
Increased turbidity	Increased bacteria, crystal formation, precipitation of amorphous material
Falsely low pH	Glucose converted to acids and alcohols by bacteria producing ammonia. Carbon dioxide (CO ₂) lost
Falsely elevated pH	Breakdown of urea by bacteria, forming ammonia
False-negative glucose	Utilization by bacteria (glycolysis)
False-negative ketone	Volatilization of acetone; breakdown of acetoacetate by bacteria
False-negative bilirubin	Destroyed by light; oxidation to biliverdin
False-negative urobilinogen	Destroyed by light
False-positive nitrite	Nitrite produced by bacteria after specimen is voided
False-negative nitrite	Nitrite converts to nitrogen and evaporates.
Increased bacteriuria	Bacteria multiply in specimen before analysis.
Disintegration of cells/casts	Unstable environment, especially in alkaline urine, hypotonic urine, or both

excretion is based on muscle mass, and because a patient's muscle mass is relatively constant, creatinine excretion is also reasonably constant. Therefore, one can measure creatinine on several 24-hour collections to assess the completeness of the specimen and keep this as part of the patient's record. One- and 2-hour timed collection specimens may suffice in some instances, depending on the analyte being measured. Urobilinogen is subject to diurnal variation, with the highest levels reached in the afternoon. Commonly, urine is collected from 2–4 PM, when a quantification of urobilinogen is requested.

Special Urine Collection Techniques

Catheterization of the urethra and bladder may cause infection but is necessary in some patients (e.g., for urine collection when patients are unable to void or control micturition). Ureteral catheters can also be inserted via a cystoscope into the ureter. Bladder urine is collected first, followed by a bladder washing. Ureteral urine specimens are useful in differentiating bladder from kidney infection, or for differential ureteral analysis, and may be obtained separately from each kidney pelvis (labeled left and right). First morning urine is optimal for cytologic examination.

Urine Storage and Preservation

Preservation of a urine specimen is essential to maintain its integrity. Unpreserved urine specimens are subject both to microbiologic decomposition and to inherent chemical changes. Table 3-13 lists common changes that occur as urine decomposes. To prevent growth of microbes, the specimen should be refrigerated promptly after collection and, when necessary, should contain the indicated chemical preservative. For some determinations, addition of a chemical preservative may be best to maintain analytes when performing 24-hour urine collections. If a preservative is added to the empty collection bottle, particularly if acid preservatives are used, a warning label is placed on the bottle. The concentrated acid adds a risk of potential chemical burns; the patient should be warned about this potential danger, and the container labeled accordingly. In this scenario, the clinician must assess the patient's risk of exposure to the preservative; therefore, refrigeration may be more appropriate, and the preservative may be added upon submission to the laboratory. Light-sensitive compounds, such as bilirubin, are protected in amber plastic bottles. Precipitation of calcium and phosphates occurs unless the urine is acidified adequately before analysis.

It is particularly important to use freshly voided and concentrated urine to identify casts and red and white blood cells, as these undergo decomposition upon storage at room temperature or with decreased concentration (<1.015 specific gravity). They disappear rapidly

TABLE 3-14

24 Hour Urine Collection Preservatives

Preservative	Tests
None (refrigerate)	Amino acids, amylase, calcium, citrate, chloride, copper, creatinine, delta ALA, glucose, 5-HIAA, heavy metals (arsenic, lead, mercury), histamine, immunoelectrophoresis, lysozyme, magnesium, methylmalonic acid, microalbumin, mucopolysaccharides, phosphorus, porphobilinogen, porphyrins, potassium, protein, protein electrophoresis, sodium, urea, uric acid, xylose tolerance
10 g boric acid	Aldosterone, cortisol
10 mL 6N HCl	Catecholamines, cystine, homovanillic acid, hydroxyproline, metanephrines, oxalate, VMA
0.5 g sodium fluoride	Glucose
If processing delayed longer than 24 hours: equal amounts of 50% alcohol, Saccomanno's fixative, and SurePath or Preserve CT	Cytologic examination

ALA, Alanine aminotransferase; 5-HIAA, 5-hydroxyindoleacetic acid; VMA, vanillyl-mandelic acid.

in hypotonic and alkaline urine. Bilirubin and urobilinogen decrease, especially after exposure to light. Glucose and ketones may be consumed, while bacterial contamination and loss of CO₂ lead to increase of pH, formation of turbidity with precipitates, and change in color. Ideally specimens should be delivered to the laboratory and analyzed within 1 hour of collection.

Urine may be frozen in aliquots to be assayed at a later date for chemical analysis only. When repeat testing is expected, the specimen should be stored in multiple aliquots to circumvent specimen degradation as a result of repeated freeze-thawing of a single specimen. Preservatives may also be added, depending on the substance to be tested. Sodium fluoride can be added to 24-hour urine for glucose determinations to inhibit bacterial growth and cell glycolysis, but not growth of yeast. About 0.5 g of sodium fluoride is added to a 3 to 4 L container. Sodium fluoride may inhibit reagent (enzyme-embedded) glucose strip tests. Tablets containing formaldehyde, mercury, and benzoate (95 mg tablet/20 mL urine) have also been used; however these preservatives elevate specific gravity (0.002/one tablet/20 mL). Boric acid in a concentration of 1 g/dL preserves urine elements such as estril and estrogen for up to 7 days. Boric acid maintains the pH at about 6.0 and preserves protein and formed elements well without interfering with routine testing except for pH. Boric acid is a bacteriostatic preservative, not a bactericidal, and it does not inhibit the growth of yeasts. Boric acid has been reported to interfere with drug and hormone analysis (Strasinger, 2001). For catecholamines, vanillylmandelic acid (VMA), or 5-hydroxyindoleacetic acid (5-HIAA) collections, 10 mL of 6N HCl is added to a 3 to 4 L container. The HCl establishes a pH of approximately <3.0 that is good for chemical testing. However, the low pH destroys formed elements and enhances uric acid precipitation. Table 3-14 lists preservatives commonly used for 24-hour urine specimens. The NCCLS approved guidelines for urinalysis and collection, transportation, and preservation of urine specimens provide useful information on various preservatives recommended for 24-hour urine collections (NCCLS, 2001).

OTHER BODY FLUIDS

Cerebrospinal Fluid

Lumbar punctures (LPs) are performed to collect cerebrospinal fluid (CSF) for laboratory evaluation to establish a diagnosis of infection (bacterial, fungal, mycobacterial, or amebic meningitis), malignancy, subarachnoid hemorrhage, multiple sclerosis, or demyelinating disorders. The most common site for lumbar puncture is between the third and fourth lumbar vertebrae, or between the fourth and fifth lumbar vertebrae. A serious complication of an LP is cerebellar tonsillar herniation in patients with

elevated intracranial pressure, and it should be avoided unless CSF findings are expected to improve treatment or outcome. Patients with spinal cord tumors with paresis may progress to paralysis following LP. Patients with sepsis in the lumbar region (skin infection, cellulitis, or epidural abscess) should not have an LP performed, to avoid introduction of infection. Other complications of LP include asphyxiation in infants due to hyperextending the head forward, thus occluding the trachea, paresthesia, headache, and, rarely, hematomas. CSF is also collected by cisternal puncture. A needle is inserted into the cisternal subarachnoid space, or small space, that serves as a reservoir for CSF between the atlas and the occipital bone in the back of the head, or by lateral cervical puncture (Kjeldsberg, 1993). Specimens can also be collected from ventricular cannulas (shunts) when present.

Before CSF is collected, the pressure should be between 90 and 180 mm Hg; this is measured by allowing fluid to rise in a sterile, graduated manometer. Holding one's breath, abdominal compression, congestive heart failure, inflammation of the meninges, obstruction of intracranial venous sinuses, mass lesions, or cerebral edema may cause the pressure to be elevated (>180 mm Hg). When pressure is normal, 20 mL of specimen may be removed. On closing, the pressure should be between 10 and 30 mm Hg. A marked decrease in pressure following this procedure suggests cerebellar herniation or spinal cord compression; thus, no additional CSF should be collected. Patients with partial or complete spinal block may have low pressure (<80 mm Hg), falling to zero after removal of only 1 mL. Again, no additional fluid should be removed. Not more than 2 mL can be removed when the pressure is greater than 200 mm Hg. Three aliquots are generally collected in separate, sterile tubes labeled appropriately with name, date, and sequential tube collection number, and distributed. Hospital policies differ as to which tube is distributed to which laboratory for analysis. It is generally recommended that Tube #1 goes to chemistry for glucose and protein analysis, or to immunology/serology; Tube #2 goes to microbiology for culture and Gram stain; Tube #3 goes to hematology for cell counts. Tube #3 is the least likely to be contaminated by a bloody tap at collection. Expansion of tests ordered on CSF to include molecular diagnostic procedures has placed even greater demand on proper utilization of the entire volume of CSF collected, with special efforts to conserve specimens in each laboratory section so that additional tests may be performed.

Synovial Fluid

Synovial fluid found in the joint cavities is an ultrafiltrate of plasma that is passed through fenestrations of the subsynovial capillary endothelium into the synovial cavity. Once in the cavity, it is combined with hyaluronic acid, a glycosaminoglycan secreted by the synovial lining cells. Synovial fluid differs from the other serous fluids in that it contains hyaluronic acid (mucin) and may contain crystals. Synovial fluid is collected by arthrocentesis, an aspiration of the joint using a syringe, moistened with an anticoagulant, usually 25 units of sodium heparin per mL of synovial fluid. Oxalate, powdered EDTA, and lithium heparin should not be used, as they can produce crystalline structures similar to monosodium urate (MSU) crystals. Once removed, the synovial fluid is usually transferred to three tubes—one sterile, one containing EDTA or heparin, and one red-top tube; 5–10 mL of fluid is added to each. The sterile tube is sent to microbiology, the anticoagulated tube is sent to hematology, and the red-top tube, after centrifugation, is used for chemical analysis. Some hospitals transfer synovial fluid to aerobic and anaerobic blood culture bottles for microbiologic culture.

Pleural Fluid, Pericardial Fluid, and Peritoneal Fluid

Pleural fluid is an ultrafiltrate of the blood plasma. It is formed continuously in the pleural cavity. This cavity, normally containing 1–10 mL of fluid, is formed by the parietal pleura, lining the chest wall, and the visceral pleura, covering the lung. Each lung is enveloped by this double membrane of contiguous mesothelial layers. Pleural fluid acts as a natural lubricant for contraction and expansion of the lungs during respiration. It is reabsorbed by the lymphatics and the venules in the pleura (Miller, 1999).

Thoracentesis is a surgical procedure to drain fluid (effusions) from the thoracic cavity and is helpful in diagnosing inflammation or neoplastic disease in the lung or pleura. Pericardiocentesis and peritoneocentesis refer to the collection of fluid from the pericardium (effusion) and the peritoneal cavities (ascites), respectively. These cavities normally contain less than 50 mL of fluid.

The patient, sitting in an upright position, with arms and head extended on an overbed table, is prepared with a local anesthetic after appropriate cleansing of the site. A 50 mL syringe is fitted with a stopcock and rubber tubing to assist in the aseptic collection process. Specimens are obtained for chemical, microbiologic, and cytologic examination and are transferred to collection tubes with appropriate additive(s). For most chemical evaluations, no additive is used and the specimen is allowed to clot. Bacteriologic and cytologic specimens may be collected in EDTA or sterile sodium heparin (without preservatives). Special studies for *Mycobacterium*, anaerobic bacteria, or viruses may require special handling procedures. Special handling procedures must be reviewed before collection is begun.

SPECIMEN TRANSPORT

Transport of blood, urine, body fluids, and tissue specimens from the collection site to the laboratory is an important component of processing. For blood samples, it accounts for approximately one third of the total turnaround time (TAT) (Howanitz, 1992). Excessive agitation of blood specimens must be avoided to minimize hemolysis. Specimens should be protected from direct exposure to light, which causes breakdown of certain analytes (e.g., bilirubin). For analysis of unstable constituents such as ammonia, plasma renin activity, and acid phosphatase, specimens must be kept at 4° C immediately after collection and transported on ice. Routine urine is collected in a sterile, disposable, 200 mL plastic container. Pediatric urine collectors are flexible polyethylene bags, which may be sealed for transportation. All laboratory specimens must be transported in a safe and convenient manner to prevent biohazard exposure or contamination of the specimen. Broken or leaking specimens are a biohazard to those who may come in contact with them and require collection of a new specimen; this can delay treatment of the patient and add to the cost.

The stability of the constituents must be determined before specimens are transported. The laboratory usually provides this information along with instructions for specimen preparation and shipping. Polystyrene or other high-impact plastic-type containers are commonly used. Specimens requiring refrigeration must be maintained at between 2° C and 10° C and can be appropriately carried in an insulated container. Large-volume urine specimens should be collected in a leak-proof, 3 to 4 L container. Stool specimens are transported in a cardboard container and placed in a polyethylene bag. To mail a specimen in the frozen state, solid carbon dioxide (dry ice) may be packed in a polystyrene container with the specimen, which can be kept frozen at temperatures as low as -70° C.

The OSHA Bloodborne Pathogens Standard (OSHA: 1910.1030) requires specimens of blood or other potentially infectious materials (OPIM) to be placed in a container that prevents leakage during collection, handling, processing, storage, transport, and/or shipping. This container must be labeled or color-coded according to specific standards (OSHA: 1910.1030[g][1][i]). Furthermore, according to the standard, if contamination of the outside of the primary container occurs, or if the specimen could puncture the primary container, the primary container must be placed in a secondary container that is puncture-resistant in addition to having the previous characteristics (OSHA: 1910.1030[d][2][xiii]).

Labeling is required on all containers used to store, transport, ship, or dispose of blood or other potentially infectious materials, except as noted in the OSHA standard. For example, if individual containers of blood or OPIM are placed in a larger container during storage, transport, shipment, or disposal, and that larger container is labeled with the OSHA "BIOHAZARD" label or is color-coded, the individual containers are exempt from the labeling requirement. OSHA accepts the Department of Transportation's (DOT's) "INFECTIOUS SUBSTANCE" label in lieu of the "BIOHAZARD" label on packages where the DOT requires its label on shipped containers, but requires the "BIOHAZARD" label where OSHA regulates a material but DOT does not. If the DOT-required label is the only label used on the outside of the transport container, the OSHA-mandated label must be applied to any internal containers containing blood or OPIM. The accepted "BIOHAZARD" label is fluorescent orange.

For local, onsite transport, pneumatic tube systems provide a rapid, efficient, and cost-effective way of transporting laboratory specimens to a specific location. For laboratory use, blood specimens are placed in a carrier with liners to prevent leakage and padding to ensure that specimen containers remain intact. The advantages of a pneumatic tube system are improved TAT, reliability, minimal training, low maintenance, availability 24 hours/day, 7 days/week, and improved staff utilization. Studies have shown that most routine chemical and hematologic evaluations, including blood gases, red cell packs, coagulation tests, and

LD values, are not substantially affected by rapid transport (Hardin, 1990; Keshgegian, 1992).

SPECIMEN PROCESSING

Processing of specimens includes three distinct phases: precentrifugation, centrifugation, and postcentrifugation. Continuing appraisal of all specimen handling activities is an important preanalytic component of total quality control. Appropriate guidelines must be established and adhered to by laboratory personnel in each phase of specimen handling to ensure the generation of reliable and medically meaningful measurement and examination results.

PRECENTRIFUGATION PHASE

Ideally, all measurements should be performed within 45 minutes to 1 hour after collection. Whenever this is not practical, the specimen should be processed to a point at which it can be properly stored to preclude alteration of constituents to be measured. With the exception of blood gases and ammonia determinations, plasma or serum is preferred for most biochemical determinations. In clinical chemistry, serum and plasma are interchangeable except for a few measurements. Serum is required for protein electrophoresis and immunofixation assays, just as plasma is necessary for fibrinogen and other coagulation measurements. Serum is most commonly the specimen of choice, owing to its simplicity in collection and handling. Additionally, interference from anticoagulants is obviated. Plasma may be used in medical emergencies because samples do not have to clot before centrifugation. Usually, a greater volume of plasma than serum is obtained from a given volume of whole blood owing to the clot formation process. Hospitalized patients are likely to be receiving heparin (especially under critical care), which can delay clotting in blood collection tubes even with activators and lead to fibrin strands that can clog up aspiration probes on instrumentation. Accordingly it is good practice to collect blood from hospitalized patients into tubes with heparin anticoagulant to obtain plasma for chemical tests.

Blood should be stoppered in the original container until ready for separation. For plasma preparation, centrifuge blood within 1 hour after collection, for 10 minutes at a relative centrifugal force (RCF) of 850–1000× gravity (g), keeping the container stoppered to prevent evaporation of plasma or serum water. Adequate time for clotting must be allowed to prevent latent fibrin formation, which may cause undesirable clogging of automated chemistry analyzers. Loosening the clot by "trimming" or "ringing" the tube may cause some hemolysis and should be avoided. When glass tubes are used, they should be centrifuged in an aerosol-contained vessel. Serum or plasma must be stored at 4° C to 6° C if analysis is to be delayed for longer than 4 hours. One study suggests that this may not be necessary (Melanson, 2004). Many laboratories store samples for 7 days in case a test is added.

CENTRIFUGATION PHASE

A centrifuge uses centrifugal force to separate phases of suspensions by different densities. It is most frequently used in processing blood to derive plasma or serum fractions. Urine and other body fluids may be centrifuged to concentrate particulate matter as sediment to be examined and to minimize interference with other determinations from the same material. Conditions for centrifugation should specify both the time and the centrifugal force. In selecting a centrifuge, one should look for the highest possible centrifugal force and not the rotational speed. The RCF in g units, that is, multiples of the gravitational force, may be calculated by using the following formula:

$$RCF = 1.118 \times 10^{-5} \times r \times (rpm)^2$$

where 1.118×10^{-5} is a constant; r is the radius, expressed in centimeters, between the axis of rotation and the center of the centrifuge tube; and rpm is the speed in revolutions per minute. The RCF can also be obtained from a nomogram that gives the RCF without the need to calculate it from the previous formula.

Several principles must be observed to avoid damage to the centrifuge, or the specimen, and danger to personnel. Tubes, carriers, or shields of equal weight, shape, and size should be placed in opposing positions in the centrifuge head to achieve appropriate balance. Tubes must be balanced across the center of rotation, and each bucket must be balanced with respect to its pivotal axis (Seamonds, 2001). Specimens must be placed with

regard for a geometrically symmetrical arrangement, using water-filled tubes to attain balance.

Recentrifugation of gel separator tubes has been associated with pseudohyperkalemia. One study demonstrated that after initial centrifugation, a new serum layer will develop under the gel within the cellular layer. During storage, potassium leaks from the cellular layer into the new serum layer, creating hyperkalemia in this layer. When the tube is recentrifuged, the new serum layer will move above the gel layer and cause a pseudohyperkalemia in the serum for analysis. The same authors also demonstrated that a pseudonormokalemia in patients with true hypokalemia may be erroneously reported after recentrifugation (Hira, 2001; Hira, 2004).

Equipment

A wide variety of centrifuges and accessories are available to meet specific needs in the clinical laboratory. These include tabletop, general laboratory centrifuges; horizontal head, fixed-angle, or angle-head; high-speed centrifuges; portable floor models, undercounter models; microcentrifuges; refrigerated and unrefrigerated types; and ultracentrifuge models. Ultracentrifuges are high speed and capable of reaching a centrifugal force of 165,000 times gravity. These centrifuges require refrigeration chambers to compensate for the considerable heat produced. Ultracentrifuges are used to clear serum of chylomicrons, which is necessary to avoid interference with clinical testing (Bermes, 2001). An example of a centrifuge designed for fast speed and quick turnaround time is the StatSpin Express 3 (StatSpin, 2005), a microprocessor-controlled, high-speed bench-top centrifuge designed to rapidly separate blood in evacuated tubes. This centrifuge accelerates rapidly and brakes very fast, decreasing specimen processing time. The centrifuge operates at a fixed speed of 8500 rpm, produces a RCF of $4440 \times (g)$, and can be operated with a 120- or 180-second spin cycle.

Centrifuge capacities vary with model type and centrifuge head. Specimen volume (per tube), number of tubes to be centrifuged, speed required for adequate separation, and durability of equipment should be considered. For every laboratory procedure requiring centrifuge operation, a written specification identifying centrifuge type, temperature, g forces, and length of centrifugation time is required. Calibration of the centrifuge must be part of the quality assurance process. Speed settings must be calibrated using rpm, and RCFs must be calculated using the earlier formula or a nomogram. Any significant changes will indicate deterioration effects, such as wearing of brushes or bearing problems. Timers must be checked for accuracy.

INTERFERENCES

One of the main concerns in the preanalysis phase is whether any substance or artifact is introduced as the result of specimen handling or other patient-related factors that lead to alterations in the technical measurement of clinical specimens in the analysis. The patient's medical condition might cause abnormalities that can be evaluated by measurement of various analytes, and some of those abnormally elevated substances can markedly interfere with some basic modes of analysis.

SPECIMEN COLLECTION

The appropriate tube should always be used for collection of blood specimens because of interferences from some anticoagulants such as EDTA, which chelates both calcium and magnesium, thereby lowering the measurement of those ions and inhibiting some enzymes that require divalent cations (e.g., alkaline phosphatase by also chelating zinc). Plasma separator tubes containing lithium heparin should not be used for lithium measurements, and electrolyte measurements are not valid in tubes with potassium EDTA or sodium citrate. Proper collection technique avoids hemolysis (release of potassium; introduction of spectral interference) and contamination of blood with tissue fluid using fingersticks or heelsticks.

Small volumes of blood may be acceptable for some chemistry tests or cell counts; however, coagulation tests require a minimal volume of blood in the collection tube to achieve correct balance with citrate anticoagulant, which also chelates calcium. Excess citrate in plasma from insufficient blood volume leads to falsely elevated clotting times. This interference is also important in polycythemia, when the hematocrit is abnormally high and plasma volume in which the citrate distributes is small. Thus, even in an apparently correctly filled tube, polycythemia can lead to falsely prolonged PT and PTT unless the amount of citrate anticoagulant

in the tube is reduced proportionally to the decrease in plasma volume in that patient.

OPTICAL INTERFERENCES

The most common interfering conditions are hemolysis and icterus, which strongly absorb particular wavelengths of light, and also lipemia, which scatters light and so blocks its transmission. All three of these interferents can have severe effects on spectrophotometric methods of analysis (Grafiner, 1995). Lipemia can potentially be cleared from a serum or plasma specimen by ultracentrifugation, and hemolysis that occurs at the time of blood collection can be eliminated by re-collection of the specimen; however, bilirubin in a specimen is not readily removed and so may cause spectral interference through its high absorbance at wavelengths between 340 and 500 nm. Bilirubin can also interfere chemically, particularly in peroxidase-coupled assays such as those for uric acid, cholesterol, and triglycerides (Spain, 1986). Result reporting should include a statement about the appearance of a specimen if it is particularly abnormal and a qualification about the validity of the results for the physician to use in interpreting any abnormal findings (e.g., elevated potassium in hemolyzed specimens).

IMMUNOASSAYS

Most modern immunoassays utilize mouse monoclonal antibodies in various configurations, often with separate solid phase capture antibody and signal antibody that detect specific antigens through molecular sandwich formation (see Chapter 44). The signal antibody is typically conjugated with an enzyme of other substance such as a chemiluminescent tag. In many enzyme immunoassays (EIAs), the label is peroxidase, which converts a colorless substrate to a colored product in solution whose optical absorbance is proportional to the concentration of the analyte. Although bilirubin and lipemia can interfere in principle with EIAs, wash steps may remove significant amounts of them and so minimize their effects from spectral interference. In contrast, Hb from a heavily hemolyzed specimen can have marked interference in peroxidase-based EIAs even after the prescribed number of wash steps because of the pseudoperoxidase activity of Hb in the residue remaining in the assay well. This effect is especially problematic for severely hemolyzed specimens such as blood collected postmortem. Consequently such hemolyzed specimens may not be at all suitable for analysis by peroxidase-based EIAs. Other EIAs that use alkaline phosphatase or β -galactosidase on the signal antibody or those that employ chemiluminescence as a tag do not have as much interference from hemolysis (Demuth, 2004).

Another problem sometimes encountered in immunoassays with mouse monoclonal antibody reagents is the presence of human anti-mouse antibodies (HAMAs) or heterophile antibodies in patients. HAMAs can arise following antigenic stimulation from therapeutic mouse monoclonal antibodies that are administered to alter immune responses (e.g., anti-T cell antibody), to bind and remove toxic levels of drugs (e.g., digoxin), or to attack tumors. Some individuals with HAMAs have no history of therapeutic exposures but could conceivably have had incidental exposure to mouse proteins through contaminated food or other environmental sources. The effect of HAMAs in immunoassays can be to cross-link capture and signal antibodies in a sandwich that mimics true antigen (Klee, 2000). For example, an immunoassay for thyroid-stimulating hormone (TSH) that has separate antibodies against α and β subunits might yield an astonishingly high false-positive result in a euthyroid person with HAMA; in this case, the other thyroid function tests could be completely normal. The presence of HAMA can be confirmed by direct measurement (usually sent to a reference laboratory) and can also be inferred by adsorption of the HAMA onto special tubes coated with mouse antibodies, followed by repeat measurement of the analyte to look for reduction in signal strength in the treated specimen (Madry, 1997).

SPECIMEN MATRIX EFFECTS

Common biochemical analytes such as electrolytes, small molecules, enzymes, etc., are generally distributed in the water phase of plasma or serum. Consequently, specimens with reduced water phase due to hyperproteinemia (e.g., from very high concentrations of a myeloma protein) or hyperlipidemia (e.g., high chylomicron content) can have reduced content of those solvent analytes even though other properties such as ionic activities in those specimens may be within normal physiologic range. This

phenomenon is termed the *solvent exclusion effect*, referring to the exclusion of water and small molecules in the aqueous phase when more volume within a specimen is occupied by protein or lipid that excludes water. The content of small molecules per volume is the osmolality (which is the measurement that can be erroneous), whereas the physiologically important aspect such as ionic activities is the osmolality. If excess lipids are the cause, they may be removed by ultracentrifugation. If interference is due to excess protein, an alternative mode of analysis such as ion-selective electrode in undiluted specimen can be employed to yield correct electrolyte activity (i.e., equivalent of osmolality).

Matrix effects from very high or very low concentrations of proteins and other constituents may be problematic when dealing with other body fluids, especially when the specimens are highly viscous or otherwise atypical (see Chapter 29). In those situations, it may be necessary to qualify results in the report to indicate the site of the body fluid and possible limitations in accuracy of measurement.

MOLECULAR DIAGNOSTICS

Laboratory manipulations of nucleic acids are susceptible to interferences at various stages, including specimen collection and processing. Introduction of inhibitory substances and contamination with false-positive signals are among the significant interferences. Blood specimens for nucleic acid testing are generally collected into EDTA anticoagulant to inhibit enzymes that might break them down. Heparin is a poor choice for anticoagulant in this application because it can be coextracted with DNA and inhibits DNA polymerase in polymerase chain reactions (PCRs). Hemin from hemolysis in plasma or serum can also inhibit DNA polymerase. RNA is labile in blood or tissues, and so these specimens must be stored appropriately by rapid freezing in liquid nitrogen if the extraction will be delayed.

Extraction of nucleic acids from clinical specimens such as plasma (e.g., for viral load measurement), blood cells (e.g., for genetic testing), or tissues (e.g., for analyzing mutations in tumors) entails lysing cells and separating nucleic acids from proteins and lipids. Reagents for extraction include salts,

proteases, and phenol-chloroform to denature the substances complexed with nucleic acids. This process must be optimized for specimen type to recover high quality nucleic acids with good quantitative yield (see Chapter 65). Care must be taken to avoid contamination of specimens with target nucleic acids from other specimens or with amplified targets from specimens that have been analyzed previously in that vicinity. Accordingly, laboratories practicing nucleic acid amplification should have separate preamplification, amplification, and postamplification areas with strict rules about personnel movements between them (see Chapters 65 and 69).

EFFECTS OF DRUGS

Analytic methods that are based on oxidation–reduction reactions may be influenced positively or negatively by ingested substances such as ascorbic acid (vitamin C). This interference is observed in chemical testing of serum on automated analyzers (Meng, 2005), and it can also occur in urine testing for glucose (positive interference for reducing substance method; negative interference with enzymatic method). In stool testing for occult blood, peroxidases from meats (myoglobin) or vegetables (horseradish) in the diet can yield a false-positive result with guaiac-based methods, as can topical iodine or chlorine used as a disinfectant.

Drugs can have unanticipated reactions with the reagents intended for specific chemical tests. The list of potential interfering drugs is extremely long, and some methods for a particular analyte may be strongly affected, whereas other methods may not be affected. A voluminous compendium of drug interactions has been developed by Dr. Donald S. Young (Young, 2007). In addition to assisting with recognition of potential interferences, this source can be used to evaluate a different method that is unaffected by a particular drug to confirm the accuracy of measurement in cases of suspected interference. These interferences are separated into those whose effects are manifested directly in the assay *in vitro* and those that are due to drug actions *in vivo*, whereby physiologic functions are changed (e.g., prolonged prothrombin time with Coumadin; lower potassium in blood with some diuretics).

SELECTED REFERENCES

Boyanton L, Blick K. Stability studies of twenty-four analytes in human plasma and serum. *Clin Chem* 2002;48(12):2242–7.

This article studies plasma and serum analyte stability over 56 hours in samples removed from cells and allowed to remain on cells. No significant changes were found in the serum and plasma specimens removed from the cells within 30 minutes of collection. The article provides an excellent historical bibliography of the major studies performed on this topic.

Centers for Disease Control and Prevention. Workbook for designing, implementing, and evaluating a sharps injury prevention program, introduction. Division of Healthcare Quality Promotion—(DHQP Home) privacy policy—Accessibility. Published date: June 4, 2004; Reviewed date: July 28, 2004. Online. Available at: http://www.cdc.gov/sharpsafety/pdf/sharpsworkbook_2008.pdf.

This excellent Internet publication available for free download includes an overview of sharps risks and prevention, organizational steps for development of prevention programs, recommendations for selection of sharps injury prevention devices, and education and training materials.

The appendices contain useful worksheets for all aspects of sharps injury and prevention documentation.

Garza D, Becan-McBride K. Phlebotomy handbook: blood collection essentials. 6th ed. Upper Saddle River N.J.: Prentice Hall; 2002, p. 163, 205, 263, 341.

This handbook presents a complete discussion of all aspects related to phlebotomy. Included are safety procedures, equipment, step-by-step procedures, and management and legal issues. It contains an excellent, basic discussion of the circulatory system with colored diagrams.

Strasinger SK, DiLorenzo MS. The phlebotomy workbook. 2nd ed. Philadelphia: FA Davis; 2003, p. 115, 164, 95, 96.

This text contains a comprehensive presentation of all aspects of phlebotomy. It is an excellent teaching guide and discusses state-of-the-art equipment and techniques. The book is divided into three parts: general phlebotomy, safety and health care information; techniques for blood collection; and medical terminology, anatomy, and physiology. Contained within the various chapters are excellent summary tables and quick reference charts. It also provides an extensive description of the various blood collection tubes and

anticoagulants/additives they contain and information on preanalytic factors affecting laboratory results.

Young DS. Effects of preanalytic variables on clinical laboratory tests. 3rd ed. Washington, DC: AACC Press; 2007.

This is the preeminent resource for interferences in laboratory tests that covers the effects of drugs, as well as other contributing conditions.

Young MB, Birmes EW. Specimen collection and other preanalytical variables. In: Burtis CA, Ashwood ER, editors. Tietz fundamentals of clinical chemistry. 5th ed. Philadelphia: WB Saunders; 2001, p. 30–54.

This chapter contains many of the most important pre-analysis factors that affect laboratory results. Dr. Young has also written a series of reference books that contain peer-reviewed information regarding test interactions; they are published by AACC Press, Washington, DC, and include the following: Young DS, Friedman RG. Effects of disease on clinical laboratory tests, 4th ed, 2001; Young DS. Effects of drugs on clinical laboratory tests, 5th ed, 2000; and Young DS. Effects of preanalytical variables on clinical laboratory tests, 2nd ed, 1997.

SELECTED REFERENCES, 63**KEY POINTS**

- Many analytic determinations made in clinical laboratories are based on measurements of radiant energy that is absorbed or transmitted. The devices used to measure absorbed or transmitted light energy are photometers and spectrophotometers.
- The basic components of spectrophotometers include radiant energy source, wavelength selector, cuvet holder, photodetector, signal processors, and readout devices.
- A reflectometer is used to measure analytes by measuring the quantity of light reflected by a liquid sample that has been dispensed onto a grainy or fibrous solid support.
- Nephelometers are used to detect light that is scattered at various angles, whereas turbidimetry measures a reduction in light transmission due to particle formation.
- A flow cytometer measures light patterns produced as particles pass single-file through a laser light beam. The flow cytometer is used to count and sort cells. It is also a key component of hematology analyzers and a technology used to differentiate white blood cells.
- Electrochemical principles are used to measure numerous analytes in biologic fluids. Specific electrochemical techniques include potentiometry, amperometry, coulometry, conductivity, and anodic stripping voltammetry.
- Analytes measured by electrochemical techniques include electrolytes, blood gases, pH, metabolites (e.g., glucose, urea nitrogen), ionized calcium, lead, and chloride in sweat.
- Chromatography is a separation technique based on the different interactions of specimen compounds with a mobile phase and a stationary phase, as the compound travels through a support medium.
- Mass spectrometers have become increasingly important clinical instruments, especially in emerging fields such as proteomics. Mass spectrometry is based on fragmentation and ionization of molecules. The relative abundance of each of the ions yields a characteristic mass spectrum of the parent molecule. The basic components of a mass spectrometer include an ion source, a mass analyzer, and an ion detector.

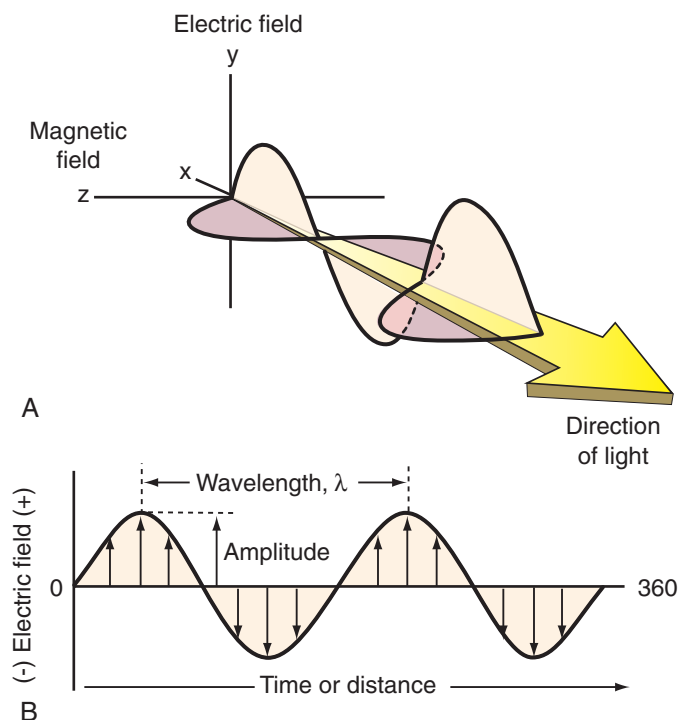

Figure 4-1 Diagram of a beam of monochromatic, plane-polarized light. **A**, Magnetic (y-axis) and electrical (x-axis) field vectors at right angles to one another. **B**, Two-dimensional view of the electrical vector.

A fundamental understanding of the principles of instrumentation used in clinical laboratories is essential. These instruments must provide the clinician with the best possible data to be of value to the patient. Without a thorough understanding of the necessary principles associated with an analyzer, operators will be ill equipped to perform maintenance procedures and calibrations, and to troubleshoot problems that may arise.

The goal of this chapter is to provide the reader with a brief and broad description of the essential principles of analytic instruments in the clinical laboratory. For a more comprehensive review of this topic, the reader is referred to references on clinical instrumentation at the end of this chapter.

PRINCIPLES OF INSTRUMENTATION

SPECTROPHOTOMETRY

Absorption spectroscopy has provided scientists with a means to use both qualitative and quantitative methods of measuring analytes in body fluids. Bouguer initially developed the principles of absorption spectroscopy in the early 1700s. Two other scientists, Lambert and Beer, continued to develop the fundamental principles of absorption spectroscopy, commonly known as Beer's law. Before reviewing the laws of spectroscopy, it is prudent to gain an understanding of light and the effects of its interactions with matter.

Diverse spectrophotometric methods use electromagnetic radiation (EMR), which can take several forms, the most recognizable being light and radiant heat. Other types of EMR include gamma (γ) rays and x-rays, as well as microwaves, radiofrequency radiation, and ultraviolet radiation. The energies involved with specific regions of the electromagnetic spectrum (EMS) and their corresponding wavelengths change dramatically from radio waves to γ radiation.

Some properties of EMR can be described by means of a classical sinusoidal wave model. Parameters associated with this waveform include wavelength, frequency, velocity, and amplitude, as shown in Figure 4-1, B. EMR requires no supporting medium for its transmission and passes readily through a vacuum.

The sine wave model does not provide the total picture when discussing the absorption and emission of radiant energy. EMR also exists as a stream of discrete particles, or packets, of energy called photons. The energy of the photons is proportional to the frequency of the radiation. This dual nature of EMR is considered complementary and applies to the behavior of streams of electrons, protons, and other elementary particles.

The wave model allows us to represent EMR as both an electrical and a magnetic field that can undergo in-phase, sinusoidal oscillation at right angles both to each other and to the direction of propagation. The electrical and magnetic fields for a monochromatic beam of plane-polarized light (with oscillation of either the electric or magnetic fields within a single plane)* in a specific direction of propagation are shown in Figure 4-1, A (Skoog, 1998).

The electrical vector or component of the waveform is shown in two-dimensional format. Remember that a vector has both magnitude and direction. The electrical field vector at a certain point in time and space is proportional to its own magnitude.

Time or distance of wave propagation is plotted on the abscissa. Most of the instrument principles widely used in the laboratory involve the electrical component of radiation and will represent the focus of discussion throughout this chapter. An exception will be nuclear magnetic resonance (NMR). With this technique, the magnetic component produces the desired effect.

Several wave parameters will be described. *Amplitude* of the sine wave is shown as the length of the electronic vector at maximum peak height. A *period*, p , is defined as the time in seconds required for the passage of successive maxima or minima through a fixed point in space. The number of oscillations of the waveform in a second is called *frequency*, ν . The unit of frequency is hertz (Hz), which corresponds to one cycle per second. Frequency is also equal to $1/p$. A *wavelength*, λ , is the linear distance between any two equivalent points on a successive wave. A widely used unit for wavelength in the visible spectrum is the nanometer, nm (10^{-9} m). Electromagnetic radiation in the x-rays or gamma region may be expressed in terms of angstrom units, Å (10^{-10} m). Finally, because of its much longer wavelength, EMR in the infrared region may have units corresponding to the micrometer, μm (10^{-6} m).

Example 4-1. $1 \text{ nm} = 10^{-9} \text{ m} = 10^{-7} \text{ cm}$; other units sometimes used include the following:

$$\begin{aligned} 1 \mu\text{m} &= 10^{-6} \text{ m} = 10^{-4} \text{ cm} \\ 1 \text{ Å} &= 10^{-10} \text{ m} = 10^{-8} \text{ cm} \end{aligned}$$

Velocity of Propagation

Velocity of propagation, v , in meters per second, is determined by multiplying frequency by wavelength. Thus:

$$v_i = v\lambda_i \quad (4-1)$$

The frequency of light is determined by the source and does not change, whereas the velocity depends upon the composition of the medium through which it passes. Therefore, Equation 4-1 implies that the wavelength of radiation is also dependent upon the medium.

The velocity of light traveling through a vacuum is independent of wavelength and is at its maximum. This velocity is represented by the symbol c , and is equivalent to $2.99792 \times 10^8 \text{ m/s}$. Equation 4-1 can then be rewritten as follows:

$$c = v\lambda = 3.00 \times 10^8 \text{ m/s} = 3.00 \times 10^8 \text{ m/s}^{-1} = 3.00 \times 10^{10} \text{ cm/s} \quad (4-2)$$

Example 4-2. What is the wavelength in nm for EMR having a frequency of $1.58 \times 10^{15} \text{ Hz}$?

SOLUTION

$$\lambda = c/\nu$$

$$\lambda (\text{nm}) = \frac{3.00 \times 10^8 \text{ m/s}}{1.58 \times 10^{15} \text{ Hz}}$$

$$\lambda (\text{nm}) = 190$$

In any medium containing matter, the propagation of radiation is slowed by the interaction between the EMR field of the radiation and the electrons bound in the atoms of that matter. Because the radiant frequency does not vary and is fixed by the source, the wavelength must decrease as radiation passes from air to a slower medium.

Energy of EMR

One should note the following safety concern: optical devices that emit high frequency EMR generate very high energies and can damage the eyes. Examples include deuterium and xenon lamps.

*Unpolarized radiation has waves in many planes.

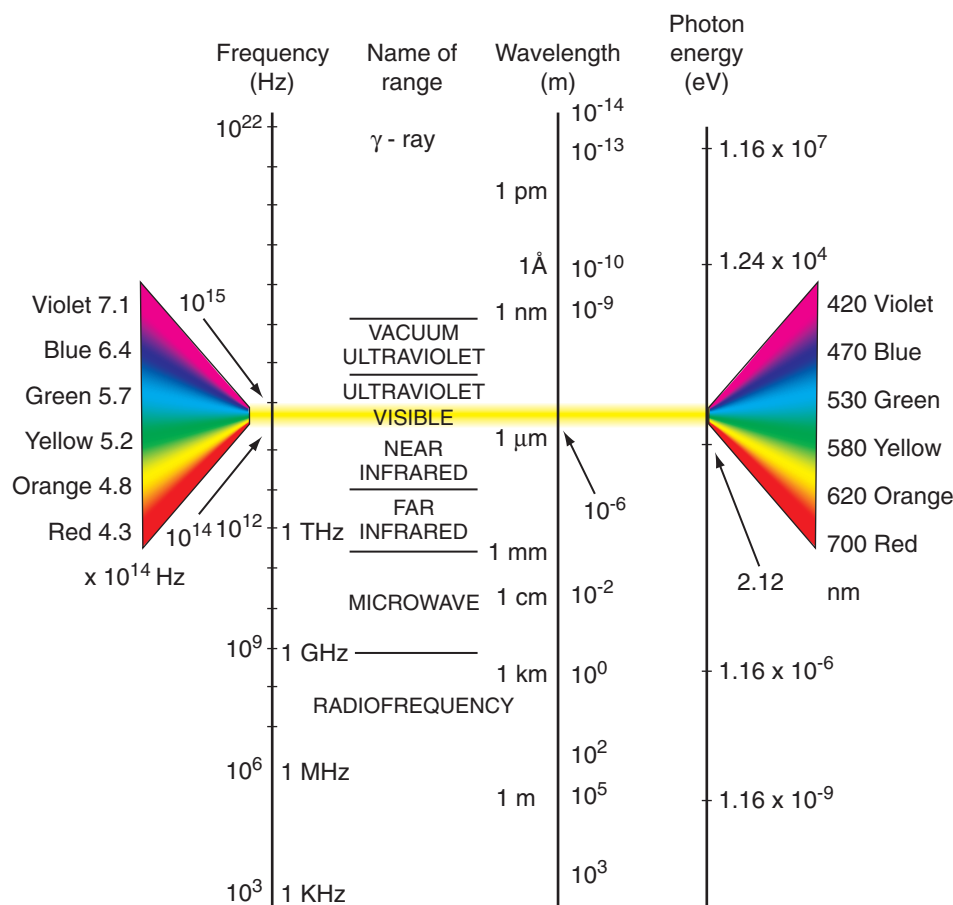

Figure 4-2 A diagram of the names, frequencies, wavelengths, and photon energies of electromagnetic radiation (EMR). Visible and ultraviolet light are widely used in analytic methods.

Wavelength and frequency are related to the energy of a photon, E , by Planck's* constant h , 6.626×10^{-34} J s, and c , the velocity of light in a vacuum (3.00×10^8 ms⁻¹):

$$E = h\nu = hc/\lambda \quad (4-3)$$

where:

E is the energy of a photon in Joules or eV

h is Planck's constant (6.626×10^{-34} J s)

ν is frequency in Hz (cycles/s).

Quite often the energies of photons are stated in terms of an electron volt (eV). An eV is defined as the energy acquired by an electron that has been accelerated through a potential of 1 volt. The conversion factors between Joules and eV are as follows:

$$1 \text{ J} = 6.24 \times 10^{18} \text{ eV}$$

$$1 \text{ eV} = 1.602 \times 10^{-19} \text{ J}$$

To illustrate the difference in energies of photons in the EMS, compare the energy of photons in the ultraviolet (UV) region versus the visible region of the EMS.

Example 4-3. What is the energy in Joules and eV of EMR equivalent to (a) 190 nm? (b) 520 nm?

SOLUTION

(a)

$$E = hc/\nu$$

$$E = \frac{(6.626 \times 10^{-34} \text{ J s})(3.0 \times 10^8 \text{ m/s})}{190 \text{ nm} (10^{-9} \text{ m/nm})}$$

$$E = 1.046 \times 10^{-18} \text{ J}$$

Or to convert to eV, use the conversion of $1 \text{ J} = 6.24 \times 10^{18} \text{ eV}$.

Therefore the number of eVs is 6.53.

(b)

$$E = hc/\nu$$

$$E = \frac{(6.626 \times 10^{-34} \text{ J s})(3.0 \times 10^8 \text{ m/s})}{520 \text{ nm} (10^{-9} \text{ m/nm})}$$

$$E = 3.82 \times 10^{-19} \text{ J or } 2.38 \text{ eV}$$

The relationship of frequency, wavelength, and photon energy throughout the EMS can be seen in Figure 4-2. This graphic illustrates for example that very-high-energy gamma photons have extremely short wavelengths and very high frequencies (Rubinson, 2000). The converse is true for television and radio wave parameters.

Scattering of Radiation

Transmission of radiation in matter can be viewed as a momentary retention of the radiant energy by atoms, ions, or molecules followed by re-emission of the radiation in all directions as particles return to their original state. Destructive interference removes most but not all of the re-emitted radiation involving atomic or molecular particles that are small relative to the wavelength of the radiation. The exception is radiation that travels in the original direction of the beam; the path of the beam appears to be unaltered because of the interaction. It has been shown that a very small fraction of the radiation is transmitted at all angles from the original path, and that the intensity of this scattered radiation increases with particle size.

Rayleigh Scattering

Scattering by molecules or aggregates of molecules with dimensions significantly smaller than the wavelength of the radiation is referred to as *Rayleigh scattering*. The intensity is proportional to the inverse fourth power of the wavelength, the square of the polarizability of the particles, and the dimensions of the scattering particles. In Rayleigh scattering, the wavelengths of absorbed and emitted photons are the same. An example of Rayleigh scattering is the blue color of the sky, which results from increased scattering of the shorter wavelength of the visible spectrum.

*Also expressed in units 6.626×10^{-27} erg s.

Figure 4-3 Attenuation of monochromatic light by an absorbing solution.

Tyndall Effect

The Tyndall effect occurs with particles of colloidal dimensions and can be seen with the naked eye. Measurements of scattered radiation are used to determine the size and shape of polymer molecules and colloidal particles.

Raman Scattering

Raman scatter involves absorption of photons producing vibrational excitation. Emission or scatter occurs at longer wavelengths. Raman scatter always varies from the excitation energy by a constant energy difference.

Beer–Lambert Law

If monochromatic EMR (P_0) is directed toward a cuvet containing an absorbing species, the amount of light (P) transmitted (T) is equal to:

$$T = P/P_0 \quad (4-4)$$

and percent transmittance is equal to $100T$.

Lambert proved that for monochromatic radiation that passes through an absorber of constant concentration, a logarithmic decrease is seen in the radiant power as the path length increases arithmetically. The absorbance (A) of a solution was determined to be equivalent to:

$$A = \log P_0/P \quad (4-5)$$

The relationship between transmittance, T , or percent transmittance ($P/P_0 \times 100$), and absorbance is shown in Figure 4-3. Absorbance and percent transmittance are inversely related as given by the following:

$$A = 2 - \log \%T \quad (4-6)$$

Example 4-4. What is the absorbance of a solution whose transmittance is 10%?

SOLUTION

$$A = 2 - \log \%T$$

$$A = 2 - \log 10\%T = 2 - 1 = 1$$

Beer followed with studies on the relationship between radiant power and concentration. His approach was to keep the path length and wavelength constant while determining the relationship of radiant power, P , and concentrations of the absorbing species. Based on previous work by Lambert, Beer discovered that for monochromatic radiation, absorbance is directly proportional to the path length, b , through the medium and the concentration, c , of the absorbing species. The work culminated in the Beer–Lambert law, or simply Beer's law.

The principles established are represented by the following:

$$A = -\log T = \log P_0/P = abc \quad (4-7)$$

where:

a is absorptivity in $L \text{ g}^{-1} \text{ cm}^{-1}$

b is path length of 1 cm

c is concentration in units of g/L .

Figure 4-4 A plot of absorbance versus concentration illustrating deviation from Beer's law.

When the concentration in Equation 4-7 is expressed in moles per liter and the path length in centimeters, the term applied is *molar absorptivity*, given the symbol ϵ , epsilon, and is equivalent to the extinction coefficient (" a ") times gram molecular weight of the absorbing species.

$$A = \epsilon bc \quad (4-8)$$

where units for ϵ are $L \text{ mol}^{-1} \text{ cm}^{-1}$.

The graph of absorbance versus concentration shows the intercept at zero and a linear plot with a slope equivalent to " ab ." Absorption spectroscopy is used best for solutions whose absorbance values are less than 2.0. Absorbance values greater than 2.0 may yield erroneous results because of other interactions of light with matter (e.g., variations in the refractive index of a solution). This may cause a deviation from Beer's law, resulting in bending of the linear plot as shown in Figure 4-4.

Deviations from Beer's law may be caused by changes in instrument functions or chemical reactions. Instrument deviation is commonly a result of the finite band pass of the filter or monochromator. Beer's law assumes monochromatic radiation, but truly monochromatic radiation is best achieved using only unique line emission sources. If absorptivity is constant over the instrument band pass, then Beer's law is followed within close limits.

Deviations from Beer's law become apparent at higher concentration (i.e., higher absorbance). In Figure 4-4, the curved line bends toward the concentration axis as opacity is approached. This lack of adherence to Beer's law in a negative direction is undesirable because of the somewhat large increase in the relative concentration error.

Deviation from Beer's law can occur with shifts or changes in chemical or physical equilibrium involving the absorbing species. Changes in solution pH, ionic strength, and temperature can result in such deviations.

Components of a Spectrophotometer

A typical photometer or spectrophotometer contains six basic components in a single or double-beam configuration. These components include (1) a stable source of radiant energy; (2) a filter that isolates a specific region of the electromagnetic spectrum; (3) a sample holder; (4) a radiation detector; (5) a signal processor, and (6) a readout device. Each component of a typical photometer is shown in Figure 4-5.

The following steps outline the function of each component in any absorption-type photometer as it detects light and provides information to the operator:

1. The light source provides the energy that the sample will modify or attenuate by absorption. The light is polychromatic (i.e., all visible wavelengths are present).
2. A wavelength selector or filter isolates a portion of the spectrum emitted by the source and focuses it on the sample.
3. The sample in a suitable container (e.g., a cuvet) absorbs a fraction of the incident light and transmits the remainder.
4. The light that passes through the cuvet and sample strikes the cathode of a photodetector and generates an electrical signal.
5. The electrical signal is processed electronically (e.g., amplified, digitized).
6. The processed signal is electronically coupled to the display unit (e.g., light-emitting diode [LED], X-Y strip chart recorder, meter).

Radiant Energy Sources

Radiant energy sources or lamps provide polychromatic light and must generate sufficient radiant energy or power to measure the analyte of interest. A regulated power supply is required to provide a stable and constant source of voltage for the lamp. Radiant energy sources are of two types: *continuum* and *line*. A continuum source emits radiation that changes in intensity very slowly as a function of wavelength. Line sources emit a limited number of discrete lines or bands of radiation, each of which spans a limited range of wavelengths.

Continuum sources find wide applications in the laboratory. Examples of continuum sources include tungsten, deuterium, and xenon. For testing in the visible region of the EMS, tungsten or tungsten-halogen lamps are widely used. The filament in the tungsten-halogen lamp is maintained at a higher temperature than in the normal tungsten lamp. This takes advantage of the Wien and Stefan relationship to provide a source with a maximum wavelength near the center of the visible spectrum (whiter), and with a greater energy output (brighter). Introducing a halogen gas into the lamp envelope counteracts the problem of increased atom vaporization from the high temperature filament.

The deuterium lamp is routinely used to provide UV radiation in analytic spectrometers. The voltage applied is typically about 100 volts, which gives the electrons enough energy to excite the deuterium atoms in a low pressure gas to emit photons across the full UV range.

The strong atomic interaction in a high pressure xenon discharge lamp produces a continuous source of radiation, which covers both the UV and the visible range. The discharge light is normally pulsed for short periods with a frequency that determines the average intensity of the light from the source and also its lifetime.

In atomic emission line sources, electrons move between atomic energy levels. If the atom is free of any interaction with other atoms, the amount of energy liberated can be very precise, and all of the photons share a very clearly defined wavelength. This is the characteristic sharp "line" emission from an electronic discharge in a low pressure gas. Line sources that emit a few discrete lines find wide use in atomic absorption, molecular, and fluorescent spectroscopy. Mercury and sodium vapor lamps provide sharp lines in the ultraviolet and visible regions and are used in several spectrophotometers. For atomic absorption spectroscopy applications, the hollow cathode lamp provides atomic emission from free metal atoms by using the heat of a gaseous discharge (e.g., in neon) to vaporize metal atoms into the discharge. Typically, each lamp is specific to a particular metal. However, some lamps use two, three, or more metals, although the emission from each of these is reduced.

A laser source is very useful in analytic instrumentation because of its high intensity and narrow bandwidth, and the coherent nature of its outputs. Several specific uses of lasers include high resolution spectroscopy, kinetic studies of processes with lifetimes in the range of 10^{-9} to 10^{-12} s, as light sources for nephelometers, and as ionization inducers in the MALDI and SELDI mass spectrometric techniques (see later).

Wavelength Selectors

A critical component of all spectrometers is the device used to select the appropriate wavelength. Several types of wavelength selectors are available, including filters, prisms, grating monochromators, and, recently, holographic gratings. The quality of these selectors is described by their nominal wavelengths, spectral bandwidths, and bandpass. *Nominal wavelength* represents the wavelength in nanometers at peak transmittance. Spectral bandwidth is the range of wavelengths above one-half peak

Figure 4-6 Comparison of spectral characteristics of two types of filters: **A**, interference filter; **B**, absorption filter. The spectral bandwidth of filter A is much less than filter B and therefore allows fewer wavelengths of light through.

transmittance. It is sometimes called the half power point or full width at half peak maximum (FWHM). The total range of wavelengths transmitted is the *bandpass*. Figure 4-6 summarizes these characteristics of wavelength selectors. This figure also summarizes the difference in wavelength selectivity between interference (**A**, left) and absorption filters (**B**, right) as we now discuss.

Filters

An important component of the spectrophotometer is the wavelength filter. Its purpose is to isolate monochromatic light, or at least as narrow a range of wavelengths of light as possible, and direct it to the sample or to the photodetector. Remember, the purpose of absorption spectroscopy is to detect how much light is absorbed by the sample. This is a measure of the absorbance of an analyte in a sample that is directly proportional to concentration (see Beer's law above). The percent transmittance is the ratio of the amount of light transmitted through the sample to the amount of light transmitted in the absence of the sample (e.g., buffer or solvent without the sample). Theoretically, it should be possible to determine this ratio without any filter at all. However, under these circumstances, most of the light that enters the sample in the cuvet will not be absorbed, so that, to determine absorbance, it would be necessary to measure a small difference between two large numbers (i.e., the amount of light transmitted in the absence [control] and the presence of the sample). Therefore, to obviate this condition, it becomes necessary to filter out as much "extraneous" light as possible to enable accurate measurements of absorbance.

Two approaches may be taken to filtering light waves. The first is to limit the wavelengths of light that enter the sample with appropriate filters, so-called pre-sample filters. The second is to allow multiwavelength light to pass through the sample and then to break up this light into its component wavelengths using a high resolution prism, and focus each of these component wavelengths on specific detectors, essentially one for each of the component wavelengths. If a sample absorbs light at one wavelength, then the ratio of the light transmittance of this wavelength of the sample to that for the control can be used to compute the percent transmittance and absorbance. This arrangement is termed post-sample filtering.

Pre-Sample Filters (Bender, 1987). Fundamentally, two types of these filters are used: absorption and interference filters. Absorption filters simply absorb regions of the electromagnetic spectrum and allow only a limited domain of this spectrum to pass through to the sample cuvet. The simplest sort of absorption filters consist of different forms of glass. One form of glass allows transmission only of wavelengths of light greater than 400 nm, while a second form allows transmission only of wavelengths of light less than 600 nm. If both glasses are arranged serially, they allow for transmission of light of wavelengths of only between 400 and 600 nm, with a peak at 500 nm. As a refinement of this approach, the older spectrophotometers utilize colored glass or transparent plastic materials. These colors are arranged in a circle or wheel so that light of a relatively narrow range of wavelengths is transmitted when each colored sector is in the light path. For example, if light in the green portion of the visible spectrum is desired, the wheel is turned so that the green filter is placed in the light path. The spectral bandwidth of these absorption filters ranges from about 30–50 nm (see Fig. 4-6).

This bandwidth is rather large but is adequate for determining the concentration of compounds in solution; absorbance filters are less adequate for scanning the absorption spectra of individual compounds

and macromolecules or for accurately determining low concentrations of molecules. To achieve the latter goals, it becomes necessary to use interference filters.

In the simplest interference filter, light on the path to the sample cuvet enters a magnesium fluoride chamber that is coated with micro-mirrors on the interior. As shown in Figure 4-7, A, light enters evenly spaced ports or slits on the left. Only light that enters each slit can continue; the rest is absorbed by the chamber. Light entering a slit, at an angle to the horizontal, travels across the chamber and is reflected back to the opposite wall. In Figure 4-7, A, if the path length ab equals bc , and the path length equals the desired wavelength of light, it can be shown from the theory of optics that the light whose wavelength equals that of the path length or integral multiples of this path length will undergo constructive interference (i.e., the waves will add to one another exactly) with incoming light at slits above it. For example, in Figure 4-7, A, light of wavelength $L = ab$, reflected from b to c , will be exactly in phase with light of wavelength L or integral multiples of L , entering the slit at c ; all other wavelengths will destructively interfere with light entering slit c . The light is then reflected again at c to d and back again to e , where, again, it will add to (constructively interfere with) only light waves of the same wavelength or integral multiples of it. Eventually, only light at the desired wavelength will be transmitted through the opposite wall at slits f and h .

It is important to note that, because integral multiples of the wavelengths of incident light will constructively interfere with transmitted light in the chamber, more than one wavelength of light can be transmitted from the chamber. The actual quantitative relationship between the wavelengths (L) transmitted by the chamber, the angle of incidence, q , of the light entering a slit, the refractive index, R , of MgF_2 (1.38), and the distance, d , across the chamber, is as follows:

$$ML = 2dR \sin(q) \quad (4-9A)$$

where M is any integer. Note that this equation predicts that for any given distance, d , many wavelengths of integral multiples to the fundamental wavelength where $M = 1$ can be transmitted. In practice, many of these other wavelengths can be excluded by using such techniques as placing appropriate glass filters in series with the interference chamber.

The above arrangement successfully transmits (close to) monochromatic light at a particular wavelength. However, it does not allow for scanning of wavelengths to obtain the absorption spectra of different samples. To accomplish this, another, similar arrangement is used. In this case, however, advantage is taken of another principle from the theory of optics—the principle of light diffraction. As shown in Figure 4-7, B, when monochromatic light is allowed to enter two slits on one surface of a chamber, very much like the one shown in Figure 4-7, A, except that there is no material (MgF_2) in the chamber, the two light waves interfere with one another such that if a screen is placed on the opposite surface of the chamber, discrete regions of light and dark bands will be seen (Bender, 1987). The light bands are from light waves that have added constructively to one another and are transmitted; the dark bands result from destructive interference of the light waves, and no light waves are transmitted. The position of the bands and the distance between the bands depend on the wavelength of light that enters the two apertures and on the angle of incidence of both beams. Because, for a given angle of incidence, the position of the light bands for transmitted monochromatic light depends exclusively on the wavelength of light, if exit apertures are placed on the opposite surface only where the light bands occur for light of a desired wavelength, only light of that wavelength will be emitted from the chamber. This effect can be enhanced by placing multiple entry apertures next to one another in a sawtooth or grating pattern, such that adjacent apertures are at a fixed distance, d , from one another, as shown in Figure 4-7, B.

Now, polychromatic light is composed of multiple different monochromatic wavelengths of light. When polychromatic light is allowed to pass through the two apertures, as in Figure 4-7, B, each of the wavelengths will constructively and destructively interfere with itself, as described earlier. Two different wavelengths of light will interfere only destructively with one another unless they are integral multiples of one another, as discussed in the case of the MgF_2 chamber described previously. This allows us to “trap” the light of the desired wavelength by placing the exit apertures where the light bands are known to occur on the opposite surface for that monochromatic wavelength. A limiting factor for selecting truly monochromatic light is the size of the aperture that can allow some “stray” light from adjacent light bands for very close wavelengths to exit.

As with the MgF_2 interference chamber described previously, another source of contaminating light can occur from light of wavelengths that are integral multiples of the desired wavelength. The relationship that

Figure 4-7 **A**, An interference MgF_2 filter. Light enters the filter at regularly spaced apertures at the same angle of incidence at each aperture. Going from the bottom of the figure, the light entering at a travels to b , where a mirror is reflecting it to c . Path lengths $ab = bc$. If these, in turn, are equal to the desired wavelength (or integral multiples of it), light of the desired wavelength arriving at c will be exactly in phase with light from the light source of that wavelength, and this will result in constructive interference. It will be out of phase with all other wavelengths and will therefore destructively interact with them. This summation process takes place multiple times until only light of the desired wavelength escapes through exit apertures such as at f and h (after Bender, 1987). **B**, A diffraction filter. When light enters multiple apertures, as in part **A**, each of which is equidistant from its two neighbors, light of each of the wavelengths interferes both constructively and destructively with itself, giving rise to light (yellow) and dark (blue) bands or fringes that can be observed on a screen. The position and spacing of these bands depend only on the wavelength and the angle of incidence. As shown in this figure, if apertures are placed only at the points where light (yellow) fringes occur in the figure, only light of a specific wavelength will pass through this exit aperture.

describes the wavelength as a function of the distance is similar to that for the MgF_2 chamber, that is,

$$ML = d \sin(q) \quad (4-9B)$$

Here, however, d is the distance between two adjacent entry slits on the near surface (toward the light source), *not* the distance across chamber as with the MgF_2 chamber. Note that for a given distance, d , and angle of incidence, q , this equation has multiple solutions. For example, if the desired wavelength is 800 nm, $d \sin(q) = 800$. But this is for $M = 1$, $L = 800$ nm. Another solution is $M = 2$, $L = 400$ nm, and another $M = 3$, $L = 266.67$ nm, etc. As discussed for the MgF_2 chamber, these other wavelengths can be filtered out by the use of appropriate glass or other filters.

Note that the system shown in Figure 4-7, B, allows for continuous scanning of the absorption spectrum for any analyte. Wavelengths can be continuously changed, most often using electronic devices, by changing the position of the aperture on the exit side of the chamber or by changing the angle of incidence of the entering light by altering the angle of the near surface of the chamber. Filters that have this capacity are called monochromators. Both interference systems in Figure 4-7 have spectral bandwidths of approximately 1.5% of the wavelength at peak transmittance, much lower than the absorption filters illustrated in Figure 4-6.

Post-Sample Filters. A different approach to obtaining monochromatic light and an accurate determination of absorbance is simply to allow the light to pass through the sample unfiltered. The light is then passed through a prism, where it is broken into its constituent wavelengths. The action of a prism depends on refraction of radiation by the prism material. The dispersive power depends on the variation of the refractive index with wavelength. A ray of radiation that enters a prism at an angle of incidence is bent toward the normal (vertical to the prism face), and at the prism-air interface, it is bent away from the vertical. As we describe in the section on photomultipliers that follows, each wavelength is focused onto a photodiode array such that each photodiode responds to only a specific set of wavelengths. The amount of transmitted light in the presence of the sample is compared with that in the absence of the sample. Photodiode arrays are examples of devices that convert photon energy into electrical currents in a system where photons excite the outer electrons in metal to move in the so-called conduction band, generating a current.

Sample Containers (Cuvets)

Sample containers (i.e., cells or cuvetts) are used to hold samples and must be made of material that is transparent to radiation in the spectral region of interest. In the ultraviolet region of the electromagnetic spectrum (below 350 nm), cuvetts are made from fused silica or quartz. Silicate glasses can be used in the region between 350 and 2000 nm. Plastic containers have also found application in the visible region. Generally, the path length of cuvetts is 1 cm, although much smaller path lengths are used in automated systems. However, to increase sensitivity, some cuvetts are designed to have path lengths of 10 cm, increasing the absorbance for a given solution by a factor of 10 (Beer's law; Equation 4-7).

Many double-beam spectrophotometers are designed with two cuvet holders: one for the sample and the other for the solvent. If two cuvetts are used, they should be optically matched for more accurate results. Matched pairs of cuvetts are obtainable from a manufacturer, but their optical performance should be verified before use by measuring the absorbance of identical solutions and comparing their values. One cell should then be reserved for the sample solution, and the other for solvent. Cells should be scrupulously cleaned before and after each use.

Photodetectors

It is necessary to determine how much light passes through the sample in the cuvet. To accomplish this task, advantage is taken of the photoelectric effect that forms the basis of the quantum theory. Photons of specific wavelength excite the outer shell electrons of metals at their resonance frequencies to high energy states in which they move through the so-called "conduction band," in which electrons move through the outer shells of the metal, thereby causing a current. This current, the magnitude of which is directly related to the intensity of the incident light, can then be detected and digitized.

Photomultiplier Tubes (PMTs). Perhaps the most common type of photon detector is the photomultiplier. Photomultiplier tubes are commonly used when radiant power is very low, which is characteristic of very low analyte concentrations. The operating principle is similar to the phototube with one significant difference. Some PMTs are designed to provide

Figure 4-8 Schematic of a photomultiplier tube. In this diagram, a tenfold amplification of the initial signal is produced at the anode. (Redrawn from Simonson MG. In Kaplan LA, Pesce AJ, editors. *Nonisotopic alternatives to radioimmunoassay*. New York: Marcel Dekker; 1981.)

an amplified signal nearly one million times larger than their phototube counterparts. This is accomplished by using multiple dynodes positioned throughout the PMT. The response of the PMT begins when incoming photons strike a photocathode. Electrons are ejected from the surface of the photocathode. A PMT has several additional electrodes called dynodes, each having a potential that is approximately 90 V higher than the previous one. Upon striking a dynode, each photoelectron causes emission of several additional electrons; these, in turn, are accelerated toward a second dynode, which is 90 V more positive than the previous dynode, which further amplifies the incident signal. This process, shown in Figure 4-8, continues within the PMT until all electrons are collected at the anode, where the resulting current is passed to an electronic amplifier.

Photomultiplier tubes are highly sensitive to ultraviolet and visible radiation. They also have very fast response times. These tubes are limited to measuring low power radiation because intense light causes irreversible damage to the photoelectric surface.

Photovoltaic or Barrier Layer Cell. A variant method of detecting photon-induced current is the photovoltaic cell. This is a basic phototransducer that is used for detecting and measuring radiation in the visible region. This cell typically has a maximum sensitivity at about 550 nm and the response falls off to about 10% of the maximum at 350 and 750 nm. It consists of a flat copper or iron electrode upon which is deposited a layer of semiconductor material, such as selenium. The outer surface of the semiconductor is coated with a thin transparent metallic film of gold or silver, which serves as the second or collector electrode. When radiation of sufficient energy reaches the semiconductor, covalent bonds are broken, with the result that conduction electrons and holes are formed. The electrons migrate toward the metallic film and the holes toward the base upon which the semiconductor is deposited. The liberated electrons are free to migrate through the external circuit to interact with these holes. The result is an electrical current of a magnitude that is proportional to the number of photons that strike the semiconductor surface and a photocurrent that is directly proportional to the intensity of the radiation that strikes the cells.

These types of photodetectors are rugged and low cost, and require no external source of electrical energy. Low sensitivity and fatigue are two distinct disadvantages of these cells. For routine analyses at optimum wavelengths, these photocells provide reliable analytic data.

Vacuum Phototubes. A vacuum phototube has a semicylindrical cathode and a wire anode sealed inside an evacuated transparent envelope. The concave surface of the electrode supports a layer of photoemissive material that tends to emit electrons when it is irradiated. When a potential is applied across the electrode, the emitted electrons flow to the wire anode, generating a photocurrent that is generally about one-tenth as great as the photocurrent associated with photovoltaic cells for a given radiant intensity. The number of electrons ejected from a photoemissive surface is directly proportional to the radiant power of the beam that strikes the surface. All of the electrons are collected at the anode. Several types of photoemissive surfaces are used in commercial phototubes. These include (1) highly sensitive bi-alkali materials made up of potassium, cesium, and antimony, (2) red sensitive material using multialkalis, for example, Na/K/Cs/Sb, (3) ultraviolet sensitive with UV transparent windows, and (4) flat response-type substances using Ga/As compositions.

Silicon Diode Transducers. Silicon diode transducers are more sensitive than vacuum phototubes but less sensitive than the PMTs described above.

Photodiodes have spectral ranges from about 190–1100 nm. These devices contain positively (p) and negatively (n) charged semiconductive materials adjoining one another embedded on a silicon chip. A power supply is attached to this arrangement so that its positive pole connects to the *n*-type, and its negative pole to the *p*-type material. This arrangement results in a depletion layer that reduces the conductance of the junction to nearly zero. If radiation is allowed to impinge on the chip, holes and electrons formed in the depletion layer are swept through the device to produce a current that is proportional to radiant power (Skoog, 1998). This process is shown in Figure 4-9.

Multichannel Photon Transducers. In the discussion of post-sample filters, it was noted that unfiltered light emerging from the sample could be broken up into its constituent wavelengths using prisms; these different wavelengths are then directed to electronic detectors such that the intensity of light of each of the constituent wavelengths can be quantitated. Here, we describe some of these multiwavelength photodetectors.

A multichannel transducer consists of an array of small photoelectric-sensitive elements arranged linearly or in a two-dimensional pattern on a single semiconductor chip. The chip, which is usually silicon and typically has dimensions of a few millimeters on a side, also contains electronic circuitry that makes it possible to determine the electrical output signal from each of the photosensitive elements sequentially or simultaneously. The alignment of a multichannel transducer is generally in the focal plane of a spectrometer, so that various elements of the dispersed spectrum can be converted and measured simultaneously. Several types of multichannel transducers currently are used; they may include (1) photodiode arrays (PDAs), (2) charge-injection devices (CIDs), and (3) charge-coupled devices (CCDs).

Photodiode Arrays. By using the modern fabrication techniques of microelectronics, it is now possible to produce a linear (one-dimensional) array of several hundred photodiodes set side-by-side on a single integrated circuit (IC), or “chip” (Fig. 4-10). Each diode is capable of recording the intensity at one point along the line, and together they provide a linear profile of the light variation along the array.

A multiplex method is used to sort all of the signals received from the PDA. It records each signal individually, and then feeds the signals sequentially to a single amplifier. The output of the PDA is a histogram profile, along the array, of the charge leaked by each photodiode. This mirrors the variation of light intensity across the array. Thus, the PDA detection occurs in three main stages:

1. initialization
2. accumulation of charge at each pixel-integration time
3. read-out signals

In comparison with the PMT, the PDA has a lower dynamic range and higher noise. It is most useful as a simultaneous multichannel detector (Skoog, 1998).

Charge-Transfer Devices. Recent developments in solid-state detection techniques have now produced very effective two-dimensional array detectors that operate on a charge-transfer process, as an alternative to

photodiodes. The term “charge-transfer device” (CTD) is a generic term that describes a detection system in which a photon, striking the IC semiconductor material, releases electrons from their bound state into a mobile state. The released charge, consisting of negative electrons and positive holes, then drifts to, and accumulates at, surface electrodes. An array of these surface electrodes divides the detector into separate, light-sensitive “pixels.” The charge that accumulated at each electrode is proportional to the integrated light intensity falling on that particular pixel.

Two distinct classes of CTDs are known: charge-injection devices (CIDs) and charge-coupled devices (CCDs). In a CCD, all of the charge packets are moved “in-step” along the array row from one pixel to the next, as in a “bucket chain.” At the end of the row, the charge packets are fed sequentially into an *on-chip* low noise amplifier, which then converts the charge into a voltage signal. The overall signal profile across the two-dimensional array is recorded one row at a time, thus giving a series of voltage signals corresponding to all of the pixels in the detection area.

In a CID, the charge accumulated in each pixel can be measured independently and nondestructively by using a network of “sensing” electrodes, which can monitor the presence of the accumulated charge. This is an important factor that differentiates CID systems from CCD and PDA systems, in which the whole of the detection area is “read” destructively in a single process.

Signal Processors and Readout

The processing of an electrical signal received from a transducer is accomplished by a device that amplifies, rectifies AC to DC (or the reverse), alters the phase of the signal, and filters it to remove unwanted components. In addition, the signal processor may need to perform mathematical operations on the signal such as differential calculations, integration, or conversion to a logarithm. Several readout devices have been used and include digital meters, d’Arsonval meters, recorders, light-emitting diodes (LEDs), cathode-ray tubes (CRTs), and liquid crystal displays (LCDs).

Quality Assurance in Spectrophotometry

Several photometric parameters must be monitored periodically by users. Monitoring these parameters is recommended by most regulatory agencies and accrediting organizations. The parameters routinely monitored include the following:

- wavelength or photometric accuracy
- absorbance check
- linearity
- stray light

Accuracy is the closeness of a measurement to its true value. Wavelength accuracy implies that a photometer is measuring at the wavelength that it is set to. Photometric accuracy can be assessed easily using special glass-type optical filters. Two examples of commonly used filters include didymium and holmium oxide. Didymium glass has a broad absorption peak around 600 nm, and holmium oxide has multiple absorption peaks with a sharp peak occurring at 360 nm.

An absorbance check is performed using glass filters or solutions that have known absorbance values for a specific wavelength. The operator simply measures the absorbance of each solution at a specified wavelength and compares the results with the stated values. Each user should establish a tolerance for the measurements based on accepted criteria.

Figure 4-9 Schematic of a semiconductor photodiode used as a detector in many spectrometers.

Figure 4-10 Photodiode array. A, Lamp; B, lens; C, shutter; D, cell; E, lens; F, slit; G, grating; H, photodiode array.

Linearity is defined as the ability of a photometric system to yield a linear relationship between the radiant power incident upon its detector and the concentration (i.e., Beer's law). The linearity of a spectrometer can be determined using optical filters or solutions that have known absorbance values for a given wavelength. Linearity measurements should be evaluated for both slope and intercept.

Stray light is described as any light that impinges upon the detector that does not originate from a polychromatic light source. Stray light can have a significant impact on any measurement made. Stray light effect can be evaluated by using special cutoff filters.

Types of Photometric Instruments

Several instrument designs and configurations may be used for absorption photometry. Each has unique terminology associated with its design. The terminology is not universal among users but is presented here as a guide. A *spectroscope* is an optical instrument used for visual identification of atomic emission lines. It has a monochromator, usually a prism or diffraction grating, in which the exit slit is replaced by an eyepiece that can be moved along the focal plane. The wavelength of an emission line can then be determined from the angle between the incident and dispersed beam when the line is centered on the eyepiece.

A *colorimeter* uses the human eye as the detector. The user compares the observed color of the unknown sample against a standard or a series of colored standards of known concentrations. *Photometers* consist of a light source, a filter, and a photoelectric transducer as well as a signal processor and readout. Some manufacturers use the term colorimeter or photoelectric colorimeters for photometers. These photometers use filters for isolation of specific wavelengths—not gratings or prisms.

A *spectrometer* is an instrument that provides information about the intensity of radiation as a function of wavelength or frequency. Spectrophotometers are spectrometers equipped with one or more exit slits and photoelectron transducers that permit determination of the ratio of the power of two beams as a function of wavelength, as in absorption spectroscopy. Most spectrophotometers use a grating monochromator to break up the light into a spectrum, as discussed earlier in the section on pre-sample filters.

Single-beam spectrophotometers are the simplest types of absorption spectrometers. These instruments are designed to make one measurement at a time at one specified wavelength. The absorption maximum of the analyte must be known in advance when a single-beam instrument is used. The wavelength is then set to this value. The reference material (solvent blank) is transferred into a suitable cuvet and is placed in the path of the monochromatic light. The spectrometer is adjusted to read 0%T when a shutter is placed, so as to block all radiation from the detector, and to read 100%T when the shutter is removed. After these adjustments have been made, the sample is placed in the light path, the absorbance is measured, and the concentration is determined using calculations based on Beer's law or by constructing a calibration curve for the analyte.

A double-beam spectrophotometer splits or chops the monochromatic beam of radiation into two components. One beam passes through the sample, and the other through a reference solution or blank. In this design, the radiant power in the reference beam varies with the source energy, monochromator transmission, reference material transmission, and detector response, making the difference between the sample and the reference beam largely a function of the sample. The output of the reference beam can be kept constant, and the absorbance of the sample can be recorded directly as the electrical output of the sample beam.

Two fundamental instrument designs are used for double-beam spectrophotometers: (1) double beam in space and (2) double beam in time. A double beam in space design uses two photodetectors: one for the sample beam and the other for the reference beam. The two signals generated are directed to a differential amplifier, which then passes on the difference between the signals to the readout device. A schematic of the double beam in space system is shown in Figure 4-11.

A double beam in time instrument uses one photodetector and alternately passes the monochromatic radiation through the sample cuvet and then to the reference cuvet using a *chopper*. A chopper is the term used for a device such as a rotating sector mirror that breaks up or rotates radiation beams. Each beam, consisting of a pulse of radiation separated in time by a dark interval, is then directed onto an appropriate detector. A schematic of the double-beam in time system is shown in Figure 4-12.

A scanning double-beam system includes a double-beam spectrophotometer and a recorder that can provide an X-Y plot of absorbance versus wavelength for a given test sample. This type of configuration is ideal for determining the wavelength spectrum of an analyte in solution. The spectrophotometer has an automatically driven wavelength cam that can rotate at a predetermined speed. The recorder can be calibrated to the

wavelength of the monochromator to facilitate the identification of each peak maxima.

REFLECTOMETRY

Measurement of analytes in biologic fluids using reflectometry has been used for decades. Two clinical applications include urine dipstick analysis and dry slide chemical analysis. The instruments used for these applications include a reflectometer. A reflectometer is a filter photometer that measures the quantity of light reflected by a liquid sample that has been dispensed onto a grainy or fibrous solid support.

Two types of reflectance are known: (1) specular, and (2) diffuse. Specular reflectance occurs on a polished surface where the angle of incidence of the radiant energy is equal to the angle of reflection. Polished surfaces, for example, a mirror, may be used to direct and manage radiant energy but are not used to determine concentration. Diffuse reflectance occurs on nonpolished surfaces (i.e., a grainy or fibrous surface), as noted earlier. The reflected radiant energy tends to go in many directions. Diffuse reflection occurs within the layers and depends on the properties and characteristics of the layers themselves. A colored substance absorbs the wavelength of its color and reflects all other wavelengths at many different angles. Therefore the amount of a substance present can be measured as an indirect function of the reflected light.

A typical reflectometer used in a clinical laboratory detects only a constant fraction of the diffuse reflected light. Thus the reflectance of a sample is represented by the following:

$$R_{(\text{diffuse reflectance})} = \frac{R'_{(\text{fraction of diffuse reflectance of sample})}}{R'_{(\text{fraction of diffuse reflectance of a standard})}} \quad (4-10A)$$

The amount of light reflected by a solution dispensed onto a white granular or grainy surface is inversely related to the concentration of the sample, as given by the following:

$$R_{\text{density}} = -\log\left(\frac{R_{\text{sample}} - R_{\text{black}}}{R_{\text{standard}}}\right) \times R_{\text{white}} \quad (4-10B)$$

where:

R_{density} is the corrected reflectance density of the sample

R_{sample} is the measured reflectance of the sample

R_{black} is the reflectance of a black reference

R_{white} is the reflectance of a white reference

R_{standard} is the reflectance of a standard solution.

The ideal reflectance value of a pure white standard of ceramic material is *one* (i.e., all light is reflected), and conversely, the ideal reflectance value of pure black material is *zero* (i.e., all light is absorbed).

The relationship of percent reflectance and concentration of an analyte is nonlinear. Several algorithms have been developed for linearizing this relationship. The specific algorithm used depends upon the reflection characteristics of the composition material of the pad or film, the nature of the illumination, and the geometry of the instrument.

Reflectometers

The components of a reflectometer are very similar to those of a photometer, as shown in Figure 4-13. A tungsten-quartz halide lamp serves as a source of polychromatic radiation. A monochromator (e.g., stationary filter or filter wheel for multiple analytes) is used to isolate the wavelength of interest. Next, the monochromatic light passes through a slit and is directed onto the surface of a urine dipstick pad or dry slide, depending upon the instrumentation used. Solid-state photodiodes are typically used to detect reflected radiant energy. Special optical devices, for example, fiberoptics or ellipsoidal mirrors, may be used to direct radiant energy onto the detector. A computer or microprocessor is used to convert nonlinear reflectance signals into direct readout concentration units.

MOLECULAR LUMINESCENCE SPECTROSCOPY (FLUOROMETRY)

Principle

Luminescence is based on an energy exchange process that occurs when certain compounds absorb electromagnetic radiation, become excited, and return to an energy level lower than or equal to their original level. Because some energy is lost before emission from the excited state by collision with

Figure 4-13 Components in a typical reflectometer used to measure analytes on urine dipstick. The different colored blocks represent different tests performed in urinalysis; the *blue* represents the quantitation of analyte using reflectance (i.e., the reflectance of light focused on the sample and reflected at an angle [yellow beam], where it is detected).

the solvent or other molecules, the wavelength of the emitted light is longer than that of the exciting light. Most uncharged molecules contain even numbers of electrons in the ground state. These electrons fill molecular orbits in pairs with their spins in opposite directions. No electron energies can be detected by application of a magnetic field to such spin patterns, and this electronic state is called the singlet state. Similarly, if an electron becomes excited by electromagnetic radiation and its spin remains paired with the ground state, this creates a singlet excited state. The lifetime of the excited state is the average length of time the molecule remains excited before emission of light. For a singlet excited state, the lifetime of the excited state is on the order of 10^{-9} to 10^{-6} s. The light emission from a singlet excited state is called *fluorescence*. When the spins of the electrons in the excited state are unpaired, the electron energy levels will be split if a magnetic field is applied, and this electronic state is called a triplet state. Triplet state lifetimes range from 10^{-4} to 10 s (Willard, 1988). Light emission from an excited triplet state is called *phosphorescence*.

Luminescence is widely used because of its high sensitivity—the signal/noise ratio is very high, because light is measured against a nearly dark background. High specificity is a function of using two spectra, the excitation and emission spectra, and the possibility of measuring the lifetime of the fluorescent state. Two compounds that are excited at the same wavelength but emit at different wavelengths are readily differentiated with this technique.

Components of Fluorometers and Spectrophotofluorometers

Instruments designed for fluorescence measurement have the following basic components: a light source, an excitation (primary) monochromator, a cuvet, an emission (secondary) monochromator, and a photodetector (Fig. 4-14). The exciter lamp is a high-intensity light source such as a mercury vapor lamp or a xenon arc lamp. Simple instruments use mercury vapor lamps that do not require any special power supply. Mercury vapor lamps produce discrete and intense resonance lines that are not ideal for compounds with absorption bands at wavelengths not coinciding with these emission bands. For such compounds, xenon arc lamps producing an intense continuous spectrum between 300 and 1300 nm are appropriate. These lamps are used in nearly all commercial spectrophotofluorometers. In fluorescence measurements, the emitted light is detected at a right angle to the incident light to eliminate potential interference by the excitation signal. Phototubes or photomultiplier tubes (PMTs) are required for fluorescence measurements because the signals are generally of low intensity. Newer fluorometers on the market today use diode array and CTDs, which allow the rapid recording of both excitation and emission spectra and are particularly useful in chromatography and electrophoresis.

Time-resolved fluorescence assays minimize problems inherent in other fluorescent assays such as overlapping excitation or emission spectra of compounds present in the sample with the fluorophore. The label most commonly used is a chelate of europium (Eu^{3+}). Energy is absorbed by the organic ligand, leading to an excited state as the electrons migrate from the ground state singlet to the excited singlet state. The excitation may

Figure 4-14 Components of a fluorometer. (From Bishop ML, Duben-Engelkirk JL, Fody EP. *Clinical chemistry: principles, procedures, correlations*. Philadelphia: JB Lippincott Company; 1992, with permission.)

lead to any vibrational multiplet of the excited state S_1 . The molecule rapidly returns to the lowest energy levels in S_1 by a nonradiative process. The energy is transferred to the metal ion, which becomes excited and subsequently emits characteristic radiation. The radiative transition of excited Eu^{3+} after an energy transfer from triplet state results in an emission wavelength of 613 nm. The fluorescence lifetime of Eu^{3+} chelate is 10–1000 μs compared with nanoseconds for the most commonly used fluorophore. Therefore, Eu^{3+} with its longer emission lifetime makes it more attractive to use over a fluorophore like fluorescein with a lifetime of 4.5 ns. Time-resolved fluorescence instruments are similar to a typical fluorometer, except that time-resolved fluorometers use a time-gated measure on only a portion of the total emission spectra.

Chemiluminescence applications have increased dramatically owing to the increased sensitivity over fluorescence. (In chemiluminescence, the light signal is measured against a completely dark background because no excitation light is required.) The primary application has been in the area of immunoassays where several chemiluminescence compounds have been used as antigen labels. Chemiluminescence differs from fluorescence and phosphorescence in that the emission of light is created from a chemical or electrochemical reaction, and not from absorption of electromagnetic energy. The chemical reaction yields an electronically excited compound that emits light as it returns to its ground state, or that transfers its energy to another compound, which then produces emission. Chemiluminescence involves the oxidation of an organic compound (e.g., dioxetane, luminol, acridinium ester) by an oxidant (hydrogen peroxide, hypochlorite, or oxygen). These oxidation reactions may occur in the presence of catalysts, such as enzymes (alkaline phosphatase, horseradish peroxidase, or microperoxidase), metal ions (Cu^{2+} or Fe^{3+} phthalocyanine complex), and hemin. The excited products formed in the oxidation reaction produce chemiluminescence on return to the singlet state. A luminometer is used to detect chemiluminescence; it contains a PMT that provides a very strong electrical output signal. A typical signal from a chemiluminescent compound rises rapidly with time and reaches a maximum when reagent and analyte are completely mixed. An exponential decay of the signal follows until baseline is reached.

NEPHELOMETRY AND TURBIDIMETRY

Nephelometry and turbidimetry are used to measure the concentrations of large particles (such as antigen–antibody complexes, prealbumin, and other serum proteins) that because of their size cannot be measured by absorption spectroscopy. Nephelometry detects light that is scattered at various angles; scattered light yields a small signal that must be amplified. In contrast, turbidimetry measures a reduction in light transmission due to particle formation; thus, it detects a small decrease in a large signal (Fig. 4-15).

Figure 4-15 Optical arrangements of nephelometry and turbidimetry. Note that nephelometry detects (right-angle or forward) scattered light, and turbidimetry measures a reduction of light transmitted in the forward direction. (Modified from Bishop ML, Duben-Engelkirk JL, Fody EP. *Clinical chemistry: principles, procedures, correlations*. Philadelphia: JB Lippincott Company; 1992, with permission.)

Principle

Nephelometry and turbidimetry are based on the scattering of radiation by particles in suspension. When a collimated light beam strikes a particle in suspension, portions of the light are absorbed, reflected, scattered, and transmitted. Nephelometry is the measurement of the light scattered by a particulate solution. Three types of light scatters occur according to the relative size of the light wavelength (Gauldie, 1981). If the wavelength (λ) of light is much larger than the diameter (d) of the particle ($d < 0.1\lambda$), the light scatter is symmetrical around the particle. Minimum light scatter occurs at 90 degrees to the incident beam and was described by Rayleigh (Rayleigh, 1885). If the wavelength of light is much smaller than the particle diameter ($d > 0.1\lambda$), then the light scatters forward owing to destructive out-of-phase backscatter, as described by the Mie theory. If the wavelength of light is approximately the same as the particle size, more light scatters in the forward direction than in other directions, as defined by the Rayleigh–Debye theory. A common application of nephelometry is the measurement of antigen–antibody reactions. Because most antigen–antibody complexes have a diameter of 250–1500 nm, and the wavelengths used are 320–650 nm, light is scattered forward (Rayleigh–Debye type).

Nephelometer

A typical nephelometer consists of a light source, a collimator, a monochromator, a sample cuvet, a stray light trap, and a photodetector. Light scattered by particles is measured at an angle, typically 15–90 degrees to the beam incident on the cuvet (see Fig. 4-15). Light scattering depends on the wavelength of incident light and particle size. For macromolecules with size close to or larger than the light wavelength, measurement of forward light scatter increases the sensitivity of nephelometry. Light sources include a mercury-arc lamp, a tungsten-filament lamp, a light-emitting diode, and a laser.

Lasers produce stable, nearly ideal monochromatic light of narrow bandwidth and emit radiant energy that is coherent, parallel, and polarized. A laser beam can be maintained as a very slim cylinder only a few micrometers in cross-section. A typical helium–neon laser lamp consists of a helium-pumping electrode (cathode) and a hollow glass laser core surrounded by a laser plasma tube (anode). Both the plasma tube and the core are filled with free helium and neon gases. The electrical discharge between the cathode and the anode is confined to the hollow glass core to keep it concentrated for maximum energy transfer. Two mirrors are positioned at the ends of the laser tube. One of them is fully reflective, and the other partially transparent. When the electrode is charged, the helium atoms are excited to a higher energy state and then transfer this energy to the neon atoms by collision. In turn, the excited neon atoms emit photons. Photons bounce back and forth between the two end mirrors, stimulating other atoms to emit additional photons, resulting in an amplification process. The amplified light eventually emerges as a laser beam through the partially transparent mirror. With the high intensity

monochromatic beam, a substantial increase in sensitivity has been seen with lasers over conventional light sources. Disadvantages of laser sources include cost, safety and cooling requirements, and limited availability of wavelengths.

Turbidimetry

The measurement of the reduction in light transmission caused by particle formation is termed turbidimetry. Light transmitted in the forward direction is detected. The amount of light absorbed by a suspension of particles depends on the specimen concentration and on the particle size. Solutions requiring quantitation by turbidimetry are measured using visible photometers or visible spectrophotometers. Higher sensitivity has been achieved using photodetectors that can detect small changes in photon signals. Sensitivity comparable with nephelometry can be attained using low wavelengths and high quality spectrophotometers. Many clinical applications exist for turbidimetry. Various microbiology analyzers measure turbidity of samples to detect bacterial growth in broth cultures. Turbidimetry is routinely used to measure the antibiotic sensitivities from such cultures. In coagulation analyzers, turbidimetric measurements detect clot formation in the sample cuvetts. Turbidimetric assays have long been available in clinical chemistry to quantify protein concentration in biologic fluids, such as urine and cerebrospinal fluid (CSF).

REFRACTOMETRY

Refractometry is based on light refraction. When light passes from one medium into another, the light beam changes its direction at the boundary surface if its speed in the second medium is different from that in the first. The angle created by the bending of the light is called the *critical angle*. The ability of a substance to bend light is called *refractivity*. The refractivity of a liquid depends on the wavelength of the incident light, the temperature, the nature of the liquid medium, and the concentration of the solute dissolved in the medium. If the first three factors are held constant, the refractivity of a solution is an indirect measurement of total solute concentration. Refractometry can be used to measure protein concentration, specific gravity of urine, and column effluent of high-performance liquid chromatography analysis.

OSMOMETRY

Osmometry is the measurement of the osmolality of an aqueous solution such as serum, plasma, or urine. As osmotically active particles (e.g., glucose, urea nitrogen, sodium) are added to a solution, causing its osmolality to increase, four other properties of the solution are also affected. These properties are osmotic pressure, boiling point, freezing point, and vapor pressure. They are called colligative properties of the solution because they can be related to each other and to the osmolality. As the osmolality of a solution increases, (1) the osmotic pressure increases, (2) the boiling point is elevated, (3) the freezing point is depressed, and (4) the vapor pressure is depressed. Osmometry is based on measuring changes in the colligative properties of solutions that occur owing to variations in particle concentration. Freezing-point depression osmometry is the most commonly used method for measuring the changes in colligative properties of a solution. It is based on the principle that addition of solute molecules lowers the temperature at which a solution freezes.

Principle of Freezing-Point Osmometry

The freezing point is the temperature at which water and ice are in equilibrium and is related to solute concentration. It is described by the following equation:

$$\rho T_f = K_f m \quad (4-11)$$

where:

ρT_f = the change in freezing-point temperature

K_f = the freezing point constant of the solvent

m = the molality

A 1.0 mOsm/kg solution has a freezing point depression of 0.00186° C when compared with pure solvent (usually water). Thus blood plasma, with an osmolality of about 285 mOsm/kg, has a freezing point of about -0.53° C.

Freezing-Point Osmometer

A freezing-point osmometer consists of a sample chamber containing a stirrer and a thermistor (temperature-sensing device) connected to a

readout device. The sample is rapidly supercooled to several degrees below its freezing point in a refrigeration chamber containing, for example, ethylene glycol. The sample is then agitated with the stirrer to initiate freezing. As ice crystals form, heat is released from the solution; this raises the temperature of the sample. The rate at which this heat of fusion is released from the ice being rapidly formed reaches equilibrium with the rate of heat removed by the colder temperature of the sample chamber. This equilibrium temperature, known as the freezing point of the solution, stays constant for several minutes once it is reached. This freezing point is detected by the thermistor, and the osmolality of the sample is converted to units of milliosmoles per kilogram of water.

FLOW CYTOMETRY

A flow cytometer measures multiple properties of cells suspended in a moving fluid medium. As each particle passes single-file through a laser light source, it produces a characteristic light pattern that is measured by multiple detectors for scattered light (forward and 90 degrees) and fluorescent light (if the cell is stained with a fluorochrome). Flow cytometry is used to count and sort cells, as well as viral particles, DNA fragments, bacteria, and latex beads. It is a core component of hematology cell counters and the technology used to differentiate white blood cells.

In flow cytometry, the term *particle* describes any object flowing through the instrument. An *event* is anything that is interpreted by the instrument to be a single particle. An *event* may be determined correctly or incorrectly by a flow cytometer. Methods have been developed to compensate for measurement of unwanted *events*. An example is the correction for measuring the simultaneous passing of two particles. Particles must be in suspension as single cells to be analyzed. If not, they can be made suitable for flow cytometry by the use of mechanical disruption or enzymatic digestion. Size restrictions also apply; cells or particles must be from 1–30 μm in diameter. Specialized flow cytometers are designed to handle smaller particles such as DNA fragments or bacteria.

Instrument Components

The system shown in Figure 4-16 has all of the design features of a flow cytometer with cell sorting capabilities. The cell suspension aliquots are introduced into the flow chamber using air pressure. As cells pass through the flow chamber, a low-pressure sheath fluid surrounds them. This outer fluid stream creates a laminar flow forcing the specimen to the center, and results in a single-file alignment of the individual cells. This process is called *hydrodynamic focusing*. A laser beam passes through each cell as it flows through the chamber. Forward light scatter is proportional to cell size, and 90-degree or right-angle scatter is related to cell granularity and nuclear irregularity. If the cells are labeled with appropriate fluorochromes, fluorescent signals proportional to the amount of bound label can be measured. Green fluorescence usually means that the dye fluorescein was used as a marker; red fluorescence usually means that a dye such as phycoerythrin was used as the contrasting marker. These dyes are usually attached to antibodies to specifically target selective antigens on cells or particles.

Forward light scatter is directed to the forward scatter photodetector. At right angles to the laser beam are mirrors that divide the right-angle light scatter among the remaining photodetectors (e.g., a right-angle scatter detector and two fluorescence detectors). Across the forward lens is an obscuration bar that blocks the laser beam after it passes through the stream. Only light from the laser that has been refracted or scattered as it strikes a particle in the stream is diverted enough from its original direction to avoid the obscuration bar and strike the forward positioned lens and the photodiode behind it. Granulocytes, monocytes, and lymphocytes are separated on the basis of size and granularity patterns, as determined by simultaneously analyzing forward and right-angle light scatter. For example, granulocytes with irregular nuclei scatter more light to the side than do lymphocytes with their spherical nuclei. Cell subpopulations can be identified by using electronic gating and analyzing fluorescence patterns (based on labels used for specific cells).

FACS, an acronym for *fluorescence-activated cell sorter*, describes the ability of a flow cytometer to physically sort cells in a liquid suspension. To do so, the instrument design has to be modified to electrically charge cells of interest. This is done by first vibrating the sheath stream to break it into drops. The stream of drops flows past two charge (high-voltage) plates where cells of interest are electrically charged with a voltage pulse.

Figure 4-16 Components of a flow cytometer and a cell sorter. (Redrawn from Ward KM, Lehmann CA, Leiken AM. *Clinical laboratory instrumentation and automation; principles, applications, and selection*. Philadelphia: WB Saunders; 1994, with permission.)

Then the flow stream enters an electrical field where charged cells are deflected into suitable collection containers. Unwanted cells are not charged and are not deflected upon passing through the field.

ELECTROCHEMISTRY

Electrochemistry involves measurement of the current or voltage generated by the activity of specific ions. Analytic techniques include potentiometry, coulometry, voltammetry, and amperometry.

Potentiometry

The measurement of potential (voltage) between two electrodes in a solution forms the basis for a variety of procedures for measuring analyte concentration. Electrical potentials are produced at the interface between a metal and ions of that metal in a solution. Such potentials also exist when a membrane semipermeable to that ion separates different concentrations of an ion. To measure the electrode potential, a constant-voltage source is

needed as the reference potential. The electrode with a constant voltage is called the reference electrode, whereas the measuring electrode is termed the indicator electrode. Concentration of ions in a solution can be calculated from the measured potential difference between the two electrodes. The measured cell potential is related to the molar concentration by the Nernst equation:

$$E = E^{\circ} - RT/nF \ln a_{\text{red}}/a_{\text{ox}} = E^{\circ} - 2.302 RT/nF \log a_{\text{red}}/a_{\text{ox}} \quad (4-12)$$

where:

E = the cell potential measured

E° = the standard reduction potential

n = the number of electrons involved in the reaction

a_{red} = activity of the reduced species

a_{ox} = activity of the oxidized species

F = faraday (96,485 C/mol)

T = absolute temperature

R = molar gas constant

Substituting molar concentration for activity and common logarithm for natural log:

$$E = E^\circ - (0.0592/n) \log C_{\text{red}}/C_{\text{ox}} \quad (4-13)$$

where:

C_{red} = concentration of reduced species

C_{ox} = concentration of oxidized species

The Nernst equation is useful for predicting the electrochemical cell potential given the concentrations of oxidized and reduced species for a given electrode system.

Reference Electrodes

In many electroanalytic applications (e.g., measuring pH), it is desirable that the half-cell potential of one electrode be known, constant, and completely insensitive to the composition of the solution under study. An electrode that fits this description is called a reference electrode.

An ideal reference electrode should (1) conform to the Nernst equation, (2) exhibit a potential that is constant with time, (3) return to its original potential after being subjected to small currents, and (4) exhibit little hysteresis (i.e., lags with temperature cycling). The standard hydrogen electrode (SHE) exhibits many of these qualities but is not practical to use in clinical laboratory instrumentation. Thus, the calomel and silver/silver chloride reference electrodes are widely used for clinical measurements.

The calomel electrode (saturated calomel electrode [SCE]) consists of mercury in contact with a solution that is saturated with mercury (I) chloride (calomel) and that also contains a known concentration of potassium chloride. The silver/silver chloride electrode consists of a silver electrode immersed in a solution of potassium chloride that has been saturated with silver chloride. Silver/silver chloride electrodes have the advantage in that they can be used at temperatures greater than 60° C, whereas calomel electrodes cannot. On the other hand, mercury (II) ions react with fewer sample components than do silver ions (which can react with proteins, for example); such reactions can lead to plugging of the junction between the electrode and the analyte solution.

Ion-Selective Electrode

An ion-selective electrode (ISE) is an electrochemical transducer capable of responding to one specific ion. An ISE is very sensitive and selective for the ion it measures. It consists of a membrane or other barrier separating a reference solution and a reference electrode from the solution to be analyzed. The complexity of ion-selective electrode design depends on the membrane/barrier composition that determines its ionic selectivity. Many types of ISEs are available, including glass electrodes, liquid membrane electrodes, precipitate-impregnated membrane electrodes, solid-state electrodes, gas electrodes, and enzyme electrodes.

pH Electrode

Glass electrodes were the first and are still the most common electrodes for measuring hydrogen ion activity (pH or negative log of the hydrogen ion concentration). A pH electrode consists of a small bulb made of layers of hydrated and nonhydrated glass, which contains a chloride ion buffer solution. The buffer has a known hydrogen ion concentration. An internal electrode, usually silver/silver chloride, serves as an internal reference electrode. A saturated calomel electrode is used as an external reference electrode. One theory suggests that the sodium ions in the hydrated glass layer drift out. Sodium ions have a large ionic radius. Specimens containing hydrogen ions, which have a smaller ionic radius, replace the sodium ions. The result is a net increase in the external membrane potential. This potential propagates through the thin, dry membrane to the inner hydrated surface of the glass. Chloride ions in the inner buffer solution respond by migrating to the internal glass layer. Potentials generated at the pH electrode are referenced to the external reference electrode (saturated calomel), and the difference or change is displayed as pH units.

pCO₂ Electrode

The pCO₂ electrode is a pH electrode contained within a plastic jacket. This plastic jacket is filled with a sodium bicarbonate buffer and has a gas-permeable membrane (Teflon or silicone) across its opening. When whole blood containing dissolved carbon dioxide (CO₂) contacts the Teflon membrane, CO₂ from the blood passes through and mixes with the buffer. The equilibrium reaction shown in Equation 4-14 shifts depending upon the number of carbon dioxide molecules in a sample. The hydrogen ion activity is measured by a potentiometric pH indicator system.

Coulometry

Coulometry measures the quantity of electricity (in coulombs) needed to convert an analyte to a different oxidation state. By definition, a coulomb is the quantity of electricity or charge that is transported in 1 second by a constant current of 1 ampere. For a constant current of 1 ampere for t seconds, the number of coulombs (Q) is given by the expression:

$$Q = It \quad (4-15)$$

A Faraday is the charge in coulombs associated with one mole of electrons. The charge of the electron is 1.6018×10^{-19} C, thus 1 Faraday is equal to 96,485 C/mol.

Coulometry is used to measure chloride ion in serum, plasma, CSF, and sweat samples. In measuring chloride with coulometry, a constant current is applied across the two silver electrodes, which liberate silver ions into the specimen at a constant rate. Chloride ions in the sample combine with released silver ions to produce insoluble silver chloride. A pair of indicator and reference electrodes senses the excess silver ions and stops the titration. The number of silver ions released by ionization, which is exactly equal to that of chloride ions in the sample, can be calculated from Faraday's law:

$$Q = It = znF \quad (4-16)$$

where:

z = the number of electrons involved in the reaction

n = the number of moles of analyte in the sample

F = Faraday's constant (96,485 C/mol of electrons)

Amperometry

Amperometry is the measurement of the current flow produced by an oxidation–reduction reaction. Several immobilized enzyme electrodes use this principle, as do pO₂ electrodes (discussed later) and chloride titrators. The measurement of chloride in samples involves the use of two electrochemical methods: coulometry (discussed earlier) and amperometry. In the chloride titrator, a pair of silver electrodes serves as the indicator electrodes. When all of the chloride has been consumed, the silver appears in excess, causing an increase in current. This signals the endpoint of the reaction.

pO₂ Gas-Sensing Electrode

A widely used oxygen-sensing electrode (to determine partial pressure of oxygen in blood) incorporated in blood gas analyzers uses an amperometric or current-sensing electrolytic cell as the indicator electrode.

The pO₂ electrode uses a gas-permeable membrane, usually polypropylene, which allows dissolved oxygen to pass through. This membrane also prevents other blood constituents (that may interfere with the electrode) from passing through. Once the oxygen permeates the membrane, it reacts with a polarized platinum cathode according to the following reaction:

This, in turn, produces a change in the current through the cell, and the change is directly proportional to the partial pressure of oxygen present in the specimen.

Voltammetry

Voltammetry is a method in which a potential is applied to an electrochemical cell and the resulting current is measured. The most important advantages of voltammetry are sensitivity and the capability for multielement measurements. Analytes can be detected in the parts-per-billion range. With careful selection of testing conditions and methods, several analytes can be measured simultaneously in a single voltammetric study. Voltammetry consumes minimal analyte, unlike coulometry, which converts all of the analyte to another state. *Anodic stripping voltammetry* is an electrochemical technique used to measure heavy metals such as lead. The measurement of lead in blood occurs in basically two steps. First, free lead is electroplated (deposited) onto the platinum cathodes at a characteristic voltage. Second, the lead is stripped off of the platinum cathode, and the current is monitored over time. The current value is proportional to the amount of lead in the blood sample. This technique allows the sample to

be preconcentrated at the electrode, which enables the method to detect very low analyte levels.

CONDUCTANCE

The principles of conductance have several applications associated with clinical laboratory procedures. Examples include monitoring water purity, measuring analytes in blood such as urea, and serving as components of detectors used in high-performance liquid chromatography (HPLC), gas chromatography (GC), cell counters, and capillary electrophoresis.

Electrolytic conductivity is a measure of the ability of a solution to carry an electrical current. Solutions of electrolytes conduct an electrical current by migration of ions under the influence of a potential gradient. The ions move at a rate dependent on their charge and size, the microscopic viscosity of the medium, and the magnitude of the potential gradient. Thus, for an applied potential, E , maintained constant but at a value that exceeds the deposition potential of the electrolyte, the current, I , that flows between the electrodes immersed in the electrolyte, varies inversely with the resistance of the electrolytic solution, R . The reciprocal of resistance, $1/R$, is called the conductance, G , and is expressed in reciprocal ohms, or mhos.

IMPEDANCE

Electrical impedance measurement is based on the change in electrical resistance across an aperture when a particle in conductive liquid passes through this aperture. Electrical impedance is used primarily in the hematology laboratory to enumerate leukocytes, erythrocytes, and platelets. In a typical electrical impedance instrument by Coulter, aspirated blood is divided into two separate volumes for measurements. One volume is mixed with diluent and is delivered to the cell bath, where erythrocyte and platelet counts are performed. As a cell passes through the aperture, partially occluding it, the electrical impedance increases, producing a voltage pulse, the size of which is proportional to the cell size. The number of pulses is directly related to the cell count. Particles measuring between 2 and 20 fL are counted as platelets, whereas those measuring greater than 36 fL are counted as erythrocytes. The other blood volume is mixed with diluent and a cytochemical-lytic reagent that lyses only the red blood cells. A leukocyte count is performed as the remaining cells pass through an aperture. Particles greater than 35 fL are recorded as leukocytes.

ELECTROPHORESIS AND DENSITOMETRY

Electrophoresis is the separation of charged compounds based on their electrical charge. When a voltage is applied to a salt solution (usually sodium chloride), an electrical current is produced by the flow of ions: cations toward the cathode, and anions toward the anode. Conductivity of a solution increases with its total ionic concentration. The greater the net charges of a dissolved compound, the faster it moves through the solution toward the oppositely charged electrode. The net charge of a compound, in turn, depends on the solution pH. Electrophoresis separations often require high voltages (50–200 V DC); therefore, the power supply should supply a constant DC voltage at these levels. The buffer solution must have a carefully controlled ionic strength. A dilute buffer causes heat to be generated in the cell, and a high ionic strength does not allow good separation of the fractions. Common support media for electrophoresis in clinical work include cellulose acetate, agarose, and polyacrylamide gels. Total volume of specimen applied depends on the sensitivity of the detection method. For clinical work, 1 μ L of serum may be applied. Once the electrophoresis is completed, the support medium is treated with a dye to identify the separated fractions. The most common dyes used for the visualization step include Amido Black, Ponceau S, Fat Red 7B, and Sudan Black B. To obtain a quantitative profile of the separated fractions, densitometry is performed on the stained support medium.

A densitometer measures the absorbance of the stain on a support medium. The basic components of a densitometer include a light source, a monochromator and a movable carriage to scan the medium over the entire area, an optical system, and a photodetector. Signals detected by the photodetector are related to the absorbance of the sample stain on the support, which is proportional to the specimen concentration. The support medium is moved through the light beam at a fixed rate, so that a graph may be constructed that represents multiple density readings taken at different points. Most densitometers have a built-in integrator to find the area under the curve, so that all sample fractions can be quantified.

ISOELECTRIC FOCUSING

Proteins are polymers of amino acids that can be anions or cations depending on the pH environment. At a specific pH, a protein will have a net charge of zero when the positive charge and the negative charge of its amino acids cancel each other out. At this pH value, known as the protein's isoelectric point (pI), the protein is isoelectric. Isoelectric focusing (IEF) techniques are performed similarly to other electrophoresis methods, except that the separating molecules migrate through a pH gradient. This pH gradient is created by adding acid to the anodic area of the electrolyte cell and adding base to the cathode area (Fig. 4-17). A solution of ampholytes (mixtures of small amphoteric ions with different pIs) is placed between the two electrodes. These ampholytes have high buffering capacity at their respective isoelectric points. The ampholytes close to the anode carry a net positive charge, and those close to the cathode carry a net negative charge. When an electrical voltage is applied, each ampholyte will rapidly migrate to the area where the pH is equal to its isoelectric point. With their high buffering capacity, the ampholytes create stable pH zones for the more slowly migrating proteins. The advantage of isoelectric focusing techniques lies in their ability to resolve mixtures of proteins. Using narrow-range ampholytes, macromolecules differing in isoelectric point by only 0.02 pH units can be identified. Isoelectric focusing has been useful in measuring serum acid phosphatase isoenzymes. Its application has also been extended to detect oligoclonal immunoglobulin bands in CSF and isoenzymes of creatine kinase and alkaline phosphatase in serum.

CHROMATOGRAPHY

Chromatography is a separation method based on different interactions of the specimen compounds with the mobile phase and with the stationary phase as the compounds travel through a support medium. Compounds interacting more strongly with the stationary phase are retained longer in the medium than those that favor the mobile phase. Chromatographic techniques may be classified according to their mobile phase: gas chromatography and liquid chromatography. Figure 4-18 shows a typical chromatogram representing the concentration of each detectable compound eluting from the column as a function of time. Retention time (t_R) is the time it takes a compound to elute. This value is characteristic of a compound and is related to the strength of its interaction with the stationary phase and the mobile phase. The retention time therefore can be used to determine a compound's identity. In this example, two compounds are separated, and their retention times are represented by (t_{R1}) and (t_{R2}). These are uncorrected retention times and are measured from the injection time, $t = 0$. A column's ability to separate two compounds depends on several factors, which include (1) the difference in retention of the compounds or capacity factor, k' , (2) the selectivity factor, α , and (3) the number of theoretical plates.

The value of k' can be calculated by the following equation:

$$k' = (t_{R1} - t_m)/t_m \text{ or } t_{R1'}/t_m \quad (4-18)$$

where:

t_m is the retention time of a unretained compound

$t_{R1'}$ is the corrected retention time.

Another measurement derived from the calculated capacity factor is the selectivity factor (α) or relative retention of two solutes. A ratio of both capacity factors is used to calculate the selectivity factor. To measure the width of each peak, draw tangents along the sides of the peak to the baseline. W_b represents the distance between the two intersected lines. Another useful concept is theoretical plates. This describes the process by which the sample is transported down the column. In each "plate," the sample equilibrates between stationary and mobile phases. The analyte moves down the column as the equilibrated mobile phase transfers sample from one plate to another. To calculate the number of theoretical plates (N), use the following equation:

$$N = 16(t_R/W_b)^2 \quad (4-19)$$

A plate number has no units, and the larger the value of N for a column, the greater is its separation efficiency. The combined effects of solvent efficiency and column efficiency are expressed in the resolution (R_s) of the column:

$$R_s = (t_{R2} - t_{R1})/0.5(W_{b1} + W_{b2}) \quad (4-20)$$

The concentration of unknown compound can be derived by integration of peak areas or by using the method of internal standardization.

Figure 4-17 Isoelectric focusing (see text). (Redrawn from Schoeff LE, Williams RH. *Principles of laboratory instruments*. St Louis: Mosby; 1993, with permission.)

Figure 4-18 Chromatogram for the separation of two compounds. Note that the uncorrected retention time (t_{R1} and t_{R2}) is from injection (Inj) to peak; the corrected time (t_{R1}' and t_{R2}') takes into account the retention time of a nonretained compound (t_M). (Redrawn from Ravindranath B. *Principles and practice of chromatography*. New York: John Wiley & Sons; 1989, with permission.)

Gas Chromatography

Gas chromatography (GC) is useful for compounds that are naturally volatile or can be easily converted into a volatile form. GC has been a widely used method for decades owing to its high resolution, low detection limits, accuracy, and short analytic time. Applications involve various organic molecules, including many drugs (see Chapter 23). Retention of a compound in GC is determined by its vapor pressure and volatility, which, in turn, depends on its interaction with the stationary phase. Two types of stationary phases commonly used in GC are solid absorbent (gas-solid chromatography [GSC]) and liquids coated on solid supports (gas-liquid chromatography [GLC]). In GSC, the same material (usually alumina, silica, or activated carbon) acts as both the stationary phase and the support phase. Although this was the first type of stationary phase developed, it is

not as widely used as other types, primarily because of the strong retention of polar and low volatile solutes by the column (Ravindranath, 1989). GLC uses liquid phases such as polymers, hydrocarbons, fluorocarbons, liquid crystals, and molten organic salts to coat the solid support material. Calcine diatomaceous earth graded into appropriate size ranges is often used as a stationary phase because it is a stable inorganic substance. The use of fused silica capillary columns in which the stationary phase is chemically bonded onto the inner surface of the column has become very popular with chromatographers. The advantage of this type of column is that the stationary phase does not leave the solid support and bleed into the detector, and a uniform monomolecular layer of the stationary phase is obtained through the bonding procedure.

Components of a typical GC system are illustrated in Figure 4-19. Its basic design consists of five components: a gas cylinder as a mobile phase source, a sample injector, a column, a detector, and a computer for data acquisition. These systems may be automated to provide the user with a more precise and efficient separation. Carrier gases (mobile phase), which must be chemically inert, include helium, hydrogen, and nitrogen. Other substances used as mobile phases include steam and supercritical fluids. Examples of these are carbon dioxide, nitrous oxide, and ammonia. The carrier gas should be of high purity, and the flow must be tightly controlled to ensure optimum column efficiency and reproducibility of test results. Samples are manually introduced into the GC using a syringe pipet or an automated syringe pipet system. A pipet tip pierces a plastic septum located in the injector port. Each injection port is heated to very high temperatures. Samples are vaporized and swept onto the column. If the molecule of interest is not volatile enough for direct injection, it is necessary to derivatize it into a more volatile form. Most derivatization reactions belong to one of three groups: silylation, alkylation, and acylation. Silylation is the most common technique that replaces active hydrogens on the compounds with alkylsilyl groups. This substitution results in a more volatile form that is also less polar and more thermally stable.

Retention of compounds in a GC column can also be adjusted by changing the column temperature. The column temperature affects the

Figure 4-19 Components of a gas chromatographic system. (Redrawn from Ravindranath B. *Principles and practice of chromatography*. New York: John Wiley & Sons; 1989, with permission.) G, Gas cylinder; NV, valve for adjusting the gas flow rate; PG, pressure gauge; PR1 and PR2, regulators.

volatility of the compounds and thus the degree of their interaction with the stationary phase. By proper selection of the starting temperature and temperature gradient during the procedure, good resolution of both weakly and strongly retained compounds may be achieved. The GC column, enclosed in a temperature-controlled oven, can be a packed column or a capillary column. Packed columns are usually 1–5 m long and 2–4 mm in diameter, and are filled with a stationary phase. Capillary columns range from 5–100 m in length and from 0.1–0.8 mm in diameter, and have a stationary phase located on their interior surface (Bartle, 1993). Capillary columns generally have higher efficiency and better detection limits. However, packed columns have a larger specimen or sample capacity, making them more useful in purification work. Examples of detectors used in GC include a flame ionization detector, a thermal conductivity detector, a nitrogen–phosphorus detector, an electron capture detector, a flame photometric detector, and a mass spectrometric detector. Flame ionization detectors (FIDs) are commonly used and are capable of detecting a wide variety of organic compounds and many inorganic compounds. This type of detector measures the ions produced by the compounds when burned in a hydrogen–air flame. An electrode collects the ions, and the magnitude of the resulting electrical current is proportional to the amount of substance (Tipler, 1993). FIDs can be modified to make them especially sensitive to molecules, including many drugs that contain either nitrogen or phosphorus (the so-called nitrogen–phosphorus detector, or NPD).

Liquid Chromatography

GC as a separation technique has some restrictions that make liquid chromatography a suitable alternative. Many organic compounds are too unstable or are insufficiently volatile to be assayed by GC without prior chemical derivatization. Liquid chromatography techniques use lower temperatures for separation, thereby achieving better separation of thermolabile compounds. These two factors allow liquid chromatography to separate compounds that cannot be separated by GC. Finally, it is easier to recover a sample in liquid chromatography than in gas chromatography. The mobile phase can be removed, and the sample can be processed further or reanalyzed under different conditions.

Many forms of liquid chromatography are available, and the selection of an appropriate form depends on a variety of factors. These factors include analysis time, type of compound, and detection limits. Paper, thin-layer, ion-exchange, and exclusion liquid chromatography often result in poor efficiency and a very long analysis time owing to low mobile phase flow rates. High-performance liquid chromatography (HPLC) emerged in the late 1960s as a viable form of liquid chromatography that provided advantages over other forms of liquid chromatography and gas chromatography. HPLC uses small, rigid supports and special mechanical pumps, producing high pressure to pass the mobile phase through the column. HPLC columns can be used many times without regeneration. The resolution achieved with HPLC columns is superior to that of other forms of liquid chromatography, analysis times are usually much shorter, and reproducibility is greatly improved. All of these attributes of HPLC render it a better method of separation over other forms of liquid chromatography.

Five separation techniques are commonly used in liquid chromatography. They include adsorption, partition, ion-exchange, affinity, and size exclusion. Each is characterized by a unique combination of stationary phase and mobile phase. In *adsorption (liquid–solid) chromatography*, the compounds are adsorbed to a solid support such as silica or alumina. Although this was the first type of column liquid chromatography developed, it is not widely used owing to the strong retention of many compounds by the supports, making them difficult to elute from the column. *Partition (liquid–liquid) chromatography* separates compounds based on their partition between a liquid mobile phase and a liquid stationary phase coated on a solid support. Partition chromatography includes normal-phase liquid chromatography, which uses a polar liquid stationary phase, and reverse-phase liquid chromatography, which uses a nonpolar stationary phase. *Ion-exchange chromatography* uses column packing material that has charge-bearing functional groups attached to a polymer matrix. The mechanism in this type of chromatography is the exchange of sample ions and mobile-phase ions with the charged group of the stationary phase. *Affinity chromatography* uses immobilized biochemical ligands as the stationary phase to separate a few solutes from other unretained solutes. This type of separation uses the so-called lock-and-key binding that is widely present in biologic systems. *Size-exclusion chromatography* separates molecules according to differences in their size. The support material has a certain range of pore sizes. As solutes travel through, the small molecules can enter the pores, whereas the larger ones cannot and will elute first from the column.

Liquid chromatography is similar in many aspects to GC, and therefore, the instrumentation is similar. A typical liquid chromatography system consists of a liquid mobile phase, a sample injector (manual or automatic), a mechanical pump, a column, a detector, and a data recorder (Fig. 4-20). The liquid mobile phase is pumped from a solvent reservoir through the column. A mechanical pump must provide precise and accurate flow, often working at high pressures (typically up to 6000 PSI). The pump must have low internal volume and be constructed of material that does not react with the solvent. Sample injection is achieved using a syringe and depositing the sample into a loop. The injection may be performed manually or automatically using a microprocessor control autosampler. Most analytic separations are performed using packed columns. Many types of packing material are available. Selection of the appropriate packing material is largely dependent on the type of compound(s) to be separated. In liquid chromatography, the physical properties of the sample and the mobile phase are often very similar. Two basic types of detectors have been developed. One is based on the differential measurement of a physical property common to both the sample and the mobile phase; examples include refractive index, conductivity, and electrochemical detectors. The other is based on the measurement of a physical property that is specific to the sample, either with or without the mobile phase; examples include absorbance and fluorescent detectors.

A widely used clinical application of HPLC is the separation and quantitation of various hemoglobins associated with specific diseases (e.g., thalassemia). Whole blood measurement of glycosylated hemoglobin (HbA_{1c}) can be accomplished using HPLC with complete analysis within 5 minutes.

Figure 4-20 Components of a high-performance liquid chromatograph.

MASS SPECTROMETRY

Mass spectrometry (MS) is based on fragmentation and ionization of molecules using a suitable source of energy. The resulting fragment masses and their relative abundance yield a characteristic mass spectrum of the parent molecule. Before a compound can be detected and quantified by mass spectrometry, it must be isolated by another method: GC or HPLC. Mass spectrometry typically involves the following major steps: (1) conversion of the parent molecule into a stream of ions (usually singly charged positive ions); (2) separation of the ions by mass/charge ratio (m/z), where m is the mass of the ion in atomic mass units and z is its charge; and (3) counting of the number of ions of each type or measurement of current produced when the ions strike a transducer. Because most of the ions formed are singly charged, the m/z is usually simply the mass of the ion. MS is also described in Chapter 23 (see especially Figs. 23-5 and 23-6) as a technique for drugs of abuse testing. MS techniques are available for proteomics, which is discussed in Chapter 77.

Atomic Weights (amu and Da)

Atomic and molecular weight are generally expressed in terms of atomic mass units (amu) or daltons (Da). The amu or Da is based upon a relative scale in which the reference is the carbon isotope ^{12}C , which is assigned a mass of exactly 12 amu. Therefore the amu or Da is defined as $1/12$ of the mass of one neutral ^{12}C atom. From this definition, we derive the following equality:

$$1 \text{ amu} = 1 \text{ Da} = 1.66054 \times 10^{-27} \text{ kg/atom } ^{12}\text{C}$$

$$\text{Also, 1 mole of } ^{12}\text{C} \text{ weight } 12.0000 \text{ g}$$

Example 4-5. What are the masses in Da for $^{12}\text{C}^1\text{H}_4$ and $^{13}\text{C}^1\text{H}_4$?

SOLUTION

$$m = 12.000 \times 1 + 1.007825 \times 4 = 16.031 \text{ Da}$$

$$m = 13.00335 \times 1 + 1.007825 \times 4 = 17.035 \text{ Da}$$

Mass/Charge Ratio

Mass/charge ratio (m/z) is obtained by dividing the atomic or molecular mass of anion m by the number of charges z that the ion bears.

Example 4-6.

$$m/z = 16.035/1 = 16.035$$

$$m/z = 17.035/2 = 8.518$$

Many ions produced in mass spectrometers are singly charged; thus the term mass/charge ratio is often shortened to the more convenient term

mass. Strictly speaking, this abbreviation is incorrect, but it is widely used in mass spectrometry literature. This term also represents the x-axis for MS spectra of molecules plotted against their relative abundance (y-axis).

Basic Components

All mass spectrometers have three basic components: an ion source, a mass analyzer, and an ion detector. The inlet unit admits samples to the mass spectrometer. When the instrument is part of a GC/MS arrangement, the inlet unit must be heated to maintain the volatile compounds in the vapor state upon coming into the ion source unit. It must also strip away most of the carrier gas to adapt to the high-vacuum condition required for mass spectrometry operation.

Ion Source Unit

The ion source unit is maintained at high temperature and vacuum to provide adequate conditions for ionizing the vaporized sample molecules. Several types of energy sources are available to ionize the sample molecules in mass spectrometry. One commonly used source is a beam of electrons produced by a heated filament. The process of bombarding the sample with electrons is called *electron-impact ionization*. Other processes of ionization include *chemical ionization*, in which the sample molecules are ionized by a reagent gas that has been ionized by an electron beam, and *fast atom bombardment*, in which a solid sample is ionized by a beam of atoms such as argon.

Most laboratorians are familiar with the use of mass spectrometers for drug and other low molecular weight compound analysis. Two examples are confirmation of positive drug screens (see Chapter 23) and amino acid analysis. These techniques conventionally couple a gas chromatograph and a mass spectrometer (GC/MS). This conventional approach had several limiting factors, including the need to separate analyte from specimen matrix and the need to make stable volatile derivatives, amenable to ionization by electron impact (EI) or chemical ionization (CI). Although these conventional techniques produced highly specific and sensitive analyses, they were also technically demanding and lacked the ruggedness required for the clinical laboratory. However, the increased focus on protein analysis, molecular diagnostics, and genetic-related testing has ushered in a new wave of mass spectrometers possessing the capabilities of evaluating complex compounds such as proteins.

The *matrix-assisted laser desorption/ionization* (MALDI) source consists of a solid mixture of analyte and matrix (including organic chromophore) on a sample plate, along with a laser light and ion optics (Fig. 4-21, A). (This technique is further described in Chapter 76.) When the chromophore absorbs the laser light, it vaporizes and lifts the analyte ions from the surface into a gas phase directly above the target plate and into the analyzer. The MALDI technique is considered an offline ionization technique because the sample is purified, deposited, and dried on the sample plate before analysis (Skoog, 1998). *Surface-enhanced laser desorption/ionization* (SELDI) is a technique that measures proteins from complex biologic

Figure 4-21 Diagrams of two systems widely used for proteomic research. **A**, Matrix-assisted laser desorption/ionization (MALDI) time-of-flight mass spectrometer. **B**, Surface-enhanced laser desorption/ionization (SELDI) time-of-flight mass spectrometer.

specimens such as serum, plasma, intestinal fluids, urine, cell lysates, and cellular secretion products (see also Chapter 76). Proteins are captured by adsorption, partition, electrostatic interaction, or affinity chromatography on a solid-phase protein chip surface. A laser ionizes samples that have been co-crystallized with a matrix on a target surface. The protein chip chromatographic surfaces in SELDI are uniquely designed to retain proteins from complex mixtures according to their specific properties. After the addition of a matrix solution, proteins can be ionized with a nitrogen laser and their molecular masses measured by time-of-flight (TOF) MS (Fig. 4-21, B) (see also Fig. 23-5). The protein chip arrays are the heart of the SELDI-TOF MS technology and distinguish it from other MS-based systems. Each array is composed of different chromatographic surfaces that, unlike HPLC or GC, are designed to retain, not elute, proteins of interest. The protein chip arrays have an aluminum base with several spots composed of a chemical (anionic, cationic, hydrophobic, hydrophilic, or metal ion) or biochemical (immobilized antibody, receptor, DNA, enzymes, etc.) active surface. Each surface is designed to retain proteins according to a general or specific physicochemical property of the proteins. Chemically active surfaces retain whole classes of proteins, and surfaces to which a biochemical agent, such as an antibody or other type of affinity reagent,

is coupled are designed to interact specifically with a single target protein (Skoog, 1998).

Mass Spectrometer Analyzer Unit

The output of the ion source is a stream of positive or negative gaseous ions that are then accelerated into the mass analyzer, which sorts the parent molecular ions and their fragment ions according to their mass/charge ratio. This is accomplished in several different ways. *Time-of-flight (TOF)* analyzer consists of a metal flight tube, and the m/z ratios of the ions are determined by accurately and precisely measuring the time it takes the ions to travel from the MALDI or SELDI sources to the detector. Given that all ions of different m/z receive the same kinetic energy, low m/z ions will reach the detector sooner than high m/z ions. In the *quadrupole mass spectrometer* (Fig. 4-22, A, and Fig. 23-5), direct electrical current and radio-frequency voltages of selected magnitudes are applied to two pairs of metallic rods. Only ions of specific mass/charge ratio can pass undeflected to the end of the rods, where they are detected. All other ions have unstable trajectories along the path and are deflected toward the rods, never reaching the detector. An advantage of this design is that this system can perform tandem mass spectrometry scan modes in the same analyzer. The *ion-trap*

Figure 4-22 Mass spectrometer: **A**, Quadrupole type; **B**, ion-trap type. (Redrawn from Schoeff LE, Williams RH. *Principles of laboratory instruments*. St Louis: Mosby; 1993, with permission.)

mass spectrometer (Fig. 4-22, B) functions as a mass analyzer and as an ion source unit. Three electrodes, in a ring shape and two end caps, produce ions in the cavity until selectively ejected to the ion detector as the scanning radiofrequency voltage on the ring electrode varies. A major advantage of the ion-trap analyzer is its ability to get full mass spectra at very low sample concentrations (Karasek, 1988). In the *magnetic sector mass spectrometer*, a very high voltage accelerates the ions out of the ion source unit onto a magnetic field. The exiting path curvature of an ion depends on its mass/charge ratio, magnetic field strength, and applied voltage. The magnetic field or the voltage can be varied to allow selective ions to exit the magnetic field.

Ion Detector

The ion detector in a mass spectrometer is usually an electron multiplier or an ion-photon conversion detector. In an *electron multiplier*, the ions strike the detector's first dynode, which triggers the release of secondary electrons. A cascade of electrons occurs similarly to that in a photomultiplier tube, resulting in amplification of about a millionfold. In an *ion-photon conversion detector*, the ions strike a phosphor that emits a photon for each corresponding ion. A conventional photomultiplier tube then amplifies the signal in the usual fashion. The computerized data unit controls the multiple operating parameters of the instrument components and stores and analyzes a vast quantity of acquired data. The built-in libraries of reference mass spectra for known compounds can be searched by computer and compared with the sample spectrum for identification. As emphasized in Chapter 23, each compound or macromolecule has a unique mass spectrum—a “fingerprint” of the molecule. A typical mass spectrum is shown in Figure 23-6.

Modern mass spectrometers are extremely powerful and versatile instruments that can be interfaced to liquid chromatographs (LC) (eliminating the need to make volatile derivatives) and can perform separations in tandem (i.e., a gentle ionization step allows separation of parent ions, which can then be identified by their individual fragmentation patterns). Such LC/MS/MS techniques are finding increased application in the clinical laboratory, although mainly in reference laboratories.

SCINTILLATION COUNTER

Scintillations are flashes of light that occur when gamma rays or charged particles interact with matter. Chemicals used to convert their energy into light energy are called scintillators. If gamma rays or ionizing particles are absorbed in a scintillator, some energy absorbed by the scintillator is emitted as a pulse of visible light or near-UV radiation. A photomultiplier tube detects light directly or through an internally reflecting optic fiber. A scintillation counter is an instrument that detects scintillations using a photomultiplier tube and counts the electrical impulses produced by the scintillations. An application for scintillation counting is radioimmunoassay (RIA). Two types of scintillation methods exist: crystal scintillation and liquid scintillation.

Crystal scintillation generally is used to detect gamma radiation. When a gamma ray penetrates the sodium iodide (NaI) crystal, which contains 1% thallium, it excites the electrons of iodide atoms and raises them to higher energy states. When the electrons return to ground state, energy is emitted as UV radiation. The UV radiation is promptly absorbed by the thallium atoms and emitted as photons in the visible or near-UV range.

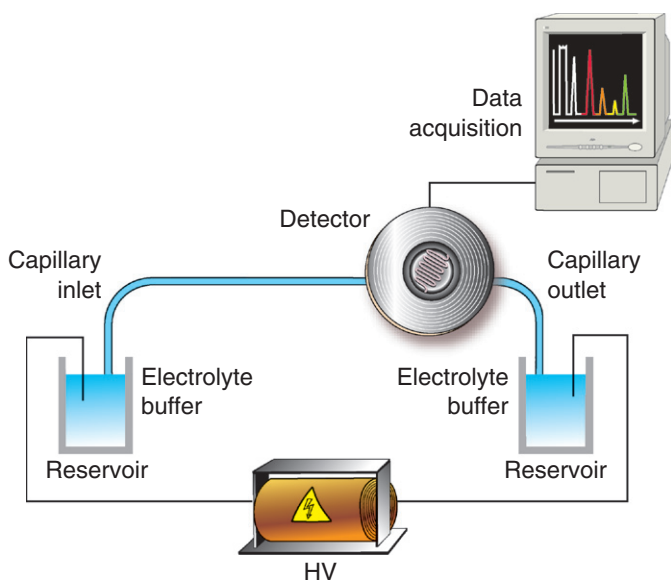

Figure 4-23 Capillary electrophoresis system. (Redrawn from Ward KM, Lehmann CA, Leiken AM. *Clinical laboratory instrumentation and automation; principles, applications, and selection*. Philadelphia: WB Saunders; 1994, with permission.) HV, High-voltage source.

The photons pass through the crystal and are detected by a photomultiplier tube. A pulse-height analyzer sorts out the pulse signals from the photomultiplier tube according to their pulse height and allows only those within a restricted range to reach the rate meter for counting.

Liquid scintillation is primarily used to count radionuclides that emit beta particles. A sample is suspended in a solution or “cocktail” consisting of a solvent such as toluene, a primary scintillator such as 2,5-diphenyloxazole (PPO), and a secondary scintillator such as 2,2′-p-phenylenebis (5-phenyloxazole) (POPOP). Beta particles from the radioactive sample ionize the primary scintillator of the solvent. A secondary scintillator absorbs the photons emitted by the primary scintillator and re-emits them at a longer wavelength. The secondary scintillator facilitates more effective energy transmission from the beta particles, especially when a large amount of quenching is present. Quenching is a process that results in a reduction of the photon output from the sample. This phenomenon may be due to chemical quenching, in which impurities in the sample compete with the scintillators for energy transfer, or color quenching, in which colored substances such as hemoglobin absorb the light photons produced by scintillation. The light photons produced in the sample are detected and amplified by the photomultiplier tubes in the same manner as for the crystal scintillation counter.

CAPILLARY ELECTROPHORESIS

Capillary electrophoresis (CE) represents another alternative in separation techniques. A typical capillary electrophoresis system, as shown in Figure 4-23, consists of a fused silica capillary, two electrolyte buffer reservoirs, a high-voltage power supply, and a detector linked to a data acquisition unit. The sample is introduced into the capillary inlet. When a high voltage is applied across the capillary ends, the sample molecules are separated by electro-osmotic flow, a bulk flow resulting from excess positive ions at the inner capillary surface moving toward the cathode. The positive ions in the specimen emerge early at the capillary outlet because the electro-osmotic flow and the ion movement are in the same direction. Negative ions in the specimen also move toward the capillary outlet but at a slower rate. As the sample ions migrate toward the capillary outlet, different types of detectors, including optical, conductivity, electrochemical, mass spectroscopy, or radioactivity detectors, are used to detect and measure them. Advantages of CE over conventional electrophoresis and HPLC are its short analytic time, improved resolving power, and microsample volumes (Love, 1994). Using nanoliter quantities of specimen, complex mixtures of molecules can be separated with a theoretical plate number approaching one million. Separations may be completed in less than 10 minutes by applying very high voltage. The application of high voltage is made possible by the capillary’s high surface/volume ratio, which allows for efficient heat transfer through the capillary wall. Applications of

capillary electrophoresis include separation of serum proteins and hemoglobin variants.

NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY

Nuclear magnetic resonance spectroscopy (NMR) is a technique for determining the structure of organic compounds. Unlike mass spectroscopy (MS), NMR is nondestructive, although it does require a larger sample volume than MS. Although NMR is widely used as a diagnostic imaging technique, it has been adapted for only a limited number of clinical laboratory analyses, the most popular being lipoprotein particle measurements (see Chapter 17). It also has the unique capability of performing chemical analysis *in vivo*.

Nuclear magnetic resonance is a phenomenon that occurs when the nuclei of certain atoms are immersed in a static magnetic field and are exposed to a second oscillating magnetic field (i.e., the magnetic component of electromagnetic radiation [EMR]). Some nuclei experience this phenomenon and others do not, depending upon whether they possess a property called spin. A single proton, or hydrogen nucleus, possesses spin, and because hydrogen atoms occur very frequently, they are useful in determining structure.

When EMR is used to bombard molecules, the hydrogen atoms present will absorb photons of different energies depending upon the location of the hydrogen atom. For example, in compounds containing hydrogen and chloride, the proton near two chloride atoms produces a different NMR than the proton located near a single chloride and a single hydrogen. The energy absorbed by the spinning nuclei can be plotted versus the frequency of the applied EMR to obtain an NMR spectrum of the molecule.

In lipoprotein subclass measurements, the NMR signal originates in the protons of the terminal methyl groups of the lipid carried in the particles (primarily the cholesterol ester and triglyceride of the particle core, and the phospholipids of the particle shell). Signals from these different lipids combine to produce one signal with a characteristic frequency and shape related to particle size (i.e., the diameter of the phospholipids shell), excluding the influence of the apolipoprotein attached to the particle.

Basic components of an automated NMR spectrometer designed to provide fast, simultaneous subclass quantitative analysis of VLDL, LDL, and HDL are presented in Figure 4-24.

The automated sampler provides a micro sample probe that aspirates an aliquot of serum or plasma from a tray and transfers it to the NMR probe in a flow injection mode. Each sample passes through the 400 MHz magnet. The magnetic property of lipoproteins that gives them a characteristic resonance is a difference in their magnetic behavior induced by the degree of orientation of phospholipids in the shell surrounding the neutral lipid core. The equation describing this effect reveals that all lipoprotein particles of different diameters should have a different lipid NMR signature. This is displayed on the NMR processor.

The signature patterns are relayed to a networked PC, which provides access to high quality spectral data from isolated subclasses of lipoproteins incorporated into proprietary analysis software. The information is contained in a reference library that is accessible with permission from the vendor.

GENERAL ANALYTIC METHODS AND ISSUES

Perhaps the most fundamental aspect of the analytic process is the preparation of high quality reagents that will be used in the analytic procedure. In this process, the quality of water, the purity of the chemical, the selection of correct glassware or plasticware, and the correct preparations of reagents are all important for the proper operation of laboratory equipment and the performance of testing procedures. In this section, several topics will be presented that relate to analytic process and will ultimately have an impact on the results of a test performed on a patient’s specimen.

CHEMICALS

The chemicals used to prepare reagents for chemical testing exist in varying degrees of purity. Proper selection of chemicals is important, so that the desired results may be attained. Chemicals acquired for reagent preparation are characterized by a grading system. The grading of any chemical is greatly influenced by its purity. The type and quantity of

Figure 4-24 Schematic of an automated nuclear magnetic resonance (NMR) system using an automated flow-injector sampler.

impurities are usually stated on the label affixed to the chemical container. Less pure grades of chemicals include practical grade, technical grade, and commercial grade. These grades of chemicals are unsuitable for use in most quantitative assays performed in a clinical laboratory.

Most qualitative and quantitative procedures performed in the clinical laboratory require the use of chemicals that meet the specifications of the American Chemical Society (ACS). These chemicals are classified as analytic grade or reagent grade. Examples of other designations of chemicals that meet high standards of purity include spectrograde, nanograde, and HPLC grade. These are often referred to as ultrapure chemicals.

Pharmaceutical chemicals are produced to meet the specifications defined in *The United States Pharmacopoeia* (USP), *The National Formulary*, and *The Food Chemical Index*. These specifications define impurity tolerances that are not injurious to health.

The International Union for Pure and Applied Chemistry (IUPAC) has developed standards and purity levels for certain chemicals. These include atomic weight standard (grade A), ultimate standard (grade B), primary standard (grade C), working standard (grade D), and secondary substances (grade E).

A very good source of highly purified chemicals, especially reference materials, is the National Institute of Standards and Testing (NIST) (Gaithersburg, Md.). NIST defines its chemical and physical properties for each compound and provides a certificate documenting their measurements. NIST also provides Standard Reference Materials (SRMs) in solid, liquid, or gaseous form. The solids may be crystalline, powder, or lyophilized.

Two professional organizations can provide laboratory staff with guidelines for proper chemical selection and reagent preparation. They are the College of American Pathologists (CAP; Northfield, Ill.) and the Clinical and Laboratory Standards Institute (CLSI), formerly the National Committee for Clinical Laboratory Standards (NCCLS) (Wayne, Pa.).

WATER

Water has numerous uses in the clinical laboratory. Water is used to prepare reagents, as diluent for controls and calibrators, to flush and clean internal components of analyzers, to serve as a heating bath for cuvettes, and to wash and rinse laboratory glassware. For most of these uses, the water must be of the highest purity, whereas the water required for rinsing glassware may be of a lesser purity.

Types of Water Purity

CLSI and CAP have defined three grades of water purity. They are types I, II, and III. The criteria for each type are outlined in the CLSI guidelines (NCCLS, 1997). When selecting a water purification system, the

purchaser must pay strict attention to these criteria, so that all of the appropriate filters and components necessary to produce type I water are included. Also, special attention must be given to the “feed-water,” which is usually the laboratory tap water. The feed-water may contain unique contaminants or may have a high mineral content (hardness), which will often require the inclusion of additional components in the water processing system.

Purification

Many laboratories produce or purify their own water. Several means are available by which to produce reagent-grade water. Most water filtration systems use a prefilter to begin the process. This prefilter has feed-water running through it to trap any particulates before sending it on to the next component. At this point in the water filtration process, water may be distilled or passed through a reverse osmosis filter. Distillation is the process by which a liquid is vaporized and condensed and is used to purify or concentrate a substance or separate a volatile substance from a less volatile substance. Water that has been distilled does not meet the specific resistivity requirements of CAP type I water. Reverse osmosis (RO) is a process by which water is forced through a semipermeable membrane that acts as a molecular filter. The RO filter removes 95%–99% of organic compounds, bacteria, and other particulate matter, and about 95% of all ionized and dissolved minerals, but not as many gaseous impurities. Reverse osmosis alone does not produce type I water, but like distillation, if additional filters such as ion-exchange and carbon particulate filters are added to the system, type I water may be produced.

Ion-exchange filters remove ions to produce mineral-free deionized water. Deionization is accomplished by passing water through insoluble resin polymers that contain anion- or cation-exchange resins. These exchange resins replace H^+ and OH^- ions for impurities present in ionized form in the water. Another type of material used is a mixed bed resin that contains both anion and cation-exchange materials. Deionizers are capable of producing water that has specific resistance exceeding 1–10 Mohm-cm ($M\Omega\cdot cm$).

Carbon filters containing activated charcoal may be added to the water purification system to help remove several types of organic compounds that may still be in the water. When these filters are used, CLSI/CAP considers the end-product to contain minimal organic material.

A particulate filter may be added to the end of the system. This filter with a mean pore size down to about 0.22 μm will serve to trap any remaining particulates as large as or larger than the pore size.

Monitoring Water Purity

Because water is such an integral part of laboratory analysis, its purity must be monitored on a consistent basis. The frequency of water testing is

dependent on many factors, including the composition of the feed-water, the availability of staff to perform water testing, and the amount of water the laboratory uses during a given period of time. At the very least, resistivity and bacterial content of the water should be monitored on a regular basis. In addition, pH, silica content, and organic contaminants may be determined. Depending on the laboratory's resources, some or all of these parameters should be checked on a periodic basis.

Most water filtration systems will have an in-line resistivity meter available. Resistivity measurements are used to assess the ionic content of purified water. The higher the ion concentration in water, the lower the resistivity value will be. CLSI/CAP requires that type I water have a resistivity greater than 10 MΩ-cm.

Bacterial contamination can be monitored easily. The water should be allowed to run for at least 1 minute to flush the system. Next an aliquot of water is taken, depending on the procedure used, and is plated on appropriate media. After an appropriate incubation time, the number of colony-forming units on the agar plate is determined. The most commonly found organisms in water after the purification process is complete are gram-negative rods.

Once Your System Has Been Installed

Most water purification systems are designed for easy access to end-product type I water. Therefore it is advisable to use only type I water for most applications in the laboratory. Type II or III water could be used for rinsing glassware and cleaning exterior surfaces. If a procedure, for example, heavy metal testing or HPLC, requires the use of specially prepared water, then type I water should not be used. Ultra pure water can be purchased from NERL Diagnostics Corporation (East Providence, RI).

MEASUREMENT OF MASS

Mass is the quantity of matter contained within an object. The weight of a body is the gravitational acceleration exerted on it, and unlike mass, it varies with altitude. The weight is equal to mass times gravity. In the laboratory, we are measuring the mass of an object.

Types of Balances

Several different types of balances are available, depending on what needs to be weighed. For example, to weigh a fecal fat specimen, an appropriate balance to use would be a top-loading precision balance capable of accurately weighing kilogram amounts. Preparation of standards for toxicology assays requires microgram quantities, thus a single-pan microbalance would be appropriate.

Unequal-Arm Substitution Balances

Unequal-arm substitution balances are typically single-pan types and are commonly used in laboratories, although almost all of these balances are being replaced by electronic-type balances. The single-pan, mechanical, unequal-arm balance operates on the principle of removing weights rather than adding them. A fixed mass counterweight is used to balance the combined mass of the pan and the removable weights across two arms of unequal weight. When a sample is placed on the weighing pan, internal weights in 1 g or 10 g increments are moved one at a time by the operator turning a set of knobs. This is continued until the system returns to equilibrium, at which time the sum of the weights removed is equal to the weight of the object.

Magnetic Force Restoration Balance

Another widely used balance is the single-pan balance that relies on magnetic force restoration. The restoring force is the force required to put the balance back into equilibrium. The unknown mass is placed on the pan, and this system goes out of equilibrium. The operator who adjusts the internal weights restores partial equilibrium. The null detector optics circuit senses when equilibrium is near and provides a signal to the sensor motor to generate a restoring current until equilibrium is reached. At this time, the unknown mass is equal to the mass of the weights removed plus the value of the restoring current.

Top-Loading Balances

Single-pan top-loading balances operate on the same principle as single-pan analytic balances (i.e., weighing by substitution). Damping is

accomplished by magnetic rather than an air-release mechanism. These balances are especially suitable for rapidly weighing larger masses (up to 10,000 g) that do not require as much analytic precision, such as large-volume reagent preparation.

Electronic Balances

Several electronic balance designs are available. One design uses a strain gauge load cell. This is a small, thin device, which changes electrical resistance when it is stretched or compressed. Typically, several strain gauges are used in a Wheatstone bridge arrangement, and they are glued onto the load cell in a protected location. A load cell is usually in the shape of a beam or plate. When the beam or plate is displaced, it bends a tiny amount, and this tiny bending is detected by the strain gauges. The amount of bending might be only a thousandth of an inch, but that is enough for a strain gauge to measure.

Another electronic balance design operates on the principle of electromagnetic force (EMF) compensation. A coil, placed between the poles of a cylindrical electromagnet, is mechanically connected to a weighing pan. Mass placed on the pan produces a force that displaces the coil within the magnetic field. A regulator generates a compensation current just sufficient to return the coil to its original position. The more mass that is placed on the pan, the larger is the deflecting force, and the stronger is the current required to correct the deflection of the coil. The measuring principle is based on a strict linear relationship between compensation current and force produced by the load placed on the pan.

Several additional features may be available on some models of electronic balances. For example, some electronic balances include an electronic vibration damper. Any excess vibration can be detected when variation of the pointer or oscillation of the number in the last decimal place of the digital display is observed. Another feature available in some models is built-in taring. This allows the weight of the weighing container to be "zeroed." Also electronic balances can be interfaced with computers to provide calculations such as weight averaging and statistical analysis of multiple weighing. The fundamental design of electronic balances allows for faster weighing, which is advantageous when doing multiple readings (e.g., pipet calibrations).

Calibration

Laboratory balances require calibration at regular intervals. The NIST states that there is no fixed calibration interval for scientific applications. Calibration intervals should coincide with the requirements of the laboratory's licensing and accrediting organizations.

The mass standard and test weight accuracy classes for weights used in calibrating balances have been updated and replace the older requirements specified by National Bureau of Standards (NBS) class S and class S1 weights. The new mass standards and test weight accuracy classes appropriate for laboratory balances include the American Society for Testing and Materials (ASTM) classes 1 and 2. Reference should also be made to ASTM E617-97 for specific information regarding range, readability, and best uncertainty applicable to these classes.

NIST class 1 weights (extra-fine accuracy) are available up to 250 mg and may be used for high-precision (e.g., single-pan and electronic) balances that are precise to four decimal places. The range of weight for class 2 balances may be in excess of 1000 g.

Handling Weights Used for Testing Accuracy

Meticulous care must be used when handling class 1 or 2 weights. The operator must avoid direct contact with the weights by using clean gloves or special lifting tools (e.g., forceps). Hand contact with the weights can cause corrosion. The weights should not be dragged across any surface, including the stainless steel weighing pan. Usually the weights are sent in a covered box and should always be stored in that box.

Environmental Concerns for Best Weighing Accuracy

Several aspects of the environment may have an impact on the performance of a laboratory balance. They include temperature, air drafts, floor vibrations, table instability, and static electricity. The effects of the environment on your weighing procedures can often be minimized easily. For example, if air drafts are present in the room, a shroud or enclosure can be placed around the balance. A marble table can be used to reduce table vibrations or instability.

Balance Specifications

An operator should be knowledgeable about several important specifications related to balances. They include the following:

- capacity—which represents the maximum load one can weigh
- accuracy—which is dependent on the smallest mass one will be weighing
- linearity—the ability of a balance to provide accurate output over its full range
- resolution (readability)—the smallest increment of weight that may be discernible

Laboratory accrediting agencies require verification of accuracy of balances at various time intervals. Several sources are available to guide the laboratory through this requirement.

LABORATORY GLASSWARE AND PLASTICWARE

Types of Glassware

The most common type of glassware encountered in volume measurements is borosilicate glass. This glass is characterized by a high degree of thermal resistance, has low alkali content, and is free from the magnesium-lime-zinc group of elements, heavy metals, arsenic, and antimony. Commercial brands are known as Pyrex (Corning, Corning, N.Y.) and Kimax (Kimble, Vineland, N.J.). The caustic conditions involved in storing concentrated alkaline solutions in borosilicate glass will etch or dissolve the glass and destroy the calibration. Borosilicate glassware with heavy walls, such as bottles, jars, and even larger beakers, should not be heated with a direct flame or hotplate. Glass should not be heated above its strain point (for Pyrex, 515° C) because rapid cooling strains and cracks glass easily when heated again. In the case of volumetric glassware, heating can destroy the calibration.

Corex (Corning, N.Y.) brand glassware is a special alumina-silicate glass strengthened chemically rather than thermally. Corex is six times stronger than borosilicate glass (e.g., Corex pipets have a typical strength of 30,000 psi, compared with 2000–5000 psi for borosilicate pipets) and will outlast conventional glassware by tenfold. Corex also resists clouding and scratching better.

Low actinic glassware is a glass of high thermal resistance with an amber or red color added as an integral part of the glass. The density of the red color is adjusted to permit adequate visibility of the contents, yet give maximum protection to light-sensitive materials, such as bilirubin standards. Low actinic glass is commonly used in containers used to store control material and reagents.

Types of Plasticware

Several types of plasticware are used in clinical laboratories, for example, pipet tips, beakers, flasks, cylinders, and cuvettes. Polypropylene, polyethylene, Teflon, polycarbonate, and polystyrene are all examples of types of plastics used for laboratory plasticware.

Plastic pipet tips are made primarily of polypropylene. This type of plastic may be flexible or rigid, is chemically resistant, and can be autoclaved. These pipet tips are translucent and come in a variety of sizes. Polypropylene is also used in several tube designs, including specimen tubes and test tubes. Specially formulated polypropylene is used for cryogenic procedures and can withstand temperatures down to –190° C.

Polyethylene is widely used in plasticware too, including test tubes, bottles, graduated tubes, stoppers, disposable transfer pipets, volumetric pipets, and test tube racks. Polyethylene may bind or absorb proteins, dyes, stains, and picric acid.

Polycarbonate is used in tubes for centrifugation, graduated cylinders, and flasks. The usable temperature range is broad: –100° C to +160° C. It is a very strong plastic but is not suitable for use with strong acids, bases, and oxidizing agents. Polycarbonate may be autoclaved but with limitations (refer to furnished instructions).

Polystyrene is a rigid, clear type of plastic that should not be autoclaved. It is used in an assortment of tubes, including capped graduated tubes and test tubes. Polystyrene tubes will crack and splinter when crushed. This type of plastic is not resistant to most hydrocarbons, ketones, and alcohols.

Teflon is widely used for manufacturing stirring bars, tubing, cryogenic vials, and bottle cap liners. Teflon is almost chemically inert and is suitable for use at temperatures ranging from –270° C to +255° C. This type of

plastic is resistant to a wide range of chemical classes, including acids, bases, alcohol, and hydrocarbons.

VOLUMETRIC LABORATORYWARE

Pipets

Many kinds of pipets are available for use in a clinical laboratory, each intended to serve a specific function. They are used for reconstituting controls and calibrators, preparing serum or plasma dilutions, and aliquoting specimens. Thus, a high degree of accuracy and precision is required. Manual pipets fall into two general categories: transfer (volumetric) and measuring. Three subclassifications include to contain (TC), to deliver (TD), and to deliver/blow-out (TD/blow-out).

Class A Designation

Class A glassware, including pipets, is manufactured and calibrated to deliver the most accurate volume of liquid. Class A specifications are defined by NIST. The College of American Pathologists (CAP) specifies that volumetric pipets must be of certified accuracy (Class A), or the volumes of the pipets must be verified by calibration techniques (e.g., gravimetric, photometric). The letter “A” appears on all pipets that conform to the standards of Class A glassware. Volumetric glassware designated as Class A has been manufactured to Class A tolerances as established by the American Society for Testing and Materials (ASTM) E694 (West Conshohocken, PA) for volumetric apparatus. Other standards include ASTM E 542 for calibration of volumetric apparatus and ASTM E 288 for volumetric flasks.

Types of Pipets

TC pipets are often referred to as rinse-out pipets because they must be refilled or rinsed out with the appropriate solvent after the initial liquid has been drained from the pipet. TC pipets contain an exact amount of liquid that must be completely transferred for accurate measurement. Examples of TC pipets are Sahli hemoglobin and Long-Levy pipets. These pipets do not meet Class A certification criteria.

TD pipets are designed to drain by gravity. They must be held vertically with the tip placed against the side of the container and must not touch the liquid in it. The stated volume is obtained when draining stops. This type of pipet should not be blown out. Examples of TD pipets include Mohr, serologic, and volumetric transfer pipets. These pipets are designed to meet the requirements of Class A type pipets.

Volumetric TD pipets have an open-ended bulb, which holds the bulk of the liquid. On one side of the pipet is a long glass tube with a line indicating the extent to which the pipet is to be filled. The other end is tapered for smooth delivery of liquid. These pipets should be allowed to drain freely and should not be shaken, or hit against the container. Any disruption of the free-flowing liquid may result in inaccurate delivery of the liquid.

Some TD pipets are designed so that most of the contents are allowed to drain freely, after which the remaining fluid in the tip is blown out. These pipets are not rinsed out. Examples of pipets designed to be blow-out-type pipets include Ostwald-Folin and serologic pipets. TD/blow-out pipets are identified by the presence of one or two frosted bands near the mouthpiece of the pipet. It is vital to remember that one should never pipet or blow out solutions by mouth. It is always necessary to use an appropriate pipetting aid (e.g., bulb).

Serologic glass or plastic pipets are long tubes with uniform diameters. They have volume graduations extending to the delivery tip of the pipet. The last volume of liquid blown out is included in the delivery volume. The design of the Mohr TD pipet is different from that of the serologic pipet. Mohr pipets are not graduated to the tip. The accuracy of the Mohr pipets is valid only when the pipet is filled. If smaller volumes are dispensed, accuracy decreases proportionately.

Micropipets

The two most widely used types of micropipets are air displacement and positive displacement. These pipets are capable of delivering liquid volumes from 1–1000 μ L. Some micropipets are designed to deliver a fixed volume, and others can deliver variable amounts of sample.

Air-displacement pipets are piston-operated devices. A disposable, one-time use polypropylene tip is attached to the pipet barrel. The pipet tip is placed into the liquid to be aspirated and is drawn into and dispensed from this tip.

Positive-displacement pipets use a capillary tip that may be siliconized glass, glass, or plastic. This type of pipet is useful if a reagent reacts to plastics. Positive-displacement pipets use a Teflon-tipped plunger that fits tightly inside the capillary. These capillary tips are reusable, and carry-over is negligible if the pipet is properly maintained. Some procedures require a washing or flushing step between samples.

Pipet Calibration

Not only is monitoring the performance of pipetting devices mandatory in most states that issue licenses to laboratories that perform diagnostic testing, it is also very wise. Micropipets should be verified for accuracy and precision before they are put into use and monitored during the course of the year. The frequency of verification depends in part on the amount of use and the requirements put forth by the licensing and/or accrediting agency. Proper maintenance of air-displacement pipets is very important. This type of pipet has a fixed stroke length that must be maintained. It also has seals to prevent air from leaking into the pipet when the piston is moved. These seals require periodic greasing to maintain their integrity.

Positive-displacement micropipets need to have their springs checked and Teflon tips replaced periodically. A slide wire is used to quickly check the plunger setting. This check does not replace scheduled precision and accuracy checks.

Several procedures are used by laboratories to verify the precision and accuracy of micropipets. Most of these procedures are time-consuming, especially those that require the weighing of water. No matter, this verification procedure must be done to ensure proper performance of the laboratory micropipets.

CLSI has provided an acceptable procedure for determining pipet accuracy and precision (I8-P; NCCLS, 1984). This gravimetric procedure is labor intensive but does provide a low-cost means of complying with the regulations set forth by the various accrediting agencies.

More expensive procedures for calibrating micropipets include the following:

- commercial photometric pipet calibration products
- calibration services providers
- Pipet Tracker (Labtronics Inc., Ontario, Canada)

One of the major concerns when considering the costs attributed to pipet calibration procedures is technologist time. The technologist time required for the photometric procedures is often 50%–60% less than for the inexpensive manual weighing techniques.

Volumetric Flasks

Volumetric flasks represent a special type of glassware in the laboratory. These flasks are often used to prepare standards for quantitative procedures. Therefore, their accuracy must be optimal. Volumetric flasks used for the preparation of standards and other solutions requiring optimal accuracy must meet Class A specifications as defined by NIST. These specifications are imprinted on the flasks. Volumetric flasks are used to contain an exact volume when the flask is filled to the *mark*. A Teflon or ground-glass stopper should be used to seal the flask. Volumetric flasks should not be used for reagent storage.

Calibration of Volumetric Glassware

According to the strictest of standards, every piece of volumetric glassware in the clinical laboratory should be coded, and a record kept of its calibration. Any piece of glassware that does not meet Class A tolerance should be rejected. To prepare a piece of glassware for calibration, thoroughly wash and dry it using appropriate cleaning procedures. CLSI can provide the laboratory with an appropriate procedure to calibrate volumetric flasks.

THERMOMETRY

Thermometers and other types of temperature-sensing devices are used in the laboratory to monitor the temperature in refrigerators, freezers, water baths, heating blocks, and incubators. Special applications of thermometry include osmometry, refrigerated centrifuges, refrigerated reagent compartments of automated analyzers, warming compartments of automated analyzers, and circulating water baths for cuvet compartments in automated analyzers. All of these temperature-monitoring applications have the same requirements: accurate measurements and a constant temperature.

Appropriate quality control procedures must be carried out and documented routinely for all of these temperature-monitoring devices. Any temperature-sensitive device that fails to perform within established tolerances must be replaced. Because many assays performed in the

laboratory are enzymatic in nature, even the slightest deviation from the optimal temperature required to perform the assay may cause an erroneous result.

Types of Thermometers

The two types of liquid-in-glass thermometers most widely used are total immersion and partial immersion. A total immersion thermometer requires that the bulb and the entire column of liquid be immersed into the medium measured. These thermometers are used to monitor freezers and refrigerators. Partial immersion thermometers must have the bulb and stem immersed to the immersion line or defined depth on the thermometer. This type of thermometer is often used for water baths and heating blocks.

Special Applications of Temperature-Sensing Devices

Thermistors are used in several types of instruments found in the laboratory, including freezing-point depression osmometers. A thermistor is a transducer that converts changes in temperature (heat) to resistance. It consists of a small bead constructed of a fused mixture of metal oxides, attached to two leads and encapsulated in glass. The metal oxide mixture has a large negative temperature coefficient of resistance. Thus a small decrease in temperature causes a relatively large increase in the resistance of the thermistor.

A thermocouple is a sensor that consists of two dissimilar metals, joined together at one end. When the junction of the two metals is heated or cooled, a voltage is produced that can be correlated back to the temperature. Thermocouples are available in several designs, including beaded wire, probes, and surface probes. An important feature of most thermocouples used in laboratory analyzers is their fast response time. The response time of a thermocouple is defined as the time required by a sensor to reach 63.2% of a step change in temperature under a specified set of conditions. Five time constants are required for the sensor to approach 100% of the step change value.

Laboratory applications for thermocouple use include gas and liquid chromatography, surface temperature measurements in heating compartments in automated analyzers, thermo-cuvets, and circulating water baths in chemistry analyzers.

Mercury-Free Laboratories

Initiatives are under way nationwide to make laboratories mercury-free. For example, in June of 1998, a landmark agreement was put together between the American Hospital Association (AHA) and the U.S. Environmental Protection Agency (EPA) (JCAHO, 2002). A memo of understanding was signed between the two organizations in an effort to decrease and eventually eliminate hospital pollution practices over a 5 to 10 year period. One of the goals is to eliminate mercury waste.

Mercury is contained in numerous chemical reagents used by the laboratory and of course in mercury thermometers. The cost associated with proper disposal of mercury and the impact of mercury in the environment make replacing mercury thermometers a sound idea. Several alternatives exist for replacement thermometers that provide the necessary accuracy for laboratory procedures. They include the following:

- thermometers containing an organic red spirit and pressurized with nitrogen gas
- thermometers containing blue biodegradable liquid (isoamyl benzoate and dye)
- a red liquid thermometer filled with kerosene
- bimetal digital thermometers
- digital thermometers with stainless steel stems

Thermometer Calibration

Monitoring the temperature accuracy of thermometers is necessary to ensure the reliability of procedures requiring temperature regulation. Thermometers may be purchased with a certificate to indicate traceability to standards provided by NIST. Also, many commercially available thermometers meet or exceed NIST and American National Standards Institute (New York)/Scientific Apparatus Makers Association (UK) (ANSI/SAMA) tolerance for accuracy.

Noncertified thermometers can be calibrated by using an NIST SRM 934 thermometer or an NIST SRM 1968 gallium melting point cell. The SRM 934 clinical laboratory thermometer is calibrated per specifications by International Temperature Scale 1990 (ITS-90) at 0, 25, 30, and 37° C. A gallium melting point cell consists of about 25 g of very pure (99.99999%) gallium metal that has a single fixed melting point at 29.7646° C (as defined by ITS-90). The gallium is sealed in an inert plastic crucible and is surrounded by a stainless steel envelope (Strouse, 1997).

Temperature-monitoring devices should be verified for accuracy at 6 or 12 month intervals. Guidelines and procedures for proper monitoring and tolerances are available (NCCLS approved standard I2-A2, 1990).

WATER BATHS

For general clinical laboratory use, constant temperature water baths must offer variable temperature control from +5° C above ambient temperature to 100° C, with accurate control to $\pm 0.2^\circ$ C. Water baths can be circulating or noncirculating. Circulating water baths provide the best temperature control. Another important consideration in the selection of a constant temperature bath is that the model should be large enough to accommodate the desired working volume.

Maintenance

Maintenance of a constant temperature water bath is improved by filling it with type II (or type I) water. This prevents the accumulation of mineral deposits from regular tap water, which can affect the temperature-sensing elements and generally lead to poor heat transfer. However, if an accumulation of these minerals does occur, a weak hydrochloric acid solution will dissolve the deposits. Frequent cleaning and fresh water will prevent overgrowth of bacteria and algae. Also a 1:1000 dilution of thimerosal (Merthiolate) can be added to help prevent bacterial growth. Overheating and subsequent damage can occur if the bath goes dry. At higher temperatures, the bath should be covered, both to maintain proper temperature control and to prevent rapid evaporation to dryness.

Quality Control

A thermometer calibrated against another certified by NIST must be a component of any water bath. The temperature should be noted and recorded for each assay. This function by the operator ensures that indeed the temperature of the bath is the same as the reading of the thermometer.

HEATING BLOCKS, DRY-BATH INCUBATORS, AND OVENS

Heating blocks and dry-bath incubators are commonly used for incubating liquids at higher temperatures. Most incubators are constructed of an aluminum alloy that is capable of distributing the heat in a uniform manner. Their heating efficiency is less than that of a circulating water bath, but they will maintain a constant temperature within $\pm 0.5^\circ$ C. A certified thermometer or NIST calibrated thermometer must be present in the heating block to monitor the temperature.

Heating ovens are used in chromatography procedures, to dry chemicals, and to assist in extraction, and they are used to dry membranes or gels in electrophoresis. Several different designs are available, depending on the desired temperature and purpose. Oven designs include programmable, vacuum, and standard laboratory types. Temperature control is usually within $\pm 1^\circ$ C. The oven must have a certified thermometer or NIST calibrated thermometer available to monitor the interior temperature.

MIXING

Mixing is an operation intended to form a homogeneous mass or create a uniform heterogeneous system. Mixing is used to bring solids into solution; to bring phases into intimate contact, for instance, in extraction procedures; to wash suspended solids; to homogenize liquid phases; and to perform many other operations. A serious consequence of inadequate mixing can be failure to completely resuspend protein that settles out under long-term frozen storage of serum controls, resulting in invalid data. In some instances, excessive mixing may cause denaturation of protein or hemolysis. A phase separation occurs when serum (or plasma) specimens stand for a period of time and must be thoroughly mixed before analysis. The concentration of even small molecules in such a system will be heterogeneous as proteins settle and become more concentrated; thus effective water concentration decreases in this layer. This produces a water concentration gradient throughout the system and, consequently, a concentration gradient of all components.

Single-Tube Mixers

A vortex mixer is capable of a variable speed oscillation that results in a swirling motion to liquid contents of a test tube or other container. The

angle of contact and the degree of pressure can be regulated for optimal mixing action. A very effective mixing action is created by a multiple-touch sequence (i.e., touching and withdrawing the tube from the neoprene oscillating cup of the mixer). The operator must be careful not to fill the container too full or to mix the liquid contents too fast, because spillage can occur.

Multiple-Tube Mixers

Various mixers are available that handle a number of tubes and tube sizes, and with different types of mixing motions. A Thermolyne Maxi-Mix (Sybron Corporation, Dubuque, Iowa) can conveniently be used for vortex mixing one tube or several tubes at the same time. Changing the pressure of the container against the replaceable foam rubber top varies mixing action. Circular motion on a tilted disk provides continuous inversion of contents in tubes, which are clip-mounted at the circumference of the rotating disk. Rotational speed can be varied to provide gentle or more vigorous mixing. Control sera are conveniently reconstituted on this type of mixer. Tube shakers that operate by tilting back and forth at variable speeds provide thorough mixing of whole blood samples.

AQUEOUS SOLUTION

The concentration of a solution may be expressed as molarity (M), normality (N), and, less frequently, molality (m). Accurate preparation of reagents requires fundamental knowledge of solution chemistry, basic mathematics, and basic techniques.

Molarity

Molarity (M) is equal to the number of moles of solute per liter of solution. A mole of a substance is the number of grams equal to the atomic or molecular weight of the substance. The atomic or molecular weight of a substance is the actual mass of the chemical particle (atom or molecule) relative to the mass of the carbon atom. One mole of any substance will contain approximately 6.02×10^{23} particles (Avogadro's number). Thus a one molar solution contains 1 mole of solute per liter of solution.

Example 4-7. How many grams of NaCl are required to prepare 1 liter of a 0.5 M solution? The gram molecular weight (GMW) of NaCl is 58.5?

$$\begin{aligned}\text{SOLUTION} \\ \text{GMW} \times M &= \text{g/L} \\ 58.5 \times 0.5 &= 29.25 \text{ g/L}\end{aligned}$$

Therefore, weigh out 29.25 g of NaCl and transfer it to a 1 L volumetric flask. Add water to the 1 L mark on the flask.

Millimoles

When small concentrations are used, they are frequently expressed in millimoles per liter (1000 mmol = 1 mol). For example, to prepare 10 mL of a 10 mmol (0.01 mole) NaOH solution, 4 mg NaOH is diluted to 10 mL.

Normality

Normality (N) is equal to the number of gram equivalents of solute per liter of solution and is dependent on the type of reaction involved (e.g., acid-base, oxidation). One-gram equivalent weight of an element or compound equals the gram molecular weight divided by the number of replaceable hydrogens or hydroxyls (also valence):

$$\text{Gram equivalent weight} = \text{GMW} / \text{Number of replaceable hydrogens, hydroxyls, or valence}$$

$$1 \text{ N} = \text{Number of gram equivalents of solute} / \text{L of solution}$$

Example 4-8. What is the gram equivalent weight of Ca(OH)_2 (GMW = 74)?

$$\begin{aligned}\text{SOLUTION} \\ \text{Gram equivalent weight} &= 74/2 = 37 \\ 1 \text{ mole} &= 2 \text{ equivalents}\end{aligned}$$

Example 4-9. What is the gram equivalent weight of H_2SO_4 (GMW = 98)?

$$\begin{aligned}\text{SOLUTION} \\ \text{Gram equivalent weight} &= 98/2 = 49 \\ 1 \text{ mole} &= 2 \text{ equivalents}\end{aligned}$$

Example 4-10. How many milliliters of concentrated H_2SO_4 (specific gravity, 1.84; percent purity, 96.2%) are required to prepare 1 liter of a 1 normal solution?

SOLUTION

Step 1: compute GEW $\text{H}_2\text{SO}_4 = 98/2 = 49$.

Step 2: compute the number of grams of H_2SO_4 in 1 liter = 98 g/L.

Step 3: compute the number of grams of H_2SO_4 per milliliter of solution = $\text{SG} \times \% \text{ assay} = 1.84 \times 96.2 = 1.77$.

Step 4: compute numbers of milliliters of concentrated H_2SO_4 required when preparing 1 liter of a 1 normal solution:

$$\frac{1.77 \text{ g}}{1 \text{ mL}} = \frac{49 \text{ g}}{X \text{ mL}}$$

$$X = 27.6 \text{ mL}$$

Molal

In the laboratory, we sometimes measure the physical properties of solutions, for example, when we measure the osmolality of serum or urine. The molality of the solution is determined instead of the molarity. A molal solution is 1 mole of solute in 1 kilogram of solvent. Molal solutions are based on weight, not volume. Because the density of water at room temperature is approximately 1 gram per milliliter, 1000 grams of water occupies about 1 liter. Therefore, a 1 molal aqueous solution is approximately the same as a 1 molar solution.

Example 4-11. How many grams of NaOH are needed to make a 2.00 molal solution?

SOLUTION

Step 1: determine the GMW of NaOH = 40 g.

Step 2: compute the number of grams of NaOH required to prepare the solution by using the following formula:

$$\text{Molality} = \frac{\text{Grams of solute/GMW of solute}}{1.0 \text{ kg of solvent}}$$

$$2 \text{ Molal} = \frac{X \text{ g of NaOH}/40.00 \text{ g}}{1.0 \text{ kg of solvent}}$$

$$X = 80 \text{ g of NaOH}$$

Dilutions

Dilution procedures are not performed as frequently as in the past owing to improvements in computers and instruments whereby the system performs the dilution automatically. But, on occasion, a dilution has to be prepared. A brief review follows.

A laboratory procedure may involve the addition of one substance to another to reduce the concentration of one of the substances. This mixture is called a dilution. Laboratory staff often confuse the terminology associated with dilutions and ratios. The term ratio is more general and refers to an amount of one thing relative to an amount of something else with no other implications. Dilution, as the term is used in laboratories, is more specific. It refers to the number of parts of a substance in the total number of parts of mixture containing the substance. The implication is how the mixture was made or how it is to be made. The following are examples of ratios followed by dilutions:

Ratios

1. The serum/saline ratio is 1:9.

2. The saline/serum ratio is 9:1.

3. The serum/total volume ratio is 1:10.

Note that a colon is used as the ratio symbol.

Dilutions

1. Make a 1:10 dilution of serum in saline.

2. Make a 1:10 dilution of serum in saline.

3. Make a 1:10 dilution of serum with saline.

Example 4-12. Prepare a 1 mL/10 mL dilution of a serum sample.

SOLUTION

Pipet 1.0 mL of serum and add 9.0 mL of saline for a total volume of 10 mL.

A clinical application may involve the dilution of a patient serum sample because the bilirubin result exceeds the upper limit of linearity. The technologist decides to make a 1:2 dilution of the sample and assay the diluted sample. To prepare the dilution, the technologist pipets 100 μL of patient serum and adds 100 μL of water, for a total volume of 200 μL . The sample is assayed for bilirubin, and the analyzer prints out a value 12 mg/dL. Before reporting the patient's bilirubin result, the technologist must multiply the analyzer value times 2 (the dilution factor) and then report the value of 24 mg/dL.

Acids, Alkalis, and pH

An acid molecule yields hydrogen ions (protons) in aqueous solutions; an alkali accepts these. At room temperature in pure water:

$$[\text{H}^+] = [\text{OH}^-] = 1 \times 10^{-7} \text{ molar}$$

In all aqueous solutions, both acid and alkaline:

$$K_w = [\text{H}^+] \times [\text{OH}^-] = 10^{-14}$$

In an acid solution, $[\text{H}^+]$ is greater than 10^{-7} mol. In an alkaline solution, $[\text{H}^+]$ is less than 10^{-7} mol. pH is the exponent that must be applied to 10 to give the value of $1/[\text{H}^+]$, that is,

$$\text{pH} = \log_{10} 1/[\text{H}^+]$$

When pH is	1	H^+ is	10^{-1}	and OH^- is	10^{-13}
	2		10^{-2}		10^{-12}
	4		10^{-4}		10^{-10}
	6		10^{-6}		10^{-8}
	10		10^{-10}		10^{-4}
	13		10^{-13}		10^{-1}

A change of one pH unit indicates a tenfold change in H^+ concentration.

Buffer Solution

The theory of buffers and their preparation can be found in Appendix 1. For most commonly used buffers, the quantities of salts of the acids and bases have been predetermined and may be found in reference books (e.g., Bates, 1973, which contains a very good discussion of the theoretical aspects of buffers and extensive information on how to prepare several buffer solutions).

ON THE HORIZON, 71**SELECTED REFERENCES, 72****KEY POINTS**

- Laboratory testing has undergone revolutionary changes over the past decade so that all routine chemistry and hematology testing is completely automated.
- This includes specimen processing; all tubes are initially bar coded; they can be directly placed on autoanalyzers, which not only read which tests to perform but can directly sample from tubes and enter all results in the laboratory computer system, which is linked directly to the hospital information system.
- The three stages of laboratory testing are pre-analytic, analytic, and post-analytic. Several examples of how these stages have been automated are presented in this chapter.
- Instrument manufacturers are attempting to design systems that will offset staff shortages, provide a safer working environment for technologists, and provide the test menus and throughputs being demanded by clinicians.

Automation in clinical laboratories has been available since the mid-1950s with the introduction of the Technicon AutoAnalyzer (Pulse Instrumentation Ltd., Saskatoon, Saskatchewan, Canada) for laboratory use. The primary driver of automation has been the need to reduce or eliminate the many manual tasks required to perform analytic procedures. Continued development has led to, at first, the consolidation of most high-volume chemistry measurements onto a single platform and, more recently, the consolidation of chemistry and immunoassay systems onto a single platform. By eliminating manual steps, error due to analyst fatigue or erroneous sample identification is reduced. In parallel with automation in chemistry, the 1960s experienced remarkable growth in hematology laboratories with the introduction of automated electronic cell counting instruments that drastically changed measurements previously performed with pipets, hemocytometers, and microscopes. After initially improving accuracy and precision with red cell measurements, subsequent development and adaptations, including flow cytometric technology, have now allowed both the automation of most white blood cell differentials and a more flow cytometry-based classification of hematopoietic neoplasms.

During the 1970s, clinical laboratories were exposed to high-level computerization with the introduction and implementation of laboratory information systems (LISs), thus augmenting the flow of information throughout

the clinical laboratory. Increased use of computers resulted in a significant reduction in errors, especially transcription errors. In the 1990s, giant leaps were made in technologies, which resulted in the introduction of intralaboratory transportation systems that used specimen carriers such as conveyors or transport tracks to move samples between analyzers, into and out of processing stations; these included centrifugation, decapping/capping, and storage and led to the design of total laboratory automation (TLA).

In the first decade of the new millennium, a significant amount of time and money has been dedicated by major vendors of laboratory automated systems, workcells, chemistry analyzers, immunoassay analyzers, and middleware systems to assemble an array of equipment that will meet the needs of small, medium, and high volume clinical laboratories. The diversity of platforms, footprints, detectors, and computer capabilities coincident with improved patient care, reduced error rates, and creation of quality laboratory results is unparalleled in any other decade in clinical laboratory technology.

Overall, the scope and magnitude of the drivers of automation have taken a direction similar to all other technologies. A list of factors that serve to drive automation is shown in Table 5-1. In this chapter, several of these drivers will be discussed in the context of how automation in the clinical laboratory has changed over time to become what it is today. Several analytic systems will be selected as examples of how manufacturers responded to the demands of the laboratory. The cause and impact of change on the three stages of laboratory testing will be presented, beginning with pre-analytic, then analytic, and finally post-analytic stages. The demands placed on the clinical laboratory are derived in part from the needs of clinicians and patients, and this has resulted in most of the drivers that push the changes seen in laboratory automation today.

AUTOMATED ANALYSIS

The measurement of samples using automated instrumentation has undergone an evolutionary process since the Technicon AutoAnalyzer. It began with a single-channel analyzer using continuous flow analysis that measured one analyte on a batch of samples (i.e., one sample, one test). These samples were measured in a sequential fashion (i.e., one sample after another). Specimen throughput rates were approximately 40–60 per hour. Technicon continued to develop and expand the capabilities of its continuous flow analyzers, and this resulted in the production of multiple-channel instruments (e.g., SMA 6-60, an SMAC II) that produced specimen throughput rates as high as 150 per hour with test throughput of

TABLE 5-1

Factors That Serve to Drive Laboratory Automation

Throughput
Computer and software technology
Primary tube sampling
Increasing the number of different analytes on one system
Increasing the number of different methods on one system
Reducing laboratory errors
Number of specimens
Types of fluids
Safety
Environmental concerns (i.e., biohazard risks)

approximately 3750 tests/hour depending on the test configuration. One significant disadvantage of continuous flow analysis is that all testing is performed in parallel fashion. This results in the measurement of every analyte configured on the system for every sample. This inflexibility in testing resulted in the development of analyzers that provide “discrete” testing (i.e., measured only the tests requested on a sample).

The next generation of automated analyzers included centrifugal analyzers and modular analyzer configurations. Centrifugal analyzers were discrete, batch-type systems. A significant limitation at the time was the throughput rates. Because the analyzers were configured to measure one analyte at a time, the only way to improve upon throughput was to purchase multiple systems so that several tests could be run simultaneously depending on how many systems the laboratory purchased.

A solution to the limitations associated with centrifugal analysis was to design a modular system that could be configured to measure multiple analytes on multiple samples with the process controlled by a computer rather than by humans. This is the essence of *random access testing*. Modular instruments allow the user to add on additional units (e.g., ion-selective electrodes [ISEs], immunoassay modules).

The ultimate result of combining modular design with random access testing was to increase specimen throughput rates to hundreds per hour and test throughput rates to thousands per hour. Patient care was improved by reduction in turnaround times. Also clinicians would request additional laboratory tests, knowing that they would receive quality patient results in a timely manner.

PREANALYTIC STAGE

The three stages of laboratory testing are preanalytic, analytic, and post-analytic. Improving efficiency and productivity during the preanalytic stage of laboratory testing was not the main focus of laboratory staff at the outset. Likewise, the postanalytic stage received very little attention. This lack of attention to improvements during these two stages was due in part to the lack of technologies that would later be developed and serve to change the scope of each of these stages. Also many of the drivers of automation that now exist were not a priority in the early days of clinical laboratories.

The preanalytic stage focuses on sample or specimen processing. For decades, specimens drawn within a facility were brought to the laboratory, usually by the blood drawers or “runners.” If the specimens were obtained from outside the laboratory facility, a courier service was often used. Courier service is a batch process that requires scheduling from a given pick-up point. These individuals represented the first link between patient and laboratory, and were the source of problems that would result in some remarkable changes and innovations to the process of laboratory testing as a whole. One example of an early solution to replacing humans as specimen carriers was the introduction of pneumatic tubes.

TABLE 5-2

Examples of Sample Processing Tasks

ID/labeling
Sorting
Centrifuging
Decapping
Aliquoting
Recapping/storage/retrieval

Pneumatic tube delivery systems were installed to provide point-to-point delivery of specimens to the laboratory and offered several advantages over specimen transport by humans. Tubes are sent quickly in the pneumatic tube to the laboratory encased in a carrier lined with a foam-type material to reduce breakage. Pneumatic tube systems are designed to prevent hemolysis by avoiding significant elevation of *g* forces during acceleration and deceleration.

Electrical track vehicles can transport a larger number of specimens than pneumatic tubes. Electrical tracks require a station for loading and unloading specimens, and this may pose a problem in facilities with limited space. Similar to couriers, electrical tracks allow for batching of specimens.

Later, robots or mobile robots of many designs were used by laboratories to transport specimens from within and outside of the facility. Samples are usually batched for pick-up, and delays in the timing of pick-up notifications occurred.

Conveyors or track systems are used in some laboratory facilities, especially if the laboratory receives a very large number of samples. Conveyor or track systems are designed to transport specimens in a horizontal fashion and upward or vertically to another floor.

Once the specimens arrive at the laboratory processing workstation, several tasks need to be done. These tasks are listed in Table 5-2. Several novel approaches were used, and these culminated in what is termed “preanalytic modules,” which are available from several instrument manufacturers. Many earlier attempts were made to process specimens with minimal human involvement before the development of preanalytic modules. Many of these devices are still used.

Labeling specimens by hand requires a substantial amount of time and proved to be a large source of laboratory error. Labeling went beyond the specimen tube and included pour-off tubes, sample cups, dilution cups, and send-out containers. The use of printed bar code labels facilitated this process tremendously. Later, as computers became more sophisticated and communication between computers improved, the bar code label system reduced processing time and pre-analytic errors.

Manual sorting or separating of samples was needed because of the diverse types of testing that most laboratories engaged in. Specimen tubes of all shapes and sizes would be received in the processing area of a clinical laboratory, and the technologist would have to sort tubes by stopper color, size, tests ordered, instrument design requirements, and tube destinations.

In the earlier days of clinical laboratories, each red-top tube was double-spun, so that clot removal was optimal. This step required manual decapping of the specimen tubes. The invention of the serum separator tube eliminated the need for this double-spin technique, and decapping at this stage was not necessary. A specimen would have to be decapped to process aliquots, poured off into sample cups, or be introduced into the analyzer. The decapping of tubes posed health hazards to the technologist via aerosol dispersal from the tubes and direct contact with blood.

Centrifugation of blood collection tubes required the technologist to manually load tube carriers and place them into the centrifuge. The tubes would then be removed from the centrifuge and re-sorted, aliquots would be processed, and the samples distributed to their destinations or target area. This whole process was fraught with potential safety hazards, opportunities for mistakes, and large increases in sample processing time.

Many specimens required aliquots to be poured off, also known as splitting of the samples. The aliquots were used by instrument operators, sent to other laboratory sections, sent out to reference laboratories, and used for dilutions. As with other manual processing steps, aliquoting blood specimens was a potential source of hazards for the laboratory staff and led to errors and increased processing time.

When the samples were no longer needed for testing, they were stored in a refrigerator or freezer. All of the samples were stored in an organized fashion in the event that they would be needed again for retesting. Manual

Figure 5-1 Beckman Coulter (formerly Olympus) OLA 2500 Lab Automation System. This system consists of a decapper, sorter, archiver, and aliquotter with throughput of 650 tubes/hour. (From Beckman Coulter [formerly Olympus], with permission.)

storage and retrieval of samples created problems for some laboratories. Samples were often lost, were not stored properly, and were difficult to locate.

AUTOMATED APPROACHES TO SPECIMEN PROCESSING

Two goals for automating specimen processing are (1) to minimize non-value-added steps in the laboratory process (e.g., sorting tubes), and (2) to increase available time for value-added steps in the tasks that technologists perform that help make a difference in the quality of the test result and, ultimately, in the diagnosis.

Advantages for automating laboratory testing include the following:

- increasing the quality of the pre-analytic steps
- reducing error rates
- reducing operator exposure to potentially hazardous biologic material
- eliminating repetitive stress injuries

Several front-end sample processing systems are available to improve upon all of the shortcomings associated with manual sample processing. The system designs may involve integrated specimen processing or modular processing. Some modular systems are designed to exist as stand-alone front-end processors.

Integrated specimen processing systems allow the user to perform some or all of the specimen handling tasks. These systems process only certain types of samples and specimen containers. This inflexibility with specimen containers caused many laboratories, especially hospital laboratories, to purchase modular specimen processing systems. Each module has its own on-board computer that is linked to a master controller computer system. Also, modular systems can accommodate several different specimen types (e.g., whole blood, serum, plasma) with their respective specimen containers.

Whatever the configuration, each automated pre-analytic system attempts to provide the user with some or all of the tasks necessary to prepare samples for testing. These tasks include the following:

- presorting
- centrifugation
- volume checks
- clot detection
- decapping
- secondary tube labeling
- aliquoting
- destination sorting into analyzer racks

The standalone system automates one portion of front-end processing, which includes sample sorting, sample uncapping, and aliquot functions. A centrifuge is not included in this design. If serum or plasma is required, the sample must be carried to the centrifuge by the technologist. One example of standalone automated units is the Roche Diagnostic Task Targeted RSD 800 PVT (Roche Diagnostics, Indianapolis, Ind.). These units

are featured as task *targeted automation*, a concept that is characterized by state-of-the-art automation of preanalytic and postanalytic steps. Samples are processed by these units and then are hand carried to their respective workstation or targets. The RSD 800 PVT is designed to improve the quality of preanalytic steps, reduce operator exposure to hazardous biologic material, and eliminate repetitive stress injuries.

Archiving and retrieval of specimens in an automated fashion are also available in standalone designs. Automated sample archiving systems use bar-coded specimens that are scanned and placed in numbered positions in numbered racks. Retrieval of specimens is initiated by entering the patient's sample accession number or a medical record number into the archival system's database. The rack number and the position in the rack are determined and displayed for the user. Some systems include a refrigerator for sample storage and automatic disposal of samples at predetermined times.

Beckman Coulter Inc. (Brea, Calif.; formerly Olympus American Inc.) has designed a fully automated preanalytic and postanalytic sample handling system that can serve as a standalone unit or a modular unit to be utilized in configurations that match the laboratory's volume and workflow patterns. The OLA 2500 Lab Automation System (Fig. 5-1) has several unique features, including the following:

- A camera station that recognizes tube types and tube sizes and can be used for sample material recognition, as well as sample volume calculations
- The aliquoting unit, which uses disposable tips to eliminate carry-over; it also can generate up to six daughter tubes from each mother tube
- Archiving, which can be performed in parallel with sorting or as a batch

Modular systems are designed to automate the entire process. The automated modular system decaps specimens, prepares aliquots, and sorts (mother and daughter samples) and transports specimens via a track system. A sample sensor or transducer senses liquid levels and separator gels and detects short samples. The Roche Modular Pre-Analytics (Roche Professional Diagnostics, Basel, Switzerland) (Fig. 5-2) combines many of the preanalytic steps that are coordinated using an intelligent process management component.

ANALYTIC STAGE

The analytic stage of testing has evolved to a very sophisticated level because of progress in technology and improvements in computer technology, and as a result of many of the drivers of automation listed earlier. Tasks in the analytic stage of laboratory testing are listed in Table 5-3.

SAMPLE INTRODUCTION

Automatic sampling may be accomplished using several different physical mechanisms. Peristaltic pumps and positive-liquid displacement pipets are two examples. Peristaltic pumps are an example of older technology but

Figure 5-2 Roche Modular Pre-Analytics with “intelligent process management” and modules that provide bar code labels, centrifuge, destopper, aliquotter, restopper, and sorter. (From Roche Diagnostics, with permission.)

TABLE 5-3

Tasks Included in the Analytic Stage of Laboratory Testing

Sample introduction and transport to cuvet or dilution cup
 Addition of reagent

 Readout and result reporting

are still used in some instrument designs (e.g., electrolyte measurements). Positive-liquid displacement pipets are usually single pipets that transfer samples from cups or tubes to the next analytic process. Most positive-displacement pipets function in one of two ways. Either they dispense aspirated samples into the reaction container, or they flush out samples together with diluent.

Movement of the sample from the sample cup or tube to its destination via the sample probe is accomplished in several different ways. Some analyzers use a robotic-like arm that pivots back and forth, picking up a sample and depositing it into a reaction vessel or onto the surface of a porous pad. Other systems may use a worm gear device that pulls the sample probe from one point to another.

In most analyzers, samples are pipetted using a thin, stainless steel probe. The probe may be required to pierce a rubber stopper or may pass directly into a test tube or a cup. A given quantity of sample is aspirated into the probe, and the probe is moved toward an appropriate container for dispensing. A potential source of problems with this type of sample probe is the formation of a clot in a sample that subsequently attaches to the probe. These clots may plug the probe, making continued use impossible. Also, the clot may occupy sample volume and thus may cause an error in measurement. Because of the sticky nature of serum or plasma, the clot may adhere to the sample probe, and, as the sample probe swings toward its next destination, the whole clot and sample vessel may move along with it. This could result in an instrument malfunction and/or sample probe misalignment. Several sample probe designs have clot detector capability and reject a sample that is clotted. Another feature associated with sampling is the ability of the sample probe to detect the presence of a liquid by using liquid level sensors. These liquid level sensors detect the presence of an inadequate or short sample and will not allow the analyzer to continue processing this sample. The pipet and the liquid level sensor travel a specified distance into the sample container to determine if liquid is present or not.

Another problem associated with reusable pipet probes is carry-over. Carry-over is contamination of one sample by the previous sample. This contamination may cause serious variation in results for subsequent tests. Several instrument modifications have been used to reduce carry-over. One method used is to aspirate a wash solution between incidents of pipetting. Another technique is to back-flush the probe using a wash solution. The wash solution flows through the probe in a direction opposite to that of the aspiration, into a waste container. This technique tends to minimize the risk of pulling a small clot farther into the system.

Many samplers use disposable plastic pipet tips to transfer samples. This has the distinct advantage of eliminating carry-over associated with contamination within the sample probe and from sample to sample. A

downside to the use of disposable tips is the increased cost associated with performing the assays.

REAGENTS

Reagents used in automated analyzers require attention to several concerns, which include the following:

- handling, preparation, and storage
- proportioning
- dispensing

Most laboratories use bulk reagents that are ready for use with little or no preparation. If the reagent is lyophilized, most analyzers will automatically dispense the proper diluent to dissolve the dried reagents. Chemistry analyzers that use unit test reagents (i.e., where sufficient reagent is present for the performance of a single test) may require some reagent preparation. For dry slide analysis, where a thin film is impregnated with the appropriate reagent, preparation consists of wetting the reagent with water, buffer, or sample. Another type of unit test reagent is a container or test tube consisting of premeasured liquid or powdered material to which water, buffer, or sample is added.

Reagents that come wet or dry are maintained within reagent compartments, and a complete inventory is established on a real-time basis within the computer. Most of the methods used in the laboratory require only a single reagent; some require two or more. When a reagent becomes depleted, the computer signals the operator that the reagent container is empty and a new one should be added. The quantity of reagents that should be available within the analyzer depends on the volume of testing done for any given analyte. On-board reagent storage compartments are refrigerated to maintain reagent stability.

Reagent identification and inventory processes are accomplished with the use of bar code labels. The bar code label may contain additional information such as expiration dates, lot numbers, and number of tests the contents of the container may provide. Some analyzers may couple a liquid level sensor onto the reagent probe, which is designed to alert the operator that an insufficient amount of reagent is available to complete the tests.

For all tests, the bar-coded reagent label stores critical information about calibrators. Examples of stored information include but are not limited to concentrations of calibrants, expected detector responses, calibration curve algorithms, and tolerances for acceptability of calibration. This information is often referred to as *master lot* or *master calibration*.

An important classification category for all automated analyzers is based on reagents. Automated analyzers are categorized as *open* or *closed* reagent systems. This distinction is often a key determinant used by laboratory staff to select and acquire an analyzer. An open reagent system is described as a system in which reagents other than the instrument manufacturer's reagents can be used. Also, in an *open* reagent system, the operator may change the parameters necessary to run the particular test. *Open* reagent systems provide users with greater flexibility and adapt easily to new methods and analytes. A *closed* reagent system is described as a system wherein the operator can use only the manufacturer's reagents. Usually the costs of reagents in a *closed* reagent systems tend to be more expensive, but *closed* reagent systems may save on expenses because reconstitution or preparation of the reagents for use does not require technologist time. Also the possibility of increased imprecision associated with the reconstitution of reagents in an *open* reagent system is negated by a *closed* reagent system. One problem with a closed system is that it may not be possible to introduce desired new tests that are not performed on the closed system.

The correct proportions of reagent(s) and sample(s) must be constant to achieve precise and accurate results. For unit test applications, reagents are already apportioned in appropriate amounts, thus only the sample needs to be added. Methods requiring the addition of bulk reagents provide an additional means of increasing imprecision. When bulk reagents are used, proportioning is accomplished by volumetric addition.

Delivery of bulk reagents requires automated volumetric dispensing devices. For random access analyzers, syringes or volumetric overflow devices are used. These devices volumetrically proportion reagent and sample into a test tube or other type of container.

Another mechanism used for proportioning reagents and sample is the continuous-flow technique. The sample and reagents are proportioned by their relative flow rates. Devices using continuous flow include peristaltic pumps. Many instrument designs use electronic valves to control the time reagents can flow. The flow rate is controlled by the air pressure applied to the reagent container and the flow resistance in the tubing connected to the reaction vessel.

Liquid reagents are aspirated, delivered, and dispensed into mixing chambers or reaction vessels by pumps or positive-displacement syringes. These pumps are connected to the reagent containers with the use of plastic tubing. On command from the computer, each pump draws a given amount of reagent or diluent out of the container and transports it via the tubing to its destination, where it is dispensed.

Syringe devices are widely used in automated systems for both reagent and sample delivery. Most are positive-displacement devices, and the volume of reagent delivered is computer controlled. If the reagent syringe is to be used for more than one reagent, adequate flushing between uses is essential to reduce carry-over of reagent.

MIXING

Many unique mixing devices and techniques are used in automated systems. They include the following:

- magnetic stirring
- rotating paddles
- forceful dispensing
- the use of ultrasonic energy
- vigorous lateral displacement

Dry slide analyzers do not require mixing of sample and reagents. The sample is allowed to flow through the layers containing the reagents.

INCUBATION

Warming components or solutions in automated analyzers is accomplished by heating air, water, or metal. The warming process must be constant and accurate. Electronic thermocouples and thermistors are used to monitor and maintain required temperatures within analyzers. Circulating water baths are used in several instruments as the warming mechanism. Thus these analyzers require a water purification and delivery system, which is usually external to the analyzer and is an additional cost to consider. With some analyzers, the cuvetts or reaction vessels are allowed to incubate within a chamber containing circulating air. Heated metal blocks are a widely used device for incubating cuvetts, test tubes, or plastic pouches containing solutions. The timing for each incubation period is monitored by the instrument's computer system and represents an extremely complex process, given the throughput for these systems.

Two novel approaches for incubating reaction mixtures have been developed and incorporated into automated chemistry analyzers. Siemens Healthcare Diagnostics (Deerfield, Ill.) uses an elongated cuvet path length and a fluorocarbon oil incubation bath to maximize result accuracy by enhancing absorbance values, while using microvolume technology for samples and reagents. This design feature is found in their model Advia chemistry systems.

Beckman Coulter uses a Peltier thermal electric module in the shape of a ring to maintain a constant temperature for analysis. Peltier modules are small solid-state devices that function as heat pumps. The Peltier thermal ring consisting of 125 quartz/glass cuvetts is made of copper. Each cuvet is surrounded on three sides by copper. Temperature is maintained by the use of heating and sensing elements in physical contact with a copper core filled with Freon 134A, and this is controlled by the *reaction heat controller board* assembly, mounted in the wheel's handle. Calibration information is stored on two electrically erasable, programmable, read-only memory integrated circuits (ICs [electrically erasable programmable read-only memory]) on the *reaction heater controller board* and the *heater/sensor board*.

DETECTION

Absorption spectroscopy has been the principal means of measurement in automated analyzer design to measure a wide variety of compounds. Reflectance photometry has been adapted to dry slide analysis and has been used in chemistry laboratories for decades. Fluorescent compounds (e.g., fluorescein) as signal generators have been used for measurement of drugs, hormones, and vitamins in several immunoassay analyzers. In the past decade, chemiluminescence compounds such as acridinium have replaced fluorescent compounds because of improvements in sensitivity. Electrochemiluminescence methods have also been incorporated into automated systems. Automated electrolyte measurements have been accomplished using ion-selective electrodes. All of these means of detection have been discussed elsewhere in this edition. In this section, the focus will be on new approaches to measuring compounds with automated analyzers.

Novel approaches to measurement designs include not only addition of new measurement principles but also inclusion of two or more unique detectors in one analytic system. Most of the integrated chemistry analyzers being marketed today incorporate several measuring platforms. Each platform requires a distinct detector. The Roche Cobas Integra 800 incorporates a photometer, ISE, fluorescence polarization immunoassay (FPIA) optics, and turbidimetric optics.

The Beckman Coulter Synchron LXi725 Clinical System includes a luminometer, a photometer, electrochemical detectors, and a near infrared detector (Fig. 5-3). Infrared detection is used for the near infrared particle immunoassay (NIPIA) method to measure high-sensitivity C-reactive protein (hs-CRP). A 940 nm light-emitting diode produces light that is directed into a cuvet to measure hs-CRP.

OTHER UNIQUE FEATURES LOCATED IN NEW AUTOMATED INSTRUMENT DESIGNS

Most chemistry analyzers use a high intensity polychromatic light source, usually a quartz/halogen lamp. Some analyzers use a xenon light source; this lamp lasts longer (5-year life span) because its operating voltage is maintained at a lower level than in other lamps. The xenon lamp provides a very intense polychromatic light that is useful for many and varied analyses.

All fully automated general chemistry analyzers are capable of sampling directly from the collection tube. Direct tube sampling along with bar code reading has eliminated the need to transfer samples into another container, has reduced errors, and has minimized technologist exposure to potentially biohazardous material. Tubes are typically decapped before sampling; however, some chemistry systems such as the Beckman Coulter UniCell Dx analyzers offer cap-piercing technology. The analyzer uses a blade to slit the stopper, and the sample probe pierces the stopper to withdraw an aliquot of sample. Note that cap-piercing technology is available on all high throughput hematology analyzers.

Laboratory automation can consolidate multiple workstations into a single unit. The Siemens Dimension RXL integrated chemistry system combines comprehensive chemistry and stat immunoassay testing in a single, compact system with the smallest footprint for an instrument of its capabilities. The Dimension Xpand Plus features a large menu of varied assays, fast time for first results, stat interrupt capabilities, throughput of approximately 400 tests/hour, as well as reagent flexibility.

The Beckman Coulter Synchron LXi725 Clinical System is constructed differently from the Dimension Xpand Plus. The Synchron LXi725 system (see Fig. 5-3) is designed as a self-contained integrated modular system. Samples are placed in a load area and are shuttled to the *closed tube aliquot unit*, which is similar to a small track design. An aliquot of each sample is placed in the immunoassay analytic unit for processing; the rack and primary tubes are then released for general chemistry testing.

POSTANALYTIC STAGE

The electrical signal generated by the detector, representing analyte concentration, is directed into the analyzer's microprocessor or computer. The instrument computer represents a means to accomplish several tasks, which include signal processing, data handling, and process control.

Signal processing involves the conversion of an analog signal derived from the detector to a digital signal that is usable by all communication devices. The processing of data by computers has allowed automation of nonisotopic immunoassays, reflectance photometry, and other nonlinear

Figure 5-3 Beckman Coulter Synchron LXi725 Clinical System has a large test menu (146 assays) and will accept user-defined chemistries. (From Beckman Coulter, Brea, Calif., with permission.)

assays because computer algorithms can transform nonlinear standard input signals into linear calibration plots.

Data processing by computers includes data acquisition, calculations, monitoring, and displaying data. In addition to transforming data into linear calibration plots, computers can perform statistics on patient and control values. Computers can perform corrections on data, can subtract blank responses, and can determine first-order linear regression for slope and intercept. Computers can monitor patient results against reference values. They can also test control data against established quality control (QC) protocols. Computer monitors can display all types of information, including patient results, QC data, and maintenance and instrumentation operation checks.

The computer has a profound impact on the entire process of automated laboratory instruments. Within the analyzer, the computer commands and times electromechanical operations so they can be done in a uniform manner, in repeatable fashion, and in the correct sequence. These operations include activating pipetting devices, moving cuvetts from one point to another, and moving sample tubes and dispensing reagents, to name a few.

A computer provides a means of communication between the analyzer and the operator. Instrument computers can display information usable by the operator, such as warnings that something may not be working properly, or that a specific reaction has exceeded method-defined parameters.

Chemistry analyzer computers can display graphic information such as Levey-Jennings QC charts and calibration curves. They also can be programmed to “flag” data that do not meet some predefined criteria. The operator can reprogram the computer to meet a specific need, such as adding a new test or changing an operating parameter.

A computer has the ability to be linked to other computers, and this has drastically improved automation efforts. Instrument computers can be linked via interfaces (e.g., RS232) to laboratory information systems (LISs) to provide a means of transmitting information in a unidirectional or bidirectional format. Instrument computers are now being equipped with the means to link to the internet via a transmission control protocol/Internet protocol (TCP/IP). Instrument manufacturers have designed analyzer computers that will link up from the laboratory's to the company's own manufacturing site. This link-up is done in real time and serves to monitor the instrument's performance at all times. If a problem with an analyzer does develop, the manufacturer can see real-time data to help the laboratory resolve the problem in the shortest time possible.

Several other features available in newer instrument designs are worth noting. On-board troubleshooting is available on many systems through the analyzer's computers. In the event a problem occurs, technologists may access the system's help protocols, which guide them through a step-by-step procedure in an effort to resolve the problem. Some of these on-board troubleshooting programs are sophisticated and include video and graphics. Another on-board feature available in some systems is a training program. This is an effective feature that serves to augment staff training of new users to the system.

AUTOMATED SYSTEM DESIGNS AVAILABLE FOR LABORATORIES

TOTAL LABORATORY AUTOMATION

The idea of totally automating a clinical laboratory has its roots in Japan, and the process was first tried in the early 1980s. Early designs used one-arm robots, conveyor belts, and modifications to existing chemistry analyzers to perform as many preanalytic and analytic tasks as possible with no human intervention. Each laboratory workstation was coupled to the conveyor belts, so that samples could be moved from one workstation to another. Continued research and modifications to these earlier systems led to the development of commercial TLA systems designed for hospital-based laboratories.

A TLA approach can be described as the combination of several instruments, consolidated instruments, workcells, integrated workcells, or integrated modular workcells that are coupled to a specimen management and transportation system, as well as a process control software component, to automate a large percentage of laboratory work.

An example of a TLA is the Roche Diagnostics system that includes Modular Pre-Analytics (MPA) and platform C (i.e., the chemistry analyzer). The Roche TLA consists of an integrated tract device that connects all of the laboratory workstations, including front-end processing, instrumentation, and archiving, to create a continuous, inclusive network that serves to automate nearly every step involved in the testing of each sample. TLA can incorporate testing specimens for chemistry, hematology, coagulation, and immunochemistry.

Advantages of TLA include a decrease in labeling errors, reduced turnaround times, and a reduction in full-time equivalents (FTEs). Laboratories using a high degree of automation thus have the ability to bring new assays into the laboratory by using some of the staff no longer needed for automated testing.

Major limitations of TLA include the need for substantial financial investment and increased floor space (Wilson, 2003). Initial investment monies may reach millions of dollars, and floor space requirements may exceed 4000 square feet. Another factor that requires the attention of planners because of the complex nature of TLA is the need for highly technical personnel to operate and troubleshoot the system. Other challenges to TLA include infrastructure remodeling, personnel team building, and software interfacing. In addition, several of these systems do not allow interruption of the workflow to analyze emergency (stat) samples (Battisto, 2004).

MODULAR INTEGRATED SYSTEMS

In the United States, only about 7% of laboratories are considered able to benefit from TLA. A hospital with fewer than 600 beds may not be suitable for TLA. Therefore, modular automation provides a more attractive approach for hospital laboratories and physician group laboratories because

Figure 5-4 Siemens StreamLab Analytic Workcell links multiple-dimension systems via a single operator interface and features automated preanalytic and postanalytic functions. (From Siemens, with permission.)

the systems are smaller, and they require less initial capital investment and less planning than TLA (Sarkozi, 2003). Modular systems can be configured to include several different platforms (e.g., hematology, immunochemistry). Also, the combination of modules can include multiple identical models of analyzers, preanalytic models, and postanalytic modules. These modules are linked into a single testing platform that interconnects through a track or other “connector”-type device. Individual modules can be added to the entire system to reflect changes in workload or testing patterns.

CONFIGURATION OF AUTOMATED MODULES

WORKSTATION CONSOLIDATION

Workstations represent a unique environment within a laboratory facility dedicated to one type of testing (e.g., hematology, immunoassays). All stages of specimen testing are carried out for a particular discipline at its respective workstation. One approach to improving workflow has been to consolidate workstation data management. This design allows a technologist to monitor a variety of analyzers (typically from the same vendor) from a single workstation.

WORKCELLS

Workcells are configured in combination with a specimen manager and instruments or consolidated instruments, including, for example, both chemistry and immunochemistry systems that provide a broad spectrum of analytic tests. A specimen manager is a mechanical device that stores and buffers specimens before and after analysis. These devices may have pre-analytic and post-analytic specimen processing capabilities (e.g., centrifugation, decapping). Modular workcells are workcells in which the instruments used are configured to interface directly with the specimen manager. The Siemens StreamLAB analytic workcell (Fig. 5-4) is an example of this type of workcell. The StreamLAB integrates pre-analytic and multiple analytic components (e.g., Dimension Systems) via a single operator interface. Siemens offers an optional centrifugation module.

FULLY INTEGRATED SYSTEMS

The trend in automation design is to integrate several modules into one continuous system that will allow the user to assay photometric chemistry, immunoassay chemistries, both homogeneous and heterogeneous, and electrochemistries. The tests menu for fully integrated systems exceeds 125 tests and includes immunoassays, routine chemistries, and ion-selective electrodes. All modular integrated systems use random access technology that allows the analysis of different chemistry assay types.

Beckman Coulter (Olympus) integrated automation can incorporate analyzers, for example, the AU5400 Integrated Chemistry-Immunoassay Analyzer (Fig. 5-5), to provide the laboratory with a combination of instrument platforms. This system is a true random access analyzer with test throughput rates exceeding 3000 photometric tests/hour. For ISE measurements, the throughput rate is approximately 600 samples/hour. A distinct advantage of these modular systems is that they can be linked to two or more modules, thereby increasing throughput.

Siemens' modular automated Advia Solutions has a full track system integrated with other testing modules via the Advia WorkCell or the Advia LabCell automated sample transportation system. The processing system automatically sends general chemistry specimens to the Advia 1650 Chemistry Analyzer and immunoassay specimens to the Advia Centaur.

Another approach to modular integrated automation is exemplified by Roche Modular Analytics, shown in Figure 5-6. Modular Analytics incorporates most of the tests that other integrated systems offer but can increase the test menu by linking one more module (e.g., Roche Diagnostic E170). The E170 module offers 25 heterogeneous immunoassays. Therefore if the laboratory integrates all available modules, including the control unit and the core load unit, the Modular Analytic can provide a very large test menu and very high specimen and test throughput rates.

Ortho-Clinical Diagnostics (Raritan, N.J.) offers the Vitros 5600 Integrated System, which uses self-contained multiuse cartridges in dry slide format. Other technologies include potentiometry, enhanced chemiluminescence, and microparticle agglutination.

OTHER ENHANCEMENTS TO INTEGRATED AUTOMATED SYSTEMS

Middleware

New versions of middleware are being designed that are user friendly and entice even small and medium-sized clinical laboratories to incorporate them into their LIS. This trend has allowed these laboratories to take advantage of their sophisticated decision management and advanced rule-based intelligence.

Middleware allows laboratories to connect their existing LIS and instrumentation to facilitate automatic information processing and to perform tasks not currently done with laboratories' existing hardware and software. Middleware packages provide several features and functionality that includes the following:

- automatic verification of test results through rules-based decision processing
- automation and customization of work and information based on a laboratory's specific needs
- automatic tracking of data and location of samples requiring storage
- automatic sample interference testing and detection
- provision for real-time reflexive testing

Figure 5-5 Beckman Coulter (formerly Olympus) AU5400 fully automated integrated system is available as a two or three photometric unit with versions including one single- or double-cell ion-selective electrode (ISE) unit. Throughput is 300–800 samples per hour, depending on analyzer configuration. (From Beckman Coulter [formerly Olympus], with permission.)

Figure 5-6 Roche Modular Analytics provides five different analyzer modules with 197 applications, producing throughput rates ranging from 170–10,000 tests/hour. (From Roche Diagnostics, with permission.)

- automatic comparison of current results with previous results on a patient's test (delta checking)

The following examples illustrate specific tasks that middleware can allow laboratories to complete, although most LISs are incapable of completing them:

1. Initiate a command that will not allow a calculated low-density lipoprotein (LDL) to be completed if the triglyceride is greater than 400 mg/dL.
2. Calculate serum indices for hemolysis, lipemia, and degree of icterus, and develop rules that will flag results that exceed their established limits.
3. Create a command that would remove an automated differential, and flag the result with a coded comment requiring that a manual differential needs to be done.
4. Implementation of autoverification protocols is gaining popularity throughout clinical laboratories in the United States. Middleware allows laboratory staff to develop their own results, guidelines, and tolerances for any analyte measured by the analyzer, whether chemistry or hematology.

Several hardware and software combinations are currently available. Software applications include the Windows-based Linux OS (Java-based embedded JResultNetSoftware), QNX (Ottawa, Ontario, Canada), and

Compuware Uniface (Detroit, Mich.). Computer hardware to run these software operating systems and applications is primarily provided on PCs. The Linux OS uses Dawning JavaLin/PDI (Ft. Myers, Fla.), and the Linux operates using the Red Hat Linux (Rayleigh, N.C.) hardware platform.

ON THE HORIZON

The drivers of automation listed above are continually changing and evolving, and this will lead to new approaches to the delivery of health care. Test menus will grow even larger, and new technologies will be needed to measure these analytes. These new technologies will have to be incorporated into existing systems. Another demand that systems manufacturers will need to address is the ability to link different instruments or modules to their systems. A standardized interface will be required to accomplish this, and LISs will need to adjust their processors as well. Increased emphasis on employee safety and support by legislative efforts will cause instrument manufacturers to continue to develop their products to reduce exposure to technologists. As the field of proteomics evolves, so will the methods and instruments required for measurement. Proteomic systems are currently coming to the marketplace, and in time, this type of testing will find a place in the clinical laboratory.

KEY POINTS

- Point-of-care testing refers to the scope of laboratory tests that are performed where patient care is delivered. This includes physician office testing as well as various hospital locations outside the laboratory, such as the emergency department, operating room, and intensive care unit.
- When performed in a physician office, simple tests (such as urine dipstick and whole blood glucose meters) are exempt from most regulations involving personnel, proficiency testing, and rigorous quality assurance requirements. These are referred to as “waived” tests under the Clinical Laboratory Improvement Act. In hospitals, these tests fall under the laboratory certificate of the parent hospital or health care facility and generally are subject to stricter requirements.
- Special personnel requirements are necessary (including those for laboratory director) if a physician office laboratory performs moderate-complexity testing.
- Key components of a hospital point-of-care testing program include method validation, training of nonlaboratory staff, and clear policies and procedures to establish who is responsible for each part of the program. Laboratory oversight is mandatory.
- Current technology of select tests in hematology, chemistry, and microbiology is reviewed and limitations are discussed.
- Point-of-care technology in a military theater is reviewed as an example of the utility of good point-of-care implementation.

Point-of-care testing (POCT; also known as near-patient testing, alternative-site testing, or patient-focused testing) is used in a variety of settings such as the emergency department, operating suites, clinics, physician offices, nursing homes, community counseling centers, ambulances, pharmacies, and health fairs. POCT brings laboratory testing to the site of the patient encounter, rather than the traditional practice of obtaining a specimen and sending it to the laboratory. Real-time measurements of a patient's status may be obtained in a short period of time, allowing the health care provider to address acute patient needs. POCT is recognized by The Joint Commission (TJC) accreditation body and the Clinical Laboratory Improvement Act (CLIA) of 1988.

Until the 20th edition of this book, this chapter was devoted to physician office laboratories (POLs). As shown in [Figure 6-1](#), the number of POLs grew from the 95,000 laboratories indicated in a similar figure in the 20th edition of this text to the 110,925 laboratories in October of 2009. However, the Centers for Medicare and Medicaid Services (CMS) CLIA database (at <http://www.cms.gov/CLIA/downloads/statupda.pdf>) shows that at present, only 59,790 of the 134,778 (or just 44%) registered Certificate of Waiver laboratories are POLs. This indicates that a large number of facilities that fall into the waived category are point-of-care facilities, such as emergency departments, operating suites, clinics, and nursing homes, as mentioned previously. This chapter will focus on the regulations and procedures recommended for small POLs and POCT sites where more of this waived testing is expected to occur.

Advances in medical technology, such as prepackaged reagent systems, microprocessor-controlled reactions and calibrations, and miniaturization of components, have led to a modern generation of laboratory instruments that require less technical skill on the part of the operator. Between 1992 and 2003, the U.S. Food and Drug Administration (FDA) rapidly granted waived status, described later, to 994 test systems ranging in scope from blood glucose to bladder tumor antigen cancer detection. Currently, more than 111 assays can be performed within this category. The global POCT market reached \$6.7 billion in 2008 and is growing at a rate of approximately 7% per year and represents 15% of the U.S. market for clinical diagnostic testing reagents (Dooley, 2009).

An alphabetical list of currently waived tests can be found at <http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfClia/analyteswaived.cfm>. As an example, a check on one of these assays at this FDA website reveals that more than 29 methods have been approved just for the measurement of high-density lipoprotein (HDL) cholesterol. New methods such as these will work their way into both POCT and POLs, blurring their technological differences. However, differences in regulatory requirements will remain and must be observed.

LABORATORY REGULATION

CLINICAL LABORATORY IMPROVEMENT ACT

Under CLIA, a laboratory is “A facility for the ... examination of materials derived from the human body for the purpose of providing information for the diagnosis, prevention, or treatment of any disease or impairment

Total CLIA Laboratories Registered
Self-selected Laboratory Types

Figure 6-1 The number of physician office laboratories in October 2009 relative to hospitals, skilled nursing facilities, and independent laboratories (from the CMS CLIA database, October 2009, at: <http://www.cms.gov/CLIA/downloads/statregi.pdf>.)

of, or the assessment of the health of, human beings. These examinations also include procedures to determine, measure, or otherwise describe the presence or absence of various substances or organisms in the body” (Federal Register, 1992). The idea behind CLIA is fairly straightforward: to ensure the accuracy of patient test results regardless of whether the test is performed in a large offsite lab or as self-testing in a patient’s home. Currently, in vivo and externally attached patient-dedicated monitoring devices (e.g., pulse oximetry, mixed venous oxygen saturation [SvO₂] pulmonary artery catheters, capnographs) are not subject to CLIA. Should it be determined at a later date that they are subject to CLIA, proper notice and opportunity for public comment will be provided (general provisions, certificates, and proficiency testing sections of the CLIA regulations).

Under this definition, “laboratories” are prohibited from soliciting or accepting human specimens for analysis unless a certificate issued by the Secretary of the Department of Health and Human Services (HHS) is held for each procedure that is to be performed. All laboratories are required to be registered with the federal government and must pay biennial license fees to have a valid CLIA identification number before performing any laboratory analysis used in patient care. With evolving technology, the primary difference between the POL and POCT will be that in the POL, this certification will be held by the POL, while POCT will be performed under the laboratory certificate of the parent hospital or health care facility.

CERTIFICATION AND LICENSING REQUIREMENTS

CLIA certification relies on laboratory standards that vary according to the complexity of the measurements performed. Simple tests that the Centers for Disease Control and Prevention (CDC) has determined to have low patient risk even if performed incorrectly are waived from most regulations. These types of procedures include those that have been approved by the FDA for home use. All laboratories must be certified under one of the five types of CLIA certificates listed in Table 6-1.

A three-tiered approach was initially implemented to classify all laboratory tests on the basis of complexity of testing. The three categories are certificate of waiver or “waived” tests, moderate complexity tests, and high complexity tests. Laboratories performing only waived tests would be exempt from the personnel qualifications, proficiency testing, and the more rigorous quality assurance requirements associated with more complex testing. CMS retains the right to conduct spot checks to ensure that these laboratories are performing only waived tests. Original exempt tests included urinalysis dipstick or tablet reagent analysis of pH, specific gravity, glucose, protein, bilirubin, hemoglobin, ketone, leukocytes, nitrite, and urobilinogen. Laboratories performing only waived tests have to register and pay a biennial fee.

TABLE 6-1

Types of CLIA Certificates

Certificate of Waiver

- Certificate issued to a laboratory to perform only waived tests

Certificate for Provider-Performed Microscopy Procedures (PPMPs)

- Certificate issued to a laboratory in which a physician, midlevel practitioner, or dentist performs no tests other than the microscopy procedures; permits the laboratory to also perform waived tests

Certificate of Registration

- Certificate issued to a laboratory that enables the entity to conduct moderate or high complexity laboratory testing or both until the entity is determined by survey to be in compliance with CLIA regulations

Certificate of Compliance

- Certificate issued to a laboratory after an inspection that finds the laboratory to be in compliance with all applicable CLIA requirements

Certificate of Accreditation

- Certificate issued to a laboratory on the basis of the laboratory’s accreditation by an accreditation organization approved by the Health Care Finance Administration

Obtained at: <http://www.cms.gov/CLIA/downloads/HowObtainCertificateofWaiver.pdf>.

CLIA, Clinical Laboratory Improvement Act.

It is important to understand that the original list of waived tests specified by Congress included only the short list of generic tests provided earlier. In addition, provision was made so manufacturers could add specific methods to the waived list through a certification process maintained by both the CDC and the FDA. This incentive to manufacturers allowed them to appeal to a larger market and has led to a rapid influx of devices and methods that are now classified as waived. The list of approved waived tests is updated regularly and can be found at the FDA website given previously. Over the past decade, a majority of office laboratories began to shift from moderately complex testing to waived testing, most likely because of this rapidly broadening menu. These same measurements are appropriate for the POCT arena.

A fourth category, provider-performed microscopy procedures (PPMPs), was created in 1993 and expanded in 1995. This category consists of any test that involves a health care provider using a microscope and includes all of the following procedures: all urine sediment examinations; direct wet mount preparations for the presence or absence of bacteria, fungi, parasites, and human cellular elements; all potassium hydroxide preparations; pinworm examinations; fern tests; postcoital direct qualitative examinations of vaginal or cervical mucus; nasal smears for granulocytes; fecal leukocyte examinations; and qualitative semen analysis.

Only certain professionals are permitted to perform the procedures under this PPMP category if an exemption from the moderate complexity designation is to be retained. These include licensed physicians, dentists, and midlevel practitioners such as nurse practitioners, nurse midwives, and physician assistants under the supervision of a physician, only if authorized by the state in which the practice is located. With PPMP, the specimen must be examined during the patient visit; the specimen must be obtained from the provider’s own patient or from a patient of a group medical practice of which the provider is a member or an employee.

The primary instrument for performing the test under the PPMP certificate is the microscope, limited to bright-field or phase-contrast microscopy. The specimen is usually labile, or a delay in performing the test could compromise the accuracy of the test result. In general, control materials are not available to monitor the entire testing process, and limited specimen handling or processing is required.

In moderately complex testing, a laboratory performs only waived tests and one or more tests designated as moderately complex by the FDA. To determine at which complexity level a particular method has been categorized, a searchable CLIA test complexity database is available at: <http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfCLIA/search.cfm>. Manufacturers of moderately complex tests must submit their testing system to the FDA for classification. Therefore, this database will be continuously updated along with the waived test list.

Laboratories must submit an application to HHS or its designee on a form prescribed by HHS detailing the number, type, and methods employed for each measurement or examination, as well as the qualifications of the persons directing, supervising, and performing these

TABLE 6-2

Personnel Requirements for a Laboratory Performing Moderately Complex Testing

Director	The director is responsible for the overall management and direction of the laboratory but does not have to be onsite at all times. A broad range of experience and education is acceptable, for example, a physician with 1 year of experience directing/supervising a nonwaived laboratory with 20 continuing medical education credits (CMEs) in laboratory practice would qualify, as would a person with a bachelor's degree and 2 years' laboratory training/experience plus 2 years' supervisory experience in nonwaived testing. Depending on education and experience, the director could qualify for all other positions.
Testing personnel	These people are responsible for specimen processing, test performance, and test results reporting. The minimum requirement is a high school diploma or equivalent and training for the testing performed.
Technical consultant	These individuals are responsible for technical and scientific oversight of testing. The minimum requirement is a bachelor's degree with 2 years' laboratory training or experience in nonwaived testing.
Clinical consultant	These people provide clinical consultation. The minimum requirement is a doctoral degree with board certification.

From Centers for Disease Control and Prevention Moderate Complexity Testing Overview at: <http://www.cdc.gov/clia/moderate.aspx>.

procedures. Certificates may be valid for up to 2 years, and any changes in the information required in the application must be submitted to HHS or its designee within 30 days of any change in ownership, name, location, or director. Changes in method complexity require notification within 6 months of the change. This application may be submitted through an approved accrediting body or state agency if the accrediting standards of the agency are equal to or are more stringent than those of HHS, and if the agency is authorized to inspect the laboratory as frequently as required and submit to HHS required records and information.

LABORATORY DIRECTORSHIP

Laboratories that perform under a Certificate of Waiver or with a certificate for PPMP can perform waived testing without the overhead of having personnel who meet established qualifications in training, experience, job performance, and competency. However, if any moderate complexity tests or measurements are performed, CLIA requires that the laboratory be directed by a laboratory director and/or a laboratory consultant with at least the directorship credentials listed in Table 6-2. This director is to be responsible for determining the qualifications of individuals performing and reporting test results, as well as ensuring compliance with all applicable regulations. The director is also responsible for the analytic performance of all assays, and must monitor ongoing proficiency, accuracy, and precision. If more than one individual in the practice qualifies as a laboratory director, the laboratory is required to designate one as being responsible. It must be demonstrated that the laboratory director is providing effective direction for the operation of the laboratory, and if he does not provide onsite direction, he must provide consultation by phone or delegate to qualified personnel with specific responsibility as required by regulation. Online courses are available that allow physicians to qualify as director of a moderately complex laboratory by obtaining 20 hours of continuing education credit. A list of courses can be found on the CMS website at: http://www.cms.gov/CLIA/15_CME_Courses_for_Laboratory_Directors_of_Moderate_Complexity_Laboratories.asp.

For POCT, a separate certification is usually not necessary when it is performed under the supervision of the laboratory director responsible for laboratory services in a health care facility. POCT that occurs within a health care facility, at sites that are located in contiguous buildings on the same campus, and under common direction can be performed under the certificate of the parent organization. When assays and procedures are performed in a situation such as this, the terms "waived" and "complexity" no longer have meaning. The test menu is no longer restricted to waived testing; however, more frequent inspections and higher scrutiny are received in return. Because the parent organization typically

TABLE 6-3

Point-of-Care Checklist

1. Equipment, if needed, must be evaluated.
2. A person of sufficient managerial authority is designated as being responsible for the site.
3. Persons performing the test must be trained and competency assessed, and this must be documented.
4. A written procedure must be available and followed.
5. Calibrations and quality control samples must be run at regular intervals.
6. All patient results must be documented, and the relationship to quality control measures must be clear.
7. Appropriate action must be taken and documented on all out-of-range quality control results.
8. Appropriate action must be documented on all abnormal patient results.

By congressional law, CLIA '88, a regulated test is any measurement used in the diagnosis, treatment, and management of a patient.
CLIA, Clinical Laboratory Improvement Act.

has a certificate that allows testing at all levels of complexity, it is the responsibility of the laboratory director to ensure that the test method used at the POCT site is appropriate for the skills and training of those performing the test. What inspectors do not tolerate could be called "rogue testing." This occurs when a clinic or service sets up a test without the knowledge and supervision of the laboratory director. With the new tracer method used by accrediting agencies such as TJC, if an inspector finds a lab result and traces it back to a laboratory that is not adequately supervised by the laboratory director, a citation may be issued to the discredit of the health care facility.

COMPLIANCE

In addition to CLIA, all laboratories must adhere to regulatory procedures, particularly in the outpatient setting. First, all testing for which Medicare is billed must be medically necessary. Screening tests and other measures of wellness generally are not covered. Medical necessity determination is implemented by Medicare, Medicaid, and other insurance carriers through Current Procedural Terminology (CPT) codes used in conjunction with International Classification of Disease (ICD) codes. When the ICD-10 code does not warrant the CPT-4 code, payment is rejected. Even worse, if it is determined that a laboratory deliberately added codes to obtain a higher payment than it deserves or payment for work that it has not done, it can be charged with fraud, which is a felony and the laboratory will be subjected to fines. Errors are assumed to be deliberate unless a compliance program is in place that actively seeks to uncover billing errors.

Another potential pitfall is Stark regulations. The Stark laws, which are named after their original sponsor Representative Fortney Pete Stark (D-CA), were intended to prevent unnecessary self-referrals intended to boost revenue. Under Stark, physicians are prohibited from referring Medicare patients to laboratories in which the physician (or a close family member) has a financial interest. Because this prohibition would be detrimental to most POLs, it is important to understand the "safe harbors" that allow legitimate self-referral.

CLIA '88 created standards for POL laboratories and POC testing in the United States that predated similar measures on the international scene. However, an international working group has proposed and adopted ISO 22870-2006 as an international standard for POCT testing. These standards are more extensive than current CLIA requirements; however, CLIA is a minimum federal requirement, and states and other accrediting agencies can impose standards that are more rigorous. An evolution of accreditation expectations may occur over the next few years to meet these international standards. Thomas has published a summary of these international standards with cross-referencing to current College of American Pathologists accreditation standards (Thomas, 2008).

RECOMMENDED POINT-OF-CARE PROTOCOL

Table 6-3 shows the recommended steps that should be taken when POCT tests are set up. In the first step, the equipment must be obtained and

evaluated. Professional laboratorians usually have a good sense of what is available on the market. Point-of-care instrumentation tends to consist of handheld, durable units with easy analysis, simple quality control (QC), varied reporting methods, low throughput, and higher unit cost per test. Easy analysis and simple QC make these methods more likely to be classifiable as waived, allowing less well trained operators. At regular intervals, cross-correlation between POCT methods and central laboratory methods should be obtained to ensure that differences between POCT devices and central laboratory results are minimized and not mistaken for changes in a patient status.

Experience has shown that a POCT site operates far more efficiently when a person of sufficient authority is designated as being responsible for the site. With a responsible person in charge, reporting of suspected equipment malfunctions will be quicker, controls will be more reliably performed, and it is less likely that untrained individuals will attempt to perform testing.

In the third step, persons performing the test must be trained and their competency assessed, and this must be documented. Training documentation should include the date of initial training, as well as any additional in-services and competency assessments conducted. This documentation can include the performance of controls and/or proficiency samples as a measure of competency assessment.

Next, a written procedure must be available and followed. These procedures should adhere to the manufacturer's recommended steps and should be simple, easy to follow, and functional, rather than a collection of articles, package inserts, and instrument protocols that are too disorganized for the inexperienced operator to use. The procedure manual should include specimen requirements; procedures for specimen collection, identification, and processing; assay methods; reference intervals; and quality control and reporting methods. Because this is standard practice in laboratories, it should be fairly easy to have a procedure designed by the central laboratory staff.

Calibrations and quality control samples must be run at regular intervals. This is often the most difficult task to implement with nonlaboratory staff members who have not been indoctrinated in the importance of controls and calibrations. For this reason, many instruments designed for the POCT arena have features that block the reporting of results when appropriate calibrations and controls have not been performed. Some instruments can even lock out staff who have not been properly trained and issued a code recognizable to the machine.

All patient results must be documented, and their relationship to QC measures must be clear. Inspectors are not pleased when they find on tracers from medical records evidence of test results being used 7 days a week and controls being run Monday through Friday by only a small fraction of the users. In addition, if laboratory analyzers are in use, records of preventive maintenance and any corrective maintenance must be kept. Finally, if the POCT is being operated under the certificate of a central laboratory, it is a requirement that these POCT tests be enrolled in a proficiency testing program, such as that provided by the College of American Pathologists, in which results of proficiency samples are sent periodically to the proficiency testing service. These results are compared with those of a peer group to ascertain the accuracy of the specific tests.

Appropriate action must be taken and documented on all out-of-range QC results. Often it is best to have POCT staff call the central laboratory when controls fail because this creates the opportunity to review procedural steps and have a better-trained POCT staff. Quality has costs, but lack of quality can cost even more.

Appropriate action must be documented on all abnormal patient results. In this day of wireless networks, it is better to have POCT results transmitted to the computer and included with laboratory results generated centrally for comparison. If this option is not available, results should at least be written in the chart rather than being acted upon without proper documentation.

SELECTION OF MEASUREMENTS

With the explosion of waived methods coming onto the market, selection of POL/POCT lab measurements should begin with a check of available methods at the FDA website listed previously. The next, if not more important, consideration is the likelihood of reimbursement. Many insurance plans have agreements with national reference laboratories and require that lab tests be referred to the contracted lab. It may be necessary to prove the value of services rendered with patient satisfaction surveys, and the lab should be prepared to document better care and value to the managed care organization.

The next most important consideration in method selection is the volume of patient samples that will be measured and reimbursed. Infrequently performed assays are difficult to control for quality and can lead to expensive outdated of reagents. Some estimate of which measurements are most frequently ordered by the physician clientele is absolutely necessary. Ongoing monitoring of usage statistics in an established laboratory is also necessary. Even university hospitals, which generally attempt to provide full service, require special circumstances before providing an assay that is ordered fewer than 10 times per week. Low volume assays can easily degrade to a situation where controls, standards, calibrators, and repeats outnumber actual billable specimens at ratios greater than 2:1.

Point-of-care instrumentation tends to consist of hand-held, durable units with easy analysis, simple QC, varied reporting methods, low throughput, and higher unit cost. Easy analysis and simple QC make these methods more likely to be classifiable as waived, allowing less well trained operators. The menu of selectable tests can be limited, but the explosion of testing methods in the waived classification is changing this.

Central laboratory equipment tends to consist of desktop or floor standing units with high throughput and low cost per test, with full sample management and reporting capabilities if not connected to a laboratory information system. Here the intent is to perform moderate and high complexity testing. Greater technical skill is usually needed by the operator, and full proficiency assessment, including controls and regular proficiency testing, is required.

With POCT, the two most important considerations that must be taken into account are whether the testing is necessary for immediate decision-making, and whether staff members at the POCT site are sufficiently motivated to comply with testing procedures, including controls and competency maintenance. Examples of immediate decision-making include troponin testing as used in the emergency department (ED) to determine the disposition of the patient, and pregnancy testing administered before radiologic procedures. In these types of situations, the cost recovery in time savings and throughput to a health care system can be greater than the additional costs of maintaining the POCT site.

Maintenance of sufficient motivation by staff members at the POCT site to comply with testing procedures is critical for a successful POCT site. The first step should be to assign responsibility for all testing to someone at the site with sufficient managerial control over staff. Failure to do this usually results in the testing site staff failing to follow procedures because they do not directly report to laboratory staff, and hence perpetual arguments occur between laboratory QC staff and testing site staff.

CURRENT TECHNOLOGY

The test menu is the greatest limitation in current POL/POCT technology. Although a large number of waived methods have been approved by the FDA, many are single test kits or single test strips, and separate devices may be needed at the POCT site to perform needed tests. With diabetes, which could be the largest market for POCT, as an example, where does one find a device that does both glucose and hemoglobin A1c (HbA1c)? This complicates staff training, method calibrations and controls, and reporting mechanisms. Incorporating results into the electronic medical record is hampered by this need for multiple devices, in that the cost of interfacing instruments that perform only one test can be prohibitive. For this reason, medical record interfaces tend to be limited to high volume tests such as bedside glucose testing or multitest platforms such as the I-Stat. The "art" of POL/POCT implementation and/or consultants is knowing how to craft the menu of POCT that would be most effective at a given location.

HEMATOLOGY

Hematology testing is somewhat limited in the POCT arena. Although hemoglobin or hematocrit is available on POCT blood gas or chemistry devices, no waived methods are available for the white blood cell count or differential. Therefore, a busy hematology/oncology service that is dependent on cell counts to decide whether to continue or change the dosage of therapy has to establish a moderate complexity lab with the associated regulatory and personnel requirements, or has to accept the delays of central lab testing.

Coagulation testing using POCT prothrombin time (PT) measurements has become a mature POCT area with the common establishment of "Coumadin clinics," where patients' anticoagulant therapy is monitored and regulated. This is advancing to self-testing with the use of waived devices, similar to home glucose monitoring, where patients monitor and

alter dosage on the basis of home testing. Although this may seem dangerous, Mennemeyer and Winkelman have shown that switching from one laboratory to another between successive PT tests increased the odds of stroke and acute myocardial infarction by factors of 1.57 and 1.32, respectively (Mennemeyer, 1993). Therefore, the use of a consistent device in a POCT setting may be less dangerous than the changes that are seen in the PT and international normalized ratio (INR) when patients switch between laboratories.

CHEMISTRY

Glucose testing is clearly the industry leader in terms of volume of POCT testing, and hemoglobin A1c testing seems to be rapidly increasing. Concern has been expressed about using bedside glucose testing for tight glucose control in the intensive care unit setting because of potential episodes of hypoglycemia (Hoedemaekers, 2008), and Eastham has demonstrated that interfering substances can produce erroneous POCT measurements in 1.2% of patients admitted over a 12-month period (Eastham, 2009).

HbA1c measurements will be used more frequently in the future for the monitoring and diagnosis of diabetes. However, current POCT methods may not be up to the proposed task. Schwartz et al. described a multipractice study that compared a one-step POCT HbA1c instrument with central laboratory measurements; investigators found a bias that indicated that 18% of patients with laboratory HbA1c >7% would have been missed by the POCT test. And in a comparative study, Lenters-Westra and Slingerland found that six of eight available HbA1c POCT sites on the market failed to meet certification criteria of the National Glycohemoglobin Standardization Program (Lenters-Westra, 2010).

Intraoperative immunoassay of parathyroid hormone (PTH) measurements has revolutionized surgery for hormone-secreting tumors such as parathyroid adenomas (Sokoll, 2004). Although the cost of specialized testing in the operating suite using dedicated instrumentation, as well as frequent in-servicing of POCT staff, is high for the laboratory, when this is compared with the per minute cost of operating room time and the labor cost of physicians and staff involved in doing the surgery, the cost to the health care system is markedly reduced by POCT. Accuracy and comparison with the central laboratory PTH level are relatively unimportant because the values that are being compared involve large changes in PTH levels before and after an intervention.

Another area of chemistry that is rapidly changing involves creatinine and cardiac markers in EDs. Creatinine measurements and pregnancy tests are used to determine whether patients can be appropriately referred for radiologic procedures. Nichols et al. (2007) questioned the accuracy of two POCT creatinine assays. But in these situations, when values near the decision points for creatinine are obtained, the specimen can be referred to the central lab for confirmation, while the remaining patients can be moved on more rapidly increasing throughput. With pregnancy testing, an assay with high sensitivity should be selected to yield a high predictive value for a negative result.

In a review of the literature on the use of POCT for serum markers of cardiac necrosis in terms of the process and outcomes of patient care in the ED, Storrow (2009) found general agreement that POCT led to significantly decreased turnaround time for cardiac marker results reporting to the ordering physician. In addition, improvements in other ED efficiency measures (e.g., time to therapy and total ED length of stay) were seen. However, investigators could find no evidence that POCT for cardiac biomarkers has an effect on clinical outcomes of patients evaluated for acute coronary syndrome. In a multicenter, randomized, controlled study comparing laboratory and POCT cardiac marker testing strategies, Ryan et al. (2009) found similar reductions in turnaround time, but effects on ED length of stay varied between institutions. Across all sites, POCT testing did not decrease time to disposition for admitted or discharged patients (Ryan, 2009).

MICROBIOLOGY

Given the long turnaround times experienced with most microbiology testing, the availability of effective POCT could radically change practice in infectious disease. This can be seen quite clearly with the advent of effective POCT for human immunodeficiency virus (HIV). Performance characteristics of the available POCT HIV assays have been reviewed and were found to have comparable sensitivity and specificity to conventional enzyme immunoassays (Campbell, 2009). In early infection, however, these

assays were found to be less sensitive than nucleic acid amplification testing. Appiah (2009) compared POCT HIV testing in a voluntary counseling and testing (VCT) clinic and in a tuberculosis (TB) clinic in Ghana and found that in both clinics, 100% of patients offered POCT accepted it, but only 93% of VCT clients and 40% of TB patients had accepted a standard HIV test offered 6 months earlier. Moreover, all patients attending the VCT or TB clinics who tested positive for HIV with the POCT test returned to the HIV clinic for care, but only 64% and 95%, respectively, of patients who tested positive in the previous cohort had returned for follow-up, indicating a strong change in patient behavior when access to POCT and immediate results is provided (Appiah, 2009).

Other infectious disease POCT is not quite so effective. Rapid group A streptococcal antigen testing is relatively insensitive, with sensitivity estimates ranging from 60% to 90%, making the recommendation necessary for backup blood agar culturing for all negative POCT antigen results. Waived testing for respiratory viruses is limited to respiratory syncytial viruses and influenza A and B viruses with similar sensitivities. Recent experience with the novel H1N1 outbreak, where all POCT tests indicating influenza A were assumed to be positive for H1N1, was less than satisfactory.

POCT IN MILITARY OPERATIONAL ENVIRONMENTS

BACKGROUND CONCEPTS

In the military operational environment, POCT utilizes hand-held testing devices to provide laboratory data on specific patient types in austere settings. Three concepts will help the reader grasp military operational POCT: the echelon of care system, planned evacuation of sick and injured patients, and hostile and/or spartan working conditions. Currently in the United States, theater medical care is organized into five ascending levels of capability (Stephenson, 2008). Echelon I, the lowest level, spans a range from “buddy” or self aid (such as placing a tourniquet on a wounded comrade in the field) to a makeshift medical tent, to a simple Troop Medical Clinic on a small base staffed by a physician and several trained assistants (called medics in the Army and corpsmen in the Navy). These small clinics will offer some POCT and are further discussed later. Echelon II sites are typically mobile facilities where emergent surgical stabilization can be performed. In the U.S. system, these are divided into forward resuscitative surgical suites (FRSSs) with two general surgeons and a few support staff, and forward surgical teams (FSTs) composed of four surgeons, including one orthopedic surgeon, and ancillary staff. The FST is a larger entity than the FRSS, but both can be transported on a few military vehicles and established and broken down in a matter of hours. Echelon II facilities include larger clinics than those in Echelon I, and some have limited in-patient capabilities. Echelon III is equivalent to a Level I trauma center in the United States. Such a facility may be a fixed structure, such as the Craig Joint Theater Hospital in Bagram, Afghanistan, or a series of tents, as in Balad, Iraq. Both offer trauma bays, surgical suites, intensive care unit patient care areas, and 24-hour physician and nurse coverage. The only theater Echelon IV facility is in Landstuhl, Germany. Echelon V centers include Walter Reed Army Medical Center in Washington, DC, the National Naval Medical Center in Bethesda, Md., and the Brooke Army Medical Center in San Antonio, Tex. Patients are successively evacuated to higher echelons, as indicated by their injury or illness, to a facility that can provide definitive treatment or rehabilitation. For the purposes of this discussion, POCT is considered in Echelons I, II, and III—those directly in the theater of operations.

UNIQUE ASPECTS OF MILITARY POCT

Three differences have been observed in military operational POCT compared with POCT in a stateside hospital or clinic: the patient population, the algorithm for decision-making, and the degree of flexibility that providers and technicians have in laboratory testing. First, patients differ in terms of demographic characteristics—most are young and healthy at baseline—and their presenting complaint. Obviously traumatic injury is the most serious complaint, and patients wounded by improvised explosive devices (IEDs) may present with massive tissue trauma and concomitant coagulopathy. Common illnesses include acute gastroenteritis, heat-related symptoms, and upper respiratory infections. Second, POCT is used to make the following decision: Treat the patient and release him to quarters

TABLE 6-4
Point-of-Care Testing (POCT) by Common Patient Type

	Goals	Data needed	POCT instrument
Trauma patient	Assess coagulopathy, anemia from blood loss	PT, PTT, Hb, Hct, electrolytes, blood gas	i-STAT or Hemochron Jr
Acute GI illness	Assess dehydration and electrolyte derangements	BUN, glucose, Hb, Hct, Na, K, Cl, HCO ₃ , anion gap, blood gas	i-STAT
Ward inpatient	Intervene as anemia, coagulopathy, electrolyte, or metabolic disturbances develop	Hb, Hct, PT, Na, K, Cl, HCO ₃ , Glucose	i-STAT, Precision Xtra

BUN, Blood urea nitrogen; GI, gastrointestinal; Hb, hemoglobin; Hct, hematocrit; PT, prothrombin time; PTT, partial thromboplastin time.

(and then have him return to duty), or stabilize the patient and evacuate him to the next echelon of care where more definitive treatment can be provided. Any patient who presents to a theater medical facility is evaluated using this algorithm, and laboratory data are an adjunct in making this decision. Third, laboratory testing in the austere setting of a military theater of operations enjoys flexibility not present in stateside facilities. Far from regulatory agencies, hospital and clinic laboratories have the option to streamline their testing as circumstances warrant. Thus, if quality control reagents cannot be delivered because the tactical environment so dictates, then tests are sometimes performed anyway. The justification is that it is more important to generate laboratory results on a wounded patient with a reasonable assumption that the data are accurate than it is to suspend testing until proper controls can be run. Laboratory staff members make great efforts to adhere to the standards in place in the United States, but do not hesitate to make well-informed adjustments to these standards when necessary.

KEY EXAMPLES OF POCT BY PATIENT TYPE

The Trauma Patient

The goals in this patient type are to stabilize the injured and then evacuate to the next appropriate echelon of care. (Table 6-4 summarizes the goals, necessary laboratory studies, and instruments in use in the theater.) Stabilization involves airway management, immediate wound care, and resuscitation with intravenous (IV) fluids and, as needed, blood products. Evacuation typically occurs within minutes to an Echelon II facility and within hours to an Echelon III hospital, although security and weather factor into this timeline. Patients may be held up to 6 hours at Echelon II and up to 3 days at Echelon III sites, but again, this is dependent on the ability of the patient to be safely evacuated if this is what is required for that individual's care. Key laboratory data in the trauma patient include Hb and hematocrit (Hct), PT, ionized calcium level, and arterial blood gases. The trauma patient with significant hemorrhage is in a dynamic state, and Hb and Hct must be interpreted accordingly; if the patient has been adequately volume resuscitated, then these data are useful. If not, then the ordering physician must integrate this fact into the assessment. A common platform in use in the theater is the i-STAT. The EG7+ cartridge provides Hb and Hct if the sample is anticoagulated with ethylenediaminetetraacetic acid (EDTA), and it provides Na, K, iCa, and blood gas parameters (pH, pCO₂, pO₂, TCO₂, HCO₃, BE, and SO₂) on whole blood samples with no anticoagulator with sodium heparin. Samples with no anticoagulant must be used for the i-STAT coagulation cartridge, which provides PT and INR. Another instrument used to assess coagulopathy is the Hemochron Jr Signature (International Technidyne Corporation, Piscataway, N.J.). It yields partial thromboplastin time (PTT) as well as PT and INR and uses citrated blood, which allows for a brief delay before the

test must be performed. The i-STAT whole blood sample obviously must be run immediately, before the blood clots.

Acute Gastrointestinal Illness

The goals are to assess dehydration and the electrolyte disturbances that accompany it, and from there to determine if the patient can be managed with supportive care where he is, or if he requires evacuation to a higher echelon facility. Echelon I capabilities often include IV fluids and beds or stretchers for very short-term care; Echelon II sites may hold a patient for several hours. Necessary laboratory data include blood urea nitrogen (BUN), glucose, Cl, K, Na, Hb, Hct, anion gap, and blood gases. The i-STAT module EC8+ provides all of these and is a particularly useful cartridge for the patient with vomiting and/or diarrhea. If the laboratory data suggest severe dehydration and electrolyte derangement at an Echelon I facility, evacuation is probably indicated. Milder abnormalities are often managed with 1 to 2 liters of IV fluids, antiemetics, and a sick-in-quarters chit. Because acute gastroenteritis is a very common illness in the operational setting, physicians readily choose an i-STAT cartridge such as the EC8+ to capture just these data.

Ward Inpatients

The goal in the ward inpatient is to assess the patient's hemostatic and metabolic status, identifying any abrupt change that would require intervention. In select patients, blood glucose may be followed easily with POCT. In others, such as trauma victims or the critically ill, PT, Hb, and Hct may be performed immediately to assess a suspected change in hemostasis. Similarly, ionized calcium and electrolytes may be measured at the bedside in a patient with electrocardiogram or mental status changes with quick turnaround. For bedside glucose measurements, the Precision Xtra (Abbott Diabetes Care, Abbott Park, Ill.) is in use in at least one Echelon III center. The i-STAT fills the role of providing the other tests, using the EG7+ and PT/INR cartridges.

LIMITATIONS OF POCT IN OPERATIONAL ENVIRONMENTS

POCT has a few limitations in the operational environment. First, some smaller medical facilities, particularly at the lower echelons, utilize medics without extensive laboratory training to perform tests. Although the military has training programs specifically for laboratory technicians, the medic assigned to an Echelon I facility may be a generalist, or may have special training in some other allied health field but must fill the role of a generalist as operational requirements dictate. Thus, the medic's familiarity and skill in performing laboratory duties is not comparable to what one would see in a stateside hospital. Related to this is the risk that attention to QC and quality assurance (QA), record keeping, and supervisory review will be decreased compared with the norm in U.S. laboratories. This is the downside to increased flexibility. Smaller medical outposts do not willfully ignore the need for QA and documentation, but may of necessity give them lower priority than emergent treatment and evacuation of casualties. Finally, logistical backlogs hinder POCT as well. If controls or reagents cannot be adequately stocked, then technicians must choose between using expired reagents (if they have them) or not performing tests at all. Although the supply chain is an occasional obstacle in stateside laboratories, this is even more likely in a military theater.

CONCLUSIONS

POCT in a military theater of operations balances the limitations incurred in an austere setting with the flexibility inherent in hand-held testing instruments and unique to the field environment. Drawbacks to POCT exist both in the rigor of testing practice—less experienced staff and patchy quality assurance and supervisory oversight—and in the range of tests offered. Logistical considerations preclude the use of all testing panels available with the i-STAT instrument. A few select menus are utilized rather than all that are commercially available. Still, small, mobile platforms such as the i-STAT allow military corpsmen and medics to perform key tests on critically ill and injured patients and to assist in their treatment in a hostile setting, thus representing an extremely valuable adjunct to patient care.

KEY POINTS

- Laboratory results must undergo a two-step postanalytic review for analytic correctness (using delta checks, linearity ranges, etc.) and for clinical significance for the patient (applying critical values, reference ranges, pretest and posttest probability, etc.)
- Reference intervals are most commonly defined as the range of values into which 95% of nondiseased individuals will fall; this definition implies that 5% of nondiseased individuals can have laboratory results outside the reference range.
- The ability of a test to discriminate disease from no disease is described by the sensitivity and specificity of the test. Sensitivity is the probability of a positive result in a person with the disease (true-positive rate). Specificity is the probability of a negative result in a person without disease (true-negative rate).
- Screening tests require high sensitivity so that no case is missed. Confirmatory tests require high specificity to be certain of the diagnosis.
- Altering a test cutoff has a reciprocal effect on sensitivity and specificity. A cutoff can be lowered to include all cases (100% sensitivity), but this reduces the specificity (i.e., increases false-positives).
- Receiver operator characteristic (ROC) curves plot the true-positive rate versus the false-positive rate and graphically present the range of sensitivities and specificities at all test cutoffs. If two tests are compared, the more accurate test is closer to the upper left-hand corner of the ROC curve.
- The likelihood ratio of a test refers to the ratio of the probability of a given test result in the disease state over the probability of the same result in the nondisease state. The likelihood ratio of a test changes as the cutoff value defining disease and nondisease is varied.
- Predictive value describes the probability of disease or no disease for a positive or negative result, respectively. The predictive value of a positive test increases with disease prevalence.

- Bayes' theorem uses information about test characteristics (sensitivity and specificity) and disease prevalence (pretest probability) to obtain the posttest probability of disease, given a positive test. Similarly, it can be used to determine the posttest probability of no disease, given a negative test.
- Evidence-based medicine is a process by which medical decisions can be made by using as many objective tools as possible; it integrates the most current and the best medical evidence with clinical expertise and patient preferences.

Every time a clinical laboratory produces a test result, the value must undergo a two-step postanalytic evaluation process. The result needs to be assessed for analytic correctness and for clinical significance. It is often assumed that these two tasks can be easily divided between the performing laboratory, which is responsible for determination of analytic correctness, and the clinical team, which is responsible for evaluation of the clinical meaning of the results. However, significant overlap is seen in the responsibilities for these tasks. Although the laboratory performs most of the review of laboratory results for analytic reliability by using techniques such as delta checks, flagging of questionable results, moving averages, and linear ranges, it is incumbent upon the clinician to review every laboratory result with regard to the patient's clinical situation and to question the analytic reliability of implausible results. On the other hand, one of the most important factors in the analysis of the clinical significance of a laboratory result is comparison of the reported value versus a reference range. In most settings, reference ranges are determined by the laboratory, with varying degrees of input from the clinical staff. Postanalytic decision-making is therefore a shared responsibility of the laboratory and the clinical staff, and it behooves both groups to maintain constant communications to optimize every part of the process. The purpose of this chapter is to discuss the process of postanalytic review of laboratory data and their use

in medical decision making, and to provide general tools for the objective interpretation of laboratory results.

ASSESSMENT OF ANALYTIC CORRECTNESS OF RESULTS

ALARMS AND FLAGS

Modern diagnostic laboratories often analyze large numbers of samples with highly automated instruments. A majority of the results are never visually inspected by a human eye, and many results are released into patients' electronic medical records without prior review by a laboratory employee. To prevent the release of erroneous results, most laboratories utilize a variety of "flags" or alarms. The flagging of specimens or results that require additional analytic steps or review before they can be released can be performed by the automated instrument itself, by specialized middleware, or by the laboratory information system. Flags can indicate a problem with the specimen (e.g., the presence of an interfering substance) or an issue with the result (e.g., a numeric value outside the analytic range of the method, or the need for confirmation by an additional assay).

Flags for Problem Specimens

Many automated instruments can measure the amount of sample present in a collection tube and flag samples that contain amounts inadequate for a reliable analysis. The laboratory will have to identify another tube containing an adequate sample volume, or will request the collection of a new sample. Another frequent cause of inadequate samples is the presence of high concentrations of interfering substances in the specimen, most commonly lipids (lipemia), hemoglobin (Hb) (hemolysis), paraproteins (gammopathies), or bilirubin (icterus). The mechanism for this interference is dependent on the substance and the analytic method. For example, in spectrophotometric assays, lipids interfere mainly by increasing light scatter (turbidity); in assays using ion-specific electrodes for measurement, lipids will affect results by solvent exclusion. A more detailed discussion of interference mechanisms is provided elsewhere in this text. Most commercial assays will list concentrations of interfering substances, above which assay results are no longer valid. Visual inspection is often an adequate means of assessing the presence of unacceptable concentrations of interfering substances. Samples that are grossly hemolyzed or icteric, for example, may be immediately flagged by the technologist as inappropriate for analysis. However, automated analyzers are able to detect troublesome levels of interfering substances, even when they are not apparent to the laboratorian at the macroscopic level. Automated systems can measure the concentrations of bilirubin, lipid, and hemoglobin in samples and can present the degree of interference present as an index (Vermeer, 2005; Kroll, 1994). If the index exceeds a given threshold, then the sample is flagged as problematic and should be rerun after removal of the interfering substance, or it should be rejected. Serum bilirubin and Hb levels have been shown to correlate very tightly with interference indices, but because of the chemical heterogeneity of serum lipids, lipemia indices do not correlate as well (Fossati, 1982).

Flags for Specimens That Require Additional Analysis With Another Method

Some laboratory technologies are screening methods that allow for rapid analysis of large numbers of samples, almost instantaneous reporting of results on most samples, and identification of potentially abnormal samples, which requires follow-up with a more labor-intensive method. Automated cell counters are the paradigm of such instruments. These instruments can often analyze more than 100 samples per hour in a highly automated fashion; samples that are normal or that show only quantitative abnormalities (e.g., increased or decreased percentage of lymphocytes, low platelet counts, low red cell counts) can be reported immediately, and samples that could potentially contain qualitative abnormalities (e.g., atypical lymphocytes, platelet clumps, red cell fragments) are flagged for preparation of a blood smear and further evaluation. The flags are generally based on forward- and side-scatter and impedance measurements that provide information about size and nuclear complexity/granularity of the cells, and on special stains that help identify the potential presence of immature cells (Fujimoto, 1999). The sensitivities and specificities of these flags show poor discriminatory power, and clinical judgment is needed if suspicion of an underlying hematologic abnormality is high (Briggs, 1999; Ruzicka, 2001; Thalhammer-Scherer, 1997).

Flags for Problematic Results

An analyte concentration outside the validated linear range is another common problem affecting samples. Generally, package inserts of commercial assays will provide end-users with an estimated range within which an increase in signal is linearly related to an increase in the analyte concentration. The laboratory may validate this range or may establish its own acceptable linear range when the assay is introduced. Analyzers, middleware, or the laboratory information system will identify and flag samples in which the measured analyte values falls outside the linear range. If the analyte falls above the linear range, many instruments can automatically dilute and reanalyze the sample. In some cases, a manual dilution may be necessary, or the information that the result is higher than a certain value may be sufficient for the requesting clinician. For example, patients in diabetic ketoacidosis will have glucose measurements >1000 mg/dL, far exceeding the linearity of most analyzers. These samples will be flagged, diluted by a predetermined factor, and then rerun before reporting. If an analyte concentration falls below the linear range, the sample is usually reported as "less than the limit of detection."

DELTA CHECKS

Advances in computer technology have facilitated the storage of data from large numbers of patients and increasingly complex calculations in laboratory information systems. This has made it possible to use patient data for quality control purposes in real time. For example, most laboratories routinely submit the results of certain laboratory assays to "delta checks" before releasing them into the patient record. Delta checks are defined as comparing a current laboratory result with results obtained on a previous specimen from the same patient. Parameters chosen for delta checks should not be subject to large intraindividual variations; for example, many laboratories have delta checks in place for the mean corpuscular volume of red cells. Suggested assays, thresholds, and time intervals between measurements can be found in the literature (Ladenson, 1975). Some studies have suggested the comparison of multiple test parameters to decrease the false-positive rate of the delta check; however, few laboratories have implemented such delta checks. Types of errors detected with delta checks include preanalytic (e.g., mislabeling of specimens) and analytic issues (e.g., aspiration of insufficient sample volume by the instrument sample probe) (Kazmierczak, 2003). Laboratories should define procedures for samples that have been flagged by delta checks; protocols usually incorporate repeating the assay, reviewing the specimen identification, and notifying the clinical staff of the possibility of a mislabeled specimen.

ASSESSMENT OF CLINICAL SIGNIFICANCE OF RESULTS

CRITICAL VALUES

A critical value (also known as a panic or alert value) is a laboratory result that may represent a life-threatening situation that may not otherwise be readily detectable and therefore requires rapid communication with a health care provider who can provide necessary medical interventions. The speedy communication of such results is required by federal law and regulatory agencies, and The Joint Commission has made it one of its National Patient Safety Goals. Regulations require that the critical value and the patient affected are read back by the health care provider to verify that the result was correctly communicated. The laboratory then has to document the communication of the critical value, the name and title of the caregiver who was notified, the time and date of notification, and the read-back by the care provider.

No universally accepted guidelines indicate which assays should have critical values, what the thresholds should be, whether critical values should be repeated before reporting, and what is an acceptable time from result availability to caregiver notification. Although it is generally established that critical values must be called to a caregiver who has the ability to act upon the information, there is no universal agreement regarding the types of caregiver (e.g., physician's assistant, registered nurse) who fulfill this definition. This has caused significant variation in procedures related to critical values at different institutions. It is ultimately the responsibility of the medical director of the laboratory to work with clinical colleagues to develop a critical values policy that meets the needs of patients and staff served by the laboratory.

REFERENCE RANGES

Definition of Reference Intervals

Comparison of a laboratory result versus a reference or “normal” range is often one of the most important aspects of medical decision making. Reference intervals are usually defined as the range of values into which 95% of nondiseased (“normal”) individuals will fall; the corollary of this definition is that 2.5% of nondiseased individuals will have laboratory results below the reference range, and 2.5% of nondiseased individuals will have laboratory results above the reference range. For some analytes, the reference range is defined as “less than” or “greater than” a certain value; for example, a prostate-specific antigen (PSA) level of 4 ng/mL is often used to distinguish patients who require no further follow-up (“normal”) from those who require a prostate biopsy (“abnormal”). Some reference ranges have been defined by professional organizations without adherence to the 95% rule. A paradigm of this is the recommendation of American and European cardiology associations that “an increased value for cardiac troponin should be defined as the measurement exceeding the 99th percentile of a reference control group” (Alpert, 2000). For other analytes (e.g., cholesterol/lipids), laboratories frequently provide therapeutic target ranges that represent recommendations based on clinical trials and/or epidemiologic studies (Grundy, 2004). Finally, it is common practice to provide therapeutic and/or toxic ranges for drug measurements.

Factors That Influence Reference Ranges

A variety of factors can influence reference ranges. Different laboratory methods often yield significantly different results and therefore require different reference ranges. This phenomenon is best documented and understood for methods in which measurement of the analyte is based on one or more antibody–antigen interactions, but it can affect all analytic methods. Because of differences in age, genetic background, or exposure to environmental factors, different populations may need different reference ranges for certain laboratory analytes. Many other factors such as the containers into which specimens were collected (e.g., glass vs. plastic tubes), the mode of transport to the laboratory (by messenger or by pneumatic tube system), the time between obtaining the specimen and analysis, and the storage conditions of the specimens before analysis can affect reference ranges.

Determination of Reference Ranges

Because many factors can affect reference ranges, laboratories are strongly encouraged to perform their own studies to establish reference ranges for all analytes they report, usually by testing at least 120 samples from nondiseased individuals in each “partition” (e.g., gender, age group). If this is not possible, the laboratory can verify a reference interval that it has previously established for a different method by transference (i.e., demonstrating that the new method yields identical results to the previous method). If the analyte was not previously tested for in the laboratory, the laboratory can verify another laboratory’s or the manufacturer’s reference interval (CLSI, 2008).

Variability of Laboratory Results

Interindividual variation of laboratory results often occurs because of factors specific to individual patients. For example, creatine kinase (CK) levels are proportional to muscle mass. Thus, a population of normal subjects will express a range of CK values according to each individual’s muscle mass, but an individual patient will have a unique set value that is “normal” for that individual. In clinical practice, this unique value, if known, is the best “reference value” for a particular individual. Comparison of test results from a patient versus such an individualized reference value has to take into account random variability. Random variability is the sum of analytic and intraindividual variability. Analytic variability is the result of assay imprecision. It is usually determined during validation studies for a new method by running the same sample multiple times and is expressed quantitatively as the coefficient of variation (CV). Intraindividual variability is due to biologic changes that cause analyte levels to fluctuate over time. Well-known examples of this phenomenon include diurnal variations in cortisol levels, estrogen levels that vary with the menstrual cycle, and seasonal variations of vitamin D. Many other analytes show some biologic variability, including changes related to exercise or food intake. Table 7-1 provides estimates of interindividual and intraindividual biologic variation for common analytes. As expected, intraindividual variation is generally less than interindividual variation. The index of individuality is the ratio of intraindividual CV to interindividual CV. A low index (<0.6) means that results from a given individual fluctuate within a

Figure 7-1 Distribution of test results from nonoverlapping populations of patients with and without disease (see Table 7-3). *TN*, True-negative; *TP*, true-positive.

Figure 7-2 Distribution of test results from overlapping populations of patients with and without disease (see Table 7-3). *FN*, False-negative; *FP*, false-positive; *TN*, true-negative; *TP*, true-positive.

narrow range of the reference interval. In such instances, serial changes in an individual’s analyte may be more useful in detecting disease than in comparing each of the measurements versus the reference interval (Lacher, 2005). Table 7-1 also shows that the method CV or degree of analytic variability is usually much lower than the biologic variability and hence is much less of a factor in affecting the overall random variability of measurements. For some analytes, guidelines have been published as to what constitutes a clinically significant difference between two consecutive patient sample results. As an example, Table 7-2 provides this information for various thyroid function tests (Baloch, 2003).

GENERAL PRINCIPLES FOR THE INTERPRETATION OF LABORATORY RESULTS

DIAGNOSTIC ACCURACY

Truth Table

Clinicians often find it helpful and intuitive to dichotomize a continuous test result into a binary one by applying a threshold value for the analyte. Although the reference range can be used to separate normal from abnormal values, clinically validated thresholds are also commonly used for disease classification. For example, the reference range for Hb A1c in a laboratory may be 4.0%–6.0%, but the clinically established threshold to classify a patient as diabetic is 6.5%. This means that a patient’s result can be outside the reference range without meeting the threshold for diabetes.

A test with perfect diagnostic accuracy could determine the presence or absence of disease with certainty, and the established cutoff point would perfectly separate diseased from not diseased populations (Galen, 1975) (Fig. 7-1). However, nearly all laboratory tests are imperfect, and overlap is seen between populations at both low and high cutoffs (Fig. 7-2).

The diagnostic accuracy of a test is determined by comparing the test’s ability to discern true disease from nondisease as determined by a diagnostic gold standard (i.e., truth). Based on results from the test and the gold standard, patients can be classified into four groups in a 2×2 table (see Fig. 7-2 and Table 7-3). Patients correctly classified as abnormal are called true-positives (TPs) and those correctly classified as normal are called true-negatives (TNs). These true results are the nonoverlapping areas of the two patient distributions. False results occur because the two populations overlap (i.e., because a test cannot completely discriminate all abnormal patients from normal ones). Patients incorrectly classified as

Truth (2 × 2) Table: Classifying Patients

Result	Disease	No disease	Total
Positive	TP	FP	TP + FP
Negative	FN	TN	FN + TN
Total	TP + FN	FP + TN	TP + FP + FN + TN
Sensitivity (%) = $100 \times \left(\frac{TP}{TP + FN} \right)$			
Specificity (%) = $100 \times \left(\frac{TN}{TN + FP} \right)$			
Positive predictive value (%) = $100 \times \left(\frac{TP}{TP + FP} \right)$			
Negative predictive value (%) = $100 \times \left(\frac{TN}{TN + FN} \right)$			

FN, False-negative; FP, false-positive; TN, true-negative; TP, true-positive.

Figure 7-3 Effects of varying the test cutoff on overlapping populations of patients with and without disease.

TABLE 7-4

Example Truth (2×2) Table

Result	Disease	No disease	Total
Positive	196	20	116
Negative	4	180	184
Total	200	200	400

$$\text{Sensitivity (\%)} = 100 \times \left(\frac{196}{196 + 4} \right) = 98\%$$

$$\text{Specificity (\%)} = 100 \times \left(\frac{180}{180 + 20} \right) = 90\%$$

$$\text{Positive predictive value (\%)} = 100 \times \left(\frac{196}{196 + 20} \right) = 91\%$$

$$\text{Negative predictive value (\%)} = 100 \times \left(\frac{180}{180 + 4} \right) = 98\%$$

In this evaluation study of a hypothetical cardiac marker, 200 patients with acute myocardial infarction (AMI) and 200 healthy subjects are recruited for a study designed to mimic a prevalence of 50%. The assay is performed and is compared with a “gold standard” test for AMI, and the 2×2 truth table shown here is generated. Measures of diagnostic accuracy are determined according to the formulas outlined in Table 7-3.

normal are false-negatives (FNs), and those incorrectly classified as abnormal are false-positives (FPs). As seen in Figure 7-3, where for ease of illustration a single cutoff is used to discriminate disease from normal populations, varying the cutoff changes the numbers of true and false results in a given population. False results are produced when an analyte has two relevant cutoffs (e.g., thyroid-stimulating hormone), with overlapping populations at both the low end and the high end.

Sensitivity and Specificity

Sensitivity and specificity are measures of the diagnostic accuracy of a test; they are indicators of a test's ability to distinguish between disease and absence of disease at a chosen cutoff. Sensitivity and specificity therefore are not fixed characteristics of a test and must be calculated from a different 2×2 table for each cutoff chosen.

Sensitivity is the ability of a test to detect disease and is expressed as the proportion of persons with disease in whom the test is positive (see Tables 7-3 and 7-4). It may also be thought of as the probability of a positive test given a true disease state as defined by the gold standard. A test that is 90% sensitive will give positive results in 90% of diseased patients (TP) and negative results in 10% of diseased patients (FN). Specificity is the ability to detect the absence of disease and is expressed as the proportion of persons without disease in whom the test is negative (see Tables 7-3 and 7-4). It may be thought of as the probability of a negative test, given no disease as defined by the gold standard. Thus a test that is 90% specific will give negative results in 90% of patients without disease (TN) and positive results in 10% of patients without disease (FP). A test with a higher sensitivity identifies a greater proportion of persons with disease, and a test with a higher specificity excludes a greater proportion of persons without disease.

Sensitivity is also the TP rate, and the inverse ($1 - \text{sensitivity}$) is the FN rate. If the sensitivity is 95%, 5 of 100 individuals with the disease will test negative. Specificity is the TN rate, and the inverse ($1 - \text{specificity}$) is the FP rate. If the specificity is 95%, 5 of 100 individuals without disease will test positive.

Effect of Altering the Test Cutoff

When a test cutoff is altered, an inverse relationship between sensitivity and specificity is noted, and a trade-off between the numbers of FP and FN results can be seen. Altering a cutoff changes a test's sensitivity and specificity because it relates to overlapping normal and abnormal patient distributions along the test value continuum (see Fig. 7-3). For tests where high values indicate disease, lowering the cutoff (i.e., moving the cutoff line to the left) will lead to more diseased persons being classified as abnormal. Thus, in Figure 7-3, changing the cutoff from C to B increases sensitivity. If the cutoff is moved to A, then all diseased persons will have a positive test, and the sensitivity will be 100%. However, increased sensitivity is associated with decreased specificity, and the number of non-diseased persons with a positive test (FPs) increases as the cutoff is moved from C to B to A. If the cutoff is raised (i.e., the cutoff line is moved to the right), more nondiseased patients are classified correctly, and specificity increases. If the cutoff is moved to E, then all nondiseased persons will have a negative test, and the specificity will be 100%. However, this will be accompanied by concomitant decreased sensitivity and additional FN results.

The Need for High Sensitivity Versus High Specificity

FP and FN results can lead to misdiagnosis and inappropriate clinical management with adverse clinical and financial consequences. For example, a FP result may cause the unnecessary admission of a patient, needless additional testing, and invasive procedures. Similarly, a FN result may lead to a patient's release from the emergency department despite a life-threatening disorder. Enhanced assays that provide improved sensitivity and specificity and thereby allow better discrimination between diseased and nondiseased populations continue to be developed. However, it is nearly impossible to eliminate false results entirely because some overlap between diseased and nondiseased persons is always evident. In most situations, the cost of a FP or a FN result supersedes the other, and the cutoff that delineates normal from abnormal can be shifted to reduce the more significant of the two consequences.

In general, the sensitivity of a test used to screen a population for a serious disease should be high to capture the majority of cases for confirmation by a gold standard. When PSA is used to screen for prostate cancer, a low threshold is used to capture all potential cases. Many men without a malignancy (e.g., prostatitis, nodular hyperplasia) will also have a positive result and need to undergo an invasive procedure for a definitive diagnosis. These “unnecessary” prostate biopsies, which are performed to confirm the true cases of prostate cancer, are the FP cost of this sensitive, but not specific, screening test. In contrast, high specificity is required when the definitive diagnosis of a serious condition will be based on a positive result; initiation of toxic or costly therapy can be based only on a test with the ability to “rule in” the disease with high confidence. A highly specific test excludes persons without disease (eliminates FPs). In a test where higher values indicate disease, specificity can be increased by increasing the cutoff, thereby excluding all persons without the disease; however, this will also exclude some persons with the disease (see Fig. 7-3).

Less expensive and less labor-intensive screening procedures with high sensitivity are often used in combination with more complex, highly specific tests for confirmation. For example, an enzyme-linked immunosorbent assay (ELISA) is used as an initial test to screen for human immunodeficiency virus (HIV) infection by detecting broadly reacting antibodies against HIV antigens. However, some noninfected individuals with cross-reactive antibodies might test positive (FPs) with the highly sensitive ELISA screen. These FP individuals can be identified with a highly specific follow-up test, usually a Western blot. In many combinations of screening and confirmatory tests, the confirmatory test is both highly specific and highly sensitive, but is inappropriate to use as a screening test because of cost or test complexity.

Predictive Value and Prevalence of Disease

The predictive value of a positive test (sometimes referred to as positive predictive value) may be understood as the probability that a positive test indicates disease. It is the proportion of persons with a positive test who truly have the disease (see Tables 7-3 and 7-4). The predictive value of a negative test (sometimes referred to as negative predictive value) is the probability that a negative test indicates absence of disease. It is the proportion of persons with a negative test who are truly without disease (see Tables 7-3 and 7-4).

TABLE 7-5

Positive Predictive Value Decreases With Decreasing Disease Prevalence

Result	Disease	No disease	Total
Positive	49	95	144
Negative	1	855	856
Total	50	950	1000

Positive predictive value (%) = $100 \times \left(\frac{49}{49 + 95} \right) = 34\%$

Negative predictive value (%) = $100 \times \left(\frac{855}{855 + 1} \right) = 100\%$

In this study, a population of 1000 hospitalized patients is studied. Fifty (50) patients are determined to have an acute myocardial infarction (AMI), and 950 patients do not have an AMI according to a "gold standard" (prevalence = 5%). If the cardiac marker described in Table 7-4 is performed on this population, we would expect a TP rate of 49 (50 AMI patients \times sensitivity = 50×0.98) and a FN rate of 1 (FN = total AMI – TP = $49 - 1$); a TN rate of 855 (950 non-AMI \times specificity = 950×0.90) and an FP rate of 95 (total non-AMI – TN = $950 - 855$). The positive predictive value of the test decreases with a lower prevalence.

FN, False-negative; FP, false-positive; TN, true-negative; TP, true-positive.

The diagnostic accuracy of a test tends to diminish as the test becomes more widely used in a population. Initial validation studies are often performed on a small group of individuals in whom disease is clearly absent or present. Those who lack the disease are often selected from a population of subjects in overall good health. In practice, however, patients exhibit a spectrum of illness, including early or mild disease, which overlaps with nondiseased individuals, including those with other diseases, some cases of which might cause an abnormal test result. Thus, the proportion of false test results is often higher in clinical practice than is claimed by the manufacturer from more limited studies in healthy individuals.

The predictive value of a positive test is highly dependent on the prevalence of the disease being tested. The higher the prevalence, or pretest probability, the higher the posttest probability, or predictive value of a positive test. Consider a test with a sensitivity of 90% and a specificity of 90% for a disease with a prevalence of 0.1%. Based on the formula, the predictive value of a positive result (PV+) would be 0.9%. If the prevalence increases to 5.0%, the PV+ increases to 32%. Thus the predictive value of a positive test increases as the prevalence increases. This effect of prevalence on predictive value is shown in Table 7-5. Predictive value theory quantifies a concept that is intuitively obvious—a positive result is more likely to truly reflect disease if it comes from a population of patients with a high prevalence of disease.

The impact of prevalence on predictive value theory has a practical application in that it enables one to derive a higher predictive value from results of a test performed in a high prevalence setting as compared with a low prevalence setting. For example, consider serum creatine kinase-MB (CK-MB) measurement for a patient in the emergency department. The predictive value of an abnormal CK-MB might be only 10%. On the other hand, if cardiac damage is strongly suspected, the patient might be transferred to the cardiac care unit (CCU), where, on repeat testing, an elevated serum CK-MB will have a much higher predictive value. In the restricted setting of a CCU, the prevalence of acute myocardial infarction is higher. We can also examine this situation from a pretest probability point of view. For the patient to be in the CCU (instead of still in the emergency department), the clinical suspicion of myocardial damage must be significantly higher. Because pretest probability determines posttest probability, the stronger pretest suspicion translates into stronger prediction of disease (see Bayes' theorem later).

For a disease with low prevalence, even a test with high sensitivity and specificity will yield a low predictive value because most positive test results will be FPs. For example, consider a disease with a prevalence of 1 in 10,000 and a test that is 99% sensitive and 99% specific. The PV+ will be only about 1% because 99 of every 100 who test positive have a FP result. One can see that the accuracy of tests for rare conditions must be very high to reliably predict disease. Thus, besides requiring near perfect sensitivity, tests that are used to screen for rare diseases have greater utility in selected populations that offer a higher pretest probability.

On the other hand, the predictive value of a negative test decreases as the prevalence of disease increases. However, the effect is small, especially when sensitivity and specificity are high. Prevalence influences the

TABLE 7-6

Predictive Value of a Positive Test: The Effect of Prevalence and Accuracy

Prevalence, %	PREDICTIVE VALUE OF A POSITIVE TEST	
	Sensitivity, 90% Specificity, 90%	Sensitivity, 99% Specificity, 99%
0.01	0.09	0.9
0.1	0.9	9
5	32.1	83.9
50	90.0	99

predictive value of a negative test to a noticeable extent only when the starting prevalence is high.

Predictive Value and Accuracy

Improved accuracy (i.e., sensitivity and specificity) enhances the predictive value of a test. The formula for predictive value (see Table 7-3) from Bayes' theorem shows that sensitivity and specificity influence the predictive value. Further, Table 7-6 shows that the predictive value of a positive test increases with increasing prevalence and improved accuracy. Specificity has the biggest impact on the predictive value of a positive test, whereas sensitivity determines the predictive value of a negative test. This is also appreciated from Table 7-5, where the number of FPs directly influences the predictive value of a positive test, whereas the numbers of FNs have the same effect on a negative test.

When a test cutoff changes, its accuracy (sensitivity/specificity) and predictive value also change. As an example, D-dimer testing is used to exclude deep vein thrombosis in patients who present to the emergency department. In the reference population, a value greater than 400 U/mL is considered abnormal and indicative of thrombosis. For a patient in the emergency department with symptoms suggestive of thrombosis, an even lower D-dimer value will predict thrombosis to the same extent as the >400 U/mL value does in the general population. (Recall that posttest probability is dependent on pretest probability.) Because a cutoff of 400 U/mL is not 100% sensitive, it excludes some patients with thrombosis, thereby yielding FNs. Because one cannot risk neglecting a possible case of thrombosis, a lower value of 200 U/mL could be selected to improve sensitivity, decrease the proportion of FNs, and greatly improve the predictive value of a negative test. A negative test could then be used to exclude thrombosis and obviate the need for additional costly diagnostic studies such as radiologic scans or lower extremity Doppler.

BAYES' THEOREM

Clinical assessment and diagnostic tests are inherently flawed, and these uncertainties must be considered when medical decisions are made. Sensitivity and specificity represent a summary of the diagnostic accuracy of a test, but they do not indicate the probability that an individual patient has a disease after the test result is obtained. It would be useful to know how the test result changes the probability of disease (i.e., posttest probability), given certain assay characteristics and disease prevalence (i.e., pretest probability). Alternatively, it is useful to know that a condition can be ruled out given a negative test if the probability of disease after a negative test is very low. To determine this information, one must consider predictive value theory, also known as Bayes' theorem. Bayes' theorem describes the relationship between posttest and pretest probability of disease or no disease based on the sensitivity and specificity of the test. $P(D)$ is the probability of disease before the test result is obtained; this is also known as clinical suspicion, prevalence, or pretest probability. $P(D|T)$ is the probability of the disease after the test result is known; this is the posttest probability. $P(D|T)$ is the probability that the test is positive when the disease is present, or the TP rate. $P(\bar{D})$ is the probability of not having the disease. $P(T|\bar{D})$ is the FP rate. The probability (posttest) of disease or no disease is calculated; examples are shown in Table 7-7.

$$P(D|T) = \frac{P(T|D) \times P(D)}{P(T|D) \times P(D) + P(T|\bar{D}) \times P(\bar{D})}$$

$$\text{Posttest probability} = \frac{\text{sensitivity} \times \text{pretest probability}}{(\text{sensitivity} \times \text{pretest probability}) + (\text{FP} \times [1 - \text{pretest probability}])}$$

TABLE 7-7

Posttest Probability (Predictive Value) from Bayes' Theorem

Posttest probability of disease (predictive value) depends on diagnostic accuracy and disease prevalence. A test for rheumatoid factor is positive in 95 of 100 patients with rheumatoid arthritis (RA) (sensitivity of 95%), but is also positive in 10 of 100 non-RA patients (specificity of 90%). The RA pretest probability (prevalence) is 5% in a rheumatology practice.

$$\text{Posttest probability} = \frac{\text{sensitivity} \times \text{pretest probability}}{(\text{sensitivity} \times \text{pretest probability}) + ((1 - \text{specificity}) \times [1 - \text{pretest probability}])}$$

$$\text{Posttest probability} = \frac{0.95 \times 0.05}{(0.95 \times 0.05) + (0.1 \times 0.95)} = 33\%$$

Posttest probability of no disease for the same test characteristics.

$$\text{Posttest probability} = \frac{(1 - \text{pretest probability}) \times \text{specificity}}{((1 - \text{pretest probability}) \times \text{specificity}) + ((1 - \text{sensitivity}) \times [1 - \text{pretest probability}])}$$

$$\text{Posttest probability} = \frac{0.95 \times 0.9}{(0.95 \times 0.9) + (0.05 \times 0.05)} = 99.7\%$$

The theorem applies population data and test characteristics directly to an individual subject, and calculates the probability of the presence of a disease for a particular patient after a positive test result is obtained and, alternatively, the probability of the absence of disease given a negative test. Although sensitivity and specificity describe a test at a particular cutoff value (e.g., what percent of diseased patients have abnormal results?), the predictive value describes the state of the patient (e.g., how likely is it that a given patient's positive result indicates disease?). The predictive value depends on sensitivity, specificity, and prevalence of the disease being tested. Table 7-6 illustrates how disease prevalence, test accuracy, and predictive value of a test are interrelated (Bayes' theorem).

This approach requires information about the individual patient and clinical suspicion of disease, which includes prevalence of the disease in different populations, to establish the pretest probability of a patient having a disease. For example, **if nothing is known about a patient other than the test result**, then the pretest probability of disease would be the prevalence of the disease in the population. Clinical suspicion may raise this pretest probability to 50% based on a thorough clinical history and physical examination, the clinician's personal experience, and knowledge of relevant literature. Pretest probability, or a priori probability, is the prevalence of disease in the patient's clinical setting. For example, the prevalence of myocardial damage among subjects with chest pain is higher in the CCU than it is in the emergency department.

The pretest probability is used in conjunction with the characteristics of diagnostic accuracy as summarized in the sensitivity and specificity of the test. Posttest probability, or a posteriori probability, is the probability of disease in the posttest situation and is commonly referred to as the predictive value of the test. As described earlier, pretest probability and posttest probability are related through Bayes' theorem (Table 7-7). Additionally, $\text{posttest probability} = \text{posttest odds} / (\text{posttest odds} + 1)$. The value of posttest odds is equal to the pretest probability \times the likelihood ratio (LR). The LR is used to change the probability based on test characteristics, as described later.

LIKELIHOOD RATIO

The LR is a convenient measure that combines sensitivity and specificity into a single number (Table 7-8). Similar to these other measures of test accuracy (sensitivity and specificity), the LR is an assessment of test performance, and not of disease status, in the patient being tested. Two likelihood ratios are known: the likelihood ratio of a positive test (LR+) and the likelihood ratio of a negative test (LR-) (see Table 7-8). The LR+ is the ratio of two probabilities: the probability of a positive test result when disease is present (TP) divided by the probability of the same test result when disease is absent (FP). In other words, the calculation gives the likelihood that a test result will occur in a diseased patient as opposed to a healthy one. For example, serum lipase is used to detect acute pancreatitis; it may be elevated (higher than the cutoff of 200 U/L) in 90 of 100 individuals with acute pancreatitis, but it may be similarly elevated in 10 of

TABLE 7-8

Likelihood Ratio (LR)

Definition:

$$\text{LR} = \frac{\text{probability of test result in persons with disease}}{\text{probability of same result in persons with no disease}}$$

Example

$$\text{LR+} = \frac{\text{sensitivity}}{1 - \text{specificity}}$$

From Table 7-7, using the test for rheumatoid factor (RF) that is positive in 95 of 100 rheumatoid arthritis (RA) patients (sensitivity of 95%) but also positive in 10 of 100 non-RA patients (specificity of 90%)

$$\text{LR+} = \frac{95}{\frac{100}{10}} = 9.5$$

$$\text{LR-} = \frac{1 - \text{sensitivity}}{\text{specificity}}$$

The same test for RF is negative in 90 of 100 non-RA patients but is also negative in 5 of 100 RA patients.

$$\text{LR-} = \frac{\left(\frac{5}{100}\right)}{\left(\frac{90}{100}\right)} = 0.06$$

100 individuals with other causes of abdominal pain. The LR+ at the 200 U/L cutoff is 9, which means that an abnormal lipase is nine times more likely in individuals with pancreatitis than in those without, or nine times as many patients with pancreatitis than with other abdominal diseases will have an elevated lipase. The LR refers to the likelihood of the test result, given the disease. This is not the same as the likelihood of pancreatitis being nine times greater, given an abnormal lipase. The latter would be the predictive value of a positive lipase. Alternatively, the LR- is the probability that an individual with the disease will have a negative test divided by the probability that an individual without the disease will have a negative test. Additional advantages of the LR are that it is not influenced by disease prevalence, and the LR can be calculated for multiple test cutoffs. Thus, a result's degree of abnormality can be taken into account and medical decisions can be made at a point where fewer FN and FP results are seen.

The LR may also be used, along with pretest probability (prevalence), to calculate posttest probability (predictive value). Although the concept is similar to Bayes' theorem, LR is used to calculate posterior probabilities in terms of odds and not direct probabilities, making it less intuitive than Bayes' method. This is illustrated in the examples in Table 7-9. For a positive test, an LR+ >1 will increase the posttest probability. The larger the LR, the greater is the difference between pretest and posttest probabilities. Regardless of prevalence, a high LR increases the probability that a positive test result predicts disease. The converse applies for a negative test result, for which any LR- <1 will decrease the posttest probability. Thus, tests likely to be useful in clinical practice are those for which a positive result has a high LR and a negative result has a low LR.

FAGAN NOMOGRAM

Table 7-9 shows two examples of how to calculate posttest probability, which can be very cumbersome. The Fagan nomogram is a convenient graphic tool that uses a logarithmic scale to determine posttest probability, given the LR at a specified cutoff and the pretest probability (Fagan, 1975). The pretest probability (e.g., clinical suspicion, prevalence) is plotted on the y-axis on the left-hand side, the posttest probability on the right-hand side, and the LR between them (Fig. 7-4, A). When the Fagan nomogram is used, the pretest probability is located on the left axis, and a line is drawn from that point to the LR+ value. Then this line is further extended until it intersects the right axis at the posttest probability. Online calculators are available to establish these values with a graphic representation (Schwartz, 2002). The example in Figure 7-4, B, is taken from the data in Example 1 in Table 7-8. In this example, a line is drawn from the pretest probability of 5% to the LR for a positive rheumatoid factor test (LR+ = 9.5) at a particular cutoff. The line is then extended and crosses the right axis to give a posttest probability of approximately 30%, which

TABLE 7-9

Likelihood Ratio (LR) and Probability of Disease

The LR and pretest probability (prevalence) can be used to calculate posttest probability (predictive value). This is best understood by expressing probability in terms of odds.

Definitions:

$$\text{Pretest odds} = \frac{\text{pretest probability}}{1 - \text{pretest probability}}$$

Step 1. Pretest probability is converted to pretest odds to calculate posttest odds of disease or no disease (see examples).

$$\text{Posttest odds} = \text{pretest odds} \times \text{LR}$$

Step 2. Posttest odds is calculated. Note: As LR of a positive or negative result increases, so do the odds that the result will predict disease or no disease, respectively.

$$\text{Posttest probability} = \frac{\text{posttest odds}}{(1 + \text{posttest odds})}$$

Step 3. Odds are converted back into probability to calculate the posttest probability (predictive value) of a positive or negative test.

Example 1

From Table 7-7, the rheumatoid arthritis pretest probability (prevalence) is 5% in a rheumatology practice. From Table 7-8, the LR of a positive rheumatoid factor test is 9.5. Note that the probability of disease increases from 5% (pretest) to 33% (posttest) because of the positive test result.

$$\text{Pretest odds} = \frac{\text{pretest probability}}{1 - \text{pretest probability}} = \frac{0.05}{1 - 0.05} = 0.053$$

$$\text{Posttest odds} = \text{pretest odds} \times \text{LR} = 0.053 \times 9.5 = 0.5$$

$$\text{Posttest probability} = \frac{\text{posttest odds}}{(1 + \text{posttest odds})} = \frac{0.5}{(1 + 0.5)} = 0.33 \text{ or } 33\%$$

Example 2

From Table 7-8, the LR of a negative rheumatoid factor test is 0.06.

Although the probability of disease increases from 5% (pretest) to 33% (posttest) because of the positive test result (Example 1), the probability of disease decreases from 5% (pretest) to 0.3% (posttest) because of the negative test result.

$$\text{Pretest odds} = \frac{\text{pretest probability}}{1 - \text{pretest probability}} = \frac{0.05}{1 - 0.05} = 0.053$$

$$\text{Posttest odds} = \text{pretest odds} \times \text{LR} = 0.053 \times 0.06 = 0.003$$

$$\text{Posttest probability} = \frac{\text{posttest odds}}{(1 + \text{posttest odds})} = \frac{0.003}{1 + 0.003} = 0.3\%$$

is similar to the numeric calculation. In Example 2, the same pretest probability with a likelihood ratio of a negative rheumatoid factor test of 0.06 shows a posttest probability of approximately 0.3%, again similar to the manual calculation.

RECEIVER OPERATOR CHARACTERISTIC CURVES

Because diagnostic tests are not perfect, there is always a tradeoff between sensitivity and specificity, making it difficult to determine an optimal cutoff. The receiver operator characteristic (ROC) curve is a useful tool for identifying the optimal cutoff for a diagnostic test by calculating the sensitivity and specificity combinations across the entire range of cutoff values. In addition, the ROC curves of two or more tests can be compared to identify the one with the greatest discriminating ability (Zweig, 1993).

An ROC curve is constructed by calculating sensitivity and specificity across the entire range of cutoffs for the diagnostic test being evaluated. Sensitivity is plotted on the y-axis and 1– specificity (or the FP rate) on the x-axis; construction of the curve shows the tradeoff between sensitivity and specificity at each cutoff. The ROC curve for a test with no ability to

Figure 7-4 Fagan nomogram (see Table 7-9). (A, Modified from Fagan TJ. Letter. Nomogram for Bayes' theorem. *N Engl J Med* 1975;293(5):257. B, Modified from Schwartz A. Diagnostic test calculator, 2002. Available at: <http://araw.mede.uic.edu/cgi-bin/testcalc.pl>.)

Figure 7-5 Receiver operator characteristics curve: effect of varying the cutoff value for separating disease from no disease (also see Fig. 7-3).

Figure 7-7 Receiver operator characteristic curves for two tests. Note that the curves cross. See text for interpretation.

Figure 7-6 Receiver operator characteristic curves for two tests. Note that Test 1 is always superior to Test 2 because it has higher sensitivity than Test 2 (i.e., it is always above and to the left of Test 2).

predict disease (i.e., random chance) is a 45-degree line drawn through the origin. As the discriminatory ability of a test increases, the curve progresses outward toward the upper left-hand corner. The area under the ROC curve (AUC) is a single measure of the overall discriminating ability of a test; the minimum AUC is 0.5, which is the area under the 45-degree line, and the maximum AUC is 1.0 for a perfect diagnostic test. Because diagnostic tests are not absolutely perfect, the AUC will range from 0.5 to 1.0; the higher the AUC, the greater is the overall discriminating ability of the test. In general, an AUC that is greater than 0.8 suggests that the diagnostic test has good discriminatory power.

Point A on the ROC curve in Figure 7-5 has the highest sensitivity but has low specificity. Increasing the specificity to point B trades the higher sensitivity for lower sensitivity. The optimal cutoff is identified by the coordinate that maximizes discriminatory power, which, in this example, is point C. Point C is also the location on the ROC curve with the largest distance perpendicular from the 45-degree line. The second useful application for the ROC curve is to compare two or more diagnostic methods by calculating the area under the curve. If the area under the curve is similar, then no difference is observed between the two tests. However, if one ROC curve has a greater AUC than a comparison test, it has better sensitivity and specificity at all cutoffs. For example, in Figure 7-6, test 1 is better than test 2 at all cutoffs and therefore would be the better test. However,

curves may cross, indicating that performance depends on the desired use of the test (i.e., whether a higher sensitivity or specificity is required for clinical use). In the example in Figure 7-7, test B has a lower FP rate than test A at high sensitivity, which makes it a better screening test; test A would be the better confirmatory test because it has greater sensitivity at high specificities.

POSITIVITY CRITERION

The LR may be used to select the optimal cutoff for an assay that best separates disease from nondisease. As was previously discussed, the LR, like sensitivity and specificity, varies with the cutoff. To select the optimal discriminatory cutoff, one might simply pick the cutoff resulting in the greatest LR for a positive test. However, this approach does not take into account the clinical impact of the test result. The clinical consequences of a FP test (e.g., unnecessary surgery) or a FN test (e.g., a missed chance to treat) need to be weighed when the optimal cutoff is determined. The *positivity criterion* is a method that allows one to assess the optimal cutoff with numeric estimates for clinical impact, or consequences, of test results.

In determining which cutoff will serve as the positivity criterion, a finite list of possible cutoffs is generated, and an LR for a positive test is calculated for each cutoff value. Next, the consequences of each of the four possible testing outcomes (TP, TN, FP, and FN) are assigned numeric estimates with respect to some outcome (e.g., morbidity, mortality, cost). For example, the clinical consequence of missing propionic acidemia on newborn screening by tandem mass spectroscopy is an increased risk of metabolic decompensation before diagnosis, with resultant developmental delay and long-term disability. One might estimate the consequence of this FN as 0.1; quality of life (QOL) lived in this state of misdiagnosis has 10% of the QOL lived without disease. It is important to note that the consequence of TP may not always be 100%, or equivalent to healthy life. Indeed, for propionic acidemia, even neonatal diagnosis may not completely alleviate the burden of disease. A possible estimate of the consequence of a TP on morbidity would be 80%. Similar estimates are determined for the remaining two outcomes. Values for the estimated consequences, as well as prevalence estimates of the disease, are then used in the equation that follows, where cTN , cFP , cTP , and cFN are the estimated consequences of each diagnostic category, and $P(D)$ is disease prevalence and $P(\bar{D})$ is 1-prevalence. The $LR_{threshold}$ is the optimal assay cutoff.

$$LR_{threshold} = \frac{P(\bar{D})}{P(D)} \times \frac{cTN - cFP}{cTP - cFN}$$

From the list of possible analyte concentrations, one can now select the cutoff that most closely approximates the $LR_{threshold}$. In this way, one may select a test cutoff that not only optimizes the discriminatory power of the assay, but also fits the clinical need that the test is meant to address.

TABLE 7-10
Positivity Criterion

Cutoff	% disease with this value or greater on assay	% without disease with this value or greater on assay	LR-positive test
R1—barely positive	5	30	0.17
R2—weakly positive	20	40	0.5
R3—intermediate positive	20	15	1.33
R4—strongly positive	25	10	2.50
R5—very strongly positive	30	5	6.00

The characteristics of a theoretical test for a disease with a prevalence of 10% are shown. Possible cutoff values for this assay ranging from a barely positive reading to a very strongly positive reading are denoted as R1 to R5, respectively. The percentage of patients with and without disease at or above each cutoff is also provided. The likelihood ratio (LR) for a positive test for R1–R5 is calculated from the information in the table (see explanation in text).

Consider a theoretical test for a disease shown in Table 7-10 with a prevalence (pretest probability) of 10%. R1–R5 represent possible assay cutoffs, where R1 represents a barely positive result and R5 a strong positive test result. Table 7-10 shows the percentage of diseased patients (defined by a gold standard) with a test result greater than the cutoffs defined as R1–R5. In addition, the percentage of patients without disease at each cutoff is shown. As the value for the cutoff increases from R1 to R5, the percentage of patients with disease increases. Using this information, an LR for a positive test can be calculated for each cutoff level.

Next we consider the consequences of an FN/FP and TP/TN result on the assay in terms of QOL. It is important to note that consequences can be estimated in terms of a variety of outcomes, including cost, excess mortality, or even cost-benefit, and each of these will result in a different positivity criterion. Assume that a missed diagnosis (FN) results in a QOL that is 70% that of a healthy person. Furthermore, assume that an FP result will lead to an unnecessary workup and anxiety, with a QOL that is 93% that of a healthy person. Finally, QOL for a TP living with a correctly diagnosed disease may be considered as 80% the QOL of a healthy person. Finally, a TN person experiences 95% the QOL as a fully healthy, untested person. Values for consequences are generally estimated from the literature or from expert opinion. By plugging the values for consequences into the above formula for $LR_{\text{threshold}}$, we obtain a value of 1.8. In other words, the assay is most efficient, in terms of maximized quality of life, at an LR+ of 1.8. From Table 7-10, the positivity criterion for this assay should be between R3 and R4, and closer to R3.

EVIDENCE-BASED MEDICINE

Historically, medical decisions have relied heavily on clinical experience, expert opinions, and other subjective or uncontrolled sources of information. This has also been true in laboratory medicine, where often an inadequate foundation of evidence is found to support existing practices (Price, 2000; Price, 2003). There may be no clear understanding of why a test is ordered, or what clinical question it is trying to answer. Alternatively, there may be no information on whether or how a test affects patient outcomes, such as morbidity, mortality, cost, patient satisfaction, risk, and discomfort (Bruns, 2001). For example, it is not clear whether point-of-care testing improves patient diagnosis and discharge in the emergency department (Price, 2003; Bruns, 2001; Kendall, 1998; Westgard, 2004; Trenti, 2003). Studies of clinical effectiveness in the clinical laboratory are hard to find because they are expensive and difficult to design (Price, 2000; McQueen, 2001). In addition, laboratory consultation is often based on the tradition of clinical and laboratory experience and less on a systematic approach to determining the current best evidence (Price, 2003). In contrast to traditional approaches, evidence-based medicine (EBM) is a process by which medical decisions can be made by using as many objective tools as possible. This, in turn, can help reduce the uncertainty of medical decision making. EBM is a systematic practice that integrates the most current and best evidence with clinical expertise and patient preferences when making medical decisions (Sackett, 2000). EBM places emphasis on critically analyzing information from the literature and developing knowledge for medical practice (Sackett, 1983; Elstein, 2004; Sackett, 1991; Ludmerer, 2004). EBM encourages the cultivation of continuous learning and sharing of medical knowledge at all levels of training from medical student to attending physician (Ludmerer, 2004). Since the time of its introduction, EBM has grown to become a key tool for all health care providers.

Practicing EBM consists of five steps (Price, 2000; Price, 2003; Sackett, 2000): (1) Ask a clinical question based on a patient encounter; (2) acquire information by searching resources; (3) analyze and critically evaluate the information, and reach a conclusion that answers the clinical question; (4) apply the information to individual patients; and (5) audit effectiveness and monitor the literature.

A clinical encounter of a patient with a health care provider generally results in a clinical question that necessitates one or more laboratory tests—whether for screening, diagnosis, prognosis, or monitoring of treatment. The question that is developed should be specific to a decision that must be made for that patient. The question compares an intervention such as ordering a diagnostic test versus accepted practice. The clinical question can be described in four parts and summarized with the acronym PICO (Sackett, 2000; Elstein, 2004): Problem (P): What is the problem of interest for the specific patient? Intervention (I): What intervention is being considered? Comparison (C): To what alternatives can the intervention be compared? Outcome (O): Is there a quantifiable clinical outcome that can be measured?

For example, a 55-year-old man, who recently returned from a trip to Europe, complains of swelling of the right leg, which upon examination is warm, red, and swollen. The clinical question can be summarized as follows: Problem: Is D-dimer a good “rule-out” test for deep vein thrombosis in a middle-aged man with a risk factor for thrombosis (such as lengthy travel)? Intervention: D-dimer test. Comparison: Venous ultrasound or venography as the reference method. Outcome: Predictive value of D-dimer in “ruling out” deep vein thrombosis.

A second example might be the following: A 58-year-old man with atrial fibrillation arrives in the emergency department with gastrointestinal bleeding due to a warfarin overdose. Problem: Is vitamin K effective in correcting coagulopathy caused by a warfarin overdose? Intervention: Vitamin K administration. Comparison: Fresh frozen plasma may be the alternative treatment. Outcome: Correction of bleeding and prothrombin time.

The strategy for answering these questions must be determined before searching the resources to prevent the introduction of selection bias. Information sources include textbooks, journals, electronic textbooks, and summary journals. Textbooks may provide an introduction to the pathophysiology of the disease, but they do not contain the current best evidence. Journal articles provide more up-to-date information than textbooks, but they too are outdated by the time the articles have been written, accepted, and published. Randomized clinical controlled trials (RCTs) that are double-blinded are the most valuable of the journal articles because they are the least biased. However, RCTs are highly dependent on the methods employed in the blinding and treatment of subjects (Lijmer, 1999).

Secondary articles and meta-analyses (a statistical technique to integrate results from multiple studies) summarize the best current evidence and provide practice guidelines. The Centre for Evidence-Based Medicine (<http://www.cebm.net>), the Cochrane Collaboration/Cochrane Library (<http://www.cochrane.org>), Up-to-Date (<http://www.uptodate.com/>), and Best Clinical Evidence (Godlee, 2004) are sources that present summarized information. The Evidence-Based Medicine (ebm.bmjournals.com) series of journals are also an excellent resource for up-to-date summaries. Although convenient, a summary article should be evaluated with caution because an “expert” may introduce bias regarding which studies are assessed and the value applied to particular articles. Medical decision-making tools help the reader to critically analyze each step in the process and have been summarized (Guyatt, 2000).

- Accurate differential diagnoses can be made from a systematic study of the laboratory profiles of patients in a large majority of cases.
- Four basic types of anemia are known: Iron deficiency, anemia of chronic disease, hemolytic anemia, and macrocytic/nutritionally deficient anemia. These can be readily distinguished from one another by the hematologic profile and by simple laboratory testing.
- By examining the urinary sodium, potassium, and osmolality, the causes of hyponatremia and hypernatremia can be readily determined.
- Liver function tests can distinguish among six different diseases of the liver: Hepatitis, cirrhosis, biliary disease, space-occupying lesions of the liver, passive congestion, and fulminant hepatic failure.
- Renal failure can be readily diagnosed by observing elevated blood urea nitrogen and creatinine; it is possible to pinpoint the site of renal failure (i.e., glomerular or tubular) from the ratio of serum to urine osmolality.
- Blood gas determinations allow determination of the causes of metabolic versus respiratory acidosis or alkalosis; a critical relationship exists between the partial pressure of oxygen and of carbon dioxide, such that in respiratory diseases, high levels of carbon dioxide block oxygenation of venous blood, leading to respiratory crisis.

- Elevation of cardiac troponin in serum, in the proper clinical context, is diagnostic of myocardial infarction.
- Elevations of serum C-reactive protein indicate inflammatory disease.
- Elevations of serum amylase and lipase point to acute pancreatitis.
- Two types of endocrine disease are discussed: Thyroid and adrenal. Serum levels of T_4 (or, better, free T_4) and thyroid-stimulating hormone can be used to diagnose primary or secondary hypothyroidism or hyperthyroidism; serum levels of cortisol and adrenocorticotrophic hormone can be used to diagnose primary or secondary hypoadrenalism or hyperadrenalism.

INTERPRETING AND CORRELATING ABNORMAL LABORATORY VALUES**GENERAL CONSIDERATIONS**

The major purpose of performing analyte determinations in the clinical laboratory is to aid in the diagnosis and management of disease and in health assessment. In this regard, the clinical pathologist is often called upon as a consultant to explain abnormal laboratory values, especially those that do not seem to correlate with one another, and to recommend or even

to order laboratory tests that may lead to the correct diagnosis in the workup of patients for particular medical problems. In addition, evaluation of laboratory test results on individual patients by the clinical pathologist not only can reveal the (infrequent) occurrence of laboratory errors, but can help in the selection of appropriate, cost-effective tests from a wide variety of increasingly complex test choices (Witte, 1997; Dighe, 2001; Bonini, 2002).

For evaluation of test results, the laboratory computer is an invaluable aid. Virtually all such systems perform daily checks for patient values that lie significantly outside of their established reference intervals, or that have undergone large changes over a 24-hour period. These are often reported as “failed delta checks.” Thus patients with significant laboratory findings can be identified.

This chapter presents an approach to interpretation of laboratory values that will enable laboratorians to aid in the establishment of clinical diagnoses and to assist in clinical management. This discussion is by no means comprehensive and cannot possibly cover every conceivable illness afflicting patients. Rather, this presentation is concerned with general approaches to interpreting abnormal values and discussion of the most common causes of such findings, so that the reader has a framework for interpreting abnormal values.

The reader may prefer to complete the Clinical Chemistry (Part 2) and Hematology, Coagulation, and Transfusion Medicine (Part 4) sections of this book before reading this section, which gives an overview of both of these vital diagnostic areas. Alternatively, the reader may decide to read this chapter to obtain the overview first before reading the chapters on chemistry and hematology.

FUNDAMENTAL PRINCIPLES IN INTERPRETATION OF VALUES

Before embarking on a discussion of specific conditions giving rise to abnormal values, certain precepts should always be followed, encapsulated as follows:

1. Never rely on a single out-of-reference range value to make a diagnosis. It is vital to establish a trend in values. A single sodium value of 130 mEq/L, for example, does not necessarily indicate hyponatremia. This single abnormal value may be spurious and may reflect such factors as improper phlebotomy technique, laboratory variability, etc. Rather, a series of low sodium values in successive serum samples from a given patient does indicate this condition. Thus it is vital to follow trends in particular values.
2. Osler's rule. Especially if the patient is younger than 60 years of age, try to attribute all abnormal laboratory findings to a single cause. Only if there is no possible way to correlate all abnormal findings should the possibility of multiple diagnoses be entertained.

ABNORMALITIES IN THE HEMATOLOGY PROFILE

Often in laboratory reports, the first section contains the hematology profile, including the CBC, or complete blood count. Comprehensive discussions of clinical hematopathology are given in Part 4. Here, we discuss very basic patterns of abnormalities to provide an overall frame of reference for interpreting values and for ordering further examinations. Although this part of the book is concerned with clinical chemistry or chemical pathology, we discuss the hematology profile because the interpretation of hematopathologic results often depends on the results of quantitative determinations performed in clinical chemistry.

ANEMIAS

Anemia, a common hematologic disorder, is defined pathophysiologically as a decrease in the oxygen-carrying capacity of the blood. All oxygen-carrying capacity of the blood is due to the binding of oxygen to hemoglobin (Hb) contained uniquely in red blood cells (RBCs). Because anemia can cause tissue hypoxia, it often produces such symptoms as fainting, fatigue, pallor, and difficulty in breathing.

Practically, the best indicator for this condition is a low RBC count or number of RBCs per volume of whole blood. Although the reference range for the red cell count varies with age, sex, and population, it encompasses values from around $4\text{--}6 \times 10^6$ RBCs per cubic millimeter (cu mm) or microliter. This range may change somewhat depending on the

population. RBC counts below the lower limit of the reference range suggest the presence of anemia. In addition, RBCs occupy a well-defined range in terms of the percent of the volume of whole blood that they occupy, or the hematocrit (Hct). Generally, normal adult Hct values range from about 36%–45% (normal values for females are generally slightly lower than those for males). In addition, the concentration of Hb in whole blood is about 12–15 g/dL or approximately 33–36 g/dL in RBCs (i.e., the mean corpuscular Hb concentration). Normal values are also dependent on patient age and altitude of residence. Normally, the Hct is about three times the value of the Hb concentration, which, in turn, is about three times the value of the RBC count.

If anemia has been diagnosed, it is mandatory to determine the cause of the anemia. An excellent history and physical examination is required for appropriate test selection and diagnosis, and the best possible patient care and treatment. In addition, a review of the peripheral blood film with respect to red and white cell morphology is often helpful.

To narrow further the differential diagnosis and facilitate appropriate test selection, a number of classification schemes for anemia have been developed, with no single ideal scheme available. A particularly useful approach utilizes the common red cell indices of mean corpuscular volume (MCV), measured in femtoliters (fL), or 1×10^{-15} L, in conjunction with the red cell distribution width (RDW) and the reticulocyte count (percent reticulocytosis), or reticulocyte production index (RPI). A further aid in diagnosis is the chromicity of the red cells (i.e., the intensity of the red color of the cells due to intracellular Hb). The chromicity is measured quantitatively by the mean corpuscular hemoglobin concentration, or MCHC. Taken together, these indices help to form a working hypothesis for the underlying cause of the anemia.

Electronic determination of MCV directly from red cell distribution data allows for classification on the basis of RBC size as macrocytic (MCV generally >100 fL), microcytic (MCV generally <80 fL), or normocytic (MCV generally between 80 and 100 fL). The sizes (volumes) of red cells vary within a certain range in which the number of cells of particular volumes form a bell-shaped or Gaussian distribution (see Chapter 9); the standard deviation of the cell volumes divided by the mean cell volume gives the RDW, measured as a percent. As it happens, the RDW is a parameter that helps to further classify an anemia because it reflects the variation in RBC size. RDW generally varies between about 12 and 17, and is dependent on the patient's age, sex, and ethnic subgroup. It can be helpful in differentiating causes of microcytosis in that moderate to severe iron deficiency anemia (IDA) is associated with an increased RDW, while thalassemia and anemia of chronic disease (ACD) are associated with a normal RDW.

Peripheral blood reticulocytosis is a measure of bone marrow response in the face of anemia. A similar measure, RPI, corrects the reticulocyte count with respect to (1) the proportion of reticulocytes present in a patient without anemia, and (2) the premature release of reticulocytes into the peripheral circulation. Bone marrow response to anemia may be appropriate (hyperproliferative) with an RPI >3 , generally indicating marrow red cell hyperproliferation; however, the anemia may be due to defective RBC production or marrow failure (hypoproliferative), which is generally indicated by an RPI <2 . Thus, although these red cell indices are not pathognomonic of the cause of a particular type of anemia, the combination of MCV, RDW, and RPI examined together often will significantly narrow the differential diagnosis and facilitate further test selection. Table 8-1 illustrates common examples of anemia and their diagnostic workup using these red cell indices, as well as other helpful analytic abnormalities.

Microcytic Anemia

Common microcytic anemias include IDA and the thalassemias. Some hemoglobinopathies and ACD may also be microcytic. In our discussion, we will focus on IDA and ACD, a common differential diagnosis for patients with microcytic anemia. Both anemias appear to be disorders involving iron metabolism.

In IDA, there is a primary deficiency of iron available to the red cell (usually resulting from blood loss, but other causes include dietary deficiency, malabsorption, and pregnancy); chronic blood loss should always lead to further investigation because it is commonly associated with malignancy. ACD, however, appears to be due to defective iron utilization/metabolism and is associated with chronic nonhematologic disorders such as chronic infections, connective tissue disorders, malignancy, and renal, thyroid, and pituitary disorders. Because iron levels in red cells are low, Hb levels are also low in both of these conditions. Thus the MCHC

TABLE 8-1

Common Types of Anemia and Their Diagnostic Workups*

Anemia	Cause	Common analyte abnormality
1. Hypoproliferative, microcytic	Iron deficiency	Low ferritin Increased IBC Decreased serum iron Reduced Fe/IBC ratio Generally increased RDW
2. Hypoproliferative, microcytic	Anemia of chronic disease	Generally high ferritin Normal IBC Decreased serum iron Normal Fe/IBC ratio Generally normal RDW
3. Hyperproliferative, normocytic	Hemolytic anemia	Schistocytosis Increased reticulocytes Low haptoglobin Elevated carboxyhemoglobin Elevated LD Elevated indirect bilirubin Generally increased RDW
4. Hypoproliferative, normocytic	Aplastic anemia	Leukopenia Thrombocytopenia Hypocellular bone marrow Generally normal RDW
5. Hypoproliferative, normocytic	Renal failure	Elevated BUN and creatinine Low erythropoietin Burr cells may be present Generally normal RDW
6. Hypoproliferative, macrocytic		
A. Megaloblastic	B ₁₂ and/or folate deficiency	Low B ₁₂ and/or folate Hyperlobulated polymorphonuclear leukocytes Macroovalocytes Increased RDW
B. Nonmegaloblastic	Hypothyroidism	Elevated TSH Normal RDW

BUN, Blood urea nitrogen; Fe, iron; IBC, iron-binding capacity; LD, lactate dehydrogenase; RDW, red cell distribution width; T₄, thyroxine; TSH, thyroid-stimulating hormone.
*In this table, low is equivalent to depressed, and high is equivalent to elevated. Ferritin, haptoglobin, LD, bilirubin, BUN, creatinine, erythropoietin, TSH, and T₄ are all expressed as concentrations. All of these analytes are measured in serum.

mentioned earlier tends to be low, giving rise to what is termed a hypochromic (low red color in red cells or low MCHC), microcytic (low MCV) anemia.

To distinguish between IDA and ACD, a number of different laboratory measurements are very useful, in addition to the RDW. The diagnosis is typically made using additional serum or whole blood laboratory tests. However, because IDA is always accompanied by loss of iron that is stored bound to the protein ferritin in bone marrow macrophages, the diagnosis can always in principle be made with a bone marrow biopsy with an iron stain (e.g., nitroprusside) that shows the absence of marrow iron. This procedure is, of course, invasive and should be performed only as a last resort.

Serum Ferritin Levels

Normally, there is an equilibrium between intracellular and extracellular ferritin. The lower the stored iron becomes, the lower is the intracellular ferritin, and, consequently, the lower the extracellular ferritin becomes. The level of extracellular ferritin can be directly measured by determining the serum ferritin level, which is readily and accurately assessed on serum aliquots, using enzyme-linked immunosorbent assay (ELISA) techniques, as described in Chapter 44. Overall, therefore, serum ferritin levels give an excellent measure of available iron stores, noninvasively. Because iron stores in ACD are abundant, serum ferritin levels are characteristically normal to elevated. In contrast, in IDA, in which iron stores become depleted, serum ferritin levels are characteristically decreased. Thus serum ferritin level is one assay that can be used in differentiating IDA from ACD.

One caveat in using serum ferritin values to provide this distinction is the fact that ferritin also happens to be an acute phase reactant. Acute phase reactants are proteins (discussed in Chapter 19) that rise in response to an acute process, usually an acute inflammatory condition. So, if a patient has an acute infection, the serum ferritin level may be spuriously elevated. The net effect may be a ferritin in the reference interval.

Usually, in IDA, accompanied by an acute process, this level is in the low reference range.

Use of Serum Iron and Iron-Binding Capacity

In addition to ferritin levels, serum iron and serum iron-binding capacity (IBC) can be measured. On average, serum iron is, of course, reduced in IDA and normal or sometimes low in ACD. The IBC is a direct measure of the protein transferrin, which transports iron from the gut to iron storage sites in bone marrow. In IDA, the serum iron is reduced, and the IBC is increased.

However, both serum iron and transferrin are subject to wide fluctuations because of such factors as diet and do not always reliably reflect iron stores. Also, transferrin is a β -protein (i.e., it migrates in the β -region in serum protein electrophoresis) and is an acute phase reactant (i.e., its serum levels change) (they usually decrease, as a so-called “negative acute phase reactant”) in inflammatory conditions. Considerable overlap has been noted between serum levels of iron and iron-binding capacity in IDA and ACD. A somewhat more reliable discriminating measure of IDA is the ratio of serum iron to IBC, known as the transferrin saturation. This ratio is around 1:3 for normal individuals, and in IDA it is significantly reduced to values of around 1:5 or lower. Again, considerable overlap is seen even in this ratio for patients with IDA and ACD, so the values should always be interpreted with care.

Use of Red Blood Cell Distribution Width

Finally, use of automated procedures for determination of cell counts and indices enables us to obtain average erythrocyte sizes and size distributions. In IDA, a marked dispersion in cell volumes (sizes) occurs, so that the RDW increases, whereas it generally remains within normal limits in ACD. Normal RDWs occur in the range of 12%–17%. Unfortunately, standard deviations for normal individuals and for patients with IDA or ACD can overlap significantly, tending to limit the validity of using the RDW exclusively for distinguishing between these conditions.

The major laboratory findings that distinguish IDA from ACD are summarized as entries 1 and 2 in Table 8-1. Note that most of the major tests used to distinguish these two conditions are performed in the clinical chemistry laboratory. This emphasizes the strong interdependence of both of these services in obtaining definitive diagnoses through laboratory measurements.

Normocytic Anemia

In these anemias, the red cells show normal MCVs and MCHCs (i.e., they are normocytic and normochromic). Common causes of normocytic anemia include acute hemorrhage, hemolytic anemia, marrow hypoplasia, renal disease, and ACD. It may seem paradoxical that acute hemorrhage presents as normocytic anemia because it involves major blood loss that is associated with loss of iron stores. However, iron depletion requires time to develop; acutely, major blood loss presents as normocytic anemia.

Hyperproliferative Normocytic Anemias

Hyperproliferative normocytic anemias, associated with an increased reticulocyte count, include both hemolytic anemia and the anemia associated with acute blood loss; hypoproliferative anemias, associated with a decreased reticulocyte count, include such causes as bone marrow aplasia/hypoplasia, renal disease, and ACD. As mentioned earlier, a history and physical, as well as examination of the patient's peripheral blood film, are helpful in establishing a differential diagnosis. In this section, we will focus on the most common causes of normocytic anemia: Hemolytic anemia, aplastic anemia, and the anemia associated with renal disease.

Hemolytic Anemia. Hemolysis is defined as destruction of the red cell membrane, causing Hb release. This may occur slowly as a normal physiologic process or may be accelerated in pathologic states. Many different underlying causes are known for the decrease in survival/increase in destruction of RBCs. These include membrane defects (e.g., hereditary spherocytosis), enzyme defects (e.g., glucose-6-phosphate dehydrogenase [G6PD] deficiency), hemoglobinopathies (e.g., sickle cell disease or β -thalassemia), immune destruction (e.g., autoimmune hemolytic anemia or hemolytic transfusion reaction), and nonimmune destruction. The latter includes destruction due to infectious agents, toxic agents/drugs, physical agents, or hypersplenism, and those classified as microangiopathic hemolytic anemias—a group of anemias due to mechanical destruction of RBCs mainly in bone marrow where they are synthesized, caused by such factors as fibrin deposition within the blood vessels of the bone marrow microvasculature, fibrosis, or malignancies, including leukemia, lymphoma, and metastatic cancer. In addition, mechanical destruction can result from extramedullary causes such as prosthetic heart valves.

Hemolytic anemia can be recognized from Hb in plasma/serum and breakdown products of heme. Specific laboratory measurements that readily confirm the diagnosis of hemolytic anemia are based on the natural events that occur subsequent to hemolysis. After erythrocyte membrane breakdown, Hb is extruded. Thus plasma and urine may contain free Hb or its degradation products. Free Hb may be present acutely in the plasma (hemoglobinemia) or urine (hemoglobinuria), and hemosiderin may be present in the urine (hemosiderinuria) in more chronic episodes of hemolysis. Extruded Hb becomes bound to the α -2 fraction protein haptoglobin. The Hb-haptoglobin complex becomes catabolized by macrophages that engulf these complexes by receptor-mediated endocytosis. Thus an excellent laboratory test for hemolytic anemia is a *low haptoglobin value*. Extremely sensitive and rapid ELISA assays for haptoglobin are available for this purpose.

Because the red cell contents are extruded into the plasma, other indicators of red cell damage, besides Hb, are known: High serum potassium, because intracellular potassium concentration is much higher in red cells than in the extracellular fluid, and serum elevations of the enzyme lactate dehydrogenase (LD). As discussed in Chapters 18 and 20, there are five major isozymes of this enzyme, labeled LD1 through LD5. Peculiarly, the predominant isozyme of LD in red cells is LD1, which occurs predominantly in cardiac tissue.

Carbon monoxide (CO) and unconjugated bilirubin become elevated in blood in hemolytic anemia. When Hb is extruded, large amounts of it become oxidized to methemoglobin. The heme portion dissociates and then becomes oxidized ultimately to bilirubin. The first step in this process is the oxidative opening of the porphyrin ring of heme with attendant liberation of CO. CO may be measured easily by gas chromatographic techniques or even more conveniently by cooximetry, based on spectrophotometry (see Chapter 4), as carboxyhemoglobin (see Chapter 34).

Elevated CO levels in normochromic, normocytic anemias are an excellent indicator of hemolytic anemia.

Because production of bilirubin, which is unconjugated, is increased (Chapter 21), at least a transient elevation of serum indirect bilirubin occurs. This elevation, in the presence of normal liver function, will be modest, usually in the range of about 2–2.5 mg/dL. (The upper limit of normal is around 1.2 mg/dL.)

Hemolytic anemia is almost always accompanied by an increased reticulocyte count and by evidence of red cell damage. As mentioned earlier, the reticulocyte count will be elevated (increase in polychromasia on the blood film), with erythroid hyperplasia present in the bone marrow, indicative of increased red cell production. In addition, the peripheral blood film may show evidence of the particular type of red cell damage associated with the particular type of hemolytic anemia (e.g., sickle cells in sickle cell disease, schistocytes/helmet cells in microangiopathic hemolytic anemia). A noticeable difference in red cell size (anisocytosis) and shape (poikilocytosis) is caused by the presence of damaged and/or young cells. Because of the often-marked changes in size and/or shape, the RDW is usually elevated. A number of nucleated RBCs may also be identified.

Other findings in hemolytic anemia can identify the cause. A direct antiglobulin test/direct Coombs' test can be used to detect immunoglobulin attached to the red cell surface that identifies immune hemolytic anemia as the cause of red cell destruction. A positive test suggests that an auto-antibody or alloantibody may be responsible for the anemia. A positive G6PD screening test for G6PD deficiency will identify this enzyme deficiency as the cause of the hemolytic anemia. Selection of these tests will be dependent on the clinical evaluation and on the preliminary laboratory data.

Laboratory findings that are diagnostic of hemolytic anemia are summarized in entry 3 of Table 8-1. Note that virtually all of the quantitative diagnostic tests for hemolytic anemia (i.e., serum and urine Hb, haptoglobin, carboxyhemoglobin, indirect bilirubin, and LD) are performed in the clinical chemistry laboratory, again emphasizing the strong interdependence of the clinical chemistry and hematology laboratories.

Microangiopathic Hemolytic Anemia. As previously mentioned, red cell fragments (schistocytes) may be present on peripheral blood films as the result of mechanical (prosthetic heart valve) or thermal (severe burns) destruction. Mechanical rupture of red cells within the microvasculature may also occur by physical damage to red cells in the microvasculature of bone marrow. This may be due to space-occupying lesions, such as metastatic tumors or leukemia or lymphoma, to myelofibrosis, or to the intravascular deposition of fibrin strands upon endothelial cell surfaces. Because RBCs are damaged and destroyed, this process leads to so-called microangiopathic (i.e., lesions in the microvasculature) hemolytic anemia (MHA).

Besides space-occupying lesions, other causes of this type of anemia include disease states in which fibrin is deposited on endothelial surfaces, also resulting in shearing and fragmentation of newly synthesized red blood cells, as in disseminated intravascular coagulopathy (DIC), which is discussed later and in Chapter 38. In this condition, an abnormal activation of the coagulation process occurs, in which fibrin-platelet clots form intravascularly and embolize to virtually any tissue. These clots block the microvasculature of tissues, including that of bone marrow, resulting in the destruction of newly synthesized red cells. In addition, other disease states may give rise to MHA that may have an immunologic component (i.e., antibodies to determinants on endothelial cells or on other structures in the microvasculature), resulting in immune complex deposits with or without fibrin deposits. These states include thrombotic thrombocytopenic purpura (TTP) and the hemolytic anemic/uremic syndrome (HUS). Because these two conditions involve the microvasculature in general, other tissues are frequently affected. Thus, in both HUS and TTP, damage to the renal microvasculature occurs, resulting in renal failure, and is associated with elevated blood urea nitrogen (BUN) and creatinine, as described in Abnormalities in Clinical Chemistry later. In TTP, involvement of the cerebral circulation gives rise to behavioral changes and other neurologic sequelae. In addition, platelets are affected, giving rise to thrombocytopenia.

MHA may also occur with other immune-mediated disorders (e.g., connective tissue disorders such as disseminated lupus erythematosus), where, again, endothelial damage from the attachment of immune complexes and complement produces fibrin deposition on endothelial surfaces.

It is important to note that because MHA results from traumatic destruction of newly formed RBCs in the microvasculature, where both

red and white blood cell (WBC) precursors are being formed, often both RBC and WBC precursors are released into the circulation. Thus, all findings of hemolytic anemia are present, in addition to which a significant number of precursor cells such as nucleated RBCs, myelocytes, and metamyelocytes are seen in the peripheral blood—a pattern termed the leukoerythroblastic picture.

As discussed later, in DIC and occasionally in TTP, laboratory findings include thrombocytopenia and increased prothrombin time, activated partial thromboplastin time, thrombin time, fibrin degradation products, and D-dimer levels (described later), but low fibrinogen levels. BUN and creatinine are also elevated.

Hypoproliferative Normocytic Anemias

Bone Marrow Hypoplasia/Aplastic Anemia. This is a hypoproliferative anemia, with MCV and RDW usually within normal limits, and typically affecting all peripheral blood elements (red cells, white cells, and platelets; see later). Immature white cells and red cells are not usually present on peripheral blood films. Bone marrow biopsy, which is commonly performed to obtain the diagnosis, typically shows severely hypoplastic/aplastic marrow with severe depletion of all hematopoietic marrow precursors. Aplastic anemia may be primary/inherited or secondary/acquired, with the latter due to chemical toxin, infection, radiation, or immune dysfunction. Serum iron may be elevated because of lack of erythropoiesis. Typical hematologic findings in this condition are summarized in entry 4 of Table 8-1. It is important to note that *none of the quantitative serum diagnostic tests for hemolytic anemia, such as haptoglobin, carboxyhemoglobin, and indirect bilirubin elevation, are positive in this condition.*

Myelodysplastic Syndrome. Another less common condition but nonetheless an important cause of hypoproliferative normocytic anemia is the myelodysplastic syndrome (MDS). This syndrome, which often presents as a normocytic anemia (although it can on occasion present as mildly macrocytic or as microcytic anemia), is refractory to treatment (e.g., transfusions of packed RBCs). It may present simply as a refractory anemia in its early stages and is thought to progress then to refractory anemia with ringed sideroblasts, and eventually to so-called preleukemic stages, in particular, refractory anemia with an excess of blasts (generally in the myeloid or lymphoid lines) and an excess of blasts in transformation. The condition may also present initially as a refractory cytopenia that involves all three (erythroid, granulocytic, megakaryocytic) hematopoietic cell lines. As might be surmised from this latter observation, MDS appears to be a clonal stem cell disorder that is characterized by ineffective hematopoiesis. Further discussion of this fascinating disease can be found in Chapter 33.

Anemia of Renal Failure. Another normocytic, hypoproliferative anemia is the anemia of chronic renal failure. Loss of the kidneys' excretory function produces an increase in BUN and creatinine, as discussed later, as well as a buildup of metabolic byproducts. The resulting uremia appears to be responsible for changes in red cell shape, with burr cells (echinocytes) and ellipsoidal cells commonly present on peripheral blood films. Identification of burr cells on peripheral blood films during the course of illness may signal the development of renal dysfunction. In addition to decreased excretory function, the kidneys' ability to produce erythropoietin is decreased, resulting in impaired erythropoiesis, such that the marrow's response to hypoxia becomes inadequate. In contrast to aplastic anemia (entry 4, Table 8-1), white cell and platelet counts usually remain within normal limits. Typical findings in this condition are summarized in entry 5 of Table 8-1. Again, as in bone marrow hypoplasia/aplastic anemia, none of the quantitative serum diagnostic tests for hemolytic anemia, such as haptoglobin, carboxyhemoglobin, and indirect bilirubin elevation, are positive in this condition.

Macrocytic Anemia

Macrocytic anemia can be diagnosed from the hemogram from a low RBC count and a high MCV, often exceeding 100 fL. By far the most common cause of macrocytic anemia is nutritional deficiency (i.e., vitamin B₁₂ and/or folate deficiency). Lack of either factor is thought to disrupt DNA synthesis but not RNA synthesis, such that the nucleus and cytoplasm of the cell no longer mature in synchrony. Morphologically, the cell cytoplasm matures, while the nucleus remains immature, and the cell appears megaloblastic. This lack of synchrony produces hypersegmented neutrophils (five-lobed nuclei in more than 5% of neutrophils or any neutrophil with six or more lobes) and large, oval red cells termed macroovalocytes, both of which are present on the blood films of patients with megaloblastic

anemia. In addition, the RDW is typically increased, and the reticulocyte count is decreased.

If macrocytic anemia is diagnosed, the first serum analytes whose concentrations should be determined are B₁₂ and folate, for which rapid and accurate ELISA assays are performed. If these analytes are both found to be within the reference range, assays for thyroid function should be performed because hypothyroidism is a cause of macrocytosis. As discussed later in the endocrine function testing section, elevated thyroid-stimulating hormone (TSH) with low or normal thyroxine (T₄) serum levels confirms the diagnosis of primary hypothyroidism. Because certain therapeutic drugs, particularly azathymidine (AZT) used in the treatment of the acquired immune deficiency syndrome (AIDS), are known to induce macrocytic anemia, it is important to ascertain whether a patient is being treated with such drugs.

In this era of the automated CBC, it is possible also that red cell precursor forms, such as nucleated RBCs, may be counted as mature erythrocytes. Therefore, in a patient with a "macrocytic" anemia with normal B₁₂, folate, and thyroid hormone levels, it is important to check the reticulocyte and the nucleated RBC count to determine whether these are significantly elevated. If so, the possibility of a hemolytic anemia should be considered. Thus the diagnostic workup for hemolytic anemia described in the preceding section should be instituted.

Other possible causes of macrocytic anemia include posthemorrhagic states (differentiated by elevation of the reticulocyte count and polychromasia), alcoholism (associated with folate deficiency), liver disease, and myelodysplasia. Note again that the definitive tests for determining the cause of macrocytic anemia (i.e., B₁₂, folate, and thyroid function tests) are often performed in the Clinical Chemistry section.

The major clinical laboratory findings for macrocytic anemia are summarized as entries 6A and 6B in Table 8-1. Note that macrocytic anemias are divided into megaloblastic (entry 6A), typical of B₁₂ and folate deficiency, and nonmegaloblastic (entry 6B), typical of hypothyroidism. Whether or not the macrocytic anemia is megaloblastic can be determined only by bone marrow biopsy. This procedure is not necessary in most cases because the cause of the macrocytosis can be determined by the assays described earlier.

Table 8-1 summarizes some of the pertinent findings and specific determinations used to distinguish and diagnose the common anemias previously discussed. Note that this table is a guide as to what specific tests should be ordered and, by implication, what tests need not be ordered. For example, a microcytic anemia should be worked up with orders for ferritin and Fe/IBC ratios, but generally there is no need to order B₁₂ and folate levels. Conversely, there is no need to order ferritin, IBC, etc., for a macrocytic anemia, for which B₁₂ and folate levels should be ordered.

QUANTITATIVE WHITE BLOOD CELL ABNORMALITIES

The WBC count encompasses several types of commonly circulating nucleated cells, including granulocytes (principally mature neutrophils, basophils, and eosinophils), lymphocytes, and monocytes. It should be noted that absolute concentrations (and not percentages) of these cells are significant in interpreting the WBC count. An increase to above the normal physiologic level in the WBC count, termed leukocytosis, may primarily involve any of these white cells, depending on which cell type is chiefly elevated (i.e., neutrophilia, basophilia, eosinophilia, monocytosis, and lymphocytosis). Occasionally, plasma cells may be found in the peripheral blood. Likewise, a decrease in the WBC count, termed leukopenia, may center on a single cell series (i.e., neutropenia, monocytopenia, and lymphocytopenia). Absolute decreases in eosinophils and basophils are difficult to identify because of the low numbers present normally. Certain differential diagnoses are commonly associated with certain WBC changes (e.g., infection and/or inflammation with neutrophilia, allergic reactions and parasitic infections with eosinophilia). In addition, elevations may be due to a benign process (e.g., infection) or a malignant process (e.g., leukemia). Here, we note several quantitative patterns and their associations that correlate with abnormal chemical findings.

Again, clinical history and physical findings are important in diagnosis and management of the patient. In addition, the CBC and white cell differential are important laboratory findings that are used, in conjunction with the clinical impression, to formulate the differential diagnosis. In adults, the reference range for the white count is approximately 4000–7000 white cells/μL; approximately two thirds of the white cells are neutrophils, and slightly less than one third are lymphocytes.

Infection: The Most Common Cause of Elevated WBC Count

An elevated WBC count between about 10,000 and 20,000/ μL commonly points to an infectious/reactive process. In general, neutrophilia is associated with infection (bacterial, fungal, viral), inflammatory states (e.g., trauma, surgery), certain drugs (e.g., corticosteroids), and myeloproliferative conditions. Exceptions to the neutrophilia seen in bacterial infections include tuberculosis, brucellosis, pertussis, where the predominant cells are lymphocytes, and infections, mainly in newborns, with *Listeria monocytogenes*, for which a monocytic response is predominant.

Eosinophilia is commonly associated with allergic reactions, parasitic infections, and hematologic malignancies (Brito-Babapulle, 2003; Fischbach, 2008). Basophilia is commonly associated with hematologic malignancies (e.g., chronic myelogenous leukemia, or CML), but may be seen in some inflammatory states and allergic reactions. Lymphocytosis is commonly associated with acute viral infections, such as infectious mononucleosis (Epstein-Barr virus infection); chronic infections, such as tuberculosis, brucellosis, and pertussis; and hematologic disease and immune stimulation. Monocytosis is commonly associated with hematologic disease, such as chronic myelomonocytic leukemia, as well as with some infectious processes, such as tuberculosis, rickettsia, and *Listeria*.

Elevated WBC Count Due to Leukemoid Reaction

In patients who do not have leukemia, very high WBC counts (generally greater than $50 \times 10^3/\mu\text{L}$) may produce a peripheral blood film appearance similar to leukemia. This is termed a leukemoid reaction. The more common type of leukemoid reaction is granulocytic, although lymphocytic reactions may also occur. The granulocytic type usually reveals reactive neutrophils present in the peripheral blood film, with a left shift in the neutrophil series (i.e., immature forms such as bands, metamyelocytes, and myelocytes). Changes in the cytoplasmic appearance of cells, such as toxic granulation and Döhle body production (see Chapter 37), are commonly seen. Causes of the granulocytic type of reaction include bacterial infection (e.g., diphtheria), malignancy (Hodgkin disease), and reactive conditions such as rebound granulocytosis. Although these changes are helpful, C-reactive protein (CRP), an acute phase plasma protein, rapidly rises and falls with the onset and resolution of inflammation. CRP appears to be an earlier and more sensitive indicator of acute inflammation and infection (Seebach, 1997; Dantzer, 2008) and can be quickly measured using present-day analyzers. Leukemoid reaction must be distinguished from CML and other myeloproliferative conditions. It is important to note that the enzyme *neutrophil alkaline phosphatase* will be normal or elevated in a granulocytic leukemoid reaction, but is *decreased* in CML.

Elevated WBC Count Due to CML

At present, the definitive diagnosis of CML rests upon the demonstration of the Philadelphia chromosome (i.e., a translocation between chromosomes #9 and #22 resulting in the BCR-ABL fusion gene) by cytogenetics or by molecular techniques (e.g., see Silver, 2003; George, 2003; Sattler, 2003; Ross, 2008). Detection of molecular or cytogenetic abnormalities is of diagnostic (and possibly prognostic) significance in other hematologic diseases as well, including acute myeloid leukemia, acute lymphoblastic leukemia, T cell leukemia/lymphoma, and myelodysplasia (Swerdlow, 2008). Molecular techniques now are utilized to detect very early stages of disease, as well as to detect minimal residual disease, that is, disease that may be apparent only at the molecular level. For example, quantitative polymerase chain reaction can be used to monitor BCR-ABL translocation levels in CML patients being treated with the kinase inhibitor imatinib (Gleevec) (Ross, 2008).

Elevated WBC Count Due to Chronic Lymphocytic Leukemia

When the lymphocytes appear normal but are significantly increased in number in an older individual, the possibility of chronic lymphocytic leukemia (CLL) must be considered. Again, molecular techniques such as flow cytometric, immunophenotypic, and cytogenetic/fluorescence in situ hybridization analysis (Jaffe, 2001; Oscier, 2004; Shanafelt, 2004) can help establish the diagnosis. In CLL, the neoplastic B lymphocytes will be found to express an unusual (but characteristic) human leukocyte differentiation antigen designated CD5, which is typical for this disease. Other

CD antigens can also be detected by flow cytometry and have become useful in resolving other hematologic diagnostic problems.

Leukocytosis Due to Acute Leukemias

Both acute myeloid and lymphoid leukemias present often as markedly elevated WBC counts. In lymphoblastic leukemia, numerous lymphoblasts are seen on the peripheral smear. Myeloid leukemias can present in a myriad of forms, including myeloblastic, promyelocytic, monoblastic/monocytic, myelomonocytic, erythroblastic, and megakaryoblastic. Again, flow cytometric, immunophenotypic, and karyotypic/molecular analyses can help establish the diagnosis and define prognosis (Winton, 2004). These are discussed fully in Chapter 33. Here, we point out that blast forms of any kind on a peripheral blood smear raise the strong diagnostic possibility of an acute leukemia.

Low White Cell Counts

Aplastic Anemia

Low WBC counts, if accompanied by marrow hypoplasia and two out of three of the following findings—anemia (with corrected reticulocyte count $<1\%$), neutropenia (neutrophil count $<500/\mu\text{L}$), and thrombocytopenia (platelet count $<20,000/\mu\text{L}$)—may be part of a generalized pancytopenia secondary to marrow failure (Guinan, 1997; Marsh, 2003, 2005). Also known as aplastic anemia, this condition may be primary/inherited or acquired/secondary. Known causes of the acquired type include drugs/toxins, infections (including hepatitis), radiation, and immune dysfunction (Gordon-Smith, 2002). Cytogenetic study may be utilized to rule out myelodysplasia; if unsuccessful, molecular techniques such as fluorescent in situ hybridization may be necessary for chromosome analysis (Guinan, 1997). The primary/inherited types may not always be present at birth (i.e., congenital), and diagnosis of this type of marrow failure relies heavily on clinical assessment in conjunction with appropriate laboratory evaluation (Alter, 1999, 2002).

Gram Negative Sepsis as a Cause of Leukopenia

Leukopenia may also be seen in other conditions, including gram-negative sepsis. It is interesting to note that gram-negative sepsis with a low WBC count is often accompanied by a cholestatic pattern in the liver (i.e., a mild rise in bilirubin and alkaline phosphatase), as discussed later and in Chapter 21.

COAGULATION DISORDERS

This vast and complex topic is discussed in Part 5. For our review, we focus on four hematologic parameters that may be important in correlation with test results in chemistry determinations: The platelet count; the bleeding time; the activated partial thromboplastin time (APTT), reflecting the function of the intrinsic coagulation system; and the prothrombin time (PT), reflecting the function of the extrinsic coagulation system. Diminished values of the platelet count and/or abnormalities in platelet aggregation can lead to abnormal bleeding times. Elevated PTs and/or APTTs are not generally associated with abnormal bleeding times, except mainly in factor VIII deficiency with concomitant deficiency of von Willebrand factor. This latter factor is needed for platelet aggregation.

Bleeding Time Measures Platelet Function

Historically, the bleeding time (BT) was utilized as a screening test for platelet function. It should be noted that the BT is not believed to correlate accurately with or to predict bleeding (DeCaterina, 1994; Gerwitz, 1996) and is now uncommonly used to screen for platelet function abnormalities (Kottke-Marchant, 2002).

Major Causes of Increased PT or APTT

The anticoagulant heparin, which accelerates the inactivation of thrombin and other coagulation factors (such as factor Xa), preferentially blocks the intrinsic system, leading to prolonged APTTs but not to significant elevations in PT. On the other hand, the vitamin K antagonist coumadin preferentially blocks factor VII in the extrinsic system, leading to prolonged PTs but not APTTs.

International Normalized Ratios for Patients Being Treated With Coumadin

The PTs of patients who are being anticoagulated on coumadin must be followed carefully to ensure that the therapeutic effect is occurring, but

that the effective levels of coumadin are not sufficiently elevated to initiate hemorrhage. Thus it is important to establish a therapeutic range for PTs for patients on coumadin. Because different methods for determining PTs are available, somewhat different reference ranges for PTs among different laboratories have been developed, making it difficult on occasion to compare PT results from different laboratories for a given patient. To attempt to correct for these differences, the PT values are used in a formula that standardizes these “raw” values. This formula takes the ratio of the observed PT to the mean value for the PT reference range of the particular laboratory and then raises the resulting ratio to the power of what is termed the international standardized index, or ISI. This index is determined from the slope of a correlation plot of the logarithm of a laboratory’s PTs for blood samples that contain different coumadin concentrations against the logarithm of the PTs determined by a reference (“gold standard”) method. Thus the international normalized ratio (INR) is expressed as $(PT_{pat}/PT_{mean})^{ISI}$, where PT_{pat} is the measured PT for the patient and PT_{mean} is the mean value for the laboratory’s reference range (Kamath, 2009). In most circumstances, INR values of 2–3 are considered to be therapeutic for patients who have atrial fibrillation, and 3–4 to be therapeutic for patients with prosthetic heart valves, but values over 4 are considered to require lowering of the coumadin dose or temporary cessation of treatment. Note that INRs are appropriate principally for patients who are being treated with coumadin.

The Other Cause of Isolated PT or APTT is Coagulation Factor Deficiency

If the PT or the APTT becomes elevated in the absence of treatment with heparin or coumadin, and the platelet count is normal, it is important to perform mixing studies of the patient’s plasma with normal plasma to determine if the coagulation time normalizes (i.e., whether there is a factor deficiency). A not infrequent cause of factor deficiency is liver failure, discussed subsequently and in Chapter 21. Thus liver function measurements should also be checked in these instances. If mixing studies do not completely correct the prolonged coagulation times, the presence of coagulation inhibitors, such as *circulating lupus anticoagulant* or *antifactor antibodies*, should be suspected.

The Major Cause of Elevated PT and APTT is DIC

If the platelet count diminishes and the APTT and the PT both rise, the diagnosis of DIC should be entertained. This diagnosis is confirmed by the finding of elevated fibrin split products (FSPs) and, more specifically, the D-dimer, discussed in Chapter 40 as the D–D fragment of fibrin that results from the proteolytic action of plasmin upon the fibrin clot that forms during intravascular coagulation. D-Dimer is detected in an assay by utilizing a very specific monoclonal antibody to this cross-linked fibrin degradation product. This method has largely replaced the less specific assay for FSPs, which likewise are elevated in this condition. DIC is an extremely dangerous condition and must be diagnosed rapidly, as indicated earlier.

In this condition, abnormal activation of both coagulation cascades and consumption of platelets occur. This activation may be caused by gram-negative sepsis (activation of the cascades may result from bacterial endotoxins), cancer, chronic inflammatory states such as collagen vascular diseases, leukemia (especially acute promyelocytic leukemia), complications of pregnancy, blood transfusion complications, liver failure, and physical trauma such as burns, drowning, and central nervous system (CNS) injuries. DIC causes the formation of microemboli that can result in widespread tissue infarction or ischemia with attendant abnormal chemical values (e.g., elevated liver function enzymes; elevated BUN and creatinine, suggestive of renal failure; and even elevation of cardiac troponin, indicating myocardial damage). Thus low platelet counts and elevated APTT and PT, together with chemical abnormalities suggestive of multi-system dysfunction, strongly suggest DIC. Anticoagulant therapy must be instituted rapidly to block further embolization and tissue destruction.

ABNORMALITIES IN CLINICAL CHEMISTRY: CHEMICAL PATHOLOGY

ELECTROLYTE ABNORMALITIES

This topic is treated at length in Chapter 14 and in Oh (2003). Here we present an overview of the regulation of serum levels of critical electrolytes

Figure 8-1 A schematic representation of a nephron showing the fundamental mechanism of water and salt conservation by the kidneys. Filtration occurs at the glomerulus (upper left, showing capillaries in red), and the filtrate passes through the proximal convoluted tubule (PCT), where about 70% of the total filtered sodium is reabsorbed. In the loop of Henle, the countercurrent multiplier mechanism is operative. Chloride ion (Cl^-) is extruded from the ascending limb into the interstitial space (shown in the upper middle part of the figure). Sodium ion passively follows. The cells of the ascending limb of the loop of Henle are impermeable to water, and the cells of the descending limb are impermeable to chloride ions. The result of this system is that high concentrations of NaCl are built up at the tip of the loop of Henle. The numbers beside the loop of Henle are osmolalities at different levels along the loop that, in humans, reach a maximum of 1200 mOsm/kg, as shown in the figure. At the top of the loop, the filtrate becomes isotonic (where the 300 mOsm/kg mark occurs) and then hypotonic because of the continuous extrusion of chloride ion. The hypertonic interstitium allows water to diffuse in from the collecting ducts (CDs), provided that antidiuretic hormone (ADH, labeled and highlighted in color in the figure) is secreted. More sodium ion can be conserved in the distal convoluted tubule (DCT), provided aldosterone (labeled and highlighted in color) is secreted, resulting in the one-to-one exchange of Na^+ for K^+ and H^+ .

to enable accurate formulation of the possible causes of abnormalities in their serum levels. Figure 8-1 summarizes the basic mechanisms by which the kidneys control electrolyte and water balance. Functionally, keep in mind that the purpose of the kidneys is to conserve fluids or, tantamount to this, to concentrate the urine. The mechanism by which this conservation of fluids is effected is the building up of high sodium chloride gradients in the interstitial space between the descending and ascending limbs of the loop of Henle, using the countercurrent multiplier mechanism. By this mechanism, sodium chloride is extruded into the interstitial space such that sodium chloride ($NaCl$) concentrations become greater toward the tip of the loop of Henle. The ascending limb of the loop of Henle is impermeable to water, as are the distal convoluted tubules and collecting ducts. However, under the effect of antidiuretic hormone (ADH), the collecting ducts are made permeable to water, allowing it to flow into the interstitial space and to penetrate the vasa recta. The entire driving force for this process is the high concentrations of $NaCl$ in the interstitium. Any interference with the countercurrent multiplier will block reabsorption of water because the ion gradients are eliminated.

As also shown in Figure 8-1, sodium ion, 70% of which is reabsorbed in the proximal convoluted tubule, can be further reabsorbed in the distal convoluted tubules and collecting ducts under the effect of aldosterone from the zona glomerulosa of the adrenal cortex. This hormone promotes the 1:1 exchange of sodium for potassium or hydrogen ion. Sodium levels in serum depend almost completely on the interplay between aldosterone and ADH. With these simple considerations in mind, the most common causes of hyponatremia and hypernatremia are now summarized with an explanation of how to identify them. It should be kept in mind that normal renal function is assumed. If renal failure occurs, the kidneys ultimately

TABLE 8-2

Common Causes of Hyponatremia and Electrolyte Patterns in Serum and Urine With Normal Renal Function*

Cause	Serum Na	Urine Na (UNa)	Urine osmolality	Serum K	24-hour UNa
1. Overhydration	Low	Low	Low	Normal or low	Low
2. Diuretics	Low	Low	Low	Low	High
3. SIADH†	Low	High	High	Normal or low	High
4. Adrenal failure	Low	Mildly elevated	Normal	High	High
5. Bartter's syndrome	Low	Low	Low	Low	High
6. Diabetic hyperosmolality‡	Low	Normal	Normal	High	Normal

SIADH, Syndrome of inappropriate antidiuretic hormone.

*All Na and K values are concentrations except for 24-hour UNa, which is the total number of milliequivalents of Na excreted in 24 hours in the urine.

†Secretion of inappropriate levels of antidiuretic hormone.

‡In this condition, serum glucose is markedly elevated.

fail to be able to concentrate the urine, so that hyponatremia will result, as is discussed in the Renal Disease section later.

Hyponatremia

The four most common causes of hyponatremia are given in Table 8-2, together with a fifth, rare cause, Bartter's syndrome. A sixth, metabolic cause, diabetes mellitus, is also presented in this table. In all forms of hyponatremia, the chloride ion concentration is generally low because chloride is the chief counter-ion for sodium.

Basic Principle

All confirmed serum sodium abnormalities must be followed up with urinalysis on the patient, who should be fluid restricted. This urinalysis should include the urine sodium and urine osmolality. For conditions 1 and 2 in Table 8-2, the serum sodium tends to correct over a 24-hour period when the patient is fluid restricted.

Overhydration

In this condition, the most common cause of which is the consumption of large amounts of water or hypotonic fluids due to such causes as psychogenic polydipsia, serum sodium is reduced to below 135 mEq/L. Because the consumed water is excreted by the kidneys, the urine is also dilute in this ion. In fact, the osmolality of urine will be low (i.e., <300 mOsm/kg). Often accompanying hyponatremia in overhydration are low values of the Hct and low values of BUN, discussed subsequently. This triad of findings strongly suggests overhydration as the cause. Urinalysis in the fluid-restricted patient will reveal urinary sodium of <25 mEq/L and low osmolalities. Potassium may also be low, although it often remains within the reference range. Because mainly water is excreted in urine in this condition, the total 24-hour sodium excretion will be low (cause no. 1, Table 8-2).

Use and/or Abuse of Diuretics

Loop diuretics block the chloride pump in the loop of Henle, thereby blocking the formation of ion gradients via the countercurrent multiplier, which is necessary for water conservation. Thus water is lost. Also, because sodium is no longer retained because it follows chloride in the loop, it also is depleted from serum. Thus, unlike in overhydration, the total 24-hour sodium excretion is high (compare 24-hour urinary sodium [UNa] values for entries 1 and 2, Table 8-2). Except for this difference, the pattern for diuretics resembles overhydration (dilute serum and urine); however, loop diuretics cause severe potassium depletion unless the diuretic is combined with a potassium-sparing diuretic like triamterene. Combined hyponatremia and hypokalemia with a high urinary sodium and potassium 24-hour excretion point to diuretic use. Of course, a history will generally reveal use of diuretics.

Syndrome of Inappropriate ADH Secretion (Entry 3, Table 8-2)

In this condition, secondary to head trauma, seizures, other CNS diseases, and neoplastic conditions, especially lung, breast, and ovarian cancers that secrete ADH-like hormones, the serum sodium is depressed because of excessive retention of water in the collecting ducts. This results in depletion of water in the renal tubules, thereby concentrating the urine. Therefore, although the serum is dilute in sodium (hypotonic), the urine is concentrated to levels >40 mEq/L, and urine osmolality exceeds 300 mOsm/kg, while the serum osmolality is <280 mOsm/kg. This pattern

clearly is diagnostic of syndrome of inappropriate antidiuretic hormone (SIADH).

Aldosterone Deficit (Entry 4, Table 8-2)

This condition occurs secondary to Addison's disease and AIDS-related hypoadrenalism. Without aldosterone, the Na⁺-K⁺ and Na⁺-H⁺ exchanges in the distal convoluted tubules and collecting ducts do not occur. Therefore, serum sodium concentration is reduced while serum potassium concentration increases, and mild metabolic acidosis is the result. Urinary sodium increases, but not to the high levels seen in SIADH, and the osmolality of urine also is not so elevated as in SIADH.

Bartter's Syndrome (Entry 5, Table 8-2)

This rare condition resembles diuretic use, except that the hyponatremia is not corrected with fluid restriction. Although the cause of this condition is not fully understood, it is known that the kidneys of these patients fail to retain potassium. This results in both hyponatremia and hypokalemia as in diuretic use/abuse. In addition, as in diuretic use, high 24-hour sodium and potassium excretion is noted.

Diabetic Hyperosmolar State (Entry 6, Table 8-2)

In patients with diabetes mellitus who are in a hyperosmolar state (i.e., where the serum glucose is markedly elevated, say around 700 mg/dL), the hyperosmolality of serum causes efflux of cellular water, with consequent osmotic dilution of serum sodium. Roughly, for each 100 mg/dL increase in serum glucose, a 1.6 mEq/L decrease in serum Na⁺ concentration is noted. Because transport of glucose into cells is accompanied by concurrent transport of potassium into cells, low insulin levels may also cause high serum potassium. So, the net effect of diabetic hyperosmolar states is a low serum sodium and a high serum potassium. This resembles hypoaldosteronism (entry 4, Table 8-1), but the presence of abnormally high glucose levels signals the possibility of diabetes mellitus as the cause.

Pseudohyponatremia

This condition is usually caused by the presence of excess lipids in serum. No sodium ions are dissolved in lipids, which can take up a considerable volume of serum. If the absolute amount of sodium in a given volume of serum is determined, as with such methods of sodium determination as flame photometry, this value is divided by the sample volume to get the concentration. But part of this volume is lipid that has no sodium. So a falsely low value of sodium can be obtained. This artifact is eliminated by the use of ion-selective electrodes that directly determine the concentration of sodium and do not depend upon knowledge of the volume of serum. Note that although most modern, high throughput chemistry analyzers measure serum sodium using ion-selective electrodes, they perform a predilution of the specimen (so-called *indirect* potentiometry), and hence the measurement is relative to volume and is susceptible to pseudohyponatremia.

Hypernatremia

Table 8-3 summarizes the three basic causes of hypernatremia. Note that each cause is the counterpart of a cause for hyponatremia. These causes are summarized as follows:

Dehydration (Entry 1, Table 8-3)

This can be caused by excess renal loss with high positive free water clearance (i.e., loss of water in excess of NaCl), excess sweating, and low water

TABLE 8-3

Common Causes of Hypernatremia and Electrolyte Patterns in Serum and Urine With Normal Renal Function*

Cause	Serum Na	Urine Na (UNa)	Urine osmolality	Serum K	24-hour UNa
1. Dehydration	High	High	High	Normal	Varies
2. Diabetes insipidus	High	Low	Low	Normal	Low
3. Cushing's disease or syndrome	High	Low	Normal	Low	Low

*All Na and K values are concentrations, except for 24-hour UNa, which is the total number of milliequivalents of Na excreted in 24 hours in the urine.

intake. The serum sodium is elevated, as is the Hct (possibly masking a true anemia), and the urine sodium is high as the result of increased renal excretion of NaCl.

Diabetes Insipidus (Entry 2, Table 8-3)

Diabetes insipidus (DI) may be central (neurogenic) (i.e., due to decreased vasopressin secretion) or nephrogenic (i.e., due to decreased renal response). Functionally, this condition is the reverse of SIADH (i.e., water retention in the tubules is not adequate). Although this condition is not completely understood and may be multifactorial, current research suggests that mutation and/or changes in protein expression of “water channel molecules” (renal aquaporins) and/or the vasopressin V2 renal collecting tubule cell receptor may play a role in both pathologic water loss, such as in nephrogenic DI, and pathologic water retention, such as SIADH (Oh, 2003; Schrier, 2003; Brown, 2003; Nguyen, 2003; Nielsen, 2002). The pattern shows elevated serum sodium but dilute urinary sodium caused by functionally inadequate levels of ADH.

Hyperaldosteronism (Entry 3, Table 8-3)

This condition may result from adrenal hyperplasia, Cushing's syndrome, and Cushing's disease. Levels of circulating aldosterone are inappropriately high, causing excessive reabsorption of Na and excretion of K⁺ and H⁺ ions. The patient will be hypernatremic and hypokalemic and will exhibit a mild metabolic alkalosis.

Hypokalemia

Many of the causes of hypokalemia, including overhydration, use of loop diuretics, SIADH, and Bartter's syndrome, overlap with those of hyponatremia, as discussed earlier. In addition to overlap of these causes with those of hyponatremia, the following states lead uniquely to hypokalemia.

1. *Infusion of insulin to diabetic individuals.* This results in rather large influxes of potassium into cells, which lower it in serum.
2. *Alkalosis.* RBCs are themselves excellent buffers. They are capable of exchanging potassium for hydrogen ions. Thus, in acidosis, H⁺ ions enter red cells in exchange for K⁺ ions. Conversely, in alkalosis, H⁺ ions leave red cells (to neutralize excess base), and K⁺ ions enter the red cells.
3. *Vomiting.* The major loss consists of both H⁺ and K⁺ from the stomach. Loss of K⁺ in gastric fluid may be less important than the overall fluid loss, which causes activation of aldosterone and renal wasting of K⁺.

Hyperkalemia

Among the major causes are those that also cause hypernatremia (e.g., dehydration, diabetes insipidus), as well as acidosis and diabetes mellitus (as discussed earlier), and hemolysis. Any kind of cell damage, such as rhabdomyolysis, and especially hemolysis of erythrocytes, can cause hyperkalemia. In hemolysis, all of the intracellular K⁺ is extruded into plasma. Another analyte that is concentrated in red cells that rises with K⁺ in hemolysis is LD. Concomitant elevations of potassium and LD in serum should be taken as indications of hemolysis that occurs artifactually after a blood sample has been taken from the patient or, less commonly, as hemolysis that results from an underlying hemolytic condition.

RENAL DISEASE (OH, 2003; SCHNERMANN, 1998)

Four analytes aid in the diagnosis of this condition: BUN, creatinine, calcium, and phosphate. It is amazing that neither BUN nor creatinine has an inherent relationship to kidney function, but both fortuitously are excellent indicators of renal condition.

BUN

Urea nitrogen is generally measured in plasma or serum but has historically been referred to as BUN. The formula for urea is H₂N-CO-NH₂. Two moles of nitrogen are present per mole of urea. This is the end product of NH₃ metabolism in the liver, as discussed in Chapter 21. Urea is excreted by the renal tubules at a rate that is roughly proportional to the glomerular filtration rate (GFR). Note, therefore, that the retained urea (i.e., plasma or serum urea or BUN) is approximately inversely proportional to the GFR, that is,

$$\text{BUN} \propto 1/\text{GFR} \quad (8-1)$$

Creatinine

Creatinine is secreted but is also reabsorbed to an approximately equal extent, so that the net effect is that the amount filtered is the amount excreted. The total amount of creatinine filtered then is its urinary concentration, Ucr \times volume of urine (V), over a given time. The total plasma that delivered this quantity of creatinine to the glomerulus is the total amount of creatinine filtered divided by the plasma concentration, Pcr. This quantity is also the creatinine clearance (Ccr). So the glomerular filtration rate is as follows:

$$\text{GFR} = \text{Ccr} = \text{Ucr} \times \text{V} / \text{Pcr} \quad (8-2)$$

Pre-Renal Disease

Suppose the BUN is abnormally high (reference range = 10–20 mg/dL). Two possible reasons for this are known. The first is pre-renal, where renal plasma flow is reduced from such lesions as renal artery stenosis, renal vein thrombosis, and the like. This causes a reduction in the GFR. From Equation 8-1, the BUN will then rise. However, the serum creatinine levels (Pcr in Equation 8-2), with a reference range of about 0.5–1.0 mg/dL, generally will remain within normal limits or may be mildly elevated because, from Equation 8-2, it can be seen that low GFR will result in lower urine flow (V in Equation 8-2). Pcr and Ucr generally will remain within normal limits. Thus a disproportionate rise in BUN over creatinine will be noted. The normal BUN/creatinine ratio is 10–20:1, and in pre-renal disease, it rises to well above 20:1.

Renal and Post-Renal Disease

The second cause of elevated BUN is true renal disease. Here again, there will be a rise in BUN due to low GFR. Now, however, creatinine filtration will be compromised, so that its serum level will rise correspondingly. Thus, in true renal disease, both BUN and creatinine rise together, maintaining the BUN/creatinine ratio at 10–20:1 (Oh, 2003). This pattern also occurs in so-called post-renal disease (i.e., obstructive uropathy due to renal or ureteral stones [nephrolithiasis or urolithiasis], prostatic enlargement from benign prostatic hyperplasia or prostatic carcinoma, urinary tract infection, bladder stasis, urothelial carcinoma, etc.

Pinpointing the Lesion

Suppose a patient is found to have a BUN of, say, 60 mg/dL and a creatinine of 3.5 mg/dL. True renal failure can therefore be diagnosed. Now, consider the kidney to be two compartments—one a filtration compartment (glomerulus), and the other a concentration compartment (renal tubules). If renal failure is present, where is the lesion—in the filtration or the concentration compartment? As discussed previously, the function of the kidneys is to conserve fluids or to concentrate the urine. Therefore, if a patient is on a fluid-restricted diet, the osmolality of urine (Uosm) should be significantly higher than the osmolality of plasma (Posm). In fact, Uosm/Posm is >1.2 for normal individuals. If a 24-hour urine specimen collection from the above patient on a fluid-restricted diet is measured for Uosm, we can determine where the lesion has occurred. If Uosm/Posm <1.2 , then the urine is not being concentrated, so a tubular lesion must be

present. On the other hand, if a normal ratio is found, then, by exclusion, the lesion must be glomerular. Causes of glomerular lesions are many and include glomerulonephritis, pyelonephritis, diabetes, and infarction among others; tubular lesions also have many causes, including pyelonephritis, diabetes, papillary necrosis, acute tubular necrosis, infarction, shock, ischemia, etc. It is remarkable that from a blood specimen of only 100 μL and several urine aliquots, not only can we determine the presence of renal failure, but we can localize the lesion and all of this virtually noninvasively.

Calcium and Phosphate

The kidneys play an important role in the regulation of calcium levels. In renal failure, calcium levels tend to fall, while phosphate levels correspondingly tend to rise. The topic of calcium and phosphorus metabolism is discussed in detail in the context of bone metabolism (see Chapter 15) and the endocrine system (see Chapter 24). Here, we discuss these two analytes for diagnostic purposes.

Remember that calcium is the most abundant cation in the body, and that most of it is stored in bone as a calcium hydroxyphosphate in hydroxyapatite crystal. Calcium complexes with phosphate in several different forms, depending on the ionization state of phosphate, that is,

The most insoluble calcium phosphate forms are those with the most basic phosphates (i.e., those in Equation 8-5). Thus alkaline conditions promote calcium deposition in bone, while acidic conditions promote leaching of calcium from bone. Therefore, alkalosis promotes hypocalcemia, while acidosis promotes hypercalcemia.

Note also an equilibrium between soluble calcium phosphate and insoluble calcium phosphate in bone. We represent this equilibrium as follows:

where P represents all ionic phosphate forms, and where the left side is all soluble calcium phosphate salts and the right side is the insoluble salt forms. The equilibrium constant, K_{sp} , for this equilibrium is as follows:

$$K_{\text{sp}} = (\text{Ca}) \times (\text{P}) / (\text{CaP}) \text{ insoluble} \quad (8-7)$$

Because (CaP) insoluble is constant in concentration, the product of soluble $\text{Ca} \times$ soluble P is a constant, called the solubility constant, or K_{sp} . Thus there is an inverse relationship between Ca and P . Hypocalcemic states are almost always accompanied by hyperphosphatemic states, and vice versa. Of the soluble calcium, in the numerator of Equation 8-7 are two forms—calcium bound to albumin and globulin and small molecules in chelate form, and so-called ionized or nonchelated calcium. Biologically active calcium is present in the ionized form. Therefore, serum levels of ionized calcium are considered to be the best measure of hypocalcemia, normocalcemia, or hypercalcemia.

Causes of Hypocalcemia

The kidneys are vital in calcium metabolism and regulate calcium levels in two ways. First, parathyroid hormone stimulates the renal tubules to excrete phosphate. By Equation 8-7, the serum calcium level must then rise. Also, the kidneys are vital to the formation of active vitamin D in the synthesis of 1,25-dihydroxycholecalciferol, necessary for the absorption of calcium in the gut. In renal disease, where tubular failure occurs, phosphate excretion is inhibited by the nonresponsiveness of the tubules to parathyroid hormone. Therefore, phosphate levels rise, while calcium levels fall. In addition, active vitamin D production is reduced, lowering absorbed calcium. Hypocalcemia and hyperphosphatemia, in the face of elevated BUN and creatinine, indicative of renal disease, strongly suggest tubular failure.

Other Causes of Hypocalcemia

Besides alkalosis and renal failure, hypocalcemia may be caused by hypoparathyroidism, also leading to hyperphosphatemia. Rarely, as in medullary thyroid carcinoma and other amine precursor uptake and decarboxylase activity cell tumors, the elaboration of calcitonin, a well-known calcium-lowering hormone, may lead to decreased serum calcium levels. In addition, vitamin D levels may be low, resulting in diminished reabsorption of calcium for the gut. These causes may be encapsulated in the acronym,

CHARD (Calcitonin, Hypoparathyroidism, Alkalosis, Renal failure, vitamin D deficit).

Causes of Hypercalcemia

Besides acidosis, possible causes of this condition may be summarized by Bakerman's "CHIMPS" mnemonic (Bakerman, 1994), or Cancer, Hyperthyroidism, Iatrogenic causes, Multiple myeloma, Hyperparathyroidism, and Sarcoidosis.

Calcium and Albumin

About half of the calcium circulating in blood is bound to serum protein, mainly albumin; the remainder may be chelated in tight complexes with ions such as citrate and oxalate or may be found in ionic complexes with counter-ions such as chloride—so-called free calcium. As is true for most hormones in the body, serum levels of parathyroid hormone (PTH) are determined by the levels of the free target of the hormone, in this case, free calcium. Also, virtually all of the effects of calcium in the body are induced by free calcium. Free or ionized calcium can be measured directly by an ion-selective electrode method. However, most laboratories measure total serum calcium using appropriate chelating dye methods; the concentrations of the calcium-dye complexes can be measured spectrophotometrically. Several formulas, none too reliable, have been developed to compute serum free calcium concentration from the total calcium ion concentration and serum albumin concentration (Larsson, 2003). More relevant is the computation of the "corrected" calcium concentration, most usually in hypocalcemia (Labriola, 2009). Generally, even if serum albumin concentrations fluctuate substantially, resulting in changes in total calcium levels, the ionized calcium levels in serum may remain relatively stable. If a patient has a total serum calcium that is lower than the lowest value for the reference range, and if the serum albumin level is concurrently low, a correction formula is used in which the total calcium is computed as the observed total calcium in mg/dL + a correction factor. Several different correction factors are known, perhaps the most commonly used of which is $0.8 \times (4 \text{ g/dL} - \text{serum albumin concentration in g/dL})$. This correction is based on the ratio of bound calcium to albumin and the mean "normal" albumin value of 4 g/dL . If the corrected value results in total calcium in the reference range, it is assumed that the free calcium is in the normal range, that is, the "lost" calcium was all bound to albumin, and no free calcium was lost. Conversely, dehydration or hemoconcentration may elevate serum albumin, resulting in a falsely elevated total serum calcium. In this case, the correction will be a negative one because the albumin levels are elevated above 4 g/dL .

BLOOD GAS ABNORMALITIES

We have discussed the effects of acidosis and alkalosis on serum calcium levels. The actual diagnosis of acidosis or alkalosis, however, depends on measurement of the pH of arterial blood. This topic is discussed in depth in Chapter 14. Here we focus on how to interpret abnormal results and to correlate them with other laboratory findings.

Blood gas determinations refer to the quantitative measurement of the pH of arterial blood, the partial pressure of carbon dioxide (pCO_2), the bicarbonate, the partial pressure of oxygen (pO_2), oxygen saturation, and base excess. Three of these quantities are interdependent on one another, that is, the PCO_2 , the bicarbonate, and the pH, by the Henderson-Hasselbalch equation as follows:

$$\text{pH} = 6.1 + \log[(\text{HCO}_3^-)/(\text{H}_2\text{CO}_3)] \quad (8-8)$$

Because the H_2CO_3 concentration in blood is directly proportional to the pCO_2 (i.e., at room temperature), $\text{H}_2\text{CO}_3 = 0.03 = \text{pCO}_2$, Equation 8-8 can be written as follows:

$$\text{pH} = 6.1 + \log[(\text{HCO}_3^-)/(0.03 \times \text{pCO}_2)] \quad (8-9)$$

Note that if bicarbonate, in the numerator of Equation 8-9, becomes consumed as in metabolic acidosis, the respiratory rate will increase, thereby decreasing the pCO_2 , causing the denominator of this equation to fall, resulting in compensation. If the pCO_2 increases, as in respiratory acidosis, the kidneys retain bicarbonate, so that both numerator and denominator increase so as to maintain the ratio relatively constant.

In interpreting blood gas results, the first number to note is the pH. Regardless of the values of the bicarbonate and pCO_2 , if the pH is less than 7.4, the patient is acidemic, that is, the hydrogen ion concentration in blood is elevated, which must reflect acidosis, that is, excessive production or retention of acid; if greater than 7.4, the patient is alkalemic, reflecting the process of alkalosis; if close or equal to 7.4, the patient is

TABLE 8-4

Patterns of pH, pCO₂, and Bicarbonate in Different Conditions

Condition	pH	Bicarbonate	pCO ₂	Typical causes
1. Metabolic acidosis	<7.40	Low	Low	Diabetic ketoacidosis; lactic acidosis
2. Metabolic alkalosis	>7.40	High	High	Vomiting
3. Respiratory acidosis	<7.40	High	High	COPD; paralysis of respiratory muscles
4. Respiratory alkalosis	>7.40	Low	Low	Anxiety; acute pain

COPD, Chronic obstructive pulmonary disease; pCO₂, partial pressure of carbon dioxide.

neither acidemic nor alkalemic, but could still have compensating processes of acidosis and alkalosis. Once the diagnosis of acidosis or alkalosis is made, then the bicarbonate and the pCO₂ can be used to decide whether it is of metabolic or respiratory origin.

Table 8-4 summarizes the four basic abnormal states: Metabolic and respiratory acidosis and metabolic and respiratory alkalosis. In metabolic acidosis, the primary problem is production of acid, as in diabetic ketoacidosis, lactic acidosis (e.g., from gram-negative sepsis), and renal failure. This acid is buffered by bicarbonate, which is therefore consumed. To compensate for the bicarbonate loss, the breathing rate increases to lower the pCO₂. So a low pH combined with a low bicarbonate and a low pCO₂ point to metabolic acidosis, as shown in condition 1 of this table.

As shown in condition 2 of the table, the opposite condition, metabolic alkalosis, results in reversal of the levels shown in condition 1. The most common cause of metabolic alkalosis is vomiting with loss of HCl from the stomach and an attendant rise in bicarbonate.

When CO₂ is abnormally retained by the lungs, as in chronic obstructive pulmonary disease (COPD), the denominator of Equation 8-9 increases, causing the pH of blood to fall. To compensate, the kidneys retain bicarbonate, thus increasing the numerator of this equation. If the blood pH is below 7.4, and the CO₂ and bicarbonate are both increased (condition 3 in Table 8-4), the acidosis is of respiratory origin. Note the mirror image condition (opposite levels) for respiratory alkalosis in condition 4 of this table. Besides COPD, the major causes of respiratory acidosis include diseases such as myasthenia gravis, in which there is partial paralysis of the accessory muscles of breathing; pneumonia; and central nervous system diseases affecting the brainstem in areas involved in respiratory control. Respiratory alkalosis is due mainly to hyperventilation, often of psychogenic origin. Here, the pCO₂ is reduced because of the rapidity of breathing.

The pH of blood can affect the levels of electrolytes in serum. In acidosis, besides bicarbonate buffering, red cells also buffer excess H⁺ ions by exchanging these for intracellular K⁺ ions, the net effect being a mild hyperkalemia. An attendant hypokalemia occurs in alkalosis. Remember also that acidosis can cause a mild hypercalcemia; alkalosis can cause a mild hypocalcemia and can especially affect the ionized calcium moiety.

Anion Gap

All sodium ions must be neutralized by counter-ions, most of which, in blood, are constituted by chloride and bicarbonate ions, and, to a lesser degree, by phosphate, sulfate, and protein carboxylate groups. Normal serum sodium is about 140 mEq/L, chloride is usually around 100 mEq/L, and bicarbonate around 2 mEq/L. The anion gap is then defined as Na⁺ – (Cl[–] + HCO₃[–]), which for normal individuals is around 16. This 16 mEq/L really accounts for the other counter-ions that neutralize sodium but are not measured in serum.

If an individual has a metabolic acidosis, in which the rise in H⁺ ion concentration is accompanied by a corresponding rise in Cl[–] ions, the acid will be buffered by bicarbonate (converted to H₂CO₃). The bicarbonate value therefore will decrease, but a 1 : 1 increase in chloride ion will occur. Thus there will be no change in the anion gap. If the metabolic acidosis is due to the presence of an acid whose counter-ion is not Cl[–], such as acetoacetic acid (in diabetic acidosis) or lactic acid as in sepsis or hypoperfusion, then bicarbonate is reduced, as above, but no corresponding increase in Cl[–] occurs. Therefore, there is an increase in the anion gap, which can reach values of 25–30 mEq/L. The presence of a widened anion gap signifies the presence of a metabolic acidosis due to a non-chloride-containing acid.

Figure 8-2 The effect of increased partial pressure of carbon dioxide (pCO₂) on the partial pressure of oxygen (pO₂) in the alveolus and in the arterial blood. This figure demonstrates that as pCO₂ increases, a greater than a one-to-one decrease in pO₂ occurs.

Low Anion Gaps

Consistently low anion gaps, typically in the range of 1–3 mEq/L, signify the presence of high levels of basic protein, often a monoclonal paraprotein as occurs in plasma cell dyscrasias. Basic protein contains ammonium ions, the counter-ions for which are chloride. Now the “invisible” ion is ammonium, and a measurable increase in chloride ion occurs. This tends to decrease the anion gap. Persistently low anion gaps are a serious sign of possible malignancy (e.g., multiple myeloma).

Oxygenation

Blood gases also give an excellent measurement of tissue perfusion through measurement of the pO₂ and the O₂ saturation of Hb. Normal pO₂ values should be between 90 and 100 mm Hg, while O₂ saturation should be 100%. Low values of either or both of these numbers flag underlying pathology. The major causes of low values for these measurements are myocardial infarction, pulmonary embolus, severe pulmonary interstitial disease (e.g., interstitial pneumonia), and tissue anoxic states secondary to hypoperfusion, as in septicemia and severe congestive heart failure. In pulmonary embolus, the pulmonary circulation is blocked by the embolus, despite adequate ventilation, giving rise to ventilation/perfusion inequalities. The hallmark of pulmonary embolus is a marked drop in the pO₂.

Hypercarbia as a Cause of Hypoxia

Another major cause of hypoxic states in arterial blood is CO₂ retentive states, as in severe COPD. This occurs because, as CO₂ builds up in alveoli, it reduces the volume of O₂ in the air space. At pCO₂ values of over 50 mm Hg, the effect on alveolar pO₂, represented as P_AO₂, becomes important, as illustrated in Figure 8-2. Oxygen, unlike CO₂, is not soluble in water or membranes, so that there is a difference of about 10–15 mm Hg pressure between alveolar and arterial O₂ (represented as P_AO₂), called the A–a gradient. Thus the P_AO₂ is even lower than the decreased P_AO₂. It is important to remember that the total oxygen breathed in, called the P_IO₂, is partitioned, therefore, between the alveolar sac and the arterial blood. This relationship may be written as follows:

$$P_{I}O_2 = P_{A}O_2 + P_{A}CO_2 \quad (8-10)$$

For each mole of O₂ consumed, approximately 0.8 mole of CO₂ is produced. The ratio of CO₂ produced to O₂ consumed is called the respiratory quotient, or the RQ. The P_AO₂ may be written as P_ACO₂/RQ. Overall, Equation 8-10 can be rewritten as follows:

$$P_{A}O_2 = P_{I}O_2 - P_{A}CO_2/RQ \quad (8-11)$$

For an RQ of 0.8:

$$P_{A}O_2 = P_{I}O_2 - 1.25 \times P_{A}CO_2 \quad (8-12)$$

This equation states that, for each increment in the P_ACO₂, there will be a more than one-to-one decrease in the P_AO₂. This will result in severe O₂ deficits.

Figure 8-3 The effects of decreasing partial pressure of oxygen (pO_2) in the allosteric zone of the oxygen-hemoglobin dissociation curve. On the pH 7.4 (middle) curve, if the pO_2 drops from 80 to 60 mm Hg, little effect on oxygen saturation is seen. However, a drop from 40 to 20 mm Hg results in a large drop in oxygen saturation, from about 80% to 30% (arrow 1 in the figure). Combined with this low oxygen saturation is a marked tissue lactic acidosis from anaerobic metabolism. The increased acidosis results in a drop in blood pH to 7.2, shifting the oxygen-hemoglobin dissociation to the right (pH, 7.2 curve). Now, for a pO_2 of 20 mm Hg, the oxygen saturation drops even farther (arrow 2 in the figure) to about 20%, setting a vicious circle in motion.

Figure 8-3 is the oxygen-hemoglobin dissociation curve. Note that the curve is sigmoidal because of the allosteric nature of the binding of oxygen to hemoglobin. For pO_2 values between 70 and 100 mm Hg, the saturation of hemoglobin is close to 100%. But at pO_2 values <70 mm Hg, a steep drop in the saturation fraction is noted, so that small drops in pO_2 lead to large decreases in percent saturation. Compounding this effect is the disproportionate decrease in pO_2 whenever pCO_2 increases, as described previously. While these detrimental events transpire, tissue perfusion severely diminishes because of the diminished O_2 saturation of arterial blood. The result is tissue acidosis (mainly from lactic acid as a result of anaerobic metabolism). Acidosis shifts the oxygen-hemoglobin dissociation to the right, as in Figure 8-3, causing even lower saturation for a given pO_2 , causing further diminished tissue perfusion and more tissue acidosis. This vicious cycle can be corrected by placing the patient on a respirator to cause increased expiration of CO_2 .

The pattern of arterial blood gas determinations for this type of patient will be low arterial blood pH, low pO_2 , low O_2 saturation, high pCO_2 , and low bicarbonate. This pattern is not typical of the four basic patterns given in Table 8-4 because, on top of a fundamental respiratory acidosis (high pCO_2), there is a superimposed tissue metabolic lactic acidosis, causing low bicarbonate. These findings, together with the low pO_2 , indicate the immediate need for ventilation of the patient on a respirator.

Unlike in myocardial infarction and pulmonary embolus, treatment of the acute hypercarbic state calls for not administering O_2 unless the patient is being adequately ventilated. Hypercarbia induces a CO_2 -induced inhibition of the respiratory centers in the pons and the medulla oblongata in the brainstem. In fact, the only impetus to breathe is hypercarbia-induced hypoxia, which causes chemoreceptors in the aortic arch to send signals to the respiratory center in the brain to continue breathing. Administration of O_2 to patients with this condition without ventilation can cause cessation of respiration and the acute demise of the patient.

GLUCOSE ABNORMALITIES

The normal reference interval for fasting serum glucose is generally between 70 and 110 mg/dL. Recently, discussion has involved lowering the upper limit to 100 mg/dL (Nathan, 2009). As described in Chapter 16, the two basic abnormalities that occur with serum glucose levels are hyperglycemia, almost always associated with diabetes mellitus, and

hypoglycemia due to iatrogenic (overdose with insulin in the diabetic patient) or to other underlying causes (such as reactive hypoglycemia due to “hypersensitivity” to insulin, insulinoma, etc.). To establish hyperglycemia, it is vital to determine whether the patient has (1) a fasting serum glucose level greater than or equal to 126 mg/dL, (2) a random serum glucose level greater than or equal to 200 mg/dL, or (3) a 2-hour postload plasma glucose concentration greater than or equal to 200 mg/dL during an oral glucose tolerance test (Nathan, 2009). Any one of these findings is diagnostic, if it can be confirmed by repeat testing on a subsequent day (Nathan, 2009).

In the glucose tolerance test, as described in Chapter 16, after giving the patient, who has not eaten for 12 hours overnight, a well-defined amount of glucose orally, blood and urine glucose levels are followed. Normally, serum glucose levels rise and then fall within about a 2-hour period. If the glucose levels remain elevated, however, the diagnosis of diabetes mellitus may again be made. If glucose is detected in the urine at any point, evidence for this condition is also obtained, although absence of urinary glucose does not in any way rule out diabetes mellitus.

High levels of serum glucose also result in the glycosylation of Hb. Glycosylated Hb levels change slowly over time and therefore constitute a stable and reliable indicator of serum glucose levels over the past 2–3 months. Glycosylated Hb levels that are greater than 6.5% are considered to be indicative of diabetes mellitus (Nathan, 2009), and efficacy of treatment is gauged by whether this serum level is reduced to less than 6.5%. Of all the methods for diagnosing and especially for monitoring the treatment of diabetes mellitus, measurement of glycosylated Hb levels is perhaps the most accurate and should be done in conjunction with blood glucose determinations (Blinco, 2001; Krishnamurti, 2001; Kilpatrick, 2004; Nathan, 2009).

Other Abnormal Laboratory Findings in Diabetes Mellitus

As discussed earlier in the electrolyte section, under the influence of insulin, whenever glucose is transported into the cell, it is accompanied by potassium. In diabetes, in the absence of insulin, blood glucose is elevated, as is potassium. Increased metabolism of fats leads to a buildup of acetoacetic acid, resulting in a metabolic acidosis. In diabetes where the blood glucose becomes exceptionally elevated (i.e., >300 mg/dL), serum osmolality becomes dangerously high and can cause nonketotic, hyperosmolar coma. In this condition, red (and white) cell water flows from the cells into the vascular volume, tending to dilute analytes such as sodium. Thus the nonketotic, hyperosmolar coma patient may have a hyperosmolar serum, hyperglycemia, hyperkalemia, and hyponatremia. In ketotic states, the patient will have, additionally, a metabolic acidosis and a large anion gap.

Hypoglycemia

Serum glucose levels of <60 mg/dL on a series of random fasting serum specimens strongly suggest hypoglycemia. The low glucose values should be associated with adrenergic and/or neuroglycopenic symptoms, which are relieved upon administration of glucose (Whipple’s triad). Glucose tolerance tests show that after an initial sharp rise in serum glucose levels, an abnormally rapid drop occurs to levels substantially below 60 mg/dL. If hypoglycemia is suspected, it is advisable to give the patient a 5-hour glucose tolerance test because the hypoglycemic “dip” often is not seen until after 3 hours. Glucose tolerance tests should be performed with great caution in patients with suspected hypoglycemia because the procedure can induce severe reactive hypoglycemia, causing loss of consciousness and even shock.

LIVER FUNCTION TESTS

Liver function is discussed in depth in Chapter 21. In that chapter, a detailed breakdown is given of different patterns in abnormal liver function tests. The reader will find it difficult to retain these patterns without a basic understanding of the underlying principles. We can reduce the most common liver test abnormalities to a set of six conditions, which are summarized in Table 8-5. The principles for these patterns are explained as follows:

1. **Hepatitis and acute injuries and/or necrotic lesions** in the liver cause primarily a marked rise in the levels of aminotransferases, aspartate aminotransferase (AST) and alanine aminotransferase (ALT). Cell injury and necrosis also cause a rise in other enzymes such as LD. These include acute hepatitis (e.g., infectious,

TABLE 8-5

Six Fundamental Patterns of Liver Function Tests

chemically induced), infarction, and trauma. The biliary tract is always affected, so that direct bilirubin rises from interference with bile flow. Because of biliary tract injury, the enzyme alkaline phosphatase (AP) rises, along with γ -glutamyl transferase (GGT) and 5'-nucleotidase (5'-N). Hepatocyte injury causes loss of conjugation of transported bilirubin, so that indirect (unconjugated) bilirubin also rises. Because, generally, in hepatitis, much less than 80% of the liver is destroyed, total regeneration will occur, and enough tissue is present to enable adequate levels of protein synthesis and ammonia fixation as urea. Therefore, total protein and albumin and ammonia levels remain normal. These typical results are summarized in condition 1 of Table 8-5.

- Cirrhosis** of the liver is characterized by two cardinal features: Fibrosis, preventing regeneration of liver tissue wherever this has occurred, and nodules of regenerating liver tissue, which are the only source of any kind of hepatocytic function. Thus, in cirrhosis, as shown in condition 2 of Table 8-5, almost the reverse pattern occurs from the one seen in condition 1 in Table 8-5 for hepatitis. Because, in panhepatic cirrhosis, destruction of >80% of liver tissue occurs, with no regeneration of damaged liver tissue, the AST/ALT aminotransferases and LD levels (all from the regenerating nodules) tend to be normal or low or occasionally mildly elevated. However, total protein and albumin are both abnormally low. Because the liver is the sole site of ammonia detoxification via the urea cycle, and because, in this condition, loss of hepatocytic function occurs, serum ammonia levels are elevated. Because insufficient viable liver tissue remains, and because fibrosis destroys the cholangioles, both indirect and direct bilirubin tend to be elevated.
- Acute biliary obstruction** caused by stones in the biliary tree, or by neoplasms that block bile excretion, results in elevations in direct bilirubin and biliary tract AP, along with the enzymes GGT and 5'-N (see earlier). All other liver function test results are normal. For simple biliary obstruction, therefore, the pattern is as shown in condition 3 of Table 8-5.
- Space-occupying lesions** of the liver are characterized, for reasons that are not well understood, by isolated elevations of the enzymes AP and LD. This pattern is shown in condition 4 of Table 8-5. The most common cause of this condition is metastatic carcinoma to the liver.
- Passive congestion** of the liver is characterized by a mild elevation of aminotransferases (AST/ALT) and LD and, in more severe cases, by elevations of total bilirubin and AP. This pattern is also seen in infectious mononucleosis, where the rise in bilirubin may be marked. The general passive congestion pattern is shown in condition 5 of Table 8-5.
- Acute fulminant hepatic failure** from a variety of causes, which include Reye's syndrome and hepatitis C (Gill, 2001; Schiodt, 2003), is discussed in Chapter 21. This condition is total liver failure. The overall pattern (Sunheimer, 1994) is shown in condition 6 of Table 8-5. It appears as a combination of hepatitis and cirrhosis. Here AST and ALT reach exceptionally high values, often in excess of 10,000 IU/L. At the same time, total protein and albumin are markedly reduced, and ammonia levels are abnormally elevated, causing hepatic encephalopathy. LD, AP, and bilirubin are also elevated. Besides the marked rise in AST and ALT, combined with hyperammonemia, a characteristic disproportionate rise in AST over ALT occurs, further confirming the diagnosis. It is vital to recognize this pattern because the underlying condition is a medical emergency, which must be treated promptly.

Correlations of Liver Function Test Results With Other Laboratory Findings

In severe liver failure secondary to cirrhosis or to fulminant hepatic failure, it is not uncommon to find electrolyte abnormalities and abnormalities in renal function tests, and in the coagulation profile. Patients with condition 2 or 6 in Table 8-5 often have ascites, with marked third space fluid loss. This results in increased levels of both ADH and aldosterone to retain intravascular water. Depending on which levels "win out," the patient may become hyponatremic or hypernatremic.

Severe liver failure can also cause the hepatorenal syndrome (i.e., renal dysfunction secondary to hepatic failure). This disease is characterized by the typical patterns shown in conditions 2 and 6 in Table 8-5. As discussed earlier in the Renal section, renal failure results in elevations in BUN and creatinine, with a 10–20:1 ratio indicative of renal failure. The Uosm/Posm ratio is <1.2:1, indicating tubular dysfunction.

Severe coagulopathies with elevated APTTs and PTs may be seen because of the absence of production of coagulation factors. Not infrequently, DIC will accompany liver failure. This condition must be distinguished from low coagulation factor production combined with hepatosplenomegaly due to portal hypertension as in cirrhosis. The splenomegaly may result in sequestration of platelets, so that the overall pattern may resemble DIC but may not be true DIC. To clinch the diagnosis of DIC, elevations of D-dimer levels should be noted. Because in DIC, emboli occur in the microvasculature of different tissues, including bone marrow, bone marrow-induced hemolytic anemia may develop, in which schistocytes, burr cells, and fragmented forms appear in the peripheral blood smear; in addition, nucleated red cells and myeloid precursor cells such as myelocytes and metamyelocytes may be seen in the blood smear, the so-called leukoerythroblastic picture referred to earlier in the Coagulation section. Also, with severe liver failure, abnormal red cell forms, called target cells, may be seen in the peripheral blood smear.

Patients with cirrhosis and acute fulminant hepatic failure tend to be immunocompromised. Many of these patients have defective T cell function but produce an excess of (ineffective) immunoglobulin. Thus these patients tend to have low serum albumin levels from diminished albumin synthesis but elevated serum immunoglobulins.

CARDIAC FUNCTION TESTS

Diagnosis of Myocardial Infarction and Acute Coronary Syndrome

These are discussed at length in Chapter 18. Because acute myocardial infarction (AMI) requires rapid and accurate diagnosis, especially now that new treatment options with thrombolytic agents are available, the clinical laboratory has been called upon to provide serum diagnostic tests that can make this diagnosis at an early stage. Until recently, laboratory diagnosis was based on serial determinations of the MB fraction of creatine phosphokinase (CK-MB); confirmation of the diagnosis was provided by the so-called flipped ratio of the isozymes of LD 24–36 hours after the initial acute event and/or by observation of the characteristic time courses for elevations of the three enzymes CK, AST, and LD.

These approaches have been replaced mainly by two other analytes, myoglobin (MY) and especially cardiac troponin (cTn), which provide more rapid and specific diagnostic capabilities (Morrow, 2007). MY is an oxygen-binding/transport protein found in both cardiac and skeletal muscle. Its relatively small size and function allow for early release from irreversibly damaged cells. However, current methods of measurement

cannot distinguish the tissue of origin of MY. Therefore, its use is confined to screening patients for possible AMI; positive results suggest the need for further workup for AMI.

Troponin is a regulatory protein complex in muscle tissue; it comprises three subunits designated troponin I (TnI), troponin T (TnT), and troponin C (TnC). Different genes encode TnI in skeletal and cardiac muscle, giving rise to isoforms that differ significantly in sequence. Cardiac TnI contains an additional 31 amino acid residues on its N-terminal. Rapid and accurate immunoassays for cardiac TnT and cardiac TnI have been developed. In AMI, cardiac TnI becomes elevated 4–8 hours after onset of chest pain, reaches a peak at about 12–16 hours, and remains elevated for 5–9 days. Values at or above 1.5 ng/mL are considered to be suggestive of AMI. However, because different assays (all immunoassays) measure different domains of TnT and TnI, reference ranges differ depending upon the antibodies used in the assays. Because cTn levels rise relatively rapidly and remain elevated for prolonged times, troponin determinations have replaced the so-called flipped ratio of the two isozymes of LD, LD1 and LD2 (LD2:LD1 ratio rises to >0.75 and often exceeds 1.0), which occurs only about 36 hours after the onset of symptoms.

CK-MB is another biomarker that can be used in diagnosing AMI. CK-MB has three isozymes composed of two chains (called the M and B chains) which are MM, MB, and BB. The MB fraction is predominantly found in cardiac muscle (Roberts, 1997). To diagnose AMI from CK-MB serum levels, it is important to show a rise both in the concentration of CK-MB and in the ratio of CK-MB to total CK (also called the cardiac index) (Thompson, 1988; Woo, 1992). Because a small amount of CK-MB is found in skeletal muscle, diseases of skeletal muscle that cause the level of CK-MM to rise to high values will also cause the levels of CK-MB to rise to high absolute concentrations in serum, which can cause false-positive values for CK-MB. In addition, to increase both the sensitivity and the specificity of CK-MB in the diagnosis of acute AMI, it has been found necessary to perform serial determinations of MB fraction (at 3- to 4-hour intervals over a 12- to 16-hour period) that show a progressive rise that reaches a peak, followed by a fall to low levels. This pattern is virtually 100% diagnostic of myocardial infarction (Lott, 1984; Wu, 1999). It is important to note that CK-MB generally rises within 4–6 hours, and sometimes only 2 hours, after the onset of chest pain, and peaks within 12 hours. Therefore, MY and CK-MB were recommended (Wu, 1999; Alpert, 2000; Fromm, 2001; Lewandrowski, 2002) for use as early markers of AMI.

However, elevated TnT and TnI levels are more specific for cardiac injury than are elevated CK-MB levels. Similar to CK-MB, they rise within 4–6 hours, and sometimes within 2 hours, after the onset of chest pain.

Current protocols for the laboratory diagnosis of AMI vary and are evolving as assays for cTn improve (see Chapter 18). In some medical centers, TnI or TnT is used exclusively; in other centers, troponin and CK-MB are used together.

Diagnosis of Congestive Heart Failure

Until recently, this condition was diagnosed strictly on the basis of symptoms and/or as a result of procedures such as echocardiography. However, a new biomarker, B-type natriuretic peptide (BNP), has been discovered and approved as a definitive test for this condition and appears to be an excellent marker for early heart failure; this test may also be both diagnostically and prognostically significant in patients presenting with acute dyspnea and chest pain. The differential diagnosis in these patients includes dyspnea caused by chronic heart failure (signs and symptoms of which are typically nonspecific) versus other causes of acute dyspnea (e.g., pneumonia, carcinoma, effusion, asthma). Normal levels (i.e., a high negative predictive value for this test) appear useful in excluding a cardiac origin in these patients. Levels of BNP may also be an independent predictor of arrhythmia, stroke, and death (Clerico, 2004; Ishii, 2003; Mueller, 2004; Prahsh, 2004; Wang, 2004; Winter, 2004; Novo, 2009). Studies suggest that serum BNP levels are useful in evaluating the efficacy of treatment of congestive heart failure (Novo, 2009).

PANCREATIC FUNCTION TESTS

Elevations in serum pancreatic amylase and lipase are definitive markers for pancreatic disease. The most common cause for such increases in the serum levels of these enzymes is pancreatitis. In acute pancreatitis, both enzymes are elevated. Because amylase can also be produced by the salivary glands, amylase is slightly less specific than lipase as a marker for pancreatitis. Elevations in the latter enzyme are definitive for pancreatic disease.

MARKERS FOR INFLAMMATORY CONDITIONS

As discussed previously in the Hematology section, increases in the WBC count, especially with a predominance of neutrophils, indicate acute infection. In most acute inflammatory conditions, as noted previously, acute phase reactant proteins are also found to be increased. These proteins occur in the α (including α -1-antitrypsin, α -2-macroglobulin) and β (including ferritin and C-reactive protein [CRP]) regions of the serum protein electrophoretogram, as discussed in Chapter 19 on serum protein electrophoresis. In this regard, quantitative determinations for serum CRP are very helpful in recognizing acute inflammatory states. Recently, specific antibodies to CRP have allowed for highly sensitive measurement of CRP (termed high-sensitivity CRP, or hs-CRP) at lower concentrations than were previously measurable (Roberts, 2000). Currently, elevated levels of hs-CRP appear to serve as an early marker of inflammation and may have utility in assessing cardiovascular risk for stroke and myocardial infarction (Abrams, 2003; Ridker, 2003; Libby, 2004).

Fibrinogen, also an acute phase reactant, may additionally increase. Often, the platelet count tends to rise, and platelets themselves have been considered as “acute phase reactants.” In addition, in both acute and chronic inflammatory conditions, erythrocytes exhibit increased mobility. Thus there is an increase in the erythrocyte sedimentation rate. Recent studies suggest that the best marker for inflammation, especially as a guide to therapeutic efficacy, is CRP (Crowson, 2009).

Finally, one common cause of acute inflammation is gout (i.e., hyperuricemia), or elevations of uric acid in serum. Uric acid crystals cause a severe, acute arthritic condition (gout). Serum levels of uric acid >7.5 mg/dL are indicative of this condition. Less constant findings are the presence of uric acid crystals in the urinary sediment (see Chapter 32) or in joint fluid (see Chapter 33).

ENDOCRINE FUNCTION TESTING

We noted that abnormal functioning of the thyroid and adrenal cortex can give rise to important abnormal laboratory findings. Hypothyroidism, for example, can give rise to macrocytic anemia, while hypoadrenalism can give rise to electrolyte abnormalities (i.e., hyponatremia, hyperkalemia, and an acidosis); hyperadrenalism produces the opposite effect (i.e., hypernatremia, hypokalemia, and an alkalosis). It is therefore important to confirm that these endocrine glands are malfunctioning. The important topic of endocrine function testing is discussed in Chapter 24. Here we present simple principles for the laboratory diagnosis and identification of the site of origin of thyroid, adrenal, and parathyroid conditions.

Principle

All endocrine systems involve a stimulating hormone that is synthesized and secreted into the blood from one tissue such as the pituitary, the parathyroid glands, etc. These hormones are delivered to their targets, which may be the thyroid gland or the adrenal glands, or a nonendocrine target such as the renal tubules, in the case of the parathyroid glands. In all cases, for normally functioning endocrine systems, *elevations* of the hormones or products elaborated by the targets will result in *decreased* levels of the primary hormones. Conversely, *decreased levels* of the targets will result in *increased* levels of the primary hormones. For example, high levels of circulating T_4 will result in low levels of TSH, a condition called *primary hyperthyroidism*, and, conversely, low levels of T_4 will result in high levels of TSH, a condition called *primary hypothyroidism*. In contrast, if the pituitary gland secretes an excess of TSH because of an adenoma or other pathologic condition, this increase in TSH will result in elevated T_4 . This condition is also referred to as *secondary hyperthyroidism*. Thus if *both* T_4 and TSH levels are elevated, a diagnosis of pituitary disease (e.g., pituitary adenoma) in which there is hypersecretion of TSH can be made. Conversely, decreases in both TSH and T_4 point to pituitary hyposecretory states also referred to as *secondary hypothyroidism*. Note that *changes in opposite directions of the stimulating and target hormones/effecter molecules point to endocrine target gland (e.g., thyroid gland) disease, while changes in the two hormones in the same direction point to stimulating hormone gland (e.g., pituitary) disease*.

Thyroid Function

Thyroid function tests are the most commonly ordered tests for endocrine function. It is important to note that in a hospital population (as opposed to an ambulatory population), thyroid screening tests may be diagnostically misleading. This is due to endocrine stress responses (as well

as medications) that may affect hormone levels (Van den Berghe, 2003). As discussed in Chapter 24, the thyroid gland synthesizes thyroid hormone, tetraiodothyronine, or T_4 , with four iodines, which requires iodine uptake by the gland. This activity is strongly stimulated by the peptide hormone, TSH, from the pituitary. In the periphery, T_4 is converted to T_3 (three iodines). More than 99% of T_4 is bound to serum proteins (i.e., thyroid-binding globulin and albumin). However, it is the free T_4 (<1 percent of total T_4) that exerts all biological effects. Accurate methods exist that directly measure serum free T_4 . Most commonly, total and free T_4 rise and fall together in serum; however, there are circumstances in which total T_4 may be elevated but T_4 -binding proteins may also be elevated, so that free T_4 levels are normal. This may result in a euthyroid state in which TSH levels are also normal. Of prime importance, high T_4 (more correctly, high free T_4) causes inhibition of TSH secretion, and low T_4 (more correctly, low free T_4) causes elevation of TSH. In *primary hypothyroidism* (primary thyroid gland disease), T_4 is present at low serum levels while TSH becomes elevated. It is important to note that often in subclinical hypothyroidism, T_4 can be within the reference range, but TSH is elevated. In ambulatory patients, elevated TSH in the presence of low levels of T_4 is diagnostic of primary hypothyroidism. In *secondary hypothyroidism*, TSH is low because of pituitary failure, resulting in low T_4 .

In *primary hyperthyroidism* (primary thyroid gland disease), excess T_4 is secreted by the thyroid gland, which is the source of the problem. As a result, TSH is decreased and T_4 is elevated. If, however, a primary lesion is present in the pituitary gland (e.g., hyperplasia, adenoma), TSH is oversecreted. Because TSH is elevated, T_4 secretion is elevated. This is known as secondary hyperthyroidism (secondary to pituitary disease).

These conditions and their patterns of T_4 and TSH levels are summarized in Table 8-6.

Adrenal Function

As discussed in depth in Chapter 24, the adrenal gland is divided anatomically into two endocrine glands: The adrenal cortex and the adrenal medulla. Adrenal cortical hormones are steroid hormones of three basic types: Mineralocorticoids, like aldosterone, that regulate sodium and potassium ions in the distal convoluted tubule, as discussed earlier; glucocorticoids, like cortisol, that are gluconeogenic; and the sex hormones (i.e., the estrogens and androgens). The adrenal medulla is a neuroendocrine gland that secretes epinephrine and norepinephrine, which act on the sympathetic nervous system. By far the most commonly ordered serum analyte used to measure adrenal cortical function is cortisol. Cortisol secretion by the adrenal cortex is stimulated by the pituitary hormone adrenocorticotropic hormone (ACTH). ACTH secretion, in turn, is stimulated by the hypothalamic hormone corticotropin-releasing hormone (CRH). Its serum levels are under diurnal control such that serum ACTH levels peak at about 200 pg/mL in the morning hours (about 7:00 AM), but they decline to their lowest values of around 100 pg/mL at midnight. Cortisol secretion follows ACTH secretion such that its serum levels are highest at 8:00–9:00 AM. Cortisol inhibits ACTH secretion by the pituitary gland both by directly blocking pituitary ACTH secretion and by inhibiting CRH secretion by the hypothalamus.

Therefore, if the adrenal cortex hypersecretes cortisol secondary to such conditions as adrenal hyperplasia, adenoma, or carcinoma, serum cortisol levels increase and block ACTH secretion. This condition is called

primary hyperadrenalism. Serum cortisol levels are elevated (Cushing's syndrome), but ACTH levels decrease.

On the other hand, as with thyroid hormone secretion, if ACTH levels are elevated by an ACTH pituitary tumor (Cushing's disease) or as ectopic ACTH secretion (e.g., by a nonpituitary tumor), cortisol levels will also increase, giving rise to secondary hyperadrenalism. Both cortisol and ACTH are elevated in this condition. Here, note that both cortisol and ACTH change in the same direction (both are elevated), pointing to pituitary, not adrenal disease. In cases of Cushing's disease or syndrome, the diurnal variation in serum ACTH is absent.

In addition to measurements of serum cortisol, it is often desirable to measure urinary free cortisol in cases of hypercortisolemia. Normally, almost all cortisol is bound to serum protein, mainly transcortin, but, in hypercortisol states, cortisol exceeds the capacity of transcortin to bind to it and is consequently filtered by the kidneys. The reference range for morning serum cortisol is ≈ 10 –25 $\mu\text{g/dL}$, and for urinary free cortisol, ≈ 24 –108 $\mu\text{g/24 h}$ for healthy males.

In cases of hypercortisolism, especially when ACTH levels may remain in the reference range or have "borderline" high or low values, it is often desirable to perform the dexamethasone suppression test. Dexamethasone is a potent glucocorticoid that strongly suppresses normal pituitary ACTH secretion. This can be accomplished with low-dose dexamethasone. If low-dose dexamethasone causes diminished serum cortisol levels and low values for urinary free cortisol, pituitary function is most likely normal while the adrenals are hypersecreting cortisol (i.e., primary hyperadrenalism). This test may be used further to distinguish the possible source of primary hyperadrenalism (i.e., hyperplasia vs. adenoma or carcinoma). High-dose dexamethasone will generally lower serum cortisol levels in adrenal hyperplasia, but it will have no effect in adrenal adenoma or carcinoma.

Conversely, in pituitary failure, serum ACTH levels decrease, as do serum cortisol levels, because ACTH stimulation of the adrenal gland decreases. This condition is referred to as secondary hypoadrenalism. If adrenal gland function is compromised (primary adrenal insufficiency), serum cortisol levels are decreased, resulting in less inhibition of pituitary secretion of ACTH and, consequently, in elevated serum levels of ACTH. This condition is referred to as primary hypoadrenalism, or Addison's disease. These conditions and the patterns of serum cortisol and ACTH levels in these conditions, including dexamethasone suppression test results where relevant, are summarized in Table 8-7.

Parathyroid Hormone and Vitamin D

In the previous Renal Disease section, it was noted that PTH induces elevated serum calcium levels by causing increased secretion of phosphate in the renal tubules and by promoting increased calcium ion absorption in the gut. Hypocalcemia with elevated PTH points to causes having to do with calcium metabolism (e.g., alkalotic states, decreased albumin, low dietary calcium and/or lack of absorption of calcium from the gut, low vitamin D levels). Hypocalcemia with low serum PTH levels points to parathyroid gland dysfunction. In rare instances, hypocalcemia that is not responsive to calcium infusions and vitamin D supplements can be caused by secretion of high levels of calcitonin, a serum calcium-lowering peptide that blocks osteoclastic resorption of bone (with attendant increases in serum calcium). Calcitonin is synthesized and secreted from the medullary cells of the thyroid. In medullary thyroid carcinoma, high levels of calcitonin are sometimes secreted. At high levels of calcitonin, hypocalcemia will result.

Hypercalcemia with low PTH again points to primary calcium metabolic causes, as in the "CHIMPS" mnemonic mentioned earlier, and acidotic states, while hypercalcemia with elevated PTH indicates parathyroid disease such as adenoma (most commonly) or carcinoma (uncommon). These conditions and the patterns of serum calcium and parathyroid hormone levels in serum in these conditions are summarized in Table 8-8.

Vitamin D

Vitamin D induces absorption of calcium from the gut by acting on vitamin D receptors in the cells lining the gut. It is produced from 7-dehydrocholesterol in skin by ultraviolet light that induces the synthesis of cholecalciferol. In the liver, cholecalciferol is converted to 25-hydroxycholecalciferol, which has a half-life of several weeks. This form is further hydroxylated in the kidneys to 1,25-dihydroxycholecalciferol, the active form of vitamin D. The half-life of active vitamin D is on the order of hours. Thus, in serum assays for vitamin D, the analyte whose serum level best reflects vitamin D levels is the precursor, 25-hydroxycholecalciferol (Zerwekh, 2008). This may give falsely elevated

TABLE 8-6

Patterns of Serum Levels of TSH and T_4 in Different Thyroid Gland Conditions

Condition	T_4 (most accurate, free T_4)	TSH	Site of disease
Euthyroid	Normal	Normal	None
Primary hypothyroidism	Low	High	Thyroid gland
Secondary hypothyroidism	Low	Low to normal	Pituitary
Primary hyperthyroidism	High	Low	Thyroid
Secondary hyperthyroidism	High	High	Pituitary

T_4 , Thyroxine; TSH, thyroid-stimulating hormone.

TABLE 8-7

Patterns of Serum Levels of ACTH and Cortisol in Different Adrenal Gland Conditions

Condition	Cortisol	ACTH	Dexamethasone suppression, low dose	Dexamethasone suppression, high dose	Site of disease
Normal adrenal	Normal	Normal	N/A	N/A	None
Primary hypoadrenalism	Low	High	N/A	N/A	Adrenal gland
Secondary hypoadrenalism	Low	Low	N/A	N/A	Pituitary
Primary hyperadrenalism—high cortisol, low ACTH	High	Low	N/A	N/A	Adrenal
Primary hyperadrenalism—high cortisol, borderline low ACTH	High	Borderline low	Positive	N/A	Adrenal
Primary hyperadrenalism due to adrenal hyperplasia—high cortisol, borderline low ACTH	High	Borderline low	Negative	Positive	Adrenal
Primary hyperadrenalism due to adrenal adenoma/carcinoma—high cortisol, borderline low ACTH	High	Borderline low	Negative	Negative	Adrenal
Secondary hyperadrenalism	High	High	N/A	N/A	Pituitary

ACTH, Adrenocorticotrophic hormone; N/A, not applicable.

TABLE 8-8

Patterns of Serum Levels of Calcium and PTH in Different Conditions

Condition*	Ionized calcium	PTH	Cause of disease
Normocalcemia	Normal	Normal	None
"Primary" hypocalcemia	Low	High	CHARD†
"Secondary" hypocalcemia	Low	Low	Parathyroid glands
"Primary" hypercalcemia	High	Low	Cancer, hyperthyroidism, iatrogenic causes, multiple myeloma, sarcoidosis
"Secondary" hypercalcemia	High	High	Parathyroid glands (e.g., adenoma, carcinoma)

PTH, Parathyroid hormone.

*The terms "primary" and "secondary" are not usually used for hypocalcemia and hypercalcemia. They are used here to emphasize the site of the disease to keep consistent with the conditions described in Tables 8-6 and 8-7.

†Mnemonic for **C**alcitonin, **H**ypoparathyroidism, **A**lkalosis, **R**enal failure, vitamin **D** deficit.

levels of vitamin D in cases of renal failure where conversion of the precursor to active vitamin D is impaired. However, 25-hydroxycholecalciferol itself has some effects on calcium reabsorption, although its affinity for the vitamin D receptor is only about one-one thousandth of that for the fully active form. The reference range for serum 25-hydroxycholecalciferol, also called 25-hydroxy vitamin D, is 30–100 ng/mL, although this is method dependent (Yates, 2008).

Over the past few years, requests for serum vitamin D levels, especially in the pediatric and geriatric populations, have greatly increased. This is due at least in part to the availability of reliable chromatographic, mass spectroscopic, and immunochemical methods that quantitate serum vitamin D levels. In the pediatric population, vitamin D levels are determined and followed for the diagnosis and treatment of vitamin D–dependent rickets. In the elderly, vitamin D levels are determined in the treatment of such diseases as osteoporosis and osteomalacia, because vitamin D supplements have been found to diminish the extent and severity of these diseases.

The discovery that many cells, besides epithelial cells of the gut, the principal site of vitamin D activity, have abundant receptors for vitamin D suggests that this vitamin has effects that go beyond regulation of calcium homeostasis (Bilke, 2009). Indeed, it has been found that vitamin D induces apoptosis in breast cancer and other malignant cells and has been used to treat such diseases as multiple sclerosis, heart failure, psoriasis, asthma, Crohn's disease, and many other conditions. Thus the demand for vitamin D levels has increased for patients with a wide variety of conditions.

EXAMPLES OF CLINICAL CASES WITH CLINICOPATHOLOGIC CORRELATIONS

Given the previous overview of many salient features of the causes of the more common abnormal laboratory findings, laboratory results from a number of different patients are now presented to illustrate how analyte levels change in different disease states, and how these analyte concentrations are used to diagnose these conditions.

CASE A

A 64-year-old white male was found unconscious in his home after suffering a cerebrovascular accident (CVA) and was brought to the emergency medicine department. His Hct was 44%, but RBC count was 4.3 million/ μ L (lower limit of normal, 4.6 million/ μ L) with an MCV of 104 fL; a series of serum sodium values ranged from 164–175 mEq/L; admission BUN was 33 mg/dL; creatinine was 1.5 mg/dL. Total serum osmolality was 357 mOsm/kg (upper limit of normal, 290 mOsm/kg), and urine osmolality was 1008 mOsm/kg (upper limit of normal, 1000 mOsm/kg) and random urine sodium was 228 mEq/L.

A liver panel showed a marginally elevated AST at 41 IU/L (upper limit of normal, 39 IU/L), elevated but continually decreasing LD (admission value of 426 IU/L; upper limit of normal, 200 IU/L), GGT of 72 U/L (upper limit of normal, 43 IU/L), and total protein of 7.8 g/dL (normal), but a low albumin of 2.8 g/dL (normal 3.5–5.0 g/dL). Lipase was mildly elevated at 127 IU/L (upper limit of normal, 60 IU/L). Occult blood found in his stool was positive for *Clostridium difficile*. Urine was nitrite positive (indicative of bacteriuria) and was markedly positive for Hb, RBCs, and WBCs. After infusion of half-normal saline, the Hct was reduced to 34% but then rose to 38%, with a persistently elevated MCV. The sodium and the BUN were reduced to within the reference range.

Evaluation

The basic diagnosis of this patient's condition is hyponatremia. This patient was dehydrated as shown by the markedly elevated serum sodium (average value of 169 mEq/L), high normal Hct, and elevated BUN. Note that the diagnosis of dehydration was confirmed by the findings of high serum and urinary (228 mEq/L) sodium and high urinary osmolality of 1008 mOsm/kg (see Table 8-3). The RBC count was low, which seems to contradict the high normal Hct. This apparent discrepancy may be explained by the macrocytosis, causing each erythrocyte to occupy a greater than normal volume. Yet the total number of cells was reduced. The low red cell count indicates a true anemia. The macrocytosis was caused by a nutritional (vitamin B₁₂) deficiency. All of these findings may be attributed to malnutrition and insufficient fluid consumption, a not uncommon finding in the elderly, especially in this stroke victim.

Note that the BUN and creatinine were mildly elevated in a pattern with a ratio >20:1, suggesting a prerenal (low perfusion) origin. The renal tubules were evidently functioning well, as evidenced by the high urine/

serum osmolality ratio ($1008/357 = 2.8$, which is greater than 1.2:1). Hypoperfusion may have caused the mild abnormalities found in some of the liver function tests and the elevated pancreatic lipase.

Note also that the total protein was normal, even though the albumin, the most abundant serum protein, was low. Because of possibly two infectious diseases identified in urine and stool examinations, the patient may have produced elevated levels of immunoglobulins. Accompanying the CVA was a peptic ulcer, so-called Cushing's ulcer, known to be associated with this condition; hence the occult blood in this patient's stool. *C. difficile* is known to infect patients with chronic debilitating disease. The urinary tract infection was responsible for the high RBC count and Hb in this patient's urine. The next case illustrates a more complex electrolyte disorder.

CASE B

A 31-year-old white male patient with known type 1 diabetes mellitus, end-stage renal disease secondary to diabetic nephropathy, and a history of alcoholism was admitted with acute abdominal pain in the midepigastrium, with a serum glucose of 736 mg/dL that rose as high as 933 mg/dL; serum sodium of 134 mEq/L, which decreased to as low as 124 mEq/L; potassium of 7.1 mEq/L, BUN of 64 mg/dL, and creatinine of 18 mg/dL. These values were confirmed and were found to follow a consistent trend. Serum osmolality was 316 mOsm/kg. Blood gas values on admission were pH of 7.58, pO₂ of 121 mm Hg, O₂ saturation of 99%, pCO₂ of 20 mm Hg, and bicarbonate of 20 mEq/L. The anion gap rose in one day from 13 (high end of normal) to 20. Serum lipase was elevated at 469 IU/L (upper limit of normal is 60 IU/L). There was no urine output, and the patient was subjected to peritoneal dialysis.

Evaluation

This diabetic patient was evidently in a hyperosmolar state because of abnormally elevated glucose levels. The low serum sodium and high serum potassium might appear to be due to low circulating aldosterone or renal tubular failure. However, there was no urine output, so no filtration could occur. The end-stage renal disease is reflected in the BUN and especially in the creatinine value (18 mg/dL). The BUN/creatinine ratio of about 4 confirms the diagnosis of true renal failure.

As noted in the discussion on glucose, in diabetes mellitus with high serum glucose levels, an efflux of cell water causes dilution of serum analytes such as sodium. Whenever glucose is transported into cells under the influence of insulin, it is accompanied by potassium. Low insulin levels can therefore result in hyperkalemia. This mechanism was operative in this patient. Although the anion gap increased after admission, it was normal on admission. Thus this patient was in a nonketotic, hyperosmolar state but subsequently became ketotic. The admission blood gas picture suggests a respiratory alkalosis in that the arterial blood pH was 7.57 (alkalosis), but the pCO₂ was low at 20 mm Hg, and the bicarbonate was low at 20 mEq/L (condition 4 in Table 8-4). This is an unusual finding in a patient with diabetes mellitus in whom a finding of metabolic acidosis is more frequently encountered.

An explanation for this finding may be found in the serum lipase, which was markedly elevated, denoting pancreatitis, a common finding in patients with a history of alcoholism. The sharp epigastric pain caused increased respiration (respiratory rate on admission was 25/min), precipitating a lowering of the pCO₂, which was partially compensated for by lowering of the bicarbonate.

Treatment of this patient with dialysis, hydration, and insulin corrected the abnormal laboratory findings, and the patient was discharged on long-term dialysis.

The next case presents multiple disorders, including electrolyte disorders, all related to liver failure.

CASE C

A 38-year-old white female with a past medical history of multiple abdominal surgical procedures over a 7-year period, sporadic alcohol abuse,

pancreatitis, and a 30 pack-year history of smoking, was brought to the emergency department in shock and acute abdominal distress. Significant laboratory values included WBC count of $12.1 \times 10^3/\mu\text{L}$, RBC count of $3.0 \times 10^6/\mu\text{L}$, Hct of 34.6%, and red cell indices that showed macrocytosis and hypochromia (low mean corpuscular Hb concentration). Vitamin B₁₂ and folate levels were normal. The peripheral blood smear showed a leukoerythroblastic pattern. Serum glucose was low at 38 mg/dL; total protein was 4.3 g/dL, and albumin 1.5 g/dL. Lactate levels were elevated. The AP was elevated at 241 IU/L (upper limit of normal, 129 IU/L), and the bilirubin was mildly elevated at 1.6 mg/dL (upper limit of normal, 1.2 mg/dL). Serum ammonia was found to be elevated at 146 $\mu\text{mol/L}$ (upper limit of normal, 30 μM). Screens for hepatitis A, B, and C were all negative. The patient was placed on broad-spectrum antibiotics. Multiple blood, urine, and throat cultures were negative. Exploratory laparotomy revealed abdominal adhesions and cholestasis. Postoperatively, the patient became encephalopathic; her liver function deteriorated, as evidenced by dramatic elevations of AST and ALT from normal levels to 1660 and 545 IU/L, respectively; of LD to 2190 IU/L; of bilirubin to 14.5 mg/dL; and of ammonia to 177 μM , despite lactulose administration. A liver-spleen scan performed on the fifth hospital day showed no dye uptake in the liver, consistent with functional liver failure. The serum sodium, normal on admission, increased within 5 days to 166 mEq/L, together with chloride levels that rose to 123 mEq/L—a pattern that persisted throughout the hospital course despite aggressive intravenous infusion of half-normal saline. Serum potassium was consistently <3.5 mEq/L. The BUN and creatinine both rose to abnormally high levels with a ratio of <20:1, suggesting renal failure. Plasma aldosterone was elevated at 13.2 ng/dL (upper limit of normal = 8.5 ng/dL). The platelet count dropped rapidly, while APTT and PT rose to values at least twice those of the corresponding normal controls, and her level of fibrin split products (FSPs) became abnormally elevated. Her condition worsened, and the patient expired on the eighth hospital day.

Evaluation

Although this is a complex patient presentation, the fundamental problem with this patient lay in the dramatically abnormal liver function test profile. Note the acute elevation in aminotransferases (transaminases), with AST/ALT ratios significantly greater than 1. Concurrent rapid elevations in bilirubin and in LD were noted. At the same time, the total protein and albumin were abnormally low. Ammonia levels rose rapidly (despite high doses of lactulose). The pattern is that of fulminant hepatic failure shown in condition 6 in Table 8-5. This condition is a medical emergency and is associated with fatal encephalopathy and severe DIC, as evidenced by the low platelet counts and elevated PT, APTT, and FSP levels. This condition can cause multiple system infarcts, resulting in multiple organ failure.

The patient's peripheral blood picture showed a macrocytosis but, concurrently, a leukoerythroblastic picture. This pattern suggests that the macrocytosis was caused by an increased number of erythrocyte precursor forms. This condition was most likely caused by DIC, which causes MHA with a leukoerythroblastic picture. It is also possible that, with the persistently elevated white cell count and the elevated lactate levels, gram-negative sepsis affecting bone marrow may have contributed to the leukoerythroblastic picture. Although cultures were consistently negative, the patient was being treated with broad-spectrum antibiotics, the effects of which may have blocked growth of the organism(s) in culture. As noted previously, patients with liver failure from cirrhosis or acute fulminant hepatic failure are generally immunocompromised. In both panhepatic cirrhosis and fulminant hepatic failure, severe third space fluid loss is associated with ascites, which invariably develops. We noted previously that, to retain vascular volume, both aldosterone and ADH rise. It appears that aldosterone became elevated to markedly high values, causing abnormal sodium retention and potassium loss in this patient. Almost always accompanying both cirrhosis and acute fulminant hepatic failure is renal failure, generally manifested by the hepatorenal syndrome. In fulminant hepatic failure, an additional possible cause is acute tubular necrosis (Sunheimer, 1994).

RESOURCES FOR STATISTICAL ANALYSIS, 118

SELECTED REFERENCES, 118

KEY POINTS

- For statistical analyses, nominal variables can take on only a limited number of values (or categories), whereas continuous variables are used to report quantitative data.
- Independent variables are considered input (cause), and dependent variables are considered output (effect).
- Distributions of continuous data are described by a measure of central tendency (e.g., mean or median) and dispersion (standard deviation). Gaussian distributions derive from a mathematical formula and hence are parametric. A common application of descriptive statistics is to establish reference ranges.
- Statistical tests such as comparisons of different groups of data points may be parametric (i.e., assume Gaussian distributions; example is Student *t*-test) or nonparametric (i.e., make no assumption of distributions; example is test based on rank order).
- Confidence intervals are preferable over point estimates to express level of certainty in the calculation of any statistical parameter.
- Nominal data are conveniently analyzed with proportions using the chi-square test.
- The effects of multiple factors in a model system can be assessed through analysis of variance.
- Regression analysis between two continuous variables is usually done by least squares fit to a straight line. Applications of regression analysis are common when different analytic methods for validation are compared in clinical laboratories.

The quantification of information in meaningful summaries and comparisons is the domain of statistical analysis. The first task in analysis is to provide a description of the magnitude of the observations and how close the different measurements are to one another. Descriptive statistics provides a consistent framework for calculating or estimating the central tendency of continuous data in the familiar forms of mean, median, and mode. The variation in data is generally described by the mathematical calculations of variances and standard deviations, or by the simple allocation of data points into a range of percentiles (e.g., interquartile range). These approaches are everyday phenomena in clinical laboratories for the monitoring of all quantitative assays. Reference ranges are initially set up with these techniques. Methods of quality control for precision and

proficiency testing for accuracy also are based on these principles. For data that are not continuous but take on only two or a few discrete values (e.g., positive or negative), the analysis might consist of counting the number in each category and looking at the proportions of all values by category.

Comparison of data typically asks the question whether one group is different from another group. These comparisons are usually done by *t*-test or by analysis of variance, depending on whether two or more groups of continuous data are compared. If the data are discrete, comparison is done by chi-square analysis. When data can take on a range of different values, it is convenient to do a correlation between two different data sets with a straight line fit. The newcomer to statistical analysis frequently poses the question: Which statistical test is best? The question of which test to use depends largely on whether the data are continuous or discrete, and whether continuous data follow particular distributions. However, statistics is based on convention, so that the investigator should try very diligently to understand the importance of differences between tests, and whether possible findings and conclusions are likely to reflect accurately the nature and significance of the question being asked. In contrast to the investigator who is interested in finding the right test for data already collected, the statistician is more interested in helping the investigator plan the experiment and collect data, so that statistical tests are most valid. This chapter relies heavily on common clinical laboratory examples for which specific statistical tests are applied to demonstrate some useful choices.

DEFINITIONS

- **Variables:** The things that we measure, count, or otherwise delineate are termed *variables* because the values they can assume vary. Variables are usually considered to fall into one of the following scales:
 - **Nominal scale** is where a variable can take on only a limited number of values, usually called categories (or characters). Examples of nominal variables are gender (male or female) and risk factors (e.g., smoker or nonsmoker).
 - **Ordinal scale** is where the variable takes on specific values that have some inherent order such as magnitude but without equivalent distances between categories (e.g., trace amount, 1+, 2+, etc. of protein in urine).
 - **Interval scale** is where a variable takes on values in a quantitative range with defined differences between points. It is conventional to treat most numeric laboratory measurements as continuous variables, even though they may be reported as discrete values (e.g., glucose values of 123 or 124 mg/dL, but not 123.857... mg/dL).

- *Coefficient of variation (CV)* is the standard deviation of a set of data points divided by the mean result expressed as a percentage or as a decimal fraction.
- *Confidence interval (CI)* is the interval that is computed to include a parameter such as the mean with a stated probability (e.g., commonly 90%, 95%, 99%) that the true value falls into that interval.
- *Degrees of freedom (df)* is a parameter related to the sample size (n). df indicates the number of quantities free to vary and is usually $n-1$ for applications such as the t -test. For the chi-square test, it is the number of rows minus one times the number of columns minus one. df is employed in calculating the p value for a statistical test.
- *Gaussian (normal) distribution* is a spread of data in which elements are distributed symmetrically around the mean with most values close to the center. It is explicitly described by a mathematical equation and so is a parametric distribution. Random scatter or random selection of a population often results in a Gaussian normal distribution. This type of distribution is often a criterion for completely valid application of many parametric tests.
- *Linear regression* is the mathematical process for calculating the best straight line to fit the relationship observed between two variables measured on the same items. *Simple* or *least squares linear regression* yields the best fit for x and y data sets by minimizing the sum of the squared y -axis (vertical distance) differences between each data point (x, y) and the line. This approach assumes the x -axis data to be nearly perfect or without error. Uneven distribution of data points across the entire range may significantly alter the reliability of linear regression. *Deming linear regression* does not assume the x -axis data to be free of error, but instead uses the weighted sum of squared y -axis and x -axis differences between the data points and the line. The *correlation coefficient (r)* describes how well the line fits the data (r ranges from -1 to 1).
- *Mean* is the sum of all results divided by the number of results. Also related are the *median*, which is the middle value that divides the distribution of data points into upper and lower halves (also called the 50th percentile); and the *mode*, which is the most common value. The mean, median, and mode are all measures of central tendency. The *geometric mean* is calculated as the n th root of the product of a distribution of n numbers; its use for estimating central tendency minimizes the effects from extreme values such as are found in a log-normal distribution.
- *Parametric statistics* are statistical measures that are calculated based on the assumption that the data points follow a Gaussian distribution and include parameters such as mean, variance, and standard deviation. *Nonparametric statistics* are based on rank or order of data.
- *Null hypothesis (H_0)* is the proposal that there is no difference in a comparison. The alternative hypothesis is that there is a difference. When the critical value of a statistic is exceeded, rejection of the null hypothesis occurs, thereby favoring the acceptability of the alternative hypothesis.
- *Significance level (p or α)* is the probability that a difference between groups occurred by chance alone, by convention set at less than .05.
- *Statistical power ($1-\beta$)* is the probability that a difference between groups will be detected by the study, generally set at least to 80%.
- *Standard deviation (SD)* is the square root of the sum of the squared differences of each data point from the mean divided by $n-1$ for samples (divided by n for populations). The SD is a predictable measure of dispersion from the mean in a Gaussian normal distribution.
- *Standard deviation index (SDI)* is the difference between the value of a data point and the mean value divided by the group's SD. The *z-transformation* is the expression of a result from the mean in SD units. The *Z-value* is the probability of a result being z SDs from the mean value. The SDI is commonly used in reporting performance in proficiency testing for an individual laboratory compared with peers.
- *Student t-test* is a statistical test for comparing means between two sample groups. The test can be paired (e.g., two separate measurements on the same individuals before and after some intervention) or unpaired. Values of t and df yield a level of statistical significance (p value).
- *Type I error (alpha error, α)* is incorrectly rejecting the null hypothesis and stating that two groups are statistically different when they really are not.
- *Type II error (beta error, β)* is incorrectly failing to reject the null hypothesis and stating that two groups are not statistically different when they really are.

VARIABLES

Statistical questions are often posed in terms of input versus output, cause and effect, or correlation between two or more variables. The input or cause is considered an *independent variable* because it is already determined and so is not influenced by other factors. Examples of independent variables are age, gender, temperature, and time. In contrast, *dependent variables* are those things that might change in response to the independent variable. Examples of dependent variables are blood glucose concentration, enzyme activities, and the presence or absence of malignancy. Of course we can change our thinking and switch which is the independent and which is the dependent variable if the experimental question changes. For graphical display, the independent variable is plotted along the horizontal (x) axis or abscissa, while dependent variables are plotted along the vertical (y) axis or ordinate. With a single independent variable (e.g., time) on the x -axis, more than one dependent variable can be plotted on the y -axis to demonstrate different relationships simultaneously. The relationship observed between an independent variable and dependent variables is used to predict future outcomes of the dependent ones based on what values the independent variable assumes.

PREPARING TO ANALYZE DATA

Most statistical calculations today are done automatically by computer with software programs that present multiple sophisticated options for analysis and even graphical displays of the data. To prepare data for these automated analyses, it is always necessary to enter them into readable format for the program. This process can entail automated transfer from one electronic data set to the statistical program or manual entry from printed sheets of data. Manual entry is obviously fraught with opportunity for typographic errors, but even automated transfer of data can result in erroneous entries, especially when translating older data sets that have been stored on media that might have been corrupted (e.g., magnetic tapes reexamined decades later). Even converting data strings to columns and rows of data points can leave some values in the wrong places. Consequently, it is always good practice to examine the data set for accuracy before performing the statistical analysis. This examination could be done by proofreading every entry or by double entry of each value and automatic comparison for discrepancies, although both of these approaches may be impractical when the data sets contain hundreds, thousands, or more values. At the very least, visual examination of the plotted values provides a quick idea of whether some serious data entry errors have occurred. For example, an incorrectly entered value of 50.0 for potassium (instead of 5.0) can be immediately identified by scanning all values on a graphical plot. The person preparing to perform statistical analyses should do this visual test to identify and correct the most obvious errors and to search for any systematic errors that might have arisen in data transfer and entry.

DESCRIPTIVE STATISTICS

When multiple data points are collected, it is useful to provide a summary of those results that makes them easier to understand rather than simply listing all values. The methods used to summarize data are termed *descriptive statistics* because they describe what the magnitude of results is and how the data points differ from one another. In the case of categorical variables, this description can be a simple count of discrete values (e.g., how many men and how many women had blood drawn in a clinic). For continuous variables, it is conventional to use some measure of *central tendency* about which the data points cluster, and a measure of how far apart they are *dispersed* from one another (e.g., what are the ages of the patients who had blood drawn).

CENTRAL TENDENCY

The most widely recognized measure of central tendency is probably the mean or average value (also referred to as the *arithmetic mean*), which is calculated by adding the values of all the individual data points and dividing that sum by the total number of data points, expressed mathematically as follows:

$$\text{Mean} = \bar{x} = (x_1 + x_2 + \dots + x_n) \div n = \frac{1}{n} \sum_{i=1}^n x_i \quad (9-1)$$

Because this technique derives the mean value from a defined formula, it is termed a *parametric method*. An alternative measure of central tendency

is the *median*, which divides all data points exactly in half, with one half being higher and one half lower. The median is also called the 50th percentile. It is not calculated from a formula because it is taken from a straight count of the data points, so it is termed a *nonparametric method*. The third commonly used measure of central tendency is the *mode*, which is the most common value (i.e., the value of the variable that has the greatest number of data points). The mode is not a very useful measure for describing or comparing data sets, but it does have a role in understanding when a data set consists of two or more different populations that result in more than one mode. If two separate subpopulations are present, it is called a bimodal population.

Another measure of central tendency is the *geometric mean*, which has the feature of minimizing the influence from extreme values in a distribution. The geometric mean is calculated as the n th root of the product of all n values from a population, or

$$\text{Geometric mean} = \sqrt[n]{x_1 \times x_2 \times \cdots \times x_n} \quad (9-2A)$$

The following transformation is more convenient for calculating the geometric mean:

$$\log \text{Geometric mean} = \frac{\sum_{i=1}^n \log x_i}{n} \quad (9-2B)$$

Thus the log of the geometric mean equals the mean of the logarithm of all observations, and taking the antilog of this summation yields the value of the geometric mean.

Consider the following distribution of values, which is heavily weighted toward the lower end but with some high values:

3, 3, 4, 4, 4, 5, 5, 5, 6, 6, 8, 9, 10, 15, 21

The arithmetic mean for these values is 7.2, whereas the geometric mean is 6.09, which better reflects the preponderance of values at the lower end than does the arithmetic mean.

In general, parametric methods allow numerous additional calculations for application of many different statistical tests that are based on specific formulas. The advantage of nonparametric methods is that they do not assume or require that the data points must follow any particular distribution for them to be applicable. Parametric methods can be applied to data sets that deviate from preferred distributions, but those calculations and conclusions may not be fully warranted if the deviations are extreme.

GAUSSIAN (NORMAL) DISTRIBUTION

The Gaussian (also called normal) distribution is a symmetrical, bell-shaped curve centered about the mean value (Fig. 9-1). It is described by the following mathematical formula:

$$P(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(x-\bar{x})^2}{2\sigma^2}} \quad (9-3)$$

where σ is the standard deviation of the ideal Gaussian population (Dawson-Saunders, 1994). It corresponds to the distance from the mean to the x value at which the curve has an inflection point.

The area under this curve within $\pm 1 \sigma$ from the mean is approximately 68.2% of the total area, meaning that 68.2% of data points from a Gaussian distribution should fall within $\pm 1 \sigma$ of the mean. Similarly 95.5% of the

Figure 9-1 Idealized Gaussian (normal) distribution showing areas under the curve corresponding to mean $\pm 1, 2$, and 3 standard deviations (SD).

data points will be within $\pm 2 \sigma$ of the mean, and 99.7% will be within $\pm 3 \sigma$ of the mean.

DISPERSION

A common parametric measure (based on the Gaussian distribution) of the dispersion of data points about the mean value of a population under examination is the standard deviation, mathematically calculated as:

$$SD = \sqrt{\frac{\sum_{i=1}^n (x_i - \bar{x})^2}{n-1}} \quad (9-4)$$

The quantity under the square root sign is termed *variance*. Use of the SD assumes that the data follow a bell-shaped curve that can be described mathematically by the formula for a normal or Gaussian distribution. To the extent that the data are normally distributed, the SD is a good estimate of the dispersion.

Two additional terms derive from the SD. One is the *coefficient of variation (CV)*, which is calculated as the SD divided by the mean. The CV is often expressed as a percentage, although it can also be expressed as a decimal fraction less than 1. For a situation where the mean = 25 and the SD = 5, the CV = 20%, or 0.20. The other term is the *standard deviation index (SDI)*, which is the distance that an individual data point is away from the mean value divided by the SD. The main use for the SDI is in such applications as proficiency testing, where performance of any one laboratory is standardized according to the dispersion of data in the performance by all laboratories.

A common clinical laboratory application of the normal distribution is to calculate the central 95% of values obtained from a healthy population when trying to establish the reference range for an analyte. This range of course is easily calculated as mean $\pm 2SD$ for a truly Gaussian normal population. An example of this application is calculation of the central 95% of values of the white blood cell (WBC) count in a group of 85 healthy medical students (Fig. 9-2). The bar graph plot is roughly bell shaped and symmetrical, although there is a slight asymmetry that can probably be ignored. The mean value is 6.60×10^9 cells/L, with an SD of 1.457×10^9 cells/L, and the calculated central 95% range is from 3.69 – 9.52×10^9 cells/L. This is a small group of individuals compared with what might be used for actual reference range calculations, but it does show a few persons with WBCs higher than this range and some lower, so this estimate of central 95% appears appropriate.

Another way of thinking about these calculations is that the persons tested represent only a sample of all persons to whom we are interested in generalizing these findings (Daniel, 1999). The mean value actually observed would probably be somewhat different if another group of 85 healthy people were tested. Based on the values observed and their spread, a confidence interval can be placed around the mean such that we can be certain by a desired percent that the true mean of WBCs from all healthy persons falls in that range. The confidence limit is calculated as follows:

$$\text{Confidence interval} = \bar{x} \pm z \frac{SD}{\sqrt{n}} \quad (9-5)$$

where the critical factor z derives from transformation of the problem to a standard normal distribution. The quantity $\frac{SD}{\sqrt{n}}$ is termed the *standard*

Figure 9-2 Distribution of white blood cells (WBCs) in the blood of 85 healthy individuals.

error of the mean. In this example, let the confidence interval be 95%, for which $z = 1.96$. The 95% confidence interval around the mean value is

$$6.60 \pm 1.96 \times \frac{1.457}{\sqrt{85}} \text{ or } 6.295 - 6.914 \times 10^9 \text{ cells/L}$$

Note that this range is the 95% confidence interval on the mean value alone, whereas the earlier calculations yielded the central 95% of all data points. Confidence intervals are used to give an idea of the broadness of the estimate of something. This can be made more certain by using 99% confidence intervals (i.e., 99% confident that the true mean falls in the interval), in which case $z = 2.575$ for the calculation, and the 99% confidence interval is broader at

$$6.60 \pm 2.575 \times \frac{1.457}{\sqrt{85}} \text{ or } 6.193 - 7.007 \times 10^9 \text{ cells/L}$$

NONPARAMETRIC MEASURES

The median value of WBC for this group of healthy persons is 6.4×10^9 cells/L, which is roughly the same as the mean value. For a perfectly Gaussian normal distribution, values of the mean, median, and mode are exactly the same. Delineation of the range from the 2.5-percentile to the 97.5-percentile also gives an estimate of the central 95% range (for the example of WBC, it is $3.94 - 9.89 \times 10^9$ cells/L, which is really the exact range for this specific population). This is a nonparametric estimate of the range because it does not use a calculation, but only divides the data points according to their order. Many applications of median use the central 50% of data points from the 25th percentile to the 75th percentile (also called interquartile range) to describe central tendency by the nonparametric method.

Sometimes the parametric method of mean ± 2 SD produces an erroneous estimate of the central 95% range. An example of this situation arises with the distribution of alanine aminotransferase (ALT) activities in the serum of apparently healthy individuals (Fig. 9-3). In this population, the mean value is 30.1 U, the SD is 12.69 U, and the calculated reference range (mean ± 2 SD) is 4.73–55.48 U. This range is not appropriate because the actual lowest value observed in the group was much higher (12 U). This estimate of the lower end of the range (4.73 U) is far too low. Similarly, the estimate of the upper end (55.48 U) is too low and excludes about 10% of the data points instead of only 2.5%. Another clue that the parametric method may not work here is that the median value is 27.0 U, which is somewhat different from the mean. The reason for this discrepancy is apparent upon looking at the distribution, which is skewed to the right with many values tailing off at the upper end. In this case, a much more useful estimate of the central 95% can be obtained simply from the 2.5-percentile to the 97.5-percentile range. It is 15.2–68.0 U. The form of this distribution for ALT is sometimes termed *log-normal*, because it can be converted to a normal distribution by using the values of log ALT instead.

Many laboratory measurements show distinctly non-Gaussian normal distributions. Values of 25-OH vitamin D in 12,434 serum specimens from 2000 through 2008 showed a skewed distribution, with lowest value 0.5 ng/mL and highest value 260.0 ng/mL (Fig. 9-4, A). The arithmetic mean of these values is 25.55 ng/mL, and the median is 20.90 ng/mL, reflecting the non-normal distribution. Plotting log 25-OH vitamin D

Figure 9-3 Distribution of alanine aminotransferase (ALT) in the serum of 86 healthy individuals.

shows a nearly normal distribution with mean value 1.3130 (Fig. 9-4, B). Then the geometric mean is $10^{1.3130} = 20.56$ ng/mL, which appears to be a better measure of central tendency for 25-OH vitamin D than the arithmetic mean.

COMPARATIVE STATISTICS

One of the questions frequently asked by statistical means is whether one group is different from another group in some characteristic. The question boils down to a comparison of the central tendency of one group versus that of the other and the scatter that each group exhibits about the central values. If the scatter of data is extreme, then calculated differences between mean values of two groups might not be important, but rather the result of adding in the extreme values. Another way to think about these comparisons is that of signal/noise ratio. If there is little noise (scatter of data), then the difference in the signal from each group is more believable.

STUDENT *t*-TEST

The most common method for comparison of a continuous variable between groups is probably the Student *t*-test (Dawson-Saunders, 1994). The pseudonym Student was used by William Gosset, a statistician working for the Guinness brewery, who wanted to keep his work for optimizing productivity unrecognized by competing companies. The *t*-test is based on a parametric calculation of the *t* statistic as follows:

$$t = \frac{\bar{x}_1 - \bar{x}_2}{SD_{12} \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}} \quad (9-6)$$

where \bar{x}_1 is the mean value in group 1,

n_1 is the number of values in group 1,

\bar{x}_2 is the mean value in group 2,

n_2 is the number of values in group 2, and

SD_{12} is the standard deviation of groups 1 and 2 combined.

Fortunately, the calculation of *t* statistics is conveniently performed by computers in modern times, so the analyst now has the responsibility of vouching for the accuracy of data input and the correct choice of statistical tests and their validity for the situation.

Some specific assumptions about the data sets are also necessary for applicability. For example, it is necessary to have sufficient numbers of data points in each group to make a valid comparison with approximately equal numbers in each. The spread of the data points should be equivalent (usually assessed by whether the variances of the groups are equivalent). The selection of data points should be independent of one another; for example, it would be inappropriate to include the same patient twice in one group. The issue of independence is usually handled experimentally by a random selection of subjects or patients. Randomization of treatments is an exacting process for important research such as clinical trials. For laboratory use, it is more likely that data come from patients who present themselves to the hospital or clinic for testing, rather than being a random sample of all people in a city or from a country. The more random the selection process, the more likely it is that results can be generalized to a much larger target population for which inference is desired.

The statistical question for consideration is reduced to two mutually exclusive hypotheses that include all the possible situations. The null hypothesis (H_0) states that there is no difference between groups. The alternative hypothesis (H_{alt}) is that the difference between mean values is significant. If the *t* statistic has a sufficiently high value, we can reject the null hypothesis and consequently must accept the alternative hypothesis that there is a significant difference. If the *t* value is on the low side, we cannot reject the null hypothesis, but neither can we accept it. This decision is somewhat like that of the verdict from a trial in which the possible outcomes are “guilty” and “not guilty.” The innocence of the defendant is never established, and similarly the null hypothesis is never proven. We could end up thinking that the null hypothesis is correct (particularly since the alternative hypothesis now seems unlikely), but the test we performed did not strictly lead to that conclusion.

Consider the distribution of hemoglobin (Hb) values in the whole blood of 36 healthy males and 49 healthy females (Fig. 9-5, A and B). Visual inspection of the bar graphs for Hb shows that the females generally have lower values (mean 13.2 g/dL, SD 0.80 g/dL) than the males (mean 15.1 g/dL, SD 0.96 g/dL). Only a portion of the males and females overlap one another in Hb values. In this example, the value of $t = 9.898$. One other factor must be taken into account, the degrees of freedom, which is

Figure 9-4 **A**, Distribution of 25-OH vitamin D in 12,434 serum specimens showing skewness to the right at higher values. **B**, Plotting log 25-OH vitamin D shows normal distribution following logarithmic transformation.

obtained from the total number of data points minus 2 or $df = n_1 + n_2 - 2 = 36 + 49 - 2 = 83$.

Significance

The value of the t statistic is assessed for significance according to the degrees of freedom. One way to approach the assessment is look up the

value of t for which the degrees of freedom yield a probability (p) value that is to be applied for significance using a table of values. More often the software does this calculation automatically. Generally p values of 0.05 or less are required to claim statistical significance. A p value of 0.05 (also called alpha) means that the difference observed between the two groups could have occurred one time in 20 with the particular spread of data

Figure 9-5 Distribution of hemoglobin (Hb) in the blood of (A) healthy men and (B) healthy women.

actually observed. The value of alpha is also thought of as the risk that we are willing to take to conclude falsely that there is a significant difference when in fact none exists (type I error). The use of $\alpha = 0.05$ is merely an arbitrary convention, but it is ingrained in the minds of reviewers and protocols for evaluating studies. Of course, if the p value is much smaller, such as 0.01 or 0.001, then the statistical significance of a difference between group means is that much more credible.

Even though an observed difference between groups might have an extraordinarily impressive p value ($p = 0.001$ means that the result should happen by chance only 1 in 1000 times), it is incumbent upon the investigator to conclude whether the observation is clinically significant. The statistical significance of any difference can always be amplified, no matter how insignificant it is for decision-making, simply by increasing the number of data points (see the formula for calculating t , Equation 9-6).

A potential problem arises when a large number of comparisons are done in studies where no clear hypothesis is stated, but instead the data are mined for whatever might fall out upon examination. In this case, the minimal level of significance should be adjusted to reflect the large number of tests that could conceivably discover “significant results” by chance alone. After all, if a p value of 0.05 is used, then by doing 20 different comparisons, one ought to find on average some comparison with a statistically significant difference regularly. The Bonferroni correction is done to lower the risk of such false discovery. It consists of dividing the usually accepted p value by the number of comparisons. Thus for five different comparisons, the correction is $p \text{ value} = 0.05/5 = 0.01$ as the acceptable threshold value for significance.

For this particular example, comparing Hb values between males and females, the p value is less than 0.0001, so we can reject the null hypothesis and can conclude that there is a significant difference between groups. Most statisticians would not report this level, but would be satisfied with saying that the p value was less than 0.001. Another condition to denote is whether this test is two-sided or one-sided, meaning that the question being asked is whether one group is simply different from the other (two-sided) as opposed to the question of whether one group is only higher than the other group (one-sided). Most journals require the use of two-sided t -tests because they are more demanding.

TABLE 9-1

Observed Values of Contamination in Blood Cultures

Result	Baseline period	Post training
Number of cultures contaminated	53	32
Number of cultures not contaminated	978	891

Sample Size

Suppose the two groups being compared showed a difference that was not quite statistically significant with a p value of .06. One way to achieve statistical significance is to increase the number of subjects studied. This will be the case if the difference remains the same, because the t -value will be increased by a greater n . A pilot study can be done in a clinical trial to establish roughly the difference between groups and the scatter of the data. These pieces of information are then used in a formula to calculate the sample size necessary to bring the results to statistical significance. Calculation of sample size also takes into account another factor called beta, which is the risk one has of missing a true effect by chance (type II error). The power of the study is $1 - \beta$. When beta is set to 0.20, the power of the study is 0.80, which says that the number of subjects calculated for use will yield a statistically significant result 80% of the time with the specified difference between groups and scatter of data.

The t -test used for this example was unpaired because the comparison was between different individuals. If the experimental design included a comparison of values on the same individuals before and after treatment, then it is appropriate to use a paired t -test. A paired test is potentially a more powerful mathematical tool because it looks only at the change between the values within each person and is not influenced by variation in background values between individuals.

NONPARAMETRIC TESTS

If the assumption about normality of the data is not valid, other nonparametric tests can be used to compare distributions between groups. The *Wilcoxon signed-ranks test* is such a technique. By this method, all values for both groups are given a numeric rank according to their magnitude. In the case of ties for the same value, both are assigned the intermediate rank (e.g., if 4th and 5th places are tied, then both are given the rank 4.5). All ranks are summed in each group and divided by the number of data points in each group. The difference between the rank scores is then given a probability. This technique is easily done by computer software and may be quite useful when assumptions required for a parametric method are not met by a data set.

ANALYZING DISCRETE DATA: TESTING PROPORTIONS

Analysis of discrete data takes on a different form from that of continuous variables that can be expressed as distributions. With discrete data, answers are typically dichotomous: Something is present or absent, patient gender is male or female, the patient lived or died. Consider the fictitious example of an intervention to lower contamination rates in blood culture collection. (This is a universal problem in all laboratories, but these data are only hypothetical.) Before the intervention, baseline information over a 2-month period showed that 53 cultures were considered contaminated and 978 were not. After training and implementation of the new collection process, a second 2-month period showed 32 contaminated cultures and 891 that were not. These nominal data are conveniently expressed in a 2×2 display termed a contingency table of observed values (Table 9-1). These data consist of simple counts in one category or another. The question to be asked is whether the proportion of contaminated cultures was significantly different in the two time periods.

CHI-SQUARE TEST

The statistical test to be used is the chi-square test. It is calculated as:

$$\chi^2 = \sum \frac{(\text{observed} - \text{expected})^2}{\text{expected}} \quad (9-7)$$

TABLE 9-2

Expected Values of Contamination in Blood Cultures

Result	Baseline period	Post training
Number of cultures contaminated	44.8	40.2
Number of cultures not contaminated	986.2	882.8

where the observed values are as listed earlier and the expected values are calculated from the overall assortment of counts (Dawson-Saunders, 1994). In this example, the expected number of contaminated cultures in the baseline period is the total number of cultures done in that period ($53 + 978 = 1031$) times the proportion of contaminated cultures in both time periods together (proportion calculated as $[53 + 32]/[53 + 978 + 32 + 891] = 0.0435$), or $1031 \times 0.0435 = 44.8$. Calculation of the other expected values follows similarly, resulting in a contingency table of expected values (Table 9-2). Then calculation of the χ^2 value is done by summing the squares of the differences (this converts all differences to positive values) between expected and observed values and dividing by the expected value in each cell of the table. In this example,

$$\chi^2 = \frac{(53 - 44.8)^2}{44.8} + \frac{(978 - 986.2)^2}{986.2} + \frac{(32 - 40.2)^2}{40.2} + \frac{(891 - 882.8)^2}{882.8} = 3.3 \quad (9-7A)$$

With one degree of freedom ($[\text{number of rows} - 1][\text{number of columns} - 1]$), the p value is 0.07, which does not meet the universal threshold of at least 0.05 for statistical significance. It is fair to say that a trend toward less contamination was observed after the intervention, but that it was not quite statistically significant. It is important to keep in mind that for χ^2 testing to be valid, each cell must have a minimum value of five observations.

TREND EVALUATION AND CORRELATIVE STATISTICS

The relationship between an independent variable and a dependent variable is demonstrated by plotting them on a scattergram or a plot with the independent (input) variable on the x -axis and the dependent (output) variable on the y -axis. If there is no relationship between the two variables, the data scatter randomly over the graph. If there is a relationship, it can be described mathematically by finding a line that is the best fit through all the data points. This line can be calculated by the least squares approach in which the vertical distances from each point to the calculated line are minimized for the entire population of values. This statistical method is referred to as *linear regression* (National Committee for Clinical Laboratory Standards, 2003).

LINEAR REGRESSION

The general form for the equation of a straight line is:

$$y = a + bx \quad (9-8)$$

in which the slope (b) indicates how the value of y changes when x changes. When $b = 1$, the relationship of change between x and y is one to one. The intercept (a) indicates how the relationship between x and y is offset or biased by a constant factor. The calculation is easily done by any of several statistical programs that also provide information about the goodness of fit of the line. This approach is commonly used when comparing an existing method (A) with a new method (B) for the same analyte (Fig. 9-6, A). This example shows a strong correlation between method A and method B because the data points fall very close to the line, which is described by the equation: $\text{Method B} = 0.62 + 0.99 \times \text{Method A}$. The slope of 0.99 is almost perfect, and the intercept of 0.62 is quite small on the scale of possible values. In fact, the 95% confidence limits on b are -0.47 to 1.72 , which includes the value 0, indicating that the intercept is not significantly different from 0.

The vertical (y axis) distances from each data point to the best fit line are termed the *residuals*. The most valid line fits are associated with relatively constant values of the residuals over the entire range of values. If the residuals grow larger at one end of the graph, then the line fit is less certain

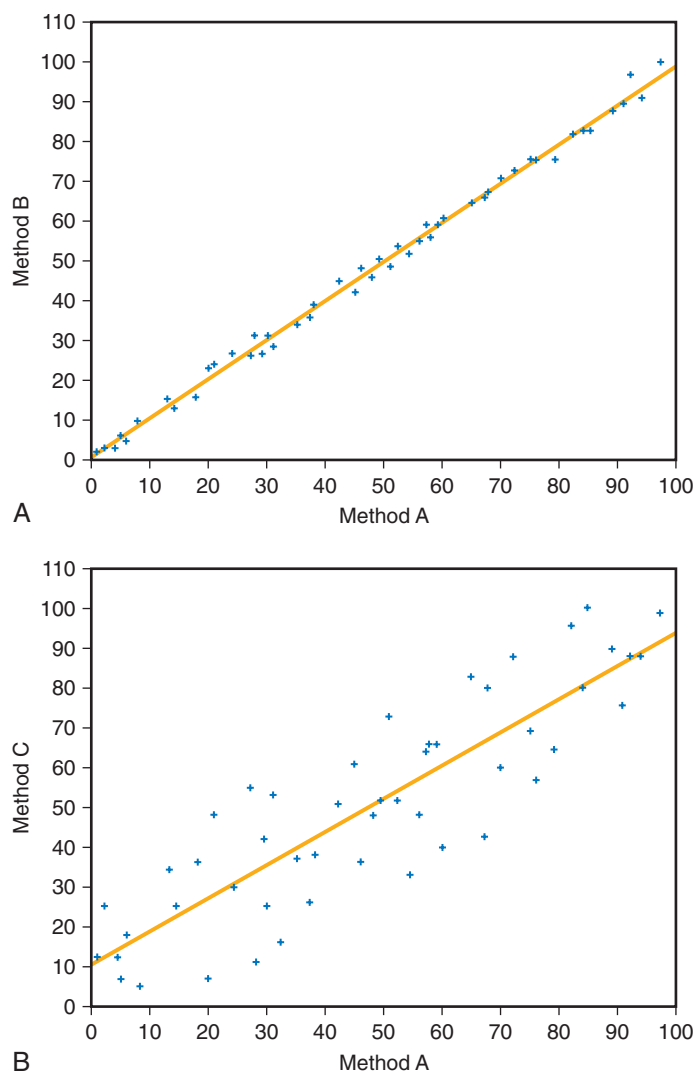

Figure 9-6 A, Regression analysis between method A and method B; strong correlation. B, Regression analysis between method A and method C; weaker correlation.

in that portion of the range. The *standard error of regression* (also called *standard error of the estimate*), denoted $S_{y,x}$, is used to estimate the variation that could be expected from doing the regression again with another sample of data points. The $S_{y,x}$ is calculated as the square root of the sum of residuals squared, divided by $n - 2$. It is important that data points from patient specimens be spread over the entire analytic range to yield the most valid comparison of methods unbiased by over-representation or under-representation of data in any region (National Committee for Clinical Laboratory Standards, 2002).

In laboratory practice, regression or correlation analysis is frequently used to compare the performance of a new method versus an old method. In this situation, the old method could have worse precision than the new one, and so it would not be appropriate to base a judgment just on how the new method compares with the old one as a “gold standard.” A common approach to this issue is Deming regression analysis, named for W. Edwards Deming (1900–1993), a mathematician influential in principles of quality improvement. In Deming regression, the best line is obtained by minimizing the sum of squares of both x and y distances from the data points to the line (Cornbleet, 1979). In addition, Deming regression applies a weighting factor (λ) that incorporates the relative variances of both x and y data. The result is more heavily weighted in favor of the data set with better precision.

The relationship between method A and method B is further described by the *correlation coefficient* (r), which can range in value from -1 to $+1$. A value of 0 indicates no relationship, and a value of 1 indicates a perfect relationship (-1 is also a perfect but inverse relationship). Other values between -1 and $+1$ indicate intermediate relationships. The square of the correlation coefficient is termed the coefficient of determination (r^2),

which describes the amount of variation observed in the dependent variable that is due to the relationship between the two variables. In this example, $r = 0.9976$ and $r^2 = 0.9952$, both of which are very high values that show an extremely strong relationship between method A and method B that accounts for 99.52% of the variation. The p value on this correlation is less than 0.0001.

In contrast with the very good correlation between method A and method B, the performance of method C versus method A (Fig. 9-6, B) is not nearly as good. By simple visual examination, the data points are scattered farther from the line, and the line is shifted upward. The value of $r = 0.8757$ is somewhat less than between method A and method B, but still shows a strong correlation with p value less than 0.0001. The value of $r^2 = 0.7668$, so 76.68% of the variation can be accounted for by the relationship between method C and method A. The equation for this line is $\text{Method C} = 10.2 + 0.84 \times \text{Method A}$, so the change in values using method C compared with method A is slightly less (slope of 0.84). A significant upward bias is seen by method C (intercept of 10.2 with 95% confidence limits of 2.8 to 17.6).

METHOD COMPARISONS

These two examples show somewhat different relationships, although both are statistically significant. It is up to the person assessing the performance to determine which is sufficient for the application. The comparison of method A versus method B is extraordinarily strong both by visual review and by statistical analysis, and so it can comfortably be said that these methods are equivalent for the purposes of replacing one with the other in clinical practice. On the other hand, the comparison of method A with method C is messier because of the larger amount of data scatter. The smaller slope suggests that the two methods do not react equivalently with the analyte, and furthermore there is a positive bias by method C. With expectations for excellent precision and accuracy on modern instrumentation, method C would probably be rejected if method B were a viable alternative. And yet the level of correlation observed between method A and method C might be very welcome to researchers trying to ask a different question related to cause and effect between biological processes that have inherently high levels of variation.

A special example of regression analysis termed *logistic regression* is employed when the outcome is a dichotomous or binary variable for continuous independent (predictor) variables.

ANALYSIS OF VARIANCE

When the mean values of more than two different groups are to be compared, the process is termed *analysis of variance (ANOVA)* (Dawson-Saunders, 1994). This analysis can be thought of as extending the t -test beyond two independent samples to three or more. The null hypothesis in this situation is that the mean values of all groups are the same. The alternative hypothesis is that not all the means are equal (some could be the same, but others different). The test statistic is the F -ratio of the mean squares among all groups (MS_A) to the error mean square (MS_E):

$$F\text{-ratio} = \frac{MS_A}{MS_E} \quad (9-9)$$

It compares the variance of the group means versus the mean of all the data (numerator) and the variance of individual data points within each group (denominator). If the group means differ from one another (signal) more than the variation within groups (noise), then the F -ratio will exceed a critical value for significance.

An example of ANOVA is the comparison of serum albumin values from patients at two inpatient sites, an outpatient clinic, and a student health clinic (Fig. 9-7). One hundred consecutive specimens from each site were recorded. The horizontal line shows the grand mean of all 400 values of 3.17 g/dL. Within each group, the diamonds indicate group means (midline) and 95% confidence intervals on those means (upper and lower vertices). The F -ratio = 279 for which the p value < 0.0001, so the null hypothesis can be rejected with the conclusion that at least some of the means are different. This approach is more conservative and realistic than comparing each group with every other group using a series of different t -tests (with four groups, six comparisons could be made). The problem with too many comparisons is the possibility of “accidentally finding significance” that is not true. To extend ANOVA, comparisons of group means by such procedures as Tukey’s honestly significant difference (HSD) can be done. In this example, Tukey’s HSD indicates that IP1 and IP2 are

Figure 9-7 Analysis of variance. Serum albumin at different patient sites. IP1, IP2, Inpatient wards 1 and 2; OP, outpatient; SH, student health.

not different from one another, but that OP and SH are both different from all other groups. At this stage, the investigator is free to elaborate on potential reasons for these observed differences without putting further statistical significance on the individual differences.

Some conditions should be met for parametric ANOVA to be completely valid mathematically:

- The data were collected using random sampling where all observations are independent of one another.
- The data in each group are normally distributed.
- Each group has an equal number of data points.
- Each group has equal variances.

If this set of ideal criteria is not met, other methods are available for comparisons. The Mann-Whitney test can be used to compare medians. The Wilcoxon and Kruskal-Wallis tests for rank sums are nonparametric alternatives. This example of serum albumin shows greater variances for the inpatient groups than for the outpatients, so nonparametric analysis could be more appropriate. (The Wilcoxon test also showed significant differences among the groups of this example.) This case dealt with one variable, and so it was one-way ANOVA. To deal with two variables, the procedure can be extended to two-way ANOVA.

Linear regression might be used in error to analyze continuous outcome data when the independent variable has the appearance of being continuous but is actually categorical. Such a situation is seen with tumor grade (1 through 4) as an independent variable. Tumor grade is not continuous but rather consists of discrete categories that are not necessarily evenly spaced along a dimension. Although statistical programs would permit calculation of a regression on tumor grade, the proper approach would be one-way ANOVA to look for differences in the dependent variable (e.g., survival time) among groups (e.g., tumor grade).

ANALYSIS INVOLVING MULTIPLE VARIABLES

Two-way analysis of variance (two-way ANOVA) is used when the experimental design has two categorical independent variables (input) and a continuous dependent variable (output). An example is the effects of both gender and different (fixed) drug levels on a physiologic measurement such as blood pressure. In addition to the one-way effects of gender on blood pressure and of drug level on blood pressure, it is necessary to investigate a possible interaction of gender and drug level in two-way ANOVA. If such an interaction is significant, then response to drug level might be different in men versus women. These interactions are conveniently displayed graphically (e.g., a plot of response to drug in men and one for women; noninteraction results in parallel lines; intersection of the lines indicates an interaction).

Multiple analysis of variance (MANOVA) applies to a model with multiple categorical independent variables and two or more continuous dependent variables.

Sometimes the way a comparison is set up by selection of subjects into different groups can lead to a confounding effect from another variable besides the variable of primary interest. In this case, it is revealing to

perform *analysis of covariance* (ANCOVA) to account for potential influence from the covariable. The intention of ANCOVA is to use statistical methods to eliminate effects arising from confounding variables that were not accounted for by random assignment in the original selection of subjects. Typically these effects might be due to an imbalance of subjects with certain characteristics in the experimental group compared with the control group (e.g., the treatment group might have 75% smokers and the control group only 25%; without adjusting for this potential confounding factor, one could not be certain that results from treatment were not in fact merely due to different proportions of smokers in each group).

As a laboratory example of ANCOVA, consider the comparison of serum calcium measurements in 61 male and 41 female healthy adults to establish whether different reference ranges of calcium would be necessary for males and females. Simple one-way ANOVA similar to that in Figure 9-7 yielded a statistically significant ($p = 0.0045$) difference between the group means of calcium (males 9.3 mg/dL, females 9.1 mg/dL). (Performing ANOVA with only two groups is equivalent to an unpaired t -test.) This finding was consistent with those of previous studies, so it probably is appropriate to have gender-specific reference ranges for serum calcium, but does this make sense from a physiologic view? It is also well recognized that serum albumin influences total calcium levels by binding some of the calcium. A linear regression for these subjects confirmed this relationship. The effects of gender and of the covariable albumin on calcium are sorted out by ANCOVA. In this example, the effect on calcium from gender was completely accounted for by the effect of albumin on calcium and the different distribution of albumin in males versus females. ANCOVA can be enlightening to discover and eliminate by statistical analysis those covariables that might not be known and planned for in the design of an experiment. Further discussion of ANCOVA can be found in more advanced texts on statistics (Matthews, 1988).

When multiple continuous independent variables (x_1, x_2, x_3 , etc.) are tested to predict a continuous dependent variable (y) as outcome, *multiple regression analysis* is used to calculate the weighting factors (b_i) for a linear combination as follows:

$$y = a + b_1x_1 + b_2x_2 + b_3x_3 + \dots \quad (9-10)$$

This analysis also allows use of nominal independent variables with so-called “dummy variables” that are arbitrarily given values of 1 or 0 (e.g., 1 for female and 0 for male). Thus if x_1 is gender, the coefficient b_1 is multiplied by 1 for females in calculating the values of y ; however, for males, b_1 is multiplied by 0. This dummy coding permits convenient use of nominal variables in regression analysis.

METHOD VALIDATION AND PROCESS CONTROL

Statistical analysis is integral to the validation of new laboratory methods and to the monitoring of analytic and workflow processes in clinical laboratories (Lott, 1998).

REFERENCE RANGES

The examples depicted in Figures 9-2, 9-3, 9-4, and 9-5 demonstrate some of the issues encountered when reference ranges are established through application of descriptive statistics. The basic aim is to establish a range of values within which the majority of healthy people will fall, while excluding individuals with disease. The simplest approach is to use the central 95% of data points from healthy individuals by calculating mean \pm 2 SD whenever the distribution is normal or bell-shaped, as for WBC in Figure 9-2. This parametric approach fails to provide a complete reference range when the data are skewed as for ALT in Figure 9-3. In this case, the central 95% can be determined nonparametrically by using the range 2.5-percentile to 97.5-percentile, which excludes 2.5% at both upper and lower ends. The distribution of ALT actually appears to have two subpopulations in these healthy people. Consequently, basing reference ranges solely on observed ranges in apparently healthy persons might not be the best approach. In fact, some new recommendations for ALT set the upper range much lower than wide-based population studies would suggest. The new guidelines try to eliminate persons who might have mild, asymptomatic liver changes such as steatosis (Prati, 2002). This approach is similar to the strategy used for setting desirable or healthy levels of cholesterol and lipid fractions (National Cholesterol Education Program, 2002) and of glucose (Report of the Expert Committee on the Diagnosis and Classification of Diabetes

Mellitus, 2003). In the future, recommendations from other consensus groups or professional organizations will probably be even more useful in setting desirable ranges for other analytes in place of population-based reference ranges.

Finally, healthy subgroups of people should be recognized by separate reference ranges whenever major differences occur according to factors such as age or gender (see Fig. 9-5).

ACCURACY

The performance of a new method can be assessed for accuracy (e.g., the ability to correctly detect and quantify an analyte) by assaying patient specimens or interlaboratory survey materials with known values. The example of a strong correlation between methods in Figure 9-6, A, indicates that the analyte reacts in a nearly one-to-one manner by each method (slope \approx 1) with essentially no bias (intercept \approx 0). In contrast, the correlation depicted in Figure 9-6, B, has a slope different from 1, indicating that the analyte reacts differently with the two methods. One explanation for this type of discrepancy is found when tumor markers are measured by two immunoassays that employ different antibodies that potentially recognize different epitopes. A bias such as that shown by method C versus method A in Figure 9-6, B, also suggests a basic methodologic difference that has an impact on accuracy, albeit in a predictable way that could be compensated for with calibration adjustment.

The accuracy of any assay depends heavily on the calibrators, that is, how they are originally constituted, how they remain stable over time, and how they compare with calibrators from other vendors (see Chapter 10). The best situation is to have an assay calibrated against internationally distributed standards such as from the World Health Organization or other professional group. By using calibrators with such traceability and standardized units of measurement, it is feasible to use values from different assays interchangeably for the same patient, or to compare outcomes in different groups of patients being monitored with different methods.

After implementation of a method, periodic proficiency survey testing of unknown specimens is usually reported in terms of SDIs away from the mean of all laboratories. For example, if the mean of creatinine measurements is 11 mg/dL for all participants with SD of 2 mg/dL, then a laboratory reporting a value of 8 mg/dL would have $SDI = (8 - 11)/2 = -1.5$.

PRECISION

The reproducibility of an assay is conveniently expressed with the CV that allows the observed SD to be normalized by the magnitude of the signal being measured. It should be kept in mind that assays typically have different CVs for different ranges of analyte values. Therefore it is good practice to establish CVs for an assay at high, low, and mid-range values.

ANALYTIC SENSITIVITY

The lowest value that an assay can reliably detect is termed the analytic sensitivity. A common approach to making this judgment is to measure a zero standard multiple times (e.g., 10 times) and calculate the SD of the signal detected, which is noise. Then set the lowest reliable detection threshold at three or four times the value of the SD. This approach is often individualized within laboratories. This characteristic is also termed the detection limit. Another use of the term analytic sensitivity refers to the change in response of an assay for a given change in the amount or concentration of the analyte (Giacomo, 1984). In this respect, a highly sensitive assay has the characteristic of readily detecting small changes in analyte at concentrations in the mid-range of measurement.

ANALYTIC SPECIFICITY

The major interferents in laboratory measurements are hemolysis, icterus, and lipemia due either to interference with optical absorbances (or light scattering) or to actual chemical interactions (e.g., peroxidase activity of Hb in many immunoassays that use horseradish peroxidase as indicator). Beyond these endogenous interferents, drugs can also interact with various chemical or immunologic assays. The magnitude of these interactions (or lack thereof) is typically documented by the addition of known, large amounts of the substances to serum samples that are tested for recovery of the analyte in the serum.

ACCEPTABILITY OF A METHOD

The final decision of whether to accept a method as valid depends on a combination of factors. Do the statistical tests show a new method to perform analytically as it should with good accuracy and precision? Does the new method provide useful medical information that is not otherwise available? Is the method feasible to do (easy to perform, low cost, rapid)? Does the maximum error fall within medically acceptable limits? The final decision is a professional judgment based on all of these items.

RESOURCES FOR STATISTICAL ANALYSIS

Calculation of descriptive statistics and performance of statistical tests are now widely done using statistical software on computers. In the scientific realm, a few software packages are particularly popular, although applications from other vendors are also available. One of the most popular in the biomedical sciences is from the SAS (originally Statistical Analysis System) Institute, Inc., in Cary, N.C. SAS also provides JMP Software that

has graphics linked to the statistics for ready visualization of results. Another well-established statistical software product is the Statistical Package for the Social Sciences (SPSS), which is now a part of IBM (SPSS Inc., Chicago). SPSS is still recognized for its prominence in the social sciences. Microsoft Excel also can provide statistical analyses along with expanded graphical capabilities.

Resources for performing statistical calculations directly online are available with simple searching. One such site is Martindale's Calculators On-Line Center at http://www.martindalecenter.com/Calculators2A_1_Cou.html#STAT-ALL.

A listing of similar sites is available on "Web Pages that Perform Statistical Calculations!" at <http://www.statpages.org/>.

When planning statistical analysis of data, in fact, even before planning the experimental design of a project, it is appropriate to consult with a biostatistician to ensure the most efficient design and one that is most likely to provide statistically sound results. A simple review of which statistical tests to employ for different combinations of categorical and continuous variables as independent (input) and dependent (output) variables can be found at The Decision Tree for Statistics at <http://www.microsirir.com/Statistical%20Decision%20Tree/>.

KEY POINTS

- Quality control samples are assayed on a regular schedule to verify that a laboratory procedure is performing correctly.
- Interpretation of quality control results is based on acceptance criteria that will identify bias, trend in bias, or imprecision that exceeds expected method performance attributes.
- In the event of an unacceptable quality control result, corrective action is taken to fix the method problem, and all patient results from the time of the previous acceptable quality control result are repeated.
- Because of commutability limitations, quality control samples should not be used to verify that two methods, or two different lots of reagents, produce the same results for patient samples.
- Proficiency testing provides external evaluation that a laboratory is using a method correctly and in conformance to the manufacturer's specifications.

The purpose of a clinical laboratory test is to evaluate the pathophysiologic condition of an individual patient to assist with diagnosis and/or to monitor therapy. To have value for clinical decision-making, an individual laboratory test result must have total error small enough to reflect the biological condition being evaluated. The total error of a result is influenced by the following:

- Biological/physiologic variability within an individual
- Preanalytic variability in sample collection, transportation, processing, and storage
- Analytic variability in test performance
- Interfering substances such as drugs or metabolic components

Quality control (QC, also called statistical process control) is a process to periodically examine a measurement procedure to verify that it is

performing according to preestablished specifications. This chapter addresses QC of an analytic measurement procedure using QC sample materials intended to simulate clinical samples from patients. Such QC sample materials are called surrogate samples. The QC samples are measured periodically in the same manner as clinical samples and their results examined to ensure that the measurement procedure meets performance requirements appropriate for patient care. Techniques for using results from patient samples in the QC program are also included. This chapter is organized as follows:

- Analytical accuracy and imprecision
- Calibration issues in quality control
- Overview of quality control procedures
- Implementing quality control procedures
- Reagent and calibrator lot changes
- Using patient data in quality control procedures
- Proficiency testing
- Quality management

ANALYTIC ACCURACY (TRUENESS) AND IMPRECISION

Figures 10-1 and 10-2 illustrate the meaning of accuracy (trueness) and imprecision for a measurement. The relationship between the terms accuracy and trueness is clarified by following Figure 10-2. In Figure 10-1, the horizontal axis represents the numeric value for an individual result, and the vertical axis represents the number of repeated measurements with the same value made on aliquots of a sample. The red line shows the dispersion of results for repeated measurements of the same sample (e.g., a QC sample), which is the random imprecision of the measurement. The imprecision frequently follows a Gaussian (normal) distribution and is described by the standard deviation (SD). The SD is a measure of expected imprecision in a result when the method is performing correctly. Note that results near the average value (mean) occur more frequently than results farther

Figure 10-1 Illustration of results distribution showing expected imprecision for repeated measurements of a quality control sample. SD, Standard deviation.

Figure 10-2 Illustration of systematic bias when a change in calibration has occurred. SD, Standard deviation.

away from the mean. A result that is 2 SD from the mean is expected to occur 4.5% of the time (100%–95.4%) in a positive or a negative direction from the mean value. Correct calibration of a method eliminates systematic bias (within uncertainty limits), so the mean of repeated measurements of a sample becomes the expected value for that sample when the method is performing correctly.

Figure 10-2 illustrates that if the calibration changes for any reason, a systematic bias is introduced into the results. The systematic bias is the difference between the observed average value and the expected value for a sample. Note that the imprecision of an incorrectly calibrated method is the same as when correctly calibrated. All methods have an inherent imprecision. The primary purpose of measuring QC samples is to statistically evaluate the measurement process to verify that the method continues to perform within the specifications consistent with acceptable systematic bias and imprecision. QC result acceptance criteria, discussed in a later section, are based on the probability for an individual QC result to be different from the variability in results expected when the method is performing correctly.

The term accuracy is used for an individual result and is the combination of systematic bias and imprecision that occurred for that specific measurement. An individual QC sample result can evaluate the combined errors caused by systematic bias in calibration and imprecision of the measurement procedure. The result for an individual patient sample can also be influenced by interfering substances that may be present in that sample. Total error for a patient sample measurement is the sum of systematic bias, imprecision, and sample specific bias caused by any interfering substances that may be present. Statistical QC does not evaluate possible interfering substances that may affect results from patient samples. However, the imprecision observed in QC results provides a measure of the variability expected for individual patient results caused by the inherent imprecision of the method.

The term trueness is used to refer to an average systematic bias that may be present in a given method. Trueness is an attribute of a method that reflects how correctly the calibration of that method is traceable to a reference system and is discussed further in the next section.

1. Calibration (or recalibration)

2. Calibration verification (is calibration unchanged?)

Figure 10-3 Calibration (1), and calibration verification (2) using method-specific calibrators (or other method-specific calibration verification materials).

CALIBRATION ISSUES IN QUALITY CONTROL

Calibration of the analytic measurement procedure is a key component in achieving quality results. Figure 10-3 part 1 shows calibration of a method, which establishes the relationship between the signal measured and the quantitative value of analyte in the calibrator materials. This relationship is used to convert the measurement signal from a patient sample into a reportable concentration for the analyte. Specific techniques for calibration are unique to individual methods and will not be covered here. However, some general principles for implementing calibration procedures can contribute to the stability and clinical reliability of laboratory results.

CALIBRATION AND VERIFICATION OF CALIBRATION

Calibration of methods is most often performed by the laboratory using calibrator materials provided by the method or instrument manufacturer. In some cases (e.g., point-of-care devices), methods are calibrated during the manufacturing process, and the laboratory performs a verification of that calibration. In either situation, traceability of result accuracy to the highest-order reference system is provided by the method manufacturer. The method manufacturer's calibrator material(s) and assigned target value(s) are designed to produce accurate results with clinical patient samples assayed using that particular manufacturer's routine method. One manufacturer's product calibrator is not intended for use with other methods, and laboratories should not use calibrator materials intended for one method with any other method. Use of a calibrator with a method for which it was not specifically intended can produce miscalibration and erroneous patient results (see next section).

In principle, a measurement procedure should be calibrated only when evidence indicates that the current calibration is no longer valid. A recalibration event may introduce a small change in the relationship between analytic system response and sample concentration that contributes to overall long-term variability in method performance. Evidence that a recalibration is needed could come from QC sample results that demonstrate a shift or trend in bias over a time period. However, QC results are expected to have random variability that may make identification of a trend in bias difficult to detect. Consequently, it is common practice to recalibrate methods on a time schedule that is established based on experience with the sources of drift that are important for a given technology. In vitro device (IVD) manufacturers frequently specify calibration intervals.

The U.S. Clinical Laboratory Improvement Act (CLIA) regulations, section 493.1255, require calibration or calibration verification at least every 6 months, or more frequently if recommended by the method manufacturer (Department of Health and Human Services, 2003). When

no change in method performance parameters has occurred, it is acceptable to verify that the current calibration has not changed (calibration verification), rather than perform a recalibration.

Figure 10-3 part 2 shows that a method's current calibration can be verified not to have changed rather than performing a recalibration. One common procedure to verify calibration is to assay the method calibrator materials as "unknowns." Recovery of target values for the calibrators indicates that the measurement system calibration has not changed (i.e., the current calibration is verified to be correct), and there is no reason to perform a recalibration to reestablish the same relationship between measurement signal and calibrator concentration that is already in use. The laboratory must establish criteria for agreement with the calibrator target value for calibration verification. Conservative criteria for agreement, such as ± 1 SD from the target value, should be considered to avoid misinterpretation of calibration status.

CALIBRATION TRACEABILITY TO A REFERENCE SYSTEM AND COMMUTABILITY CONSIDERATIONS

Whenever possible, calibration of routine methods should be traceable to a higher-order reference measurement procedure or international reference material (Vesper, 2009). For commercially available methods cleared by the U.S. Food and Drug Administration (FDA), the IVD manufacturer provides product calibrators that have calibration traceable to the applicable reference system for an analyte (measured in international terminology).

It is important to recognize that IVD manufacturer-provided calibrators typically have matrix characteristics and target values that are intended only for use with that specific method and cannot be used with any other manufacturer's methods. An IVD manufacturer can assign a target value to a method-specific calibrator that corrects for any matrix-related bias that may be present, so that results for clinical samples are correctly traceable to the reference system for an analyte. However, if such a method-specific calibrator is used with a different method, its target value will cause miscalibration, because it does not compensate for a different matrix-related bias with that different method (i.e., the calibrator is not commutable with clinical samples when used with a different method; see later).

A clinical laboratory may wish to verify that a method's calibration conforms to a method manufacturer's claim for traceability to the reference system used for a given analyte. Some method manufacturers provide calibration verification materials specifically intended for this purpose. Such materials may be provided as method-specific QC materials. As for method-specific calibrators, such method manufacturer-provided QC materials typically have matrix characteristics and target values that are intended only for use with the specific methods claimed in the instructions for use and cannot be used with any other manufacturer's methods. Such method-specific calibration verification materials may have target values that are specific for stated reagent lots, or may have values certified by the manufacturer to be suitable for all reagent lots. IVD manufacturer-supplied calibrators and calibration verification materials will not be commutable with clinical patient samples when used with a different method (see later).

National and international reference materials are available for some analytes. In most cases, these reference materials are intended for use with higher-order reference measurement procedures and may not be suitable for use with routine clinical laboratory methods. Laboratories should not use national or international reference materials to calibrate a routine method (or to verify calibration of a routine method) unless the reference material's commutability with patient samples has been verified for the specific routine method used by a laboratory. A commutable reference material has the same numeric relationship between two or more methods as is observed for a panel of clinical patient samples (Miller, 2006; CLSI, 2008; ISO, 2003). Consequently, a commutable reference material (or calibrator) reacts in a measurement system to give a numeric result that would be equivalent to that expected for a patient sample with the same amount of analyte. Differences in matrix-related bias between a reference material (or calibrator) and clinical patient samples cause a noncommutable relationship between the reference material (or calibrator) and the patient samples.

A reference material's certificate of analysis should be reviewed for commutability documentation. If a reference material is commutable with patient samples for a given method, it can be used for calibration or

verification of calibration traceability to the reference system. Otherwise, its use for calibration or verification of calibration could cause the routine method to be miscalibrated and could produce erroneous patient results (Koch, 1988; Naito, 1993; Franzini, 1998; Thienpont, 2003; Miller, 2003, 2006). Most higher-order reference materials have not been evaluated for commutability with patient samples measured using clinical laboratory methods. If a reference material's commutability status is unknown, it must be assumed not to be commutable with patient samples.

Third-party QC materials (i.e., those provided by a manufacturer other than the routine method's manufacturer) are not suitable to verify calibration traceability. These materials are not validated for commutability with clinical samples for different routine methods, and they do not have target values that are traceable to higher-order reference measurement procedures. Such QC materials are designed to be used as QC samples for statistical process control, with target values and SD values assigned as described later in the Implementing Quality Control Procedures section. When third-party QC materials are used in an interlaboratory method comparison program with method-specific peer group mean values, these values can be used to confirm that a laboratory is using a specific method in conformance with other users of the same method (see [Proficiency Testing](#) section, later).

OVERVIEW OF QUALITY CONTROL PROCEDURES

Statistical QC evaluates the measurement procedure by periodically assaying QC materials for which the correct result is known in advance. If the result for a QC material is within acceptable limits of the known value, the measurement procedure is verified to be performing as expected, and results for patient samples can be reported with good probability that they are suitable for clinical use. If QC results are not within acceptable limits, patient results are not reported and corrective action is necessary. Good laboratory practice requires verification that a method is performing correctly at the time patient results are measured.

Figure 10-4 summarizes statistical QC and emphasizes its role as a component of an integrated quality management system. The key elements of statistical QC involve sampling the measurement system using QC samples for which the expected result is known. If the QC results indicate a stable measurement process (i.e., results are within acceptable limits, consistent with expected method performance), then the patient results have a high probability of being suitable for clinical use and can be reported. If the QC results fail evaluation criteria, then the patient results may not be reliable for clinical use. In the latter case, corrective action must be taken to fix the analytic process; this is followed by repeat assay of patient samples and QC samples to confirm that the defect was corrected.

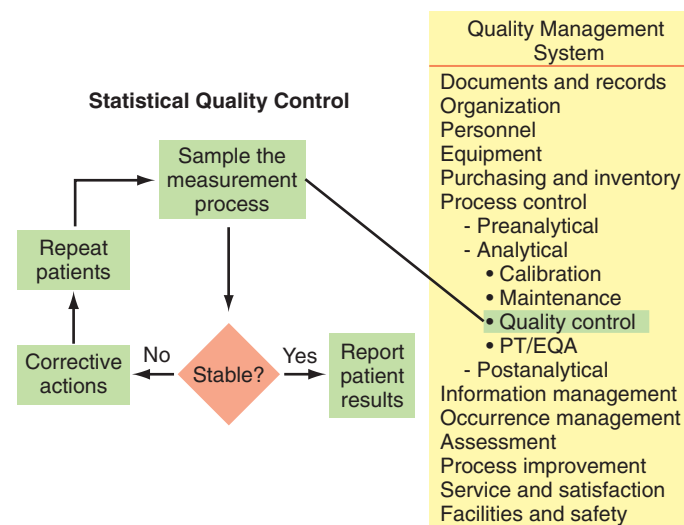

Figure 10-4 Overview of statistical quality control and its integration into a quality management system. (Reprinted with permission from Miller WG, Nichols JH. *Quality control*. Figure 10-5 Levey-Jennings plot of quality control (QC) results (N = 199) for a single lot of QC material used for a 49-day period. SD, Standard deviation.

Statistical QC is part of the analytic component of the overall quality management system. The quality management system integrates good laboratory practices to ensure correct results for patient care. Well-trained and competent personnel are critical for all aspects of laboratory medicine, including quality control. Written standard operating procedures (SOPs) are required for all aspects of laboratory operation, including preanalytic, analytic, and postanalytic components. For statistical process control, the SOP should include all aspects of the program, including the selection of QC materials, how frequently to sample the measurement process, how to determine statistical parameters to describe method performance, criteria for acceptability of QC results, corrective action when problems are identified, and documentation and review processes. The SOP should include who is authorized to establish acceptable control limits and interpretive rules for release of results, who should review performance parameters including statistical quality control results, and who can authorize exceptions to or modify an established QC policy or procedure.

Figure 10-5 shows a Levey-Jennings (Levey, 1950), also called Shewhart (Shewhart, 1931), plot, which is the most common presentation for evaluating QC results. This format shows each QC result sequentially over time and allows a quick visual assessment of method performance, including trend detection. The mean value represents the target (or expected) value for the result, and the SD lines represent the expected imprecision for the method. Assuming a Gaussian (normal) distribution of imprecision, the results are distributed as expected, with results scattered uniformly around the mean, and with results observed more frequently closer to the mean than near the extremes of the distribution. Note that a few results are greater than 2 SD, and two results slightly exceed 3 SD, which is expected on the basis of a Gaussian distribution of imprecision. For a large number of repeated assays, the number of results expected within the SD intervals is as follows:

- ± 1 SD = 68.3% of observations
- ± 2 SD = 95.4% of observations
- ± 3 SD = 99.7% of observations

Interpretation of an individual QC result is based on its probability to be part of the expected distribution of results for the method when the method is performing correctly. A later section provides details regarding interpretive rules for evaluation of QC results.

IMPLEMENTING QUALITY CONTROL PROCEDURES

SELECTION OF QC MATERIALS

Generally, two different concentrations are necessary for adequate statistical QC. For quantitative methods, QC materials should be selected to provide analyte concentrations that monitor the analytic measurement range of the method. In practice, laboratories are frequently limited by concentrations available in commercial QC products. When possible, it is important to confirm that method performance is stable near the limits of the assay because defects may affect these concentrations before others. Many quantitative assays have a linear response over the analytic measurement range, and it is reasonable to assume that their performance over the range is acceptable if the results near the assay limits are acceptable. In the case of non-linear method response, it may be necessary to use additional controls at intermediate concentrations. Critical concentrations for clinical decisions (e.g., glucose, therapeutic drugs, thyroid-stimulating hormone,

prostate-specific antigen, troponin) may also warrant QC monitoring. In the case of analytes that have poor precision at low concentrations, such as troponin or bilirubin, the concentration must be chosen to provide adequate SD for practical evaluation. For procedures with extraction or other pretreatment, controls must be used in the extraction or pretreatment step.

This chapter is primarily focused on QC procedures for quantitative methods. However, the principles can be adapted to most qualitative procedures with allowances for the lack of numeric results. For tests based on qualitative interpretation of quantitative measurements (e.g., drugs of abuse, human chorionic gonadotropin), negative and positive controls should be selected that have concentrations relatively near the threshold to adequately control for discrimination between negative and positive. For qualitative procedures with graded responses (e.g., dipstick urinalysis), negative, positive, and graded response controls are required. For qualitative tests based on other properties (e.g., electrophoretic procedures, stain adequacy, immunofluorescence, organism identification), it is necessary to ensure that the QC procedure will appropriately discriminate normal from pathologic conditions.

The QC materials selected must be manufactured to provide a stable product that can be used for an extended time period, preferably one or more years for stable analytes. Use of a single lot for an extended period allows reliable interpretive criteria to be established that will permit efficient identification of an assay problem, avoid false alerts due to poorly defined expected ranges for the QC results, and minimize limitations in interpreting values following reagent and calibrator lot changes.

Limitations of QC Materials

Limitations are inherent in currently available QC materials. One limitation is that the QC material is frequently noncommutable with clinical patient samples. A commutable QC material (or other reference material such as a method calibrator or proficiency testing [PT] material) is one that reacts in a measurement system to give a result that would be equivalent to that expected for an authentic patient sample with the same amount of analyte. QC and PT materials are typically noncommutable with clinical patient samples because the serum or other biological fluid matrix is usually altered from that of a patient sample (Franzini, 1998; Cattazzo, 2001; Thienpont, 2003; Miller, 2003, 2005, 2008). The matrix alteration is due to processing of the biological fluid during product manufacturing, use of partially purified human and nonhuman analyte additives to achieve desired concentrations, and various stabilization processes that alter proteins, cells, and other components. The impact of the matrix alteration on the recovery of an analyte in an assay system is not predictable and is frequently different for different lots of QC material, for different lots of reagent within a given analytic method, and for different analytic methods. Because of the noncommutability limitation, special procedures are required (discussed in later sections) when changing lots of reagent or comparing QC results among two or more methods.

A second limitation of QC materials is deterioration of the analyte during storage. Analyte stability during unopened storage is generally excellent, but slow deterioration eventually limits the shelf life of a product and can introduce a gradual drift into monitoring data. Analyte stability after reconstitution, thawing, or vial opening can be an important source of variability in QC results and can vary substantially among analytes in the same vial. User variables to be controlled are the time spent at room temperature and the time spent uncapped with the potential for evaporation. An expiration time after opening is provided by the product manufacturer but may need to be established by a laboratory for each QC material, and may be different for different analytes in the same control product. For QC materials reconstituted by adding a diluent, vial-to-vial variability can be minimized by standardizing the pipetting procedure (e.g., using the same pipet or filling device [preferably an automated device], having the same person prepare the controls) whenever practical.

Another limitation is that analyte concentrations in multiconstituent control materials may not be at levels optimal for all assays. This limitation may be caused by solubility considerations or potential interactions between different constituents, particularly at higher concentrations. It may be necessary to use supplementary QC materials to adequately monitor the analytic measurement range.

FREQUENCY TO ASSAY QC SAMPLES

The frequency to assay QC samples is a function of several parameters:

- Analytic stability of the method
- Risk of clinical action being taken before a significant error is detected

- Number of patient results produced in a period of time that may need to be repeated when an error condition is identified
- Need to verify a method's performance before recalibration or significant maintenance alters the condition of the measurement system
- Training and competency of the test operator, particularly for manual or semiautomated methods
- Residual risk of failure of the measuring device

Stability of the Measurement System

The stability of the measurement system is a fundamental determinant of how frequently a QC sample needs to be assayed. The more stable the system, the less frequently a statistical QC evaluation needs to be performed. Minimum laboratory practice, consistent with CLIA regulations, section 493.1256 (Department of Health and Human Services, 2003), is to assay controls at least once per 24 hours, or more frequently if specified by the method manufacturer, or if the laboratory determines that more frequent QC assays are necessary for the performance characteristics of a method. Some types of tests have more stringent requirements. For example, CLIA section 493.1267 requires that at least one control be assayed every 8 hours (including both high and low concentrations over a period of 24 hours) for blood gas measurements; in addition, a control must be run with each patient sample unless the instrument automatically calibrates at least every 30 minutes.

Risk of Harm to a Patient

The risk of clinical action being taken before a significant error is detected is an important consideration for more frequent QC sampling than one based strictly on method stability characteristics, or on regulatory minimum requirements. More frequent QC sampling is appropriate to avoid the situation of discovering a methodologic problem many hours after a physician has performed a clinical intervention based on an erroneous result. For example, QC sampling performed on a 24-hour cycle might be performed at 9 AM. If QC results indicate a method problem, the erroneous condition could have started at any time during the previous 24 hours. If the problem had occurred at 3 PM the previous day, erroneous results would have been reported for 18 hours.

The medical risk of harm to a patient from erroneous results must be considered and the frequency of QC testing established to minimize risk. From a practical perspective, the cost of a medical error, or simply the cost of repeating questionable patient samples since the last acceptable QC results, could be more expensive than a more frequent QC sampling schedule that would detect an error condition in a more timely manner.

CLSI has published a guideline addressing risk-based QC procedures. The document provides guidance to clinical laboratories on how to develop a QC plan based on evaluation of risk of harm to a patient and assessment of the effectiveness of risk mitigation procedures using information from the manufacturer and from other sources combined with the clinical requirements of the local health care setting and conditions in the laboratory (CLSI, 2010).

In general terms, the laboratory director is responsible to ensure that a result has a high probability to be correct at the time it is reported for clinical use. To make this judgment, the laboratory director needs to understand the risks that can cause a measurement technology to perform incorrectly, needs to evaluate the effectiveness of built-in control processes to mitigate those risks, and needs to ensure that adequate control procedures are in place to confirm that a result is correct at the time it is reported. A combination of built-in and external monitoring procedures using surrogate QC samples can be utilized to ensure that all risks have been appropriately mitigated and/or monitored at a frequency commensurate with the risk of malfunction and the risk of harm to a patient if an incorrect result was reported.

Equivalent Quality Control

The phrase "equivalent quality control" was introduced in the Survey Procedures and Interpretive Guidelines for Laboratories and Laboratory Services (Appendix C, 2003) of the CLIA quality control requirements (Department of Health and Human Services, 2003). "Equivalent quality control" was intended to justify less frequent assay of surrogate QC samples for measurement systems that utilized built-in control procedures to monitor various aspects of the measurement process. The survey procedures and interpretive guidelines defined three conditions to qualify a measurement system for less frequent assay of surrogate QC samples. No scientific evidence supports the validity of the arbitrarily defined options, and controversy surrounded their implementation (CLSI, 2005).

Some measurement systems have been designed with sophisticated built-in control procedures to mitigate the risk that an erroneous result may be produced. These control procedures have included electronic sensors, as well as liquid solutions integrated with reagent packaging, and measurement sensor devices with algorithms that prevent a result from being produced if any monitored conditions fail to meet criteria. Some of these measurement systems may be sufficiently stable and self-monitored to justify reduced frequency of surrogate QC sample testing. Because of the lack of scientific credibility for the three conditions used by the CLIA Survey Procedures and Interpretive Guidelines for Laboratories and Laboratory Services to qualify for reduced QC frequency, laboratory directors should use the risk assessment approach described in the CLSI (2010) document when evaluating the acceptability of manufacturers' claims.

QC Sample Assay Before Recalibration or Maintenance

It is necessary to assay QC samples before scheduled recalibration or maintenance. Each of these operations is intended to restore the measurement conditions to optimal specifications and to correct for any calibration drift or component deterioration that may have occurred. It is generally required to assay QC samples after these operations to verify correct method performance. It is also necessary to assay QC samples before these operations to verify that no significant errors in results have occurred since the last time QC samples were assayed, and before recalibration or maintenance alters the condition of the measurement system.

ESTABLISHING QC TARGET VALUE AND SD THAT REPRESENT A STABLE MEASUREMENT OPERATING CONDITION

QC target values and acceptable performance limits are established to optimize the probability to detect a measurement defect that is large enough to have an impact on clinical care, while minimizing the frequency of "false alerts" due to statistical limitations of the criteria used to evaluate QC results. The measurement system must be correctly calibrated and operating within acceptable performance specifications before the statistical parameters to establish QC interpretive rules can be established. Some sources of measurement variability are listed in Table 10-1. Measurement variability includes sources with short time interval frequencies, many of which can be described by Gaussian error distributions, and intermittent and longer time interval sources, which can cause cyclic fluctuations over several days or weeks, gradual drift over weeks or months, and more abrupt small shifts in results. QC interpretive rules need to be established that adequately account for all sources of variability in results that are consistent with the measurement system performing to specifications.

A QC material must have a reliable target value that represents the condition when systematic bias is as small as possible. This condition requires the method to be calibrated correctly and adequate replicate measurements to be obtained over a sufficient time interval to include the typical sources of measurement variability that will ensure that a representative mean value is calculated from the data. This objective is rarely met for longer-term variability components. The generally accepted minimum protocol for target value assignment is to use the mean value from assaying a QC material a minimum of 20 times, on 20 different days (CLSI, 2006). If a 20-day protocol is not practical, provisional target values can be established with fewer data but should be updated when additional replicate results are available. When applicable, more than one method of calibration should be represented in the 20-day period to adequately include the variability associated with the calibration process. If a QC material will be used for longer than 1 day, a single vial should be stored correctly and assayed on as many days as the material is planned to be used. This protocol will allow any variability caused by deterioration of the analyte to be averaged into the target value.

Some QC materials are provided by the method manufacturer with preassigned target values and ranges intended to confirm that the method meets the manufacturer's specifications. Such assigned values may be used initially by the laboratory. It is recommended that both the target value and the SD should be reevaluated and adjusted by the laboratory after adequate replicate results have been obtained because the QC interpretive rules used in a single laboratory should reflect performance for the method in that laboratory. The acceptability limits (product insert ranges) suggested by a manufacturer typically are based on data collected from several

TABLE 10-1
Common Sources of Measurement Variability

Source	Time interval for fluctuation	Likely statistical distribution
Pipet volume	Short	Gaussian
Instrument temperature control	Short or long	Gaussian or other
Electronic noise in the measuring system	Short	Gaussian
Calibration cycles	Short to long	Gaussian or shift (periodic step)
Reagent deterioration in storage	Long	Drift
Reagent deterioration after opening	Intermediate	Cyclic, periodic drift/step
Calibrator deterioration in storage	Long	Drift
Calibrator deterioration after opening	Intermediate	Cyclic, periodic drift/step
Control material deterioration in storage	Long	Drift
Control material deterioration after opening	Intermediate	Cyclic, periodic drift/step
Environmental temperature and humidity	Variable	Variable
Reagent lot changes	Long	Shift (random step)
Calibrator lot changes	Long	Shift (random step)
Instrument maintenance	Variable	Cyclic or shift (periodic step)
Deterioration of instrument components	Variable	Variable

laboratories. These data will inevitably account for sources of variability, such as between instruments, between reagent lots, and between calibrator lots, that will be greater than the variability expected for a method used in an individual laboratory. Use of product insert ranges that are too large will reduce a laboratory's ability to detect an erroneous measurement condition.

QC materials with assigned target values are also available from third-party manufacturers (i.e., manufacturers not affiliated with the method manufacturer). Caution should be used with third-party QC materials because the target values may have been assigned using inadequate statistical protocols. On the other hand, reliable peer group target values may be obtained from an interlaboratory comparison program with large numbers of laboratories using the same method.

Once a target value has been assigned to a QC material, a SD must be assigned that represents the typical imprecision of the method when it is performing according to its design specifications. SD is the conventional way to express method variability, even though non-Gaussian components of variability may influence QC results, because the statistical packages in instrument and laboratory computer systems are designed for QC data analysis that assumes only Gaussian uncertainty distribution. SD based on data from the 20-day target value assignment, or a 30-day monthly summary, has a large uncertainty (typically 30% for $N = 20$; CLSI, 2006) and is very unlikely to include all sources of variability expected over a longer time interval. It is recommended to determine the SD for stable measurement performance from the cumulative SD over a 6- to 12-month period for a single lot of QC material. This approach is likely to include all expected sources of variation. (See an important limitation when determining a cumulative SD, described later in the section [Verifying QC Evaluation Parameters Following a Reagent Lot Change](#)).

Figure 10-6 illustrates (with actual data for a glucose method) the fluctuation in SD that occurs when calculated for monthly intervals compared with the relatively stable value observed for the cumulative SD after a period of 6 months. Note that the cumulative SD is not the average of the monthly values but is the SD determined from all individual results obtained over a time interval since the lot of QC material was first used. Different sources of long-term variability occur at different times during the use of a method. The monthly SD does not adequately reflect the longer-term components of variability. However, the cumulative SD includes contributions from all sources of variability. Consequently, the cumulative SD will typically be larger than the monthly values, and will better represent the actual variability of the method. If the imprecision expected during normal stable operation is underestimated, the acceptable range for QC results will be too small, and the false alert rate will be unacceptably high. If imprecision for the stable condition is overestimated, the acceptable range will be too large, and a significant measurement error might go undetected.

It is important to include all valid QC results in the calculation of SD to ensure that the SD correctly represents expected method variability. A valid QC result is one that was, or would have been in the case of preliminary value assignment, used to verify acceptable assay performance and

Figure 10-6 Cumulative standard deviation (SD) versus single monthly values calculated from the data in [Figure 10-8](#).

reporting of patient results. Only QC results that were, or would have been, responsible for not releasing patient results should be deleted (with documentation) from summary calculations. If inappropriate editing of QC results occurs, the method SD may be inappropriately small, which will produce inappropriately small evaluation limits and an increase in false QC alerts with concomitant reduction in the effectiveness of statistical QC evaluation.

When a method has been established in a laboratory, and a new lot of QC material is being introduced, the target value for the new lot is used along with the cumulative SD from the previous lot to establish acceptable ranges for the new lot of QC material. This practice is appropriate because in most cases measurement imprecision is a property of the method and equipment used and is unlikely to change with a different lot of QC material. If target values for the old and new lots are substantially different, a different imprecision may occur, and adjustment to the SD may be necessary as additional experience with the new lot is accumulated.

If a new method is introduced for which no historical performance information is available, the SD for stable performance must be established using data available from the method validation and target value assignment of the QC materials. In this case, the initial SD and evaluation criteria will need to be monitored closely and adjustments made as additional experience allows measurement imprecision from all sources to be reflected in the cumulative SD.

TABLE 10-2

Abbreviation Nomenclature for QC Evaluation Rules

Rule	Meaning	Detects
1_{2S}	One observation exceeds 2 SD from the target value. The 1_{2S} rule is not recommended because it has an excessive false alert rate.	Not recommended
1_{3S}	One observation exceeds 3 SD from the target value.	Imprecision or systematic bias
2_{2S} ($2_{2.5S}$)	Two sequential observations, or observations for two QC samples in the same run, exceed 2 SD (or 2.5 SD) from the target value in the same direction.	Bias
R_{4S}	Range between two observations in the same run exceeds 4 SD.	Imprecision
10_x or 10_m	Ten sequential observations for the same QC sample are on the same side of the target value (x or mean). The 10_x rule is not recommended because it has an excessive false alert rate.	Not recommended
8_{1S} ($8_{1.5S}$)	Eight sequential observations for the same QC sample exceed 1 SD (or 1.5 SD) in the same direction from the target value.	Bias trend
CUSUM	Cumulative sum of SDI for a specified number of previous results.	Bias trend
EWMA	Exponentially weighted moving average for a specified number of previous results with newer results having more influence (weight).	Bias trend

CUSUM, Cumulative sum; EWMA, exponentially weighted moving averages; QC, quality control; SD, standard deviation; SDI, standard deviation interval.

ESTABLISHING RULES TO EVALUATE QC RESULTS

The acceptable range and rules for interpretation of QC results are based on the probability of detecting a significant analytic error condition with an acceptably small false alert rate. The desired process control performance characteristics must be established for each analyte before the appropriate QC rules can be selected.

The conventional way to express QC interpretive rules is by using an abbreviation nomenclature popularized among clinical laboratories by Westgard (1981) and summarized in Table 10-2. Note that fractional standard deviation intervals are permissible as in the $2_{2.5S}$ example. Statistical procedures such as cumulative sum (CUSUM) or exponentially weighted moving averages (EWMA) are preferred to monitor for bias trends (Ryan, 1989). It is recommended to use one of these more advanced trend monitoring procedures if supported by an available computer system because they are more powerful than the 8_{1S} (or $8_{1.5S}$) approach for detecting trends. EWMA and CUSUM must be carefully implemented to avoid being too sensitive to small changes that may cause an excessive frequency of false alerts.

Power function graphs were developed (Westgard, 1979) to express the probability that a QC interpretive rule will detect an analytic error of a given magnitude. Westgard's statistical model assumed Gaussian (normal) error distributions and, despite the fact that non-Gaussian error distributions exist in measurement systems, has provided useful guidelines for selecting rules to interpret QC results. Other literature reports have addressed rule selection criteria using other statistical models and assumptions regarding distribution of errors (Parvin, 1997; Parvin and Gronowski, 1997; Westgard, 1992; Linnet, 1989).

Figure 10-7 shows a power function graph that plots the probability to detect a measurement error (y-axis), which is the probability that a result will exceed a particular interpretive rule, versus a systematic bias of known magnitude in a result (x-axis) with a fixed random imprecision of 1 SD. The three lines in Figure 10-7 represent the probabilities of different interpretive rules to detect systematic biases of various magnitudes. For example, for the 1_{2S} rule, a result with a systematic bias of 1 SD (x-axis) has a 0.35 (35%) probability (y-axis) of violating the rule (i.e., of having a result >2 SD from the target value). Note that this figure shows only systematic bias as SD on the x-axis, and a result with 1 SD systematic bias will also have imprecision that causes the 1_{2S} rule to be exceeded. Thus, a 1_{2S} interpretive rule has a 35% probability to detect a systematic error that is 1 SD in magnitude. Similar graphs can be created for other interpretive rules for both systematic bias and imprecision error conditions.

Note in Figure 10-7 that none of these interpretive rules has a 100% probability to detect a systematic bias until the error becomes relatively large. The 1_{2S} rule has a good probability of detecting errors (e.g. almost 90% probability of detecting a 2.5 SD bias) but has a high false alert rate as indicated by the y-intercept (note arrow showing that because of imprecision, the probability of indicating an error condition for zero bias is 10%). Because of this high false alert rate, it is not recommended to use a 1_{2S} rule. The 1_{3S} rule has a low false alert rate, but a lower probability to detect an error (e.g., a 55% probability to detect a 2.5 SD bias). It

Figure 10-7 Power function graphs for the ability of different quality control interpretive rules to detect systematic error using two controls. Systematic error is expressed as number of standard deviations (SDs) from the target value. (Adapted from Westgard JO, Smith FA, Mountain PJ, Boss S. Design and assessment of average of normals [AON] patient data algorithms to maximize run lengths for automatic process control. Clin Chem 1996;42:1683-1688, used with permission.)

is recommended to improve the efficiency of QC interpretive rules by combining two or more rules and applying them simultaneously as multi-rule criteria. For example, the $1_{3S}/2_{2S}$ multi-rule identifies an error condition if one control exceeds ± 3 SD from the target value, or if two controls exceed ± 2 SD in the same direction from the target value. In Figure 10-7, the $1_{3S}/2_{2S}$ multi-rule has a low false alert rate similar to the 1_{3S} rule, but improved probability to detect an error (e.g., a 65% probability to detect a 2.5 SD bias and a 90% probability to detect a 3.2 SD bias). In this multi-rule example, the 1_{3S} component is sensitive to imprecision or large systematic bias, while the 2_{2S} component is sensitive to systematic bias.

A challenge in selecting interpretive rules for QC results is that the different sources of variation listed in Table 10-1 occur in most contemporary automated assay systems and introduce longer-term cyclic and step fluctuations in performance. These types of variability are not adequately described by Gaussian models for rules selection. Consequently, data acquired over a significant time period are necessary to determine an appropriately representative SD that represents typical variability when the method is stable and performing correctly. A representative SD is needed because essentially all commercially available QC computer systems use SD-based rules with an assumption of Gaussian error distributions. Laboratorians need to derive an SD that can be used in available computer algorithms and that reflects longer-term non-Gaussian contributions to imprecision. At certain periods of time, the short-term SD will be noticeably smaller than the long-term cumulative value (see Fig. 10-6). One must avoid concluding that the SD used for evaluation is too large because over

time the cumulative value will be more consistent with method performance, as periodic sources of variability are encountered.

Figure 10-8 shows how non-Gaussian error sources influenced results for a single lot of QC material used over a 10-month period for an automated glucose method. The glucose method stability and performance over the 10 months were considered acceptable for clinical use. Data for the first 49 days are the same as in Figure 10-5 and represent the initial experience with this lot of QC material. Examination of these data shows several fluctuations that cannot be described by a Gaussian statistical model. The first reagent lot change caused a step shift to higher values. The second reagent lot change had no effect on QC results. Between March and April, a transition to lower values occurred that did not correspond to any maintenance, reagent lot change, or calibration events. Throughout the 10-month period, intervals of several weeks' duration occurred when the imprecision was better or worse than at other time periods (also see Fig. 10-6 calculated from the same data).

In practice, empirical judgment is frequently used to establish acceptance criteria (rules) to evaluate QC results based on data acquired over a long enough time to adequately quantify the expected variability when a method is working correctly. It is not recommended to select QC rules based only on Gaussian models of imprecision because the rules will not correctly accommodate all the types of variability observed for many analytic systems.

Table 10-3 gives an example of an empirically developed multi-rule based on the data in Figure 10-8. This multi-rule had 0.6% false alerts when applied to the data in Figure 10-8, using the mean from the November–January (Fig. 10-4) period as the target value and the SD for the 10-month period to represent overall imprecision. If a 2_{2S} rule had been used instead of a $2_{2.5S}$ rule, the false alert rate would have increased by 1.2%, but the rule would detect slightly smaller biases. An $8_{1.5S}$ rule was used to provide detection of bias trends because it had a 0% false alert rate (compared with 0.5% for an 8_{1S} rule) and was adequate to detect a developing trend before it became clinically important because the SD was small, 4.0 mg/dL, at a concentration of 274 mg/dL. At other clinical concentration ranges, or for other analytes, an 8_{1S} or $6_{1.5S}$ rule may be more appropriate. A 10_x rule was not used because it would have increased the false alert rate by 10.6%. Many contemporary analyzers are very stable and may produce QC results with a small standard deviation interval (SDI) on one side of the target value for extended periods of time. Consequently, a 10_x rule generally is not recommended, as this condition does not infer a

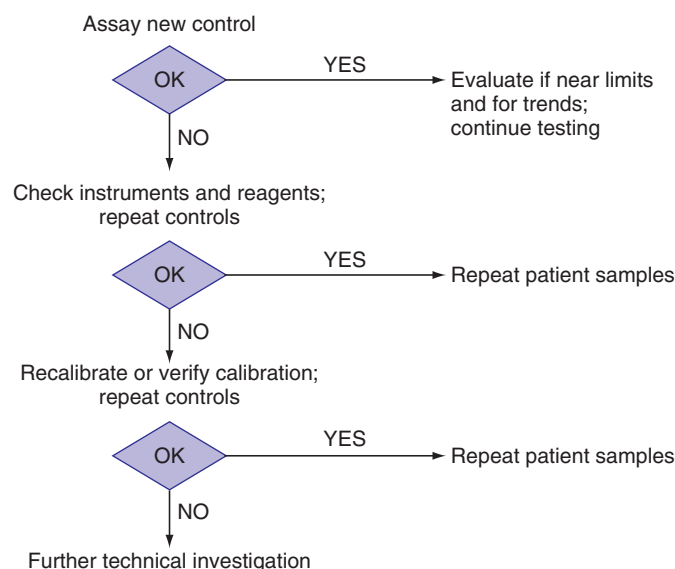

Figure 10-9 Generalized troubleshooting sequence following an unacceptable quality control result. (Reprinted with permission from Miller WG, Nichols JH. *Quality control*. In: Clarke WA, editor. *Contemporary practice in clinical chemistry*, 2nd ed. Washington DC: AACC Press; 2010.)

problem with clinical interpretation of patient results when the magnitude of the difference is small.

Whatever statistical approach is used, the balance between false alerts and the probability of detecting an error is improved when multiple rules are used in combination. When establishing rules to interpret QC results, it is important to remember that statistical process control can only verify that a measurement system is producing results that conform to the expected variability when the system is properly calibrated and in a stable operating condition. QC rules are chosen to detect changes in calibration and changes in imprecision that are significant enough to require correction before patient results are reported. Periodic measurement of QC samples does not identify random events (e.g., a temporary clot in a sample pipet, a random reagent pipet error) that do not persist until the next QC sample is measured.

It may be determined in the process of reviewing statistical parameters for QC data that a method's variability is too great to meet medical requirements. If the method is performing in a stable condition, the observed variability is an inherent limitation of the technology. In this case, the only solution is to improve the method or to use a different method. If the method performance cannot be improved and a better method is not available, the laboratory must accept the method limitations and communicate them to patient care providers. It is important in this circumstance not to make the QC limits or interpretive rules artificially stringent. This incorrect approach will not improve method performance, but will increase the QC false alert rate and will decrease the efficiency and practicality of the statistical QC process.

CORRECTIVE ACTION WHEN A QC RESULT INDICATES A MEASUREMENT PROBLEM

A QC alert occurs when a QC result fails an evaluation rule, which indicates that an analytic problem may exist. A QC alert means there is a high probability that the assay is producing results unreliable for patient care. When this condition occurs, it is necessary to take corrective action to investigate the cause of the QC alert. Figure 10-9 presents a generalized troubleshooting sequence. Repeating the QC measurement on the same QC sample is not recommended because, with properly designed control rules, it is more likely that a measurement system problem exists, than the QC result was a statistical outlier. However, QC materials can deteriorate after opening caused by improper handling and storage or because of unstable analytes. Thus, repeating the measurement on a new sample of the QC material is a useful step to determine if the alert was caused by deteriorated QC material rather than by a method problem. In this situation, if the result for the new QC sample is acceptable, testing of patient samples can resume. One caution, if the repeat result is near acceptability limits, is to consider that the repeat and original results may be essentially

TABLE 10-4

Example for Selected Chemistry Analytes of Empirical Criteria for Patient Test Result Agreement Between Repeated Assays; and for Agreement Among Results for a Single Patient Sample Measured on Multiple Instruments

*Whichever is greater.

of the same magnitude. In this situation, the probability is fairly high that a measurement problem exists, and this possibility should be investigated. In addition, current and preceding QC results should be examined for a trend in bias that indicates a measurement issue that needs to be corrected. These precautions in evaluating repeat results for a new QC sample can be challenging or impossible for automated evaluation by computer systems, thus requiring the laboratory technologist to be vigilant in reviewing results.

When repeat testing of a new QC sample does not resolve the alert situation, the instrument and reagents should be inspected for component deterioration, mechanical problems, etc. In many cases, it will be necessary to recalibrate (or verify calibration). When the problem is identified and corrected, QC samples should be assayed to verify the correction, and all patient samples since the time of the last acceptable QC results should be reassayed. The laboratory director must establish acceptable criteria to determine if the repeat results agree adequately to permit reporting of original results without issuing a corrected report. Otherwise, corrected results must be reported. As an example, Table 10-4 lists empirical criteria used in the author's laboratory for this purpose. The criteria for acceptability of repeated tests are based on method characteristics, population served, and clinical requirements of the medical services.

In some cases, sample volume may not be adequate (quantity not sufficient [QNS]) for repeat testing. In these situations, no results can be reported unless it is documented that the impact of the method defect on the original results was small enough to have minimal effect on clinical interpretation. A protocol to evaluate the clinical impact of the methodologic problem is to repeat those samples that have adequate volume. The repeated samples must represent the concentration range of the QNS samples, must represent the time span since the previous acceptable QC results, and should include a substantial proportion of the total samples

Figure 10-10 Levey-Jennings plot showing impact of a reagent lot change on matrix bias with quality control (QC) samples. (Reprinted with permission from Miller WG, Nichols JH. *Quality control*. In: Clarke WA, editor. *Contemporary practice in clinical chemistry*, 2nd ed. Washington DC: AACC Press; 2010.)

originally assayed while the method was in the unacceptable condition. If the repeat results for this sample group are within established criteria for repeat testing of patient samples, the original results for the QNS samples can be reported. Otherwise, the original results for the QNS samples are considered erroneous; no results can be reported, and the original results already reported need to be corrected to a “no result” condition.

VERIFYING QC EVALUATION PARAMETERS FOLLOWING A REAGENT LOT CHANGE

Changing reagent lots can have an unexpected impact on QC results. Careful reagent lot crossover evaluation of QC target values is necessary. Because the matrix-related interaction between a QC material and a reagent can change with a different reagent lot, QC results may not be a reliable indicator of a method's performance for patient samples following a reagent lot change. In the example in Figure 10-10, QC values for the high concentration control shifted following the change to a new lot of reagents, but there was no change in results for the low control. A comparison of results for a panel of patient samples assayed using the new and old reagent lots, as shown in Figure 10-11, verified that patient results were the same when either lot of reagents was used. Patient results spanned the analytic measurement range and had nearly identical values, as indicated by the slope of 1.00 and the small intercept of -3 mg/dL. Consequently, the change in QC values for the high concentration material was due to a difference in matrix-related bias between the QC material and each of the reagent lots.

It is well documented that QC materials and PT materials, both of which are prepared similarly, have unpredictable matrix interactions when different methods and different reagent lots are used with the same method (Franzini, 1998; Cattazzo, 2001; Thienpont, 2003; Miller, 2003, 2005, 2008, 2011; Waymack, 1993). For this reason, it is necessary to use clinical patient samples to verify the consistency of results between old and new lots of reagents.

Figure 10-12 presents a procedure to verify or adjust QC material target values following a reagent lot change. The first step is to verify that calibration of the new reagent lot produces results for a group of patient samples that are consistent with results from the previous lot. The patient sample results, not the QC results, provide the basis for verifying that the method calibration is consistent with that of the previous reagent lot. If a problem is identified, the calibration of the new reagent lot must be investigated and corrected, or the new reagent lot may be defective and should not be used. When evaluating the new patient results, keep in mind that the

Figure 10-11 Deming regression analysis of results from a patient sample comparison between the same old and new lots of reagent shown in Figure 10-10 for quality control samples.

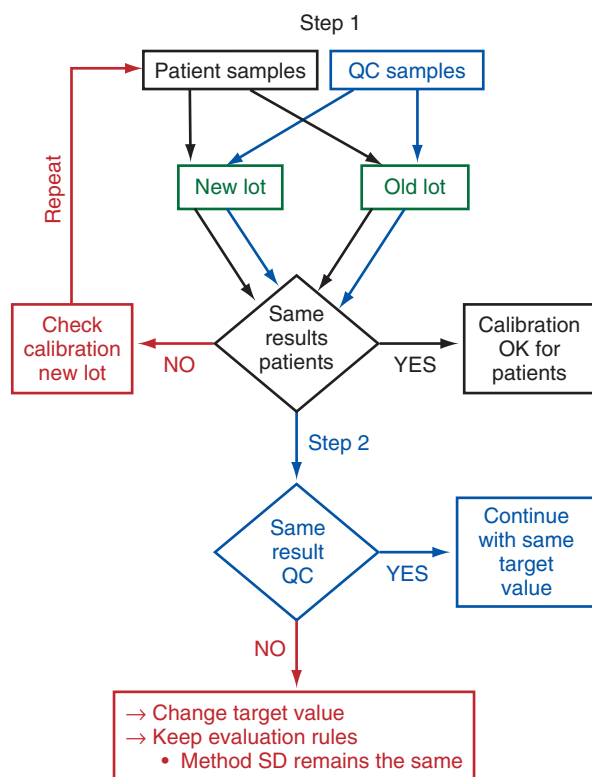

Figure 10-12 Process for assessment of potential matrix impact on quality control (QC) samples following a reagent lot change. SD, Standard deviation.

calibration of the old reagent lot may have drifted and should be verified before concluding that the new reagent lot calibration is not correct.

There are no well established guidelines regarding the number of patient samples to use in this type of comparison when reagent lots are changed. It is recommended to select a group of patient samples that span the analytic measurement range to verify comparable results. A minimum of five samples is reasonable to cover the analytic measurement range. CLSI document C54, "Verification of Comparability of Patient Results Within One Healthcare System," includes a section on reagent lot changes and provides a statistical approach suitable for small sample sizes. Deming

regression analysis (Cornbleet, 1979; Linnet, 1993) can be used with 10 or more patient samples and provides a more robust approach that allows assessment of average performance over the range of concentrations represented by the patient samples.

There are no well established clinical acceptance criteria for agreement between results; consequently, the laboratory must establish acceptance criteria consistent with the relatively small number of samples used, the analytic capability of a method, and the clinical requirements for interpreting results. As an example, empirical acceptance criteria used in the author's laboratory for assessment of individual results when five samples are used are provided in Table 10-4.

Once the results for patients are acceptable, the second step in Figure 10-12 evaluates results for each QC material to determine if its target value is correct for use with the new lot of reagent(s). If the target value has changed, it must be adjusted to correct for the change in matrix-related bias between old and new lots of reagent(s). This adjustment keeps the expected variability centered around the QC target value, so that QC interpretive rules will remain valid. Failure to make a target value adjustment will introduce an artifactual bias in subsequent QC results, causing an increased false alert rate. The SD used to evaluate QC results will not typically change when a new lot of reagent(s) is put into service. The SD represents expected variability when the method is stable and is performing according to specifications. In most cases, the variability of a method will be the same with any lot of reagent(s). However, occasional exceptions may occur, for example, if the new reagent lot is a reformulation, it may be necessary to adjust the SD after additional numbers of QC results are accumulated with the new reagent lot. A reagent lot verification typically is performed on a single day and will likely provide only a few QC results from which to evaluate if the target value has changed. Consequently, it is necessary to carefully monitor QC results as more data are acquired using the new reagent lot and, if needed, to further refine the new target value.

Note that a matrix-related bias can cause the numeric values for the QC results to shift, and this shift is an artifact of the interaction between the QC material and the reagent, not a property of the measurement system. The shift may cause an artifactual increase in the cumulative SD such that the cumulative SD may be larger than the inherent measurement variability. It is recommended to use cumulative SD from one or more single reagent lots when determining the SD to use for interpreting QC rules.

VERIFYING METHOD PERFORMANCE FOLLOWING USE OF A NEW LOT OF METHOD CALIBRATOR

When a new lot of calibrator is used, with no change in reagents, there is no change in matrix interaction between the QC material and the reagents. In this situation, QC results provide a reliable indication of calibration status with the new lot of calibrator. If the QC results indicate a bias following use of a new lot of calibrator, the calibration has changed and needs to be corrected to ensure consistent results for patient samples.

Some methods are packaged as kits that include reagents, calibrators, and QC materials. In this case, QC results could fail to identify a calibration shift when a new kit lot is used, and it is necessary to assay clinical patient samples with the old and new kit lots to verify consistency of patient results. When possible, it is recommended to use QC materials that are independent of the kit lot, and to avoid changing lots of QC material at the same time as changing lots of reagent or calibrators. Assaying patient samples always provides a reliable approach to verify the consistency of results following changes in lots of reagents or calibrators.

USING PATIENT DATA IN QUALITY CONTROL PROCEDURES

Results from patient samples are used in four principal ways to support the QC processes in a laboratory.

- To verify consistency of patient results when changing lots of reagent or calibrators for a method (discussed in the previous section)
- To identify inconsistent results using a delta check with a previous result for a patient
- To verify consistency of patient results when an analyte is measured using more than one instrument or method in a health care system
- To verify method performance using results from patient samples in a statistical QC scheme

TABLE 10-5

Example Delta Check Criteria Intended to Identify Samples That Are Potentially Mislabeled or Contaminated With IV Fluids Due to Incorrect Collection

Test	Delta criteria
Sodium	5% change within previous 48 hours

DELTA CHECK WITH A PREVIOUS RESULT FOR A PATIENT

Some types of laboratory errors can be identified by comparing a patient's current test result against a previous result for the same analyte. This comparison is called a "delta check." The previous result is taken from a specified time interval in the past during which the result is not likely to have changed physiologically. This limitation restricts the analytes that can be effectively monitored with a delta check. Delta checks can detect analytic errors; however, their main purpose is to detect mislabeled samples and samples altered by dilution with IV fluid. Consequently, an effective delta check process can be established using a limited number of analytes. The difference between results that causes a delta check alert must be sufficiently large to avoid excessive numbers of false alerts and adequate to allow identification of samples that may be compromised and require follow-up investigation. Table 10-5 shows, as an example, the delta check parameters for automated chemistry used in the author's laboratory. Kazmierczak (2003) has reviewed and presented recommendations for using delta check and other patient data-based quality control procedures.

VERIFY CONSISTENCY OF RESULTS BETWEEN MORE THAN ONE INSTRUMENT OR METHOD

Another common use of patient results in a QC process is to verify consistency of patient results when an analyte is measured by using more than one instrument or method within the same health delivery system. Good laboratory medicine requires that multiple instruments or methods for the same analyte be calibrated to produce the same results for patient samples whenever possible. It may be necessary to modify the calibration settings of one measurement system to match another system's results. This strategy allows a common reference interval to be used, provides continuity in results between different laboratory testing locations, and avoids clinical confusion regarding interpretation of laboratory results. CLIA regulations, section 493.1281, require that the relationship between test results from different methods or from multiple locations should be evaluated at least twice a year (Department of Health and Human Services, 2003).

As illustrated in Figure 10-13, clinical patient sample aliquots are measured using each of two or more methods (or analyzers) to evaluate and if

necessary adjust the calibration as needed to achieve agreement in results for patient samples. Such an analysis design is called a "round robin." One method/analyzer may be chosen to represent the primary method to which others will be adjusted to achieve equivalent results. The primary method should be chosen based on quality and reliability of results with consideration of its calibration traceability to national or international standards, its performance stability, its specificity for the analyte, and its susceptibility to interfering substances. An alternate approach is to evaluate each method for agreement with the mean of all methods and to adjust the calibration of any methods/analyzers as necessary to produce equivalent results among the group. When like analyzers in a group are compared, if results for one analyzer are different from results for the others, that analyzer's calibration is adjusted to conform to that of the group.

As mentioned previously, for evaluating consistency following reagent lot changes, there are no well established guidelines regarding the number of samples to use for a round robin exchange. The laboratory needs to establish the frequency of evaluation and the number of samples based on the stability of the methods, the frequency of reagent and calibrator lot changes, and the clinical requirements of the health delivery system. Common practices include a round robin exchange of one or more individual patient samples, or a pool prepared from several samples, on a weekly basis for high volume methods; or on a monthly or quarterly basis for lower volume or very stable methods; or the regulatory minimum of every 6 months. For frequent comparisons with one or two samples, concentrations should be chosen to evaluate the analytic measurement range over a period of several examinations. For less frequent comparisons, a larger number of samples is recommended to cover the analytic measurement range. When establishing interpretation criteria, the laboratory needs to consider the limited statistical power for the number of results available. CLSI document C54, "Verification of Comparability of Patient Results Within One Healthcare System," provides a statistical approach suitable for using 1–5 samples in a comparison.

Table 10-4 provides, as an example, empirical criteria used in the author's laboratory for evaluation of agreement among results for a single patient sample assayed weekly among multiple analyzers. These criteria were established based on the expected imprecision of the methods used and the clinical impact of discrepant results. To allow for the limitations of a single measurement of a single sample in a comparison, a result outside a criterion is typically not acted on unless the magnitude of a difference is much larger than the criterion, or the situation persists for 2 or more weeks.

It is recommended to use patient samples to verify agreement between multiple methods or analyzers. Results for QC materials should not be used for the purpose of verifying consistency of results for patient samples assayed using different methods or analyzers. As discussed in an earlier section, QC materials are not validated to be commutable with patient samples between different methods. Even when more than one method/analyzer from the same manufacturer is used, differences may be seen in the measured value for QC materials between different reagent lots. In principle, if more than one of the same model analyzer with the same reagent lots are used, all should have the same results for the same lot of QC material. In practice, differences in measurement details between different analyzers cause small differences in QC results. The acceptance criteria can be set to allow for such differences. However, more reliable conclusions will be drawn when patient samples are used to evaluate agreement among different analyzers.

USING PATIENT DATA FOR STATISTICAL QUALITY CONTROL

Patient results can be used in a statistical QC process to monitor method performance. For a sufficiently large number of results, the mean (or preferably median) value may be sufficiently stable to be used as an indicator of method consistency over time. This approach can be used on a periodic basis by extracting data for a specified time period (e.g., 1 month), calculating the mean and SD for the distribution of results, and comparing one time period versus another to determine whether any changes have occurred. This type of periodic evaluation can identify changes in calibration stability or in overall imprecision for a method. The mean and SD can also be compared for consistency between multiple methods for the same analyte.

Patient populations for sampling must be selected with consideration of the physiologic homogeneity of results. Important considerations include parameters likely to influence the reference interval, such as disease

Figure 10-14 Histograms for distribution of sequential patient results for albumin from a student health outpatient clinic and a hospital general medicine inpatient unit.

status, pediatric versus adult, gender, and ethnic differences. Figure 10-14 shows an example of the potential impact of a nonhomogeneous sample of patients on distribution of albumin results for hospital general medicine inpatients compared with a student health outpatient clinic. The histograms are very different because the two patient groups differ in severity of disease, and in recumbent versus supine position for blood collection, which influences vascular water volume and the concentration of albumin.

Automated approaches to determine the mean (or median) for groups of sequential patient results used as a continuous process control parameter have been described. These methods are called “average of normals” (AON) or “moving average” techniques and are suitable for use in higher volume assays in chemistry and hematology (Westgard, 1996; Smith, 1996; Cembrowski, 1984; Ye, 2000; Kazmierczak, 2003). In general, these approaches evaluate sequential patient results over time intervals such as several hours to 1 or more days. For some analytes, patients may need to be partitioned to obtain subgroups whose results are expected to be homogeneous. Consideration of influences for partitioning includes age, gender, ethnicity, and disease conditions. Some approaches have arbitrarily trimmed abnormal results in an attempt to restrict results to more normal health conditions. Trimming approaches must be used with caution as excessive trimming will create an artificial subset of results that may not reflect a method’s calibration condition.

The mean, median, or other statistical parameter for a group of results is tracked over time intervals to monitor method performance. Statistical procedures such as cumulative sum or exponentially weighted moving average are used to monitor trends in method calibration status. These approaches can be useful for supplementing traditional QC sampling techniques to monitor a method’s calibration stability and to monitor calibration uniformity between multiple methods in higher volume settings. However, patient-based monitoring procedures have not been widely adopted because of lack of consensus guidelines for their use, and lack of computer support from instrument manufacturers and laboratory information system vendors.

PROFICIENCY TESTING

Proficiency testing (or external quality assessment) consists of evaluation of method performance by comparison of results versus those of other laboratories for the same set of samples. PT providers circulate a set of samples among a group of laboratories. Each laboratory includes the PT samples along with patient samples in the usual assay process. Results for the PT samples are reported to the PT provider for evaluation. PT allows a laboratory to verify that its results are consistent with those of other laboratories using the same or similar methods for an analyte, and to verify that it is using a method in conformance with the manufacturer’s specifications.

PT is not available for some analytes because a particular test may be new to the clinical laboratory or is not commonly performed, or because analyte stability makes it difficult to include in PT material. In these situations, the laboratory should use an alternate approach to periodically

Figure 10-15 Example of noncommutable results between proficiency testing materials and pooled patient samples for a specific method. (Adapted from Naito HK, Kwak YS, Hartfiel JL, et al. Matrix effects on proficiency testing materials: impact on accuracy of cholesterol measurement in laboratories in the nation’s largest hospital system. *Arch Pathol Lab Med* 1993;117:345–351, used with permission.)

verify acceptable performance of the method. CLSI has published a guideline document that provides several approaches for verifying method performance when formal PT is not available (CLSI, 2008).

QC material manufacturers may provide a data analysis service that uses peer groups for each method and calculates group statistics for performance evaluation. As with PT evaluation, this type of interlaboratory QC data analysis allows a laboratory to verify that it is producing QC results that are consistent with those of other laboratories using the same method.

NONCOMMUTABILITY OF PT MATERIALS AND PEER GROUP GRADING

It is a common practice for PT providers to organize results into “peer groups” of methods that represent similar technology expected to have the same result for a PT sample. The mean value of the peer group results is the target value. Peer group evaluation is used for PT because the materials typically used as PT samples are not commutable with native patient samples. As discussed earlier, matrix-related bias is unique to each combination of method and QC or PT material and can be quantitatively different for different method/material combinations for the same analyte. Several investigations have reported >50% incidence of noncommutable materials for many different analytes (Ross, 1998; Miller, 1993, 2003, 2005, 2008).

Figure 10-15 illustrates the effects of noncommutable materials on interpretation of PT results and demonstrates why “peer group” evaluation is used. In this example, pooled patient sera and PT samples were assayed by the duPont Dimension Analyzer (duPont, Wilmington, Del.) and by the Abell-Kendall reference method for cholesterol (Naito, 1993). The Abell-Kendall method is known to be unaffected by matrix-induced changes in PT samples (Ellerbe, 1990). The patient samples showed excellent agreement between the two methods (average bias = 0.2%). However, the PT samples had a large negative bias (–9.5%) between methods, caused by a matrix-related bias with the duPont method that was not present with the reference method (Kroll, 1990).

In this example, the routine method was correctly calibrated and produced results for patient samples that were traceable to the reference method. However, PT results gave an incorrect impression of the method’s calibration relationship to the reference method. If the routine method’s calibration had been erroneously adjusted on the basis of PT results, the results for patient samples would then be incorrect. PT results were useful for evaluating the performance of all laboratories using the duPont method, because the matrix-related bias was uniform within this peer

Test units method	Specimen	Reported result	Mean	SD	N labs	SDI	LIMITS OF ACCEPTABILITY	
							Lower	Upper

group. Consequently, if an individual laboratory's results agreed with those of the peer group, the individual laboratory could conclude that the method was performing in conformance with the manufacturer's specifications. In general, an individual laboratory depends on the manufacturer to correctly calibrate a clinical laboratory routine method to be traceable to the reference system for an analyte.

REPORTING PT RESULTS WHEN ONE METHOD IS ADJUSTED TO AGREE WITH ANOTHER METHOD

It is good laboratory practice (and consistent with CLIA regulations, section 493.1281) to adjust the calibration of different methods for the same analyte used within a health delivery system, so the results for patient samples are consistent, irrespective of which method is used. Such harmonization of results is important for uniform use of reference intervals and decision thresholds within a health delivery system. In this situation, it is important to report PT results such that they can be properly evaluated against the peer group target value. The peer group target value will reflect the method calibration established by the method manufacturer. For an individual laboratory's PT result to be evaluated against the peer group mean, that individual result must be reported to the PT provider after removing any calibration adjustments, so the reported result is consistent with the manufacturer's nonadjusted calibration. The most convenient way to remove a calibration adjustment is to first assay PT samples with the method calibration adjustment applied to the measurement system, as would be the usual assay process for patient samples. After the assay, adjust the PT results "in reverse" by mathematically removing the calibration adjustment factors, and report the results with any adjustment factors removed. One should not recalibrate the instrument with a new set of calibrators for the purpose of assaying PT samples, because this practice would violate regulations requiring the PT material to be assayed in the same manner as patient samples.

For example, a laboratory has performed a patient sample comparison between Method A used in the main laboratory and Method B used in a satellite laboratory. Method B consistently gave 10% higher results. Method B was adjusted to agree with Method A by putting the adjustment factor 0.9 in the Method B instrument to automatically multiply each measured result by 0.9 to lower the reported result by 10%. When PT results from Method B are reported, it is necessary to remove the 0.9 factor to allow the reported result to be compared with the peer group mean of measured results from all laboratories using Method B. Removing the 0.9 factor is accomplished by multiplying the reported PT result from Method B by the factor 1.10 to increase its numeric value by 10% to the nonadjusted value that was actually measured by the instrument according to the manufacturer's defined calibration procedure. This process allows the PT result measured by Method B to be appropriately evaluated in comparison with its peer group mean, which will reflect the manufacturer's established calibration. This process permits the PT sample to be assayed in the same

manner as patient samples, and the numeric result reported to the PT provider to reflect the actual measured result using the manufacturer's recommended calibration settings.

INTERPRETATION OF PT RESULTS

Many countries have regulations (e.g., CLIA in the United States) requiring PT and specifying the evaluation criteria for acceptable performance. When criteria are not set by regulations, the PT provider sets evaluation criteria on the basis of clinically acceptable performance. PT evaluation criteria are designed to evaluate the total error of a single measurement. The acceptability limits for PT include bias and imprecision components considered clinically acceptable for an analyte plus other error components that are unique to PT samples, such as between-laboratories variation in calibration; homogeneity of the PT material vials; stability variability in the PT material both in storage/shipping and after reconstitution or opening in the laboratory; and variable matrix-related bias with different lots of reagent within a peer group. Consequently, the acceptability limits for PT samples are larger than what might be expected for clinically acceptable total error with patient samples.

Figure 10-16 is an example of a typical evaluation report sent to a participating laboratory. Each reported result is compared with the mean result for the peer group using the same method. The report also includes the SD for the peer group distribution of results, the number of laboratories in the peer group, and the SDI, which expresses the reported result as the number of SDs it is from the mean value [$SDI = (result - mean) / SD$]. The limits of acceptability are shown. Acceptability criteria may be a number of standard deviations from the mean value, a fixed percent from the mean value, or a fixed concentration from the mean value. In Figure 10-16, calcium acceptability criteria are ± 1 mg/dL from the mean value, and iron criteria are $\pm 20\%$ from the mean value.

Peer group evaluation allows a laboratory to verify that it is using a method according to the manufacturer's specifications and is producing patient results that are consistent with those of other laboratories using the same method (Miller, 2009). In Figure 10-16, the calcium results are in close agreement with the peer group mean (SDI ranges from -0.2 to -1.4). However, the iron results show greater variability, with one result +3.5 SDI. Although that iron result is within the acceptability criteria, it is recommended to investigate the method, as discussed in the next paragraph.

If an unacceptable PT result is identified, the method must be investigated for possible causes, and any necessary corrective action taken. Even when a PT result is within acceptability criteria, it is good laboratory practice to investigate PT results that are more than approximately 2.5 SDI from the peer group mean. When the SDI is 2.5, there is only a 0.6% probability that the result will be within the expected distribution for the peer group; consequently, the probability is reasonable that a method problem may need to be corrected. In addition, PT result(s) that have been near the failure limit for more than one PT event, even if the result(s) have passed the PT acceptance criteria, should initiate a review of systematic

TABLE 10-6

Examples of Causes of Proficiency Testing (PT) Failures

Condition	Examples
Technical problem with a method or equipment	<ul style="list-style-type: none"> • Calibration drift or incorrect calibrator target value • Deterioration of reagents or calibrators • Lot-to-lot variability in reagents or calibrators • Deterioration of other components (e.g., automated pipette system) • Method lacks adequate specificity for the analyte • Method lacks adequate sensitivity to measure the concentration • Inadequate SOP or QC procedures • Incorrect instrument settings or data processing procedures • Inadequate environmental control in the laboratory
Technical problem caused by laboratory personnel	<ul style="list-style-type: none"> • Failure to follow SOP • Incorrect instrument operation, maintenance, etc. • Incorrect preparation or handling of reagents, calibrators, or PT samples • Incorrect pipetting or dilution process • Incorrect calculation of result • Misinterpretation of result
Incorrect reporting of PT result (clerical errors)	<ul style="list-style-type: none"> • Failure to convert measurement units to those required for the PT report • Failure to identify correct method used • Transcription error on report form • PT sample was mislabeled in the laboratory.
Problem with the PT material	<ul style="list-style-type: none"> • Analyte not stable in PT material • Interfering substance in PT material • Sample deterioration in transit • Sample had weak or borderline reaction

QC, Quality control; SOP, standard operating procedure.

problems with the method. These practices support identification of potential problems before they progress to more serious situations. When results are investigated, a limitation of SD-based grading criteria should be considered. Very precise methods may have a very small SD, and a result may be outside an SD limit when the magnitude in reporting units is small and is not consistent with a clinical problem.

Common causes for PT failure are listed in Table 10-6 (based on Miller, 2009; CLSI, 2007). Incorrect handling and reporting are frequently unique to PT events and may not reflect the same process used in the laboratory for patient samples. Nonetheless, these situations reflect attention to detail, which is a necessary attribute for quality laboratory testing. Occasionally, the PT material may have a defect that causes it to perform inappropriately for all or a subgroup of methods. In this case, the PT provider will identify the situation and will not grade participants for that sample.

PT results are usually received several weeks after the date of testing. Consequently, investigation of unacceptable results requiring review of quality control, reagent, calibration, and maintenance records for the date of the test and the preceding several weeks or months is necessary. If review of these records suggests a stable operating condition, and review of the PT material handling and documentation does not identify a cause for the erroneous PT result, it may be concluded that the PT failure was a random event. Investigative steps, data reviewed, and conclusions from the review must be documented in a written report of the unacceptable PT result and reviewed by the laboratory director.

Limitations in Interpreting PT Results

PT providers also prepare a summary report, which includes the mean and SD for all peer groups represented by the participants' results. Similar reports are available from interlaboratory QC programs. Summary reports are very useful but must be interpreted with consideration of the limitations of noncommutable samples. The peer group mean and SD are useful for evaluating the uniformity of results between laboratories using the same method, to confirm that an individual laboratory is using the method correctly as designed by the manufacturer, and to evaluate the consistency of an individual laboratory's method performance relative to the peer group over time intervals from one PT event to the next

(trend monitoring). Summary information also allows evaluation of the imprecision of various method groups, and the number of users in each method group reveals which methods are commonly used.

The frequent occurrence of noncommutability of PT materials makes it incorrect to use PT summary reports to compare an individual laboratory's result with the peer group mean for another method group, to compare method peer group mean values to each other, or to compare an individual method peer group value to a value from a reference measurement procedure. The noncommutability limitation prevents PT (or QC) results from being used to infer agreement, or lack of agreement, for patient results among different methods for the same analyte.

ACCURACY-BASED PT PROGRAMS

In special cases, PT providers have used commutable samples in PT programs. Commutable samples are typically prepared by pooling clinical patient samples with minimal processing or additives to avoid any alteration of the sample matrix. To achieve samples with abnormal values for analytes, donors are identified with known pathologic conditions, or blood and serum units from a general donor population can be prescreened for selected analytes. Supplementing patient samples or pools with purified analytes may be acceptable in some cases but has not been rigorously evaluated. When commutable PT samples can be prepared, the results reflect what would be expected if patient samples were sent to each of the different laboratories. Thus, agreement among different laboratories and methods (called harmonization) can be correctly evaluated. The agreement between an individual laboratory result and a reference measurement result (accuracy), and the agreement between a method group mean value and the reference measurement result (called trueness), can be evaluated when a reference measurement procedure is available for an analyte.

For example, the College of American Pathologists glycohemoglobin survey for many years has used pooled, freshly collected whole blood from both normal and diabetic donors. The target values for the pooled blood are assigned by reference measurement procedures for hemoglobin A1c. In this survey, the accuracy of individual laboratory results and the trueness of method group means versus the reference measurement procedure values can be evaluated because the PT samples are commutable with clinical patient samples. Method group trueness can be used by the respective method manufacturers to monitor the effectiveness of their calibration processes.

It has been challenging to prepare commutable materials for use in large PT programs. However, use of commutable materials adds substantial value to the information obtained from the results (Bock, 2005; Knight, 2005; Miller, 2003, 2005, 2008; Palmer-Toy, 2005; Schreiber, 2005; Steele, 2005). Procedures have been developed to validate the commutability of QC, PT, and reference materials (Vesper, 2007; CLSI, document C53-A, 2010).

QUALITY MANAGEMENT

Quality management (QM) refers to the overall process used to ensure that laboratory results meet the requirements for health care services to patients. The components of a QM system shown in Figure 10-4 were derived from the CLSI document GP26-A3, Application of a Quality Management System Model for Laboratory Services, and are consistent with the ISO document 15189:2007, Medical Laboratories—Particular Requirements for Quality and Competence. Laboratories are required to develop procedures to monitor and ensure quality in all aspects of laboratory services. A QM program is an accreditation requirement, and good documentation of the metrics, the review process, and the improvements made is necessary.

Statistical quality control and proficiency testing, covered in detail in this chapter, are two important components of a QM program that address measurement procedures. Metrics related to QC activities may be evaluated as part of monitoring the performance of a measurement system. The following may be useful indicators of method performance issues:

- Frequency of QC alerts
- Frequency of recalibration based on QC alerts
- Number of reagent changes due to QC alerts
- Number of times controls were repeated because of QC alerts
- Frequency of unscheduled maintenance due to QC alerts

Directly related to the quality of test results are preanalytic components such as patient preparation; sample collection, transportation, storage, and preparation for testing; and postanalytic components such as result reporting, critical value notification, and provision of interpretive information.

The other components listed in Figure 10-4 are also important to ensure that quality laboratory results are available for patient care. In some cases, the quality requirements extend outside the laboratory and require cooperation with health care partners who order laboratory tests and act on the results.

A QM program defines data-based metrics or indicators that are monitored at regular recurring intervals to provide information on the adequacy of all influences on laboratory quality. A QM committee oversees the development of metrics and their regular review, and initiates quality improvement actions in response to metrics that indicate a need for improved performance in a particular aspect of laboratory management. A QM committee is typically chaired by a laboratory director or section director and includes senior level representation from all service areas, including the laboratory information system. Monthly meetings are typical. The data collected are frequently from the previous month, so the review is retrospective. However, automation of data management can

make some metrics available close to real time for more immediate monitoring and intervention. For example, turnaround time from specimen receipt to result reporting can be monitored continuously with a scrolling computer display report to assist medical technologists in tracking stat requests.

Table 10-7 provides a list of typical metrics that could be included in a QM program. In addition to the metrics, thresholds for acceptable values need to be defined for each metric. Metrics that exceed thresholds require analysis, and a plan is developed for corrective action. Thresholds are established on the basis of what is considered good laboratory practice and may be different in different situations. The example thresholds in Table 10-7 are illustrative and should not be taken as recommendations. It is not possible to have zero mistakes in laboratory service; consequently, thresholds need to be realistic and can be changed as quality improvement programs are applied. The total number of observations examined by a metric should be recorded, along with the data for a given reporting interval.

TABLE 10-7

Examples of Quality Management Metrics

Service monitor (metric)	Threshold	Total number reviewed	Example data	Analysis and action plan
Result Reporting				
Micro: Gram stain correlation with culture (% disagreement)	≤1%	1513	0%	
Micro: Blood culture contamination	≤3%	2468	2.7%	
Hematopathology consensus conference				
Percent bone marrow cases reviewed in consensus	≥10%	146	28.8%	
Number of cases with disagreements	2	146	0

It is recommended that the metrics are reported to allow trends to be identified, for example, by showing data for 6 or more months on a page. Graphical presentation is very effective to monitor trends and can easily include 1 or more years on a single graph. Many metrics are useful to track indefinitely to document that laboratory service continues to meet performance expectations, and to have an alert mechanism when a change in the environment has adversely affected laboratory service. However, data

cannot be collected for all possible metrics, and the QM committee needs to determine which aspects of laboratory performance are most critical or in need of improvement and should develop suitable metrics to drive a quality improvement process. Specific interventions should be documented with a written report that describes the quality issue, the data used to understand the issue, the improvements made, and the data that document the effectiveness of the improvement.

KEY POINTS

- Certain concepts and terms specific to informatics should be familiar to pathologists working in an ever-modernizing laboratory environment.
- The laboratory information system is typically part of a hospital or health care system network of clinical, registration, patient management, and financial systems that exchange information with one another.
- The laboratory information system supports workflow and information flow at all steps of the laboratory testing process, including patient registration, test ordering, sample collection, and testing and reporting.
- Informatics plays a key role in assisting physicians to manage laboratory orders (e.g., clinical pathways, decision support systems) and results (e.g., clinical alerts, interpretive reports, reflex tests). Together, these approaches maximize the usefulness of the laboratory to clinicians.
- Data exchange among diverse applications in health care depends on coding protocols for identifying procedures and medical conditions, as well as a communication language.

DEFINITION

The website (www.pathologyinformatics.org) for the Association for Pathology Informatics describes the field of pathology informatics as “[involving] collecting, examining, reporting, and storing large complex sets of data derived from tests performed in clinical laboratories, anatomic pathology laboratories, or research laboratories in order to improve patient care and enhance our understanding of disease-related processes.” The high volume, detailed, and time-sensitive nature of the workflow in the clinical laboratory has helped push the implementation of computing technology to assist in information management.

BASIC INFORMATICS CONCEPTS AND TERMINOLOGY

Before the issues that pertain to each step in the information flow are addressed, certain basic definitions are warranted to facilitate comprehension of the technology on which this field is based. The following section is intended only to provide a brief summary of some pathology informatics concepts; readers interested in expanding their knowledge about this field are advised to refer to a more comprehensive list of relevant topics (Henricks, 2003).

HARDWARE AND SOFTWARE

A *computer* is a device that follows instructions to work with electronic data based on user input. *Hardware* refers to the physical components of an information system. *Software* refers to programs (which are essentially sets of instructions) that allow computers or other devices to perform tasks.

A *file* is a collection of data identified by a specific name and grouped in relation to a specific purpose. The two main types are *applications* (also referred to as “executable” files) and *data* files (e.g., image, text/document, sound). A *folder* (or *directory*) simply refers to a collection of files.

A *bit* (derived from “binary digit”) is the basic unit of digital information, and a *byte*, the most common unit of measurement used, almost always refers to 8 bits. ASCII (American Standard Code for Information Interchange) is the standard dictionary for combinations of bits that represent the common letters, numbers, and symbols by which characters are represented on a computer screen or paper printout.

The *central processing unit* (CPU) refers to the circuitry that serves as the main information processor, and is driven by clock pulses; the speed is most commonly measured in Gigahertz (1 GHz = 1 billion clock pulses per second). *Memory* refers to the physical chips on the motherboard that hold programs and data for rapid access by the CPU. The two types are read only memory (ROM), which is permanent, and random access memory (RAM), which is volatile (i.e., the contents of these chips are lost when the computer is turned off).

Storage refers to the physical media that store data permanently. It can be internal (hard drive) or removable (CD-ROM, USB drive). Many labs utilize *drive arrays*, which are multiple hard drives configured to look like a single drive to the system. A common type of drive array is the redundant array of independent/inexpensive disks (RAID), in which two or more hard disk drives are used simultaneously to achieve greater levels of performance, reliability, and/or larger data volume sizes. *Mirrored drive arrays* refer to arrays where copies of files are written to each drive in array. Different parts of files are read simultaneously from different disks and “assembled” for delivery. This system is redundant: If one drive fails, files can be read from the other intact drive(s).

The *operating system* of a device, whether a computer or an analyzer, refers to a set of programs responsible for the management and coordination of activities and the sharing of resources. In the case of a computer, the operating system acts as a host for application programs. Applications are created within programming languages, which are artificial languages used to control the behavior of a computer. Programming languages can be specific for a hardware platform (e.g., BASIC, FORTRAN) or hardware-independent (e.g., Java). In addition, the computer needs small specialized files called *drivers* that are specific for an operating system and allow identification and utilization of various external peripherals and other devices. Ensuring hardware and software compatibility with all the different electronic components of a clinical laboratory can be an onerous task,

Example of a Computer Network

Figure 11-1 The red and green lines represent physically cabled connections (e.g., Ethernet), and the waves represent wireless connections.

TABLE 11-1

Common Network Components

Component	Function
Modem ("modulator-demodulator")	Modulates an analog carrier signal to encode digital information
Router	Routes and forwards information
Server	Accepts connections to service requests by sending back responses
Client	Application or system that accesses the server
Firewall	Device and/or software that inspects network traffic passing through it, and denies or permits passage based on a set of rules

especially if some of the equipment was introduced before an operating system upgrade of the predominant computing platform in the laboratory. As such, it often may be necessary to wrestle with compatibility issues when various software upgrades are introduced into a preexisting system.

NETWORKS AND SECURITY

A *network* is an interconnected group of computers that share information and resources, and as it pertains to the laboratory, the term refers to the ability to obtain orders from and send results to other information systems. Most computers need a card or adapter to connect to the network, and Ethernet is the most common type of networking standard. A variety of network types may be used: *Local area network*, which covers a small geographic area, and *wide area network*, which covers a broad area. The concept of *bandwidth* refers to the rate of data transmission. The different components of a network are listed in Table 11-1 and illustrated in Figure 11-1.

Networking often involves a *client* and a *server* environment. The client is the workstation with which the end user interacts and the server runs applications and maintains databases. The different client types are "thin" and "thick" or "fat"; the difference between the two is that in the former, all application logic executes on the client server, whereas in the latter, the client performs the bulk of any data processing operations itself. The

traditional incarnation of the client-server relationship consisted of *main-frames* and *terminals* that fulfilled the roles of the servers and thin clients, respectively. An older laboratory information system (LIS) that still has this type of configuration generally cannot replace the old terminals once they begin to fail and therefore needs to run a program called a *terminal emulator*, which acts like a terminal but can be run on more modern hardware.

The *Internet* refers to a worldwide, publicly accessible series of inter-connected computer networks. Data are transmitted by packet switching using the standard *Internet protocol (IP)*. The *World Wide Web (WWW)* refers to a hypertext-based data system that uses the Internet as its transportation (hypertext = text on a computer that will lead the user to other related information on demand). The language used is most commonly *hypertext markup language (HTML)*, which specifies the appearance of a web page when interpreted by a web browser. An *intranet* refers to a private network that uses the aforementioned Internet protocols to share information within an organization as opposed to between separate entities.

Data security is of paramount importance for all networks, and particularly in health care, where patient privacy is a major concern. One way of ensuring secure data is *encryption*, which refers to the conversion of data via an algorithm that rearranges bits that cannot be deciphered without decryption. A common way of engaging in safe networking is through a *virtual private network*, which is a method by which a user can access an organization's internal network over the Internet in a secure manner. It provides users who are not on that internal network secure access to resources inside it. This is done by applying a software layer on top of an existing network, essentially creating virtual "tunnels" that wrap data packets destined for the internal network, and then encrypting those packets to send them across the Internet.

DATABASES

At their core, the building blocks of information systems are databases, which are structured collections of records comprising data fields. They need to be managed by a set of programs called a database management system. The two types of databases are *flat file* and *relational*. A flat file database is a single, two-dimensional array of data elements, similar to an electronic spreadsheet. In contrast, in a relational database, the data are organized in tables. In a table, each record (row) contains a unique instance of data for the fields (columns), and tables are related by a single field (the *primary key*) between common fields. Figure 11-2 gives a simplified example of a relational database for clinical laboratory data, comprising four linked tables: Patient Registration, Test Orders, Test Results, and Reference Ranges. The virtue of this structure is that redundancy is

Relational Database Structure

Patient Registration				
Patient ID #	First Name	Last Name	Age	Sex
P1234	John	Smith	33	M
P3456	Mary	White	58	F
Test Order				
Order #	Patient ID #	Date	Physician	Test
034782	P1234	04/12/2009	Jones	Hemoglobin
034783	P3456	04/12/2009	Chen	Hematocrit
Test Result				
Order #	Test	Result		
034782	Hemoglobin	15		
034783	Hematocrit	33		
Reference Range				
Test	Adult Male	Adult Female	Child	Units
Hemoglobin	14-18	12-16	11-16	g/dL
Hematocrit	42-52	37-47	31-43	%

Figure 11-2 Sample relational database.

TABLE 11-2

Common Health Care Enterprise Information Systems

System	Functionality
Admission–discharge–transfer (ADT)	Runs the entire patient care workflow, from registration of patient information to bed tracking and discharge
Health information system (HIS)	Stores patient information generated by different departments during one or more visits
Laboratory information system (LIS)	Electronic data processing and information management functions necessary for laboratory operations
Electronic medical record (EMR)	A chronologically ordered paperless chart that summarizes the clinical history with diagnostic test results
Electronic data repository (EDR)	Contains patient information from all inpatient and outpatient systems in an enterprise, and is used for reviewing patient data
Electronic data warehouse (EDW)	Similar to the EDR, except the information is utilized for research by using databases and data analysis tools to uncover hidden patterns and relationships in data (“data mining”)
Billing	Receives information on charges and/or tests performed to calculate charges to patient insurance

eliminated—a concept known as *normalization*. For example, demographic data about each patient are given only once, in the Patient Registration table. Other tables then link to that information using only the unique Patient ID identifier. If instead, other tables included both Patient ID and, for example, the patient’s name, there would be an opportunity for inconsistencies to arise, and it would be more difficult to make updates such as a correction to the spelling of the name. The modest penalty for the normalized, relational architecture is that useful reports must typically integrate information from several tables, rather than simply printing records from a single table. However, this can be readily accomplished using a powerful, generic language known as Structured Query Language.

LABORATORY INFORMATION SYSTEMS

An *information system (IS)* refers empirically to the hardware, software, and connectivity designed to perform data management functions. Different types of ISs are listed in Table 11-2. The LIS was classically a standalone insulated system that generated results for manual reporting by laboratory personnel or for viewing by the clinician. The LIS was used to communicate with analyzers and external systems such as the larger health information system (HIS) and/or billing systems. Today, it is frequently a major part of a health care system network with communication with the patient registration and billing systems and the electronic medical record (EMR). The LIS exchanges information with all these systems, and the effectiveness of this exchange is dependent on successful hardware and software implementation. Most LIS constructs have an interface, which is a combination of software and connections that translate electronic messages, so that data can be exchanged with different systems. The types of interfaces are instrument interfaces and application (other systems) interfaces. If the systems are not compatible, a laboratory may engage in ad hoc development of software known as *middleware* to enable communication between them. If multiple systems need to exchange information, an application known as an interface engine reduces the number of individual interfaces.

As well as the aforementioned interrelated programs and hardware that provide data management functions necessary for laboratory operations, the LIS often refers to the database that establishes and maintains standard definitions and information processing procedures. All LIS constructs utilize *dictionaries* (also referred to as *maintenance tables*), which provide a logical framework for laboratory operations and workflow. Dictionaries structure and standardize procedures and standardize laboratory and LIS terminology. They define allowable entries for data fields, in addition to

the content and format of elements that appear on reports. The different worksheets and workstations that are available in the laboratory are specified in the LIS tables, and part of a test definition is assignment of the test to a laboratory workstation/instrument or laboratory location. Test orders are routed to LIS worksheets that are associated with given workstations; essentially, worksheets define the workflow in the laboratory because they define which tests are performed at different workstations. An emerging and popular feature of the LIS is its ability to perform *autoverification*, which refers to release of results from automated analyzers directly to LIS without prior human review. The autoverification criteria are defined and detailed in LIS tables and specify things such as allowable numeric result range and delta checks (in comparison with previous results).

Because of great variation in the types of data handled by different parts of the laboratory, LIS systems typically comprise several modules, which may even be entirely disparate systems from different vendors. A general laboratory module might include tests in the area of chemistry, hematology, and serology, where tests are usually relatively discrete, and results consist of a single number or a short string of text. The general LIS module serves many functions, some of which are listed in Table 11-3. Other areas of the lab may require very different functionality, as described later.

LEGAL REQUIREMENTS

A number of regulatory/accrediting bodies are pertinent to LIS constructs. In the U.S. government, these include the Centers for Medicare/Medicaid Services, the Food and Drug Administration, the College of American Pathologists (CAP), The Joint Commission, and the American Association of Blood Banks. The legal requirements for LISs involve issues such as unique specimen and patient identification, date of specimen collection, date and time of specimen receipt in the lab, records and dates of all specimen testing, personnel who performed the test(s), and the name and address of the laboratory where testing was performed, among others. The CAP Laboratory General Checklist requires periodic verification of data sent from the LIS to other computer systems.

The Health Insurance Portability and Accountability Act of 1996 (HIPAA) requires all health plans to accept electronically filed claims in a standard format (electronic data interchange). There must exist security measures to protect health information. There are limits on use/disclosure of health information. A requirement of reasonable safeguards to protect against incidental disclosure is also present. HIPAA addresses issues of consent with respect to protected health information (PHI), which refers to anything that could be used to identify an individual and is related to

TABLE 11-3
LIS Functions

Preanalysis	Patient registration (if not received from external system) Test ordering Customized requisitions (e.g., outreach clients) Phlebotomy draw lists Bar-coded collection labels and aliquot labels Specimen tracking/racking system
Analysis	Instrument worklist (via interface and automatic download) Manual worklist Manual results entry Automated results entry via interface Results validation and manual or automatic release Quality control
Postanalysis	Requisition-based patient reports (final, partial) Cumulative patient reports Corrected report Results inquiry Electronic reporting to external interfaced systems (e.g., HIS, billing)
Management	Pending (incomplete) list Turnaround time reports Workload statistics Ad hoc report writer HIS and instrument integrity monitoring tools

HIS, Health information system; LIS, laboratory information system.

health care or payment. The patient's consent is required to use or disclose PHI for treatment, payment, or health care operations. The law requires minimum necessary use or disclosure of PHI.

COMMUNICATION STANDARDS

The use of conventions and definitions to standardize information exchange between different systems is a less complex and time-consuming strategy than the traditional creation of custom interfaces between such applications. Originally, the major need for electronic transmission of these data was so that the Federal government (Medicare) and other payers could be billed for individual services provided. For this purpose, coding of laboratory procedures using Current Procedural Terminology (CPT) and coding of medical conditions using the International Classification of Diseases have been the norm. One example of a newer, and currently the most prevalent, standard developed by the health care industry is Health Level 7 (HL7) (www.hl7.org), which is a protocol for electronic data exchange that specifies syntax and rules for messaging. Another standard is Logical Observation Identifier Names and Codes (www.loinc.org), which is a set of universal identifiers for laboratory test code data fields within HL7 messages and in databases (McDonald, 2003). It provides a structured naming convention for describing laboratory tests and has fewer limitations than CPT. The American Society for Testing and Materials specifies protocols and formats for instrument interfaces, bar codes (e.g., Code 39, Code 128), other systems and components. The Systematic Nomenclature of Medicine—Clinical Terms system is a very elaborate nomenclature for medical conditions and related concepts, containing more than 300,000 unique clinical concepts. Originally developed by CAP, it is now maintained by the International Healthcare Terminology Standards Development Organisation, which was formed in 2006. A receiving system may not recognize certain codes as written, so the use of a *translation table* relates a code to its equivalent in the receiving system.

COMMON DATA ELEMENTS AND METADATA

The concept of a common data element (CDE) refers to the standardized component of a data set. CDEs are defined by metadata, which literally translate to “data about data,” or a description and definition of data element attributes (e.g., type of data). CDEs have standardized, consistent metadata descriptions for discrete data elements. CDEs structure data in a way to facilitate reproducible capture at the time of entry and to ensure consistent data collection and categorization, while providing standard formatting for data exchange.

```

```

Figure 11-3 Example of an Extensible Markup Language (XML) database. This XML code contains the data from the Patients table shown in Figure 11-2. This text can be entered into Microsoft Excel, for example, which can then generate a spreadsheet to display the data.

A relatively new development in CDEs is the language XML, which stands for Extensible Markup Language. XML is a method to describe data, to structure information, and to format documents. The main purpose is to enable integration and sharing of information across disparate sources that otherwise have incompatible formats and data standards. XML markup tags describe the data marked by tag; thus XML tags are a type of CDE with specific metadata (an example is given in Figure 11-3). XML has great potential for becoming the standard by which textual information is encoded into a searchable format (Dolin, 1998; Sokolowski, 1999).

INFORMATION FLOW

The flow of information as it pertains to the LIS is generally uniform across different laboratories and is summarized in Table 11-4 and Figure 11-4, although obviously variations exist among different institutions. The critical issues of this workflow include patient safety and confidentiality, capture of clinically meaningful data, unambiguous identification of data elements, and synchronization of information among different systems within the health care institution (Aller, 2001). This section of the chapter will provide an overview of the information exchange steps as well as the key issues that pertain to each.

PATIENT REGISTRATION/IDENTIFICATION

The critically important initial step is registration of the patient with assignment of a unique patient identification number to the patient, often within the admission-discharge-transfer system. A unique laboratory encounter number may also be generated at this time, and again for subsequent encounters for the patient. No tests can be ordered until the patient record is created.

Patient identification information includes data such as name, birth date, sex, race, address, phone number, social security number, and medical record number, among others. Insurance and billing information generally is also included. Because the patient identification number needs to be unique, the social security number or an institution-generated number exclusive to the registration system should be utilized. Bar-coding may be utilized to ensure correct patient identification when obtaining samples. The radiofrequency identification (RFID) system is a new technology that provides hands-off, zero-error identification (Westra, 2009). It consists of a patient tag and a computerized scanner or reader. The “smart” label or tag contains human-readable information, a bar code, and an integrated circuit chip with memory. A small amount of radiofrequency energy (“excitation signal”) is released from the scanner, energizing the RFID tag, which then emits a radiofrequency signal (“return signal”) that transmits the patient's ID. Although several issues (e.g., data encryption, protocol standardization) are not completely resolved, RFID technology offers several benefits, including passive operation and dynamic data storage, features that favor its use in sample collection and tracking, bedside testing, drug management, and infection control.

TABLE 11-4

Key Steps in Laboratory Information Flow for a Hospital Patient

Step	Description
Register patient	Patient record (e.g., ID#, name, sex, age, location) must be created in LIS before tests can be ordered. LIS usually automatically receives these data from a hospital registration system (when the patient is admitted).
Order tests	Physician orders tests on a patient to be drawn as part of the laboratory's morning blood collection rounds. The order is entered into the HIS and is electronically sent to the LIS.
Collect sample	Before morning blood collection, the LIS prints a list of all patients whose blood is to be drawn and the appropriate number of sample bar code labels for each patient order. Each bar code has a patient ID, a sample container type (e.g., red-top tube), and a laboratory workstation (that can be used to sort the tube once it reaches the laboratory). Another and increasingly popular approach is for patient caregivers or nurses to collect the blood sample. Immediately before collection, sample bar code labels can be printed (on demand) at the nursing station on an LIS printer.
Receive sample	When samples arrive in the laboratory, their status has to be updated in the LIS from "collected" to "received." This can be done by scanning each sample container's bar code ID into the LIS. Once the sample is "received," the LIS transmits the test order to the analyzer that will perform the test.
Run sample	The sample is loaded onto the analyzer and the bar code is read. Having already received the test order from the LIS, the analyzer knows which tests to perform on the patient. No worklist is needed. For manually performed tests, the technologist prints a worklist from the LIS. The worklist contains a list of patients and the tests ordered on each. Next to each test is a space to record the result.
Review results	The analyzer produces the results and sends them to the LIS. These results are viewable only by technologists because they have not been released for general viewing. The LIS can be programmed to flag certain results (e.g., critical values) so a technologist can easily identify what needs to be repeated or further evaluated.
Release results	The technologist releases results (unflagged results are usually reviewed and released at the same time). The LIS can also be programmed to automatically review and release normal results or results that fall within a certain range. The latter approach reduces the number of tests that a technologist has to review. Upon release, results are automatically transmitted to the HIS.
Report results	Physician can view the results on the HIS screen. Reports are printed when needed from the LIS.

HIS, Health information system; ID, identification; LIS, laboratory information system.

TEST ORDERS

After the patient has been identified, tests are ordered manually with paper forms or electronically through the HIS, with orders then electronically sent to the LIS. Having the physician at the point of care directly enter laboratory orders electronically is an effective way to reduce the possibility of introducing error that is inherent in having to re-key requested tests from the paper form. Computerized pathology test order entry has also been shown to reduce laboratory turnaround time (Westbrook, 2006). Important data pertaining to the request (date/time/location of collection, storage medium, etc.) can be automatically generated at this time as well. The electronic nature of the patient's clinical data and the test ordering system allows the use of logic operations to ensure patient safety and optimal test utilization.

SAMPLE COLLECTION AND LABELING

A patient sample may be collected by the lab after an order is received or may be sent directly to the lab with a request. For inpatient samples, the LIS prints the list of patients who need to be drawn. At this point, labels can be printed identifying the necessary tubes and/or containers; this label printing can also take place at the patient's bedside using portable printers connected wirelessly to the LIS to confirm correct patient identification immediately after the patient's wristband has been scanned and read. When the sample is received, the LIS indicates receipt of the sample by changing its status from the previous value of "to be collected." The collected sample is then run on an analyzer.

PERFORMING TESTS

The analyzers of a clinical laboratory can communicate with the LIS unidirectionally or bidirectionally. Unidirectional analyzer communication typically refers to reporting of results to the LIS with no input from the latter during the testing process. Alternatively, analyzers that bidirectionally communicate with the LIS are able to receive orders from the LIS and then send results back. Many analyzers have the ability to read bar codes off specimen containers to identify which samples are about to be processed and send corresponding specimen status updates to the LIS.

RELEASING RESULTS

Regardless of whether the results are manually entered or automatically transferred, the computer performs a validity check on the results once

they are received. Panic values can be flagged by the LIS once a valid result is determined to fall into a critical range. Autovalidation protocols can be used to automatically release results without review by the technologist or pathologist.

REPORTING RESULTS

Laboratory results can be electronically reported to a variety of clinical systems, including the HIS, the electronic data repository (EDR), the EMR, and state or federal public health agencies (White, 1999). The proliferation of different communication technologies allows a number of ways of reporting results to physicians, especially time-sensitive critical values. Computerized alerts can assist in improving the timeliness of reporting and clinicians' responses to laboratory values (Staes, 2008). For routine test results, the advent of the WWW allows a physician to review at his convenience the patient's results on the HIS screen and print as needed. The HTML code in web pages can generate new content automatically in response to user commands and therefore is well suited to automating report generation and facilitating custom data searches (Yearworth, 1998; Lowe, 1996). Data in the EDR can be transferred in batches to an electronic data warehouse, where algorithms can be performed to reveal general patterns and potentially assist in developing new knowledge about disease (Elevitch, 1999).

BIOINFORMATICS

Bioinformatics most commonly refers to the division of informatics that studies how information is stored in biological systems, from the molecular to the macromolecular level, with a large part of the focus being on DNA, RNA, and protein sequences (Sinard, 2006). As Batley and Edwards have noted, numerous improvements in DNA sequencing technology have led to a corresponding marked increase in the quantity of sequence data generated, which provides a challenge for bioinformatics in terms of management, storage, and visualization (Batley, 2009). Implemented properly, informatics can facilitate patient registration, specimen tracking, tissue cataloging, quality assurance, and specimen availability (Qualman, 2003). Research is currently under way that would eventually allow a patient's genetic profile to be handled by, or communicated to, the EMR. In turn, the EMR could then fulfill a valuable role by providing the information contained in the patient's bioinformatics profile to help pathologists and clinicians in determining the optimal diagnostic tests and/or therapeutic measures, respectively.

(Adapted from Lifshitz MS, Blank GE, Schexneider KI. *Clinical laboratory informatics*. In: McPherson RA, Pincus MR, editors. *Clinical Diagnosis and Management by Laboratory Methods*, 21st ed. Philadelphia: WB Saunders; 2007.) EDR, Electronic data repository; HIS, health information system; POCT, point-of-care testing.

ISSUES REGARDING IMPLEMENTATION

Although the opportunities to streamline workflow offered by computing technology are numerous, there are also a number of potential pitfalls and opportunities for error of which diligent informaticians should be aware.

When deciding to purchase hardware or software for the laboratory, a request for proposal (RFP) should be submitted to the vendor. The main

component of the RFP is a detailed listing of required functionality and features. The RFP asks the vendor to specify whether specified capabilities are present and to provide corporate information, pricing, and details of other attributes of the system. The RFP responses become part of the final contract. A different model is the application service provider (ASP) model, which is composed of a contractual agreement: The provider delivers service(s) remotely over a network, and the vendor manages everything (hardware, software, security, upgrades). Often there is a fixed subscription

fee, which may be per transaction or a flat rate. Another type is the service level agreement (SLA), which is a contract that defines the technical and business parameters of the relationship between IT vendor and client, particularly for an ASP arrangement. The key terms of the SLA are *responsibility* (who does what), *performance*, and *remediation* for resolving problems. Quantifiable metrics such as system uptime (%), system response time, and time to address problem calls need to be specified. Lack of appropriate attention to these issues can cause considerable logistical and operational problems down the road.

One of the most critical features of an information system is the assurance that data that are transferred from one system to another are accurate and valid. The CAP Laboratory General Checklist Questionnaire requires periodic verification of data sent from the LIS to other computer systems. Absence of proof of fulfilling this requirement is a phase II violation.

Because many pathology practices evaluate patient samples from independent private physician offices, in addition to those from their own institutions, patients will need a unique identifier generated by the clinical information system (CIS); the CIS will also have to be able to store and link together all identifiers generated for this same patient if and when the patient ends up submitting additional specimens within the hosting institution.

Security is of paramount concern when it comes to transferring patient data many times over a network. To comply with HIPAA, all laboratories should have safeguards in place to ensure that patient data are accessed only by appropriate individuals in appropriate circumstances. This is essential not just with transfer of data between information systems, but also with electronic correspondence (e.g., e-mail), which laboratory personnel frequently use.

THE FUTURE OF INFORMATICS

With the emergence of new technologies, especially in the realm of bioinformatics, the roles of pathologists and of the laboratory will undoubtedly be redefined over time. Microfluidic instrumentation is being applied to common laboratory techniques, essentially providing a “lab-on-a-chip” solution that allows a patient-centric approach to testing, and may eventually perform at levels comparable to centralized analyzers (Yager, 2006). The efforts of Patel et al. (2007) in creating an informatics model for sharing information involving tissue banks from different institutions demonstrate how standardized communication protocols and shared common data elements allow free exchange of information to assist with research projects, thus enabling any laboratory to have a role in real-time collaboration in research. As society in general continues to become more knowledgeable about information technology, many patients may entrust private companies to safeguard their personalized health information; the laboratory will have to be able to communicate with those companies. Furthermore, as point-of-care (POC) instrumentation becomes more prevalent in the clinical marketplace, cross-talk between the clinical laboratory and POC centers (surgical suites, operating rooms, physicians’ offices, etc.) may be warranted toward accessioning a patient’s laboratory data set for efficient patient management and avoiding testing redundancy.

With all these developments taking place, the traditional role of the pathologist as one who provides data and interpretation to the clinician from which a therapeutic decision will be made will be expanded to include bioinformatics design and management. The pathologist will have to use informatics tools that span different diagnostic methods to integrate all available data and produce an outcomes-based treatment recommendation for optimal patient care.

KEY POINTS

- Costs can be described in different ways, depending on how they relate to laboratory operations (direct/indirect), change with test volume (variable/fixed), pertain to staffing (salary/nonsalary), or are associated with the useful life of supplies or equipment (operating/capital). Cost per reportable result is a key indicator.
- Reimbursement for laboratory services comes mostly from third-party payers such as Medicare (government) and insurance companies (nongovernment/private insurance), and payments are almost always less than charges.
- Inpatient laboratory testing charges are usually not reimbursed directly; they are considered part of a per diem rate (i.e., general hospital daily room reimbursement rate) or a case rate, such as diagnosis-related group rate (i.e., set rate for the entire hospital stay, regardless of actual length of stay). Thus, inpatient laboratory testing is usually considered a "cost center." In contrast, outpatient laboratory charges are reimbursed directly; therefore, outpatient testing is usually considered a "revenue center."
- For reimbursement purposes, Current Procedural Terminology codes describe tests and International Classification of Diseases, Ninth Revision codes describe the diagnosis. Medical necessity requirements may limit reimbursement to those tests associated with specific predefined diagnoses.
- Budgeting is the process of planning, forecasting, controlling, and monitoring the financial resources of an organization.
- A variety of financial tools are used to evaluate a capital project, such as purchasing a chemistry analyzer. These measure how long it takes to recoup an investment (payback) and how much it generates in today's dollars (net present value) and its rate of return (internal rate of return).
- Laboratory equipment can be acquired in different ways, including purchase, lease, and per-test payment. Each has pros and cons.

Every organization, no matter the products or services it provides, must be concerned with the management, oversight, and accounting of its monetary resources. To sustain a viable, competitive entity, an organization not only must recoup the cost of operations, but must have a positive net income to reinvest in itself. The laboratory is no exception. To be

successful in the financial management of the laboratory, the director/manager must be able to identify and categorize costs, understand the relationships between revenue and reimbursement, become familiar with the budget process, and use financial ratios and information to make sound decisions. Credibility with administrators and colleagues demands that the director/manager be comfortable and confident when explaining financial issues and when justifying the need for additional resources.

INDUSTRY OVERVIEW

Most industries in the United States are subject to traditional free-market competition. However, this principle does not fully apply to health care because relatively few people who use health care pay directly for it. Most people are beneficiaries of some form of health insurance. This, in combination with the increasing numbers of uninsured and underinsured, has led to a system that provides services even when no one pays adequately for them. Most medical claims are paid by a "third party" such as the government (Medicare, Medicaid) or a private insurance company. Thus, someone other than the patient usually pays the provider of health care services (Snyder, 1998).

The health care industry is one of the largest industries in the United States and continues to be a growing sector of the gross domestic product, having increased from 5.1% (\$27 billion) in 1960 to 16.2% (\$2.2 trillion) in 2007 (CMS, 2010a). Hospitals continue to be a driving force behind escalating health care costs. Most U.S. hospitals are tax exempt, not-for-profit entities. Though "not-for-profit" suggests that no profit is made, it actually means that profits are not distributed to owners or shareholders; instead, profits are reinvested in the organization. Historically, not-for-profit status led hospital administrators to be less profit conscious than counterparts in other businesses. However, today's hospitals are having a difficult time just covering operating costs, given dwindling reimbursement and increasing supply and labor costs. With scarce money left for capital reinvestment in equipment, buildings, facilities, and technology, hospitals are aggressively seeking new ways to produce a profit to invest for the future.

DEFINING AND IDENTIFYING COSTS

A cost (expense) is the supply, labor, and overhead money spent on a product or service (Travers, 1997). It is important to understand costs to accurately price tests and other services, to determine when and how to offer new tests, and to determine whether to acquire new outreach client

TABLE 12-1
Cost Classification

Proficiency testing								
Analyzer service								
Analyzer								
Testing staff								
Management staff								
Rent								

Figure 12-1 Fixed costs such as rent remain constant. Variable costs such as reagents are directly proportional to test volume.

business or a managed care contract. Costs can be classified in different ways (Table 12-1).

Direct costs are expenses that can easily be traced directly to an end product. In the laboratory setting, the end product is a billable test. Examples are reagents, consumables, and hands-on technologist time. In contrast, **indirect costs** are not directly related to a billable test, but are necessary for its production. Indirect costs are often referred to as overhead. Examples are proficiency testing and utility expenses.

Variable costs change proportionately with the volume of tests. As test volume grows, so do reagent costs. If the reagent cost per test is \$1.00, when 1000 tests are performed, the reagent cost is \$1000; when 20,000 tests are performed, the reagent cost is \$20,000. **Fixed costs** do not change with the volume of tests performed. If a laboratory pays \$5000 per month to rent its space, this expense remains the same if the laboratory produces 1000 or 20,000 tests per month (Fig. 12-1).

Because fixed costs do not vary with activity, the goal is to produce as much as possible from fixed costs to achieve economies of scale. The more that is produced, the lower is the *fixed cost per activity*. In the preceding scenario, if the laboratory produced 1000 tests, the fixed cost per test is \$5.00; with 20,000 tests, the fixed cost per test falls to \$0.25. Note that even some fixed costs have a variable component. For example, if an instrument's capacity is 20,000 tests per month and the volume increases beyond that, another instrument will have to be purchased, increasing the fixed costs per test. Fixed costs that change with increments of volume are called *step costs*.

Salary costs need to be looked at differently from **nonsalary costs** because salary costs have fringe benefits associated with them. Salary expenses account for approximately 60%–80% of the laboratory budget. Because salary expenses are generally fixed, it is important to strive for economies of scale. The hourly pay or salaried wage of an employee is not the entire cost of employment. Fringe benefits such as Social Security, health insurance, tuition reimbursement, pension plans, and life insurance can represent an additional 16%–28% expense above the base salary. Costs are also associated with the recruitment, interview, and selection process. Once an employee is hired, orientation, training, and ongoing growth and development costs are incurred.

Operating costs are the expenses incurred to produce a product or service. Many items have only a one-time use, and once used the item has no further value. Examples of one-time operating costs include reagents, electricity, disposable pipets, and the salary expense in the production of a test. Other items, such as analytic equipment, computers, and the physical plant, have a useful life greater than one production cycle. These items are capital items. To qualify as a *capital* item, the item must meet three criteria: Time, price, and purpose. To meet the time criterion, the item must have a useful life of longer than 1 year. The institution must designate a minimum dollar amount, usually \$1000–\$5000, that qualifies an item as capital. The purpose of acquiring capital items is usually to replace older equipment with safer and more efficient models, or to add new equipment to support new products or services. With time, capital equipment loses its value. The annual loss of a capital item's value is called *depreciation* and is an annual expense that is deducted from the revenue of a business. Depreciation is not a cash expense (i.e., you do not "pay it" each year), but it is a real expense in that it recognizes the "wearing out" of an asset that was acquired with cash and eventually will have to be replaced. If an analyzer has not yet been fully depreciated, it still has "book value." Note that operating and capital costs are budgeted separately (see later).

The cost of producing a test can be derived in different ways. **Microcosting** determines the total direct labor and supply costs of producing a test, and is the starting point for determining the fully loaded cost and ultimately the price for a test. Most testing in the clinical laboratory is performed in batches or continuous "runs" of many samples during one or more shifts. A run can be a group of tests that are performed once or many times during a shift or an entire 24-hour period. A run includes all quality control and calibration costs needed to produce patient results. When microcosting a test, it is important to consider how a test is performed because labor and supply costs vary according to workflow and laboratory policy for quality control and repeats. The *cost per reportable result* (CPRR) distributes the total direct costs of a run over the patient "reportable" results for that run. Testing efficiency is defined as the total reportable patient results/total test results. Thus, the more repeats and controls are performed, the lower is the efficiency, and the higher is the CPRR. As

testing efficiency increases, the CPRR decreases. The *incremental cost* is the cost of producing one additional test that, typically, does not require additional salary or capital. For example, the incremental cost of running a chemistry test is usually the cost of dispensing reagent for one additional test, assuming there are no sample collection costs. Other associated costs, like technologist time, equipment, or quality control, are fixed costs that are incurred irrespective of the additional test. The incremental cost is usually the lowest possible cost incurred to produce a result. It is best used to assess how much it costs to produce small increments in test volume. As volume grows, a laboratory may need additional staff and equipment, and these costs would have to be included in the incremental costing analysis. Incremental costing is especially useful when one is trying to determine whether additional outreach work is profitable or not. The *fully loaded cost* for a test is the sum of direct and indirect costs. The allocation of indirect costs is usually done using a formula. The goal of allocating indirect costs is to apply the costs based on the strongest correlation

between the indirect cost and to what it is being applied. For example, utilities could be based on departmental square footage, while human resources costs could be based on the number of employees in the department. *Make versus buy* decisions should be based on the fully loaded cost to produce the test compared with the price offered by a commercial or reference laboratory. If it costs more to produce a test than to buy it from another supplier, the test should be considered for outsourcing. However, when make versus buy decisions are made, cost is only one factor to consider. Medically necessary turnaround time, methods, and reliability of the potential alternative supplier should also be considered. The price charged for a test needs to be marked up (increased) from the fully loaded cost to realize a profit. One must also take into consideration the expected collection rate, relative to charge. The *contribution margin* is the balance remaining after the fully loaded costs are deducted from the price charged for a test. Table 12-2 demonstrates various ways to determine the cost of a test and how to establish its charge.

TABLE 12-2
Test Cost Analysis*

Test: Prostate-Specific Antigen

A. Microcosting: Instrument Run of One Reportable Test

Direct Labor

Determine the total "hands-on" time in minutes required to perform an instrument "run" of one patient test. Assume labor cost is \$20 per hour.

	Minutes	Expense
Prepare specimen	5	
Prepare reagents	10	
Prepare instrument	10	
Computer and/or worksheet setup	5	
Documentation of results/quality control/maintenance	10	
Clean-up	10	
Total direct labor	50	\$16.67

Direct Supplies

List all consumables needed to perform the test. Note 4 tests (1 sample and 3 controls) are needed to produce 1 patient reportable result.

Calibration costs should be added if they are required with each run.

	Unit cost	Units	Expense
Reagent (\$700 kit/100 tests)	\$7	4	\$28.00
Disposable pipets (\$10/100 pipets)	\$0.10	4	\$0.40
Disposable reagent cups (\$10/200 cups)	\$0.05	4	\$0.20
Low, medium, and high control material (0.05 mL/test @ \$20/mL)	\$1	3	\$3.00
Total direct supplies			\$31.60
Total direct costs			\$48.27
Cost per reportable (total direct cost/reportable results)	\$48.27/1		\$48.27
Testing efficiency (reportable patient results/tests)	1 result/4 tests		25%

B. Microcosting: Instrument Run of 15 Reportable Tests

Direct Labor

For a group of tests run on automated analyzers, use direct labor expense from microcosting. For manual batch testing, direct labor costs may apply to each batch; additional labor time studies may be necessary to derive accurate data.

	Minutes	Expense
Total direct labor per batch (same as microcosting in this example)	50	\$16.67

Direct Supplies

Note: 18 tests (15 samples and 3 controls) are needed to produce 15 reportable results. Fixed costs (controls) are spread over more than 1 sample, in contrast to first example.

	Unit cost	Units	Expense
Reagent (\$700 kit/100 tests)	\$7	18	\$126.00
Disposable pipets (\$10/100 pipets)	\$0.10	18	\$1.80
Disposable reagent cups (\$10/200 cups)	\$0.05	18	\$0.90
Low, medium, and high control material (0.05 mL/test @ \$20/mL)	\$1	3	\$3.00
Total direct supplies			\$131.70
Total direct costs			\$148.37
Cost per reportable (total direct cost/reportable results)	\$148.37/15		\$9.89
Testing efficiency (reportable patient results/tests)	15 results/18 tests	83%	

Continued

TABLE 12-2

Test Cost Analysis—Cont'd

C. Incremental Cost: Cost for One More Test

	Units	Expense
Reagent (\$700 kit/100 tests)	1	\$7
Disposable pipets (\$10/100 pipets)	1	\$0.10
Disposable reagent cups (\$10/200 cups)	1	\$0.05
Total		\$7.15
	Unit cost	Units

D. Fully Loaded Cost

Direct cost (cost per reportable result for typical size run) from Example B above	\$9.89	
Indirect cost (estimated by typical hospital as 2.5 × direct costs)	\$24.73	
Fully loaded cost		\$34.62

E. Contribution Margin

Example of Charging a 20% Mark-up for Laboratory Tests

Fully loaded cost plus 20% mark-up (test charge at list price)	\$34.62 × 1.2	\$41.54
Fully loaded cost from Example D above		(\$34.62)
Contribution margin		\$6.92

*This analysis is for illustration purposes only.

TABLE 12-3

Reimbursement Comparison for PSA* by Payer Type

	List price	Reimbursement terms	Amount paid	Contractual allowance
Inpatient				
Managed care (HMO)	\$41.54	No separate reimbursement for laboratory tests because they are included in the contracted per diem rate	0	N/A
Medicare	\$41.54	No separate reimbursement for laboratory tests because they are included in the DRG rate	0	N/A
Outpatient				
Indemnity insurance	\$41.54	Usual and customary charge (UCC) is \$38; insurance pays 80% of UCC.	\$30.40	\$11.14
Managed care (PPO)	\$41.54	Contract pays 110% of Medicare fee schedule (\$25.70 for PSA).	\$28.27	\$13.27
Managed care (HMO)	\$41.54	No separate reimbursement for laboratory tests because of capitation arrangement: laboratory receives per member per month payment irrespective of usage	N/A	N/A
Medicare	\$41.54	Medicare fee schedule	\$25.70	\$15.84

DRG, Diagnosis-related group; HMO, health maintenance organization; N/A, not applicable; PPO, preferred provider organization; PSA, prostate-specific antigen.

*Reimbursement amounts are for illustrative purposes only and may not accurately reflect current Medicare reimbursement.

The *total cost of ownership* (TCO) for a laboratory is the life cycle cost of its capital assets. It focuses attention on the sum of all costs of owning and maintaining all assets for a specific service or product, as opposed to the initial capital or operating costs. In the laboratory, TCO includes acquisition, setup (construction, training), support (ordering supplies, dealing with back orders), ongoing maintenance (scheduled and unscheduled downtime), service, and operating expenses (reagents, controls, repeat testing, inventory control, proficiency testing, testing personnel, supervisory personnel) of a specific workbench and its associated testing instrumentation. TCO is useful in considering make versus buy decisions, but determining an accurate TCO can be very difficult.

REVENUE

Revenue is the total price of services rendered or products sold (Harmening, 2007). It is the money a business is entitled to receive for the services and products it produces. In health care, revenue should not be confused with reimbursement or cash collected. *Gross patient revenue* consists of the total charges at a facility's full-established rates (list price) for provision of inpatient and outpatient care before deductions from revenue are applied. *Net patient revenue* is the gross inpatient and outpatient revenue

minus all related deductions. *Deductions* from revenue include contractual adjustments, provision for bad debts, charity care, and other adjustments and allowances that reduce gross patient revenue. *Contractual adjustments* account for the difference between billings at full-established rates and amounts received or receivable from third-party payers under formal contract agreements. For example, if the list price of a test is \$10 but the contracted payment from the insurance company is \$6, the adjustment is \$4. If all deductions and contractual allowances are correct, net patient revenue should equal cash collected, or \$6 in the above example.

In health care, it is important to distinguish between inpatient and outpatient care because they are reimbursed differently. Inpatient laboratory testing charges usually are not reimbursed separately; they are considered to be part of a per diem rate (i.e., general hospital daily room reimbursement rate) or diagnosis-related group (DRG) rate (i.e., set rate for the entire hospital stay, regardless of actual length of stay). Thus, inpatient laboratory testing is considered a "cost center." The hospital is paid the same rate regardless of how many tests are provided. In contrast, outpatient laboratory testing is a revenue center because each test is separately reimbursed, usually by a third party (Table 12-3). Thus there is a financial disincentive to perform inpatient tests and an incentive to perform outpatient tests.

PAYERS AND REIMBURSEMENT

Hospitals in early America served a different purpose from those of today. A visiting physician usually provided health care in the patient's home, and care was administered by family members, midwives, and servants. Early hospitals were founded to shelter older adults, the dying, orphans, those with mental illness, and vagrants, and to protect the citizens of a community from contagious diseases and the dangerously insane. Many of today's county, municipal, or religious order hospitals were originally a combination of these almshouses and isolation hospitals (Sultz, 2009).

The transformation of hospitals from charitable institutions to complex technical organizations came about with the passage of the Hill-Burton Hospital Construction Act of 1946 and the growth of private hospital insurance. The Hill-Burton Act provided federal money to the states to plan and construct new facilities. The first private health insurance policy was formed by a group of teachers and Baylor Hospital in Dallas, to provide coverage for certain hospital expenses. This arrangement created the model for the development of what was to become Blue Cross Insurance. The development of health insurance to provide reimbursement for routine medical care carried gigantic implications. The original concept of any insurance was to guard against the low risk of a rare occurrence such as premature death or accident. Today's health insurance provides for coverage of routine, predictable services, as well as unforeseen illnesses and injuries (Sultz, 2009).

PRIVATE INSURANCE

Private health insurance falls into two main categories: indemnity and managed care. Indemnity plans, also known as fee-for-service, are traditional insurance plans that give patients absolute freedom to choose their physicians and medical facilities. Insurance companies usually require the beneficiaries to fulfill a yearly deductible, usually between \$300 and \$500 per person per year. After the deductible is fulfilled, the insurance company pays a certain coinsurance rate of the usual and customary charge (UCC). The UCC (or fee schedule) is set by the payer and is usually less than the actual billed charge, in which case the patient may be responsible for the balance. Generally, the coinsurance is split 70%/30% or 80%/20%, where the insurance company pays the higher percentage and the insured the lower. Indemnity plans were the mainstay of the health insurance world before the 1980s. Today, managed care is the norm. Some employers still offer indemnity plans despite their high premium payments to allow their employees the freedom to choose medical services.

As an alternative to indemnity health insurance, managed care was introduced in 1973 with the passage of the Health Maintenance Organization Act. This Act encouraged and funded the development of health maintenance organizations (HMOs) as a strategy to contain the rising cost of health care (Sultz, 2009). HMOs utilized managed care features that coupled health care reimbursement with delivery of service and allowed payers significant economic control over how, where, and what services were delivered. Common features in managed care include the following: specific physicians and hospitals are selected to care for members; referrals from a case manager are usually necessary for specialty or inpatient services; and providers share in the financial risk through capitation agreements and per diem rates.

Capitation agreements pay the service provider (e.g., physician) a fixed dollar amount per member per month (PMPM). From this amount, the provider agrees to cover all care for plan members. For example, if a laboratory signs a capitation agreement to accept \$1.50 PMPM for the outpatient testing needs of 2000 HMO members, the laboratory receives \$3000 per month, and \$36,000 per year. If it costs the laboratory more than \$36,000/year to provide the services, it realizes a financial loss; if it costs less than \$36,000, it realizes a profit. In a capitation testing agreement, a laboratory assumes the risk of spending more than it is paid. One key to managing this risk is gaining access to test utilization of plan members and accurately assessing laboratory costs.

Per diem rates are negotiated with hospitals to provide all necessary care and services for managed members requiring inpatient care. Reimbursement for any laboratory testing during the inpatient stay is included in the per diem amount. As with capitation, if it costs more to provide inpatient services than the per diem rate, the hospital is at financial risk.

Sometimes, a service is separately negotiated (i.e., it is not included as part of the capitation or per diem rate). This is called a "carve out." Esoteric and expensive tests (chromosome analysis, certain molecular testing)

should be targeted as carve outs from capitation outpatient laboratory testing agreements. A negotiated fee-for-service price for these tests is appropriate. By excluding these tests from capitation, one can avoid huge financial losses due to unexpectedly high utilization of these costly services.

GOVERNMENT PAYERS

Medicare is federal health insurance for individuals age 65 and older, individuals who are permanently disabled, and those with end-stage renal disease who have met the specified waiting period. Medicare was established in 1965 by Title XVIII of the Social Security Act. It is administered by the Centers for Medicare and Medicaid Services (CMS), a division of the U.S. Department of Health and Human Services (HHS). Coverage is provided under Parts A, B, C, and D. Claims are processed by CMS-approved contractors. These contractors are usually private companies that serve as fiscal intermediaries (generally processing Part A claims) and carriers (generally processing Part B claims). However, CMS is moving to a new model, whereby the Medicare Administrative Contractor (MAC) will administer both Part A and Part B claims via 15 MAC jurisdictions. For a clinical laboratory to qualify for Medicare/Medicaid reimbursement, the laboratory must maintain Clinical Laboratory Improvement Act of 1988 certification (Washington G-2, 2009).

Medicare Part A covers inpatient hospitalization, hospice care, skilled nursing care, and home health care. Coverage is automatic for those who are eligible. Before the Tax Equity and Fiscal Responsibility Act of 1982 (TEFRA), inpatient hospitalization was reimbursed on a retrospective cost-based system. This system paid hospitals for all costs incurred during an inpatient stay. After TEFRA, the system switched to a prospective payment system (PPS), which reimbursed hospitals on the basis of preset payments for services provided to patients with similar diagnoses. With this DRG payment system, hospitals are reimbursed the same amount for a specific DRG no matter how many discrete units of services are provided. Thus, hospitals can earn a profit or realize a loss on each inpatient stay, depending on whether their costs are lower or higher than the DRG payment. The aim of the PPS, with its fixed DRG reimbursements, was to force hospitals to contain costs by reducing the length of stay and eliminating unnecessary and/or overutilized services (Sultz, 2009).

Medicare Part B covers outpatient laboratory tests, physician professional services, and other medical services and devices. Coverage is not automatic. Eligible beneficiaries must enroll for Part B coverage and pay premiums. Beneficiaries must pay an annual deductible and a 20% copayment for all Part B services, except for clinical laboratory testing, which is covered in full, provided certain conditions are met (see later).

The Part B fee schedule plays an important role in reimbursement because it is a baseline that nongovernment payers use to establish their own rates. For example, a private insurance company may set its fee schedule at 110% of the Part B fee schedule.

Medicare Part C (also known as Medicare Advantage) is an alternative to the traditional Part B fee-for-service program. It is designed to reduce patient "out of pocket" costs by providing services through health maintenance organizations and other managed care service models. *Medicare Part D* provides prescription drug coverage.

Medicaid is a Federal program that offers health care coverage for select low-income families. It was authorized in 1965 as a Federal/State-sponsored program designed to pay medical costs for certain families with low income or inadequate resources. Eligibility extends to people who are aged, blind, or disabled, and those in families with dependent children. Although Medicaid is a Federal program, it is under the jurisdiction of each individual state. This means that each state determines who is eligible, the range of health services offered, and how they are reimbursed. It is a common misconception that Medicaid covers health care costs for all low-income persons. Medicaid does not provide paid medical assistance to every single poor person. To receive medical assistance, a person must meet eligibility requirements.

REIMBURSEMENT CODING SYSTEMS

To be paid, a medical claim must document the patient's medical condition (or diagnosis) and must list the services (or tests) provided. This information is conveyed via a standardized coding system, recognized by all government and private payers: *Healthcare Common Procedure Coding System (HCPCS)* codes describe the test or service (HCPCS 2010, 2009), and *International Classification of Diseases, 9th Revision with Clinical Modification (ICD-9-CM)*, codes describe the patient's condition or

diagnosis (ICD-9-CM 2010, 2009). These coding standards allow data to be accurately communicated among physicians, patients, and third-party payers.

HCPCS was developed in 1983 and consists of two levels of codes. Level I is the Current Procedural Terminology (CPT) coding system and is used to identify nearly all clinical laboratory tests and most medical services (CPT, 2009, 2010). CPT codes are assigned by the American Medical Association (AMA) and are reviewed and updated annually to keep current with changes in technology and medical practice. Each CPT code consists of five digits and a description of the test or service. For example, the CPT code for a total prostate-specific antigen (PSA) test is 84153.

Level II HCPCS codes are assigned by CMS. CPT does not contain all the codes needed to report services or to describe special circumstances that may apply to Medicare. CMS developed this second level of codes to fill the gap. HCPCS Level II codes begin with a single letter (A through V) followed by four digits. These codes are updated annually by CMS. An example of Level II coding is prostate-specific antigen for cancer screening, G0103. Note that CMS treats this test differently than the PSA CPT code described earlier, even though the tests are identical to those of the laboratory. This allows CMS to assign different criteria for reimbursement, based on why a test is ordered.

The ICD-9 was originally developed by the World Health Organization (WHO) as a classification system for reporting of mortality and morbidity statistics by physicians throughout the world. The ICD-9-CM is a U.S. clinically modified revision of the WHO's ICD-9. This modification is maintained and updated by the National Center for Health Statistics. These modifications assist health care providers to index patient records, retrieve case data for clinical studies, and submit claims for health care services. It is worth noting that the WHO has already developed ICD-10, and HHS has set a deadline of October 1, 2013, for adoption of ICD-10 in the United States (Washington G-2, 2009).

WHY ACCURATE CODING IS IMPORTANT

Correct coding is important for three reasons. First, one should be paid for services rendered. Insufficient or incorrect coding may yield lower reimbursement than is rightfully due. Second, one must not receive more reimbursement than is rightfully due. Coding for services not provided or assigning a code that recoups more reimbursement (this practice is known

as “up-coding”) is illegal and constitutes fraud. Third, one must comply with *medical necessity* requirements established by CMS for Medicare patients. These policies define under what conditions a test is considered “medically necessary” and thus reimbursable. Certain tests are considered “medically necessary” only if they are associated with specific diagnoses. Thus, reimbursement depends on whether the diagnosis or medical condition code (ICD-9 code) supports the test code (HCPCS code). For example, “malignant neoplasm of the prostate” supports the medical necessity of doing a PSA test, so Medicare would pay for the test; in contrast, “congestive heart failure” is not considered a medically necessary reason for a PSA test, so the test would not be reimbursed. Note that a physician (or other provider) can order any test on a patient, even if it is not “medically necessary,” but it will not be reimbursed.

Most laboratory fee schedules are set by the local Medicare contractor (fiscal intermediary or carrier). Historically, each contractor established separate guidelines for determining which tests were subject to medically necessary diagnosis codes. *Local medical review policies* and local coverage decisions differ from one carrier to another, making it very difficult to submit and process claims. In some instances, a diagnosis code valid for a test from one carrier may not be considered medically necessary by another carrier. In an effort to standardize all carrier reimbursement guidelines for specific outpatient laboratory tests, 23 tests have been assigned *national coverage decisions (NCDs)*; these medical necessity guidelines apply to all carriers in the country. See Table 12-4 for the list of NCD tests (CMS, 2010b).

Coding at any level should be as specific as possible. Medicare contractors employ the national Correct Coding Initiative to ensure correct coding practices based on the codes defined in the AMA's CPT code set (Washington G-2, 2009). These software edits flag inappropriate code combinations that should not be billed together for the same patient on the same day of service. Medicare has also added a system of medically unlikely edits (MUEs) that limit the units of service payable for a particular CPT code per patient, per provider, per day of service. Claims that exceed the MUE are rejected. Most analytes or tests have a specific CPT, similar to that of PSA. However, sometimes a new test does not have its own code. When that happens, the test must be identified by the method used to perform the analysis (e.g., 82486-Chromatography or 83519-Immunoassay, radioimmunoassay). A method code is usually reimbursed at a lower rate than a CPT code for a specific analyte.

TABLE 12-4

National Coverage Determinations for Laboratory Testing (CMS, 2010b)

General testing category	CPT codes included
Alpha-fetoprotein	82105
Blood counts	85004, 85007, 85008, 85013, 85014, 85018, 85025, 85027, 85032, 85045, 85049
Blood glucose testing	82947, 82948, 82962
Carcinoembryonic antigen	82378
Collagen crosslinks, any method	82523
Digoxin therapeutic drug assay	80162
Fecal occult blood test	82270
Gamma-glutamyl transferase	82977
Glycated hemoglobin/glycated protein	82985, 83036
Hepatitis panel/acute hepatitis panel	80074
Human chorionic gonadotropin	84702
Human immunodeficiency virus (HIV) testing (diagnosis)	86689, 86701, 86702, 86703, 87390, 87391, 87534, 87535, 87637, 87538
HIV testing (prognosis, including monitoring)	87536, 87539
Lipids	80061, 82465, 83715, 83716, 83718, 83721, 84478
Partial thromboplastin time	85730
Prostate-specific antigen	84153
Prothrombin time	85610
Serum iron studies	82728, 83540, 83550, 84466
Thyroid testing	84436, 84439, 84443, 84479
Tumor antigen by immunoassay CA 125	86304
Tumor antigen by immunoassay CA 15-3 (CA 27.29)	86300
Tumor antigen by immunoassay CA 19-9	86301
Urine culture, bacterial	87086, 87088, 87184, 87186

Certain tests that are performed together (i.e., as a panel) must be coded correctly. Ten panels have been approved by the AMA (Table 12-5). When these panels are performed, they must be coded with the unique panel code and not by each individual test's CPT code. Reimbursement is much lower for a panel than it is for the sum total reimbursement of each test. Coding for each individual test component as opposed to one panel code is considered "unbundling," which is a fraudulent billing practice.

Professional pathology physician services (e.g., test interpretation, slide review) are not included in the laboratory fee schedule. They are paid by the Medicare physician fee schedule, which uses a resource-based relative value scale to determine the payment based on a service's relative value unit. These amounts are adjusted to reflect local economic factors. Unlike the laboratory fee schedule, these professional services are subject to the annual deductible and the 20% copayment (Washington G-2, 2009).

MEDICARE REIMBURSEMENT

Medicare is the largest insurance program in the country. In many hospitals, it accounts for 25%–40% of all revenue. Outpatient services are reimbursed differently from inpatient ones.

Medicare Inpatients

DRGs make up a patient classification system that is used to reimburse inpatient (Part A) hospital costs for Medicare patients. Although the costs associated with inpatient clinical laboratory tests are included in the DRG, it does not cover physician services (Part B). After a Medicare patient has been discharged from the hospital, the patient's medical record is reviewed by health information management coders and is assigned appropriate ICD-9-CM and HCPCS codes for one or more diagnoses and procedures for the inpatient stay. These codes along with the patient's demographic

AMA Organ or Disease-Oriented Panels (CPT, 2009)—Cont'd

CPT	Panel	Required components
80061	Lipid panel	Cholesterol, total (85465) HDL cholesterol (83718) Triglycerides (84478)
80069	Renal function panel	Albumin (82040) Calcium (82310) Carbon dioxide (82374) Chloride (82435) Creatinine (82565) Glucose (82947) Phosphorus, inorganic (84100) Potassium (84132) Sodium (84295) BUN (84520)
80074	Acute hepatitis panel	Hepatitis A antibody, IgM (86709) Hepatitis B core antibody, IgM (86705) Hepatitis B surface antigen (87340) Hepatitis C antibody (86803)
80076	Hepatic function panel	Albumin (82040) Bilirubin, total (82247) Bilirubin, direct (82248) Phosphatase, alkaline (84075) Protein, total (84155) Transferase, alanine amino (84460) Transferase, aspartate amino (84450)

ABO, Blood group; HDL, high-density lipoprotein; IgM, immunoglobulin M; RBC, red blood cell.

TABLE 12-6

National Coverage Determinations (NCDs) for Laboratory Testing (CMS, 2010)

Category	Medicare coverage	ABN necessary?
LMRP or NCD tests	Provider paid according to outpatient fee schedule, if medical necessity met	No, unless test is not "medically necessary"
FDA cleared or "homebrew" tests not included above	Provider paid according to outpatient fee schedule, if medical necessity met	No, unless test is not "medically necessary"
Investigational use only or research tests (i.e., not FDA cleared)	Not covered, no payment	Yes
Health and wellness screening	Not covered, with few exceptions: PAP smears covered every 2 years for all women and every year for those with high cancer risk or abnormal smear; PSA covered every year for men older than 50	Yes, unless it is one of the allowable exceptions

ABN, Advanced beneficiary notice; FDA, U.S. Food and Drug Administration; LMRP, local medical review policies; PAP, Papanicolaou smear; PSA, prostate-specific antigen.

information are grouped by decision trees (this process is computerized) into a specific DRG. Currently, more than 500 DRGs are used. CMS assigns a weight to each DRG based on the severity of the diagnoses, the types of procedures performed, the number of laboratory tests, the volume and type of drugs administered, and the presence of complications or comorbidity conditions. CMS assigns each hospital a specific rate that is calculated on the basis of the type of facility (community hospital vs. teaching hospital), the setting (urban vs. rural), and the location (West Coast vs. Midwest). The CMS-assigned rate for the DRG is multiplied by the hospital's assigned rate to determine reimbursement for the hospital stay. This amount is payment-in-full for the inpatient hospitalization. If it costs the hospital more than the reimbursed amount to treat the patient, the hospital must absorb the cost. The patient cannot be billed for any non-reimbursed Part A services (Sultz, 2009).

Medicare Outpatients

For many years after the enactment of DRGs, each outpatient service continued to be reimbursed individually (Harmening, 2007). However, the reimbursement system changed when CMS started to implement an outpatient prospective payment system with the introduction of the Ambulatory Payment Classification (APC) system in 2000. Under this system, virtually all hospital-based outpatient services (e.g., emergency department and clinic visits, oncology treatment and surgery) provided to Medicare patients are reimbursed on a prospective basis according to a preset rate,

similar to DRGs. Clinical diagnostic laboratory tests are not currently included in the APC and are still reimbursed individually on the basis of the CMS fee schedule, with some exceptions.

Under certain conditions, Medicare does not pay for laboratory tests (Table 12-6). If a laboratory expects Medicare to deny payment because a test does not meet medical necessity requirements, it must inform the patient before the service is provided. An *advanced beneficiary notice (ABN)* is used to document that the beneficiary was told the test might not be covered by Medicare, the reason(s) for the possible denial, and the decision by the patient to pay for the test if Medicare does not reimburse or to refuse the test entirely (Washington G-2, 2009).

An important consideration for hospitals that have laboratories that perform outpatient testing on Medicare patients is the *72-hour rule* (CMS, 2010c). This rule states that a hospital cannot bill an outpatient (Part B) claim for laboratory tests performed within 72 hours of an inpatient admission. Outpatient testing that is performed 72 hours before the admission must be included with the inpatient claim and is reimbursed according to the assigned DRG for that stay. Hospital laboratories must identify outpatient Medicare services that are affected by this rule and must make sure they are not billed separately. A nonhospital independent laboratory is not subject to the 72-hour rule. Thus preadmission tests performed 3 days before hospitalization are not reimbursed if performed in the admitting hospital's laboratory but are reimbursed if done in an independent laboratory.

TABLE 12-7

Pro Forma Laboratory Budget

Category	Current year	Assumptions	Change	Projection for new year
Revenue	\$3,000,000	4% growth	\$120,000	\$3,120,000
Total tests	370,000	4% growth	14,800	384,800
Revenue/test	\$8.11			\$8.11
Expenses				
Salaries	\$950,000	3% cost of living increase	\$28,500	\$978,500
Laboratory supplies	\$421,000	4% growth (no price increase)	\$16,840	\$437,840
Reference lab fees	\$250,000	4% growth	\$10,000	\$262,600
		1% price increase (on projected \$260,000)	\$2600	
Phlebotomy supplies	\$35,500	4% growth	\$1420	\$36,920
Maintenance contracts	\$40,000	No change		\$40,000
Total expense	\$1,696,500		\$59,360	\$1,755,860
Cost per test	\$4.59			\$4.56

FINANCIAL PERFORMANCE AND MONITORING

BUDGETING

Budgeting is the process of planning, forecasting, controlling, and monitoring the financial resources of an organization (Garcia, 2004). The *operational budget provides a target* of day-to-day revenues and expenditures that are to be achieved in the forthcoming year.

Different budget-planning strategies are used based on the type and seasonality of the business; however, all use a method to forecast and project what will occur in the next budget cycle. Projections are made for the expected increases and decreases in revenues and expenses based on historical information and adjustments for inflation, loss of business, new business, and new product lines. The laboratory typically uses a *pro forma* budget. It provides in a pro forma or “predetermined set form” the expected annual revenue and expense based on various projections and assumptions, including test volume. It uses actual costs, ratios, and percent calculations to extrapolate from historical data what the new budget will be. Table 12-7 presents an example of a pro forma budget.

In contrast to the pro forma budget, which uses baseline data from 1 year to develop data for the next, a *zero-based budget* has no baseline. A zero-based budget requires management to annually evaluate all services and products to determine which should be funded or eliminated. Each department manager must justify its budget as if all of its activities are new. It assumes that no existing program is entitled to automatic budget approval, but rather must prove its financial merit when compared with the organization's other programs. Programs are ranked and funded by merit priority to the level of the organization's available funds. Laboratories use a zero-based approach to propose a new service (e.g., blood donor program, outpatient blood collection center) or laboratory section (e.g., mycology) or test (polymerase chain reaction assay) (Travers, 1997).

The *capital budget* is used to fund large capital projects such as acquiring an instrument or information system, or remodeling the laboratory (Garcia, 2004). These projects may cost thousands or millions of dollars and require several years to plan or implement. The laboratory's proposed projects must compete with those of other hospital departments for limited capital dollars. Each project is evaluated (see later) and ranked on the basis of a variety of financial and clinical factors. The operational budget must be linked to the capital budget, for it is the revenues generated by operations that are used to fund needed capital items and projects. Operational budgets must generate surplus revenue to fund capital projects; a business must reinvest in itself to remain competitive.

VARIANCE ANALYSIS

The operational budget should be reviewed periodically, usually monthly, to determine how closely the projected budget matches actual revenues and expenses (Garcia, 2004). A variance is the difference between the projected budget and the actual revenue and expenses (Budget – Actual = Variance). Both favorable variances (more than expected revenue or less than expected expenses) and unfavorable variances (less than expected revenue or more than expected expenses) need to be analyzed. By analyzing

a variance, one can identify whether it can be controlled or not. Once the cause is determined, one can take necessary action to improve performance and more accurately prepare future budgets.

If revenues (and expected test volume) are within budget, but laboratory supplies show an unfavorable variance, one must investigate the reason for the discrepancy. For example, technologists may be repeating tests too frequently, running too many controls, or scheduling work inefficiently, in many small batches. This is an example of a variance that can be controlled by the laboratory if it changes its practices. Actions to consider include increasing the frequency of instrument maintenance to reduce problems that require repeats and controls, providing staff education to reinforce policies on when repeats and controls are needed, and rescheduling work into more efficient batch sizes.

An example of an uncontrollable variance occurs if a hospital decides to eliminate the cardiac chest pain service. In this scenario, a favorable reagent expense variance (i.e., less money spent on reagents than expected) would be related to doing fewer cardiac marker tests. A laboratory manager can do nothing to correct this variance. However, this does not absolve the manager from a duty to review it. One must verify the amount of the variance and must determine if it is appropriate for the amount of lost business. When forecasting for the next budget cycle, one should decrease projected revenues and expenses attributed to the loss of cardiac services.

FINANCIAL REPORTING AND STATEMENTS

Managerial accounting is used to prepare and monitor budgets. Revenue and expenses are organized into logical groupings known as cost centers that represent a laboratory section (such as microbiology, core lab, blood bank) or function (phlebotomy). Each cost center is subdivided into a variety of expense and revenue categories. Salary and nonsalary expense categories are grouped separately. Periodic review, at least monthly, of the cost center's accounts is needed to monitor the variances and put corrective action in place to keep the organization on its expected financial plan. Table 12-8 provides an example of a laboratory cost center's accounts.

Financial accounting is a system used to report business information to external entities such as the Internal Revenue Service or its stockholders. Generally accepted accounting principles are used to standardize this information. Balance sheet, income statement, and statement of cash flows are the financial statements most commonly used to assess an organization's financial position. Banks and investors rely heavily on these statements to determine whether to lend money to a business or to purchase shares of stock.

The *balance sheet* is the statement of an organization's financial position at a specific point in time. This statement is usually generated at the end of an organization's fiscal year or at the end of the calendar year. It records the organization's assets (what it owns), its liabilities (what it owes), and its equity or net worth (what is left after subtracting what it owes from what it owns). From this statement is derived the fundamental accounting equation: Assets = Liabilities + Equity (net worth). This statement is used to assess an organization's level of indebtedness to what it owns.

The *income statement*, also known as the statement of profit and loss, summarizes the organization's revenues and expenses over an accounting period, usually quarterly or annually. The income statement records all of

TABLE 12-8

Cost Center: Microbiology

Account number	Account name	Current month			Year to date		
		REVENUE					
		Actual	Budget	Variance	Actual	Budget	Variance
20100	Inpatient revenue	\$1,414,245	\$1,403,172	\$11,073	\$2,892,427	\$2,764,597	\$127,830

Total nonsalary expense		\$127,803	\$113,117	\$14,686	\$228,596	\$222,399	\$6197
Total expense		\$238,394	\$244,245	\$(5851)	\$449,056	\$484,655	\$(35,599)

a laboratory's gross patient revenue, less allowances for a given period, and deducts the expenses for that same period to arrive at net income before taxes. Taxes are paid only if the organization is for-profit. Net income is realized when net revenues exceed expenses. A net loss is realized when expenses exceed net revenues. Note that revenue does not necessarily equate to cash generated. Many times a test is performed and recorded as income, although the payment (cash) may not be received for several months. The income statement records the organization's ability to make a profit; it does not reflect its cash position.

The *statement of cash flows* shows the amount of cash generated by an organization over a period of time, usually a calendar or fiscal year. Cash outflows (cash paid out) are subtracted from cash inflows (cash received) to calculate the net change in cash for the period. Excess cash in a given period can be reinvested in the organization, used to make additional debt payments, or placed in easily liquidated securities for emergency use. If the net cash position for a period is negative, the organization must meet its cash obligations by using cash reserves from previous periods. If this trend is not reversed, the organization eventually will run out of cash.

BENCHMARKING AND PRODUCTIVITY MEASURES

Benchmarking and productivity measures go hand in hand. It does no good to collect productivity data if they are not compared with a standard or evaluated for trends over time. Benchmarking is the measurement of an organization's products or services against specific standards for comparison and improvement (Wallace, 1998). Benchmarking can be internal or external.

Internal benchmarking trends an organization's productivity over time. Productivity is the relationship between input (labor and supplies) and output (product or service) (Travers, 1997). It is usually expressed as a ratio of the product or service to the various inputs used for the production of the product or service. See Table 12-9 for common productivity ratios used in the laboratory. The purpose of trending internal productivity is to determine if internal standards are being met, exceeded, or not met. If adjustments to workflow or personnel are made, the next period's benchmarking data can be used to determine if the adjustments were the probable cause for improvements or for decreased productivity.

External benchmarking compares a laboratory's productivity with that of other laboratories. Its purpose is to identify top performers in a particular field. Top performers can be contacted to find out what processes or resources have been used to achieve high productivity. This information may guide a laboratory to make similar changes that could result in higher productivity. Professional organizations such as the College of American Pathologists or the University Healthsystem Consortium offer external

TABLE 12-9

Common Productivity Measures for Clinical Laboratories

Productivity measure	Target*	Quarter 1	Quarter 2
Billable tests/paid FTE	>3680	3798	3500
Billable tests/worked FTE	>4000	4128	4080
Worked FTE/paid FTE	>92%	95.2%	90%
Labor cost/billable test	<\$5.00	\$4.68	\$5.01
Supply cost/billable test	<\$1.00	\$0.99	\$1.01
Overtime/worked straight time	<3%	2.7%	3.5%

FTE, Full-time equivalent or 2080 paid hours in a year; paid FTE, all salaries paid (benefit time plus worked time).

*Target is for illustration purposes only. It should not be considered a laboratory standard.

laboratory specific benchmarking programs. Caution should always be used when interpreting external benchmarking information. Although clinical laboratories are similar, no two are exactly alike, and, despite best efforts, sometimes data are collected and reported differently. A laboratory may never be able to achieve productivity as high as its peers because of factors beyond the laboratory's control. Labor availability, the disease and acuity mix of patients, and access to technology and automation will each have an effect on how productive a laboratory is, and how much more productive it can become.

EVALUATING A CAPITAL PROJECT

A hospital has limited capital; it cannot fund all requested projects, so it must prioritize them according to a variety of factors, including clinical need, patient or employee safety, and financial impact. Whether or not money is borrowed to finance these projects, it may be necessary for the project or investment to pay for itself and even generate excess cash to fund other projects. The following section discusses different ways to evaluate a capital project to answer the question, "Is it a good investment?" Table 12-10 compares these methods.

PAYBACK PERIOD

The payback period is commonly used to evaluate a capital project. The payback is the length of time required for an investment's net revenue to cover the cost of the initial investment (Brigham, 2009).

Because laboratory equipment or technology can become obsolete in a very short period of time, it is important to recover the investment cost as soon as possible. Many institutions want to see a payback in 3 years or

TABLE 12-10

Financial Evaluation of a New Automated Analyzer

GIVEN		
Investment (cost of analyzer)		\$200,000
Discount rate (rate of inflation or interest rate of borrowed money)		10.00%
Useful life of analyzer	5 years	
Annual depreciation expense	\$200,000/5 years	\$40,000
Annual revenue	100,000 tests at \$5.00/test	\$500,000
Annual labor expense	100,000 tests at \$2.50/test	\$250,000
Annual supply expense	100,000 tests at \$2.00/test	\$200,000
Annual net revenue (annual revenue – annual expense)	\$500,000 – (\$250,000 + \$200,000)	\$50,000
Net revenue per test (test revenue – test expense)	\$5.00 – (\$2.50 + \$2.00)	\$0.50
CALCULATIONS		
PAYBACK PERIOD = Investment/Annual net revenue	\$200,000/\$50,000	4 years
BREAKEVEN		
Per year = Depreciation/Net revenue per test	\$40,000/\$0.50	80,000 tests
Life of analyzer = Investment/(net revenue per test)	\$200,000/\$0.50	400,000 tests
RETURN ON INVESTMENT (ROI) = Annual net revenue/Investment	\$50,000/\$200,000	25% per year
NET PRESENT VALUE (NPV) = Present value of the sum of future net revenue (cash flows) minus investment. <i>Note:</i> Present value interest factor (PVIF) for each year based on 10% discount rate is multiplied by net revenue to determine present value. PVIF is available from any financial data resource. NPV can also be calculated with financial calculator		
Today's investment	(\$200,000)	
Year 1 Net revenue × PVIF	\$50,000 × 0.9091 = \$45,455	
Year 2 Net revenue × PVIF	\$50,000 × 0.8264 = \$41,320	
Year 3 Net revenue × PVIF	\$50,000 × 0.7513 = \$37,565	
Year 4 Net revenue × PVIF	\$50,000 × 0.6830 = \$34,150	
Year 5 Net revenue × PVIF	\$50,000 × 0.6209 = \$31,045	
Present value of sum of future NPV net revenue	\$189,535	\$(10,465)
INTERNAL RATE OF RETURN (IRR) = Discounted interest rate at which NPV = 0. <i>Note:</i> Financial calculator is used to determine IRR by entering cash flow and discount rate.		
Today's investment	(\$200,000)	
Year 1 Net revenue × PVIF	\$50,000 × 0.9265 = \$46,326	
Year 2 Net revenue × PVIF	\$50,000 × 0.8585 = \$42,923	
Year 3 Net revenue × PVIF	\$50,000 × 0.7954 = \$39,769	
Year 4 Net revenue × PVIF	\$50,000 × 0.7369 = \$36,847	
Year 5 Net revenue × PVIF	\$50,000 × 0.6828 = \$34,140	
Present value of sum of future net revenue	\$200,000	
NPV	\$0	
IRR		8%

less. Once the initial investment is recovered, net revenue (Revenue – Expense) from this investment represents a profit to the organization. The sooner a capital project's payback period is reached, the sooner an organization can realize a profit from the investment.

BREAKEVEN POINT

The breakeven point of a capital project is reached when the volume of sales is such that total revenue equals total costs (fixed and variable), and therefore profit is zero. Before the breakeven point is reached, the project is operating at a loss; after it is reached, the project is realizing a profit (Brigham, 2009). As with the payback period, the sooner the breakeven point is reached, the better it is for the organization.

RETURN ON INVESTMENT*

The rate of return on an investment (ROI) for a capital project is the ratio of net income it generates to the total investment of the project (Travers,

1997). ROI is a standard for evaluating how wisely management uses its capital dollars, whether from its own cash reserves or from borrowing activities. The higher the rate of return is, the better the capital dollars are used. ROI is the formal means of expressing the phrase “better bang for your buck.” Some institutions have automated the ROI process. Most information can be pulled from the financial data banks of the hospital computer system after a limited amount of information is provided by the laboratory. An ROI is pretty much a standard requirement of most facilities for any capital project.

NET PRESENT VALUE*

Money loses its value over time; \$10,000 today is more valuable than \$10,000 3 years from now. This concept is known as the time value of money. The payback period and return on investment calculations do not consider the time value of money. They assume that the value of future cash flows remains constant. To address this shortcoming, the net present value (NPV) calculation is used to determine whether a project's cash flows (i.e., cash it generates in the future) are sufficient to repay the original investment, taking into account that money loses value over time. Thus, cash received in the future has to be *discounted* (i.e., the value has to be reduced) to determine how much it is worth in today's dollars. The discount rate is usually the inflation rate (if no money was borrowed to finance

*Note: Financial calculators and financial software packages are programmed to calculate ROI, NPV, and IRR. The NPV and IRR are very tedious calculations requiring multiple steps and the use of discount tables. It is not recommended to do these calculations manually.

the project) or the interest rate on a loan used to fund the project. *Net present value (NPV)* is defined as the present value of future cash flows, which have been discounted at the interest rate used to fund the capital project (Brigham, 2009).

When the NPV is a positive number, the project will generate enough cash to pay for the original investment. When the NPV is a negative number, the project cost is not recouped and/or the future cash flows are not sufficient to cover the interest costs for borrowing the money.

INTERNAL RATE OF RETURN*

The internal rate of return (IRR) also discounts cash flow into today's value. It determines the actual rate of return that the investment earns. The IRR is the discount rate at which the present value of a capital project's expected cash inflows equals the present value of its costs, or in other words, when the NPV equals zero.

Identifying a project's IRR is necessary to ensure that its rate is higher than the cost of the capital borrowed for the project. The higher the IRR, the faster the project pays for itself. Hospitals and corporations use the IRR as one way to rank projects.

INTERPRETATION OF FINANCIAL CALCULATIONS

Although the preceding calculations are important tools, an organization should not make its capital decisions based strictly on the outcome of the equations. As with all budgeting activities, there is an element of the unknown in assumptions. Predicting future cash flows for replacement instrumentation is usually more reliable than predicting it for new product lines or technology. Assigning an expected life to a piece of capital equipment is also an educated estimate. Having a good sense of how reliable predictions are will determine how much credence should be given to the calculations.

If only the payback period, breakeven analysis, and ROI were considered when evaluating the example in Table 12-10, the project would look acceptable. However, when the NPV and IRR are also considered, it does not look as good. The NPV is unfavorable, and the IRR is much less than the ROI because the cost of capital is high (10%). Does this mean the project should not go forward? Not necessarily. Depending on other issues, it may be determined that this new chemistry analyzer is absolutely essential to support the mission of the organization.

These calculations have other inherent drawbacks. As mentioned earlier, some of the calculations take into account the time value of money, and others do not. The time value of money is a very important consideration when the cost of capital is high (as in the example in Table 12-10) or during periods of high inflation. The rate of return calculations yield a percentage, but the actual dollars they represent are not immediately apparent. A capital project that yields an ROI of 15% might look better initially than one that yields 10%. However, the size of the projects may differ considerably. For example, in the former, an initial investment of \$10,000 could produce \$1500 in net revenue, but in the latter project, an initial investment of \$200,000 produces \$20,000 in net revenue. None of these financial calculations should be considered in isolation, but they should be used in aggregate to assist in the analysis of capital projects.

CAPITAL ACQUISITION METHODS

When a capital project is evaluated, the method for acquiring the equipment is also an important consideration. Table 12-11 summarizes the advantages and disadvantages of acquisition methods: Purchase, leasing, and renting. Just as there is not a single best financial calculation when evaluating a project, there is not a single best acquisition method. The method selected depends on individual needs, characteristics and financial philosophy of the organization, and availability of capital dollars.

The concept of purchasing needed equipment is easy to understand, but is it the wisest use of an organization's money? If the capital (money) needed to fund the project is currently invested in a security that is earning a higher interest rate than the rate needed to borrow money, it makes financial sense to borrow the needed capital. Conversely, if capital earns a lower interest rate than the borrowing rate, it makes sense to use the organization's capital.

Once the equipment is purchased, it is an asset of the organization and is depreciated by a method appropriate for such a piece of equipment. Most

TABLE 12-11

Capital Acquisition Options

	Advantages	Disadvantages
Purchase	Ownership	Risk of obsolescence; opportunity cost
Operating (true) lease	Hedging obsolescence; flexibility in financing; cancelable	Nonownership; interest/financing cost
Financial lease	Ownership; flexibility in financing	Noncancelable; interest/financing cost
Rental	Hedging obsolescence; flexibility in length of use	High cost; nonownership

laboratory equipment is depreciated over a 5-year period using the straight line depreciation method. The depreciation expense is noted in the income statement but probably will not be included in the monthly operational budget documents. It will depend on each organization as to whether depreciation is listed on the monthly budget reports. The operational expense for the equipment will consist of the supplies, maintenance, and labor needed to support it.

Many different variations and contract terms may be associated with a leasing agreement. Being certain to "read the fine print" never rings truer than when an equipment leasing arrangement is considered. Nonetheless, no matter how complicated the terms of a leasing contract are, there are only two types of leases.

An *operating lease* (also known as a "true" lease) allows an organization (lessee) full use of the equipment for a predetermined time. The time period is usually 1–3 years, but is always less than the useful life of the equipment. A termination clause could be included in the agreement. Equipment maintenance is included in an operating lease. The lessee has no right to ownership during or after the lease period. No equity is established during the term. The owner (lessor) retains full ownership of the equipment and full responsibility for it. The leasing agreement may or may not contain an option to allow the lessee to purchase the equipment at the end of the term. This is only an option, however, and should not be misinterpreted as established equity over the course of the agreement. If a purchase option is provided, it is usually for the equipment's fair market value at the end of the lease period. If the original lessee decides not to purchase the equipment at the end of the lease term, the lessor could re-lease it to the original lessee or to another organization, as the equipment still has useful life (Brigham, 2009).

The other lease type is a financial lease. With a *financial lease* (also known as a capital lease or lease-purchase), the lessee eventually gains ownership of the equipment. The lease period corresponds to the economic life of the equipment. Through lease payments, the lessor recovers the cost of the equipment plus an interest factor to ensure a return on its investment. A financial lease is not cancelable, and equipment maintenance is not included (Brigham, 2009).

Renting equipment is not the same as leasing it. The major differentiators include the following: Renting does not carry an option for later purchase, there is no predetermined specified length of time for renting, it can be terminated at any time, and maintenance and repair are the responsibility of the owner, not the renter (Travers, 1997). A reagent rental agreement is a misnomer; it is not a rental, but a lease. These agreements require the lessee to purchase reagents that are specific for a particular piece of equipment. The price of the reagents is marked up by a certain amount to cover the "rent" of the equipment. The mark-up is a lease payment to cover the cost of the capital. Whether or not the equipment will be owned at the end of the reagent rental agreement will determine if the agreement was a financial lease. Recent federal legislation requires vendors to clearly state the proportion of annual payments that are allocated to the capital portion of the lease. This simplifies the analysis of competing lease agreements.

Regardless of which method of capital acquisition is utilized, you should always have the vendor or lessor break out the agreement into cost of equipment, cost of service agreement, and costs of reagents and supplies. This way, you can see and negotiate the cost of each. It is prudent to include someone from the institution's purchasing department to help with negotiations.

BUILD IN A CAP FOR REAGENT/SUPPLY COSTS

Most equipment and instrumentation in laboratory medicine today are very complex, and because of industry competition, many “bells and whistles” have been added. At times, equipment can fail, and reagents and/or supplies can be a “bad lot” and not function correctly. This can result in a laboratory having to repeat patient testing over and over again. This repeating of tests and “getting the instrument to work properly” can result in a significant increase in costs for reagents and supplies beyond what you thought you needed based on the vendor recommendations.

One can protect the laboratory from the above costs by building a “cap” in any agreement for reagents and supplies as part of any equipment acquisition. One way to do this is to base the payment for reagents and supplies only on reportable patient results. If you need to repeat tests because of reagent or equipment failure, you do not pay for the increased reagent and supply usage.

CREATING FINANCIAL VALUE/CONCLUSIONS

Financial oversight of any organization is not easy. For a clinical laboratory, this oversight is especially difficult because to remain competitive, it must offer state-of-the-art technologies that are often complex, expensive, and quick to become obsolete. This, combined with strict coding criteria for submitting claims that yield a predetermined fixed reimbursement rate, leaves little opportunity for the laboratory to cover costs, let alone make a profit.

The equation for net profit is defined as revenue minus expenses. Therefore the only way to increase net profit is to increase net revenue or to decrease expenses. In a managed care environment, increasing patient

volume (and gross revenue) does little to increase net profit because variable expenses increase proportionately with the larger volume. For an increase in gross revenue to have a positive impact on net profit, the newly generated revenue must have a closer relationship to what is billed and to what is collected. The best way to achieve this is by providing testing to clients that is paid according to a fee schedule, instead of a DRG, APC, per diem, or capitation. Many laboratories attempt to do this by offering commercial or reference outreach programs. Target markets for outreach business include physician offices, clinics, and other laboratories or hospitals. Academic institutions also offer testing for grants, research, and clinical trials. If a laboratory has excess capacity for testing and can perform this additional testing without adding fixed costs, the increase in this revenue should increase the net profit. This of course also assumes that prices charged for the tests cover the expenses for this outreach testing. Once the increase in volume requires the addition of fixed costs (more labor, equipment, space, or other resources), careful evaluation of this new volume needs to be performed to ensure that the increase can cover the new costs.

Expense reduction seems to be the norm when one is trying to increase net profit in a managed care environment. Eliminating as much of the fixed cost as possible is the most effective way to accomplish this. Although it is very important to negotiate favorable pricing for supplies, reagents, and other variable cost items, reducing their unit cost by several cents or even several dollars will not have as great an impact as eliminating unneeded or underutilized fixed costs. Achieving economies of scale through maximum use and efficiency of an organization's fixed costs is critical in realizing substantial cost reductions.

Effective financial management requires careful planning, analysis, and critical thinking when decisions need to be made regarding how best to acquire capital equipment, assign pricing, and reduce costs. Keeping abreast of the various payer requirements ensures that the laboratory is reimbursed appropriately for services rendered. When applied with common sense, these tools and knowledge base will promote the financial success of a clinical laboratory operation.

KEY POINTS

- Level A laboratories, also known as sentinel laboratories, may be the first to identify an unusual organism or cluster of isolates that may signal a bioterrorism event.
- The responsibility of a Level A laboratory is to “rule out” suspected biological agents rather than perform complete identification or highly complex analyses.
- Suspect samples must be handled safely and legally (using chain of custody).
- Specific protocols (and presumptive identification criteria) must be applied for each biological agent.
- Category A (highest priority) biological agents are easily disseminated, can cause high mortality, and can generate public panic. They include bacterial (anthrax, plague, tularemia), viral (smallpox, viral hemorrhagic fever) and toxin-mediated (botulism) agents.
- Level A laboratories play mostly a supportive role in the management of hospitalized patients who are victims of a chemical terror attack.

BIOTERRORISM

OVERVIEW

On September 11, 2001, following the unimaginable terrorist attacks on New York City and Washington, DC, the Centers for Disease Control and Prevention (CDC) recommended that health care professionals increase surveillance for any unusual disease occurrences, or clusters of disease, asserting that these may be sentinel indicators of bioterrorist attack. As predicted, anthrax cases were reported in several states, thereby justifying the CDC's suspicions that a bioterrorist was at large. Over the years, it has become clear that germ warfare is equally attractive to terrorist cells, organizations, and even disgruntled individuals as it is to countries. It delivers the greatest impact for the smallest amount of money, and it is relatively easy to carry out. It also comes with a big bonus—it has a dramatic psychological effect on the population. Compared with nuclear weapons or conventional armaments, biological weapons are relatively cheap and easy to make. For anyone with a rudimentary understanding of

microbiology and the requisite materials, making biological agents of death in quantity is little more technically demanding than brewing beer. The microorganisms involved are often readily obtainable in nature, like the anthrax bacillus that abounds in soil throughout most of the world, or can be easily acquired from other sources such as a country's pharmaceutical and agricultural industries, or academic institutions. Toxic ricin, for example, which strikes at the central nervous system, can be extracted from the same castor beans that are the source of castor oil.

The U.S. Department of Defense and the CDC has published a list of the most likely biological weapons (NATO, 1996). They fall into three categories. The first includes deadly bacteria such as anthrax and plague. The second comprises viruses, such as those that cause smallpox, encephalitis, and hemorrhagic fevers like Ebola, Lassa, and Rift Valley fever. The last group is made up of toxins that attack the central nervous system, such as botulinum, fungal toxins, and ricin.

An effective national strategy to detect, prevent, and limit bioterrorism should consider the following:

- A coordinated plan is needed to network all federal, state, and municipal antibioterrorism programs. All first responders must be adequately educated and equipped to deal with any biowarfare or bioterrorism event.
- Military and law enforcement personnel and medical and health practitioners, especially first responders, should be vaccinated whenever possible so that they can more effectively carry out their respective missions.
- Research and development of new wave (subparticle) vaccines, blocking agents, and antibiotics are needed to prevent and treat disease caused by biological weapons.
- Vaccination programs for the general public should be instituted to protect against the likeliest biological weapons.
- The public should be kept informed about germ warfare and should be instructed to report unusual neighborhood activities to local authorities. “Bioterrorism watches” could be introduced on the model of “neighborhood crime watches.”
- All physicians and health care providers should be familiar with the symptoms and treatment of diseases caused by the likeliest biological warfare agents. All hospitals and medical facilities should develop emergency preparedness plans and should establish disaster policies to deal with any bioterror event or other disaster. Included in such plans is the development of a clinical laboratory preparedness and response plan.

TABLE 13-1

Biological Safety Level (BSL) Practices

BSL-1 practices: For work with agents of minimal hazard

- Restrict or limit access when working.
- Prohibit eating, drinking, and smoking.
- Prohibit mouth pipetting.
- Needles and sharps precautions

BSL-2 practices: For agents of moderate hazard

BSL-1 practices plus:

- Use Biological Safety Cabinet (BSC)-Class II
 - Type A1: 30% air exhausted to room
 - Type A2: 30% air exhausted to outside
 - Type B1: 70% air exhausted to outside
 - Type B2: 100% air exhausted to outside
- Use leakproof containers.

BSL-3 practices: For agents of serious or potential lethal hazard

BSL-2 practices plus:

- Use BSC-Class II 100% air exhausted to outside through double high-efficiency particulate air (HEPA) filtration or HEPA plus incineration. Cabinet is gas tight and sealed, with operation performed through rubber gloves.
- Use PPE (personal protective equipment).

- A nationwide epidemiologic surveillance program should link all medical facilities with the CDC or another assigned federal, state, or local agency to identify clusters of cases (sentinel events). Small clusters may signal a terrorist practicing before a larger-scale act is carried out.

The keynote to all this is vigilance. Any complacency or overconfidence will surely prove fatal, sooner or later. The bottom line is that we must remain on alert for animal and human epidemics and must keep searching for better ways to respond to them, whether they are of natural or unnatural origin (Tierno, 2004).

This chapter explains how a Level A laboratory responds to a bioterror event as part of a health facility's larger emergency preparedness plan. This chapter excludes some common potential bioterror agents such as *Salmonella*, *Shigella*, *Escherichia coli* 0157, *Campylobacter*, *Vibrio*, etc., because they are well known and are routinely cultured by Level A laboratories (see Part 7, Medical Microbiology). Instead, it focuses on several more likely bioterror agents with which a Level A laboratory may be less familiar.

ROLE OF A LEVEL A LABORATORY

The Laboratory Response Network (LRN) is a new laboratory testing and referral system formed as an outgrowth of the CDC's Health Alert Network. Its purpose is to prepare for and provide a coordinated, rapid response to bioterrorism and other public health emergencies. The LRN consists of four types of laboratories, designated Levels A, B, C, and D.

Safety Issues

Level A laboratories must always operate in compliance with accepted biological safety level 2 (BSL-2) requirements, including regulations, policies, and procedures for handling blood-borne pathogens (Table 13-1). When handling any potential pathogen, all Level A laboratories should utilize BSL-3 practices for all culture manipulations that might produce aerosols. Level B laboratories operate in compliance with all BSL-2 requirements and always practice BSL-3 safety procedures. Level C laboratories operate in compliance with all BSL-3 safety requirements and are certified as BSL-3 facilities. Their staff is specially trained to handle highly pathogenic and potentially lethal agents.

It is of paramount importance to practice good laboratory safety. For example, staff that process viral cell cultures are at risk of contracting unsuspected bioterror agents, such as smallpox or hemorrhagic fever viruses (BSL-4 agents). To minimize exposure, staff must practice universal precautions and use biological safety cabinets to set up cultures (Gilchrist, 2000; NCCLS, 2001; CDC, 2001).

Laboratory Designations

Level A facilities are also known as sentinel laboratories, in that they may identify an unusual organism that may be highly suspect and therefore may be first to signal that a bioterrorism event has occurred. Alternatively, the Level A laboratory might report a cluster of isolates of the same organism

for a number of patients that may be unusual and thus signal an event. Most clinical laboratories fall into this category. The cardinal responsibility of a Level A laboratory is to "rule out" suspected agents of bioterror rather than perform complete identification or highly complex analyses. Once a Level A laboratory reports a finding to a state or municipal public laboratory, it may be instructed to forward the microbe to a Level B or C laboratory, so that it can be "confirmed" using advanced methods. For example, if an agent is suspected of being *Bacillus anthracis*, but this cannot be ruled out by the Level A laboratory, it must be shipped out to a Level B or C facility.

Level D laboratories are even more advanced and may help develop and evaluate new tests for future use in Level B and C laboratories. They can usually type confirmed bioterror agents or may perform more sophisticated molecular testing on strains. Level D laboratories also archive organisms for future studies or reference (Gilchrist, 2000; CDC, 2001; NCCLS, 2001).

Once a Level A laboratory decides that it cannot "rule out" an agent, it is common policy for the laboratory to notify the infection control officer or hospital epidemiologist, who, in turn, notifies the local health department. The laboratory should be prepared to follow instructions for shipping the suspect agent according to the Infectious Substance Guidelines provided by the Department of Transportation or the International Air Transport Association. It is not the responsibility of the Level A laboratory to declare that a bioterrorist event has taken place. Such responsibility rests with the state and/or federal authorities.

Because environmental specimens usually become evidence in a legal case, these specimens require full chain of custody management that is the domain of Level B and C laboratories. Such *environmental* samples may also pose a hazard for patients in a hospital setting; therefore in no case should Level A laboratories accept or process environmental specimens. It is the FBI's responsibility to manage the investigation of environmental samples that are submitted to Level B and C laboratories.

Law Enforcement Issues

The Level A laboratory may play a role in a criminal investigation. If a specimen is suspected or known to possess a biological threat, it is important to preserve the original specimen, plates, cultures, etc. If the laboratory is contacted by the FBI or other law enforcement agencies, the Level A laboratory must notify state health authorities, as well as the hospital infection control officer or epidemiologist. Any information relevant to analysis of potential evidence cannot be released to the public and should be conveyed only to the appropriate law enforcement officials and health authorities.

Chain of custody is a legal document that describes how evidence is handled from the time it is acquired and through all subsequent examinations and storage. The laboratory should have a written chain of custody policy and should appoint one person to serve as an "evidence custodian," that is, the one who controls storage of evidence and documents access to it on a chain of custody form that is securely stored under lock and key. The LRN suggests completing a "receipt of property" form each time the laboratory receives evidence. This form should contain a unique identifier, the quality and quantity of each item, a description of each item, and as much information as possible regarding the submitter, etc. (Gilchrist, 2000; CDC/NIH, 2001; NCCLS, 2001).

BIOLOGICAL AGENTS/DISEASES

The CDC and other governmental agencies list biological agents/diseases in three categories (A, B, and C) according to priority of risk and ease of ability to disseminate to the population. Some representative examples in each category are listed in Tables 13-2, 13-3, and 13-4 (Gilchrist, 2000; USAMRIID, 2001; Tierno, 2002). Table 13-5 summarizes diagnosis and treatment issues related to the bioterror agents discussed later. The role of the Level A laboratory is described in Tables 13-6 through 13-14 for each agent discussed in this chapter.

Anthrax

(Table 13-6)

History and Background

Bacillus anthracis, the etiologic agent of anthrax, is a rod-shaped gram-positive bacterium that produces a spore. Ordinarily, these bacteria grow in a vegetative form, but when conditions are not ideal for growth, they sporulate. Thus, they can survive even under adverse conditions. The vegetative forms are relatively easy to kill with simple germicides, such as

TABLE 13-2

Category A Agents

HIGHEST PRIORITY OF AGENTS THAT POSE A NATIONAL SECURITY RISK	
Characteristics	Agents
Easily disseminated and/or transmitted from person to person	Anthrax (<i>Bacillus anthracis</i>) Botulism (<i>Clostridium botulinum</i>) Plague (<i>Yersinia pestis</i>)
Can result in high mortality rates with a major public health impact	Smallpox (<i>variola major</i>) Tularemia (<i>Francisella tularensis</i>)
Might cause public panic	Viral hemorrhagic fevers—filoviruses (i.e., Ebola, Marburg) and arenaviruses (i.e., Lassa, Machupo)

TABLE 13-3

Category B Agents

Characteristics	Agents
Moderately easy to disseminate	Brucellosis (<i>Brucella</i> species)
Moderate morbidity and low mortality	Epsilon toxin of <i>Clostridium perfringens</i>
May require enhanced Centers for Disease Control and Prevention diagnostic capacity	Food safety threats (i.e., <i>Salmonella</i> sp., <i>Escherichia coli</i> 0157:H7, <i>Shigella</i>) Glanders (<i>Burkholderia malleri</i>) Meliodosis (<i>Burkholderia pseudomallei</i>) Psittacosis (<i>Chlamydia psittaci</i>) Q fever (<i>Coxiella burnetii</i>) Ricin toxin from <i>Ricinus communis</i> (castor beans) Staphylococcal enterotoxin B Typhus fever (<i>Rickettsia prowazekii</i>) Viral encephalitis (alphaviruses: Venezuelan equine encephalitis, Eastern and Western equine encephalitis) Water safety threats (i.e., <i>Vibrio cholerae</i> , <i>Cryptosporidium parvum</i>)

alcohol or peroxide, or even heat, but spores are very resistant to both chemicals and heat. *B. anthracis* spores survive for decades. This is a key point because spores cause infection. In nature, anthrax is usually associated with grazing animals such as sheep, goats, cattle, and wildlife that acquire spores as they feed on vegetation or meat from infected animals. *B. anthracis* is present in soil throughout the world; in the United States, it is found mostly along old cattle trails in Texas, Louisiana, Mississippi, Arkansas, New Mexico, Oklahoma, and some Midwestern states. However, anthrax is rare in the United States because it is controlled in animal populations by vaccination programs. Spores occur when the pH of a richly organic soil is higher than 6.0 and rainfall gives way to drought conditions. When herbivorous animals contract the infection, they can transmit the infection to humans by direct contact with animal products such as hair, wool, hides, bones, etc. Individuals in certain occupations, such as animal handlers, agricultural workers, and veterinarians, are at increased risk for contracting anthrax. About 90% of all human anthrax cases reportedly occur in millworkers handling imported goat hair. Humans can be infected three ways: (1) via the skin (cutaneous) through scratches or abrasions, (2) by inhalation of spores, or (3) by eating contaminated insufficiently cooked meat or meat products. The word *anthracis* comes from the Greek word meaning “coal,” and the bacterium was so named because the microbe can cause a black scab (eschar) to form on the skin of cutaneous anthrax victims. For the same reason, it is sometimes called the “black carbuncle” (Tierno, 2002).

Anthrax is the single greatest biowarfare threat because it is easy to cultivate spores, although production of a weaponized spore is not so simple. The media sometimes refer to “weapons grade” anthrax versus “nonweapons grade.” Criteria for weapons grade include small spore size, usually 1–3 microns; lack of clumping (usually accomplished by adding a polymer that prevents the natural tendency of spores to clump); the quantity of spores present; and an effective delivery system. By this description, the anthrax unleashed on the United States in the fall of 2001 was near weapons grade because it fulfilled two of the four criteria. The spores were small and dispersed well in the air, but particles were present in limited quantities and were delivered via the mail. If enough product had been

Potential major health impact	

made, and if it had been delivered effectively, it would have been considered weapons grade.

In nature, spores in soil tend to clump together, making it very difficult for a person to contract inhalation anthrax naturally. For a terrorist to weaponize anthrax spores, he must first prevent clumping of particles and then must deliver the weapon in sufficient quantity. Clearly, both of these tasks are very difficult. Even a crop-duster would have to be retrofitted quite extensively to deliver spores effectively. To be an effective weapon, the anthrax spores must remain airborne in a concentration that is high enough to be inhaled deep into the lungs. Based on available data, it appears that number varies from about 8000–40,000 spores. A few studies suggest that inhalation of small numbers of spores, around 500 over an 8 hour period, did not make goat mill workers develop disease. Although *B. anthracis* can cause three types of infection (skin, inhalation, and gastrointestinal) a bioterrorist would be most interested in causing inhalation anthrax because of the high mortality rate associated with it. In nature, however, approximately 95% of human cases of anthrax are cutaneous infections (Lew, 2000; Tierno, 2002).

Anthrax spores can survive inside macrophages, eventually vegetating and growing to such numbers that they cause the cells to burst and release bacilli into the bloodstream. These bacteria produce four virulence factors; three are toxins that cause systemic symptoms: protective antigen toxin, the lethal factor, and the edema factor. Last, anthrax produces a capsule that protects it from destruction by the body's leukocytes. Once systemic symptoms occur, antibiotics are useless because they have no effect on the circulating toxins (Tierno, 2002).

Clinical Features

Inhalation Anthrax. This form is a biphasic disease. The *initial* phase is characterized by mild flu-like symptoms (e.g., malaise, fatigue, low-grade fever) followed by a period of apparent wellness for about a day. This is immediately followed by the *acute* phase, which eventually leads to more serious symptoms (e.g., acute respiratory distress). The incubation period can vary from 1–5 days, depending on the number of spores inhaled, but can be as long as 60 days. Shock and death usually occur 24–36 hours after the onset of respiratory distress. The fatality rate of inhalation anthrax approaches 90%, even with antibiotic therapy. However, this figure will probably change for the better owing to the availability of newer antibiotics and superior intensive care treatment facilities. Inhalation anthrax is not spread via person-to-person transmission.

Cutaneous Anthrax. This skin form of anthrax occurs after spores are introduced beneath the skin by inoculation or contamination of a preexisting lesion or break in the skin. The incubation period is 2–7 days (rarely after 1 day) but more often lasts between 2 and 5 days. Lesions begin as small, painless pimples on exposed skin and progress to vesicles and eventually an ulceration that develops a black scab (eschar) at the center (within 2–6 days). Untreated cutaneous anthrax can have a fatality rate of up to 20%, but fatalities are rare (1%) with proper antibiotic treatment. Although anthrax is not transmitted person-to-person, secondary lesions can develop from direct exposure to vesicle secretions.

Gastrointestinal Anthrax. This form of anthrax occurs by ingesting contaminated meat, in particular raw or undercooked, from infected animals. It has recently been reported in association with animal-hide drumming events in New England (CDC, 2010).

The incubation period is 2–7 days. Two types of GI anthrax are characterized by different symptoms: intestinal (e.g., nausea, vomiting, diarrhea) and oropharyngeal (e.g., neck swelling, difficulty swallowing). Shock and toxemia can characterize both forms of the disease, especially in the terminal stages. The fatality rate is 25%–60%. Inhalation, cutaneous, and GI anthrax can be complicated by meningitis, which occurs in about 5% of cases (Lew, 2000).

TABLE 13-5

Bioterrorism Agents: Diagnosis and Treatment

Agent	Diagnosis	Tests and specimens	Treatment
Anthrax	Clinical evaluation and laboratory findings	<i>Culture</i> : Blood, CSF, wounds (definitive) <i>Nasal culture</i> : Determines extent of spore spread in population <i>Immunohistochemical (IHC)</i> : Tissue <i>PCR</i> : Can confirm diagnosis if culture is negative <i>Serology</i> : ELISA, IFA	Antibiotics, including penicillin, quinolones, tetracycline. Treat inhalation anthrax for 60 days. Can combine antibiotics (30 days) and vaccine (3 doses at 0, 14, and 28 days). Full vaccination regimen is 6 doses at 0, 2, and 4 weeks and 6, 12, and 18 months followed by yearly boosters.
Plague	Clinical evaluation and laboratory findings	<i>Culture</i> : Sputum, blood, lymph <i>Direct FA</i> : Respiratory secretions <i>Serology</i> : F1–V antigen (fusion protein) assay	Antibiotics, including tetracycline; quinolones, streptomycin, gentamicin, and chloramphenicol for 10–14 days. <i>Prophylaxis</i> : Medication for 7 days. Formalin-killed vaccine given 0, 1, and 4–7 months Boosters every 1–2 years
Brucella	Difficult with many rule-outs; laboratory required	<i>Culture</i> : Nasal, sputum, respiratory specimens (can also use PCR); blood culture is definitive test <i>Serology</i> : IFA, ELISA, and microagglutination (gold standard) to detect antibodies	<i>Combination antibiotics (6 weeks)</i> : Doxycycline and rifampin or quinolone and rifampin. Prophylaxis requires 3 weeks. Numerous vaccines (both killed or live attenuated) available with no proven success.
Tularemia	Difficult with many rule-outs; laboratory required <i>Key symptom</i> : Pneumonia with nonproductive cough	General laboratory tests not helpful <i>Culture</i> : Bacterium does not grow on ordinary media, needs cysteine blood or chocolate agar <i>Capsular AG detection or PCR</i> : Whole unclotted blood <i>Direct FA and PCR</i> : Nasal, induced respiratory specimens <i>IHC</i> : Tissue sometimes helpful <i>Serology</i> : ELISA AB	<i>Treatment</i> : Antibiotics like gentamicin, streptomycin, ciprofloxacin <i>Prophylaxis</i> : Doxycycline <i>Vaccine</i> : Live attenuated available
Botulism	Clinical evaluation; routine laboratory tests are of no value; toxin assay may be useful if toxin present in serum	<i>PCR and toxin assay</i> : Use nasal induced respiratory secretions and blood	<i>Supportive treatment</i> : Antitoxin can be administered up to 24 hours after exposure: two types, trivalent and pentavalent. Also available is a pentavalent toxoid vaccine.
Smallpox	Clinical findings (exanthems)	<i>Cell or chick embryo culture</i> : Skin lesions ideal; nasal swabs, respiratory secretions, serum specimens can also be cultured <i>Electron microscopy</i> : Identifies virus <i>PCR</i> : Use same specimens as earlier <i>Agar gel precipitation</i> : Skin lesions <i>Serology</i> : Tests are available	VIG must be used in conjunction with vaccinia vaccine if exposure occurs beyond a 3-day time frame. Within 3 days, only vaccinia vaccine need be given by scarification. Cidofovir offers promise.
VEE	Difficult with many rule-outs; laboratory required	<i>PCR or culture in cells/suckling mice</i> : Nasal, induced respiratory secretions and serum <i>Serology</i> : ELISA, IFA, and hemagglutination inhibition; detect AB	Some drugs show promise. At present, no specific therapy. Treatment geared toward relieving symptoms. Some vaccines show promise (i.e., TC-84).
VHF	Clinical evaluation; key finding is vascular involvement (i.e., petechiae, bleeding, postural hypotension, edema, etc.)	<i>General</i> : Leukopenia, thrombocytopenia; elevated AST <i>Serology</i> : ELISA, IFA, and PCR; detect different VHF	Management of hypotension and fluid loss. Aggressive supportive care needed. Ribavirin and immune globulin therapy show some promise. Several vaccines under development.

AB, Antibody; AG, antigen; AST, aspartate aminotransferase; CSF, cerebrospinal fluid; ELISA, enzyme-linked immunosorbent assay; FA, fluorescent antibody; IFA, indirect fluorescent antibody; PCR, polymerase chain reaction; VEE, Venezuelan equine encephalitis; VHF, viral hemorrhagic fever, VIG, vaccinia immune globulin.

TABLE 13-6

Bacillus anthracis: Level A Laboratory Role

Presumptively identify based on criteria below, and then submit culture to a Level B or C laboratory for final identification.

Direct smears	Samples such as blood, CSF, and skin (eschar) show encapsulated gram-positive rods, single or in chains. Generally, spores not seen.
Culture smears	Large gram-positive bacilli (1–1.5 by 3–5 µm), which may be gram-variable after 72 hours; spores can be found in culture, especially under non-CO ₂ atmosphere but are nonswollen and are terminal or subterminal.
Colonies on sheep blood agar plates	Rapidly growing 2–5 mm (overnight at 35° C), nonhemolytic, nonpigmented, dry “ground-glass” surface colonies with irregular edges having comma-shaped projections (Medusa head). The colony has a sticky (tenacious) consistency when teased with a loop.
Other criteria	Nonmotile, catalase-positive, urease-negative, nitrate-positive, encapsulated bacillus that can be lysed by gamma phage (gamma phage typing is usually performed by Level B or C laboratory).

CO₂, Carbon dioxide; CSF, cerebrospinal fluid.

Practical Considerations

- Hand washing is the single most important protective measure. Spores are effectively removed with soap and water.
- Any article suspected of being contaminated with spores should be sanitized with a 1:10 dilution of household bleach. Let bleach remain in contact for at least 30 minutes before rinsing. If heavy spore contamination is suspected, use concentrated bleach to decontaminate the article.
- N95 respirator masks are protective against spore aerosols.
- Any cut, scratch, or abrasion should be covered with a dressing that has been coated with 1% tincture of iodine. If the cut or abrasion is not too extensive, apply tincture of iodine to its surface. Iodine is an outstanding antiseptic and can be sporicidal. No contusion is too small to warrant attention.
- Homes that have central air conditioning fitted with high-efficiency particulate air (HEPA) will remove more than 99.97% of particles 0.3 microns or larger. Because anthrax spores tend to clump, they will be efficiently trapped by HEPA filters. Alternatively, an air purifier outfitted with a HEPA filter will serve to keep a “safe-room” free of spores.

Plague

(Table 13-7)

History and Background

“Black Death” or the “plague” that befell Europe in the 14th century killed more than 25 million people, or about 25% of the population. This period is called the “second” pandemic. The first of three pandemics started in 541 AD and continued through to the 8th century, with an estimated 40 million deaths. The third and last pandemic began in China in the 1860s and spread to Africa, Europe, and the Americas. The plague is a zoonotic disease that primarily infects rodents and is caused by the bacterium *Yersinia pestis*, transmitted by a rat flea (*Xenopsylla cheopis*, the oriental flea, or *Pulex irritans*, the human flea). In the past, human epidemics originated by contact with fleas of infected rodents. The great plagues spread from rats to man in crowded unsanitary urban areas. Man is only accidental to the usual cycle: rodent–flea–rodent. In the United States, most naturally occurring human cases of plague (about 12/year) are concentrated in the Southwest and Pacific states (Perry, 1997; Tierno, 2002).

In a biowarfare scenario, the plague bacillus could be delivered by contaminated fleas as vectors causing the bubonic plague, or could more likely be spread by an aerosol that would cause pneumonic plague. In

nature, a rat flea regurgitates the bacterium upon biting its host. Cats are also susceptible and can transmit the pneumonic plague to humans. Unlike anthrax, which cannot be transmitted person-to-person, pneumonic plague can be transmitted via large aerosol droplets from a coughing patient.

Yersinia pestis can be killed by polymorphonuclear cells, but they can survive in monocytes, where they produce a capsule to resist phagocytosis. These bacteria can then rapidly reach the lymph system and bloodstream and be disseminated to all organs, causing hemorrhage and necrosis.

Fewer than 100 organisms are necessary to cause human infection. Studies have shown that the bacterium can remain alive for up to 1 year in soil and up to 270 days in live tissue. The bacterium is killed after heat exposure (15 minutes at 72° C/160° F) and within several hours of exposure to sunlight (Tierno, 2002).

Clinical Features

Plague occurs in three clinical forms: Bubonic, characterized by swelling of the lymph nodes (buboes); pneumonic, in which the lungs are extensively involved; and septicemic, in which the bloodstream is infected with *Yersinia pestis*. The mortality rate of untreated pneumonic plague is 100%, and that of untreated bubonic plague is about 50%.

Bubonic Plague. The incubation period of 2–10 days is characterized by malaise, high fever, and tender lymph nodes (buboes) that enlarge and eventually necrose. Septicemia may occur, and bacteria can spread to the central nervous system, the lungs (this produces the pneumonic disease, which can then be spread person-to-person), and the rest of the body, eventually causing death.

Pneumonic Plague. The 1 to 3 day incubation period is shorter than that of bubonic plague. Symptoms include high fever, cough, chest pain, and bloody sputum; pneumonia can lead to respiratory and circulatory collapse (Perry, 1997).

Practical Considerations

- Pneumonic plague patients transmit infection through large particle droplets (greater than 5 microns) generated by coughing, talking, or sneezing. A simple surgical-type mask can protect workers or family members. “Droplet Precautions” should be maintained for 3 complete days of antibiotic therapy, after which a person is no longer contagious.
- Because “droplets” occur only within 3–5 feet of a patient, central air conditioning systems do not need to be fitted with HEPA filters (i.e., they do not need to provide bacteria- and particle-free air).
- If an outbreak occurs, it is important to control fleas, rats, and other animals such as cats. Insecticides and repellents are widely available.
- Hand washing is an essential prevention strategy.
- Because *Y. pestis* does not have a spore form, surfaces can be decontaminated with a simple germicide such as 10% bleach solution. Skin can be decontaminated by using any germicidal soap product. Alcohol-based hand sanitizers such as Purell can also be effective.
- Clothing should be washed with a germicidal detergent and hot water (155° F), even though exposure is unlikely to occur from re-aerosolization of bacteria from contaminated clothing.
- Stand clear (farther than 3–5 feet) of individuals taking a coughing fit or producing sputum with or without blood.

Brucellosis

(Table 13-8)

History and Background

Brucellosis is a systemic zoonotic disease caused by *Brucella melitensis*, *B. suis*, *B. abortus*, and *B. canis*. These bacteria ordinarily cause disease in domestic animals, such as goats, sheep, and camels (*B. melitensis*); cattle (*B. abortus*); and pigs (*B. suis*). The primary pathogen of dogs, *B. canis* rarely causes disease in humans. Natural infection in humans occurs when bacteria are inhaled as aerosols, ingested in raw unpasteurized infected milk or meat, or introduced into abrasions in skin or through contact with conjunctival surfaces. Human disease is called undulant fever, Malta fever, Bang's disease, Gibraltar fever, and Mediterranean fever and occurs worldwide. In developed countries, human infection is associated with the meat packing and dairy industries. Several studies report that human brucellosis is underdiagnosed and under-reported. By some estimates, 25–30 cases go unrecognized for every reported case. As a biological warfare agent, brucellae would likely be delivered via the aerosol route. Brucellae are intracellular bacteria; they are able to survive phagocytosis and thus can

TABLE 13-7

Yersinia pestis: Level A Laboratory Role

Presumptively identify based on criteria below, and then submit culture to a Level B or C laboratory for final identification.

Direct smears	More likely to see bipolar staining (“safety pin”) from clinical specimens (blood, sputum, aspirates, etc.) than from cultures. Bipolarity is better seen using Wayson or Wright-Giemsa stain. Beware that bipolar staining is not always observed and is not unique to <i>Y. pestis</i> .
Culture smears	Plump gram-negative rods (1–2 by 0.5 µm), single or in short chains.
Colonies on sheep blood agar plates	Grow at 35° C (faster at room temperature) as gray-white, nonhemolytic, translucent, pinpoint colonies at 24 hours, but by 48 hours, colonies are 1–2 mm in diameter, becoming yellowish with age. Growth occurs with or without carbon dioxide. Colonies can appear as “fried egg” or with “hammered copper” shiny surface. On MacConkey, grow as pinpoint non-lactose-fermenting colonies after 24 hours; slightly larger at 48 hours.
Other criteria	The bacterium is nonmotile at 35° C to 37° C and at room temperature (<i>Y. pestis</i> is the only <i>Yersinia</i> that is nonmotile at room temperature). It is oxidase and urease negative and catalase positive; growth in broth is flocculent and is described as “stalactite”; clumps at side and bottom of tube.

TABLE 13-8

***Brucella* species: Level A Laboratory Role**

Presumptively identify based on criteria below, and then submit culture to a Level B or C laboratory for final identification and/or confirmation, although most Level A laboratories are able to completely identify *Brucella*.

Direct smears	Blood and/or bone marrow most often submitted. <i>Brucella</i> appears as faintly staining, small gram-negative coccobacilli (0.5–0.7 by 0.6–1.5 μm), mostly seen as single cells appearing like “fine sand.”
Culture smears	Similar to above.
Colonies on sheep blood (SBA) and chocolate (CA) agars	Usually not visible or are pinpoint at 24 hours; at 48 hours, colonies are tiny, nonpigmented, and smooth with an entire edge, and are nonhemolytic on SBA. Growth of some strains is enhanced by carbon dioxide tension. Some strains grow on MacConkey; Thayer-Martin can be used as a selective medium. Blood cultures are held for 21 days for suspect cases.
Other criteria	These coccobacilli are catalase, urease, and oxidase positive (<i>B. canis</i> is variable). They are nonmotile and do not require X and V factors. Brucellosis is one of the most commonly reported laboratory-acquired infections. Automated systems are not useful, nor are they recommended for identification. Remember that sniffing culture plates of <i>Brucella</i> can result in infection.

TABLE 13-9

***Francisella tularensis*: Level A Laboratory Role**

Presumptively identify based on criteria below, and then submit culture to a Level B or C laboratory for final identification.

Direct smears	Gram stain of blood, biopsy material, scrapings, or aspirates may be difficult to interpret because bacteria are tiny, pleomorphic, poorly staining gram-negative coccobacilli seen mostly as single cells.
Culture smear	Very tiny (0.2–0.5 by 0.7–1.0 μm), poorly staining, pleomorphic, gram-negative coccobacilli. They are smaller than <i>Haemophilus influenzae</i> and <i>Brucella</i> spp. Their minuscule size should raise awareness.
Colonies on sheep blood (SBA), chocolate (CA), and blood cysteine (BCA) agars	Grow poorly and slowly on SBA as 1–2 mm gray-white, nonhemolytic colonies after 48–72 hours. On CA and BCA, colonies are slightly larger, 1–3 mm, gray-white to bluish-gray with an entire edge and smooth flat surface. Colonies do not subculture well to SBA (viability is usually lost). Subcultures should be made onto CA, BCA, or Thayer-Martin agar. Carbon dioxide is not required for growth. No growth occurs on MacConkey or eosin methylene blue agar.
Other criteria	<i>F. tularensis</i> is nonmotile and oxidase and urease negative; catalase can be weakly positive or negative. X and V factors are not required. Slow growth in thioglycollate broth with a dense band near top, which eventually diffuses downward with time.

be carried from lymph tissue to blood and deposited in numerous organs. Inside the phagocytes, the bacteria grow, and eventually their host cells are killed, and a new crop of bacteria is released. The “undulant” fever pattern observed with this disease corresponds to the release of bacteria into the blood, thereby causing fever. As these bacteria are eliminated, the fever subsides, only to recur when another crop of bacteria is released. Relapses are common. *Brucella* species have two morphologically different colony types: smooth and rough. The smooth form is more pathogenic

because of the presence of a capsule that protects the bacterium from phagocytosis and destruction. *B. melitensis* and *B. suis* are more virulent than the other two species and have better intracellular survival. On the other hand, *B. abortus* and *B. canis* have an insidious onset but cause milder disease and fewer complications (Shapiro, 1998, 1999; Tierno, 2002).

Clinical Features

The incubation period can be 1–8 weeks but is usually 3–4 weeks. Onset is insidious, with malaise, fever, chills, sweats, headache, fatigue, myalgias, and arthralgias. Fever usually rises in the afternoon; it falls during the night and is accompanied by drenching sweat. Swollen lymph, spleen, and liver may also be present. The undulant fever can occur over weeks, months, or even years. Yet, there are many days when a patient has no fever and feels relatively well, only to experience another cycle of waxing and waning fever. Patients are often diagnosed with a fever of unknown origin. Cough occurs in about 20% of cases, but the radiograph appears normal. Mortality rate is about 6% for *B. melitensis* but 1% for the other species. Most deaths are associated with endocarditis or meningitis. Gastrointestinal symptoms occur in up to 70% of adult cases, although less frequently in children.

Practical Considerations

- Although *Brucella* species have a long incubation period and a slow onset, the characteristic undulant fever syndrome helps make a diagnosis, so that treatment can start.
- *Brucella* has such a low fatality rate (especially with proper antibiotic therapy) that it is not a very effective biological weapon.
- Brucellosis cannot be transmitted person-to-person, so that patient isolation is not required. However, contact precautions are indicated if a draining lesion is present.
- *Brucella* species have no spore form, so they are readily killed with any common germicide. Pasteurization (at 155° F) kills bacteria in contaminated food.
- Brucellosis is contracted through eye contact (i.e., rubbing or touching your eyes), so hand washing with germicidal soap or alcohol-based hand sanitizers is an important protective strategy.

Tularemia

(Table 13-9)

History and Background

The causative agent of tularemia (also known as “rabbit fever”) is *Francisella tularensis*. These bacteria are gram-negative bacilli that are nonmotile and have no spore form. Humans acquire this zoonotic disease through contact with animals, usually through the inoculation of skin or their mucous membranes with blood or tissue fluids of infected animals or bites from infected ticks, mosquitoes, or flies. A less common method of acquiring infection is through inhalation of contaminated dusts or ingestion of contaminated foods or water. A bioterrorist would likely use an aerosol to deliver *Francisella* because it causes typhoidal (systemic) tularemia, a disease with a >10% fatality rate.

Because the bacterium is highly contagious, as few as 25 inhaled organisms or as few as 10 organisms administered subcutaneously can cause infection. The smallest break in the skin can serve as a portal of entry. The bacterium is so contagious that numerous cases of tularemia have resulted from laboratory accidents during processing of infected clinical or research samples. *Francisella* is distributed worldwide. In the United States, the disease has been reported primarily in Southern and South Central states.

F. tularensis produces a capsule that allows the organism to avoid immediate destruction by the body’s phagocytes. It can survive as an intracellular parasite within cells of the lymph system.

Clinical Features

Six major syndromes are associated with tularemia; they differ by mode of infection.

1. *Ulceroglandular tularemia* (70%–85% of cases) typically presents with a skin ulcer, usually as the result of a tick bite, and swollen lymph nodes, fever, chills, headache, sweating, and coughing.
2. *Glandular tularemia* (5%–12% of cases) is characterized by fever and swollen lymph nodes but no obvious skin lesion.
3. *Typhoidal tularemia* (7%–14% cases) presents with acute onset of fever, chills, headache, vomiting, and diarrhea. Usually no skin lesions or swollen lymph nodes are present, but the condition is associated with primary or secondary pneumonia. This form has the highest mortality rate and is the most likely bioterror form.

TABLE 13-10

Botulinum Toxin Exposure: Level A Laboratory Role

Submit specimens immediately to public health laboratory for evaluation and referral, even if criminal activity is not suspected. Level A laboratories should not manipulate specimens, culture, identify, or perform toxin assays. Level A laboratory responsibility is limited to advising the medical staff on specimen selection, packing, shipping, and notifying the recipient laboratory about specimens from a suspected case.

	Specimen	Transport
Suspect food samples	25–50 g of food should be submitted in original containers that have been placed in a leakproof sealed system.	4° C
Nasal swabs	If aerosolized release is suspected, collect nasal swabs for toxin testing and/or polymerase chain reaction analysis.	Room temperature
Stool, enema fluid	Collect 25–50 g of stool into sterile leakproof containers.	4° C
Serum	Collect approximately 10 mL for serologic assays.	4° C
Other	Collect environmental and/or other samples on swabs.	4° C

Note: Level A laboratory responsibility for other suspected toxins such as staphylococcal toxins, mycotoxin, saxitoxin, ricin, etc., should be treated in a similar manner.

4. *Oculoglandular tularemia* (1%–2% cases) presents with severe conjunctivitis and swollen lymph nodes, usually as the result of self-inoculating the organism into the conjunctivae.
5. *Oropharyngeal tularemia* occurs in patients who have a primary lesion in the oropharynx. Patients present with severe headache and bilateral tonsillitis or severe streptococcal-type sore throat. Persistent swollen lymph nodes in the neck appear after 1–2 weeks.
6. *Pneumonic tularemia* (8%–13% cases) is primarily a complication of the other forms, especially typhoidal tularemia. It is also acquired by inhaling of infectious aerosols or as a result of blood-borne dissemination. Lymph nodes in the lungs are enlarged. Sometimes, the pneumonia is not evident (Wong, 1999).

In all tularemia syndromes, lymph nodes may remain enlarged for a long time and eventually may become necrotic and drain. Fever (usually low grade) is accompanied by malaise, headache, and pain in the regional lymph nodes.

Practical Considerations

- Hand washing with germicidal soap or alcohol-based hand sanitizers is the most important protective strategy. Any aerosolized bioterror attack would contaminate the surrounding environment and could lead to secondary exposure through direct contact with skin and mucous membranes. Simple germicides, such as bleach, destroy the bacterium on contaminated surfaces.
- Because there are no spore forms, only vegetative ones, bacteria are easily killed by heat (30 minutes at 145° F). The relatively low fatality rate does not make it a very effective biological weapon. Infected patients rapidly improve on adequate (10–14 days) antibiotic therapy.
- Because tularemia can be transmitted by contact with household pets such as cats and dogs, it is important to observe any changing habits and the health status of pets. They can be the sentinel event to warn you of an impending disaster, much like the “canary in the mine.”
- *Francisella* is rarely transmitted by food or water; nevertheless, it is important to be alert to that possibility. Cooking food renders the bacterium harmless, as does filtering or heating water.

Botulinum Toxins

(Table 13-10)

History and Background

Clostridia are anaerobic, gram-positive, spore-forming bacilli that elaborate toxins. The most pathogenic species are *Clostridium perfringens* (agent of gas gangrene), *C. tetani* (agent of tetanus), and *C. botulinum* (agent of botulism). The aforementioned diseases are the result of exposure to the protein toxins that the bacteria produce, the most powerful of which is the

botulinum toxin. Seven *C. botulinum* toxins are known: A, B, C, D, E, F, and G. Human illness is caused by four of the seven toxins: types A, B, E, and F. The toxins bind to synaptic vesicles of cholinergic nerves, preventing release of acetylcholinesterase at peripheral nerve endings (including neuromuscular junctions). Patients develop acute flaccid descending paralysis. By blocking neurotransmission, the toxins cause palsies and skeletal muscle weakness, which are common clinical features. *C. botulinum* toxins are among the most toxic substances known to man. A lethal human dose is only one-millionth of a gram (Tierno, 2002; Angulo, 1998).

Several forms of botulism occur in humans. The classic type is food-borne botulism, which typically occurs in adults and is caused by ingestion of toxins present in contaminated food. *C. botulinum* grows in food and produces its toxin. The usual foods involved are canned alkaline foods that are eaten without cooking, and smoked and vacuum-packed foods. Under anaerobic conditions, *C. botulinum* spores grow into vegetative forms that produce toxin. Wound botulism, the rarest form, occurs when bacteria gain access to a wound site and then produce toxins in vivo. Infant botulism, the most common type, occurs when a child consumes food contaminated with *C. botulinum* rather than consuming pre-formed toxins. Toxin is produced in the infant's gut, de novo, and poisons from within. Some botulism patients do not have an obvious food or wound source; they fall into the “classification undetermined” group.

As a bioterror weapon, botulinum toxin may be purified from large stores of toxin-producing *C. botulinum*. It then can be delivered as an aerosol that causes symptoms like those of food-borne botulism. Another approach might be to sabotage food supplies with toxin, although the latter is not an efficient delivery system (USAMRIID, 2001; Tierno, 2002). We know that botulinum toxins can be weaponized because the Iraqi government admitted to a United Nations inspection team in August 1991 that it had done research on these toxins before the Persian Gulf War. It is possible to weaponize any of the seven known botulinum toxins because they all would have the same effect.

Clinical Features

Symptoms usually begin 18–24 hours after ingestion or inhalation of toxin, although this may take several days. Initial symptoms include double vision, lack of coordination of eye muscles, inability to swallow, speech difficulty, generalized weakness, and dizziness. These are followed by descending progressive weakness of the extremities and weakness of the respiratory muscles. No fever is present, and the patient may be totally alert and oriented. Neurologic examination shows flaccid muscle weakness of the tongue, larynx, respiratory muscles, and extremities. A patient remains fully conscious until shortly before death from respiratory paralysis or cardiac arrest. Mortality rate is high. Patients who recover do not develop antitoxin in the blood. Suppression of antibody production is probably caused by the toxins, in much the same way that toxic shock syndrome toxin-1 produced by *Staphylococcus aureus* prevents antibody production. In infants, signs of paralysis are called “floppy baby” syndrome (Tierno, 2002).

Practical Considerations

- Antitoxins and vaccines are available for treatment and prophylaxis.
- Botulinum toxin is *less* toxic and lethal when delivered by inhalation than by a food-borne assault.
- Soap and water can be very effective at removing most toxins from skin, clothing, and equipment, so that decontamination of a toxin is *not* as critical as decontamination of an infectious microbe. A very mild bleach solution (1 part bleach in 9 parts water) effectively inactivates most protein toxins.
- A protective N95 mask if worn properly is effective against toxin aerosols. However, it is important that a tight fit is achieved because even a small leak could result in significant exposure. Bearded individuals would not be able to achieve a tight fit but nevertheless would reduce their exposure with a mask.
- Because botulinum toxin does not permeate the skin, special protective clothing is not as important as it would be for other agents, including chemical attacks.

Smallpox

(Table 13-11)

History and Background

Smallpox has the distinct honor of being the greatest single killer in recorded history; it is estimated that this virus has killed about 500 million people.

The smallpox virus, a.k.a. variola, is a member of the Orthopoxvirus group of viruses. Two variants of smallpox are known: variola major, which is associated with a higher mortality rate of 15%–40%, and variola minor, which causes a milder disease and is associated with a mortality rate of only 1%. Smallpox is the human type of poxvirus. Other poxviruses naturally infect animals but also can cause incidental infection in humans (zoonoses). These viruses share common antigens with smallpox, thus allowing them to be used as vaccines for humans. Thus, vaccinia virus has been the historically chosen animal virus for vaccine production. As the incidence of smallpox has waned, more complications related to the vaccinations have occurred than smallpox cases. Some of these complications were severe and included encephalitis and fatal reactions in immunocompromised patients who were vaccinated, sometimes inadvertently. Vaccinia viruses spread easily among unvaccinated immunocompromised patients in close contact. This still would be the case if a massive national vaccination program were to be considered. A large group of immunocompromised patients simply would not be candidates for the vaccine (Tierno, 2002).

In 1967, the World Health Organization introduced a worldwide campaign to eradicate smallpox. At the time, 33 countries had endemic smallpox, and about 15 million cases were reported per year. By 1979, smallpox was eradicated. Smallpox virus currently exists in only two laboratories: one in the United States and the other in Russia. The fate of these remaining stocks is debated. Destroying the stocks will preclude further research in the event of an outbreak. Similar to the plague, smallpox is very contagious from man to man. It is currently assumed that an aerosol infective dose is low and presumably ranges from 10–100 organisms (Tierno, 2002).

How would smallpox be weaponized? Smallpox can be spread in two ways: aerosol dispersal and contact. Because smallpox is highly contagious

and is efficiently spread through air, an aerosol delivery system poses the greatest threat and exposes the greatest number of people. However, as learned with anthrax, this is not so easy to do. Smallpox can also be delivered by direct contact. One way would be to self-contaminate a group of volunteers, who would then interact with the general population, infecting people over days or weeks as they came in contact with them. If a smallpox outbreak is detected in an area, the CDC and other health authorities would be able to contain the outbreak by immediately vaccinating all individuals surrounding the index case or cases. Postexposure immunization with smallpox vaccine (vaccinia virus) is effective and is recommended if given within 3 days of exposure. However, even if more than 3 days elapse, vaccination and vaccinia immune globulin may provide protection. It is necessary to establish a ring of immunity around index cases. This is precisely the method used to eradicate smallpox worldwide and should be just cause for some optimism.

Clinical Features

The entry portal for smallpox virus is the mucous membranes of the upper respiratory tract. Smallpox is transmitted by large or small respiratory droplets, and by contact with skin lesions or secretions. Patients are considered more infectious if they are actively coughing. The incubation period is typically 12 days, with a range of 10–12 days. Clinical illness begins with a 2 to 3 day period of vague symptoms such as malaise, fever, headache, chills, and backache. The fever can last as long as 5 days or may be as short as 1 day. After the fever, an exanthem (eruption of skin or rash) appears that undergoes papular, pustular, and crustular stages. The latter falls off 2–4 weeks after the initial lesion and leaves a pink scar. An important characteristic of smallpox is that lesions in affected areas appear in the same state. This differs from chickenpox, where lesions are not synchronous and occur in crops. Smallpox lesions are distributed centrifugally (more numerous on the face and extremities than on the trunk), unlike chickenpox. Hence, the smallpox exanthem is very characteristic and is a useful diagnostic tool. The fatality rate is 15%–40% in unvaccinated patients and <1% in those vaccinated.

Patients with smallpox are infectious as soon as a rash occurs and remain infectious until scabs fall off, approximately 3 weeks later. A rare form of smallpox called “hemorrhagic variola” is very pathogenic and has a very high mortality rate.

Practical Considerations

- If a major outbreak of smallpox occurs, prepare to stay indoors for a few days or weeks to reduce contact with those contaminated; this will contain the epidemic. Households should be stocked with adequate food supplies.
- Generally, respiratory droplets become infectious earlier than skin lesions. In hospitals, both airborne and contact precautions are required to prevent contagion. In contrast to plague precautions, a simple surgical mask is insufficient protection. A special respirator mask, N95 (certified to have at least 95% filter efficiency), is recommended and must be worn for such protection. Smallpox patients should be quarantined from the time the rash first appears until the scab finally falls off (about 3 weeks).
- If a household member contracts smallpox, all clothing, bed linens, or other materials that contacted the patient must be decontaminated with a germicide such as a 1:10 bleach solution, steam, or heat.
- Hand washing with germicidal soap is essential after any contact with a smallpox patient or his or her environment.

TABLE 13-11

Smallpox: Level A Laboratory Role

Smallpox is highest-level emergency; submit specimens immediately to public health laboratory. Virus is highly infectious; avoid manipulation; if necessary use Biological Safety Level-3 practices. Responsibility of Level A laboratories is limited to advising medical staff on specimen selection, packing and shipping sample, and communicating with reference laboratory. Level A laboratories should not culture, sample, or perform assays on specimens suspected of containing the virus. Clinical diagnosis is confirmed by Level D laboratory techniques.

	Specimen	Transport	Storage
Biopsy	Aseptically place two to four portions of tissue into sterile, leakproof, freezable container.	≤6 hours/4° C	–20° C to –70° C
Scabs	Aseptically place scrapings/material into sterile, leakproof freezable container.	≤6 hours/4° C	–20° C to –70° C
Vesicular fluid	Collect fluid from separate lesions onto separate sterile swabs. Always include material from base of each vesicle.	≤6 hours/4° C	–20° C to –70° C

TABLE 13-12

VEE or Other Encephalitides: Level A Laboratory Role

Submit samples immediately to public health laboratory for evaluation and referral. Level A laboratory responsibility is limited to advising medical staff on specimen selection, packing and shipping sample, and communicating with reference laboratory.

	Specimen	Transport	Storage
Serum	For culture, PCR, or serologies (ELISA, FA, etc.)	<6 hours/4° C	–20° C to –70° C
CSF	For culture, PCR, or serologies	<6 hours/4° C	–20° C to –70° C
Nasal, respiratory (including induced samples)	For culture and PCR	<6 hours/4° C	–20° C to –70° C
Other	Biopsy, autopsy, stool, etc., for pathology, culture, hematology/chemistry analysis, etc.	<6 hours/4° C	–20° C to –70° C

CSF, Cerebrospinal fluid; ELISA, enzyme-linked immunosorbent assay; FA, fluorescent antibody (direct); PCR, polymerase chain reaction; VEE, Venezuelan equine encephalitis.

Venezuelan Equine Encephalitis

(Table 13-12)

History and Background

Venezuelan equine encephalitis (VEE) is clinically indistinguishable from other encephalitis viruses such as St Louis encephalitis, Eastern and Western equine encephalitis, Japanese B-type encephalitis, Russian Far East encephalitis, and even West Nile encephalitis virus. The first question to consider is why other such agents are not high on the list as potential bioterror weapons. Many can be, but the attack rate, that is, the number of people who would probably get the disease after being exposed to the agent, is much lower than for VEE. VEE has an attack rate of about 100% (pretty hard to beat). This is precisely the reason the U.S. government weaponized it in the 1950s and 1960s before terminating its offensive biowarfare program. However, it remains a potential weapon and one likely to serve as a surrogate virus to deliver more pathogens. Nevertheless, Level A laboratory responsibility is similar for all encephalitis viruses such as VEE (USAMRIID, 2001; Tierno, 2002). VEE can be weaponized in liquid or dry form for aerosol dispersal. It can be transmitted in three ways: (1) via mosquitoes, although the naturally occurring incidence of VEE is low; (2) via aerosol, either liquid or dry form; and (3) via secondary spread from person to person (although this has not yet been conclusively demonstrated).

In nature, VEE is a mosquito-borne viral disease that is neurotrophic, causing encephalitis in equine animals and an unremarkable febrile illness in humans. More than 50% of equines that become infected develop encephalitis, and among humans, almost 100% of those exposed develop an influenza-like illness. In naturally contracted disease, only 2%–4% of patients develop signs of central nervous system involvement, and less than 1% die (Tierno, 2002).

In the United States, VEE is a rare disease. The disease was first reported in Venezuela in 1936. VEE is prevalent in South and Central America, Trinidad, Mexico, and Panama. In the case of the West Nile encephalitis virus, a sentinel animal (birds) indicated the presence of disease before human infection occurred. In the case of VEE, that would have been horses, but because we vaccinate them, no sentinel animal system is available to warn us that a VEE virus attack has occurred. On the other hand, because we have eradicated VEE from the United States, any human with the disease would likely signal bioterrorism (Tierno, 2002).

VEE is an arthropod-borne alphavirus that has been incidentally associated with human disease. Eight serologically distinct viruses exist, but only two are important pathogens for humans: variants A/B and C (Tierno, 2002). Most encephalitis viruses are destroyed by heat and are easily killed by ordinary disinfectants.

Clinical Features

The incubation period is 1–5 days, after which there is rapid onset of fever (usually high), headache, dizziness, lethargy, depression, anorexia, chills, myalgia, photophobia, nausea, vomiting, cough, sore throat, and sometimes diarrhea. VEE is indistinguishable from other viruses that cause encephalitis. The acute phase of the disease lasts from 1–3 days and is followed by a prolonged period (up to 2 weeks) of lethargy. Full recovery usually occurs after 2 weeks. It is estimated that inoculation with 10–100 viruses can cause infection. In a naturally occurring epidemic, <5% of patients have a neurologic manifestation, one characterized by convulsions, coma, and paralysis.

Practical Considerations

- VEE has very low lethality and in most victims might manifest only as a flu-like disease. *Note:* Bioterrorists may use any encephalitis virus as a surrogate for a more pathogenic weapon via genetic engineering.
- If an outbreak occurs, the mosquito population must be controlled, similar to the approach used for West Nile virus.
- Hand washing can prevent the otherwise rare person-to-person transmission (via contact spread).
- Simple germicides such as a 10% bleach solution or Lysol and heat (165° F) easily destroy the VEE virus.
- Contaminated clothing can be washed with any detergent.

Crimean Congo and Other Hemorrhagic Fevers

(Table 13-13)

History and Background

Crimean Congo hemorrhagic fever (CCHF) is only one of many illnesses referred to as viral hemorrhagic fevers (VHFs). These agents and their

TABLE 13-13

Crimean Congo and Other Hemorrhagic Fevers: Level A Laboratory Role

Submit samples immediately to public health laboratory for evaluation and referral. Some viruses are highly infectious; avoid manipulation; if necessary, use Biological Safety Level-3 practices. Level A laboratory responsibility is limited to advising medical staff on specimen selection, packing and shipping sample, and communicating with reference laboratory.

	Specimen	Transport	Storage
Serum	For culture, PCR, or serologies (ELISA, HI, FA, etc.)	<6 hours/4° C	–20° C to –70° C
Other	Biopsy, autopsy, etc., for pathology, culture, hematology/chemistry analysis, etc.	<6 hours/4° C	–20° C to –70° C

ELISA, Enzyme-linked immunosorbent assay; FA, fluorescent antibody (direct); HI, hemagglutination inhibition; PCR, polymerase chain reaction.

TABLE 13-14

Viral Hemorrhagic Fever Means of Transmission

VHF agent	Natural means of transmission
Ebola	Contact
Marburg	Contact
Lassa fever	Contact
Argentine (Junin)	Contact and aerosol
Bolivian (Machupo)	Contact and aerosol
Crimean Congo	Ticks and contact
Hantavirus	Contact and aerosol
Rift Valley fever	Mosquito and aerosol
Dengue	Mosquito
Yellow fever	Mosquito

natural mode of transmission are listed in Table 13-14. Any one of these hemorrhagic viruses, except dengue (which is transmissible only via mosquito), can be weaponized via aerosol delivery (USAMRIID, 2001; Tierno, 2002). In general, VHFs are very difficult to weaponize because there is no real carrier state.

CCHF is transmitted by ticks. Several reports describe person-to-person spread of CCHF in hospitals. As few as 1–10 viral particles can cause infection (USAMRIID, 2001). Rift Valley fever (RVF) is transmitted by mosquitoes as well as by aerosols; an inactivated vaccine is available for prevention, and RVF virus is susceptible to the antiviral drug ribavirin. The Ebola and Marburg viruses are transmitted by direct contact with blood, secretions, organs, or semen of infected patients. Argentine, Bolivian, and Hantavirus hemorrhagic fevers are also spread by dried rodent excreta (USAMRIID, 2001).

Clinical Features

The general clinical syndrome associated with all of the aforementioned viruses is similar and is called “viral hemorrhagic fever,” or VHF. The most common presenting symptoms are fever, myalgia, low blood pressure, flushing, and ecchymoses anywhere on the body. Typically, the onset of CCHF occurs 3–12 days after tick exposure or inhalation of an aerosol. Extensive gastrointestinal bleeding and extensive ecchymoses may occur. Other symptoms include headache, back pain, nausea, vomiting, delirium, jaundice, and hepatomegaly. Mortality for CCHF is 15%–30%, but some hemorrhagic fevers, such as Ebola, can have a death rate near 90% (Tierno, 2002).

Practical Considerations

- Any individual who may have been exposed to blood, body fluids, secretions, or excretions from a patient with suspected VHF should immediately and thoroughly wash skin surfaces with soap and water; a shower is preferable.
- In hospitals, contact precautions should be instituted to prevent contagion. An N95 mask is recommended and should be worn for

protection. Infected patients should be quarantined for the duration of the illness.

- Anyone caring for (or visiting during convalescence) a patient who is stricken with VHF must practice strict “barrier nursing” techniques (in other words, must completely protect self from the infected patient by dressing in gown, gloves, mask, eye protection, hat, booties, etc.), because evidence indicates that large droplets or even fomites (inanimate objects) may act as mediators of virus transmission.
- Any contamination of mucous membranes must be immediately diluted with copious quantities of water. If contaminated, eyes can be irrigated with saline or products like Visine.
- Clorox (10% solution) can be used to decontaminate surfaces, equipment, or other articles.
- Deceased individuals should be sealed in leakproof material for prompt burial or cremation.
- Heavily soiled clothing should be discarded, or washed with bleach or a strong germicide-containing detergent.

CHEMICAL TERRORISM

HISTORY AND BACKGROUND

Chemical weapons were first used in modern warfare during World War I. On April 22, 1915, outside the Belgian village of Ypres, the German army released about 60 tons of chlorine gas from about 6000 pressurized gas cylinders into the winds, which carried clouds of chlorine gas over the Allied forces. A second attack using chlorine gas occurred 2 days later. The end result of both attacks was the grotesque choking death of approximately 10,000 troops. By the end of 1915, a more deadly gas agent, phosgene, was introduced by the Germans; it was 10 times more effective than chlorine. Both gases are considered chemical weapons that affect the lungs; thus they are called “pulmonary agents.” They damage the membranes that separate air sacs (alveoli) from capillary blood vessels. Fluid (plasma) leaks into the air sacs, accumulates, and prevents air exchange. The victim is usually unable to get enough oxygen and eventually suffocates to death after an agonizing 2- to 24-hour period. Victims initially have shortness of breath with coughing fits, which can be quite severe. The production of large amounts of yellowish (chlorine) to clear (phosgene) frothy sputum occurs before death. Significant irritation of the eyes and nose and burning in the throat are reported (Byrnes, 2003).

By the time the Germans introduced phosgene, they were becoming very proficient at producing chemical weapons of various types and were equally proficient at delivering them. Great Britain quickly followed in kind with the use of chemical weapons against the German army. Great skill was needed to deliver gas weapons because if wind direction changed, or if the weapon was inappropriately delivered, poison gas could fall on one’s own troops. This did happen often, especially during the early use of such chemical weapons. By the summer of 1917, the Germans introduced a new type of gas called mustard. Mustard gas is a chemical weapon that belongs to a group of agents called “blistering agents.” As the name implies, one of the symptoms is a blistering of the skin and internal organs. The skin, eyes, and lungs, the gastrointestinal tract, the mucous membranes, bone marrow, and other organs can be severely damaged.

These early weapons forced armies to defend themselves by using gas masks, as well as protective suits or outer coverings, both of which hampered efficient fighting on the battlefield. Nevertheless, by the end of the war, more than 110,000 tons of chemical weapons were used by both sides, and the number of casualties measured over a million, including about 100,000 dead.

The Geneva Protocol

Because of the agonizing deaths and horrendous suffering that were inflicted by chemical weapons during World War I, an effort was made to ban their use after the war. The League of Nations met at Geneva and developed a protocol to eliminate chemical weapons during warfare. The “Protocol for the Prohibition of the Use in War of Asphyxiating, Poisonous, or Other Gases, and of Bacteriological Methods of Warfare” was signed by 38 nations in 1925 (Byrnes, 2003), although it had many loopholes and no provision to punish nations that violate the pact. During World War II, it was surprising that no chemical weapons were used in battle, even though the Germans had developed new chemical weapons, “nerve agents,” including tabun, sarin, and soman. Nerve agents are a particularly potent class of chemical weapons that share some interesting properties. The mechanism of action of nerve agents such as sarin is that

they disrupt nerve communication with the organs that they stimulate. In other words, the nerve is normal, but transmission of the nerve impulse to the muscle or other organ is faulty, usually causing overactivity. This interferes with basic bodily functions, and death can occur as soon as 1–10 minutes after inhalation. If a nerve agent is in liquid form, it is characteristically heavier than water. The vapors are also heavier than air, and they therefore tend to sink toward the ground or the basement of a building. Although nerve agent vapor affects victims within a very short period of time, the range of these effects will vary greatly, depending upon the degree of exposure. Exposure to nerve agents will initially affect airways and the portions of the face that come into contact with the agent: the eyes, nose, and mouth. The pupils become small (pinpoint), the eyes redden, and vision becomes blurred. Some patients also experience eye pain, headache, and nausea and vomiting. Rhinorrhea may be an important feature, as is excessive salivation. If a nerve agent is inhaled, airways can become constricted, and coughing fits or shortness of breath may be induced. If a sufficient quantity of the agent is inhaled, sudden loss of consciousness may be followed by convulsions. Within a few minutes, a victim stops breathing and becomes flaccid. Even a very small amount of a nerve agent like sarin can produce fasciculations (muscular twitching). Nausea and vomiting may accompany exposure. In cases of greater exposure, involuntary defecation and urination may also occur (Byrnes, 2003).

Many new “nerve agent” chemical weapons were developed from ordinary insecticides and/or pesticides. (People actually use weaker forms of nerve agents every time they tend their garden with insecticides. For example, insecticides such as malathion or carbaryl [Sevin] and dozens of others are actually nerve agents. They do the exact same thing to humans that sarin or other more potent nerve agents do, although they require much larger doses and longer contact time to have a similar effect.) In the early 1950s, Great Britain made what was considered a breakthrough discovery of a new nerve agent that was magnitudes greater in its lethal abilities than any other known substance at the time. The agent was called by its code name—VX. This agent not only was more lethal but also was more persistent (because it remains a liquid for longer than 24 hours) and could enter the body by inhalation or directly via the skin. Entry through the skin was possible because this agent is nonvolatile and is persistent. The United States cooperated with Great Britain on this project, eventually taking over the large-scale production of agent VX. Production and stockpiling of VX continued into the 1960s, until an accidental release of VX occurred at the manufacturing facility in Dugway, Utah, killing more than 6000 sheep. Probably the most infamous U.S. chemical agent, used primarily during the Vietnam War in the 1960s, was Agent Orange, an herbicide used to defoliate vegetation that offered cover to the enemy. Agent Orange contained varying quantities of dioxin (tetrachlorodibenzo-dioxin), which was later considered to be so dangerous that the Environmental Protection Agency, in 1986, prohibited its use anywhere. Animal studies have linked the chemical to non-Hodgkin’s lymphomas, sarcomas, and carcinomas, as well as a host of other diseases (Byrnes, 2003).

Chemical weapons such as nerve agents and blistering agents are less convenient than toxins or poisons. For example, ricin is very convenient because it is a highly potent protein toxin derived from the mash left over from processing castor beans for their oil. Such processing is a worldwide activity, and the poison (toxin) is easily produced. The castor plant, *Ricinus communis*, received attention in the 1978 “umbrella murder case,” when Bulgarian intelligence operations assassinated Bulgarian dissident George Markov in London, using an umbrella to deliver a ricin-containing pellet (Tierno, 2002). Mr. Markov died a day after the attack of ricin poisoning. Ricin blocks protein synthesis and is very toxic to cells, eventually killing them. Ricin can be delivered by aerosol, and within 8 hours after inhalation, severe respiratory symptoms occur, leading to respiratory failure. If the toxin is ingested (food or water), severe gastrointestinal symptoms will occur, followed by vascular collapse and death. If injected, ricin can cause multiorgan failure and death (Tierno, 2002). Numerous other toxic poisons such as mycotoxins and saxitoxins produce similar outcomes.

The 1972 Convention on Prohibition of Biological and Chemical Weapons

Throughout recent decades, efforts have been made to limit or ban the use of toxic weapons (both chemical and biological). In 1972, more than 140 countries, including the United States, signed the “Convention on the Prohibition of the Development, Production, and Stockpiling of Biologic and Toxic Weapons and Their Destruction,” which theoretically limited further development and use of biological or chemical weapons (Byrnes, 2003). Unfortunately, numerous breaches have been made in that accord.

TABLE 13-15

Chemical Weapons

Category	Examples	Comments
Nerve agents	Sarin, tabun, soman, VX, malathion, carbaryl (Sevin)	Interfere with transmission of message from nerve to organ or muscle
Blood agents	Hydrogen cyanide, cyanogen chloride	Usually absorbed after inhalation; in the bloodstream cause lethal damage by acting on the cytochrome oxidase enzyme responsible for cellular respiration. Oxygen starvation occurs because cells are unable to use oxygen. (See Chapter 23.)
Blister agents	Nitrogen and sulfur mustards, lewisite	Cause blistering of skin as well as internal organs and tissues. This destroys the tissue and also causes massive numbers of mutations by crosslinking DNA and RNA.
Heavy metals	Arsenic	Metallic elements form poisonous compounds, disrupting cellular metabolic processes.
Pulmonary agents	Chlorine gas, phosgene	Damage the membranes of the lungs, causing fluid buildup and oxygen deprivation and eventually suffocation.
Dioxins	Tetrachlorodibenzodioxine	Associated with lymphomas, sarcomas, carcinomas, chloracne, and a host of other diseases. (A major long-term complication is type 2 diabetes.)
Incapacitating or psychotomimetic agents	Quinuclidinylbenzylate, phencyclidine	Cause pseudopsychotic disorders; affect ability to make decisions; cause disorientation, any of which could incapacitate an individual. Death due to respiratory arrest can occur with high doses.
Corrosive acids and bases	Sulfuric acid, sodium hydroxide	Cause severe burning and destruction of tissue in exposed areas.

To take two relatively recent examples of an ongoing trend, in 1988 Libya built a chemical weapons plant in the guise of a pharmaceutical factory. Often this occurs with the cooperation of companies that sell so-called dual-use technology to countries such as Iraq and Libya. A plant for making pesticides can readily be turned into one for making chemical weapons. Iraq used mustard gas in its long war with Iran and has used both mustard gas and toxic nerve agents against its own dissident Kurdish population. The 1980s saw the use of chemical warfare agents in Afghanistan, Cambodia, Iran, Iraq, and Laos (Tierno, 2002; Byrnes, 2003).

In March of 1995, a Japanese religious cult, Aum Shinrikyo, released sarin nerve gas in the Tokyo subway system (Tierno, 2002). Thousands were injured, and 11 people were killed. This recent use of chemical weapons on the civilian population underscores the relative availability and ease of use of such weapons and raises public and governmental awareness.

Weaponization and Delivery of Chemical Agents

Any chemical agent must be weaponized before its delivery. In general, the process of weaponization involves numerous steps. First, an agent must be made in sufficient quantity and temporarily stored and stabilized to prevent evaporation or degradation. Thickeners are added to increase the viscosity of liquid agents, and a carrier agent is required to improve dispersion of the chemical. Next, the chemical agent must be inserted into an appropriate delivery device such as explosive, pneumatic, or mechanical munitions or a dissemination device. Regardless of approach, the goal is to aerosolize the chemical agent to a particulate size of 1–7 microns. This can be accomplished by using very sophisticated delivery systems such as munitions devices usually only available to governments, or unsophisticated devices like aerosol generators, such as underarm deodorants or garden sprayers, which can serve as an effective dissemination system. The important caveat here is that these unsophisticated devices are readily available to the masses. Numerous other factors might affect the weaponization and delivery of a chemical weapon, such as the following:

- *Temperature (air and ground)*: Generally, higher temperatures cause faster evaporation.
- *Humidity*: High humidity may cause enlargement of particle size, reducing effectiveness.
- *Precipitation*: Heavy rain can dilute and disperse a chemical weapon; snow increases the persistence of a chemical weapon.
- *Wind speed*: Wind can disperse vapors, aerosols, and liquids, affecting the target area
- *Nature of buildings*: Buildings may absorb or adsorb agents; they can also offer protection.
- *Nature of terrain*: Woodlands and hills can create greater turbulence of low-lying clouds of the agent.

Categories of Chemical Weapons

Literally, hundreds of chemical agents and poisonous gases can be used in an attack, along with potentially new ones under development using newly described genetic engineering methods. Governmental agencies classify chemical weapons in various categories (Table 13-15).

ROLE OF LEVEL A LABORATORY: CHEMICAL TERRORISM

It goes without saying that timely detection of the relatively quick-acting chemical agents that a terrorist might use, such as nerve agents (i.e., sarin and VX), is critical not only for the patient (casualty) but also for the first responder or hazardous material (HAZMAT) unit member responding to an event. Rapid detection of the type of agent, as well as its concentration after a terror incident, can allow for effective treatment of the victim, including proper antidote selection, and can allow for an appropriate protective response to ensure the safety of the public at large. As such, it may be obvious, but the most appropriate entity to detect such agents is not the clinical laboratory; instead, it is the bailiwick of the first responder unit or HAZMAT team. These teams use a wide variety of commercially available equipment manufactured for the rapid detection of hazardous chemicals, including the agents of chemical terrorism. Likewise, the military has provided a number of devices that can be used to detect such chemical agents or their vapors. The most portable chemical vapor detector is the chemical agent monitor. It uses ion mobility spectroscopy to detect nerve, blister, and blood agents. The simplest and most rapid liquid detectors are also products of the military, namely, the M8 and M9 papers that can be used to detect mustard or nerve agents. These are mostly rapid screening devices that may show false-positive reactions (Byrnes, 2003). However, colorimetric tubes are the most common detection technology used by HAZMAT teams. Their analytic capabilities are broad and usually include tests for chlorine and phosgene gas (pulmonary agents), cyanide (blood agents), and organophosphates (nerve agents). In addition, HAZMAT teams possess a wide variety of some newer post-9/11 technologies, enabling their members to detect virtually ALL necessary chemical agents in a relatively rapid time frame (Byrnes, 2003).

Although the role of Level A clinical laboratories may be a secondary one, they nevertheless can still provide some support for detecting chemical agents used in an attack or their degradation products in victims, which can be useful for triage or treatment of incoming hospital patients. For practical purposes, we can divide the potential chemical agents that a clinical chemistry laboratory may offer in their analytic repertoire into four major categories: nerve agents, blood agents (cyanide), blister agents (vesicants), and pulmonary agents. The laboratory can also be useful in detecting toxins such as ricin or saxitoxins. These can be detected by specialized enzyme-linked immunosorbent assay methods, polymerase chain reaction

assays that detect nucleic acid from the relevant plant source, or sensitive mass spectrometric methods.

Most modern clinical chemistry laboratories currently have the capacity to provide some specific and useful analytic data to support hospitalized victims of a chemical attack. For example, several automated chemistry analyzers can measure increased cholinesterase activity, which would be a hallmark of patients exposed to nerve agents. This information is used to measure progress and recovery of victims exposed to nerve agents. Gas chromatography–mass spectrometry has been used to detect metabolites of vesicants such as mustard gas or Lewisite (Byrnes, 2003), and is useful for measuring the progress of a patient's recovery post exposure. Unfortunately for patients exposed to pulmonary agents such as chlorine or phosgene, the laboratory's role is limited to supportive monitoring such as blood gas analysis (for measuring partial pressure of oxygen [pO_2]). This also applies to patients exposed to a blood agent such as cyanide. Gaseous cyanide is lethal in seconds, and patients who ingest cyanide need an antidote immediately to prevent anoxia and respiratory arrest. Therefore, the HAZMAT team may do the best job of analyzing and identifying such agents, and then providing antidotes to poisoned patients in the field, well before they reach a hospital.

In short, Level A laboratories play mostly a supportive role in the management of hospitalized patients who are victims of a chemical terror attack.

NUCLEAR TERRORISM

HISTORY AND BACKGROUND OF NUCLEAR WEAPONS

In 1895, Ernest Roentgen discovered penetrating radiations that produced fluorescence; he named them X-rays. The following year, Henri Becquerel identified that these penetrating radiations (later classified as alpha, beta, and gamma rays) are emitted by uranium. In 1905, Albert Einstein formulated his now famous equation $E = mc^2$, which concluded that matter could be converted to energy. These discoveries provided the scientific framework used to eventually harness nuclear energy, although this did not occur until World War II. In 1942, Los Alamos, New Mexico, was selected as the central site for a laboratory to research the physics and design of atomic weapons. In approximately 30 months, the Manhattan Project (the name ascribed to the program that resulted in the production of the first atomic weapon) had achieved its goal of producing a nuclear weapon. By 1945, Germany had surrendered, but Japan continued its war effort. On July 26,

1945, the Potsdam Declaration was issued, wherein President Harry Truman, Chiang Kai-Shek of China, and Winston Churchill of Great Britain advised the Japanese government to proclaim an unconditional surrender of all Japanese armed forces, cautioning against the alternative. The Japanese government rejected the declaration on July 29, 1945 (Byrnes, 2003). On the morning of August 6, 1945, a U.S. aircraft named *Enola Gay* dropped *Little Boy*, an enriched uranium bomb, on Hiroshima, Japan (15 kilotons). Several days later, *Fat Man* was dropped on Nagasaki. The nuclear age had arrived.

The Potential Threat of Nuclear Terrorism

Since the end of World War II, the United States has manufactured more than 70,000 nuclear weapons, although many have since been retired. Today's weapons are larger (1000 kilotons, or 1 megaton) and far more destructive than the 15 kiloton Hiroshima bomb. Although the Cold War with Russia has officially ended, and efforts have been made to reduce the number of nuclear weapons, other countries possess or are trying to develop nuclear capabilities. There is concern that such weapons may fall into the hands of terrorists or might be used by rogue nations. Although it is possible that terrorists may gain access to nuclear weapons of mass destruction, it is much more likely that they will construct *dirty bombs*—a combination of conventional explosives and radioactive materials. Dirty bombs are relatively simple to build and detonate. The main purpose of a dirty bomb is not to kill people so much as it is to create widespread panic and psychological fear. The amount of radioactivity a dirty bomb yields depends on the radioactive material used in the device. However, even a small amount of radiation from such a device has the potential to cause a relatively large decontamination cost.

ROLE OF LEVEL A LABORATORY: NUCLEAR TERRORISM

The clinical laboratory is not actively involved in detecting radiation contamination. This is more likely done in a hospital emergency department with the use of one or more hand-held radiation survey instruments, such as the Ludlum Model 3/Model 44-9 combo Geiger-Mueller detector (Ludlum Measurements, Inc., Sweetwater, TX), which is able to detect alpha-, beta-, and gamma-emitting radionuclides. Routine HAZMAT and other first responder teams have such analytic capabilities and are the likely entity to first identify or detect a nuclear event. Clinical chemistry and hematology laboratories merely play a support role for any patients who may require hospitalization.

KEY POINTS

- Normal volumes and composition of electrolytes in various body fluid compartments are essential for maintenance of life.
- The kidney is the most important organ in the maintenance of normal fluid volume and composition.
- The most important function of the kidney is elimination of the waste products of metabolism, and this function is best represented by the glomerular filtration rate.

- Glomerular filtration rate can be measured using exogenous or endogenous markers. The most important endogenous marker is creatinine. Glomerular filtration rate can be estimated from a determination of creatinine clearance, which requires measurement of creatinine in both plasma and a timed urine specimen. For many patients, however, a better estimate is obtained from an equation such as the Modification of Diet in Renal Disease, which requires only a measurement of plasma creatinine.

Continued

- Causes of abnormal potassium concentration include laboratory artifacts, cellular redistribution, renal failure, alterations in the renin-angiotensin-aldosterone axis drugs, poor intake, and various acquired or inherited disorders affecting renal excretion of potassium.
- Causes of abnormal sodium concentrations include laboratory artifacts, dehydration, disorders of thirst and antidiuretic hormone, renal disorders, water redistribution due to osmotically active substances such as glucose, drugs, and endocrine disorders.
- Causes of abnormal hydrogen ion concentration (i.e., acid-base disorders) include hypoventilation and hyperventilation, ketoacidosis, lactic acidosis, and toxic ingestions.

Laboratory tests for evaluation of disorders of renal, water, electrolyte, and acid-base status are the most common procedures performed in clinical chemistry laboratories; collectively, screening tests for these are often grouped together in a basic metabolic panel. Disorders of acid-base status and electrolytes are seen in a high percentage of hospitalized individuals, and electrolyte disorders are frequent complications of treatment for a variety of common conditions. Renal disease is one of the major sequelae of common disorders such as diabetes and hypertension. Proper interpretation of laboratory tests for renal, electrolyte, and acid-base disorders requires an understanding of the physiology and pathophysiology of these systems. Most central to an understanding of these disorders is knowledge of renal function and how the kidneys regulate extracellular volume.

VOLUME AND OSMOLALITY OF BODY FLUID

The body fluid is an aqueous solution containing electrolytes and non-electrolytes, consisting of intracellular and extracellular compartments. The intracellular compartment is not a single compartment, but each cell has its own separate environment, communicating with other cells only via interstitial fluid and plasma. Consequently, differences exist among cells in various tissues in their solute composition and concentrations. Because cell membranes are permeable to water through the ubiquitous presence of aquaporins (water channels), osmotic equilibrium is maintained, so that the osmolality of all cells is the same and is in equilibrium with the extracellular osmolality (Agre, 2002; Nielsen, 2002; Frigeri, 2004).

Operation of normal metabolic functions of the body requires maintenance of optimal ionic strength in its environment, primarily the intracellular fluid (ICF), where most metabolic activities occur. The homeostatic mechanisms of the body are at work to provide such an environment. Because the extracellular fluid (ECF) is not the site of major metabolic activity, substantial alteration in its ionic strength may occur without adverse effects on body function. The main function of the ECF is to serve as a conduit among cells and organs. The plasma provides a route of rapid transit, and the interstitial fluid serves as a slow supply zone. The ability of the ECF to function efficiently as a conduit requires maintenance of optimal volume, particularly of vascular volume. An additional important function of the ECF is regulation of intracellular volume and its ionic strength. Because an osmotic equilibrium exists between the cells and the ECF, any alteration in extracellular osmolality is followed by an identical change in intracellular osmolality, which is accompanied by a reciprocal change in cell volume (Carroll, 1989).

Although cells and organs can be supplied with substrate and relieved of metabolic products with a much slower circulation, normal circulation is required to supply sufficient oxygen for the body's metabolic needs. Normal plasma volume is a prerequisite for maintenance of normal circulation. Because plasma is in equilibrium with the interstitial fluid, the maintenance of normal vascular volume requires normal extracellular volume. A low extracellular volume results in impaired organ perfusion, and an excessive extracellular volume leads to vascular congestion and pulmonary edema.

MEASUREMENT OF BODY FLUID VOLUMES

Total body water can be determined by dilution of various substances, including deuterium, tritium, and antipyrine. The gold standard of measurement is that using tritiated water or deuterium oxide (Lichtenbelt,

1994; Brans, 1990). The former is a radioactive isotope (Lister, 1962), and the latter requires a complicated method for its measurement. Both are very expensive. Antipyrine has been introduced as a cheap alternative, and was used extensively in the 1940s and 1950s (Axelrod, 1949). However, subsequent studies indicated that antipyrine is not a very reliable dilution marker (Brans, 1990; Garrett, 1959). It is metabolized in the liver; therefore, the equilibrium concentration at time zero must be obtained by interpolating the results.

Recently, the measurement of body fluid volumes by bioelectrical impedance analysis has become very popular. However, the results are not as accurate as those of dilution methods, and the technology is still evolving. The main advantages of this method include its easy applicability, noninvasiveness, and portability of measurements. The portability allows measurement of body fluid volumes in outpatient clinics and at the bedside (Woodrow, 2007).

The method is based on the principle that the body is an electrical conductor with a certain amount of resistance to flow (impedance), and resistance (R) is proportional to its length and inversely proportional to the cross-sectional area (A) (Kyle, 2004). Hence, $R = \rho L/A$, where ρ is the resistivity of the conducting material (i.e., the body). Because $V = AL$, $V = \rho L^2/R$. The body fluid offers two types of resistance to an electrical flow: resistive resistance and capacitive resistance. The former is simply called resistance, whereas the latter is called reactance. Impedance of the body to an electrical flow is a combination of these two types of resistance. The cell membrane, which is made of lipid, acts like capacitance, and is the cause of capacitive resistance. At zero or low frequency, the electrical current does not penetrate the cell membrane and therefore flows only through the ECF. At a very high frequency, the electrical current flows through both extracellular and ICF compartments (Kyle, 2004).

The term bioelectrical impedance analysis is used when a single or multiple frequencies of up to 8 frequencies are used, whereas the term bioelectrical spectroscopy is used when 256 or more multiple frequencies are used (Gudivaka, 1999). In bioelectrical spectroscopy, mathematical modeling and mixture equations are used to generate a relationship between R and body fluid volumes. Bioelectrical impedance analysis has been used to measure fat free mass, ECF volume, ICF volume, and total body water.

BODY FLUID VOLUMES

Total body water measured with antipyrine in hospitalized adults without fluid and electrolyte disorders is about 54% of body weight (Carroll, 1989). The fractional water content is higher in infants and children, and decreases progressively with aging. The water content also depends on the body content of fat; women and obese persons, because of their higher fat content, have less water for a given weight. A useful short cut for the calculation of total body water, using the fact that 54% of body weight in kg is body water, and 1 kg is 2.2 lb, is as follows:

$$\text{Total body water (L)} = \text{body weight (lb)} / 4 \quad (14-1)$$

For an obese subject, subtract 10% from the calculated body water, and for a lean person, add 10%. For a very obese person, subtract 20%. Women have about 10% less body water than men for the same body weight. Extracellular volume is measured directly, and intracellular volume is estimated as the difference between total body water and extracellular volume. The measurement of total body water is reliable, but the measurement of extracellular volume is not, because no ideal marker has been found. Markers such as sodium, chloride, and bromide are not located exclusively in the extracellular compartment, but they penetrate the cells to some extent, whereas other markers such as mannitol, inulin, and sucrose do not penetrate certain parts of the ECF. Thus, depending on the type of marker used, the ECF volume could vary from 27% to 53% of total body water (Carroll, 1989).

Extracellular volume measured with chloride and expressed as percent of total body water varies from 42% to 53%, greater in older subjects and women. Extracellular volume measured with inulin or sulfate is smaller, about 30% to 33% of total body water (Carroll, 1989). For discussion in this chapter, a value of 40% of total body water will be considered to represent extracellular volume. Extracellular volume is further divided into three fractions: interstitial (space between cells) volume (28% of total body water), plasma volume (8%), and transcellular water volume (4%) (Table 14-1). Transcellular water includes luminal fluid of the gastrointestinal tract, the fluids of the central nervous system, and the fluid in the eye, as well as lubricating fluids at the serous surface.

COMPOSITION OF THE BODY FLUID

Extracellular Composition

The concentrations of electrolytes in plasma are easily measured, and their values are well known. These concentrations increase by about 7% when expressed in plasma water because about 7% of plasma is solids (Nguyen, 2007). Thus, plasma sodium is 140 mmol/L, but the concentration in plasma water is about 150 mmol/L. The concentrations of electrolytes in interstitial fluid are different from those in the plasma because of differences in protein concentrations between plasma and interstitial fluid. Differences in electrolyte concentrations between plasma and interstitial fluid can be predicted by the Donnan equilibrium (Table 14-2) (Oh, 1995). With normal plasma protein concentrations, the concentrations of diffusible cations are higher in plasma water than in interstitial water by about 4%, while the concentrations of diffusible anions are lower in plasma than in interstitial fluid by about 4%. The concentrations of calcium and magnesium in the interstitial fluid are lower than the values predicted by the Donnan equilibrium because they are substantially protein-bound.

Part of the interstitial space is occupied by a ground substance consisting of glycosaminoglycans; the most abundant glycosaminoglycan is hyaluronan (hyaluronic acid) (Stern, 2004), and this space excludes the distribution of proteins. In the other part, proteins diffuse freely and communicate with lymphatics. The first part is a gel phase, and the second part is a free phase. Interspersed within the interstitial space is elastin, which provides the elastic property of the interstitial tissue; this property is necessary for generation of a normal negative pressure of the interstitial space and a positive pressure with the development of edema (Reed, 1992; Aukland, 1993; Burton, 1988).

Intracellular Composition

Whereas sodium, chloride, and bicarbonate are the main solutes in the ECF, potassium, magnesium, phosphate, and proteins are the main solutes in the cell. Intracellular concentrations of sodium and chloride cannot be measured with accuracy and are estimated by subtracting the amount that is extracellular from the total tissue value. Because concentrations of electrolytes in the ECF are high, a small error in extracellular water volume measurement will cause a large error in the measurement of intracellular concentration of these ions.

The concentration of bicarbonate is calculated from cell pH, and the bicarbonate concentration shown in Table 14-2 is based on the assumption that average cell pH is 7.0.

The electrolyte composition of ICF is not identical throughout the tissues. For example, the concentration of chloride in muscle is very low, about 3 mmol/L, but it is about 75 mmol/L in erythrocytes. The concentration of potassium in the muscle cell is about 140 mmol/L, but in the platelets, it is only about 118 mmol/L. The concentration of sodium in the muscle and the red blood cell is about 13 mmol/L, but in the leukocytes about 34 mmol/L. The main phosphate in the red blood cell is 2,3-diphosphoglycerate, but in the muscle, adenosine triphosphate and creatinine phosphate are the main phosphates. Because the muscle represents the bulk of the body cell mass, it is customary to use the electrolyte concentration of the muscle cells as representative of the intracellular electrolyte concentration. A substantial portion of the anions inside the cell are polyvalent ions such as phosphate and protein, and consequently, the total ionic concentration in the cell in mmol/L is greater than that of the ECF to maintain osmotic equilibrium with the ECF.

MEASUREMENT OF PLASMA OSMOLALITY

Osmolarity refers to the number of moles of solute in a liter of solution, whereas osmolality refers to the number of moles of solute in a kg of water (solvent). Osmolality is the preferred term, because measurements of both osmolarity and osmolality are based on colligative properties, which are physical properties that are based on the number of particles dissolved in a given number of water molecules. Examples of colligative properties include freezing point, boiling point, and vapor pressure. The molecular mass of water represents the number of water molecules more accurately than the volume because water volume changes with temperature, but the molecular mass does not. However, the terms osmolality and osmolarity are often used interchangeably, because changes in the volume of liquid water with temperature change are negligible. One should note, however, that 1 kg of water occupies exactly 1 L at 4° C.

One mole of NaCl in solution contains 2 osmoles because NaCl is dissociated to Na⁺ and Cl⁻. One mole of D-glucose in solution contains 1 osmole because glucose does not dissociate. One mole of Na₃PO₄ in solution contains 4 osmoles, because it will dissociate into 3 Na⁺ ions and one PO₄³⁻ ion. To calculate the osmolality of a solution whose solute dissociates into more than one particle, the following equation is used:

$$M \times a = \text{Osm/L} \quad (14-2)$$

where M is molarity, and a is the number of particles into which a molecule of the substance dissociates.

When the osmolal concentration of the ECF increases by accumulation of solutes that are restricted to the ECF (effective osmoles) (e.g., glucose, mannitol, sodium), osmotic equilibrium is reestablished as water shifts from the cell to the ECF, increasing intracellular osmolality to the same level as the extracellular osmolality (Hill, 1990; Oh, 1995; Weisberg, 1978). When the extracellular osmolality increases by accumulation of solutes that can enter the cell freely (ineffective osmoles) (e.g., urea, alcohol),

TABLE 14-1

Volumes of Body Fluid Compartments*

Intracellular volume: 24 L (60%)

Extracellular volume: 16 L (40%)

Interstitial volume: 11.2 L (28%)

Plasma volume: 3.2 L (8%)

Transcellular volume: 1.6 L (4%)

*A normal man weighing 73 kg (160 lb) with 40 L of total body water is used as a model.

TABLE 14-2

Electrolyte Concentrations in Extracellular and Intracellular Fluids

	PLASMA		INTERSTITIAL FLUID		PLASMA WATER		CELL WATER (MUSCLE)	
	(mmol/L)	(mmol/L)	(mmol/L)	(mmol/L)	(mmol/L)	(mmol/L)	(mmol/L)	(mmol/L)
Na ⁺	140	140	145.3	145.3	149.8	149.8	13	13
K ⁺	4.5	4.5	4.7	4.7	4.8	4.8	140	140
Ca ⁺⁺	5.0	2.5	2.8	2.8	5.3	5.3	10 ⁻⁷	0.5 × 10 ⁻⁷
Mg ⁺⁺	1.7	0.85	1.0	0.5	1.8	0.9	7.0	3.5
Cl ⁻	104	104	114.7	114.7	111.4	111.4	3	3
HCO ₃ ⁻	24	24	26.5	26.5	25.7	25.7	10	10
SO ₄ ²⁻	1.0	0.5	1.2	0.6	1.1	0.55	—	—
P	2.1	1.2*	2.3	1.3*	2.2	1.2*	107	57†
Protein	15	1	8	0.5	16	1	40	2.5‡
Organic anion	5	5	5.6	5.6	5.3	5.3	—	—

*The calculation is based on the assumption that the pH of the extracellular fluid is 7.4, and the pK of inorganic H₂PO₄⁻ is 6.8.

†The intracellular molal concentration of phosphate is calculated with the assumption that the pK of organic phosphates in the cells is 6.1, and the intracellular pH is 7.0.

‡The calculation is based on the assumption that each mmol of intracellular protein has on average 15 mEq.

osmotic equilibrium is achieved by entry of those solutes into the cell. Because most of the solutes normally present in the ECF are effective osmols, loss of extracellular water (e.g., insensible losses) will increase effective osmolality, and hence will cause shifting of water from the cells. Reduction in extracellular osmolality by loss of normal extracellular solutes or by retention of water reduces effective osmolality for the same reasons, and hence causes shifting of water into the cells.

Osmolality of serum or plasma can be measured directly with an osmometer, as described in Chapter 4 on the principles of instrumentation, or estimated as the sum of the concentration of all solutes in the plasma. Because an osmometer does not distinguish between effective and ineffective osmols, effective osmolality can only be estimated. As it happens, urea is the only ineffective osmol that has substantial concentration in the normal plasma, 5 mOsm/L. In the normal plasma, therefore, total osmolality is nearly equal to effective osmolality. Plasma osmolality is estimated as follows:

$$\text{Serum osmolality} = \{\text{serum Na}^+ (\text{mmol/L}) \times 2\} + \{\text{glucose (mg/dL)/18}\} + \{\text{urea (mg/dL)/2.8}\} \quad (14-3)$$

With use of the above formula, osmolality of sodium and accompanying anions is overestimated by not considering the osmotic coefficient and assuming that all serum anions are univalent. On the other hand, osmolality is underestimated by ignoring nonsodium cations and their accompanying anions. At normal serum glucose and urea concentrations, osmolality almost equals serum $\text{Na}^+ \times 2$ because the opposing errors cancel each other. It should be noted that for the contributions of urea nitrogen and glucose for serum osmolality, their values in mg/dL are divided by one tenth of each (2.8 and 18) of their molecular weights (28 and 180), because osmolality is expressed as mOsm/L, not mOsm/dL.

Many of the solutes that may accumulate in the body in certain abnormal states are anions of an acid (e.g., salicylate, glycolate, formate, lactate, β -hydroxybutyrate). These substances should not be added in estimating plasma osmolality because they are largely balanced by sodium and therefore are already accounted for when plasma sodium is multiplied by 2. Non-electrolyte solutes that accumulate abnormally in the serum (e.g., ethanol, ethylene glycol, methanol, mannitol) will cause the measured osmolality to exceed the calculated osmolality, producing an osmolal gap (Gennari, 1984; Kruse, 1994). This osmolal gap is a useful clinical clue to the presence of the toxic substances listed previously. Accumulation of neutral and cationic amino acids also causes a serum osmolal gap.

Effect of Hyperglycemia on Serum Na^+

The permeability of a membrane for a given solute varies with the cell type. For example, glucose does not accumulate in the muscle. It does not enter the muscle cell freely, and when it enters the cell with the help of insulin, it is quickly metabolized. Thus, glucose is an effective osmol for the muscle cell (e.g., hyperglycemia will cause shift of water from the muscle cell). On the other hand, glucose is an ineffective osmol for red blood cells, liver, kidney cells, and most brain cells because it enters these cells freely. Glucose is generally categorized as an effective osmol mainly because the muscle cells represent the largest body cell mass, as noted previously in this chapter. Accumulation of glucose or mannitol in the ECF is a well-known cause of hyponatremia because, as discussed in Chapter 8, glucose is osmotically active and induces diffusion of water from the cells to the ECF, thus diluting its electrolytes. The fluid shift affects concentrations of all extracellular electrolytes, but its absolute effect is greatest on serum sodium because of its highest concentration. The relationship between change in serum sodium and change in glucose concentration in a normal adult is about 1.6 mmol/L of Na^+ for 100 mg/dL of glucose (Katz, 1973). However, the correction factor is not linear. When hyperglycemia is more severe, the change in serum sodium for a given change in glucose tends to be less, approaching 1.4 at serum glucose concentration of 1000 mg/dL (Moran, 1985). In sharp contrast, Hillier et al, on the basis of experiments on normal subjects, concluded that the correction factor was much larger—a 2.4 mmol/L change in serum sodium for every 100 mg/dL change in glucose (Hillier, 1999). A problem with this experiment and with the conclusion was that the authors disregarded the effects of water contained in intravenous glucose and urine output on serum sodium. Furthermore, infusion of somatostatin during induction of hyperglycemia would have increased serum potassium, and infusion of insulin during treatment of hyperglycemia would have had an opposite effect on serum potassium concentration. Changes in

serum potassium would have the opposite effects on serum sodium concentration.

These figures suggested by various formulas are valid, however, only when the volume of distribution of glucose is between 40% and 50% of total body water. The volume of distribution of glucose refers to a theoretical volume into which glucose would be evenly distributed when none of the administered glucose is excreted and none is metabolized. For example, if 10 g (10,000 mg) of glucose is given to a person, and is the serum concentration increases by 1000 mg/L (100 mg/dL) (with the assumption that none was metabolized and none excreted), the volume of distribution would be 10 L. Normally, the volume of distribution of glucose is slightly greater than the extracellular volume because some cells allow free diffusion of glucose. As the volume of distribution of glucose in relation to total body water is increased, the effect of glucose on serum sodium decreases. Decreased volume of distribution of glucose has an opposite effect. The change in serum Na caused by hyperglycemia can be estimated with the following formula (Oh, 1995):

$$\Delta\text{Na}^+ (\text{mmol/L}) = (5.6 - 5.6a)/2 \quad (14-4)$$

where ΔNa is a reduction in serum Na^+ in mmol/L for each 100 mg/dL increase in glucose, and a is the fraction of the volume of glucose distribution over total body water.

In conditions with marked expansion of extracellular volume (e.g., congestive heart failure, other edema-forming states), the volume of distribution of glucose represents a much greater fraction of total body water; hence a fall in serum sodium caused by hyperglycemia would be much less than usual. For example, when the volume of distribution of glucose is 80% of total body water (0.8), the decrease in serum Na^+ for a 100 mg/dL rise in glucose would be only 0.56 mmol/L: $(5.6 - 5.6 \times 0.8)/2 = 0.56$. When the volume of distribution of glucose is 20% of total body water, ΔNa^+ would be 2.2 mmol/L for a 100 mg/dL increase in glucose.

Tonicity

The concept of tonicity of a solution is based on the effect of a particular solution on the volume of cells. A hypertonic solution is one that shrinks the cells, and a hypotonic solution is one that causes swelling of the cells. An isotonic solution is one that does not induce any volume change in the cells. A solution of 0.9% saline (154 mM solution of sodium chloride) is isotonic in relation to normal body fluid. When the term tonicity is applied to a fluid in vitro, as in the urine, it is used almost interchangeably with total osmolality. Thus, urine with a high concentration of urea is called hypertonic (Pradella, 1988).

Osmolality and Specific Gravity

The specific gravity of a solution is the mass of the solution divided by the volume of the solution. Whereas the osmolality of fluid depends on the osmolal concentration of its solute, specific gravity is determined by the weight of the solute relative to the volume it displaces in solution. Plasma protein contributes little to osmolality because of its low molal concentration despite its great weight, but it is the major factor determining specific gravity of plasma. Urinary specific gravity and osmolality usually change in parallel, but discrepancy occurs between the two with heavy proteinuria and severe glycosuria (Carroll, 1989).

REGULATION OF EXTRACELLULAR VOLUME

As discussed below, the extracellular volume depends primarily on its sodium concentration, which is closely regulated by two hormones: Antidiuretic hormone (ADH) that promotes water retention, and aldosterone that promotes sodium retention, which in turn causes water to be retained with it, as discussed in Chapter 8. Because the extracellular sodium concentration is maintained within a fairly narrow range through the regulation of ADH release, the extracellular volume depends primarily on its sodium content. In most clinical situations, the extracellular volume correlates well with vascular volume, which in turn usually correlates positively with the effective vascular volume. Effective vascular volume is an imaginary volume that reflects cardiac output in relation to the tissue's demand for oxygen (Oh, 1995). Sometimes, effective vascular volume does not correlate well with vascular volume or extracellular volume.

Effective vascular volume, rather than extracellular volume or vascular volume, is the chief determinant of how much ECF is retained. The location and type of sensors that perceive changes in effective vascular volume

are not well known. Most physiologists consider the baroreceptors, located in the atria of the heart and the aortic arch, likely candidates that send neural signals to the central nervous system, resulting in increases or decreases in ADH, and that alter sympathetic tone. However, a preponderance of evidence argues against the effectiveness of such receptors in chronic states of altered effective vascular volume. For example, in a hypertensive patient with congestive heart failure, both atrial low pressure and arterial high pressure baroreceptors would sense a higher than normal pressure. Yet, the neurohumoral responses (e.g., high ADH, high catecholamines, high renin and angiotensin concentrations) in such states suggest that the body senses low effective vascular volume. In such conditions, the kidney of course responds appropriately by reducing urinary excretion of sodium and chloride. These physiologic responses to low effective vascular volume sometimes lead to a pathologic retention of salt. For example, salt is retained in congestive heart failure despite markedly expanded extracellular volume and vascular volume, because effective vascular volume is decreased.

Theoretically, the salt content of the body can be altered in two ways: to alter the intake of salt, or to alter renal salt output. No well-developed mechanism influences salt intake in response to changes in effective vascular volume. Thus, alterations in salt content of the body are achieved primarily through changes in renal salt output. Changes in renal salt output can be achieved through physical and humoral factors. The physical factors for renal salt regulation work through changes in the glomerular filtration rate (GFR) and in peritubular capillary oncotic and hydrostatic pressures. When other factors that influence renal salt output are kept unchanged, the greater the GFR, the greater is the amount of sodium filtered, and the greater is the amount of sodium excreted. In general, however, tubular reabsorption rather than glomerular filtration plays a major role in the regulation of renal excretion of sodium. In advanced renal failure, GFR may be 10% of normal, but patients with renal failure excrete their usual amount of sodium intake, as do normal people.

Tubular reabsorption of sodium is regulated by humoral factors and physical factors. The influence of the latter on sodium reabsorption is limited mainly to the proximal tubule, where a great deal of sodium reabsorption occurs passively through the paracellular (between cells) pathway. Increased hydrostatic pressure on the peritubular capillary retards passive fluid reabsorption through the paracellular pathway, while it promotes passive back-diffusion of fluid into the tubular lumen. Increased oncotic pressure has the opposite effects. For example, in congestive heart failure, peritubular hydrostatic pressure is reduced by increased renal vascular resistance caused by constriction of both afferent and efferent arterioles. Constriction of afferent arterioles would tend to reduce glomerular capillary hydrostatic pressure. However, the glomerular pressure does not decrease much because the constriction of efferent arterioles is even greater than that of afferent arterioles. Maintenance of glomerular filtration pressure helps to minimize the fall in GFR in volume depletion states. The result is an increase in filtration fraction (the ratio of GFR to renal plasma flow), which increases to a greater extent than usual the concentration of plasma protein in the blood leaving the glomerular capillary through the efferent arterioles. Because the blood in the efferent arterioles flows into the peritubular capillaries, the oncotic pressure of the peritubular capillary would be higher than usual. A lower than usual hydrostatic pressure and a higher than usual oncotic pressure of the peritubular capillary blood in volume depletion states tend to favor reabsorption of salt and water through the paracellular pathway of the proximal tubule, the tubular segment, in which passive reabsorption of salt through the paracellular pathway plays a big role in overall renal tubular salt transport. Normally, the oncotic pressure of the peritubular capillary plasma in the proximal tubule is about 20% higher than the peripheral blood plasma because the filtration fraction is 0.25. In states of volume depletion, the value could be 30% or 40% higher than that of the peripheral plasma.

Humoral factors that influence tubular reabsorption of sodium include angiotensin II, aldosterone, and catecholamines. Angiotensin II directly increases proximal tubular sodium reabsorption through its effect on the sodium-hydrogen exchanger-3, and also indirectly by increasing aldosterone secretion, which, in turn, increases sodium reabsorption in the cortical collecting duct. Catecholamines influence sodium reabsorption mainly through their effects on renal blood flow, but they may have some direct tubular effect in the proximal nephron.

The role of ADH in the regulation of extracellular volume is modest because of the overwhelming importance of osmolality as the main regulator of ADH secretion. For this reason, *salt content of the body is the main determinant of the extracellular volume*. When sodium is retained, a

proportionate amount of water is retained to maintain normal serum osmolality. Only when the effective vascular volume depletion is very great will ADH secretion occur despite hyponatremia.

In the presence of primary water retention, as in the syndrome of inappropriate ADH secretion, extracellular volume could theoretically increase in the absence of sodium retention. However, massive water retention without sodium retention will cause only a modest increase in extracellular volume. For example, if a person with 40 L of total body water gains 10 L of water without a change in sodium content, serum sodium would decrease from 140 mmol/L to 112 mmol/L ($140 \times 40/50 = 112$), a value that would cause severe morbidity or even death. This would increase the extracellular volume by only by 4 L, because the bulk (60%) of retained water would enter the cell. On the other hand, the same fluid volume retained with salt would remain almost exclusively in the extracellular space. In other words, the amount of water that can be retained without salt is limited by severe and fatal hyponatremia. This is the reason why a massive increase in extracellular volume as seen in severe congestive heart failure is possible only with massive sodium retention.

The ultimate source of energy for reabsorption of sodium at various nephron segments is $\text{Na}^+\text{-K}^+\text{-ATPase}$ located on the basolateral membrane, which transports 3 Na^+ out of the cell in exchange for 2 K^+ transported into the cell. The resulting reduction in intracellular sodium concentration and the negative cellular electrical potential allow passive diffusion of Na^+ into the cell through the luminal membrane. Four major sites of sodium reabsorption in the nephron utilize four different mechanisms of luminal sodium entry (Fig. 14-1). A number of humoral factors have been proven or suggested to participate in the regulation of renal salt output. Those with well proven physiologic effects are aldosterone, catecholamines, angiotensin II, and perhaps ADH and prostaglandins (Oh, 1995; Biggi, 1995).

NONRENAL CONTROL OF WATER AND ELECTROLYTE BALANCE

1. *Insensible loss of water from the skin.* Water is lost from the skin primarily as a means of eliminating heat. Water loss from the skin without sweat is called insensible perspiration. Sweat contains about 50 mmol/L of sodium and 5 mmol/L of potassium. Because the main purpose of water loss from the skin is elimination of heat, water loss from the skin depends mainly on the amount of heat generated in the body:

$$\text{Water loss from the skin} = 30 \text{ mL per } 100 \text{ calories} \quad (14-5)$$

Figure 14-1 Mechanisms of sodium reabsorption at different nephron segments. The main source of energy for sodium reabsorption at all nephron segments is the basolateral $\text{Na}^+\text{-K}^+\text{-ATPase}$, which transports 3 Na^+ out of the cell in exchange for 2 K^+ into the cell. This pump creates a low intracellular sodium concentration and negative cellular potential, which allow passive diffusion of Na^+ into the cell through the luminal membrane. In the proximal tubule, Na^+ entry is accompanied by exit of H^+ through sodium-hydrogen exchanger type 3 (NHE-3). In the thick ascending limb of Henle, a Na^+ enters along with a K^+ and 2 Cl^- through the sodium-potassium-chloride co-transporter (NKCC). In the distal convoluted tubule, sodium enters with chloride through sodium chloride co-transporter (NCCT), and in the cortical collecting duct, sodium enters through the epithelial sodium channel (ENaC).

2. *Loss of respiratory water.* The water content of inspired air is less than that of expired air; hence water is lost during normal ventilation. Because the ventilatory volume is determined by the amount of carbon dioxide (CO₂) production, which in turn is determined by the caloric expenditure, ventilatory water loss in normal environmental conditions depends also on caloric expenditure:

Respiratory water loss = 13 mL per 100 calories at normal pCO₂

(14-6)

By coincidence, the quantity of water lost during normal respiration is about equal to the metabolic water production. Hence, in calculating water balance, respiratory water loss may be ignored in the measurement of insensible water loss, provided that metabolic water gain is also ignored. Respiratory water loss increases with hyperventilation or fever disproportionately to metabolic water production (Carroll, 1989).

3. *Loss of water in the gastrointestinal tract.* The net activity of the gastrointestinal tract to the level of the jejunum consists of secretion of water and electrolytes. The net activity from jejunum to colon is reabsorption. Most of the fluid entering the small intestine is absorbed in the small intestine, and the remainder is absorbed by the colon, leaving only about 100 mL of water to be excreted daily in the feces. The contents of the gastrointestinal tract are isotonic with plasma, and any fluid that enters the gastrointestinal tract becomes isotonic. Thus, if water is ingested and vomited, solute is lost from the body.

MEASUREMENT OF RENAL FUNCTION

CONCEPT OF CLEARANCE

Renal clearance relates the rate of urinary excretion of material to the plasma concentration of that material. It is defined as the volume of plasma that would theoretically have to be "cleared" of the substance to account for the amount of the substance excreted in the urine during a given period. To calculate clearance, one first must know the amount of substance that is excreted in the urine, which is simply calculated from the urine concentration (U_x) and the volume (V). The next step is to know the plasma concentration of the substance (P_x) to determine the volume of plasma needed to account for the material excreted. For example, if a person excreted 1500 mg of creatinine in a day, he would need 150 L of plasma to account for that 1500 mg of creatinine if the plasma concentration were 10 mg/L (1 mg/dL); creatinine clearance (C_{creat}) then would be 150 L/day. At a plasma concentration of 100 mg/L (10 mg/dL), only 15 L of plasma would be needed to account for the same 1500 mg of creatinine; C_{creat} in this case would be 15 L/day. Customarily, clearance is expressed in mL/minute, but any volume and time units can be used. Thus, clearance of 150 L/day is equal to 6.25 L/hour and 104 mL/minute. The formal equation for clearance is as follows:

$$C_x = (U_x V) / P_x \quad (14-7)$$

where C_x is clearance of a substance x, U_x and P_x are concentrations of the substance in urine and plasma, respectively, and V is the volume of urine per unit time.

In estimating clearance, concentration and volume units must be consistent. For example, if urine creatinine concentration is 70 mg/dL and volume is 2000 mL/day, urine creatinine must also be expressed in mg/mL, not in mg/dL. So the total amount excreted is 0.7 mg/mL × 2000 mL/day = 1400 mg/day.

Clearance in mL/24 hours can be converted to clearance in mL/minute by dividing the value by 1440, because 24 hours equals 1440 minutes.

Quick Formulas for the Calculation of Clearance

When a 24 hour clearance is calculated in mL/minute, urine creatinine excretion may be expressed in g/24 hours instead of in mg/24 hours, while plasma creatinine is expressed as mg/dL instead of in mg/mL, as long as incorrect use of these units is corrected by multiplying the final result by 1000 (for using g instead of mg), and then by 100 (for using mg/dL instead of mg/mL). Further correction requires dividing the value by 1440 to convert a 24 hour clearance value to a value in mL/minute as follows (Carroll, 1989):

$$C_x = U_x V \text{ (g/24 hours)} / P_x \text{ (mg/dL)} \times 100\,000 \times 1/1440 \quad (14-8)$$

Because 100 000/1440 = 70,

$$C_x \text{ (mL/minute)} = 70 \times \{U_x \text{ (g/day)} / P_x \text{ (mg/dL)}\} \quad (14-9)$$

Conversion of Clearance in L/Week to mL/Minute

The conventional unit for clearance is mL/minute, but in certain situations, different units are more useful. For example, when one compares clearances of peritoneal dialysis in a patient on a continuous ambulatory peritoneal dialysis (CAPD) program versus hemodialysis, the clearance unit often used is L/week. A patient on CAPD treatment typically has 2 L of dialysate exchanged every 6 hours. Because the volume drained is usually about 2.5 L (a slightly higher volume because of transudation of fluid from the blood to peritoneal cavity), creatinine clearance is about 10 L/day or 70 L/week. In comparison, hemodialysis provides about 48 L of creatinine clearance with each treatment, or 144 L of clearance per week because usually three treatments are given each week. If weekly clearance in L/week is to be converted to mL/minute, the following shortcut may be useful.

$$\begin{aligned} \text{L/week} &= 1000 \text{ mL/week} = 1000 \text{ mL} / (7 \times 24 \times 60) \text{ minutes} \\ &= 1000/10\,080 = 0.1 \text{ mL/minute} \end{aligned} \quad (14-10)$$

In other words, (weekly clearance in L/week)/10 = minute clearance in mL/minute. For example, 70 L/week of clearance is equal to 7 mL/minute of clearance.

MEASUREMENT OF GLOMERULAR FILTRATION RATE

GFR is generally considered the best overall indicator of the level of kidney function (Smith, 1951). Two different approaches have been utilized for the measurement of GFR. One approach has been to use an endogenous substance, and the other has been to use an exogenous substance. It is important that whatever molecular marker is used to determine GFR, the substance is minimally reabsorbed and is minimally secreted by the renal tubules.

Measurement of GFR With Exogenous Substances

Clearance of inulin, a complex polysaccharide produced by certain plants, has been widely regarded as the gold standard for measuring GFR. Inulin clearance in healthy young adults has a mean value of 127 mL/min/1.73 m² in men and 118 mL/min/1.73 m² in women. GFR declines with age. After age 20 to 30 years, GFR decreases by approximately 1.0 mL/min/1.73 m² per year. The classic method of inulin clearance requires an intravenous infusion and timed urine collections over many hours. Determination of inulin clearance is not clinically practical at the present time. Consequently, a number of alternative measures for estimating GFR have been introduced (Price, 2000; Gaspari, 1997). The urinary clearance of exogenous radioactive markers such as ¹²⁵I-iothalamate and ^{99m}Tc-DTPA (metastable technetium-99-labeled diethylene triamine pentaacetic acid) provides good measures of GFR (Biggi, 1995; Brochner-Mortensen, 1969; Christensen, 1986; Fleming, 1991). Plasma disappearance of exogenous substances such as iothexol and chromium⁵¹-labeled ethylenediaminetetraacetic acid (⁵¹Cr-EDTA) has also been used to estimate GFR; an advantage of this method is that it does not require urine collection (Krutzen, 1984; Russel, 1985; Agarwal, 2003). However, plasma clearance methods are not as accurate as those that require urine collection. GFR has also been measured with nonradiolabeled iothalamate in blood and urine; an obvious advantage of this method is avoidance of radioactive materials (Rule, 2004).

Measurement of GFR With Endogenous Substances

Endogenous substances that are widely used to determine GFR include urea, creatinine, cystatin C, β trace protein [BTP], β-2 microglobulin, and tryptophan glycoconjugate. The first two are widely used in clinical practice, mainly because of their ready availability, but cystatin C is gaining popularity.

Creatinine as a Measure of Renal Function

Creatinine is an endogenous substance with a molecular weight of 113 Da. It is produced by the muscle from creatine and creatine phosphate through a nonenzymatic dehydration process. The rate of production of creatinine

is proportionate to the creatine–creatine phosphate pool, which, in turn, is proportionate to the muscle mass (Oh, 1993). An additional source of creatinine is creatine contained in ingested meat or dietary supplements. The rate of *in vitro* conversion of creatine to creatinine in meat is dependent on temperature and acidity; high temperature and low pH increase conversion (Oh, 1993). Creatinine is the most widely used marker of GFR for several reasons. First, it is an endogenous substance with a fairly constant rate of production. Second, creatinine is not bound to plasma proteins; therefore it is filtered freely by the glomerulus. It is not reabsorbed by the renal tubules, and only a small amount is secreted by the tubules.

With the use of creatinine clearance, the inconvenience of urine collection and the uncertainty of its completeness can be avoided by estimating the excretion rate. When renal function is normal and stable, creatinine excretion is almost equal to its production, which depends primarily on muscle mass (Oh, 1993). Muscle mass varies with sex, age, and body weight. The creatinine production rate is estimated as follows ($A = \text{age}$):

$$\text{Creatinine production (mg/kg/day): } 28 - 0.2A \text{ (men)} \quad (14-11A)$$

$$\text{Creatinine production (mg/kg/day): } 23.8 - 0.17A \text{ (women)} \quad (14-11B)$$

In obese patients and wasted patients, the above formula will overestimate creatinine production. Normally, creatinine excretion in urine is slightly less than its production because some creatinine is broken down by colonic bacteria. The discrepancy increases progressively with decreasing renal function because of the nonrenal clearance of creatinine, which is about 0.04 L/kg/day (Oh, 1993). However, the metabolism of creatinine by colonic bacteria is inducible, and is increased more in chronic renal failure than in acute renal failure (Owen, 1979). Normally, a 70 kg man would have an extrarenal creatinine clearance of 2.8 L/day or 2 mL/minute, less than 2% of normal renal clearance. However, at a renal clearance of 4 mL/minute, 2 mL/minute of extrarenal clearance would represent one third of the total plasma clearance of creatinine.

However, several drawbacks to the use of creatinine as a measure of GFR have been identified. First, although the rate of production is fairly constant, it has substantial individual variation, depending mainly on the muscle mass (Oh, 1993). In the presence of severe muscle wasting, production of creatinine could be reduced to less than 25% of the amount predicted from the body weight (Kaizu, 2002). Second, creatinine is also derived from the dietary meat, and the quantity of meat ingestion can substantially influence total daily production. Third, creatinine measurement is made most commonly by the alkaline picrate method (see later for a more detailed discussion), and a number of chromogens, both endogenous and exogenous, interfere with its measurement by this technique. Finally, creatinine is partially secreted by the proximal tubules via the organic cation transport pathway, and tubular secretion is blocked by various drugs, including cimetidine, trimethoprim, pyrimethamine, and salicylate (Hilbrands, 1991; Van Acker, 1992). The extent of tubular secretion varies among individuals, and variation is much greater in the presence of renal dysfunction; tubular secretion could involve as much as 50% of the amount excreted in the urine in advanced renal failure. To obviate the errors due to tubular secretion, creatinine clearance has been obtained with the simultaneous administration of cimetidine, which inhibits tubular secretion of creatinine. However, suppression of creatinine secretion by cimetidine is not complete and demonstrates wide individual variation.

Creatinine Measurement

The most widely used method of creatinine measurement is based on the Jaffe reaction, described more than 100 years ago, which is based on the reaction of creatinine with trinitrophenol, an explosive compound also known as picric acid (Spencer, 1986; Weber, 1991). Alkaline conditions enhance the reaction, hence the term alkaline picrate method. Several substances such as ketones, glucose, fructose, protein, urea, and ascorbic acid also react with picrate and falsely increase creatinine concentration (Spencer, 1986; Weber, 1991; Kroll, 1983; Molitch, 1998; Watkins, 1967). Interference with creatinine measurement by glucose becomes significant when glucose concentration is very high, as in diabetic ketoacidosis or hyperglycemic coma (Sjoland, 2003). Glucose concentration is extremely high in dialysate fluid used in peritoneal dialysis, and a correction for the high glucose is needed when creatinine concentration is measured in the effluent of peritoneal dialysate. The magnitude of glucose interference with creatinine measurement has been shown not only in the glucose concentration but also in the creatinine concentration (Mak, 1997). Alterations in reaction and measurement conditions can minimize but not eliminate these interferences. The method of Hare involves isolating creatinine

by absorption into Lloyd's reagent and discarding the plasma containing interfering chromogens (Abdul-Karim, 1986). Such pretreatment methods are cumbersome and are not suited to automation. Bilirubin and hemoglobin also interfere with the alkaline picrate method, resulting in falsely low values (Schoenmakers, 1993). Cephalosporin antibiotics also positively interfere with the alkaline picrate method, resulting in falsely elevated values (Swain, 1977; Kroll, 1983). Creatinine can alternatively be measured enzymatically with the use of creatinine amidohydrolase or creatinine iminohydrolase (Suzuki, 1984; Fossati, 1994). Creatinine is hydrolyzed by creatinine iminohydrolase to ammonia and N-methylhydantoin. The ammonia then combines with 2-oxoglutarate and nicotinamide adenine dinucleotide (NADH) in the presence of glutamate dehydrogenase to produce glutamate and NAD⁺. Consumption of NADH measured as a decrease in absorbance at 340 nm is used to measure the concentration of creatinine. Creatinine can also be measured by converting creatinine to creatine by creatinine amidohydrolase. Creatine is then hydrolyzed by imidinohydrolase and sarcosine oxidase to produce hydrogen peroxide. In the presence of horseradish peroxidase, 2,4-dichlorophenolsulfonate is converted to a colorless polymer by hydrogen peroxide, and the concentration of the polymer is then measured at 510 nm. Interference by glucose and other Jaffe chromogens in creatinine measurement does not occur with enzymatic methods. However, enzymatic methods have certain interferences of their own (e.g., possible negative interference from bilirubin and catecholamines) (Peake, 2007; Saenger, 2009).

The ultimate reference standard for creatinine measurement is isotope dilution–mass spectrometry (IDMS) (Welch, 1986). Recent efforts are under way to make the calibration of routine creatinine measurements traceable to this standard, although this of course does not affect the problem of interference in individual samples.

Without removing noncreatinine chromogens, the upper limit of normal measured by the Jaffe reaction is 1.6–1.9 mg/dL for adults. The upper limit of normal for serum creatinine measured after removal of the chromogens is 1.2–1.4 mg/dL. Values for women are 0.1–0.2 mg/dL lower. When serum creatinine is very high, noncreatinine chromogens contribute proportionately less to the total reaction. With normal renal function, noncreatinine chromogens make up 14% (range, 4.5%–22.3%) of the total, but with advanced renal dysfunction, they contribute only about 5%.

Cimetidine-Enhanced Creatinine Clearance

Tubular secretion of creatinine results in falsely elevated values in creatinine clearance, especially in renal insufficiency; measurement of creatinine clearance with inhibition of tubular secretion with cimetidine substantially improves the creatinine clearance estimate of GFR in patients with mild to moderate renal impairment (Hilbrands, 1991; Van Acker, 1992; Hellerstein, 1998). However, tubular secretion of creatinine is not completely blocked by cimetidine; hence the method still overestimates glomerular filtration rate.

Formulas to Estimate Creatinine Clearance as an Estimate of GFR

With the realization that accurate urine collection is a major limitation of creatinine clearance as a measure of GFR, attempts have been made to mathematically transform serum creatinine to estimate glomerular filtration rate. In part because of the convenience, these methods are widely used in clinical practice. The two most widely used formulas are the Cockcroft–Gault formula and the Modification of Diet in Renal Disease (MDRD) formula (Levey formula).

Cockcroft–Gault formula (mL/minute) (Cockcroft, 1976):

$$([140 - \text{Age}] \cdot [\text{IBW}]) / (72 \times \text{SCr}); \text{ multiply by } 0.85 \text{ if female} \quad (14-12)$$

where *IBW* is ideal body weight and *SCr* is serum creatinine concentration. *IBW* is calculated by the following formula:

$$\text{Males: } \text{IBW} = 50 \text{ kg} + 2.3 \text{ kg for each inch over 5 feet} \quad (14-13A)$$

$$\text{Females: } \text{IBW} = 45.5 \text{ kg} + 2.3 \text{ kg for each inch over 5 feet} \quad (14-13B)$$

The Cockcroft–Gault formula reduces the variability of serum creatinine estimates of GFR caused by differences in creatinine production due to differences in muscle mass based on sex and age. However, because the formula does not take into account differences in creatinine production due to variation in muscle mass caused by disease states, it systematically overestimates GFR in individuals who have relatively low muscle mass in relation to their body weight such as obese, edematous, or chronically

debilitated individuals. Moreover, it does not take into account variations caused by extrarenal elimination and tubular secretion.

In the MDRD study, Levey and coworkers measured GFR by I^{125} -iodothalamate to derive a formula for estimating GFR using six variables: age, sex, serum urea nitrogen, serum creatinine, race, and serum albumin concentration (Levey, 1999). In 2000, the same investigators produced a simplified MDRD formula based on four variables: serum creatinine, age, race, and sex. Few diabetic individuals were included in the original studies, and these formulas when tested in diabetic patients were found to be inaccurate.

$$\text{MDRD formula (mL/min/1.73 m}^3\text{): GFR} = 170 \cdot \text{Cr}^{-0.999} \cdot \text{Age}^{-0.176} \cdot (0.762 \text{ if female}) \cdot (1.180 \text{ if black}) \cdot \text{BUN}^{-0.170} \cdot \text{Alb}^{0.318} \quad (14-14A)$$

$$\text{The simplified MDRD formula (mL/min/1.73 m}^3\text{) based on four variables (serum creatinine, age, race, and sex): GFR} = 186 \cdot \text{Cr}^{-1.154} \cdot \text{Age}^{-0.203} \times 1.212 \text{ (for black)} \times 0.742 \text{ (for women)} \quad (14-14B)$$

where *Cr* is serum creatinine (mg/dL)

Wt is body weight (kg)

BUN is blood urea nitrogen (mg/dL)

Alb is serum albumin (g/dL).

The previous equation was derived before routine creatinine methods were commonly made traceable to the IDMS standard. For methods traceable to the IDMS standard, creatinine results tend to be lower, and the equation should be used with a smaller initial constant:

$$\text{GFR} = 175 \cdot \text{Cr}^{-1.154} \cdot \text{Age}^{-0.203} \times 1.212 \text{ (for black)} \times 0.742 \text{ (for women)} \quad (14-14C)$$

Whereas the Cockcroft-Gault formula includes body weight, the MDRD formula does not include body weight, because the result of the latter is expressed in mL/min/1.73 m² rather than as an absolute value. The same errors resulting from variations in creatinine production rate caused by disease states are not eliminated by the Cockcroft-Gault formula or by the MDRD formula. Both Cockcroft-Gault formula and MDRD formula estimate GFR in adults and are not applicable to measurement of GFR in children. Following are the formulas used most often for estimating creatinine clearance for children (Schwartz, 1976; Counahan, 1976; Leger, 2002; Pierrat, 2003):

Schwartz Formula:

$$\text{GFR} = 0.55 \times \text{height (cm)}/\text{serum creatinine (mg/dL)} \quad (14-15A)$$

$$\text{GFR} = 48 \times \text{height (cm)}/\text{serum creatinine (}\mu\text{mol/L)} \quad (14-15B)$$

Counahan-Barrett Formula:

$$\text{GFR} = 40 \times \text{height (cm)}/\text{serum creatinine (}\mu\text{mol/L)} \quad (14-16)$$

In 2009, Schwartz et al further modified their formula to estimate GFR more accurately in children (Schwartz, 2009). The new formula is very similar to the MDRD equation in that it uses multiple exponential functions; use of the formula requires knowing values of serum creatinine, height, BUN, and serum cystatin C.

Modified Schwartz Formula:

$$\text{GFR (mL/min/1.73 m}^2\text{)} = 39.1 [\text{height (m)}/\text{Cr (mg/dL)}]^{0.516} \times [1.8/\text{cystatin C (mg/L)}]^{0.294} [30/\text{BUN (mg/dL)}]^{0.169} [1.099]^{\text{male}} [\text{height (m)}/1.4]^{0.188} \quad (14-17)$$

It has been shown that GFR estimated from these various formulas is not very accurate. However, creatinine clearance values estimated from the formulas are still more accurate than those derived from direct measurements, mainly because of the inaccurate urine collections and variations in plasma creatinine concentration in the latter. Consequently, K/DOQI (Kidney Disease Outcomes Quality Initiative) guidelines have recommended the use of these formulas instead of direct measurements in calculating creatinine clearance (Levey, 1999).

All these formula are useful in the estimation of GFR in chronic states when creatinine production is assumed to be equal to the amount excreted in the urine. In acute renal failure, when serum creatinine rises rapidly

during the development of renal failure and falls rapidly during the recovery phase, such an assumption is invalid; hence the estimation of GFR by either method is invalid. Measurement of creatinine in the urine with timed urine collection is more useful in determining creatinine clearance in acute renal failure.

Most recently, a new formula, known as the CKD-EPI (Chronic Kidney Disease Epidemiology Collaboration) equation, was reported to give improved performance over the widely used MDRD equation (Levey, 1999).

Urea as Measure of Renal Function

Urea is the main waste product of nitrogen-containing chemicals in the body. It has a molecular weight of 60 Da. However, by custom the concentration of urea is expressed only by the nitrogen content of urea. For this reason, the term serum or urine urea nitrogen is widely used in place of serum or urine urea. Because a molecule of urea contains 2 nitrogen atoms, the molecular weight of urea nitrogen is 28 Da.

Serum urea is widely used as a measure of renal dysfunction, but its value as a measure of GFR is not very good for several reasons. First, urea concentration in the serum depends not only on renal function but also on the rate of urea production, which depends largely on protein intake. The rate of protein intake varies widely from individual to individual.

Urea is freely filtered at the glomerulus but is reabsorbed substantially in the proximal convoluted tubule and the inner medullary collecting duct. Reabsorption of urea in the proximal tubule occurs passively through the lipid membrane without the help of urea transporters (Quigley, 2001), whereas in the inner medullary collecting duct, urea reabsorption is mediated by urea transporters (Pallone, 2007). Some of the urea reabsorbed from the inner medullary collecting duct then reenters the tubule in the thin descending limb of the cortical nephrons, which also express urea transporters (Pallone, 2007). The amount of urea reabsorbed in the proximal tubule varies greatly depending on the status of effective vascular volume; reabsorption is markedly increased in states of volume depletion because the luminal concentration of urea is high owing to the increased fractional reabsorption of salt and water. The amount reabsorbed in the inner medullary collecting duct is increased when urine osmolality is high because of the high urea concentration. For these reasons, urea clearance does not reflect GFR very accurately, but serum urea nitrogen is still widely used as a measure of renal dysfunction. In the presence of normal renal function without volume depletion, urea clearance is about 50% of creatinine clearance, but in the presence of severe volume depletion, its clearance could be as little as 10% of creatinine clearance. In advanced renal failure, urea clearance approaches unity with GFR, and is better than creatinine clearance as a measure of GFR (Schück, 1990).

Measurement of Urea

Essentially, three methods are available for the measurement of urea. The gold standard, which is used only as a reference method because of its high cost, is isotope dilution mass spectrometry (Kessler, 1999). In the clinical laboratory, urea is measured either by the colorimetric method based on a reaction of urea with diacetyl monoxime or by enzymatic methods (Barbour, 1992; Natelson, 1951; Passey, 1980). In the former, urea reacts directly with diacetyl monoxime under strong acidic conditions to give a yellow condensation product. The reaction is intensified by the presence of ferric ions and thiosemicarbazide. The intense red color formed is measured at 540 nm.

The initial reaction in all enzymatic methods is hydrolysis of urea by urease, which produces ammonia and CO₂. Ammonia and CO₂ produced are measured by various methods to calculate the concentration of urea in the original sample. Measurement of ammonia is most often used. In one of these methods, ammonia produced by urease converts glutamate and ATP to glutamine and adenosine diphosphate (ADP). The ADP so produced is consumed in reactions catalyzed sequentially by pyruvate kinase and pyruvate oxidase to generate hydrogen peroxide (Lepinas, 1989). The hydrogen peroxide is then measured as an indirect estimate of urea concentration. In another enzymatic method, as in the one used for creatinine described in the preceding section, ammonia produced from urea hydrolysis reacts with alpha-keto-glutarate and NADH to produce glutamic acid and NAD⁺ by glutamate dehydrogenase (Fawcett, 1960). The amount of NADH consumed is measured photometrically to determine the urea concentration. Another urease method involves the indophenol method, in which ammonium produced by urease reacts with hypochlorite to form monochloramine (Higashi, 2000). In the presence of phenol and with an excess of hypochlorite, the monochloramine forms a blue compound, indophenol, the concentration of which is determined

spectrophotometrically at 630 nm. Yet in another enzymatic method, CO₂ produced by urease is measured by thermal conductivity gas chromatography.

Other Measures of GFR

Cystatin C

Cystatin C is a 122 amino acid protein with a molecular weight of 13,000 Da; it is an inhibitor of cysteine proteinase. The substance is produced by all nucleated cells, and its production rate is relatively constant from age 4 months to 70 years (Massey, 2004; Laterza, 2002; Ylinen, 1999). The rate of production is not affected by muscle mass, sex, or race. Because of its small size (small for a protein) and a positive net charge, it is freely filtered at the glomerulus at the same concentration as in the plasma. The filtered peptide is completely reabsorbed by the proximal tubule, but then is destroyed rather than reentering the circulation. Because cystatin C has no extrarenal means of elimination, its plasma concentration is inversely related to GFR. Some evidence suggests that glucocorticoids reduce production of cystatin C (Risch, 2001), and this might result in overestimation of renal function in renal transplantation patients, who are regularly given glucocorticoids. A number of studies made comparison of serum creatinine versus serum cystatin C an indicator of renal function, and general consensus is that cystatin C is better than creatinine. However, cystatin C is not widely used clinically because measurements are difficult and expensive (Massey, 2004). It must be noted that cystatin C renal clearance cannot be measured because normally it is completely reabsorbed, and none is excreted in the urine. For this reason, changes in serum concentration of cystatin C are used as indirect estimates of GFR. A complex equation to estimate GFR using the exponential functions and plasma cystatin C concentrations has been developed, and the results were found to be better than those achieved by the MDRD equation and the Schwartz formula for estimation of GFR (Grubb, 2005).

$$\text{Modified cystatin C equation: GFR} \left[\text{mL} \cdot \text{min}^{-1} \cdot (1.73 \text{ m}^2)^{-1} \right] = 84.69 \times \text{cystatin C (mg/L)}^{-1.680} \times 1.384 \text{ (if a child <14 years)} \quad (14-18)$$

β -2-Microglobulin

β -2-microglobulin, a polypeptide with molecular weight of 11.6 kDa and length of 99 amino acids, is a component of the major histocompatibility complex class I molecule. It is present in all nucleated cells, and is needed for production of CD8 cells. Its production is increased in multiple myeloma and lymphoma. Because of the low molecular weight, β -2 microglobulin is freely filtered at the glomerulus, and then is reabsorbed and metabolized completely by the proximal tubule. Similar to cystatin C and BTP, the plasma level increases in renal failure. The protein appears in the urine when reabsorption is incomplete because of proximal tubular damage, as in acute kidney injury. The protein has a tendency to fold into a β -sheet configuration, resulting in amyloid formation; it is a common cause of dialysis-associated amyloidosis (Schwalbe, 1997; Bianchi, 2001).

β Trace Protein

BTP is a low molecular weight glycoprotein with 168 amino acids. The molecular weight varies between 23 000 and 29 000 Da, depending on the degree of glycosylation. BTP belongs to the lipocalin protein family and functions as prostaglandin D synthase. Because prostaglandin D is the major prostaglandin in the brain, BTP is isolated primarily from cerebrospinal fluid. Plasma BTP originates from the brain and is freely filtered at the glomerulus, then is reabsorbed completely by the proximal tubule and is catabolized there. The plasma level is increased in patients with renal disease because of reduced filtration in the presence of constant production. White et al (2007, 2009) and Pöge et al (2005, 2008) developed formulas to estimate GFR on the basis of plasma concentration of BTP and urea or creatinine. They claimed that the results were better than those obtained by the MDRD equation and serum cystatin C measurements. However, others showed that BTP was less sensitive than cystatin C (Abbink, 2008).

White Formula using β trace protein:

$$\text{GFR1} = 112.1 \times \text{BTP}^{-0.662} \times \text{urea}^{-0.280} \times (0.880 \text{ if female}) \quad (14-19A)$$

$$\text{GFR2} = 167.8 \times \text{BTP}^{-0.758} \times \text{creatinine}^{-0.204} \times (0.871 \text{ if female}) \quad (14-19B)$$

Pöge Formula using BTP:

$$\text{GFR1} = 89.85 \times \text{BTP}^{-0.5541} \times \text{urea}^{-0.3018} \quad (14-20A)$$

$$\text{GFR2} = 974.31 \times \text{BTP}^{-0.2594} \times \text{creatinine}^{-0.647} \quad (14-20B)$$

GFR in mL/min/1.73 m²; BTP in mg/dL; urea in mmol/L; creatinine in μ mol/L.

Tryptophan Glycoconjugate

Mannopyranosyl-L-tryptophan (MPT) is a substance that is normally produced in the body by glycoconjugation of tryptophan; it is filtered at the glomerulus freely and is not reabsorbed. A strong linear correlation has been noted between clearances of MPT and inulin in rats ($r = 0.97$) and humans ($r = 0.87$), indicating that renal handling of MPT is similar to that of inulin. The current limitation for the use of MPT for renal function estimation is that it can be measured only by the high-performance liquid chromatography (HPLC) method, which is time consuming and expensive. Serum level of MPT increases progressively with declining renal function, but unlike creatinine, serum MPT concentration is not affected by muscle mass. It is not known whether dietary intake of tryptophan affects the serum concentration (Takahira, 2001).

UREA CLEARANCE AND UREA/CREATININE RATIO IN SERUM

In the absence of renal dysfunction and severe dehydration, urea clearance is about 50% of creatinine clearance, and hence about 50% of GFR, because about 50% of the filtered urea is reabsorbed. The bulk of urea reabsorption occurs in the proximal tubule, about 40% of the filtered load. Among the distal nephron sites, the inner medullary collecting duct reabsorbs urea extensively along a concentration gradient when urine is being concentrated. Most of the urea reabsorbed from the inner medulla reenters the tubule at the descending thin limb; this reentry represents intrarenal recycling of urea (Pallone, 2007). Urea reentry occurs mainly in the short loop of Henle. Some of the urea reabsorbed from the inner medullary collecting duct is carried away from the medulla by the ascending vasa recta; this amount represents about 10% of the filtered load with normal urine flow, but with marked urine concentration the amount can increase greatly (Lyman, 1986).

A marked reduction in urea clearance occurs when the proximal reabsorption of urea is greatly increased by a reduction in effective vascular volume. Reabsorption of urea in the proximal tubule is passive and depends on a favorable urea concentration gradient. This gradient is created by reabsorption of water in the proximal tubule. Normally, about 83% of the filtered water is reabsorbed in the proximal tubule as a result of reabsorption of salt (mainly sodium chloride). Loss of 83% of the water in the tubule increases urea concentration in the tubule six-fold, creating a favorable gradient for urea diffusion out of the tubule. When water reabsorption is 95% of the filtered load, the urea concentration would increase to 20 times the plasma concentration. Volume depletion and decreased renal plasma flow without volume depletion (e.g., renal artery stenosis) also reduce glomerular filtration rate, thereby reducing clearance of both creatinine and urea. Volume depletion decreases creatinine clearance only by reduced filtration, and urea clearance by both reduced filtration and increased reabsorption. Hence, in volume depletion, urea clearance decreases more than creatinine clearance does. Normally, the ratio of plasma urea nitrogen to plasma creatinine is about 10:1, but in volume depletion, the ratio is usually greater than 20:1.

Prediction of volume status by the urea/creatinine ratio is based on the assumption of constancy of urea and creatinine production, which often is not the case. Glucocorticoids and a high protein diet increase urea production, whereas chronic protein malnutrition decreases it. Creatinine production also varies considerably; marked muscle wasting may reduce its production to less than one fifth of the usual value. Nowadays, the main cause of a high BUN/creatinine ratio in the hospital is not dehydration, but adequate protein intake (often by a tube feeding) in a patient with severe muscle wasting. Thus, fractional excretion of urea (see below) would be a more reliable index of volume status than plasma urea/creatinine ratio (Carvounis, 2002). Mechanisms by which low effective vascular volume increases the proximal reabsorption of salt and water were explained earlier in the section on the control of extracellular volume.

As stated previously, because about 50% of filtered urea is reabsorbed, normal urea clearance underestimates GFR greatly, whereas creatinine

clearance slightly overestimates GFR. As renal function declines, the fraction of urea reabsorbed declines progressively, whereas the tubular secretion of creatinine increases progressively (Herrera, 1998). As a result, in the presence of advanced renal dysfunction, urea clearance is a better predictor of GFR than is creatinine clearance (Schück, 1990).

GLOMERULAR FILTRATION RATE, RENAL PLASMA FLOW, AND FILTRATION FRACTION

As discussed in the preceding section, because inulin is filtered freely at the glomerulus but is neither reabsorbed nor secreted by the tubules, its clearance equals GFR, which is the rate (mL/minute) of plasma filtered by the glomerulus from the blood into the tubular system. The clearance of para-aminohippurate (PAH) measures another aspect of renal function. As it happens, whatever PAH is not filtered at the glomerulus is almost all secreted into the proximal tubule, thereby allowing PAH clearance to be a measure of renal plasma flow, which is the total quantity of plasma perfusing the glomerular capillary. The quantity of plasma filtered as a fraction of the total quantity perfusing the glomerular capillary is the filtration fraction (Smith, 1951). Because inulin clearance represents GFR and PAH clearance, the quantity of plasma perfusing the glomerulus,

$$\text{Filtration fraction (FF)} = C_{IN}/C_{PAH}, \quad (14-21)$$

where C_{IN} is inulin clearance, and C_{PAH} PAH clearance.

Filtration fraction in man is normally about 0.2. As was discussed earlier, low effective vascular volume as in heart failure decreases renal perfusion, but GFR decreases to a lesser degree because glomerular capillary pressure is maintained by increased efferent arteriolar tone. The result is an increase in filtration fraction. An increase in glomerular filtration for a given plasma flow (i.e., increased filtration fraction) increases the concentrations of plasma proteins by concentrating the nonfilterable plasma constituents. This increases the oncotic pressure of peritubular capillary blood, resulting in increased fluid movement from the tubular interstitium to the capillary. This in turn helps to increase fluid reabsorption from the proximal tubule into the interstitial space. Similarly, increased tone of efferent arterioles in an attempt to maintain a high glomerular capillary pressure tends to reduce the peritubular capillary hydrostatic pressure. This contributes to increased salt reabsorption by the proximal tubule.

The expanded effective vascular volume decreases filtration fraction because the increase in renal plasma flow is greater than the increase in GFR. Changes in oncotic pressure and hydrostatic pressure in the peritubular capillary blood and their effects on proximal salt and water reabsorption are the opposite of those encountered in conditions of reduced effective vascular volume (Oh, 1995).

FRACTIONAL EXCRETION

Fractional excretion (FE) is the quantity of a substance excreted in the urine expressed as a fraction of the filtered load of the same substance.

$$F_x = P_x \cdot \text{GFR} \quad (14-22)$$

where F_x is the amount of a substance x filtered.

$$F_x = P_x \cdot C_{\text{creat}} \quad (\text{GFR} = C_{\text{creat}}) = P_x \cdot (U_{\text{creat}} V / P_{\text{creat}}) \\ E_x = V \cdot U_x \quad (14-23)$$

where E_x is the amount excreted in the urine, and U_x is the urine concentration of substance x .

$$\text{Hence, FE} = [(V \cdot U_x)] / [P_x \cdot (V \cdot U_{\text{creat}} / P_{\text{creat}})] \quad (14-24)$$

When V is cancelled on both sides, the equation is simplified as follows:

$$\text{FE} = (U_x / P_x) / (U_{\text{creat}} / P_{\text{creat}}) \quad (20) \text{ or} \\ \text{FE} = (U_x / P_x) \cdot (P_{\text{creat}} / U_{\text{creat}}) \quad (14-25)$$

Thus, the measurement of fractional excretion can be obtained in a spot urine sample. When the substance excreted in the urine has a clearance less than the creatinine clearance, fractional excretion is less than 1. When FE is multiplied by 100, the result is %FE. FE of sodium is often used to distinguish between acute tubular necrosis (acute kidney injury) and prerenal azotemia. A value of FE of sodium of less than 0.01 (less than 1%) suggests prerenal azotemia, and a value greater than 0.01 suggests acute tubular necrosis (acute kidney injury).

RENAL FAILURE INDEX

Renal failure index (RFI) is another formula that is used for the differential diagnosis of acute renal failure. It is expressed as $U_{Na^+}/(U_{\text{creat}}/P_{\text{creat}})$. The renal failure index is different from fractional excretion of sodium by the exclusion of plasma Na^+ concentration in the formula. Hence, the value of the renal failure index will be 140 times the value of fractional excretion of Na^+ when the serum Na^+ concentration is 140 mmol/L. When fractional excretion of Na^+ is expressed as a % value,

$$\%FE_{Na^+} \times 1.4 = \text{RFI} \quad (14-26)$$

A word of caution: Both FE of Na^+ and the renal failure index are used only in the differential diagnosis of acute renal failure (acute kidney injury) with oliguria. For example, usual fractional excretion of Na^+ on regular salt intake in a normal person is usually less than 0.01, but this does not indicate the presence of prerenal azotemia.

FRACTIONAL REABSORPTION

Fractional reabsorption (FR) is the quantity of a substance reabsorbed expressed as a fraction of the filtered load. It is estimated from fractional excretion as follows:

$$\text{FR} = 1 - \text{FE} \quad (14-27)$$

FREE WATER CLEARANCE AND NEGATIVE FREE WATER CLEARANCE

Free water is the volume of water excreted in excess of the amount necessary to keep the urine isotonic to plasma. In other words, it is the volume of water that would have to be removed to make the urine isotonic. Free water clearance, like all other clearances, is expressed as volume per unit time, usually as mL/minute. To determine free water clearance, one first determines the total amount of solute in the urine ($mOsm$), which is measured from urine osmolality and urine volume ($U_{\text{osm}} \times V$), and then determines the amount of water required to hold that quantity of solute at the same osmolality as plasma, which is called osmolar clearance. Free water clearance is the difference between osmolar clearance and urine volume (Carroll, 1989).

$$\text{Osmolar clearance } (C_{\text{osm}}) = (U_{\text{osm}} \times V) / P_{\text{osm}} \quad (14-28)$$

$$\text{Free water clearance } (C_{H_2O}) = V - C_{\text{osm}} \text{ or } C_{H_2O} \\ = V - (U_{\text{osm}} \times V / P_{\text{osm}}) \quad (14-29)$$

If the urine is more concentrated than the plasma, then in a sense free water has been removed from isotonic urine, and the term negative free water clearance is used. In other words, it is the amount of water that would have to be added to make the urine isotonic.

$$\text{Negative free water clearance } (T_{CH_2O}) = C_{\text{osm}} - V \quad (14-30)$$

In the presence of normal renal function, the kidneys usually concentrate the urine, and therefore U_{osm} is greater than P_{osm} , resulting in a negative value for C_{H_2O} . On the other hand, loop diuretics block reabsorption of sodium chloride in the loop of Henle, interfering with both concentration and dilution of urine, and urine is approximately isotonic with little free water or negative free water.

BIOMARKERS OF ACUTE KIDNEY INJURY

Although many clinicians use acute kidney injury (AKI) and acute renal failure (ARF) almost interchangeably, the former term is used mainly when the actual injury occurs to the kidney, either biochemically or histologically, whereas the latter term encompasses all causes of acute renal failure, including prerenal azotemia and obstructive uropathy. This transition in terminology has called attention to the spectrum of disease much broader than previously emphasized with the realization that kidney injury exists along a continuum, ranging from minor injury with no change in serum creatinine or urine output to those who end up with end-stage renal disease requiring dialysis treatment (Honore, 2007). Furthermore, some authors use the term acute kidney injury to mean only acute tubular necrosis, which is a subset of causes of ARF, that includes all causes of intrinsic renal disease resulting in acute renal dysfunction, including acute glomerulonephritis and acute interstitial disease.

TABLE 14-3

RIFLE Criteria for Acute Kidney Injury

GFR and serum	Creatinine changes	Urine volume changes
R (Risk)	Increase in S-Creat $>1.5\times$	Urine volume <0.5 mL/kg/hr >6 hr Decrease in GFR $>25\%$
I (Injury)	Increase in S-Creat $>2\times$	Urine volume <0.5 mL/kg/hr >12 hr Decrease in GFR $>50\%$
F (Failure)	Increase in S-Creat $>3\times$ Decrease in GFR $>75\%$ S-Creat >4 mg/dL	Urine volume <0.3 mL/kg/hr >24 hr Anuria >12 hr
L (Loss)	Complete loss of kidney function >4 weeks	
E (ESRD)	End-stage kidney disease >3 months	

ESRD, End-stage renal disease; GFR, glomerular filtration rate; S-Creat, serum concentration of creatinine.

TABLE 14-4

New Classification for Acute Kidney Injury

Stage	Serum creatinine criteria	Urine output criteria
1	>0.3 mg/dL (26.4 μ mol/L) or $>150\%$ – 200%	<0.5 mL/kg for >6 hr
2	$>200\%$ – 300%	<0.5 mL/kg for >12 hr
3	$>300\%$, 4 mg/dL (354 μ mol/L), or acute increase of >0.5 mg/dL	<0.3 mL/kg for >24 hr or anuria >12 hr

The Acute Kidney Injury Network was formed recently in an effort to improve the care of patients who are in AKI or at risk of developing AKI (Bellomo, 2004; Mehta, 2007). This group defined AKI as “functional or structural abnormalities or markers of kidney damage including abnormalities in blood, urine, or tissue tests or imaging studies present for less than three months.” AKI is associated with retention of creatinine, urea, and other metabolic waste products that are normally excreted by the kidney. Although severe AKI may result in oliguria or even anuria, urine volume may be normal or even increased. Nevertheless, the committee defined AKI on the basis of increases in serum creatinine and changes in urine output. Initially, AKI was classified into five categories (Table 14-3); subsequently, this was simplified into three categories (Table 14-4).

Various biomarkers of AKI that are in clinical use include chemical components of serum or urine, imaging studies, and any other quantifiable parameter. The urine has yielded the most promising markers for the early detection of AKI. These urinary markers may be produced by the kidney as the result of kidney injury or may be filtered by the glomerulus but not well reabsorbed by the tubules because of injury to the tubules. Increased renal excretion is increased in part because some of these chemicals are produced in increasing amounts as the result of renal injury or conditions associated with renal injury. The advantage of these biomarkers over conventional markers of AKI such as serum creatinine and serum urea nitrogen is that the levels often increase long before any changes in serum creatinine or urea nitrogen or urine output occur (Lassning, 2004; Dennen, 2007). Earlier detection of renal injury can allow for better care of patients in anticipation of clinically overt AKI or perhaps can allow physicians to intervene by employing certain therapeutic measures, thereby preventing progression to overt AKI (Honore, 2007; Vaidya, 2008; Devarajan, 2008).

Thus, biomarkers of AKI help in diagnosing AKI before changes in serum creatinine are noted. These biomarkers also help to reveal the primary location of injury (i.e., proximal tubule, distal tubule, interstitium, or vasculature) to distinguish among different subtypes of AKI (e.g., prerenal, intrinsic renal, postrenal) and to delineate causes of AKI (e.g., ischemia, toxins, sepsis, or a combination) (Devarajan, 2008). Urine is likely to contain biomarkers of renal origin; therefore, urinary biomarkers are most widely used. On the other hand, urine samples are more prone to protein degradation, and their concentrations may be affected by urine flow rate. Serum samples are readily available and serum biomarkers are more stable, but serum biomarkers may reflect the systemic response to a disease process rather than specific organ involvement.

Conventional urinary biomarkers such as casts and fractional excretion of sodium are shown to be insensitive and nonspecific for the early recognition of AKI. Other traditional urinary biomarkers such as filtered high molecular mass proteins and tubular proteins or enzymes suffer from the lack of specificity. Application of innovative technologies has uncovered several new candidates that are promising biomarkers of AKI. Several of these candidates have now progressed through the first three stages of the biomarker development process and have entered phase IV drug trials. More than 20 biomarkers of AKI have been extensively studied; only the four most promising biomarkers are discussed here. These include neutrophil gelatinase-associated lipocalin (NGAL), interleukin (IL)-18, kidney injury molecule-1 (KIM-1), and liver-type fatty acid-binding protein (L-FABP). It seems that among these biomarkers, NGAL and L-FABP are likely the earliest biomarkers of AKI, and KIM-1 and IL-18 are later biomarkers that improve specificity (Honore, 2007).

KIDNEY INJURY MOLECULE-1

KIM-1 is a type I cell membrane glycoprotein that contains an immunoglobulin-like domain and a mucin domain in its extracellular region. KIM-1 mRNA levels increase more than any other known gene after kidney injury. The ectodomain of KIM-1 is shed into the urine after proximal tubular injury. In preclinical and clinical studies using several different models of kidney injury, urinary KIM-1 serves as an earlier diagnostic indicator of kidney injury when compared with any of the conventional biomarkers (e.g., plasma creatinine, BUN) (Han, 2008; Vaidya, 2008).

NGAL (to be discussed later) appears to be most sensitive at the earliest time points, but KIM-1 potentially adds specificity at later time points because expression of KIM-1 is limited to the kidney, and no systemic source of KIM-1 has been detected (Han, 2006; Ichimura, 2004). KIM-1 is induced in the kidney and is upregulated in the urine by a large number of nephrotoxins, including cyclosporine, cisplatin, cadmium, gentamicin, mercury, and chromium (Orfeas, 2009).

NEUTROPHIL GELATINASE-ASSOCIATED LIPOCALIN

NGAL is a 25 kDa protein initially identified bound to gelatinase in granules of the neutrophil. Other names for NGAL are lipocalin 2 and human neutrophil lipocalin.

NGAL is synthesized during a narrow window of granulocyte maturation in the bone marrow, but it also may be induced in epithelial cells in the setting of inflammation or malignancy. NGAL is upregulated and can be detected in the kidney and urine of mice 3 hours after cisplatin administration (Mishra, 2004; Mishra, 2006; Ronco, 2007); it has been proposed as an early biomarker for diagnosing AKI. A prospective study of pediatric and adult patients undergoing cardiopulmonary bypass for cardiac corrective surgery found urinary NGAL to be a powerful early marker of AKI, showing increased concentrations within 2–6 hours of the insult, preceding any increases in serum creatinine by 1–3 days (Bennet, 2008; Dent, 2007; Mishra, 2006; Devarajan, 2008). However, serum NGAL levels are known to increase in the setting of a number of inflammatory and infective conditions, and more studies are needed to determine the specificity of urinary NGAL for AKI in the setting of sepsis. NGAL has also been evaluated as a biomarker of AKI after contrast-induced nephropathy (Hirsch, 2007).

INTERLEUKIN-18

IL-18 is a cytokine, which is an interferon- γ -inducing factor. IL-18 activity has been described in a number of inflammatory diseases across a broad range of tissues. Renal IL-18 mRNA levels have been shown to be significantly upregulated in the proximal tubule following ischemia-reperfusion injury, inflammatory/autoimmune nephritis, and cisplatin-induced nephrotoxicity. Urinary IL-18 levels are elevated in patients with AKI and delayed graft function (Parikh, 2006), compared with normal subjects and patients with prerenal azotemia, urinary tract infection, chronic renal insufficiency, and nephrotic syndrome. Increased urinary IL-18 was found to be an early marker of AKI, preceding changes in serum creatinine by 1–2 days, and was an independent predictor of death (Washburn, 2008).

FATTY ACID-BINDING PROTEIN

FABPs are 14–15 kDa cytoplasmic proteins abundantly expressed in all tissues and particularly in the proximal convoluted and straight tubule of

the kidney (Maatman, 1992; Negishi, 2009). Urinary L-FABP has been identified in preclinical and clinical models of AKI, and has been found to be a potential biomarker in a number of pathologic conditions, including chronic kidney disease, diabetic nephropathy, immunoglobulin A nephropathy, and contrast nephropathy. In a model of cisplatin-induced AKI, increased shedding of urinary L-FABP occurred within the first 24 hours, whereas a rise in serum creatinine was not detectable until after 72 hours of cisplatin treatment. Urinary L-FABP levels were significantly increased before the increase in serum creatinine only in those patients who developed AKI post contrast dye. In a recent study involving 12 living-related kidney transplant patients, a significant direct correlation was found between urinary L-FABP level and both peritubular capillary blood flow and ischemic time of the transplanted kidney. In AKI following cardiac surgery, increases in serum creatinine occurred 2–3 days post surgery, whereas urine L-FABP levels increased at 4 hours after surgery (Yamamoto, 2007; Portilla, 2008).

The previous discussion concerns the overall mechanisms by which the kidneys control extracellular volume and how measurements of specific chemicals, such as BUN and creatinine, in serum and urine are used to measure renal function. The kidneys regulate extracellular volume by regulating the concentrations of ions that are retained in blood. Disorders of renal function frequently result in electrolyte imbalances, and disorders of electrolytes often can be at least partially corrected by normally functioning kidneys.

In the following sections, three common disorders of electrolytes and acid-base balance, namely, disorders of potassium, disorders of sodium, water, and ADH, and finally disorders of acid-base equilibrium, are discussed.

DISORDERS OF POTASSIUM

Total body K^+ in hospitalized adults is about 43 mEq/kg of body weight, and only about 2% of this is found in the ECF. When potassium concentrations across the cell membrane are in electrochemical equilibrium, the gradient of K^+ is the main determinant of, and is also predicted by, the membrane potential (E_m) according to the Nernst equation (Veech, 1995; Goldman, 1943):

$$E_m \text{ (mV)} = -61 \log (\text{intracellular } K^+ / \text{extracellular } K^+) \quad (14-31)$$

The normal ratio of (intracellular K^+ /extracellular K^+) for the skeletal muscle is about 30; therefore, normal E_m is -90 mV. The membrane potential tends to increase with hypokalemia and to decrease with hyperkalemia. In hypokalemia, both intracellular and extracellular K^+ tend to decrease, but the extracellular concentration tends to decrease proportionately more than the intracellular concentration. Hence, the ratio of (intracellular K^+ /extracellular K^+) tends to increase. In hyperkalemia, the membrane potential tends to decrease because an increase in the extracellular K^+ is proportionately greater than that in the intracellular K^+ . However, in dogs with severe hypokalemia, the resting membrane potential of the skeletal muscle is actually reduced rather than increased, indicating that the permeability of the membrane to potassium may change with severe hypokalemia (Bilbrey, 1973).

CONTROL OF TRANSCELLULAR FLUX OF POTASSIUM

Transmembrane electrical gradients cause diffusion of cellular K^+ out of cells and Na^+ into cells. Because the Na^+ - K^+ pump, which reverses this process, is stimulated by insulin (Benziane, 2008) and catecholamines (through β -2-adrenergic receptors) (Putcha, 2007), alterations in levels of these hormones can affect K^+ transport and its serum levels (Meister, 1993; Feraille, 1999; Sweeney, 1998; Goguen, 1993; Putcha, 2007).

Cells can act as buffers. In acidosis, cells can take up H^+ ions in exchange for K^+ ions, and, in alkalosis, cells extrude H^+ ions in exchange for K^+ ions. These effects are summarized in Figure 14-2. The effects of acidosis and alkalosis on transcellular K^+ flux depend not only on the pH but also on the type of anion that accumulates. In general, metabolic acidosis causes greater K^+ efflux than respiratory acidosis. Metabolic acidosis due to inorganic acids (e.g., sulfuric acid, hydrochloric acid) causes greater K^+ efflux than that due to organic acids (e.g., lactic acid, keto acids). The reason is that organic anions accumulate substantially in the cell, as well as in the ECF, whereas inorganic anions accumulate mainly in the ECF. Acidosis causes efflux of K^+ from the cell because of the shift of H^+ into the cell in exchange for K^+ . A modifying factor appears to be anion

Figure 14-2 Control of transcellular movement of potassium. Potassium enters the cell through Na^+ - K^+ -ATPase (stimulated by beta-adrenergic agents or insulin) or through the sodium-potassium-chloride co-transporter (NKCC) (stimulated by insulin and catecholamines). Stimulation of the sodium-hydrogen exchanges (NHE) by high extracellular pH, catecholamines, or insulin increases intracellular sodium concentration, which in turn stimulates Na^+ - K^+ -ATPase and thereby increases intracellular movement of potassium.

accumulation in the cells. In organic acidosis, much of H^+ entering the cell is balanced by organic anions; therefore efflux of K^+ is prevented. In respiratory acidosis, the anion that accumulates in the cell to balance the incoming H^+ is bicarbonate (Perez, 1981). This explains why little K^+ efflux from the cell occurs in respiratory acidosis. Alkalosis tends to lower serum K^+ because, as noted above, H^+ leaves cells in exchange for K^+ , which enters the cells. As with acidosis, K^+ influx varies with the type of alkalosis. In respiratory alkalosis, with its lower partial pressure of carbon dioxide (pCO_2) and attendant lower intracellular bicarbonate by cellular buffering, K^+ influx is not as great as in metabolic alkalosis. When pH is kept normal with proportionately increased concentration of bicarbonate and pCO_2 , K^+ tends to move into the cells; accumulation of bicarbonate in the cell must be accompanied by Na^+ and K^+ . Similarly, when pH is kept normal with proportionately low bicarbonate and low pCO_2 , K^+ tends to move out of the cells.

CONTROL OF RENAL EXCRETION OF POTASSIUM

About 90% of the daily K^+ intake (60–100 mEq) is excreted in the urine, and 10% in the stool. Potassium filtered at the glomerulus is mostly (70%–80%) reabsorbed by active and passive mechanisms in the proximal tubule. In the ascending limb of Henle's loop, K^+ is reabsorbed together with Na^+ and Cl^- by the sodium potassium chloride cotransporter. Because the quantities of Na^+ and Cl^- are far greater than K^+ , most of the reabsorbed K^+ diffuses back to the lumen to maintain the reabsorption of Na^+ and Cl^- , but net reabsorption of K^+ still occurs in the thick ascending limb of Henle. The concentration of K^+ at the beginning of the distal convoluted tubule is about 1 mmol/L with fluid volume of about 25 L. Thus, K^+ excreted in the urine is largely what is secreted into the cortical collecting duct by mechanisms shown in Figure 14-3. Na^+ - K^+ -ATPase located on the basolateral side of the cortical collecting duct pumps K^+ into the cell, while it pumps Na^+ out of the cell. The luminal Na^+ enters the cell through the epithelial sodium channel (ENaC), providing a continuous supply of Na^+ . The reabsorption of Na^+ through these steps is an absolute requirement of secretion of potassium in the cortical collecting duct. Aldosterone is the main regulator of the expression of ENaC on the luminal membrane through its genomic effect on the activity of serum and glucocorticoid-regulated kinase 1 (Fakitsas, 2007; Zhang, 2007, 2008), and therefore is the main determinant of renal excretion of potassium. The negative luminal potential that develops as a result of sodium reabsorption through ENaC causes reabsorption of Cl^- through the paracellular channels. Because Na^+ reabsorption is not followed one to one by Cl^- reabsorption, the charge imbalance occurs and is corrected by secretion of K^+ through a specialized K^+ channel, the renal outer medullary K (ROMK)

Figure 14-3 Control of potassium secretion at the cortical collecting duct. Sodium enters from the luminal fluid into the cell through the epithelial sodium channel (ENaC) and is transported out of the cell through the $\text{Na}^+\text{-K}^+\text{-ATPase}$ on the basolateral membrane. These processes create the luminal electrical potential that is more negative than the electrical potential of the peritubular fluid. The electrical charge imbalance created by sodium reabsorption causes paracellular reabsorption of chloride, and allows entry of potassium into the lumen through the renal outer medullary K (ROMK), a potassium channel. Binding of aldosterone to its receptor results in upregulation of SGK-1 (serum- and glucocorticoid-regulated kinase-1), which, in turn, results in increased expression of ENaC on the luminal membrane. Upregulation of SGK-1 also stimulates ROMK and $\text{Na}^+\text{-K}^+\text{-ATPase}$. All three effects help to increase potassium secretion. (ENaC, Epithelial Na channel; ROMK, renal outer medulla K channel.)

channel (Yue, 2009; Wang, 2009). Thus, aldosterone increases K^+ secretion by increasing the passive entry of Na^+ from the lumen to the cell through increased expression of ENaC on the luminal membrane. The resulting increase in cellular concentration of sodium indirectly stimulates $\text{Na}^+\text{-K}^+\text{-ATPase}$, but aldosterone also directly stimulates $\text{Na}^+\text{-K}^+\text{-ATPase}$ and ROMK activities (Yue, 2009). The peritubular K^+ concentration and the pH also influence K^+ secretion through their effects on $\text{Na}^+\text{-K}^+\text{-ATPase}$ activity. High serum K^+ concentration and alkaline pH stimulate enzyme activity, and low serum K^+ and acidic pH inhibit this activity.

When Na^+ is accompanied by anions that are less permeable than Cl^- , luminal negativity is increased, resulting in enhanced K^+ secretion. Examples of such anions include sulfate, bicarbonate, and anionic antibiotics such as penicillin and carbenicillin. Bicarbonate in the tubular fluid enhances K^+ secretion, not only through its effect as a poorly reabsorbable anion, but also by enhancing ROMK activity. An increase in renal K^+ excretion in patients who vomit and develop metabolic alkalosis may be explained by this mechanism. ADH also increases the luminal K^+ channel activity. K^+ secretion is increased by rapid urine flow by maintaining a low luminal K^+ concentration. Renal K^+ wasting during osmotic diuresis could be explained by this mechanism. A high urine flow also activates another secretory K channel called maxi-K channel (Wang 2009). The more Na^+ is presented to the distal nephron, the more can be absorbed and the more K^+ can be secreted “in exchange.” The increased Na^+ delivery to the collecting duct also increases renal K^+ excretion by its effect on urine flow (Giebisch, 1998; Halperin, 1998; Wang, 2009). A higher urine flow allows greater secretion of potassium into the luminal fluid, while reducing back-diffusion of potassium into the tubular cells, because the luminal concentration would be lower for a given amount of potassium secreted (Oh, 2003).

PLASMA RENIN ACTIVITY, PLASMA ALDOSTERONE CONCENTRATION, AND ABNORMALITIES IN POTASSIUM METABOLISM

Because abnormalities in plasma renin activity (PRA) and plasma aldosterone (PA) are frequently responsible for or are caused by abnormalities in K^+ metabolism, it is important to understand their relationships (Bock, 1992; Hollenberg, 2000; Laragh, 1995; Hall, 1991). The general principles are as follows: (1) Expansion of effective arterial volume caused by a primary increase in aldosterone (primary aldosteronism) or by other mineralocorticoids will cause suppression of PRA. When mineralocorticoids

TABLE 14-5

Causes of Hypokalemia

Alkalosis
Hypokalemic periodic paralysis
Beta-2-adrenergic agonists
Barium poisoning
Insulin
Nutritional recovery state

Poor Intake

Gastrointestinal loss
Vomiting
Diarrhea
Intestinal drainage
Laxative abuse

Excessive Renal Loss

Primary aldosteronism (adrenal adenoma or hyperplasia); PRA is suppressed
Secondary aldosteronism (increase in aldosterone is secondary to increase in renin)
Malignant hypertension
Renal artery stenosis
Reninoma
Diuretics
Bartter's syndrome
Gitelman's syndrome
Excess mineralocorticoids other than aldosterone (e.g., Cushing's syndrome, ACTH-producing tumor, licorice)
Chronic metabolic acidosis
Delivery of poorly reabsorbed anions to the distal tubule (e.g., bicarbonate, ketone anions, carbenicillin)
Miscellaneous causes: Magnesium deficiency, acute leukemia, Liddle's syndrome

ACTH, Adrenocorticotrophic hormone; PRA, plasma renin activity.

other than aldosterone are present in excess, they induce retention of salt and water, and the resulting volume expansion leads to suppression of both PRA and PA; and (2) a primary increase in PRA will always lead to an increase in PA (secondary aldosteronism). On the other hand, a primary defect in aldosterone secretion will cause volume depletion and will secondarily increase PRA. PRA may be high because of the following:

1. Volume depletion secondary to renal or extrarenal salt loss
2. Abnormality in renin secretion (e.g., reninoma [hemangiopericytoma of afferent arteriole], malignant hypertension, renal artery stenosis)
3. Increased renin substrate production (e.g., oral contraceptives)

Elevations in serum K^+ can directly stimulate the adrenal cortex to release aldosterone. When renin is deficient primarily, aldosterone is always low (e.g., hyporeninemic hypoaldosteronism).

CAUSES AND PATHOGENESIS OF HYPOKALEMIA

Hypokalemia occurs by one of three main mechanisms: intracellular shift, reduced intake, or increased loss (Table 14-5). Because the intracellular concentration greatly exceeds the extracellular concentration, the K^+ shift into the cell can cause severe hypokalemia with little change in its intracellular concentration (Clemessy, 1995; Matsumura, 2000; Rakhmanina, 1998; Jordan, 1999; Ogawa, 1999; Cannon, 2002; Jurkat-Rott, 2000; Bradberry, 1995; Steen, 1981). Alkalosis, insulin, and β -2-agonists can cause hypokalemia by stimulating $\text{Na}^+\text{-K}^+\text{-ATPase}$ activity (Matsumura, 2000; Putcha, 2007). Defective activity of dihydropyridine-responsive Ca^{++} channels and potassium channels has been documented in some patients (Jurkat-Rott, 2000; Bradberry, 1995; Fontaine, 2008). A defect in the sodium channel is also known to cause hypokalemic periodic paralysis, but a defect in the sodium channel sometimes causes hyperkalemic or normokalemic paralysis (Fontaine, 2008). In barium poisoning, K^+ accumulates in the cell and hypokalemia develops because of inhibition of the K^+ channel by barium, resulting in inhibition of K^+ efflux from the cell (Bradberry, 1995), in the face of continuous cellular uptake of K^+ through the action of $\text{Na}^+\text{-K}^+\text{-ATPase}$. K^+ accumulates in the cell along with anions

as the cell mass increases during nutritional recovery because K^+ is the main intracellular cation.

Poor intake of K^+ by itself is rarely a cause of hypokalemia because it is usually accompanied by poor caloric intake, which causes catabolism and release of K^+ from the tissues (Steen, 1981). Vomiting and diarrhea are common causes of hypokalemia (Steen, 1981). Diarrhea causes direct K^+ loss in the stool, but in vomiting, hypokalemia is mainly the result of K^+ loss in the urine rather than in the vomitus, because vomiting causes metabolic alkalosis, and the subsequent renal excretion of bicarbonate leads to renal K^+ wasting.

Renal loss of K^+ is by far the most common cause of hypokalemia. With rare exceptions, hypokalemia due to increased renal wasting of potassium can be attributed to increased activity of aldosterone or other mineralocorticoids. Increased aldosterone could be a primary disorder as in primary hyperaldosteronism, or it could be due to increased renin secretion as in secondary hyperaldosteronism. Even with increased aldosterone, renal K^+ wasting occurs only if it is accompanied by adequate distal delivery of Na^+ (Torpy, 1998; Stowasser, 1995; Abdelhamid, 1995; Litchfield, 1997; Vargas-Poussou, 2002; Finer, 2003; Kunchaparty, 1999; Seyberth, 1985; Krozowski, 1999; Heilmann, 1999). In primary aldosteronism, distal delivery of Na^+ is increased because increased $NaCl$ reabsorption in the cortical collecting duct by the action of aldosterone inhibits salt reabsorption in the proximal tubule as the result of volume expansion. In secondary aldosteronism, hypokalemia occurs only in conditions that are accompanied by increased distal Na^+ delivery. Examples of secondary hyperaldosteronism that result in hypokalemia include renal artery stenosis, diuretic therapy, and malignant hypertension, and congenital defects in renal salt transport such as Bartter's syndrome and Gitelman's syndrome. It must be noted that, in the absence of extrarenal salt loss, renal salt excretion ultimately equals salt intake even in conditions of increased aldosterone or aldosterone deficiency, because prolonged imbalance between intake and output is impossible; without eventual balance, an individual could not survive volume excess or volume depletion, which would occur inevitably. However, when salt reabsorption is increased at the mineralocorticoid active site (i.e., cortical collecting duct), the amount of salt delivered to this site must be increased when the final salt output eventually equals the intake; when balance is achieved, an increased amount is delivered to the site, and an increased amount is reabsorbed, so that the normal amount equaling the intake is excreted; ultimate balance is possible only when the amount entering the body equals the amount leaving the body. This is the mechanism by which salt delivery to the aldosterone site is increased in primary hyperaldosteronism, as well as in all cases of secondary hyperaldosteronism that are associated with hypokalemia (Oh, 2003).

Bartter's syndrome, a rare potassium-losing autosomal recessive disorder, is caused by defective $NaCl$ reabsorption in the thick ascending limb of Henle (Sakakida, 2003; Finer, 2003; Kunchaparty, 1999; Seyberth, 1985; Schultheis, 1998), whereas in Gitelman's syndrome, the defect in $NaCl$ reabsorption occurs in the distal convoluted tubule (Schultheis, 1998). Defective Na^+ reabsorption proximal to the aldosterone effective site in these conditions results in increased delivery of Na^+ to the cortical collecting duct, and hence in hypokalemia. Heart failure does not lead to hypokalemia despite secondary hyperaldosteronism, unless distal delivery of Na^+ is increased by diuretic therapy.

Substances that are not aldosterone but have mineralocorticoid activity include corticosterone, deoxycorticosterone, and synthetic mineralocorticoid such as 9- α -fluorocortisone (Florinef). With licorice intake, mineralocorticoid activity is increased, because cortisol, which is normally a potent mineralocorticoid but has a negligible concentration in the cortical collecting duct cells owing to rapid breakdown by the enzyme 11- β -hydroxy steroid dehydrogenase, maintains a high intracellular concentration, because compounds in licorice inhibit the enzyme (Krozowski, 1999; Heilmann, 1999).

Among rare causes of renal potassium wasting that are not accompanied by increased mineralocorticoid activity is Liddle's syndrome. Liddle's syndrome is a congenital disorder that is characterized by increased ENaC activity in the collecting duct in the absence of increased aldosterone, resulting in increased sodium reabsorption and enhanced potassium secretion; aldosterone secretion is reduced because salt retention due to increased ENaC activity leads to physiologic suppression of renin secretion (Warnock, 2001). In chronic metabolic acidosis, hypokalemia develops, probably because reduced proximal reabsorption of $NaCl$ allows increased delivery of $NaCl$ to the distal nephron. Direct stimulation of aldosterone secretion by metabolic acidosis (Gyorke, 1991) appears to be an additional mechanism that contributes to hypokalemia.

DIFFERENTIAL DIAGNOSIS OF HYPOKALEMIA

The first step in the differential diagnosis is to measure urinary excretion of K^+ . If urinary K^+ excretion is low (<20 mEq/day or <0.01 mEq/mg of creatinine), the cause is low intake, extrarenal loss of K^+ , or intracellular shift. Supercute development of hypokalemia usually suggests intracellular shift as the mechanism. The most common cause of extrarenal loss is diarrhea, which can be suspected by history and a low or negative urine anion gap (urine $Na^+ + K^+ - \text{urine } Cl^-$); the normal urine anion gap is about 40 mmol/24 hours. Intracellular shift is suggested by the history and clinical findings. If urinary excretion is normal or increased (urine $K^+ >30$ mEq/day or 0.02 mEq/mg of creatinine), the cause is renal loss. Once a renal cause is suspected, the next step should be the measurement of PRA and plasma aldosterone.

High PRA and high aldosterone suggest secondary hyperaldosteronism, which includes diuretic therapy, renal artery stenosis, malignant hypertension, renin producing tumors, and hereditary defects in renal salt transport (Bartter's syndrome and Gitelman's syndrome). Blood pressure would be normal in subjects with Bartter's syndrome or Gitelman's syndrome, and in a normotensive person on diuretic therapy. Blood pressure would be high in all other conditions and in a hypertensive subject on diuretic therapy. Low PRA and high plasma aldosterone suggest primary hyperaldosteronism, which is caused by adrenal adenoma or bilateral hyperplasia. If PRA and plasma aldosterone are low, likely conditions include Liddle's syndrome, apparent mineralocorticoid excess states (both hereditary and drug- or licorice-induced), 11-hydroxylase deficiency, and 17-hydroxylase deficiency. Reduction in renal K^+ excretion will be achieved with spironolactone in all these conditions except for Liddle's syndrome, which will respond to ENaC blockers such as triamterene and amiloride (Oh, 2003).

CAUSES AND PATHOGENESIS OF HYPERKALEMIA

Hyperkalemia may be caused by one of three mechanisms: (1) shift of potassium from the cells to the ECF (Wasserman, 1997; Perazella, 1999; McIvor, 1985; McIvor, 1987; Emser, 1982), (2) increased potassium intake, or (3) reduced renal potassium excretion (Table 14-6). Hyperkalemic familial periodic paralysis, administration of succinylcholine in paralyzed patients (Fontaine, 2008; Delphin, 1987; Cooperman, 1970; Gronert, 1975; Larach, 1997), administration of cationic amino acids such as arginine and lysine, use of epsilon-aminocaproic acid (this chemical is neutral in its charge, but becomes a cationic amino acid in the cell),

TABLE 14-6
Causes of Hyperkalemia

Pseudohyperkalemia
Thrombocytosis, severe leukocytosis, use of tourniquet with fist exercise, in vitro hemolysis
True Hyperkalemia
Due to extracellular shift:
Acute acidosis (more with inorganic acidosis)
Catabolic states
Periodic paralysis
Succinylcholine (esp. in those with muscular dystrophy)
Cationic amino acids
Vigorous exercise
Digitalis intoxication
Due to excessive ingestion: Rare if renal excretion of K^+ is normal
Decreased renal excretion:
Hypoaldosteronism: Addison's disease; selective hypoaldosteronism (hyporeninemic hypoaldosteronism, heparin, congenital adrenal enzyme deficiencies, angiotensin-converting enzyme inhibitors)
Tubular unresponsiveness to aldosterone (pseudohypoaldosteronism type I and II): Congenital, salt-losing nephropathy
Potassium-sparing diuretics: Spironolactone, amiloride, triamterene
Antibiotics with ENaC-blocking effects: Pentamidine, trimethoprim
Antirejection medications: Cyclosporine, tacrolimus
Severe dehydration

ENaC, Epithelial sodium channel.

rhabdomyolysis or hemolysis, and acute acidosis all cause hyperkalemia by extracellular potassium shift. Rhabdomyolysis and hemolysis cause hyperkalemia only when they are accompanied by renal failure. Although hyperkalemia is not as predictable with organic acidosis as with inorganic acidosis in experimental situations, hyperkalemia is common in diabetic ketoacidosis and phenformin-induced lactic acidosis. The more frequent occurrence of hyperkalemia in clinical organic acidosis may be explained by the longer duration of acidosis and the presence of other factors such as dehydration and renal failure and insulin deficiency in diabetic ketoacidosis (Perez, 1981).

Hyperkalemia can also occur in severe digitalis intoxication by extracellular shift of potassium as digitalis inhibits the $\text{Na}^+\text{-K}^+$ -ATPase pump. The ability of the kidney to excrete potassium is so great that hyperkalemia rarely occurs solely on the basis of increased intake of potassium. Thus, hyperkalemia is almost always due to impaired renal excretion. Three major mechanisms of diminished renal potassium excretion are known: reduced aldosterone or aldosterone responsiveness, renal failure, and reduced distal delivery of sodium. Aldosterone deficiency may be part of a generalized deficiency of adrenal hormones (e.g., Addison's disease), or it may represent a selective process (e.g., hyporeninemic hypoaldosteronism). Hyporeninemic hypoaldosteronism is the most common cause of all aldosterone deficiency states, and is by far the most common cause of chronic hyperkalemia among nondialysis patients (Oh, 1974; Phelps, 1980). Selective hypoaldosteronism can also occur with heparin therapy, which inhibits steroid production in the zona glomerulosa (Phelps, 1980). In patients with reduced aldosterone secretion, any agent that limits the supply of renin or angiotensin II may provoke hyperkalemia, for example, angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory agents, and beta blockers. The latter compound also interferes with potassium transport into cells. Renal tubular unresponsiveness to aldosterone (pseudohypoaldosteronism) may be congenital, but it is more often an acquired defect. This defect may involve only potassium secretion (pseudohypoaldosteronism type II), or sodium reabsorption and potassium secretion (pseudohypoaldosteronism type I) (Wilson, 2001; Wilson, 2003; Sebastian, 1981; Brautbar, 1978). Most cases of so-called "salt losing nephritis" appear to represent the latter defect. Severe volume depletion may cause hyperkalemia despite secondary hyperaldosteronism because volume depletion causes a marked reduction in delivery of sodium to the cortical collecting duct.

Pseudohyperkalemia is defined as an increase in potassium concentration only in the local blood vessel or in vitro, and has no physiologic consequences (Stewart, 1965; Stewart, 1979; Kim, 1990; Zaltzman, 1982; Bellevue, 1975; Iolascon, 1999; Hayward, 1999; Delaunay, 1999; Don, 1990). Prolonged use of a tourniquet with fist exercises can increase the serum potassium level by as much as 1 mmol/L. Thrombocytosis and severe leukocytosis cause pseudohyperkalemia through potassium release from the platelets and white blood cells, respectively, during blood clotting (see Table 14-6).

DIFFERENTIAL DIAGNOSIS OF HYPERKALEMIA

The first step in the differential diagnosis of hyperkalemia should be to rule out pseudohyperkalemia. Electrocardiographic (ECG) abnormalities of hyperkalemia are absent in pseudohyperkalemia, but the absence of ECG changes does not rule out true hyperkalemia because ECG changes are rare in chronic hyperkalemia. Pseudohyperkalemia should be suspected when conditions known to cause pseudohyperkalemia, such as thrombocytosis or in vitro hemolysis (pink serum), exist. In pseudohyperkalemia due to thrombocytosis, both serum and plasma K^+ should be obtained simultaneously. Once pseudohyperkalemia is ruled out, the next step is to differentiate among the three major causes of hyperkalemia: increased K^+ intake, shift of K^+ from the cell, and impaired renal excretion. Measurement of a 24 hour urine K^+ will distinguish increased intake from the other two causes. Although hyperkalemia due to a shift of K^+ from the cell would result in increased urinary excretion of K^+ , renal excretion of K^+ is often not increased because conditions that impair renal excretion of K^+ often coexist. A careful dietary history will be sufficient to rule out hyperkalemia due to increased intake, unless the patient is deliberately trying to deceive the physician.

Chronic hyperkalemia is almost always due to impaired renal excretion, and a 24 hour urine K^+ measurement is rarely needed to prove impaired renal excretion of K^+ as the cause of hyperkalemia. Among the renal causes of hyperkalemia, acute renal failure is the most common cause of acute

hyperkalemia, and this will be obvious from the serum creatinine and BUN. For differential diagnosis of chronic hyperkalemia of renal causes, the first step is to measure plasma renin activity, plasma aldosterone, and urinary excretion of Na^+ and K^+ . A very low urinary Na^+ and a low K^+ in the absence of polyuria suggest that the aldosterone effect is normal; in this setting, K^+ excretion is impaired by the reduced availability of Na^+ and a marked reduction in collecting duct urine flow. Markedly increased proximal reabsorption of Na^+ due to low effective vascular volume, such as severe congestive heart failure, can cause hyperkalemia by such a mechanism. If urinary Na^+ is adequate (>20 mmol/L), plasma renin activity and aldosterone should be measured.

Low PRA and low aldosterone suggest hyporeninemic hypoaldosteronism, whereas high PRA and low aldosterone suggest a primary defect in aldosterone secretion such as Addison's disease, heparin therapy, and aldosterone biosynthetic defect. When PRA and aldosterone are both increased, the likely culprit is (1) pseudohypoaldosteronism, (2) very low Na^+ delivery to the cortical collecting duct, or (3) drugs that impair ENaC function or aldosterone action, such as potassium-sparing diuretics (e.g., amiloride, triamterene, spironolactone) and certain antibiotics (e.g., trimethoprim, pentamidine) (Oh, 2003). The presence of low PRA and high aldosterone in the setting of hyperkalemia is not a very likely combination, but it has been observed occasionally in a patient with a genetic defect of an enzyme WNK kinase, called pseudohypoaldosteronism type II (also known as Gordon's syndrome). The defect in WNK kinase causes increased NaCl transport in the distal convoluted tubule, resulting in hypertension and a defect in potassium secretion (Goldbang, 2005; Yang, 2007; San-Cristobal, 2008). The condition is a mirror image of Gitelman's syndrome, and is characterized by low PRA (due to hyperabsorption of NaCl) and low aldosterone, resulting in hyperkalemia; however, a variant of the condition is characterized by a separate severe defect in K secretion, resulting in hyperkalemia despite normal or sometimes high aldosterone. In such a patient, a high plasma aldosterone occurs in response to hyperkalemia, but renin is low because of volume expansion. By far, the most common cause of chronic hyperkalemia due to impaired renal excretion of potassium is hyporeninemic hypoaldosteronism, which is caused by chronic renal insufficiency of primarily tubulointerstitial disease (Phelps, 1980). The suggested mechanism is primary renal salt retention caused by renal disease, which leads to physiologic suppression of renin secretion and hence of aldosterone, ultimately resulting in hyperkalemia often accompanied by hypertension (Oh, 1974).

DISORDERS OF WATER, SODIUM, AND ANTIDIURETIC HORMONE METABOLISM

REGULATION OF THIRST AND ADH RELEASE

A rise in effective osmolality shrinks the hypothalamic osmoreceptor cells, which then stimulate the thirst center in the cerebral cortex and stimulate ADH production in the supraoptic and paraventricular nuclei. Conversely, a decline in effective osmolality causes swelling of the osmoreceptor cells, resulting in inhibition of ADH production. ADH produced in the hypothalamus is carried through long axons and is secreted from the posterior pituitary gland (McKinley, 1998; Ibata, 1999). Stimulation and inhibition of osmoreceptor cells affect both production by the hypothalamus and secretion of ADH by the pituitary.

Regulation of ADH secretion by a change in effective osmolality is extremely sensitive. It was thought that ADH secretion in response to a change in effective osmolality was so sensitive that a change of only 2%–3% would stimulate ADH secretion sufficiently to result in a maximally concentrated urine, and a decline in plasma osmolality of only 2%–3% would produce maximally dilute urine (<100 mOsm/L) (Bourque, 1997; Olsson, 1983). However, a more recent study has shown that changes in serum sodium concentration by 2%–3% in venous blood are accompanied by a much greater change in arterial serum sodium concentrations when oral intake of water is rapid. For example, drinking 20 mL/kg of water in 15 minutes reduced arterial serum sodium by about 8 mmol/L and resulted in rapid water diuresis, but the same amount given by slow sipping did not produce water diuresis. With rapid intake of water, venous sodium concentration was about 4 mmol/L higher than that of arterial blood. The osmoreceptors of course would respond to arterial, rather than venous, sodium concentration (Shafiee, 2005).

ADH release is also regulated by nonosmotic factors. Low effective vascular volume provokes thirst and ADH release, and high effective vascular volume has the reverse effects (Wells, 1998; Aguilera, 2000; Nielsen, 2002; Schrier, 1979). These effects are mediated through baroreceptors and some humoral factors. Alpha-catecholamines suppress and β -catecholamines enhance ADH output. Prostaglandins inhibit the effects of ADH on the kidney. Angiotensin II stimulates thirst and ADH release. Lack of glucocorticoid enhances ADH action on the kidney and increases ADH release. ADH in the pituitary gland acts similarly to corticotropin-releasing hormone and stimulates production of adrenocorticotrophic hormone (ACTH). Cortisol in turn inhibits the release of ADH (Bahr, 2006). Physical and emotional stress (e.g., major surgery) increase ADH output, possibly in part through emetic stimuli, which are common complications of major surgery and are attributed to the effects of anesthesia and surgical trauma. Many drugs affect ADH release or its action; ethanol inhibits the output of ADH. Lithium and demeclocycline inhibit the effect of ADH on the kidney. Chlorpropamide increases the action of ADH on the kidney. Some drugs may operate through the emetic stimulus, which is one of the most potent physiologic stimuli to ADH release. The urine may become osmotically concentrated in the absence of ADH, if effective vascular volume is very low. The combination of reduced GFR and enhanced proximal reabsorption of filtrate reduces urine flow to the collecting duct so greatly that even the limited permeability of the membrane permits withdrawal of sufficient amounts of water to concentrate urine.

Three classes of ADH receptors are known: V1 receptors cause a rise in vasomotor tone and certain metabolic effects, V2 receptors are associated with antidiuresis, and V3 receptors cause stimulation of ACTH secretion in the anterior pituitary (Ma, 1999; Mouri, 1993; Bahr, 2006). The antidiuretic effect of ADH is mediated by promoting expression of aquaporin-2 on the luminal membrane of the collecting duct to make the tubule permeable to water, and by stimulating reabsorption of salt on the outer medullary thick ascending limb of Henle's loop (Knepper, 1997). Vasopressinase, which normally breaks down ADH, may be increased in pregnancy and may cause polyuria (Molitch, 1998). 1-Deamino-8-D-arginine vasopressin, a synthetic analog of arginine vasopressin, which resists vasopressinase, is useful in polyuria of pregnancy.

URINE CONCENTRATION AND DILUTION

About 180 L of water is filtered daily; 150 L is reabsorbed in the proximal tubule, and about 5 L in the descending limb of Henle of cortical nephrons. About 25 L of dilute urine is delivered to the ascending limb of Henle. Because the tubules from this point to the beginning of the cortical collecting duct are water impermeable, the volume remains unchanged at 25 L, but the osmolality decreases progressively to about 60–80 mOsm/L. Because of the conditional expression of aquaporin-2 on the luminal membrane of collecting ducts, which depends on the action of ADH, no water reabsorption occurs in the cortical and outer medullary collecting ducts when ADH is absent (Fig. 14-4). However, a small amount of water (about 5 L during water diuresis) is reabsorbed in the terminal portion of the inner medullary collecting duct, even when ADH is absent. Aquaporins may be present constitutively in this part of the nephron, or the membrane may be permeable to water without ADH. During maximal water diuresis, the combined effect of further salt reabsorption in the collecting duct and of small additional reabsorption of water in the inner medullary collecting duct allows final excretion of about 20 L of dilute urine at an osmolality of about 40 mOsm/L. It must be noted that maximal urine output during water diuresis depends greatly on salt intake, because the maximal urine output can never exceed the amount delivered into the ascending limb of Henle. Even with mild salt restriction (e.g., 2 g/day), the resulting mild volume depletion increases reabsorption of salt and water in the proximal tubule sufficiently to reduce volume delivery to the ascending limb of Henle's loop to 12–15 L/day, and final maximal urine output to 10–12 L/day.

In the presence of maximal ADH, urine can be concentrated to as high as 1200 mOsm/L as water is reabsorbed in the cortical and medullary collecting duct, with urine volume as low as 0.5 L/day (see Fig. 14-4). In the proximal tubule, water reabsorption passively follows salt reabsorption, whereas in the descending thin limb, water reabsorption is unaccompanied by salt reabsorption but occurs in response to salt reabsorption that takes place in the ascending limb. The osmolality of urine as it enters the ADH effective site (i.e., the cortical collecting duct) is the same during water diuresis and during antidiuresis, and the value is quite low, at about 60 mOsm/L. Urine osmolality is reduced by continuous salt reabsorption without water reabsorption in the ascending thin and thick limbs of Henle

Figure 14-4 Transport of water at various nephron sites. The proximal tubules are always water permeable because aquaporins are constitutively expressed at these sites. The descending thin limbs of juxtamedullary nephrons (15% of all nephrons) also show expression of aquaporins and are therefore water permeable, but the descending thin limb of cortical nephrons (85%) lacks aquaporins and is water impermeable. The ascending thin limb and the ascending thick limb of Henle, the distal convoluted tubule, and the connecting tubule do not express aquaporins, and are always water impermeable. The collecting duct is water permeable when ADH action allows expression of aquaporins. ADH, Antidiuretic hormone.

and in the distal convoluted tubule and connecting tubule. Urine concentration is achieved by reabsorption of water in the collecting duct through transcellular reabsorption of water through the cells of the collecting duct; water first enters the cell through the luminal membrane, and then leaves the cell through the basolateral membranes. Diffusion of water through each membrane requires expression of aquaporins. Aquaporin-3 is constitutively expressed in the basolateral membrane of the cortical collecting duct, and aquaporin-4 is constitutively expressed in the basolateral membrane of the medullary collecting duct. Entry of water in the collecting duct, both cortical and medullary, from the lumen into the cell requires expression of aquaporin-2 on the luminal membrane; this is an ADH-mediated mechanism.

An increase in urine osmolality from a very low value at the beginning of the cortical collecting duct to an isotonic value at the corticomedullary junction requires only the presence of ADH and tubular responsiveness to ADH, because the interstitium of the cortex is always isotonic. However, the reabsorption of water in the medullary collecting duct requires not only the ADH action but also the hypertonicity of the medullary interstitium. Maintenance of medullary hypertonicity is achieved by the countercurrent multiplication mechanism. In short, the medullary interstitial fluid becomes progressively hypertonic, starting at the isotonic level at the corticomedullary junction and increasing to a level of about 1200 mOsm/L at the tip of the papilla. Medullary hypertonicity in the outer medullary area is achieved by active reabsorption of salt in the thick ascending limb of Henle that is not accompanied by water reabsorption. In the inner medulla, salt reabsorption in the thin ascending limb of Henle (the inner medulla lacks the thick ascending limb of Henle) is passive, and occurs with the help of urea that diffuses from the inner medullary collecting duct. The mechanism by which urea contributes to the concentration of urine is still hotly debated, and is beyond the scope of this discussion. Achievement of medullary hypertonicity is attributed to the countercurrent mechanism, which had been traditionally explained in the following manner: (1) selective reabsorption of salt from the ascending limbs of Henle without water reabsorption, (2) selective reabsorption of water from the descending limb of Henle, and (3) countercurrent arrangement of the descending and ascending limbs of Henle by bending of the tubule at the tip of Henle's loop (Hogg, 1986; Pallone, 2003; de Rouffignac, 1987; Oh, 1997; Sands, 1996; Burg, 1995; Schmidt-Nielsen, 1977; Knepper, 1983; Hogg, 1978; Gregor, 1983).

It is now clear, however, that the previous sequence of events to achieve progressive hypertonicity of fluid in the descending thin limb of Henle is applicable to only a small fraction of nephrons, namely, the juxtamedullary nephrons, which represent only 15% of the total nephron population (Zhai, 2007). The cortical nephrons, representing 85% of the nephron population in humans, do not express aquaporins on the thin descending

limb of Henle; therefore, those tubular segments are water impermeable. The progressive urine concentration that occurs along the descending limb of Henle occurs instead sodium and chloride entry (Halperin, 2008). This would create a wasted effort, in that sodium entering the descending limb will have to be reabsorbed again in the ascending limb, but the absence of water permeability of the descending limb of Henle allows relatively constant urine flow rates entering the distal convoluted tubule during water diuresis and antidiuresis (Halperin, 2008).

POLYURIA

Polyuria is arbitrarily defined as urine volume in excess of 2.5 L/day. Two types of polyuria are known: osmotic diuresis and water diuresis (Carroll, 1989).

Osmotic Diuresis

Osmotic diuresis is defined as increased urine output due to an excessive rate of solute excretion; the commonly accepted level of solute excretion for osmotic diuresis is a rate in excess of 60 mOsm/hour, or 1440 mOsm/day, in the adult (Carroll, 1989). Urine osmolality is usually greater than that of plasma, but it may be lower than plasma osmolality when it coexists with water diuresis. Solutes commonly responsible for osmotic diuresis include glucose, urea, mannitol, radiopaque media, and NaCl.

Water Diuresis

Water diuresis is characterized by excretion of a large volume of dilute urine. The polyuria is caused by reduced reabsorption of water in the collecting duct. Reasons for reduced water reabsorption in the collecting duct include lack of ADH (Vokes, 1988; Leggett, 1999; Siggaard, 1999; Rutishauser, 1999; Ito, 1997; Halperin, 2001) and unresponsiveness to ADH (nephrogenic diabetes insipidus). Nephrogenic diabetes insipidus (DI) can be congenital or acquired (Boone, 2009). Congenital nephrogenic DI may be due to a defective ADH receptor or to an aquaporin defect (Weir, 1992; Lam, 2000; Nielsen, 2002; Spruce, 1984; Li, 2001; Canada, 2003; Marples, 1995).

Lack of ADH, which may be congenital or acquired (Levine, 1987; Vokes, 1988; Arai, 1999; Leggett, 1999; Siggaard, 1999; Rutishauser, 1999; Ito, 1997), is due to primary deficiency (central diabetes insipidus) or to physiologic suppression by low serum osmolality (primary polydipsia, dipsogenic diabetes insipidus) (Levine, 1987; Rendell, 1978; Hariprasad, 1980). Deficiency of ADH can be mild, moderate, or severe. When ADH deficiency is partial, urine osmolality may be fairly close to normal. In rare instances, ADH is made but cannot be released in response to a rise in body fluid osmolality because of a defect involving osmoreceptor cells (e.g., hypothalamic lesions) (Leggett, 1999; Siggaard, 1999; Rutishauser, 1999; Ito, 1997; Loh, 2008). In such instances, ADH may be released in response to hypovolemia or to drugs. During pregnancy, ADH deficiency may be caused by excessive production of vasopressinase (gestational DI) (Molitch, 1998). Causes of polyuria, including central and nephrogenic DI, are listed in Table 14-7.

Primary polydipsia is defined as increased water drinking that is not caused by physiologically stimulated thirst (i.e., hyperosmolality or volume depletion) (Rendell, 1980; Hariprasad, 1980; Levine, 1987). Primary polydipsia is usually psychogenic in origin, hence the term psychogenic

polydipsia. In contrast, polydipsia in patients with diabetes insipidus or in diabetic patients with severe glycosuria is secondary polydipsia, which is due to thirst stimulation in response to hyperosmolality. In primary polydipsia, increased urine output is due to physiologic suppression of ADH secretion; hence, serum Na^+ is usually in the low range of normal. In contrast, in central or nephrogenic DI, serum sodium is in the high normal range. Occasionally, serum sodium is frankly low in severe primary polydipsia, indicating that the capacity of the gastrointestinal (GI) tract to absorb water exceeds the capacity of the kidney to excrete water.

CAUSES AND PATHOGENESIS OF HYPONATREMIA (Table 14-8)

Hyponatremia, the most common electrolyte disorder, is defined as reduced plasma sodium concentration to a value less than 135 mmol/L. Generally, clinical concern arises when the concentration is less than 130 mmol/L.

The term pseudohyponatremia, as discussed in Chapter 8, is applied to a spurious reduction in serum sodium concentration caused by a systematic error in measurement. The most common, yet not widely known, cause of pseudohyponatremia is *in vitro* hemolysis, a well known cause of pseudohyperkalemia (Oh, 2003). Because cell lysis does not change osmolality of the plasma, any rise in serum potassium must be met by a reciprocal decrease in serum sodium. However, the reduction in serum Na^+ from hemolysis is somewhat greater than the increase in serum K^+ , by a factor of 1.3, because hemoglobin released from the red cells cause additional reduction in serum Na^+ , as in hyperproteinemia; this error occurs because hemoglobin is mostly a protein, and it has the same effect as hyperproteinemia in displacing plasma water. This additional error occurs only when samples are diluted before the measurement of serum sodium, just as pseudohyponatremia of hyperlipidemia and hyperproteinemia occurs only when samples are diluted before the measurement.

Other causes of pseudohyponatremia include hyperlipidemia, hyperproteinemia, and increased viscosity of the plasma (Weisberg, 1989; Milionis, 2002). The error in measurement in pseudohyponatremia due to hyperproteinemia and hyperlipidemia results from dilution of the sample, as occurs with the common technique of indirect ion-specific electrode measurement. In pseudohyponatremia, plasma osmolality, which is

TABLE 14-8

Classification of Hyponatremia by Pathogenesis

Due to Na^+ Loss

Thiazide diuretics in the presence of ADH

Saline infusion in the presence of ADH

Due to Water Retention

Excessive water intake: Primary polydipsia

Advanced renal failure

Appropriate ADH secretion: Edema-forming states (CHF, nephritic syndrome, ascites), salt depletion states (GI loss, diuretic therapy, aldosterone deficiency, hypothyroidism)

Inappropriate ADH secretion

Tumors: Cancers of the lung, pancreas, duodenum, ureter, bladder, prostate, lymphoma, thymoma, mesothelioma, Ewing's sarcoma
Intrathoracic causes: Bacterial and viral pneumonia, tuberculosis, lung abscess, aspergillosis, asthma, positive-pressure breathing, pneumothorax, cystic fibrosis

CNS abnormalities: Encephalitis, meningitis, brain tumors and abscess, head trauma, subdural hematoma, cerebrovascular accidents, Guillain-Barré syndrome, acute intermittent porphyria, brain atrophy, schizophrenia, hydrocephalus, acute psychosis, multiple sclerosis, cavernous vein thrombosis, lupus cerebritis, Shy-Drager syndrome, Rocky Mountain spotted fever, delirium tremens, seizure disorder

Drugs: Arginine vasopressin and its analogs, sulfonyleureas, tricyclic antidepressants, clofibrate, carbamazepine, vinca alkaloids, cyclophosphamide, selective serotonin reuptake inhibitors, opiates, phenothiazines, haloperidol

Surgical and emotional stress

Emesis

Endocrine causes: Glucocorticoid deficiency, myxedema

ADH, Antidiuretic hormone; CHF, congestive heart failure; CNS, central nervous system; GI, gastrointestinal.

TABLE 14-7

Causes of Polyuria Due to Water Diuresis

Lack of ADH

Central DI: Congenital or acquired (idiopathic cell degeneration, tumors and granulomas, surgery, trauma, infarction, and infection of the pituitary or hypothalamus)

Dipsogenic: Psychogenic, organic brain disease, iatrogenic

Gestational DI: Excess vasopressinase

Failure of the Kidney to Respond to ADH (Nephrogenic DI)

Congenital nephrogenic DI: A defect in ADH receptor, a defect in aquaporin expression

Chronic renal failure

Acquired nephrogenic DI: Lithium toxicity, demeclocycline toxicity, methoxyflurane toxicity, amyloidosis, light-chain nephropathy, hypercalcemia, hypokalemia, obstructive uropathy

ADH, Antidiuretic hormone; DI, diabetes insipidus.

customarily measured without dilution, is normal. However, low plasma sodium concentration with normal plasma osmolality need not indicate the presence of pseudohyponatremia; true hyponatremia may be accompanied by a normal plasma osmolality because of the accumulation of some abnormal osmols or abnormal concentrations of normal nonsodium osmols such as urea and glucose. In hypergammaglobulinemic states, such as multiple myeloma, serum sodium may be falsely low because of displacement of serum water by gamma globulins, but the sodium concentration is also truly low because cationic charges of gamma globulins displace sodium to maintain electrical neutrality (Weisberg, 1978; Weisberg, 1989). Hyponatremia induced by acute hyperglycemia is not pseudohyponatremia because sodium concentration in the ECF is truly low; this occurs as a result of water shift from the cell caused by hyperglycemia. Serum sodium is decreased by 1.6 mmol/L for every 100 mg/dL rise in serum glucose, as discussed earlier (Katz, 1973).

The immediate mechanisms responsible for a reduction in extracellular sodium concentration are (1) shift of water from the cell caused by accumulation of extracellular solutes, such as glucose, other than sodium salts (Agraharkar, 1997; Akan, 1996; Agarwal, 1994); (2) retention of excess water in the body; (3) loss of sodium (Gowrishankar, 1998; Sonnenblick, 1993); and (4) shift of sodium into the cells. The appropriate physiologic response to hypotonicity is suppression of ADH release, which leads to rapid excretion of excess water and correction of hyponatremia. Persistence of hyponatremia therefore indicates the failure of this compensatory mechanism. In most instances, hyponatremia is maintained because the kidney fails to produce water diuresis, but sometimes ingestion of water in excess of the limits of normal renal excretion is responsible. Reasons for the inability of the kidney to excrete water include (1) renal failure, (2) reduced delivery of glomerular filtrate to the distal nephron, and (3) inappropriate presence of ADH.

The mechanism for impaired water excretion in renal failure is obvious and needs no further explanation. Reduced distal delivery of filtrate results from low glomerular filtration rate and enhanced proximal tubular reabsorption of salt and water when effective vascular volume is reduced.

In most cases of hyponatremia, the main reason for the fall of serum sodium is abnormal retention of water, which is ingested as such or is administered as hypotonic fluids. However, in certain clinical settings, reduction in serum sodium can occur without the administration or ingestion of hypotonic fluid. The latter phenomenon occurs when urine is excreted with sodium and potassium at concentrations that exceed the sum of serum concentrations of the two ions, for example, if urine contains sodium at 140 mmol/L and potassium at 100 mmol/L, the combined concentration would be 240 mmol/L, which is far greater than the sum of serum sodium and potassium. Excretion of hypertonic urine with regard to sodium and chloride occurs in the setting of increased urinary sodium excretion in the presence of ADH, as occurs in patients with syndrome of inappropriate ADH (SIADH) who are given an infusion of normal saline, or in individuals who are given a thiazide diuretic. Excretion of such urine may cause hyponatremia without net water retention.

Loss of potassium has the same effect on serum sodium as loss of sodium. It must be noted that the development of hyponatremia with excretion of hypertonic urine occurs only when hypertonicity of urine is caused by increased excretion of sodium or potassium. Hypertonic urine by increased excretion of urea would not produce hyponatremia for obvious reasons.

The physiologic requirement for the excretion of hypertonic urine is an increased amount of ADH in the presence of marked sodium diuresis (Halperin, 2001; Halperin, 2008). Clinical examples include (1) the patient who receives a large amount of isotonic fluid in the immediate postoperative period, (2) the patient with SIADH who is treated with isotonic fluid, and (3) the patient who receives a thiazide diuretic (Gowrishankar, 1998; Sonnenblick, 1993). Normal dilution of urine requires delivery of adequate amounts of fluid to the diluting segment and reabsorption of solute without water at that segment. Increased body fluid tonicity causes release of ADH, which allows reabsorption of water in the collecting duct, helping to restore body fluid tonicity. The response is considered appropriate when ADH is released in response to hypertonicity of body fluid. However, release of ADH in the presence of hyponatremia is also considered appropriate if the effective vascular volume is reduced. The term syndrome of inappropriate ADH secretion, or SIADH, is therefore reserved for ADH secretion that occurs despite hyponatremia and normal or increased effective vascular volume.

Causes of SIADH include tumors, pulmonary diseases such as tuberculosis and pneumonia, central nervous system diseases, and drugs

(Bartter, 1967; Ajalo, 1998; Fallon, 1998; Gold, 1983; Hensen, 1995; North, 2000; Arlt, 1997; Johnson, 1997; Argani, 1997; Ferlito, 1997; Friedmann, 1994). Hyponatremia in clinical states associated with reduced effective vascular volume such as congestive heart failure and cirrhosis of the liver is caused by a combination of reduced delivery of fluid to the distal nephron and increased secretion of ADH. Salt restriction and diuretics increase the severity of hyponatremia. ADH secretion may be present despite hyponatremia in myxedema (Macaron, 1978) and glucocorticoid deficiency states. It is not clear, however, whether ADH secretion in these conditions is truly inappropriate or appropriate. Finally, mild hyponatremia may be caused by “resetting of the osmostat” at an osmolality lower than the usual level. In such cases, urine dilution occurs normally when the plasma osmolality is reduced below the reset level. Resetting of the osmostat is a form of SIADH (Robertson, 2006; Decaux, 2009), in that ADH secretion occurs inappropriately at hyponatremic levels in the absence of reduced effective vascular volume. Patients with chronic debilitating diseases such as pulmonary tuberculosis often manifest this phenomenon (Hill, 1990).

Some authorities believe the existence of a cerebral salt wasting syndrome, which is defined as renal loss of salt caused by humoral substances released in response to cerebral disorders such as acute subarachnoid hemorrhage. These patients are thought to manifest volume depletion that results in hyponatremia. However, careful analysis of existing data does not support the existence of such an entity, and those cases labeled as cerebral salt wasting syndrome probably represents cases of inappropriate ADH secretion (Oh, 2003).

CAUSES AND PATHOGENESIS OF HYPERNATREMIA

Hypernatremia is defined as an increased sodium concentration in plasma water, and is generally diagnosed at serum sodium levels >145 mmol/L. Whereas hyponatremia may not be accompanied by hypoosmolality, hypernatremia is always associated with an increased effective plasma osmolality, and hence with a reduced cell volume. However, the extracellular volume in hypernatremia may be normal, decreased, or increased.

Hypernatremia is caused by loss of water, gain of sodium, or both (Table 14-9). Loss of water may be due to increased loss or reduced intake, and gain of sodium may be due to increased intake or to reduced renal excretion. Increased loss of water can occur through the kidney (e.g., in diabetes insipidus, in osmotic diuresis), the gastrointestinal tract (e.g., gastric suction, osmotic diarrhea), or the skin. Reduced water intake occurs most commonly in comatose patients or in those with a defective thirst mechanism. Less frequent causes of reduced water intake include continuous vomiting, lack of access to water, and mechanical obstruction to the esophagus (e.g., esophageal tumor, stricture). Gain of sodium in a conscious person does not result in hypernatremia because a proportional amount of water is retained to maintain normal body fluid osmolality as long as the person has normal perception of thirst, is able to drink water, and water is available. Whereas the main physiologic defense against hyponatremia is increased renal water excretion, the most effective physiologic

TABLE 14-9

Causes of Hypernatremia

Reduced Water Intake

Defective thirst due to altered mental state or thirst center defect
Inability to drink water
Lack of access to water

Increased Water Loss (Water Intake Must Be Impaired)

Gastrointestinal loss: vomiting, osmotic diarrhea
Cutaneous loss: sweating and fever
Respiratory loss: hyperventilation and fever
Renal loss: diabetes insipidus, osmotic diuresis

Increased Sodium Content of the Body (Water Intake Must Be Impaired)

Increased oral or intravenous intake of sodium chloride
Hypertonic saline or sodium bicarbonate infusion
Ingestion of sea water
Renal salt retention, usually in response to primary water deficit

defense against hypernatremia is increased drinking of water in response to thirst. Because thirst is such an effective and sensitive defense mechanism against hypernatremia, it is virtually impossible to increase serum sodium by more than a few mmol/L if the water drinking mechanism is intact. Therefore, in a patient with hypernatremia, there will always be reasons for reduced water intake. These reasons include a defective thirst mechanism, inability to drink water, and unavailability of water (Marazuela, 2007). Excessive gain of sodium leading to hypernatremia is usually iatrogenic (e.g., from hypertonic saline infusion, accidental entry into maternal circulation during abortion with hypertonic saline, administration of hypertonic sodium bicarbonate during cardiopulmonary resuscitation, treatment of lactic acidosis). Reduced renal sodium excretion leading to sodium gain and hypernatremia usually occurs in response to dehydration caused by primary water deficit. Water depletion due to diabetes insipidus, osmotic diuresis, or insufficient water intake leads to secondary sodium retention through volume-mediated activation of sodium-retaining mechanisms. Consequently, in chronic hypernatremia, sodium retention plays a more important role than water loss (Carroll, 1989; Oh, 2003). Of course, net sodium retention is possible only if sodium is ingested or given.

Whether hypernatremia is due to sodium retention or to water loss can be determined by examination of the patient's volume status. For example, if a patient with a serum sodium concentration of 170 mmol/L has no obvious evidence of dehydration, one must conclude that hypernatremia is caused by water loss and by salt retention. Increasing the serum sodium to 170 mmol/L by water deficit alone would require loss of more than 20% of total body water.

ACID-BASE DISORDERS

BICARBONATE AND CARBON DIOXIDE BUFFER SYSTEM

All body buffers are in equilibrium with protons (H^+) and therefore with pH , as is shown in the following equation (Ramsay 1965):

$$pH = pK + \log A^- / HA, \text{ where } A^- \text{ is a conjugate base of an acid } HA \quad (14-32)$$

Because HCO_3^- and CO_2 are the major buffers of the body, pH is typically expressed as a function of their ratio, as discussed in Chapter 8 and shown in the Henderson-Hasselbalch equation as follows:

$$pH = 6.1 + \log HCO_3^- / pCO_2 \times 0.03 \quad (14-33)$$

where 6.1 is the pK of the HCO_3^- and CO_2 buffer system, and 0.03 is the solubility coefficient of CO_2 .

The equation can be further simplified by combining the two constants, pK and solubility coefficient of CO_2 (Carroll 1989):

$$\begin{aligned} pH &= 6.1 + \log HCO_3^- / pCO_2 \times 0.03 = 6.1 + \log 1/0.03 + \\ &\log HCO_3^- / pCO_2 = 7.62 + \log HCO_3^- / pCO_2 = \\ &7.62 + \log HCO_3^- - \log pCO_2 \end{aligned} \quad (14-34)$$

When H^+ is expressed in nM instead of a negative log value (pH), pCO_2 can be related to HCO_3^- in an equation, such as the following:

$$H (nM) = 24 \times pCO_2 (mmHg) / HCO_3^- (mM) \quad (14-35)$$

The Henderson-Hasselbalch equation indicates that pH depends on the ratio of HCO_3^- / pCO_2 . pH increases when the ratio increases (alkalosis), and pH decreases when the ratio decreases (acidosis). The ratio may be increased by an increase in HCO_3^- (metabolic alkalosis) or by a decrease in pCO_2 (respiratory alkalosis). The ratio may be decreased by a decrease in HCO_3^- (metabolic acidosis) or by an increase in pCO_2 (respiratory acidosis).

DEFINITIONS OF ACID AND BASE

Arrhenius's definition: An acid is a substance that increases the concentration of hydrogen ion (H^+) when dissolved in water, and a base is a substance that increases the concentration of hydroxyl ion (OH^-) when dissolved in water.

Bronsted and Lowry's definition: An acid is a substance that donates a proton in a reaction, and a base is a substance that accepts a proton in a reaction.

Lewis's definition: An acid is a molecule or ion that accepts a pair of electrons to form a covalent bond, and a base is a molecule that donates a pair of electrons for a covalent bond. The definition of Bronsted-Lowry is the most widely accepted and most relevant clinically.

WHOLE BODY ACID-BASE BALANCE

Metabolic acidosis occurs because net acid production is increased, or because net acid excretion is reduced. Because a typical modern diet results in acid production, the normal function of the kidney is to excrete acid to remain in acid-base balance. For these reasons, proper understanding of disorders of acid-base balance requires knowledge of the sources of acid production and of the mechanisms by which acids are disposed of.

Net Acid Production

On a typical American diet, the daily production of nonvolatile acid is about 90 mEq/day. The main acids are sulfuric acid (about 40 mEq/day), which originates from the metabolism of sulfur-containing amino acids such as methionine and cysteine, and incompletely metabolized organic acids (about 50 mEq/day) (Oh, 1992). The source of sulfuric acid is protein, but the sulfur content varies greatly with the types of protein that are ingested (Lemann, 1959). In general, proteins of animal sources (meat, fish, milk, and egg) contain higher amounts of sulfur for a given amount of protein than proteins of plant origin (cereal, beans, and nuts). The sulfur content is much greater in fruits, vegetables, and potatoes, but these food groups are not important sources of protein in the amounts usually eaten. The total amount of acid/alkali content depends not only on the sulfur content but also on the alkali content of food, which is present mainly as salts of organic acids. When both factors are considered, milk has a net alkali value, whereas meat and fish have a net acid value. As a whole, fruits and vegetables contain a large quantity of net alkali because they contain large quantities of organic anions. The total quantity of organic acids normally produced is much more than 50 mEq/day, but the bulk of organic acids produced in the body is metabolized; only a small amount is lost in the urine as organic anions that escape metabolism (e.g., citrate) or as a metabolic end product (e.g., urate). On typical American diets, the amount of alkali absorbed from the GI tract is about 30 mEq/day (Lemann, 1959; Oh, 1992). Thus, the net amount of acid produced daily can be estimated as follows:

$$\begin{aligned} \text{Net acid production} &= (\text{urine sulfate} + \text{urine organic anions}) - \\ &\text{Net alkali absorbed from GI tract} \end{aligned} \quad (14-36)$$

Determination of the net alkali (or acid) content of diet is based on the metabolic fates of the chemicals in the diet after absorption into the body, rather than on its *in vitro* states. For example, citric acid in food is considered neutral because it would be metabolized to CO_2 and water in the body, whereas K^+ citrate is an alkali because it would be converted to K^+ bicarbonate after metabolism. Similarly, arginine Cl^- is an acid because metabolism of arginine in the body would result in the formation of HCl (Lemann, 1959). Thus, the net alkali value of a diet is best determined by the total number of noncombustible cations (Na^+ , K^+ , Ca^{++} , and Mg^{++}) in comparison with the total number of noncombustible anions (Cl^- and P):

$$\text{Net alkali content} = (Na^+ + K^+ + Ca^{++} + Mg^{++}) - (Cl^- + 1.8 P) \quad (14-37)$$

All units are expressed as mEq/day, except for P , which is expressed as mmol/day multiplied by 1.8, because phosphate valence depends on pH , and at pH 7.4 the average valence of phosphate is 1.8. Only the above six ions are considered in the equation because other noncombustible ions are present in negligible amounts in normal food. Sulfate is not included here because sulfate is derived almost entirely from the metabolism of sulfur-containing amino acids, and is not ingested as such. The amount of alkali absorbed from the food is not equal to the amount present in the food because the absorption of divalent noncombustible ions, Ca^{++} , Mg^{++} , and P , is incomplete. Hence, traditionally, measurement of the net GI alkali absorption required analysis of the food, as well as the stool, which necessitated prolonged collection of stool (Oh, 1992; Relman, 1961). Thus, the net GI alkali absorption is expressed as follows:

$$\text{Net GI alkali absorbed} = \text{Net alkali of food} - \text{Net alkali of stool} \quad (14-38)$$

Analysis of the food for the measurement of net alkali content is cumbersome, and analysis of the stool is even more cumbersome. Such analyses typically require admitting the patient to a special metabolic unit. An alternative method has been developed to measure net GI alkali absorption. In this method, urine electrolytes, instead of diet and stool electrolytes, are measured. The method is based on the principle that noncombustible ions absorbed from the GI tract would eventually be excreted in the urine, and therefore, that the individual amounts of these electrolytes excreted in the urine would equal those absorbed from the GI tract. Hence,

$$\begin{aligned}\text{Net GI alkali absorption} &= \text{urine } (\text{Na}^+ + \text{K}^+ + \text{Ca}^{++} + \text{Mg}^{++}) - \\ &\quad \text{urine } (\text{Cl}^- + 1.8 \text{ P})\end{aligned}\quad (14-39)$$

Twenty-four hour urine can be collected in outpatient settings, while patients are eating their usual diets. The amount of net alkali absorbed on a typical American diet as stated earlier, 30 mEq/day, was measured by analysis of urine electrolytes using the above formula (Oh, 1992).

Net Acid Excretion

The most important function of the kidney in acid-base homeostasis is excretion of acid, which is tantamount to generation of alkali. Acid is excreted in the form of NH_4^+ and titratable acid. Another important function of the kidney is excretion of HCO_3^- . Usually, the main function of renal excretion of HCO_3^- is prevention of metabolic alkalosis, but a small amount of bicarbonate is normally excreted in the urine (about 10 mEq/day). Thus, net acid excretion, which is tantamount to net renal production of alkali, can be determined by subtracting HCO_3^- excretion from acid excretion (Lemann, 1959).

$$\begin{aligned}\text{Net acid excretion} &= \text{Acid excretion} - \text{HCO}_3^- \text{ excretion} \\ &= \text{NH}_4^+ + \text{Titratable acid} - \text{HCO}_3^-\end{aligned}\quad (14-40)$$

Normally, about two thirds of acid excretion occurs in the form of NH_4^+ , but in acidosis, NH_4^+ excretion may increase by as much as 10-fold. Excretion of titratable acid is usually modest because of the limited amount of buffer that produces titratable acid (i.e., phosphate, creatinine, and urate) but may be increased markedly in disease states (e.g., BB in diabetic ketoacidosis). Maintenance of acid-base balance requires that net acid production equals net acid excretion. Metabolic acidosis develops when net acid production exceeds net acid excretion, and metabolic alkalosis develops when net acid excretion exceeds net acid production.

METABOLIC ACIDOSIS

Classification

All metabolic acidoses result from reduction in the bicarbonate content of the body, with two minor exceptions: acidosis resulting from dilution of body fluid by administration of a large amount of saline solution that does not contain alkali (dilution acidosis), and acidosis that results from shift of H^+ from the cell. Reduction in bicarbonate content may be due to a primary increase in acid production (*extrarenal acidosis*) or to a primary reduction in net acid excretion (*renal acidosis*) (Table 14-10). In this classification, nonrenal loss of bicarbonate or an alkali precursor is considered as part of increased acid production. In extrarenal acidosis, net acid excretion is markedly increased as the kidney compensates to correct the acidic pH. On the other hand, net acid excretion may be restored to normal in chronic renal acidosis as acidosis stimulates renal H^+ excretion. Normal net acid excretion in the presence of acidic pH suggests a defect in renal acid excretion, and therefore renal acidosis. If the renal acid excretion capacity is normal, net acid excretion should be markedly increased in the presence of extrarenal acidosis (Gennari, 2008; Goulet, 2009).

Renal Acidosis

Renal acidosis is further classified into two types: uremic acidosis and renal tubular acidosis (RTA). In uremic acidosis, reduced net acid excretion results from reduced nephron mass or generalized renal dysfunction (i.e., chronic or acute renal failure), whereas in RTA, reduction in net acid excretion results from a specific tubular dysfunction in acid excretory function. Because development of renal acidosis depends on the rate of net acid excretion, as well as the rate of net acid production, and the latter varies greatly according to the diet of individuals, the level of renal failure at which uremic acidosis develops depends on the dietary intake of acid. On

TABLE 14-10

Causes of Metabolic Acidosis According to Net Acid Excretion

Renal Acidosis: Absolute or Relative Reduction in Net Acid Excretion

Uremic acidosis

Renal tubular acidosis

Distal renal tubular acidosis (type I)

Proximal renal tubular acidosis (type II)

Aldosterone deficiency or unresponsiveness (type IV)

Extrarenal Acidosis: Increase in Net Acid Excretion

Gastrointestinal loss of bicarbonate

Ingestion of acids or acid precursors: Ammonium chloride, sulfur

Acid precursors or toxins: Salicylate, ethylene glycol, methanol, toluene, acetaminophen, paraldehyde

Organic acidosis

L-Lactic acidosis

D-Lactic acidosis

Ketoacidosis

a usual diet, uremic acidosis typically develops when GFR falls below 20% of normal (Bommer, 1996; Oh, 1992).

Three types of RTA are known: Type I RTA, also called classical RTA or distal RTA, is characterized by an inability to reduce urine pH below 5.5. Because acidification of urine to a very low urine pH occurs at the collecting duct, the likely site of defect is the collecting duct, which is a part of the distal nephron, hence the term distal RTA. Because H^+ secretion in the collecting duct is also impaired in type IV RTA, some authors consider both type I and type IV RTA a form of distal RTA. However, the terms type I RTA and distal RTA are used synonymously. Type I RTA can develop as a primary disorder or secondary to drug toxicity, tubulointerstitial renal disease, or other renal disease (Rodriguez-Soriano, 2002).

Type II RTA, also called proximal RTA, has defective proximal bicarbonate reabsorption characterized by a reduced renal bicarbonate threshold. Urine can be made free of bicarbonate and acidified normally when serum bicarbonate decreases to a sufficiently low level. Most patients with proximal RTA have evidence of generalized proximal tubular dysfunction (i.e., Fanconi's syndrome) manifested by bicarbonaturia, aminoaciduria, glycosuria, phosphaturia, and uricosuria. Of these, renal glycosuria (glycosuria in the presence of normal blood glucose) is most useful in diagnosing Fanconi's syndrome. Type II RTA may be a primary disorder or may occur secondary to genetic or acquired renal dysfunction. Hypokalemia is a characteristic finding of both type I and type II RTA, but it tends to be more severe in type I than in type II. Type III RTA, a term used to describe a hybrid form of types I and II RTA, is no longer in use.

Type IV RTA is caused by aldosterone deficiency or tubular unresponsiveness to aldosterone, resulting in impaired renal tubular potassium secretion and hence hyperkalemia. Although reduced H^+ secretion in the collecting duct plays a role, the major mechanism of acidosis in type IV RTA is hyperkalemia-induced impairment in ammonia production in the proximal tubule. Type IV RTA is far more common than type I or type II RTA, and the most common cause of type IV RTA is hyporeninemic hypoaldosteronism. Diabetic nephropathy is the most common cause of hyporeninemic hypoaldosteronism leading to type IV RTA (Oh, 1974; Phelps, 1981).

Organic Acidosis

Among external causes of acidosis, overproduction of endogenous acids, especially lactic acid and ketoacid, is the most important mechanism. Only marked overproduction, well in excess of 1000 mmol/day of lactic acid, leads to acidosis because of the enormous capacity to metabolize organic acids. When organic acids react with bicarbonate, organic anions and CO_2 are formed. Retention of organic anions results in increased anion gap. Retained organic anions are potential bicarbonate; when they are metabolized, bicarbonate is regenerated. However, renal excretion of organic anions results in hyperchloremic acidosis with normal anion gap. Thus, loss of organic anions in the urine is tantamount to loss of bicarbonate. If an organic anion produced from organic acid is entirely retained, subsequent metabolism of the entire amount will result in complete recovery of the lost alkali. Characteristically, organic acidosis is rapid in onset and in recovery.

Lactic Acidosis. Lactic acid is produced from pyruvic acid by the action of the enzyme lactate dehydrogenase (LD) and the cofactor NADH.

TABLE 14-11

Causes of L-Lactic Acidosis

Type A Lactic Acidosis Due to Tissue Hypoxia

Circulatory shock
Severe hypoxemia
Heart failure
Severe anemia
Grand mal seizure

Type B Lactic Acidosis (No Tissue Hypoxia)

Acute alcoholism
Drugs and toxins (e.g., phenformin, antiretroviral drugs, salicylate intoxication)
Diabetes mellitus
Leukemia
Deficiency of thiamine or riboflavin
Idiopathic

Metabolism of lactic acid requires its conversion back to pyruvic acid, using the same enzyme and NAD^+ as a cofactor. For this reason, both production and metabolism of lactic acid are influenced by the same factors; increased concentrations of pyruvic acid and increased ratios of NADH/NAD^+ increase lactic acid production and reduce its metabolism. Consequently, in most cases of lactic acidosis, lactic acid production is increased, while its metabolism is reduced. By far the most common cause of lactic acidosis is tissue hypoxia, which results from circulatory shock, severe anemia, severe heart failure, acute pulmonary edema, cardiac arrest, carbon monoxide poisoning, seizures, vigorous muscular exercise, etc. (Carroll, 1989; Oh, 2003; Arenas-Pinto, 2003). Lactic acidosis in the absence of tissue hypoxia is called type B lactic acidosis, whereas that associated with tissue hypoxia is called type A lactic acidosis. In recent years, common causes of type B lactic acidosis include antiretroviral drugs and metformin (Strack, 2008; McGuire, 2006). Impaired metabolism of lactic acid is the cause of lactic acidosis in acute alcoholism and severe liver disease (Table 14-11).

D-Lactic Acidosis. Lactic acidosis, unless specified, refers to acidosis caused by L-lactic acid, which is the isomer produced in the human body, because the enzyme LD is an L-isomer. Accumulation of D-lactic acid causes D-lactic acidosis. The condition is characterized by severe acidosis accompanied by neurologic manifestations such as mental confusion and staggering gait, mimicking ethanol intoxication without elevated plasma levels of ethanol. The mechanism of D-lactic acidosis is the colonic overproduction of D-lactic acid by bacteria (Oh, 1979; Day, 1999). Requirements for overproduction of D-lactic acid in the colon include delivery of a large amount of carbohydrate to the colon (i.e., malabsorption syndrome) and proliferation of D-LD-forming bacteria in the colon (Uribarri, 1998; Oh, 1979). Treatment of D-lactic acidosis includes oral administration of poorly absorbable antibiotics such as neomycin and measures to alter the colonic bacterial flora (Uribarri, 1998).

Ketoacidosis. Keto acids, acetoacetic acid, and β -hydroxybutyric acid are produced in the liver from free fatty acids (FFAs) and are metabolized by extrahepatic tissues. Increased production of keto acids is the main mechanism for keto acid accumulation, although decreased utilization of keto acids by the brain with the patient in a coma may accelerate keto acid accumulation. Increased production requires a high concentration of FFA and its conversion to keto acids in the liver. Insulin deficiency is responsible for increased mobilization of FFA from the adipose tissue, and glucagon excess and insulin deficiency stimulate conversion of FFA to keto acids in the liver. The initial step in keto acid production from FFA is the entry of FFA into the mitochondria, which requires acyl-carnitine transferase. This step is stimulated by glucagon excess. The next step is metabolism of FFA to acetyl-coenzyme A (CoA), and then finally to keto acids. Diversion of acetyl-CoA to fatty acid resynthesis requires the enzyme acetyl-CoA carboxylase, and inhibition of this enzyme by insulin deficiency, glucagon excess, and an excess of stress-induced hormones such as catecholamines further contributes to increased keto acid synthesis.

The clinical diagnosis of ketoacidosis is usually made with Acetest, which detects acetoacetate (AA) but not BB. Although BB is the predominant acid in typical ketoacidosis (the usual ratio of BB/AA is about 2.5:3.0), the reaction to Acetest represents a fair estimate of the total concentration

Figure 14-5 The anatomy of anion gap. When UC is defined as all serum cations other than Na, and UA as all serum anions other than Cl or bicarbonate, the serum anion gap can be stated as UA minus UC.

of keto acids as long as the ratio remains within the usual range. When the ratio of BB/AA is greatly increased, Acetest may be negative or only slightly positive, despite retention of a large quantity of total ketones in the form of BB. Such a condition is called BB acidosis, and it is commonly seen in alcoholic ketoacidosis (Delaney, 2000; Oh, 1977; Falco, 2003).

SERUM ANION GAP

Serum anion gap (AG) is estimated as follows: $\text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-)$ or $(\text{Na}^+ + \text{K}^+) - (\text{Cl}^- + \text{HCO}_3^-)$. Because normal serum potassium concentration is quantitatively a minor component of serum electrolytes, the fluctuation in its concentration affects the overall result very little; hence, the first of the two equations is more commonly used to estimate the AG. The normal value is about 12 mmol/L (8–16 mmol/L). Although the term anion gap implies that there is a gap between cation and anion concentrations, the total concentration of all cations in the serum is exactly equal to the total concentration of all anions. The anion gap, $\text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-)$, is 12 mmol/L because the total concentration of unmeasured anions (i.e., all anions other than chloride and bicarbonate) is about 23 mmol/L, and the total concentration of unmeasured cations (i.e., all cations other than sodium) is about 11 mmol/L.

Let us assume that total serum cations = Na^+ + unmeasured cations (UC), and that total serum anions = $\text{Cl}^- + \text{HCO}_3^-$ + unmeasured anions (UA). Because total serum cations = Total serum anions, $\text{Na}^+ + \text{UC} = (\text{Cl}^- + \text{HCO}_3^-) + \text{UA}$. Hence, $\text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-) = \text{UA} - \text{UC}$. Because the anion gap = $\text{Na}^+ - (\text{Cl}^- + \text{HCO}_3^-)$, the anion gap = $\text{UA} - \text{UC}$ (Fig. 14-5; Oh, 1977).

It is apparent that a change in the anion gap must involve changes in unmeasured anions or unmeasured cations, unless a laboratory error involves the measurement of Na^+ , Cl^- , or HCO_3^- . The anion gap can be increased by increased UA or decreased UC, or by a laboratory error resulting in a false increase in serum Na^+ or a false decrease in serum Cl^- or HCO_3^- . AG can be decreased by decreased UA or increased UC, or by a laboratory error resulting in a false decrease in serum Na^+ or a false increase in serum Cl^- or HCO_3^- . The equation also predicts that a change in UA may not change AG if UC is also changed to the same extent in the same direction.

Decreased AG is most commonly due to reduction in serum albumin concentration; increased AG is most often due to accumulation of anions of acids, such as sulfate, lactate, and ketone anions. Although bromide is

an unmeasured anion, bromide intoxication is accompanied by low serum anion gap because bromide causes a false increase in serum Cl^- . A change in serum Na^+ usually does not cause a change in AG because serum Cl^- usually changes in the same direction. For the same reason, HCO_3^- concentrations cannot be used to predict a change in AG. For example, when serum HCO_3^- concentration increases in metabolic alkalosis, Cl^- concentration usually decreases reciprocally to maintain electrical neutrality, so the AG is unchanged. When HCO_3^- concentration decreases, Cl^- concentration may remain unchanged or may be increased. If bicarbonate is replaced by another anion, Cl^- concentration remains unchanged, hence normochloremic acidosis with increased AG. Examples are organic acidosis, uremic acidosis, and acidosis due to toxic alcohols (Kraut, 2008). When bicarbonate concentration decreases without another anion replacing it, electrical neutrality is maintained by a higher Cl^- concentration: hence, hyperchloremic acidosis with normal AG. Proper interpretation of serum AG requires knowledge of the existence of conditions that influence anion gap, even though they may have no direct effect on metabolic acidosis. For example, if a person with hypoalbuminemia develops lactic acidosis, the AG could be normal because the low albumin and the lactate accumulation have opposite effects on the AG (Kraut, 2007). Similarly, hypermagnesemia (increased unmeasured cation) does not decrease the AG if it is accompanied by increased sulfate (unmeasured anion), as in magnesium sulfate intoxication (Oh, 1977).

It has been suggested that in pure high AG metabolic acidosis, the decrease in serum bicarbonate is about equal to the increase in serum anion gap. A concentration of serum bicarbonate higher than expected has been taken as evidence for the presence of complicating metabolic alkalosis. However, this rule often does not apply in individual cases (Kraut, 2007; Rastegar, 2007).

Differential Diagnosis

One approach to the differential diagnosis of metabolic acidosis is to calculate the serum anion gap. The increased AG suggests organic acidosis, uremic acidosis, and acidosis due to various toxic alcohols (Kraut, 2008; Fenves, 2006; Judge, 2005; Schwert, 2007; Zar, 2007) (Table 14-12). The normal AG suggests renal tubular acidosis and acidosis due to diarrheal loss of bicarbonate. Most cases of uremic acidosis are accompanied by normal AG; only in advanced chronic and acute renal failure is AG increased. Furthermore, a vast majority of patients with ketoacidosis pass through a phase of hyperchloremic acidosis (normal AG) during the recovery phase (Oh, 1990).

Another approach to the differential diagnosis of metabolic acidosis is to classify the acidosis into renal and extrarenal acidosis. Three major causes of extrarenal acidosis are organic acidosis, diarrheal loss of bicarbonate, and acidosis due to exogenous toxins. The presence of organic acidosis is usually obvious from clinical findings (e.g., evidence of tissue hypoxia in lactic acidosis, hyperglycemia and ketonemia in ketoacidosis). Diarrhea as the cause of metabolic acidosis is first suspected from history, but history is often misleading because the severity of diarrhea cannot be easily determined. The measurement of urine AG is useful in determining the severity of diarrhea. Urine AG, which is measured as urine $(\text{Na}^+ + \text{K}^+) - \text{urine } \text{Cl}^-$, is reduced or negative when diarrhea is severe. The low urine

TABLE 14-12

Classification of Metabolic Acidosis by Anion Gap

Metabolic Acidosis with Increased Anion Gap (Normochloremic Acidosis)

Ketoacidosis

L-Lactic acidosis

D-Lactic acidosis

β-Hydroxybutyric acidosis

Uremic acidosis

Ingestion of toxins: Salicylate, methanol, ethylene glycol, toluene, acetaminophen

Metabolic Acidosis with Normal Anion Gap (Hyperchloremic Acidosis)

Renal tubular acidosis

Uremic acidosis (early)

Acidosis following respiratory alkalosis

Intestinal loss of bicarbonate

Administration of chloride-containing acid: HCl, NH_4Cl

Ketoacidosis during recovery phase

AG in diarrhea is explained by the preferential loss of $\text{Na}^+ + \text{K}^+$ in excess of Cl^- because diarrheal fluid contains more $\text{Na}^+ + \text{K}^+$ than Cl^- , as some of these cations are balanced by bicarbonate and organic anions. In other types of metabolic acidosis, urine AG is not altered as long as there is no extrarenal loss of electrolytes that are components of urine AG (Oh, 2002a). A history of drug ingestion and acute onset will suggest acidosis caused by exogenous toxins (Judge, 2005).

Once extrarenal acidosis is excluded, renal acidosis is the only alternative diagnosis. Of the two types of renal acidosis, uremic acidosis can be readily ruled out by normal values of serum creatinine and BUN. If renal acidosis is confirmed but uremic acidosis is ruled out, the diagnosis must be renal tubular acidosis. Among the three types of RTA, type IV RTA is suspected by the presence of hyperkalemia. Hypokalemia suggests type I or type II RTA. If spontaneous urine pH is below 5.5, type I RTA is ruled out. If urine pH is higher than 5.5, urine pH should be measured after oral administration of 40 mg of furosemide or 10 mg of torsemide (Han, 2005). The latter drug has higher sensitivity and specificity (Han, 2005). If the urine pH remains above 5.5, the likely diagnosis is type I RTA. Evidence of Fanconi's syndrome (the best evidence is renal glycosuria) suggests type II RTA.

Compensation of Metabolic Acidosis

Compensation of metabolic acidosis is achieved by hyperventilation, which results in decreased pCO_2 . The compensation is moderately effective, and the maximal compensation is completed within 12 to 24 hours. The formula that predicts the expected decrease in pCO_2 (ΔpCO_2) is as follows:

$$\Delta\text{pCO}_2 = \Delta\text{HCO}_3^- \times 1.2 \pm 2 (\Delta\text{HCO}_3^- \text{ a given decrease in a serum } \text{HCO}_3^- \text{ concentration}) \quad (14-41)$$

METABOLIC ALKALOSIS

Causes and Pathogenesis

At normal serum bicarbonate concentrations, bicarbonate filtered at the glomerulus is almost completely reabsorbed. As serum bicarbonate concentrations rise above the normal level, bicarbonate reabsorption is incomplete, and bicarbonaturia begins. A slight increase in serum bicarbonate above 24 mmol/L causes marked bicarbonaturia. Hence, when renal tubular bicarbonate handling and GFR are normal, maintenance of a high plasma bicarbonate concentration is extremely difficult unless an enormous amount of bicarbonate is given. Therefore, maintenance of metabolic alkalosis requires two conditions: a mechanism to increase plasma bicarbonate and a mechanism to maintain an increased concentration. A bicarbonate concentration may be increased by administration of alkali, gastric loss of HCl through vomiting or nasogastric suction, or renal generation of bicarbonate (Table 14-13). Maintenance of high plasma bicarbonate concentration occurs in advanced renal failure, or when the renal threshold for bicarbonate is increased (Palmer, 1997). The two most common causes of increased renal bicarbonate threshold are volume depletion and K^+ depletion. Potassium deficiency reduces the intracellular pH of the proximal tubules, and this stimulates bicarbonate reabsorption. Increased reabsorption of potassium in exchange for proton by $\text{K}^+ - \text{H}^+$ -ATPase in the collecting duct appears to contribute to metabolic alkalosis in potassium deficiency states (Codina, 2006). Metabolic alkalosis corrected by administration of chloride-containing fluid (e.g., NaCl, KCl solution) is called chloride-responsive metabolic alkalosis (e.g., vomiting-induced alkalosis). Patients with chloride-responsive metabolic alkalosis are typically volume depleted (Oh, 2002b). However, in edema-forming

TABLE 14-13

Mechanisms and Causes to Increase Extracellular Bicarbonate Concentration

Loss of HCl from the stomach (e.g., gastric suction, vomiting)

Administration of bicarbonate or bicarbonate precursors (e.g., sodium lactate, sodium acetate, sodium citrate)

Shift of H^+ into the cell (e.g., K^+ depletion, refeeding alkalosis)

Rapid contraction of extracellular volume without loss of bicarbonate (e.g., contraction alkalosis by the use of loop diuretics)

Increased renal excretion of acid (e.g., diuretic therapy, high aldosterone state, potassium depletion, high pCO_2 , secondary hypoparathyroidism)

pCO_2 , Partial pressure of carbon dioxide.

conditions, administration of Cl^- may not improve metabolic alkalosis, even though the mechanism of a high renal bicarbonate threshold is volume depletion, because administered chloride is retained in the edema fluid. Parathyroid hormone normally interferes with bicarbonate reabsorption in the proximal tubule; therefore, the renal tubular bicarbonate threshold tends to be increased in hypoparathyroidism (Khanna, 2006).

Compensation of Metabolic Alkalosis

Compensation of metabolic alkalosis is achieved by hypoventilation that results in increased pCO_2 . In part because hypoxemia occurs inevitably with hypoventilation in the absence of oxygen supplement, among the four types of acid-base disorders, compensation is least effective in metabolic alkalosis. The formula that predicts the expected increase in pCO_2 (ΔpCO_2) is as follows:

$$\Delta\text{pCO}_2 = \Delta\text{HCO}_3^- \times 0.7 \pm 5 \quad (\Delta\text{HCO}_3^- \text{ is a given increase in serum } \text{HCO}_3^- \text{ concentration}) \quad (14-42)$$

The maximal compensation is completed within 12–24 hours. Observations have shown that no matter how severe the metabolic alkalosis, pCO_2 rarely exceeds 60 mmHg unless a complicating independent respiratory disorder that compromises ventilation coexists (Oh, 2003).

RESPIRATORY ACIDOSIS

Causes and Pathogenesis

Causes are usually apparent and include diseases of the lung (most common causes), respiratory muscle, respiratory nerve, thoracic cage, and airways, and suppression of the respiratory center by stroke, drugs such as phenobarbital, or severe hypothyroidism (Table 14-14).

Compensation of Respiratory Acidosis

The normal compensatory response to respiratory acidosis is to increase HCO_3^- concentration in an attempt to minimize the reduction in pH. This occurs in two distinct stages: first, by tissue buffering of CO_2 , and second, by increased renal excretion of acid.

Tissue Buffering

This phase of compensation is extremely fast and occurs within a second. The chemical reaction is as follows:

KBuf is a non- HCO_3^- buffer and HBuf is cellular acid buffers, and the reaction proceeds to the right because of the rising pCO_2 . Because ECF has few non- HCO_3^- buffers, most of this buffering occurs in the cell. The increased concentration of cellular HCO_3^- causes an extracellular shift of HCO_3^- in exchange for Cl^- through the ubiquitous anion exchanger on the red blood cell membrane. The relationship between an increase in pCO_2 (ΔpCO_2) and the increase in serum levels of HCO_3^- (ΔHCO_3^-) in acute respiratory acidosis is shown in the following equation:

$$\Delta\text{HCO}_3^- (\text{mmol/L}) = \Delta\text{pCO}_2 (\text{mmHg}) \times 0.07 \pm 1.5 \quad (14-45)$$

Renal Compensation

Renal compensation for respiratory acidosis is delayed, but it increases the HCO_3^- concentration to a much higher level. The increased concentration of HCO_3^- is achieved by increased net acid excretion, primarily in the form

of NH_4^+ . Maximal compensation requires 5 days but is 90% complete in 3 days. Increased excretion of NH_4^+ is accompanied by Cl^- . As new HCO_3^- is retained, Cl^- is lost. It follows therefore that when respiratory acidosis is corrected, excretion of HCO_3^- must be accompanied by retention of Cl^- , which is possible only if Cl^- is taken in. Restriction of NaCl intake during the recovery phase of chronic respiratory acidosis results in the maintenance of a high serum HCO_3^- . Such a condition is called posthypercapnic metabolic alkalosis.

The relationship between the increase in pCO_2 (ΔpCO_2) and the increase in HCO_3^- (ΔHCO_3^-) in chronic fully compensated respiratory acidosis is shown in the following equation:

$$\Delta\text{HCO}_3^- (\text{mmol/L}) = \Delta\text{pCO}_2 (\text{mmHg}) \times 0.4 \pm 3 \quad (14-46)$$

RESPIRATORY ALKALOSIS

Causes and Pathogenesis

With the exception of respirator-induced alkalosis and voluntary hypoventilation, respiratory alkalosis is the result of stimulation of the respiratory center. The two most common causes of respiratory alkalosis are hypoxic stimulation of the peripheral respiratory center and stimulation through pulmonary receptors caused by various disorders of the lung, such as pneumonia, pulmonary congestion, and pulmonary embolism. Certain drugs (e.g., salicylate, progesterone) stimulate the respiratory center directly (Saaresranta, 1999; Bayliss, 1992). High progesterone levels are responsible for chronic respiratory alkalosis of pregnancy (Wise, 2006). Respiratory alkalosis is also common in gram-negative sepsis and liver disease through unknown mechanisms (Ahya, 2006). Blood pH tends to be extremely high when respiratory alkalosis is caused by psychogenic stimulation of the respiratory center, because the condition is usually superacute, and therefore there is no time for compensation. Causes of respiratory alkalosis are listed in Table 14-15.

Compensation of Respiratory Alkalosis

Two types of compensation lower plasma HCO_3^- and minimize the increase in blood pH in respiratory alkalosis: tissue buffering and renal compensation.

Tissue Buffering

Compensation by buffering of HCO_3^- is completed within a second with the following reactions (Carroll, 1989):

The reactions proceed to the right because CO_2 is lost by hyperventilation. The magnitude of reduction in HCO_3^- content depends on the number of HBuf that react with HCO_3^- . As cellular HCO_3^- is consumed in the buffer reaction, extracellular HCO_3^- enters the cell in exchange for cellular Cl^- that enters the ECF. An additional mechanism of tissue buffering is increased production of lactic acid and other organic acids (Hood, 1998). Increased lactic acid production is explained in part by the stimulatory effect of alkaline pH on phosphofructokinase, a rate-limiting enzyme for glycolysis. The magnitude of reduction in plasma HCO_3^- concentration by acute compensation is predicted from the following equation:

$$\Delta\text{HCO}_3^- (\text{mmol/L}) = \Delta\text{pCO}_2 (\text{mmHg}) \times 0.2 \pm 2.5 \quad (14-49)$$

(ΔHCO_3^- [mmol/L] is the expected decrease in plasma HCO_3^- for a given decrease in pCO_2 [ΔpCO_2] in mmHg.)

TABLE 14-14

Causes of Respiratory Acidosis

Lung diseases: Chronic obstructive lung disease, advanced interstitial lung disease, acute asthma
Thoracic deformity or airway obstruction

Causes of Respiratory Alkalosis

Diseases of the lung: Any intrapulmonary pathology such as pneumonia, pulmonary fibrosis, pulmonary congestion, pulmonary embolism
Hypoxemia
CNS lesions
Gram-negative sepsis
Liver disease
Drugs: Salicylate, progesterone

CNS, Central nervous system.

Renal Compensation

Renal compensation of respiratory alkalosis is achieved by reduction in net acid excretion (Carroll, 1989; Oh, 2003). This is achieved initially by increased excretion of HCO_3^- , but later by reduced excretion of NH_4^+ and titratable acid. The magnitude of reduction in plasma HCO_3^- concentration due to renal compensation can be predicted from the following equation:

$$\Delta\text{HCO}_3^- (\text{mmol/L}) = \Delta\text{pCO}_2 (\text{mmHg}) \times 0.5 \pm 2.5 \quad (14-50)$$

(ΔHCO_3^- [mmol/L] is the expected decrease in plasma HCO_3^- for a given decrease in pCO_2 [ΔpCO_2] in mmHg.)

Among the four types of acid-base disorders, compensation is most effective in respiratory alkalosis; pH after compensation sometimes returns to normal levels. The process is completed within 2–3 days. When complete compensation does occur, one should look for evidence of complicating metabolic acidosis.

MIXED ACID-BASE DISORDERS

The term mixed acid-base disorder refers to a clinical condition in which two or more primary acid-base disorders coexist. They generally present with one obvious disturbance with what appears to be an inappropriate (excessive or inadequate) compensation. The “inappropriateness” of the compensatory process is probably the result of a separate primary disorder. Appropriate degrees of compensation for primary acid-base disorders have been determined by analysis of data from a large number of patients, and are expressed in the form of equations in the next table. When two disorders influence the blood pH in opposite directions, the blood pH will be determined by the dominant disorder. If disorders cancel out each other's effects, blood pH can be normal. When there is any degree of compensation for acid-base disorders, both pCO_2 and HCO_3^- change in the same

TABLE 14-16

Formulas for Predicting Normal Acid-Base Compensation*

Metabolic acidosis: $\Delta\text{pCO}_2 = \Delta\text{HCO}_3^- \times 1.2 \pm 2$
Metabolic alkalosis†: $\Delta\text{pCO}_2 = \Delta\text{HCO}_3^- \times 0.7 \pm 5$
Acute respiratory acidosis: $\Delta\text{HCO}_3^- = \Delta\text{pCO}_2 \times 0.07 \pm 1.5$
Chronic respiratory acidosis: $\Delta\text{HCO}_3^- = \Delta\text{pCO}_2 \times 0.4 \pm 3$
Acute respiratory alkalosis: $\Delta\text{HCO}_3^- = \Delta\text{pCO}_2 \times 0.2 \pm 2.5$
Chronic respiratory alkalosis: $\Delta\text{HCO}_3^- = \Delta\text{pCO}_2 \times 0.5 \pm 2.5$

pCO_2 , Partial pressure of carbon dioxide.

* ΔHCO_3^- and ΔpCO_2 represent the difference between normal and actual values.

†No matter how high the serum HCO_3^- rises, pCO_2 rarely rises above 60 mm Hg in metabolic alkalosis.

direction (i.e., both are high or both are low). If pCO_2 and HCO_3^- have changed in opposite directions (e.g., pCO_2 is high and HCO_3^- is low, or pCO_2 is low and HCO_3^- is high), the presence of a mixed acid-base disorder is certain. Appropriateness of compensation can be determined by consulting Table 14-16. Compensation may be excessive, insufficient, or appropriate. One can also have an approximate idea about the appropriateness of compensation from the degree of pH deviation without consulting the formula for normal compensation.

In general, compensation is most effective in respiratory alkalosis (pH is often normalized); the next best is respiratory acidosis (pH may become normal), and the third best is metabolic acidosis. Compensation is least effective in metabolic alkalosis, probably because hypoxemia, an inevitable consequence of hypoventilation, stimulates ventilation. If a patient has low pCO_2 and low HCO_3^- with normal pH, the likely diagnosis is compensated respiratory alkalosis rather than compensated metabolic acidosis (Carroll, 1989; Oh, 2003).

KEY POINTS

- The plasma concentration of calcium, phosphate, and magnesium is dependent on the net balance of bone mineral deposition and resorption, intestinal absorption, and renal excretion. The principal hormones regulating these processes are parathyroid hormone (PTH), calcitonin, and 1,25-dihydroxyvitamin D.
- The most common causes of hypercalcemia are primary hyperparathyroidism (elevated PTH) and malignant neoplasms (decreased PTH and usually elevated PTH-related peptide). They account for 80%–90% of all patients with hypercalcemia.
- The most common causes of hypocalcemia are chronic renal failure, hypomagnesemia, hypoparathyroidism, pseudohypoparathyroidism, vitamin D deficiency, and acute pancreatitis.
- Bio-intact PTH measures biologically active PTH; it is useful in patients with impaired renal function when various metabolites accumulate and interfere with traditional PTH assays.
- In patients undergoing surgery for primary hyperparathyroidism, intraoperative PTH measurements are useful in identifying whether the abnormal tissue is completely removed.
- Osteoporosis is the most common metabolic disease of bone and is characterized by decreased organic bone matrix. Serial bone resorption marker measurements can predict early response to therapy.
- Osteomalacia is failure to mineralize newly formed organic matrix (osteoid) in the mature skeleton.
- Phosphatonins comprise a newly described cascade of hormones, enzymes, and proteins related to phosphate metabolism.

MINERAL AND BONE METABOLISM

The skeleton is a metabolically active organ that undergoes continuous remodeling throughout life. This remodeling is necessary both to maintain the structural integrity of the skeleton and to fulfill its metabolic functions as a storehouse of calcium and phosphorus. Skeletal remodeling can be

triggered by changes in mechanical forces or microdamage, and by hormonal response to changes in circulating calcium and phosphorus levels. The skeleton also serves as the second line of defense against acidosis, and it is able to liberate buffers in the form of inorganic phosphates (Raisz, 1999).

Bone can be classified into two types: cortical or compact bone, and cancellous or trabecular bone (Fig. 15-1, *A* and *B*). Cortical bone plays an important role in the supportive, protective, and mechanical functions of the skeleton; it comprises the shafts of long bones and the outer envelope of all bones. It constitutes approximately 80% of skeletal mass, and it is 90% bone and 10% space (vascular canals, osteocyte lacunae, and canaliculi) by volume. Cancellous bone, which constitutes the remaining 20% of skeletal mass, is 25% bone and 75% space by volume. It is present at the ends of long and short tubular bones, within carpal and tarsal bones, and in the medullary cavities of vertebral bodies and flat bones. It is arranged in highly perforated vertical plates interconnected by horizontal struts and has a honeycombed appearance. It serves as a repository for hematopoietic cells and provides a large surface area for short-term mineral exchange (Watts, 1999). Even though cancellous bone represents only 20% of the total skeletal mass, it provides such a large surface area—that it accounts for 50% of active bone turnover at any given time (Erikson, 1994). Both compact and cancellous bones are composed primarily of inorganic minerals (calcium and phosphorus) and an organic matrix. Approximately 90%–95% of this organic matrix is type I collagen, and the remaining 5%–10% consists of noncollagenous proteins, including osteocalcin, osteopontin, osteonectin, thrombospondin, sialoproteins, and other less well-characterized proteins. Osteoclasts actively resorb bone by producing hydrogen ions to mobilize the minerals and proteolytic enzymes to hydrolyze the organic matrix. Osteoblasts synthesize the organic matrix and control the mineralization of the newly synthesized matrix (Endres, 1999).

The plasma concentration of calcium, phosphate, and magnesium is dependent upon the net balance of bone mineral deposition and resorption, intestinal absorption, and renal excretion. The principal hormones regulating these processes are PTH, calcitonin, and 1,25-dihydroxyvitamin D. Much of bone metabolism reflects the body's effort to maintain serum calcium and phosphorus levels.

Figure 15-1 **A**, Compact bone, long bone, cross-section. The compact bone of the cortex of the femur in this 30-year-old male is continuous and solid, and the vascular spaces are not grossly visible. The hollow medullary cavity is filled with fatty marrow in vivo. **B**, Cancellous bone, longitudinal section. The cancellous bone is arranged in highly perforated vertical plates interconnected by delicate horizontal struts (braces). Most of its volume appears to be empty space once the marrow has been removed.

CALCIUM

Physiology

Distribution

Calcium is the fifth most common element and is the most prevalent cation in the human body. A healthy adult contains approximately 1–1.3 kg of calcium, and 99% of this is in the form of hydroxyapatite in the skeleton. The remaining 1% is contained in the extracellular fluid (ECF) and soft tissues. Additionally, less than 1% of the skeletal content of calcium is in bone fluid and exchanges freely with the ECF (Mundy, 1999).

Serum (plasma) calcium exists in three distinct forms: (1) free or ionized calcium, which is the physiologically active form, accounting for approximately 50% of the total serum calcium; (2) complexed calcium, which is bound tightly to a variety of anions, including bicarbonate, lactate, phosphate, and citrate, accounting for approximately 10%; and (3) plasma protein-bound calcium, accounting for approximately 40%. Both ionized calcium and the calcium complexes are freely dialyzable. Approximately 80% of the protein-bound calcium fraction is associated with albumin.

Because ionized calcium binds to negatively charged sites on the protein molecules, there is competition with hydrogen ions for binding sites on albumin and other calcium-binding proteins, and its binding is pH dependent. Although total serum calcium levels may remain unchanged, the relative distribution of the three forms is altered as a result of pH changes in ECF. Alkalosis promotes increased protein binding, with a subsequent decrease in free calcium, whereas acidosis decreases protein binding, causing an increase in free calcium levels. Because calcium is bound to proteins, total calcium levels are also altered by plasma protein concentration.

Function

In addition to its obvious importance in skeletal mineralization, calcium plays a vital role in such basic physiologic processes as blood coagulation, neural transmission, plasma buffering capacity and enzyme activity, and in

Figure 15-2 Calcium homeostasis. Solid arrows and block arrows indicate effects that increase serum calcium levels; dashed arrows indicate negative effects that decrease serum calcium.

the maintenance of normal muscle tone and excitability of skeletal and cardiac muscle. It is an activator of intracellular signal transduction processes and is essential for DNA and RNA biosynthesis. Calcium is also involved in glandular synthesis and in regulation of exocrine and endocrine glands, as well as in the preservation of cell membrane integrity and permeability, particularly in terms of sodium and potassium exchange.

The average dietary intake of calcium for most adults in the United States is approximately 15–20 mmol/day (600–800 mg/day), most of which is derived from milk or other dairy products. The National Osteoporosis Foundation recommends that all adults have a daily intake of at least 1200 mg of elemental calcium with diet plus supplements. Lactating females and postmenopausal females not given exogenous estrogen therapy should probably have at least 1500 mg/day (Lewiecki, 2004).

Calcium is absorbed in the duodenum and upper jejunum via an active transport process. Less than half of dietary calcium is absorbed in adults. However, calcium absorption increases during periods of rapid growth in children, in pregnancy, and during lactation. It decreases with advancing age. The major stimulus to calcium absorption is vitamin D (see later). Calcium absorption is also enhanced by growth hormone, an acid medium in the intestines, and by increased dietary protein. The ratio of calcium to phosphorus in the intestinal contents is also important, because a ratio greater than 2 : 1 results in the formation of insoluble calcium phosphates and tends to inhibit calcium absorption. Phytic acid, derived from various cereal grains, can also form insoluble calcium compounds, as can dietary oxalate and fatty acids. Cortisol and excessive alkalinity of the intestinal contents are both inhibitory to calcium absorption.

Estimates of daily calcium excretion in sweat vary widely—from 15 mg to more than 100 mg. The loss can greatly exceed this range during extreme environmental conditions. The major net loss of calcium occurs via urinary excretion, and varies between 2.5 and 10 mmol/day (100–200 mg/day). In normal individuals, wide variations in dietary calcium intake have little effect on urinary calcium. Urinary calcium excretion is enhanced by hypercalcemia, phosphate deprivation, acidosis, and glucocorticoids. PTH, certain diuretics, and probably vitamin D diminish urinary calcium excretion. The physiology of calcium, its regulating hormones, and alterations of calcium homeostasis in disease have been extensively reviewed (Boden, 1990).

Calcium Homeostasis

Ionized calcium concentration of the ECF is kept constant within a narrow range of approximately 1.25 mmol/L (Fig. 15-2). It is the ionized calcium concentration of the ECF that is the primary determinant of the hormonal

influences that exert effects on ECF calcium levels. These effects are sometimes achieved at the expense of bone integrity. Adjustment of the ionized calcium concentration of the ECF is achieved mainly by the actions of PTH and active 1,25-dihydroxyvitamin D₃ (1,25[OH]₂D₃), and calcitonin plays a smaller yet significant role. The principal target organs of these hormones are bone, kidney, and intestine. When plasma-ionized calcium concentration decreases, the parathyroid glands sense the change via membrane-bound calcium sensor protein and secrete PTH immediately. Although parathyroid hormone has no direct effect on osteoclasts, it stimulates osteoblasts and their precursors to produce RANKL (the receptor activator of nuclear factor κB ligand). This substance, a member of the tumor necrosis factor superfamily, activates its receptor, RANK, which is expressed on osteoclasts and their precursors. This, in turn, promotes osteoclast formation and activity, and prolongs osteoclast survival by suppressing apoptosis (Hsu, 1999). This explains why bone formation and bone resorption are coupled in normal bone physiology. The resorption of bone matrix releases calcium and phosphate into the ECF. At the same time, PTH also acts on the kidney to stimulate increased urine phosphate excretion and some calcium reabsorption in the distal nephron, returning the ionized calcium concentration to normal. It has been suggested that sufficient action of 1,25(OH)₂D₃ is mandatory for these steps to work appropriately. The kidney is almost exclusively responsible for this vitamin D activation (Kurokawa, 1999). Calcitonin may play a role in the regulating process, although its significance in humans is controversial. Other hormones that affect calcium metabolism but whose secretions are not primarily affected by changes in plasma calcium and phosphate include thyroid hormone, growth hormone, adrenal glucocorticoids, and gonadal steroids.

Analytic Techniques

Total calcium measurements include protein-bound calcium and ionized calcium; alternatively, ionized calcium alone can be measured. The total calcium measurement is easier to perform in the laboratory, but this result must be interpreted in clinical context. For example, patients with malignancies often exhibit hypoalbuminemia, a condition that may result in falsely low total calcium levels. When this occurs, the total calcium level (expressed in mg/dL) can be corrected with the following equation:

$$\begin{aligned} &\text{Total calcium (mg/dL) corrected for hypoalbuminemia} = \\ &\quad \text{Total calcium (measured)} + [(\text{Normal albumin} - \\ &\quad \text{Patient's albumin}) \times 0.8] \end{aligned} \quad (15-1)$$

An albumin of about 4.4 is typically used as the normal value in the previous formula. This corrected value is a more accurate assessment of the patient's calcium status. Because albumin is the primary protein that binds calcium, variations in this protein are clinically significant. Only a small percentage of calcium binds to other proteins such as γ-globulins. Therefore, clinical states such as hypogammaglobulinemia are unlikely to drastically alter the total calcium levels.

Total and Ionized Calcium

Although many total calcium procedures have been reported, only three methods are commonly used: (1) colorimetric analysis with metallochromic indicators; (2) atomic absorption spectrometry (AAS); and (3) indirect potentiometry.

Total calcium is most widely measured by spectrophotometric determination of the colored complex when various metallochromic indicators or dyes bind calcium. Orthocresolphthalein complexone (CPC) and arsenazo III are the most widely used indicators. The structures of both of these dyes are shown in Chapter 27. CPC reacts with calcium to form a red color in alkaline solution, which is measured at near 580 nm. Interference by magnesium ions is reduced by the addition of 8-hydroxyquinoline. Arsenazo III reacts with calcium to form a calcium-indicator complex usually measured at near 650 nm. The stable reagent exhibits high specificity for calcium at slightly acidic pH. These reactions are also discussed in Chapter 27.

Atomic absorption spectrophotometry is the reference method for determining calcium in serum. Despite its greater accuracy and precision compared with other methods, very few laboratories continue to use AAS for routine determination of total calcium. This may be because laboratories performing large numbers of sample determinations rely on automated methods that are not widely available for this technique. In addition, the level of equipment maintenance required in this technique is difficult for high-volume laboratories.

In indirect potentiometry, an electrode selective for calcium measures a sample that is also measured against a sodium-selective electrode, and calcium concentrations are proportional to the difference in potential between the electrodes.

Instruments with calcium-selective electrodes (see Chapter 27) provide accurate, precise, and automatic determinations of free (ionized) calcium. Calcium ion-selective electrodes (ISEs) consist of a calcium-selective membrane enclosing an inner reference solution of CaCl₂, AgCl, and other ions, as well as a reference electrode. Ion-selective electrodes are discussed in Chapters 4 and 27. In Chapter 27, use of ISEs to measure total calcium is also discussed.

Reference Interval

The reference interval for total calcium in normal adults ranges between 8.8 and 10.3 mg/dL (2.20–2.58 mmol/L). Serum is the preferred specimen for total calcium determination, although heparinized plasma is also acceptable. Citrate, oxalate, and ethylenediaminetetraacetic acid (EDTA) interfere with commonly used methods. Other factors that have been reported to interfere with the colorimetric methods include hemolysis, icterus, lipemia, paraproteins, and magnesium.

The reference interval for *ionized (free) calcium* in normal adults is 4.6–5.3 mg/dL (1.16–1.32 mmol/L). Whole blood, heparinized plasma, or serum may be used. Specimens should be collected anaerobically, transported on ice, and stored at 4° C to prevent loss of carbon dioxide (CO₂) and glycolysis, and to stabilize pH (because pH changes alter the ionized calcium fraction). Proper collection technique is important to ensure accurate ionized calcium results; a tourniquet left on too long can lower pH at the site of collection and falsely elevate levels.

The reference interval for *urinary calcium* varies with diet. Individuals on an average diet excrete up to 300 mg/day (7.49 mmol/day). Urine specimens should be collected with appropriate acidification to prevent calcium salt precipitation.

PHOSPHORUS

Physiology

Distribution

The total body phosphorus content in normal adults is around 700–800 g. Approximately 80%–85% is present in the skeleton; the remaining 15% is present in the ECF in the form of inorganic phosphate, and intracellularly in the soft tissues as organic phosphates such as phospholipids, nucleic acids, and adenosine triphosphate (ATP). The skeleton contains primarily inorganic phosphate, predominantly as hydroxyapatite and calcium phosphate.

In blood, organic phosphate is located primarily in erythrocytes, with the plasma containing mostly inorganic phosphate. Approximately two thirds of blood phosphorus is organic, while only about 3–4 mg/dL of the total of 12 mg/dL represents the inorganic form. Inorganic phosphate in serum exists as both divalent (HPO₄²⁻) and monovalent (H₂PO₄⁻) phosphate anions, both of which represent important buffers. The ratio of H₂PO₄⁻:HPO₄²⁻ is pH dependent and varies between 1:1 in acidosis, 1:4 at pH of 7.4, and 1:9 in alkalosis. Approximately 10% of the serum phosphorus is bound to proteins; 35% is complexed with sodium, calcium, and magnesium; and the remaining 55% is free. Only inorganic phosphorus is measured in routine clinical settings.

Function

In addition to its role in the skeleton, phosphate has important intracellular and extracellular functions. Phosphate is an important constituent of nucleic acids in that both RNA and DNA represent complex phosphodi-esters. In addition, phosphorus is contained in phospholipids and phosphoproteins. It forms high-energy compounds (ATP) and cofactors (nicotinamide adenine dinucleotide phosphate [NADPH]) and is involved in intermediary metabolism and various enzyme systems (adenylate cyclase). Phosphorus is essential for normal muscle contractility, neurologic function, electrolyte transport, and oxygen carrying by hemoglobin (2,3-diphosphoglycerate).

Phosphorus Homeostasis

Most blood phosphate is derived from diet, but some is derived from bone metabolism. Phosphorus is present in virtually all foods. The average dietary intake for adults is about 800–1400 mg, most of which is derived from dairy products, cereals, eggs, and meat. About 60%–80% of ingested phosphate is absorbed in the gut, mainly by passive transport. However,

there is also an active energy-dependent process, which is stimulated by $1,25(\text{OH})_2\text{D}_3$. Serum calcium and phosphorus generally maintain a reciprocal relationship. Phosphorus is freely filtered in the glomerulus. More than 80% of the filtered phosphorus is reabsorbed in the proximal tubule, and a small amount in the distal tubule. Proximal reabsorption occurs by passive transport coupled to sodium (Na-P co-transport). Phosphorus intake and PTH mainly regulate this co-transport. Phosphorus restriction increases reabsorption, and intake decreases it. PTH induces phosphaturia by inhibition of Na-P co-transport. The effect is exerted mainly in the proximal tubule. The hormone binds to specific receptors in the basolateral membrane, resulting in the activation of two pathways—the adenylate cyclase/cyclic adenosine monophosphate/protein kinase A and the phospholipase C/calcium/protein kinase C systems, both of which are involved in inhibition of Na-P co-transport (Bellorin-Font, 1990).

Although PTH lowers serum phosphate, serum levels of phosphate are increased by administration of vitamin D and growth hormone. Vitamin D increases intestinal absorption and renal reabsorption of phosphorus. Growth hormone is a main regulator of skeletal growth. Its presence in the bloodstream reduces renal excretion of phosphates, thereby increasing serum levels.

Recently, a regulation cascade comprising a hormone, fibroblast growth factor 23 (FGF-23), an enzyme (phosphate-regulating gene with homologies to endopeptidases [PHEX]) thought to be involved in the metabolism of FGF-23, and a protein (matrix extracellular glycoprotein [MEPE]) has been elucidated (Quarles, 2003). This cascade is thought to be involved in phosphate homeostasis but remains only partially understood. FGF-23 is normally produced by osteocytes and osteoblasts, as well as in marrow pericytes, thymus, and lymph nodes; however, current data support that most of FGF-23 is derived from bone in response to phosphate levels (Lu, 2007) and provide the first evidence of an independent hormonal regulation of phosphate levels. Elevated levels of FGF-23 result in hyperphosphaturia, primarily by inhibiting sodium-dependent phosphate resorption channels; FGF-23 also inhibits intestinal phosphorus absorption by inhibiting $25\text{OH-vitamin D } 1\text{-}\alpha\text{-hydroxylase}$ in the renal proximal tubules (Lu, 2007). Mutations involving FGF-23, PHEX, and MEPE have been implicated in phosphate wasting by the kidneys and have been associated with various mineralization abnormalities (Quarles, 2003).

Analytic Techniques

Most commonly used methods for determination of inorganic phosphate are based on the reaction of phosphate with ammonium molybdate to form phosphomolybdate complex (see Chapter 44). Direct ultraviolet (UV) measurement of the colorless unreduced complex by absorption at 340 nm, as originally described by Daly and Ertinghausen in 1972, has been adapted for use on most of the automated analyzers. Alternatively, the phosphomolybdate complex can be reduced by a wide variety of agents (e.g., aminonaphtholsulfonic acid, ascorbic acid, methyl-p-aminophenol sulfate, ferrous sulfate) to produce molybdenum blue, which can be measured at 600–700 nm. The formation of phosphomolybdate complex is pH dependent, and the rate of its formation is influenced by protein concentration. Measurements of unreduced complexes have the advantages of being simple, fast, and stable. An enzymatic method has also been described whereby phosphorus undergoes successive enzymatic reactions catalyzed by glycogen phosphorylase, phosphoglucosmutase, and glucose-6-phosphate dehydrogenase. The NADPH produced can be quantitated fluorometrically or spectrophotometrically. The reaction takes place at neutral pH, thus permitting the measurement of inorganic phosphorus in the presence of unstable organic phosphate.

Serum is preferred because most anticoagulants, except heparin, interfere with results and yield falsely low values. Phosphorus levels are increased by prolonged storage with cells at room temperature. Hemolyzed specimens are unacceptable because erythrocytes contain high levels of organic esters, which are hydrolyzed to inorganic phosphate during storage, and thus yield elevated levels.

Reference Interval

In normal adults, serum phosphorus varies between 2.8 and 4.5 mg/dL (0.89–1.44 mmol/L). Higher phosphorus levels occur in growing children (4.0–7.0 mg/dL or 1.29–2.26 mmol/L). Serum phosphate is best measured in fasting morning specimens because of diurnal variation, with higher levels in the afternoon and evening, as well as a reduction in serum phosphate after meals. Levels are influenced by dietary intake, meals, and exercise.

MAGNESIUM

Physiology

Distribution

Magnesium is the fourth most abundant cation in the body after calcium, sodium, and potassium; it is the second most prevalent intracellular cation. The normal body magnesium content in an adult is approximately 1000 mmol, or 22.66 g, of which 50%–60% is in bone, and the remaining 40%–50% is in the soft tissues. One third of skeletal magnesium is exchangeable and probably serves as a reservoir for maintaining a normal extracellular magnesium concentration.

Only 1% of the total body magnesium (TBMg) is in extracellular fluid. In serum, about 55% of magnesium is ionized or free magnesium (Mg^{++}), 30% is associated with proteins (primarily albumin), and 15% is complexed with phosphate, citrate, and other anions. The interstitial fluid concentration is approximately 0.5 mmol/L. In cerebrospinal fluid (CSF), 55% of the magnesium is free or ionized, and the remaining 45% is complexed with other compounds (Elin, 1988).

Approximately 99% of the TBMg is in bone matrix or is intracellular. About 60% of this total is within bone matrix, and the other 40% is within skeletal muscle, within blood cells, or in the cells of other tissues. Intracellular magnesium concentration is approximately 1–3 mmol/L (2.4–7.3 mg/dL). Within the cell, magnesium is compartmentalized, and most of it is bound to proteins and negatively charged molecules; approximately 80% of cytosolic magnesium is bound to ATP. Significant amounts of magnesium are found in the nucleus, mitochondria, and endoplasmic reticulum. Free magnesium accounts for 0.5%–5.0% of the total cellular magnesium, and is the fraction that is probably important as a cofactor supporting enzyme activity.

Function

Magnesium is essential for the function of more than 300 cellular enzymes, including those related to the transfer of phosphate groups, all reactions that require ATP, and every step related to the replication and transcription of DNA and the translation of mRNA. This cation is also required for cellular energy metabolism and has an important role in membrane stabilization, nerve conduction, ion transport, and calcium channel activity. In addition, magnesium plays a critical role in the maintenance of intracellular potassium concentration by regulating potassium movement through the membranes of the myocardial cells. Thus, magnesium deficiency can result in a variety of metabolic abnormalities and clinical consequences, including refractory plasma electrolyte abnormalities (especially depressed potassium) and cardiac arrhythmias most often observed after stress such as cardiac surgery (Weisinger, 1998).

Magnesium Homeostasis

Total body magnesium depends mainly on gastrointestinal absorption and renal excretion. The average dietary intake of magnesium fluctuates between 300 and 350 mg/day, and intestinal absorption is inversely proportional to the ingested amount. The factors controlling the intestinal absorption of magnesium remain poorly understood.

The kidney is the principal organ involved in magnesium regulation. Renal excretion is about 120–140 mg/24 hours for a person on a normal diet. Approximately 70%–80% of the plasma magnesium is filtered through the glomerular membrane. Tubular reabsorption of Mg^{++} is different from that for other ions because the proximal tubule has a limited role, and 60%–70% of the reabsorption of Mg^{++} takes place within the thick ascending loop of Henle (Quamme, 1989). Even though the distal tubules reabsorb only 10% of the filtered Mg^{++} , they are the major sites of magnesium regulation. Many factors, both hormonal and nonhormonal (e.g., parathyroid hormone, calcitonin, glucagon, vasopressin, magnesium restriction, acid-base changes, potassium depletion), influence both Henle's loop and distal tubule reabsorption. However, the major regulator of reabsorption is the plasma concentration of Mg^{++} itself. Increased Mg^{++} concentration inhibits loop transport, whereas decreased concentration stimulates transport, regardless of whether or not there is magnesium depletion. The mechanisms appear to be regulated by the $\text{Ca}^{++}/\text{Mg}^{++}$ -sensing receptor, located on the capillary side of the thick-ascending-limb cells, which senses the changes in Mg^{++} (Quamme, 1997). Other factors that may play a role in magnesium regulation include calcium concentration and rate of sodium chloride reabsorption.

In magnesium deficiency, serum levels decrease, and this leads to reduced urinary excretion. Later, bone stores of magnesium are

affected as the process of equilibration with bone stores takes place over several weeks.

Because serum contains only about 1% of total body magnesium, it may not accurately reflect total stores. In general, a low serum level indicates deficiency, and a high level indicates adequate stores. However, the most common result—a normal level—should be interpreted with caution because it does not exclude an underlying deficiency. The most accurate assessment of magnesium status is generally considered to be the loading test, wherein magnesium is given intravenously. Magnesium-deficient individuals retain a greater proportion of the load and excrete less in the urine than normal individuals (Papazachariou, 2000). However, the test is not commonly used because it is difficult to administer.

Analytic Techniques

Total Magnesium

Serum is preferred over plasma for magnesium determination because anticoagulant interferes with most procedures. Serum magnesium is usually measured by photometry. The reference method for total magnesium is atomic absorption spectrophotometry. Most clinical laboratories use a photometric method on an automated analyzer. These methods use metallochromic indicators or dyes that change color upon selectively binding magnesium from the sample. Some of the chromophores used include calmagite, methylthymol blue, formazan dye, and magon (see Chapter 27). In the calmagite photometric method, which is the one most commonly used, calmagite, whose structure is shown in Chapter 27 (see Fig. 27-2), forms a colored complex with magnesium in alkaline solution. This complex is stable for over 30 minutes, and its absorbance at 520 nm is directly proportional to the magnesium concentration in the specimen aliquot. Some of these measurements are affected by increased serum bilirubin levels, which can result in a significant underestimation of Mg in the sample.

Ionized (Free) Magnesium. Ionized magnesium can be measured with magnesium ISEs that have been incorporated into several commercial clinical analyzers (Huijgen, 1999). These ISEs employ neutral carrier ionophores that are selective for Mg^{++} . However, in addition to Mg^{++} , these ISEs measure Ca^{++} , thus requiring a chemometric correction to calculate the true free magnesium levels in the sample. Studies have shown significant differences in the measured ionized magnesium on different analyzers that were attributed to interference from free calcium in the sample, as well as to insufficient specificity and lack of standardization of the calibrators (Hristova, 1995; Cecco, 1997). Further improvements in the method for ISEs for ionized magnesium will improve the performance and increase the availability of Mg^{++} determination in the clinical laboratory.

As with ionized calcium determinations, ionized magnesium measurements are affected by pH. The rate of change of ionized magnesium measurements is not as significant as that seen in ionized calcium determinations. Changes in magnesium in relation to alterations of pH are similar to those in ionized calcium, although less well characterized. With an increase in pH, ionized magnesium is decreased, and with a decrease in pH, it is increased (Wang, 2002).

Reference Interval

The reference interval for serum total magnesium in normal adults ranges between 0.75 and 0.95 mmol/L (1.7–2.2 mg/dL or 1.5–1.9 mEq/L). There appear to be no significant sex or age differences. Erythrocyte magnesium is about three times that of serum. The magnesium concentration in CSF is 2.0–2.7 mg/dL (1.0–1.4 mmol/L). The reference interval for ionized magnesium depends on the analyzer used for its measurement and varies from 0.44–0.60 mmol/L (Hristova, 1995).

HORMONES REGULATING MINERAL METABOLISM

The three principal hormones regulating mineral and bone metabolism are parathyroid hormone (PTH), 1,25-dihydroxyvitamin D_3 ($1,25[OH]_2D_3$), and calcitonin. PTH and $1,25(OH)_2D_3$ are the primary hormones that exert an effect, while calcitonin is less prominent in the cycle that maintains mineral metabolism. In addition, the metabolic effects of calcitonin are less well understood.

Parathyroid Hormone

Physiology

Synthesis. PTH is synthesized and secreted by the chief cells of the parathyroid gland. Intact PTH is a single-chain polypeptide consisting of 84 amino acids with a molecular mass of 9500Da. It is derived from a larger precursor, pre-pro-PTH, of 115 amino acids, which undergoes two successive cleavages, both at the amino-terminal sequences. This yields, first, an intermediate precursor, pro-PTH, and then the hormone itself. Any pro-PTH that reaches the circulation is immediately converted to PTH and other products.

Secretion. Multiple factors control the release of PTH from the parathyroid glands, but only a small number are known to be physiologically important. PTH secretion is regulated on a time scale of seconds by extracellular ionized calcium and represents a simple negative-feedback loop. Extracellular signals are detected by a calcium-sensing receptor, located on the plasma membrane of the parathyroid chief cell. Stimulation of this receptor leads to suppression of the rate of PTH secretion via intracellular signals (inositol triphosphate and diacylglycerol) generated by the active receptor. The receptor is present in parathyroid glands, the calcitonin-secreting cells of the thyroid, brain, and kidney. This G-protein-linked receptor is mutated in the disorders of familial hypocalciuric hypercalcemia, neonatal severe hyperparathyroidism, and autosomal dominant hypocalcemia (Mundy, 1999).

Ionized magnesium has also been shown to influence the secretion of PTH. Hypocalcemic patients with low serum magnesium concentration often require administration of magnesium to increase serum PTH levels before the serum calcium concentration can be restored to the desired interval. Chronic severe hypomagnesemia such as that seen in alcoholism has been associated with impaired PTH secretion, whereas an acute decrease in the serum magnesium concentration can lead to an increased PTH.

Other levels of PTH control include regulation of PTH gene transcription and parathyroid chief cell mass by vitamin D and extracellular calcium. $1,25$ -Dihydroxyvitamin D_3 chronically suppresses the synthesis of PTH by interacting with vitamin D receptors in the parathyroid gland.

Function. The primary physiologic function of PTH is to maintain the concentration of ionized calcium in the ECF, which is achieved by the following mechanisms: (1) stimulation of osteoclastic bone resorption and release of calcium and phosphate from bone; (2) stimulation of calcium reabsorption and inhibition of phosphate reabsorption from the renal tubules; and (3) stimulation of renal production of $1,25(OH)_2D_3$, which increases intestinal absorption of calcium and phosphate. The amino-terminal end of the PTH molecule binds to the PTH receptor, which modulates adenylate cyclase and phospholipase C. Activating mutations in this receptor may cause the hypercalcemia and epiphyseal disorganization seen in Jansen's chondrodysplasia (Bastepe, 2004).

The net effects of PTH actions on bone, kidney, and indirectly on intestine include increased serum total and ionized calcium concentrations and decreased serum phosphate. Its immediate effects on the kidney are to increase renal plasma flow and cause a diuresis. At the level of the distal convoluted tubule, it causes increased reabsorption of calcium and chloride with the exchange of phosphate into the urine. These effects are mediated through its activation of renal adenyl cyclase. As a result, urinary cyclic adenosine monophosphate (cAMP) and urinary phosphate are increased with a mild secondary hyperchloremic acidosis. In the absence of disease, the increase in serum calcium reduces PTH secretion through a negative-feedback loop, thus maintaining calcium homeostasis. If this negative-feedback loop is sufficiently interrupted by an autonomously functioning parathyroid gland to increase resting calcium to abnormally high levels, the capacity of the distal tubules to reabsorb calcium is exceeded, and hypercalciuria results.

Heterogeneity. PTH metabolism is complex and produces several fragments of varying biological and immunologic reactivity. The intact PTH is the biologically active form and has a half-life in the circulation of less than 4 minutes. The kidney and liver clear intact PTH rapidly. In the liver, intact PTH is cleaved into discrete fragments and smaller peptides that are released into the circulation. The released inactive carboxy-terminal fragments circulate considerably longer than the intact hormone, mainly because they are cleared exclusively by glomerular filtration (Mundy, 1999).

Analytic Techniques

Historically, PTH immunoassays were developed to measure mid-region, N-terminal, and C-terminal regions. However, these assays cross-reacted with amino acid sequences present in both mid-region and carboxyl fragments of the intact hormone and measured mostly inactive fragments because they are present in greater concentration than the intact molecule. Because the kidney clears inactive PTH fragments, results from these assays were difficult to interpret, especially in patients with impaired renal function. PTH intact is measured by noncompetitive immunometric (sandwich) assays (see Chapter 44), which, depending on the type of detection system used, are divided into immunoradiometric assay (IRMA), when radiolabeled, and immunochemiluminometric assay, when labeled with a chemiluminescent compound. Most automated systems use immunochemiluminometric assays. These immunometric assays have several advantages over earlier assays: (1) increased sensitivity and specificity through the use of sequence-specific and affinity-purified antibodies, (2) extended assay concentration range, and (3) decreased incubation time, and (4) they do not utilize radioactive compounds.

Reference Interval

The reference interval for intact PTH in normal adults is 10–65 pg/mL (ng/L) when a two-site immunometric method is used. Studies have demonstrated that intact PTH is secreted in episodic or pulsatile fashion, with an overall circadian rhythm characterized by a nocturnal rise in intact PTH. Serum is the preferred specimen for measurement of PTH. Prolonged storage of the specimen aliquot causes falsely decreased levels.

Bio-Intact PTH

Physiology

Traditional tests for intact PTH detect and measure both the biologically intact 84 amino acid PTH molecule (1-84) and its minimally active to inactive metabolites. Recall that the intact, biologically active molecule is cleaved within minutes to the many metabolites that have a longer half-life, and of which there is a much higher concentration in the circulation at any given time. One of these cleavage products, the 7-84 PTH breakdown fragment, is a weak antagonist to PTH activity and may actually lower patient serum calcium levels. It is therefore important to distinguish between intact PTH and breakdown products in the setting of patients with chronic renal failure (Brossard, 2000). In uremic patients, the metabolites, including the 7-84 breakdown fragment, accumulate as the result of decreased renal clearance, and can therefore give the impression of an elevated PTH (Quarles, 1992).

Recent advances have made available a test for only the biologically active, intact PTH. This third-generation test eliminates interference by the metabolites and is of great clinical utility in patients with impaired renal function. The bio-intact PTH test specifically measures the (1-84) molecule via a two-site chemiluminescent assay. This assay yields a higher specificity than second-generation tests for the biologically active intact PTH, but cost and availability considerations make this a second-line test that is used primarily in following metabolic bone status in patients with renal insufficiency.

Normal ranges for this test show seasonal variation, in part because of lower serum 25(OH)D during the wintertime in the healthy population. Normal values for this test range from 8–50 pg/mL (Nichols Advantage, 2004).

Intraoperative PTH

Historically, parathyroid surgery has consisted of bilateral neck exploration in an attempt to identify enlarged parathyroid glands. In recent years, clinical practice has moved away from this costly and invasive procedure, which often requires an overnight hospital stay, to minimally invasive parathyroidectomy with or without the use of a hand-held gamma probe. This procedure consists of preoperative administration of technetium-99 m sestamibi 2 hours preoperatively followed by performance of a parathyroid scan. The parathyroid adenoma, with its increased numbers of cytoplasmic mitochondria, selectively absorbs large amounts of this radioactive substance, which then allows identification of the adenoma(s) with a hand-held gamma probe. This method of identifying the enlarged gland allows for removal of only the hyperfunctional parathyroid gland in cases of parathyroid adenoma. Cases of parathyroid hyperplasia still require bilateral neck exploration. Depending on the size of these enlarged glands, they may or may not be identified on the preoperative parathyroid scan (Goldstein, 2000; Sofferman, 1998; Sokoll, 2000).

Once the hyperfunctioning parathyroid gland is identified via sestamibi scan, and only a single parathyroid gland has been shown to be involved, patients are taken to surgery for minimally invasive parathyroidectomy. This approach has reduced surgical and hospital costs, as well as admission time (Goldstein, 1991).

Before surgery, a baseline PTH value is obtained. Following incision, dissection to the radioactive parathyroid gland is guided by the use of a gamma probe. Once identified, the parathyroid gland is removed. After removal, the surgeon waits about 10–20 minutes and obtains a post-removal PTH value. This post-removal PTH value should decrease to at least 50%–75% below the preoperative level or should have a “significant” trend toward normal in patients with markedly elevated preoperative PTH levels. The decrease in PTH levels reassures the surgeon that the adenomatous gland has been removed. If no or minimal decrease is noted in the intraoperative PTH level, the surgeon is obligated to resume neck exploration for additional abnormal glands, and multiple adenomas or hyperplasia is suggested as the underlying process. Intraoperative PTH testing is recommended for patients undergoing surgery for primary hyperparathyroidism, reoperative hyperparathyroidism, and venous/tumor localization presurgery in the angiography suite (Sokoll, 2004).

Analytic Techniques

The intraoperative technique for intact PTH customarily requires blood collected in an EDTA tube (plasma) or a red-top tube (serum). The sample is maintained at a cold temperature to minimize breakdown, and is submitted for rapid PTH testing. These immunochemiluminometric assays provide rapid results by modifying certain test parameters on the standard assay. Specifically, increased incubation temperature, continuous shaking of the reaction contents, and alterations in sample and reagent volumes are used to expedite antibody–antigen reactions. The end result is a more rapid assay, albeit one that is more costly, less sensitive, and more imprecise than the standard assay. These assays correlate well with standard assays and are totally acceptable for measuring large drops in PTH concentration during surgery.

Parathyroid Hormone–Related Peptide

Physiology

Parathyroid hormone–related peptide (PTH-rP) was first discovered in tumors derived from lung, breast, kidney, and other solid tissues. It has since been described as a hormone with paracrine and autocrine functions. PTH-rP is composed of 141 amino acids and shows significant homology with PTH in the first 13 amino acids. It is the product of a large gene on chromosome 12 that is syngeneic to the PTH gene on chromosome 11. This peptide shares the same receptor as PTH. Its actions include binding to and activating the PTH receptor, thus simulating the PTH biological effects on bone, kidney, and intestine. Similar to PTH, PTH-rP increases bone resorption by stimulating osteoclasts and promotes renal tubular reabsorption of calcium. The net effect is elevated serum calcium concentration. It is now known that PTH-rP is produced by approximately 50% of primary breast cancers, and its production may be enhanced by bone-derived factors such as transforming growth factor- β (Yin, 1999; see Chapter 74 for a description of this growth factor). Other malignant tumors also elaborate this peptide. PTH-rP has been implicated as the agent responsible for humoral hypercalcemia in patients with malignancy.

Elevation of PTH-rP has been observed in approximately 50%–90% of patients with malignancy-associated hypercalcemia. Increased PTH-rP is seen in squamous cell carcinomas of the lung, esophagus, cervix, and skin, as well as in other malignancies (e.g., islet cell carcinomas, T-cell and B-cell lymphomas, multiple myeloma). PTH-rP levels are normal in patients with primary hyperparathyroidism, hypoparathyroidism, chronic renal failure, and other conditions with hypercalcemia.

Some benign hyperplasias, including massive mammary hypertrophy, vasoactive intestinal peptide-secreting tumors, pheochromocytomas, and lactational changes of the breast, may elaborate this peptide (Strewler, 1997).

A recent study demonstrated that PTH-rP has therapeutic potential in the treatment of postmenopausal osteoporosis; PTH-rP increased bone mineral density by nearly 5%—a rate that exceeds those of current therapeutic approaches (Horwitz, 2003).

Analytic Technique and Reference Interval

PTH-rP is measured by immunometric assay (usually IRMA) in which antibodies to different sequences of the PTH-rP molecule are used as

capture antibodies and radiolabeled signal antibodies. The limit of detection of these assays is between 0.1 and 1.0 pmol/L (Endres, 1999). The reference interval for PTH-rP is method-dependent. In normal individuals, PTH-rP levels range from undetectable to around 2 pmol/L, whereas the mean concentration of PTH-rP in patients with humoral hypercalcemia of malignancy has been reported to be 22.2 pmol/L. Recent studies have shown that most patients (95%) with a PTH level >26 ng/mL had no increased PTH-rP, a number that increased to 100% when only patients with hypercalcemia were evaluated. This study suggests that testing for PTH-rP in patients with low or low normal PTH may not be of clinical utility (Fritchie, 2009).

Calcitonin

Physiology

Synthesis and Metabolism. Calcitonin is synthesized and secreted by specialized C cells (parafollicular cells) of the thyroid gland and acts on the bones, kidneys, and gastrointestinal tract. Circulating immunoreactive calcitonin is derived from a larger precursor, and the monomeric form is the only biologically active entity. Calcitonin monomer is a 32 amino acid peptide with a molecular mass of 3500 Da. The ionized calcium concentration is the most important regulator of calcitonin secretion. Increases in ionized calcium lead to an increase in calcitonin secretion. Other potent calcitonin secretagogues include the gastrointestinal peptide hormones and gastrin in particular (Care, 1971). The latter could explain the presence of a mild postprandial increase in calcitonin concentration.

The calcitonin receptor is structurally similar to PTH/PTH-rP and secretin receptors; it exists in several isoforms, and its expression seems to be influenced by ambient concentrations of calcitonin itself (Mundy, 1999). Calcitonin is metabolized within minutes of secretion, primarily by the kidney.

Physiologic Role and Clinical Use. Although calcitonin has been viewed as a major calcium-regulating factor because of its calcium-lowering and phosphorus-lowering properties, its precise physiologic role is still unclear. Calcitonin directly inhibits osteoclastic bone resorption by directly binding to osteoclasts. The effect of this binding action is observed within minutes after calcitonin administration. This inhibition is transient and likely has little role in overall calcium homeostasis, although it may be important in the short-term control of calcium loads. Calcitonin also inhibits the action of PTH and vitamin D. Although some clinical studies suggest that serum calcium does not appear to be affected in patients with total thyroidectomy, other studies suggest that medullary thyroid carcinoma and an excess of calcitonin can give rise to marked hypocalcemia. In the kidney, calcitonin causes increased clearance of calcium and phosphate. The mechanisms of its action on the GI tract have not been elucidated entirely.

In addition to evaluation of calcitonin in the setting of bony abnormalities, testing for calcitonin is an important adjunct in the evaluation of the patient with nodular thyroid disease, and is often performed in the hope of identifying the patient with early medullary thyroid carcinoma, which may be seen in the setting of type II multiple endocrine adenomatosis (MEN II), as described in Chapter 24. Therapeutic success in medullary thyroid carcinoma hinges on its early identification, and slight elevations of calcitonin with subsequent surgical exploration of the thyroid may identify this lesion in its early, nonpalpable stage of development. It is well known that the therapeutic efficacy is poor in cases that are identified as well-developed palpable tumors because many such patients already have metastatic disease (Rieu, 1995; Horvit, 1997). Until recently, routine testing for calcitonin in patients with nodular thyroid disease was not considered cost-effective in the United States. Studies in Europe, however, have shown this to be cost-effective. A recent cost-effectiveness analysis performed in the United States concluded that routine calcitonin testing in patients with nodular thyroid disease is, in fact, of comparable cost-effectiveness as other screening tests, such as those for thyroid-stimulating hormone, breast cancer (mammography), and colon cancer (colonoscopy) (Cheung, 2008). Diagnostic sensitivity for medullary thyroid carcinoma is increased by pentagastrin stimulation before calcitonin level testing. A high index of suspicion for this aggressive neoplasm should exist in patients with plasma or serum calcitonin levels >100 pg/nL (Vierhapper, 1997).

Therapeutic applications of calcitonin have been explored and include its use in the treatment of osteoporosis and in the treatment of Paget's disease, the early stages of which are characterized by increased bone resorption.

Analytic Technique and Reference Interval

In the past, serum calcitonin was measured primarily by radioimmunoassay (RIA). However, differences in assay specificity and sensitivity, matrix and nonspecific serum effects, and heterogeneity of the circulating calcitonin have contributed to contradicting results and discrepancies in reference values for the hormone. At present, a number of highly sensitive (limit of detection as low as 2 pg/mL), two-site immunometric methods (electroimmunoassays and IRMAs) for serum calcitonin are available. These tests are now regarded as the most reliable methods of testing for serum calcitonin.

The reference interval for serum calcitonin in normal adults is less than 25 pg/mL for males, and less than 20 pg/mL for females. Gender, age, growth, pregnancy, lactation, and ingestion of food have been reported to affect the levels of calcitonin.

Vitamin D and Metabolites

Physiology

Synthesis and Metabolism. (See also Chapters 8 and 26.)

The steroid hormone $1,25(\text{OH})_2\text{D}_3$ is the major biologically active metabolite of the vitamin D sterol family. The vitamin D precursor (cholecalciferol or vitamin D_3) may be ingested in the diet or synthesized in the skin from 7-dehydrocholesterol (provitamin D_3) through exposure to sunlight. The plant-derived form of vitamin D is called vitamin D_2 or ergosterol. Neither form of vitamin D has any significant biological activity; both must be metabolized to hormonally active forms. This activation occurs in two steps, the first of which takes place in the liver, and the second of which takes place in the kidney. Cholecalciferol is transported to the liver bound to a specific α_1 -globulin. In the liver, vitamin D undergoes hydroxylation to produce 25-hydroxyvitamin D (calcidiol), a metabolite with limited biological activity. Because the liver only loosely regulates this step, circulating levels of 25-hydroxyvitamin D mirror the amounts of vitamin D that may be ingested or synthesized by the skin. The 25-hydroxyvitamin D is then bound by the vitamin D-binding protein and is transported to the kidney, where it undergoes further hydroxylation by $1\text{-}\alpha$ -hydroxylase in the proximal tubular mitochondria to form the more potent metabolite $1,25(\text{OH})_2\text{D}_3$ (calcitriol). Renal hydroxylation of 25-hydroxyvitamin D is the major controlling point in vitamin D metabolism—a step that is regulated by serum phosphate, calcium, and circulating PTH concentrations. PTH and phosphate depletion act independently to increase $1,25(\text{OH})_2\text{D}_3$ production by inducing $1\text{-}\alpha$ -hydroxylase activity, with PTH being the more potent stimulus. Decreased blood calcium stimulates the parathyroid glands to secrete PTH, which in turn increases production of $1,25(\text{OH})_2\text{D}_3$ in the renal proximal tubules. Conversely, a rise in blood calcium suppresses PTH secretion, which lowers the production of $1,25(\text{OH})_2\text{D}_3$. The only other known important extrarenal sites of $1,25(\text{OH})_2\text{D}_3$ production are the placenta and the granulomatous tissue. In humans, the half-life of $1,25(\text{OH})_2\text{D}_3$ in the circulation is approximately 5 hours. It is excreted as urinary and fecal metabolites (Mundy, 1999). Several other vitamin D metabolites are produced in the kidney; most of these have been shown to be biologically inert. The most notable of these is 24,25-dihydroxyvitamin D_3 , produced by the action of $24\text{-}\alpha$ -hydroxylase in the kidney; it is activated when PTH levels are low, or when inorganic phosphate levels are elevated (Fig. 15-3).

Physiologic Role. $1,25(\text{OH})_2\text{D}_3$ bound to a vitamin D-binding protein is delivered to the intestine, where the free form is taken up by the cells and transported to a specific nuclear receptor protein. Although the receptor binds several forms of vitamin D, its affinity for $1,25\text{-dihydroxyvitamin D}_3$ is about 1000 times that of 25-hydroxyvitamin D_3 , thus accounting for why the former is so much more biologically active than the latter. As a result of this interaction in the intestine, calcium-binding protein is synthesized. In bone, osteocalcin, osteopontin, and alkaline phosphatase are produced. In the intestine, the net effect of $1,25(\text{OH})_2\text{D}_3$ is to transport calcium and phosphate from the lumen of the small intestine into the circulation by stimulating the expression of calcium-carrying proteins, thus increasing plasma calcium and phosphate concentrations. It also increases bone resorption and enhances the effects of PTH in the nephron to promote renal tubular calcium reabsorption. $1,25(\text{OH})_2\text{D}_3$ is a powerful differentiating agent for committed osteoclast precursors, causing their maturation to form multinucleated cells that are capable of resorbing bone. These pathways enable $1,25(\text{OH})_2\text{D}_3$ to provide a supply of calcium and phosphate available at bone surfaces for the formation of normal mineralized bone (Mundy, 1999).

Figure 15-3 Pathways of vitamin D synthesis and their end-organ effects. The large green arrows indicate increases in calcium and phosphate induced by vitamin D (dihydroxycholecalciferol).

The demonstration that the sites of action of $1,25(\text{OH})_2\text{D}_3$ are not limited to its target tissues, namely, the intestine, bone, and kidney, has expanded the therapeutic function of vitamin D. Administration of vitamin D hormone has been shown to be effective in the therapeutic management and prevention of postmenopausal and age-related osteoporosis. A recent study showed that higher-than-recommended (700–800 vs. recommended 600 IU) doses of vitamin D in nursing home residents reduced the number of patients with falls and the total number of falls in nursing home residents (Kerry, 2007). Another study showed that a similar dose acts to prevent fracture in a comparable population (Bischoff-Ferrari, 2005). Evidence suggests that, besides exhibiting calciotropic properties, vitamin D may be a developmental hormone. As discussed in Chapters 8 and 26, vitamin D has been found to exhibit antitumor growth activity.

Analytic Techniques

Of the more than 35 metabolites of vitamin D_2 and vitamin D_3 , only $25(\text{OH})\text{D}$ and $1,25(\text{OH})_2\text{D}$ measurements are clinically important. $25(\text{OH})\text{D}$ is a better marker than vitamin D for evaluation of vitamin D status because of its longer half-life (2–3 weeks vs. 5–8 hours) (Papapoulos, 1982), more limited fluctuation with exposure to sunlight and dietary intake, larger concentration, and ease of measurement. Measurement of $1,25(\text{OH})_2\text{D}_3$ is useful in detecting certain states of inadequate or excessive hormone production in the evaluation of hypercalcemia, hypercalciuria, and hypocalcemia, as well as in bone and mineral disorders. Because both vitamin D_2 and vitamin D_3 are metabolized to compounds of similar if not equal biological activity, for clinical purposes the assays should measure $25(\text{OH})\text{D}_2$ and $25(\text{OH})\text{D}_3$ or $1,25(\text{OH})_2\text{D}_2$ and $1,25(\text{OH})_2\text{D}_3$, respectively. At present, the reference method for the assay of $25(\text{OH})\text{D}_2$ and $25(\text{OH})\text{D}_3$ is dual mass spectrometry. Most other assays for vitamin D metabolites are measured by RIA or chemiluminescent immunoassay.

Reference Interval

The reference interval for $25(\text{OH})\text{D}$ in serum is approximately 10–50 ng/mL (25–125 nmol/L), and for $1,25(\text{OH})_2\text{D}$ is 15–60 pg/mL (36–144 pmol/L) (Endres, 1999). Levels for $25(\text{OH})\text{D}$ are influenced by sunlight exposure, latitude, skin pigmentation, sunscreen use, and hepatic function. $25(\text{OH})\text{D}$ levels also exhibit seasonal variation. Winter values may be 40%–50% lower than summer values because of reduced UV radiation exposure. Concentrations of vitamin D metabolites vary with age and are increased in pregnancy.

Phosphatonins

Phosphatonins represent a new group of phosphate-regulating factors that remain incompletely understood, yet have thus far shed much light on the many disorders of phosphate and calcium metabolism. These factors include FGF-23, MEPE, and frizzled related protein 4. These substances act to reduce renal inorganic phosphate reabsorption both directly by their action on the renal tubules and indirectly through the inhibition of $25\text{-hydroxyvitamin D}_1$ α -hydroxylase, causing a reduction in $1\alpha,25(\text{OH})_2\text{D}$ formation that results in decreased inorganic phosphate absorption and reduced calcium absorption. Both mechanisms produce decreased serum inorganic phosphate levels, resulting in rickets in children and osteomalacia in adults. Increased levels of these factors, as well as the previously discussed PHEX, have been causally implicated in tumor-induced osteomalacia, X-linked hypophosphatemic rickets, and autosomal dominant hypophosphatemic rickets (ADHR). X-linked hypophosphatemic rickets is associated with varied mutations of the *PHEX* gene, and ADHR is due to activating mutations of FGF-23 (Pettifor, 2008; Roetzer, 2007; Gaucher, 2009; Ichikawa, 2008; Schiavi, 2004). All of these entities are clinically characterized by reduced serum phosphate, increased urinary phosphate levels, and aberrant bone mineralization. In addition, these entities are customarily seen in the setting of normal serum calcium.

Although the previous entities result largely from increased FGF-23, mutations in FGF-23 resulting in a net reduced level of effective FGF-23 have also been described at multiple loci. They produce disease through a common mechanism of reduced phosphaturic activity, creating the clinical picture of hyperphosphatemic tumoral calcinosis (Araya, 2005; Larsson, 2005; Masi, 2009). Another factor implicated in the hyperphosphatemic form of this disease is UDP-N-acetyl- α -D galactosamine/polypeptide N-acetylgalactosaminyltransferase 3. Inactivating mutations of this gene result in accelerated degradation of FGF-23 into inactive metabolites (Jueppner, 2007).

Analytic Techniques

Thus far, there are no commercially available assays for these mutations. Currently, these growth factors have been evaluated experimentally via polymerase chain reaction (PCR) and more recently by enzyme-linked immunosorbent assay for intact FGF-23 and the processed fragments (18 and 12 kDa). In addition, reverse transcriptase-PCR (RT-PCR) for FGF-23 has been performed on formalin-fixed, paraffin-embedded tissue in the setting of phosphaturic mesenchymal tumors of the mixed connective tissue type with high sensitivity and specificity (Bahrami, 2009).

DISORDERS OF MINERAL METABOLISM

HYPERCALCEMIA

Increased serum calcium is associated with anorexia, nausea, vomiting, constipation, hypotonia, depression, high-voltage T waves on electrocardiography, and occasionally lethargy and coma. Persistent hypercalcemia or persistently elevated calcium–phosphorus ionic activity product may cause ectopic depositions of calcium in tissues throughout the body. This may take the form of ectopically calcified blood vessel walls associated with necrotic skin lesions in calciphylaxis. It may also lead to calcifications in viable tissues (metastatic calcification/tumoral calcinosis), particularly those developing pH gradients with localized relative alkalosis (e.g., pulmonary alveolar walls, renal medullary pyramids, deep gastric mucosa). The most common causes of hypercalcemia are primary hyperparathyroidism and malignant neoplasms, which account for 80%–90% of all patients with hypercalcemia. Less frequent causes include renal failure, diuretics, vitamin A and D intoxication, lithium therapy, milk–alkali syndrome, immobilization, hyperthyroidism and other nonparathyroid endocrinopathies, and familial hypercalciuric hypercalcemia (Table 15-1). Recently, mutations in *FGF-23* and in another gene encoding the so-called N-terminal sterile α motif protein (*SAMD9* gene) have also been implicated in tumoral calcinosis. Mutations in *FGF-23* characteristically cause hyperphosphatemic tumoral calcinosis, while mutations in *SAMD9* cause normophosphatemic tumoral calcinosis. The tumoral calcinosis caused by both is familial (Araya, 2005; Larsson, 2005; Masi, 2009; Chetetz, 2005; Topaz, 2006; Chetetz, 2008). Disease due to *SAMD9* mutations appears to affect Yemenite Jews predominantly. *Primary hyperparathyroidism* (PHPT) is characterized by excessive secretion of PTH in the absence of an appropriate physiologic stimulus and with no response to the physiologic negative-feedback loop of hypercalcemia. This results in a generalized disorder of calcium, phosphate, and bone metabolism. Approximately

TABLE 15-1

Causes of Hypercalcemia

Parathyroid hormone (PTH) Mediated

Primary hyperparathyroidism (most common):
 Sporadic
 Multiple endocrine neoplasia (types 1 and 2)
 Familial hypocalciuric hypercalcemia
 Ectopic secretion of PTH by neoplasms (rare)?

Non-PTH Mediated

Malignancy associated (most common)
 Vitamin D mediated
 Vitamin D intoxication
 Increased generation of $1,25(\text{OH})_2\text{D}$
 Other endocrinopathies
 Thyrotoxicosis
 Hypoadrenalism
 Immobilization with increased bone turnover
 Milk-alkali syndrome
 Sarcoidosis
 Multiple myeloma

100,000 cases of PHPT occur each year in the United States, and the incidence increases with age. The disease affects women twice as frequently as it affects men. Most cases are caused by solitary parathyroid adenomas. Other causes include multiple parathyroid adenomas, hyperplasia, and, rarely, parathyroid carcinoma. Hypercalcemia in PHPT is characteristically associated with decreased serum phosphate due to PTH-induced phosphate diuresis and is frequently accompanied by mild acidosis from decreased renal reabsorption of bicarbonate. The hypercalcemia is attributed to (1) the direct action of PTH on bone, causing increased resorption; (2) PTH-activated renal tubular reabsorption; and (3) PTH-stimulated increased renal biosynthesis of $1,25(\text{OH})_2\text{D}_3$, which increases intestinal absorption of calcium (Boden, 1990). Half or more of patients with PHPT are asymptomatic. Symptomatic patients usually present with recurrent nephrolithiasis, chronic constipation, mental depression, neuromuscular dysfunction, recurrent chronic pancreatitis, or peptic ulcer, and less frequently with unexplained or premature osteopenia (Deftos, 1993).

The unique bone manifestation of PHPT is osteitis fibrosa cystica generalisata. This is characterized by diffuse skeletal radiolucency with focal cystic bone lesions, subperiosteal bone resorption most pronounced in the digits, and osseous deformities on routine radiographs. Histologically, paratrabeular fibrosis and marrow hypervascularity are accompanied by increased numbers of osteoclasts, causing trabecular scalloping (Howship's lacunae) as a result of accelerated bone resorption (Fig. 15-4, A and B). As the disease progresses, the marrow cavity is gradually replaced by fibrous tissue. The process is even more pronounced in compact bone, where large aggregates of osteoclasts demonstrate wedge-shaped resorption that enlarges Haversian canals (cutting cones). Fractures that develop through this altered bone tend to heal poorly and result in space-occupying lesions filled with fibrous tissue, multinucleated giant cells, hemorrhage, and hemosiderin; these are sometimes referred to as "brown tumors" even though they are not neoplastic. Generalized osteitis fibrosa cystica is now very uncommon because serum calcium and phosphate screening usually reveal early parathyroid hyperfunction long before signs or symptoms develop.

PHPT may be inherited as an autosomal dominant trait and may present as a part of MEN. MEN 1 consists of hyperparathyroidism and tumors of the pituitary gland and pancreas. It is often associated with Zollinger-Ellison syndrome, characterized by islet cell tumors with gastrin hypersecretion and peptic ulcer disease. MEN 2A consists of hyperparathyroidism, pheochromocytoma, and medullary carcinoma of the thyroid. Studies have identified the molecular defects in hyperparathyroidism. A gene locus on chromosome 11 has been associated with MEN 1. The same locus appears to be lost in approximately 25% of solitary parathyroid adenomas, implying that the defect responsible for MEN 1 can also cause the sporadic disease.

Secondary hyperparathyroidism is present when there is resistance to the metabolic actions of PTH, as occurs in patients with renal failure, vitamin D deficiency (osteomalacia), and pseudohypoparathyroidism. This leads to parathyroid gland hyperplasia and excessive production of PTH.

Figure 15-4 Hyperparathyroid bone disease (osteitis fibrosa cystica). **A**, The hand radiograph demonstrates scalloped cortical resorption on the radial (left) side of the phalanges and radiolucency of the terminal phalangeal tufts. **B**, Biopsy of compact bone with advanced hyperparathyroid disease demonstrates conversion of compact to cancellous bone with internal resorption of Haversian systems by osteoclastic cutting cones (CC) and paratrabeular fibrosis (100 \times).

The pathogenesis varies somewhat, depending on the nature and severity of renal disease. However, decreased renal excretion of phosphate as a consequence of impaired glomerular filtration is paramount. In such patients, there is an initial tendency toward hypocalcemia because as phosphate levels rise, calcium levels decrease, because their ionic activity product constant makes their serum concentrations inversely related (see Chapter 8 for a discussion of the solubility product constant). In addition, chronic renal failure includes reduced production of $1,25(\text{OH})_2\text{D}$ by the kidney. Decreased $1,25(\text{OH})_2\text{D}$ causes a reduced response of the skeleton to PTH and decreased calcium absorption from the intestine, contributing to hypocalcemia. Because of the decreased serum ionic calcium, there is positive feedback to increase parathyroid hormone secretion; this causes parathyroid gland hyperplasia. Initial clinical manifestations include low to normal serum calcium and hyperphosphatemia. Later, in cases with severe secondary hyperparathyroidism, both hypercalcemia and hyperphosphatemia develop. In addition, bone pain, ectopic calcifications, and pruritus may be seen. The complex bone disease occurring in secondary hyperparathyroidism and renal failure is usually termed renal osteodystrophy (Fig. 15-5) and is discussed in greater detail later. Autonomous hyperparathyroidism may sometimes supervene in the setting of chronic parathyroid stimulation. Typical patients are those with chronic renal failure or with some other disease that chronically lowers serum ionized calcium levels and stimulates long-term parathyroid hormone secretion. This chronic parathyroid stimulation results in increased parathyroid mass and diffuse parathyroid hyperplasia. If increased levels of parathyroid hormone are not diminished by hypercalcemia, whether it occurs in the setting of continued calcium wasting or if the calcium level is corrected

Figure 15-5 Relationships leading to renal osteodystrophy in chronic renal failure.

(e.g., after renal transplantation), the clinical syndrome is sometimes referred to as *tertiary hyperparathyroidism*. Patients with this syndrome may have parathyroid adenomas, parathyroid hyperplasia, and even parathyroid carcinomas. There is also a tendency for these patients to develop metastatic calcifications because their transiently increased calcium and phosphate levels may exceed the ionic product for these ions and cause precipitation of the excess.

Malignant tumors are the most frequent cause of hypercalcemia in the hospital inpatient population. *Malignancy-associated hypercalcemia* can be divided into cases with or without bony metastases. Radiolucent bone lesions indicative of metastatic disease are frequently seen in patients with hematologic malignancies (multiple myeloma, lymphomas, and leukemias), lung carcinoma, renal cell carcinoma, and thyroid carcinoma. Several possible mechanisms have been implicated in the development of malignancy-associated hypercalcemia, including direct tumor lysis, secretion of osteoclast-activating factor by tumor cells, and secretion of lymphokines with osteoclast potentiating activity such as interleukin-1 and tumor necrosis factor. Conventional bone radiographs and bone scanning can detect most bony metastases. Hypercalcemia without bony metastases is also known as *humoral hypercalcemia of malignancy* (HHM). Diagnosis in these cases, in general, is more difficult because the primary tumor may be occult. A variety of tumor types have been associated with this syndrome, including renal carcinoma, hepatocellular carcinoma, carcinomas of the head and neck, lung carcinomas, and islet cell tumors of the pancreas. The most common cause of HHM is secretion of PTH-rP by the tumor. The diagnosis is highly suggestive when urinary cAMP excretion (typically seen in hyperparathyroidism) is increased in the setting of reduced or normal PTH.

Vitamin D intoxication is another cause of hypercalcemia and is usually the result of excessive intake of vitamin supplements over a prolonged period of time. Excess vitamin D causes increased calcium absorption by the intestines, enhanced bone resorption, and hypercalciuria. PTH is suppressed, but the frequent development of renal failure may make it difficult to exclude hyperparathyroidism; 25(OH)D has been implicated as the major metabolite responsible for the syndrome. The diagnosis is supported by careful history taking, measurements of 25(OH)D, and a prompt response following steroid administration. Clinically, vitamin D intoxication is manifest by weakness, irritability, nausea, vomiting, and diarrhea. Soft tissue calcification is a common feature because serum phosphorus tends to be elevated. Intoxication may persist for months because of storage of vitamin D in adipose tissue.

1,25(OH)₂ deficiency

Reversible inhibition of 1-hydroxylase

Intrinsic renal defects (chronic renal failure, tubulopathies, Fanconi's syndrome)

Defective response to 1,25(OH)₂D

Mutations of vitamin D receptor

Hypercalcemia associated with *granulomatous disorders* is seen commonly in patients with sarcoidosis and less frequently in patients with tuberculosis, silicone-induced granulomas, and fungal diseases such as coccidioidomycosis and candidiasis. Renal failure, soft tissue calcification, nephrolithiasis, and severe hypercalcemia are potential manifestations. Different mechanisms in the development of hypercalcemia have been implicated, including enhanced sensitivity to vitamin D, increased concentration of vitamin D metabolites, and unregulated generation of 1,25(OH)₂D by macrophages in granulomatous tissue.

Milk-alkali syndrome was first reported in patients with peptic ulcer disease taking large amounts of milk and absorbable alkali (e.g., calcium carbonate). Recently, a rise in the incidence of the syndrome has been reported; this may be due to the widespread use of calcium carbonate preparations in the treatment and prophylaxis of osteoporosis. The syndrome is manifest by hypercalcemia, hypocalciuria, alkalosis, azotemia, and soft tissue calcifications.

Laboratory testing in the differential diagnosis of hypercalcemia includes measurements of serum total and ionized calcium, urine calcium, serum and urine phosphorus, alkaline phosphatase, albumin, intact PTH, PTH-rP, and urine cAMP. Determination of various other analytes (e.g., growth hormone, cortisol, cortisone suppression test, selective venous catheterization with measurement of local PTH concentration, measurements of vitamin D metabolites) can provide valuable information in selected cases. Meaningful interpretation of relevant laboratory data often requires various special studies, in addition to a complete history and physical examination. Renal function tests and studies of acid-base balance may be indicated. Histopathologic examination of bone biopsy specimens from appropriate sites can be of unique value in selected cases.

HYPOCALCEMIA

Chronic hypocalcemia presents with neuromuscular and neurologic manifestations, including muscle spasms, carpopedal spasm, peripheral and perioral paresthesias, cardiac arrhythmias, lengthening of the QT interval and low-voltage T waves on the electrocardiogram, and, in severe cases, laryngeal spasm and convulsions. Respiratory arrest may occur. Severe hypocalcemia will eventually result in tetany. Hypocalcemia has many causes, which can be divided into several major categories: (1) deficiencies in PTH production or secretion, (2) resistance to PTH action, (3) deficiency of vitamin D or vitamin D metabolites, and (4) deficiencies in bone mineralization with normal metabolism of PTH and vitamin D (Table 15-2). The most common causes of hypocalcemia are chronic renal failure, hypomagnesemia, hypoparathyroidism, pseudohypoparathyroidism, vitamin D deficiency, and acute pancreatitis. Less frequently, low plasma calcium may be seen in critically ill patients with sepsis, burns,

*Calcium may be normal in the setting of concurrent 1,25(OH)₂D₃ deficiency.

and acute renal failure. Transient hypocalcemia can be observed after administration of a number of drugs, including heparin, glucagon, and protamine, as well as after massive transfusions of citrated blood products.

Hypoparathyroidism, hereditary or acquired, is characterized by diminished or absent PTH production by the parathyroid glands, which leads to a fall in plasma calcium and corresponding hyperphosphatemia. In addition, these patients have absent or low levels of 1,25(OH)₂D. In the past, acquired hypoparathyroidism secondary to neck surgeries and thyroidectomies, in particular, was more common than hereditary hypoparathyroidism. With improvement in surgical techniques, however, its incidence has diminished dramatically. Hereditary hypoparathyroidism can occur as an isolated entity with a variable pattern of inheritance (idiopathic hypoparathyroidism), in association with defective development of both the thymus and the parathyroid glands (DiGeorge syndrome or branchial dysgenesis), or as part of a complex hereditary autoimmune syndrome involving failure of the adrenals, ovaries, and parathyroids, usually referred to as autoimmune polyglandular deficiency. Hereditary hypoparathyroidism is often manifested within the first decade of life. In addition to low or absent PTH and hypocalcemia, certain skin manifestations, such as alopecia and candidiasis, occur frequently.

Pseudohypoparathyroidism (PHP), also known as Albright's hereditary osteodystrophy, is a rare genetic disorder characterized by ineffective PTH action rather than failure of parathyroid gland hormone production. Clinically, PHP presents with some of the features of hypoparathyroidism, such as extraosseous calcifications, extrapyramidal symptoms and signs such as choreoathetotic movements and dystonia, chronic changes in fingernails and hair, lenticular cataracts, and increased intracranial pressure with papilledema. Serum calcium is depressed despite an increased concentration of PTH, suggesting resistance to PTH. Moreover, whereas infusion of PTH in patients with hypoparathyroidism generally results in a marked increase in both urinary cAMP and phosphaturia, patients with PHP usually respond with subnormal urinary phosphate excretion and cAMP production. This is due to a defect in the stimulatory G-protein of adenylate cyclase that is necessary for the action of PTH.

Hypocalcemia associated with hypomagnesemia is associated with both deficient PTH release from the parathyroid glands and impaired responsiveness to the hormone.

Hypocalcemia associated with hypovitaminosis D may occur as a result of inadequate production of vitamin D₃ in the skin, insufficient dietary supplementation, inability of the small intestine to absorb adequate amounts of the vitamin from the diet, and resistance to the effects of vitamin D. The latter may be due to deficient or defective receptors for 1,25(OH)₂D or to use of drugs that antagonize vitamin D action. Hypovitaminosis D is associated with disturbances in mineral metabolism and secretion of PTH and mineralization defects in the skeleton such as rickets in children and osteomalacia in adults (see later). Decreased levels of vitamin D lead to insufficient intestinal absorption of calcium and hypocalcemia, followed by increased secretion of PTH (secondary hyperparathyroidism). Increased PTH stimulates calcium release from bone and decreases calcium clearance by the kidney, thus increasing calcium levels

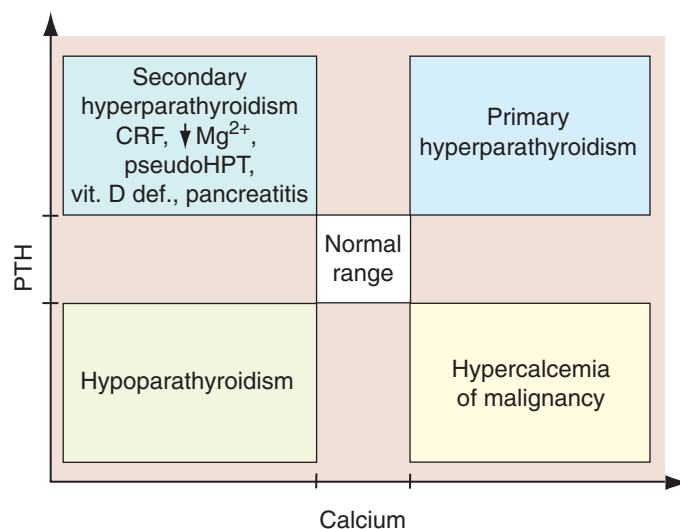

Figure 15-6 Graph correlating alterations in serum calcium levels and parathyroid hormone levels with the diseases most frequently causing these alterations.

in the circulation. If hypovitaminosis D persists, severe hypocalcemia may occur.

An inherited disorder, characterized by defective production of 1,25(OH)₂D in the kidney, has been described. In this syndrome, known as pseudovitamin D-deficient rickets or vitamin D-dependent rickets type I, there is a deficiency in renal 25(OH)D-1 α -hydroxylase activity, which results in low production of 1,25(OH)₂D and decreased levels in the circulation, but with a normal response to physiologic doses of calcitriol. In vitamin D-dependent rickets type II, mutations impair the function of the 1,25(OH)₂D receptor by altering the binding of the hormone to the receptor, causing elevated levels of circulating 1,25(OH)₂D. Although administration of high doses of calcitriol produces further increases in the levels of 1,25(OH)₂D, no physiologic response occurs. Another inherited disease associated with impaired vitamin D metabolism is X-linked hypophosphatemic rickets. This condition is characterized by a functional defect in 25(OH)D-1 α -hydroxylase, hypophosphatemia, and normal or low serum levels of 1,25(OH)₂D. Figure 15-6 summarizes the more common causes of abnormal calcium levels, along with their differential diagnoses.

Tables 15-3 and 15-4 summarize serum calcium, phosphate, vitamin D levels, and other laboratory values in altered metabolic states.

HYPERPHOSPHATEMIA

Hyperphosphatemia is usually caused by decreased renal excretion in acute and chronic renal failure; increased intake with excessive oral, rectal, or

TABLE 15-4

Laboratory Values in Various Altered States of Calcium Metabolism

	Primary hyperparathyroidism	Humoral hypercalcemia of malignancy	Secondary hyperparathyroidism	Tertiary hyperparathyroidism	Familial hypocalciuric hypercalcemia

intravenous administration; or an increased extracellular load due to a transcellular shift in acidosis. Less common causes include increased tubular reabsorption in hypoparathyroidism; pseudohypoparathyroidism; and increased extracellular load due to cell lysis in rhabdomyolysis, intravascular hemolysis, leukemia, lymphoma, and cytotoxic therapy. In addition, hyperphosphatemia may be seen secondary to overmedication with vitamin D and production of vitamin D by granulomatous diseases such as sarcoidosis and tuberculosis.

No direct symptoms result from hyperphosphatemia. When high levels are maintained for long periods, however, mineralization is enhanced, and calcium phosphate may be deposited in abnormal sites. Ectopic calcification is a frequent complication in patients with chronic renal failure receiving supplements of vitamin D when correction of hyperphosphatemia is inadequate (Weisinger, 1998).

HYPOPHOSPHATEMIA

Hypophosphatemia is observed in 0.25%–2.15% of general hospital admissions. Alcohol abuse is the most common cause of severe hypophosphatemia, probably as the result of poor food intake, vomiting, antacid use, and marked phosphaturia. It is also caused by ingestion of large amounts of nonabsorbable antacids that bind phosphate. Hypophosphatemia is induced by several mechanisms, including internal redistribution, increased urinary excretion, decreased intestinal absorption, or a combination of these abnormalities. The most common cause is a shift of phosphorus from extracellular fluid into cells, which can be observed in acute respiratory alkalosis associated with sepsis, salicylate poisoning, alcohol withdrawal, heatstroke, hepatic coma, increased insulin during glucose administration, recovery from diabetic ketoacidosis, and refeeding of malnourished patients. Increased urinary excretion is usually secondary to hyperparathyroidism, renal tubular defects as in Fanconi's syndrome and familial hypophosphatemia, X-linked vitamin D-resistant rickets, aldosteronism, glucocorticoid and mineralocorticoid administration, and diuretic therapy. Hypophosphatemia due to urinary losses is observed in osmotic diuresis, acute volume expansion, and up to 30% of patients with malignant neoplasms such as certain leukemias and lymphomas. In oncogenic hypophosphatemia with osteomalacia, also referred to as tumor-induced osteomalacia, mesenchymal tumors, which are more often benign than malignant, produce hyperphosphaturia by a mechanism in which overproduction of FGF-23 has been implicated (Nelson, 2003; Folpe, 2004). Increased intestinal loss is due to vomiting, diarrhea, and use of phosphate-binding antacids. Decreased intestinal absorption is observed in malabsorption, vitamin D deficiency, and steatorrhea (Table 15-5).

Symptomatic hypophosphatemia is usually observed when plasma phosphorus falls below 0.32 mmol/L. Clinical manifestations include proximal weakness, anorexia, dizziness, myopathy, dysphagia, ileus, respiratory failure due to weakness of the respiratory muscles, impairment of cardiac contractility due to depletion of ATP in myocardial cells, and metabolic encephalopathy.

HYPERMAGNESEMIA

Hypermagnesemia (i.e., plasma Mg^{++} concentration >0.9 mmol/L) is rare and usually iatrogenic. Those most at risk are the elderly and patients with bowel disorders or renal insufficiency. Clinical manifestations of hypermagnesemia include hypotension, bradycardia, respiratory depression,

depressed mental status, and electrocardiographic abnormalities (Weisinger, 1998).

HYPOMAGNESEMIA

Magnesium deficiency is found in approximately 11% of hospitalized patients. The usual reason is loss of magnesium from the gastrointestinal (GI) tract or the kidney. Depletion by GI tract occurs during acute and chronic diarrhea, malabsorption, and steatorrhea after extensive bowel resection, and in patients with the rare inborn error of metabolism, primary intestinal hypomagnesemia. Na^{+} resorption may serve as the basis for magnesium depletion in the kidney because of a sodium-dependent magnesium efflux pathway in the same tubular segment (Ikari, 2003), or because of a primary defect in renal tubular reabsorption of Mg^{++} . Factors that can cause Mg^{++} losses from the urine include thiazide and loop diuretics, increased sodium excretion and volume expansion (parenteral fluid therapy), hypercalcemia and hypercalciuria (hyperthyroidism or malignancy), and nephrotoxic drugs (aminoglycoside antibiotics, cisplatin, amphotericin B, cyclosporine). Diabetes mellitus is a common cause of hypomagnesemia, probably secondary to glycosuria and osmotic diuresis. Another important and very common cause of magnesium deficiency is alcohol; this is found in approximately 30% of alcoholic patients admitted to hospital. Sustained and extensive stress, including that seen with varied surgical procedures and acute illnesses, may be associated with depressed serum magnesium levels (Table 15-6).

Signs and symptoms of magnesium depletion do not usually appear until extracellular levels have fallen to 0.5 mmol/L or less. Manifestations of significant magnesium depletion are largely due to the associated hypocalcemia and include neuromuscular hyperexcitability characterized by carpopedal spasm, seizures, muscular weakness, depression, and psychosis; metabolic abnormalities (carbohydrate intolerance, hyperinsulinism); and cardiac arrhythmias.

TABLE 15-6

Causes of Hypomagnesemia

Decreased Intake/Absorption

Protein-calorie malnutrition
 Starvation
 Alcoholism
 Prolonged intravenous therapy
 Inadequate parenteral supplementation
 Malabsorption (e.g., celiac sprue)
 Neonatal gut immaturity
 Excessive GI losses
 Prolonged gastric suction
 Laxatives
 Intestinal or biliary fistula
 Severe diarrhea

Excessive Renal Losses

Diuretics
 Acute tubular necrosis—diuretic phase
 Acute renal failure—diuresis

 Multiple transfusions with citrated blood
 Endocrine
 Hyperthyroidism
 Hyperparathyroidism
 Diabetes mellitus with diabetic ketoacidosis
 Hyperaldosteronism
 Medications (e.g., cisplatin, cyclosporine, gentamicin, ticarcillin)

Laboratory assessment of these markers has been the focus of much attention in recent years (Ju, 1997; Souberbielle, 1999).

BONE RESORPTION MARKERS

Bone tissue has three components: an organic matrix (called osteoid), bone mineral, and bone cells. Bone resorption markers have included constituents of bone matrix such as calcium and collagen degradation products such as hydroxyproline, pyridinium crosslinks, and telopeptides, as well as cellular products involved with degradation of the mineralized matrix such as tartrate-resistant acid phosphatase (TRAP). Urinary calcium is affected by diet and renal function; thus, it is not sensitive or specific for assessment of bone remodeling (Watts, 1999). Tartrate-resistant acid phosphatase, a lysosomal enzyme found in osteoclasts, is not considered a useful test. Measurement of the amino acids hydroxyproline and glycosylated (galactosyl and glucosyl-galactosyl) hydroxylysine is not specific for skeletal collagen and has been found to correlate poorly with bone resorption, as determined by bone histomorphometry and calcium kinetics. The most useful tests measure pyridinium crosslinks and cross-linked telopeptides. Bone resorption markers have a diurnal rhythm, making the timing of sample collection critical, and serial samples that are to be utilized for monitoring response to antiresorptive medications should be collected at the same time of day. Values are highest in the mornings, thus collection of the sample during this time is indicated.

Recently, serum cathepsin K, the primary enzyme involved in proteolysis of bone type I collagen by osteoclasts, has been implicated as a possible valuable marker of bone resorption. However, the data are incomplete with respect to its efficacy as a useful clinical marker. Several other bone metabolism regulators, such as RANK, RANKL, and even osteoprotegerin, a decoy receptor of nuclear factor kappa, may be of interest. None of these have been evaluated to the extent where they have proven efficacy in following bone metabolism clinically. In fact, conflicting reports have described the utility of determining a osteoprotegerin/RANKL ratio, with some suggesting that this ratio in patients beginning therapy for rheumatoid arthritis was the single most important predictor of joint erosion measured 11 years later (van Tuyl, 2010). Another study with shorter follow-up did not show that this ratio predicted disease progression.

Pyridinium Crosslinks (Pyridinoline and Deoxypyridinoline)

Collagen fibrils consist of many cross-linked amino acids that effectively stabilize the mature collagen molecule. These include pyridinoline (Pyr), a cross-linked polymer formed from three hydroxylysine residues, and deoxypyridinoline (DPyr), which is formed from two hydroxylysine residues and one lysine residue. These crosslinks are found in collagen types I, II, and III. Although these crosslinks are not unique to bone, they are found in a unique ratio in the bone, a fact that makes these substances ideal candidates as markers for bone breakdown. In the collagen of most other tissues, the ratio of Pyr/DPyr is 10:1, while in bone it is 3–3.5:1. This difference means that DPyr is more pronounced in bone and metabolic bone disease. DPyr is essentially specific for bone, in that it is found in relatively significant amounts only in bone and has been shown to correlate well with bone turnover (Robins, 1995). An additional characteristic that makes evaluation of pyridinium crosslinks ideal is that they are neither metabolized upon their release nor absorbed from the diet. They are excreted in urine in free form (40%) and in peptide-bound form (60%). Because crosslink molecules are found only in mature collagen, their excretion in the urine reflects breakdown of mature collagen and is not an expression of newly synthesized bone collagen (Watts, 1999). Thus, their presence in urine suggests active bone resorption. Excretion of Pyr and DPyr is increased after menopause and can be utilized to study the effects of hormone replacement therapy on bone turnover (Fledelius, 1994). The clinical applications of measuring these substances include identification of individuals at risk for bone loss and fracture, assessment of metabolic bone disease, prediction of bone metastases, subsequent skeletal complications, and even outcome in cancer patients afflicted by solid tumors (prostate, breast, and lung most commonly) and primary bone tumors, as well as management of antiresorptive therapy. Pyr and DPyr are measured in urine by high-pressure liquid chromatography (HPLC) (see Chapter 23 for a discussion of HPLC) or immunoassays. Care must be taken to account for the marked diurnal variation that is seen with urinary pyridinolines, with a peak late at night and early in the morning. Although a 24-hour urine collection avoids this issue and does not require correction

BIOCHEMICAL MARKERS OF BONE REMODELING

The skeleton constantly undergoes a process of remodeling that is essential for bone health. Bone remodeling is a coupled process that begins with resorption of old bone by osteoclasts, a process that takes approximately 50 days, followed by formation of new bone by osteoblasts, which takes another 150 days, for a total turnover cycle lasting approximately 200 days (Erikson, 1994). Beginning at middle age or earlier, net bone loss occurs because resorption exceeds formation, a fact that was identified more than 50 years ago by Dr. Alton Fuller, the father of metabolic bone disease. He noted that postmenopausal women had elevated urinary calcium levels and deduced that this reflects a negative calcium balance that can result in osteoporotic fractures. Estrogen deficiency and many other diseases and conditions accentuate bone resorption (Watts, 1999).

Three major diagnostic procedures are available to monitor bone turnover and evaluate metabolic bone disease: bone imaging techniques, bone biopsy, and biochemical markers of bone turnover. Although bone density measurement is an important diagnostic tool in osteoporosis, it is difficult for the test to detect increased bone turnover in its early stages or to monitor acute changes. Also, bone densitometry gives a summated measure of mineralized bone matrix; it does not define abnormal distribution of bone loss. Bone biopsy can define the distribution of bone mass and can answer questions about bone mineralization that cannot be answered with bone densitometry. However, bone biopsy is invasive, and, in the absence of mineralization defects, it provides a relatively static glimpse into long and slowly developing processes; thus, it is not useful in routine clinical management of osteoporosis. In osteoporosis, net bone loss is caused by only a slight imbalance of bone resorption over formation, so conventional markers, such as calcium and PTH, are usually normal. In contrast, bone turnover markers are more sensitive to subtle change and can be used to noninvasively detect and monitor progression of metabolic bone disease.

for the creatinine concentration, an early morning fasting sample corrected for creatinine concentration is a more sensitive marker of bone turnover (Bettica, 1992).

Cross-linked Telopectides

During bone resorption, only 40% of crosslinks are released as free pyridinium crosslinks; the remaining 60% are peptide-attached crosslinks (Risteli, 1993). Type I collagen has two sites with attached crosslinks. These are called telopectides, and they occur in the amino-terminal and carboxy-terminal regions of the collagen molecule. These telopectides are released into the circulation as collagen is degraded; they are then excreted into the urine. Amino-telopectides (NTx) and carboxy-telopectides (CTx) are excreted in the urine and can be measured by immunoassay. Testing for these crosslinks is widely available.

Cross-linked telopectides have been utilized in estimating relative risks of hip fracture in postmenopausal women, and show promise in predicting such complications of osteoporosis (Chapurlat, 2000; Swaminathan, 2001).

Although baseline levels of cross-linked telopectides do not necessarily correlate with baseline bone mineral density, their serial measurement has shown the capacity to predict early response to therapy (Fink, 2000). Studies have shown reductions of urinary CTx and NTx in the range of 50%–60% with 3–6 months of antiresorptive therapy (Eatell, 2003) and correlation of these reductions with the prediction of long-term bone mass response (Ravn, 2003).

BONE FORMATION MARKERS

Bone formation markers include alkaline phosphatase and three byproducts of bone matrix synthesis, including osteocalcin and amino- and carboxy-terminal procollagen I extension peptides.

Alkaline Phosphatase

(See Chapter 20.)

Bone alkaline phosphatase (ALP-B), an osteoblast membrane-bound enzyme, is released into the circulation by phosphatidylinositol glycanase activity and formation of membrane vesicles. Studies have shown that the amount of ALP-B activity in osteoblasts and in bone is proportional to collagen formation; thus, it can provide an index of the rate of bone formation. Human serum contains a variable mixture of ALP isoenzymes from liver, intestine, kidney, and bone. During pregnancy, alkaline phosphatase may be derived from the placenta (Farley, 1994). Certain malignant tumors may also produce a heat-stable ALP isoenzyme. The function of ALP is unknown; however, it has been postulated that ALP probably has a role in the mineralization of newly formed bone. Measurements of total serum ALP are useful to follow disease activity when the amount of bone isoenzyme is exceptionally high, as in Paget's disease or osteosarcoma.

The two major circulating ALP isoenzymes, bone and liver, are difficult to distinguish because they are the products of a single gene and differ only by post-translational glycosylation. Separation of the skeletal ALP can be achieved by heat inactivation, wheat germ agglutinin precipitation, electrophoresis, isoelectric focusing, and two-site immunoradiometric assays. At present, immunoassay is the method of choice because of high specificity and satisfactory precision.

Osteocalcin

Osteocalcin is the major noncollagenous protein of the bone matrix, and is produced by osteoblasts, odontoblasts, and even chondrocytes. It is a 49 amino acid polypeptide that is rich in glutamic acid. Its function is incompletely understood, but it may serve as a site of deposition for hydroxyapatite crystals. In addition, recent studies suggest that osteocalcin has effects on energy metabolism by affecting the production and even the action of insulin (Lee, 2007). During bone matrix synthesis, some osteocalcin is released into the circulation and is rapidly cleared by the kidneys. Osteocalcin can be measured by immunoassay in plasma or serum. However, assays for osteocalcin are not yet standardized because different antibodies recognize different fragments. Antibodies that recognize both the intact molecule and the large amino-terminal mid-molecule fragment appear to provide the best clinical information (Watts, 1999). Recent studies have shown that although vitamin K does not affect the amount of osteocalcin concentration, it does affect the amount of carboxylation. Undercarboxylated osteocalcin has been suggested to be a better predictor of certain outcomes such as fracture (Vergnaud, 1997). Osteocalcin is metabolized mainly in the kidneys and to a lesser extent in the liver; the half-life in the circulation is about 5 minutes. Osteocalcin is increased when there is high

bone turnover, as occurs in hyperparathyroidism, acromegaly, and Paget's disease. It is decreased in hypoparathyroidism and hypothyroidism and in patients on glucocorticoid therapy. Osteocalcin reference intervals are approximately 1.1–11 ng/mL (adult male) and 0.7–6.5 ng/mL (adult female), and testing is not routinely available.

Procollagen Type I N-Terminal and C-Terminal Peptides

Procollagen type I N-terminal peptide and procollagen type I C-terminal peptide are the precursor peptides that are removed from procollagen type I to produce type I collagen. Upon cleavage, these peptides are released into the circulation, where they can be measured, thus serving as markers of collagen type I synthesis. Of the two markers, procollagen type I N-terminus is more stable and thus is a more reliable marker. Incidentally, the procollagen type I C-terminal peptide has also been implicated as a potentially useful marker in predicting the extent and severity of disease in systemic sclerosis (Kikuchi, 1994).

METABOLIC BONE DISEASE

Metabolic bone disease may be defined as a general disease of metabolism that affects the entire skeleton. Because the disease is generalized, by definition every bone is involved. Consequently, a biopsy of any bone in the body should reflect these metabolic alterations to some extent. Although a very few metabolic disorders (e.g., fluorosis, vitamin A toxicity) may increase bone density, a vast majority of metabolic bone diseases are clinical problems resulting in decreased bone density. The result may be bones with decreased organic matrix with normal mineralization (e.g., osteoporosis), bones with decreased mineral content without a significant decrease in organic matrix (e.g., osteomalacia), or bones with both diminished organic matrix and decreased mineral content (e.g., renal osteodystrophy).

OSTEOPOROSIS

Osteoporosis is the most common metabolic disease of bone (Table 15-7). It is a systemic skeletal disorder characterized by decreased organic matrix and microarchitectural deterioration of bone tissue, with a subsequent increase in bone fragility and susceptibility to fracture (Ferrari, 1999). Although this may be expressed as low bone mineral density as measured by dual-energy x-ray absorptiometry (DEXA), the abnormality in no way reflects abnormal mineralization in that the mineral is normal in both structure and content. Rather, total bone mass is decreased in osteoporosis primarily because of a decrease in bone collagen.

Bone mass and strength are related to volumetric density, bone size, microarchitecture, and intrinsic tissue quality. These factors are likely to change during bone growth and bone loss, with selective modifications

TABLE 15-7

Deficiencies in Organic Bone Matrix

Primary Osteoporosis

Idiopathic (children and young adults)

Postmenopausal

Senile

Secondary Osteoporosis

Hyperparathyroidism

Hyperadrenocorticism

Hypogonadism

Thyrotoxicosis

Immobilization

Calcium deficiency

Prolonged heparin administration

Miscellaneous (alcoholism, malnutrition, liver disease, rheumatoid arthritis, malabsorption)

Disorders of Connective Tissue

Osteogenesis imperfecta

Ehlers-Danlos syndrome

Marfan syndrome

Figure 15-7 Schematic comparison of femoral cortex in a 30-year-old male (left) and a 75-year-old male (right). Note that the proportionate strength of the bone shaft on the right is greater than that on the left.

according to the skeletal site. Postmenopausal white and Asian women who are thin or small and have a positive family history are at greatest risk. Other risk factors include cigarette smoking, alcohol abuse, a sedentary lifestyle, and consumption of too little calcium. Strong evidence indicates that genetic and lifestyle factors are important determinants of peak bone mass.

As bone becomes less dense, it becomes more radiolucent; this appearance may be due to decreased collagen and/or decreased mineral. Collectively, this state is called *osteopenia*, a radiographic term that does not discriminate between the various sorts of metabolic bone disease. This term should not be confused with its use in bone densitometry studies, wherein osteopenia refers to a significant loss of bone density that is about one standard deviation less than is defined as osteoporosis. Radiologic loss of bone mass is due to loss of compact and cancellous bone, but the most common skeletal problems associated with osteoporosis arise from the loss of cancellous bone. This is as much due to the arrangement of each bone type as it is to actual decreased bone mass.

So long as the bony cortex forms a continuous ring, the strength of the shaft of a long bone is proportional to the distance from the center of the medullary cavity to the outside of the cortex raised to the third power; its stiffness is proportional to this distance raised to the fourth power. Because resorption of compact bone is primarily an endosteal event caused by osteoclasts, this means that as compact bones become more osteoporotic, their shafts become more hollow. Hollowing of the shafts is somewhat compensated for by intramembranous ossification on the cortical surface. Consequently, when the medullary cavity enlarges by endosteal osteoclasts, the diameter of the cortex also enlarges. This enlargement means that the radius from medullary midpoint to outer cortex increases. Because the strength of the intact bone is proportional to this distance raised to the third power, a small increase in appositional bone can biomechanically compensate for a relatively large loss of endosteal bone (Fig. 15-7).

Cancellous (trabecular) bone, on the other hand, is affected earlier by osteoporosis not only because it has less mass but because of its architecture. Cancellous bone is arranged in thin, highly perforated, vertically oriented parallel plates braced laterally by even thinner horizontal struts. Only 25% of the cancellous bone compartment is bone by volume; the remaining intertrabecular spaces are filled with fat and marrow (see Fig. 15-1, B). Compared with the cortex, the surface/volume ratio in the cancellous bone is very high, giving all bone cells free access to the delicate surfaces of the trabeculae; so cancellous bone is resorbed more rapidly than cortical bone. Furthermore, if osteoclastic resorption progresses at an equal rate in all parts of cancellous bone, the horizontal struts that serve to brace and reinforce the vertical plates are lost earlier because they began with significantly less bone mass than the vertical plates. Resorption of these horizontal braces contributes proportionately more to the morbidity of osteoporosis than the diffuse loss of bone mass. As these struts disappear, the vertical trabeculae form longer and longer vertical line segments that are subject to progressively increased bending forces (Fig. 15-8).

Figure 15-8 Osteoporosis of lumbar vertebra. There is generalized loss of bone. The vertical plates have become more perforated and the number of horizontal cross-braces is decreased markedly in proportion to the vertical plates (compare to Fig. 15-1, B).

Increasing the length of each of these vertical trabecular line segments increases their susceptibility to fatigue fracture by a factor of the incremental length squared. So if the unprotected length of a vertical plate is doubled, it is four times more likely to fracture. It is not surprising that pain, skeletal deformities, and fractures are common sequelae.

Osteoporosis may be divided etiologically into primary and secondary types. In primary osteoporosis, there are typical complex associations and patient ages, but the exact cause of bone loss is not known. The most common type of primary osteoporosis is postmenopausal osteoporosis, which occurs in the setting of hormonal decrease, has its maximal loss of bone mass in the first menopausal decade, and seems to be associated with increased osteoclastic activity. It is manifest mainly as a loss of cancellous bone. So-called senile osteoporosis manifests a decade or more later than the postmenopausal variety and is associated with a decline in osteoblast number proportionate to the demand for their activity; it affects mainly compact bone (Manolagas, 1995). Idiopathic juvenile osteoporosis occurs in the peripubertal period and is associated with increased osteoclastic activity. Unlike the postmenopausal and senile varieties, it is usually self-limited, and the skeleton may regain much of its bone mass.

In secondary osteoporosis, there is a known reason for the loss of bone mass, which may sometimes be preventable or even reversed. Etiologies include hyperparathyroidism and other endocrinopathies, space-occupying marrow lesions causing increased pressure in the marrow cavity, calcium deficiency, malabsorption, administration of steroids or heparin, and immobilization.

Certain connective tissue disorders such as osteogenesis imperfecta, Marfan syndrome, and Ehlers-Danlos syndrome also result in structural or functional osteoporosis.

Current treatment efforts are aimed at preventing resorption or stimulating new bone production. Current antiresorptive treatments include estrogens, selective estrogen receptor modulators (SERMs), vitamin D, calcitonin, and bisphosphonates, and the only anabolic agent is parathyroid hormone. Of these modalities, a more rapid effect is noted with antiresorptive medications; anabolic medications require a longer time to produce a measurable effect.

OSTEOMALACIA AND RICKETS

Osteomalacia and rickets are disorders of calcification. Osteomalacia is a failure to mineralize newly formed organic matrix (osteoid) in the mature skeleton. Osteoid formation continues, but the bones gradually become softer as the ratio of osteoid to mineralized bone increases over time. Weakness, skeletal pain and deformities, and fractures can occur as the disease progresses. Roentgenographic examination reveals a generalized decrease in skeletal radiodensity. Although the skeleton becomes less radiodense, this does not discriminate between absolute loss of mineralization and loss of mineralized organic matrix (osteoporosis).

Rickets, a disease of children, is the designation for osteomalacia that occurs before cessation of growth, that is, before closure of the epiphyseal plates of long bones. The skeletal deformities in rickets are accentuated as a consequence of compensatory overgrowth of epiphyseal cartilage, wide bands of which remain unmineralized and unresorbed. In severe cases of rickets, decreased growth can be associated with such evident deformities as swelling of the costochondral junctions of the ribs (rachitic rosary), a protuberant sternum, costodiaphragmatic depression (Harrison's sulcus), delayed closure of the anterior fontanelle with frontal bossing, and visibly widened metaphyses of the long bones.

Figure 15-9 Renal osteodystrophy with hyperparathyroidism and osteomalacia. This undecalcified section is stained by the Von Kossa method, which stains mineralized bone black and osteoid with Alizarin red. The *thick red areas* represent seams of newly formed osteoid resulting from renal failure (see Fig. 15-10, A). The *solid black arrows* point to the cutting cones of osteoclasts tunneling into the mineralized substance of the bone trabeculae. Note that these scalloped resorption surfaces occur only in the black areas. The red areas are devoid of osteoclasts and are smooth (250 \times).

Optimal mineralization requires (1) an adequate supply of calcium and phosphate ions from the extracellular fluid, (2) an appropriate pH (≈ 7.6), (3) bone matrix of normal chemical composition and rate of synthesis, and (4) control of inhibitors of mineralization. The major categories of diseases that produce osteomalacia or rickets are vitamin D deficiency states, phosphate depletion, systemic acidosis, and inhibitors of mineralization.

Vitamin D deficiency is particularly important in childhood and may be caused by inadequate dietary intake, intestinal malabsorption, diminished synthesis of active metabolites, increased catabolism, or peripheral resistance to vitamin D action. Dietary deficiency is very uncommon in the United States because of the widespread use of fortified milk and bread and vitamin supplements. When vitamin D deficiency occurs in adults, it is usually a consequence of malabsorption. Because vitamin D is a fat-soluble vitamin, its absorption is impaired in celiac disease (nontropical sprue), biliary and pancreatic disease, or steatorrhea from other causes. Systemic resistance to vitamin D can be of major importance in the osteomalacia that accompanies chronic renal disease. On the other hand, hereditary resistance to $1,25(\text{OH})_2\text{D}_3$, often called vitamin D-dependent rickets type II, is a rare disorder caused by a variety of defects in the vitamin D receptor.

RENAL OSTEODYSTROPHY

Renal osteodystrophy refers to the spectrum of bone abnormalities that occur in patients with end-stage renal disease (ESRD), predominantly osteitis fibrosa cystica, osteomalacia, or a combination of the two (see Fig. 15-5). Osteitis fibrosa cystica is characterized by increased bone turnover due to secondary hyperparathyroidism, a consequence of decreased levels of $1,25(\text{OH})_2\text{D}_3$ and ionized calcium. (In general, bone dissolution is accelerated and bone formation decreased.) Osteomalacia is characterized by poor mineralization of bone resulting in the accumulation of surface osteoid (unmineralized bone). Osteoclasts cannot penetrate (resorb) these osteoid surfaces because they are attracted only to mineralized surfaces. Thus, osteoclasts dig cutting cones through the few remaining mineralized surfaces into the mineralized cores of old trabeculae. This phenomenon is histologically referred to as tunneling resorption because of the manner in which osteoclasts gain access to mineralized bone (Fig. 15-9).

The defective mineralization process in osteomalacia of ESRD patients can be attributed to low serum calcium levels, the accumulation of aluminum in bone, or other as yet unexplained factors. Renal failure patients who are treated orally with aluminum-containing phosphate binders to control hyperphosphatemia, or who undergo hemodialysis using aluminum-containing dialysates, can experience osteomalacia because aluminum ion can interfere with normal hydroxyapatite lattice formation. Undecalcified bone biopsies stained for aluminum can distinguish between this and the more usual types of osteomalacia (Fig. 15-10, A and B).

Figure 15-10 Osteomalacia in renal osteodystrophy. **A**, Von Kossa stain shows previously formed bone in black; newly synthesized, unmineralized osteoid stains magenta. Note that all surfaces are covered with thick magenta osteoid seams (125 \times). **B**, The same field of the same biopsy stained with solochrome azurine to detect aluminum. Note that the lines corresponding to the demarcation between black and magenta in the Von Kossa section are stained with a dark blue line. This corresponds to aluminum derived from dietary phosphate binders that has been incorporated into the hydroxyapatite matrix of the bone and interferes with further mineralization (125 \times).

PAGET'S DISEASE

Paget's disease of bone (osteitis deformans) is a chronic disorder of bone that may be unifocal or multifocal. Although it resembles a metabolic disease because involved bones are structurally and functionally abnormal, it is not a true metabolic disease because uninvolved bones are normal. The cause of Paget's disease is currently unknown; however, it has been suspected to be of viral origin because paramyxovirus-like particles have been identified in the nuclei of osteoclasts from affected bone. A family history of the disorder is sometimes identified. Regardless of its origin, the disease displays uncoupling of osteoclast and osteoblast function with osteoclastic activity predominating early in the disease and osteoblastic activity predominating late in the disease. The osteoclasts are often large and bizarre, with 50 or more nuclei; trabecular scalloping with multiple Howship's lacunae, paratrabeal fibrosis, and marrow hypervascularity may occur. The early histologic picture resembles osteitis fibrosa of hyperparathyroidism. As osteoblastic new bone production takes place, Howship's lacunae are filled in by irregular patches of mature and immature bone; the outlines of the original delimitations of osteoclast resorption are preserved as irregularly disposed reversal cement lines, and the resulting bone comes to resemble a tile mosaic. This results in structurally weak bone that is prone to both deformities and fractures. Patients with extensive bone lesions who have underlying heart disease may develop high output cardiac failure as a complication. Approximately 1% of patients eventually develop bone sarcomas, usually with osteosarcomatous differentiation. Laboratory findings are of some interest. Although serum calcium and inorganic phosphorus concentrations are typically normal, they may occasionally become elevated. Serum calcium levels may, in fact, become very elevated if an extensive area of Paget's disease is immobilized. Once osteoblast activity begins, serum alkaline phosphatase increases and may be used to follow the activity of the bone-synthesizing phase of the disease. Alkaline phosphatase levels rise further if a patient with Paget's disease develops osteosarcoma. Urinary excretion of calcium and phosphorus is normal or increased, whereas excretion of hydroxyproline is usually significantly increased. Paget's disease frequently responds both clinically and pathologically to therapeutic administration of calcitonin.

- Normal fasting plasma glucose is <100 mg/dL (5.6 mmol/L), and normal glucose levels 2 hours post glucose load are <140 mg/dL (7.8 mmol/L).
- The diagnosis of diabetes requires a fasting plasma glucose ≥ 126 mg/dL (7.0 mmol/L) on at least two occasions or a casual plasma glucose level (or 2 hours post glucose load level) ≥ 200 mg/dL (11.1 mmol/L).
- Glycated hemoglobin (HbA_{1c}) $\geq 6.5\%$ on at least two occasions can be used to diagnose diabetes using a method that is National Glycohemoglobin Standardization Program certified and standardized to the DCCT (Diabetes Control and Complications Trial) assay.
- Impaired fasting glucose (100–125 mg/dL), a 2-hour plasma glucose value 140–199 mg/dL after a 75-g glucose load, or HbA_{1c} 5.7%–6.4% indicates increased risk for diabetes.
- Oral glucose tolerance tests should be performed to diagnose gestational diabetes.
- Whole blood capillary glucose values obtained with point-of-care devices are useful for the detection of hyperglycemia and hypoglycemia in individuals with diabetes, and help to monitor and direct therapy. They should not be used to diagnose diabetes or hypoglycemic disorders. To establish these diagnoses, confirmation with laboratory measures of plasma glucose are essential because of their greater accuracy.
- HbA_{1c} levels should be performed every 3–6 months in individuals with diabetes to monitor glycemic control using a certified method, traceable to the DCCT reference method. Reliability and accuracy are diminished in the presence of shortened red blood cell survival, lower mean blood cell age, or need for transfusions, as seen with certain hemoglobinopathies and hemolytic conditions, as well as with uremia.
- Commonly used strips and tablets for ketone testing use sodium nitroprusside, which does not detect β -hydroxybutyrate. Because β -hydroxybutyrate levels are high in diabetic ketoacidosis (DKA) and fall with treatment, whereas acetoacetic acid and acetone levels rise

with treatment, these strips are not useful for monitoring therapy. Calculation of the anion gap is commonly used to monitor recovery from DKA. Enzymatic methods for measuring β -hydroxybutyrate are also available.

- Circulating autoantibodies (GAD65, ICA512, IA-2, IAA) may be present before and at the onset of autoimmune type 1 diabetes. These tests should not be used for routine screening of asymptomatic nondiabetic individuals except in a research setting. When performed, assays should be used that have been shown by the Diabetes Antibody Standardization Program to have the best performance.
- Hypoglycemic symptoms with a plasma glucose level ≤ 55 mg/dL (3.0 mmol/L) in an individual who is not receiving medications for diabetes warrant further evaluation. A careful drug and medical history and measurements of insulin, C-peptide, proinsulin, insulin autoantibodies, β -hydroxybutyrate, and drug levels (sulfonylureas, repaglinide, nateglinide) during the hypoglycemic episode are recommended to determine the diagnosis.
- Glycogen storage diseases that primarily affect the liver usually manifest with hypoglycemia and hepatomegaly, whereas those affecting muscle commonly cause muscle cramps, weakness, fatigue, and exercise intolerance.

Carbohydrates are major constituents of physiologic systems. They are organic compounds composed of carbon, hydrogen, and oxygen [$C_x(H_2O)_x$], which, along with lipids and proteins, provide energy and contribute to the structure of organisms. Complex carbohydrates are digested into simple sugars, principally glucose, which is used primarily as an energy source or stored as glycogen. The most important dietary hexoses (six carbon-containing carbohydrates) are D-glucose, D-galactose, and D-fructose, but the principal sugar circulating in the bloodstream is glucose. Lactose (glucose and galactose) and sucrose (glucose and fructose) are important disaccharides. Carbohydrates are needed for specific cellular functions (such as ribose in nucleic acids) and can modify proteins and their function by glycosylation. Carbohydrates are measured

in whole blood, serum, or plasma. In addition, measurements of glucose in urine, cerebrospinal fluid, and other body fluids are important clinically.

The concentration of glucose in blood is normally controlled within narrow limits by many hormones, the most significant of which, insulin, is produced by the endocrine pancreas. Diabetes mellitus is the most common disease of carbohydrate metabolism. Most individuals with diabetes have either type 1 (beta cell destruction with absolute insulin deficiency) or type 2 (insulin resistance and an insulin secretory defect). Measurements of glycemic control are increasingly important in diabetes, because the development and progression of microvascular and macrovascular complications are associated with glycemia. This chapter will review the aspects of carbohydrate metabolism most critical to the practice of medicine.

FUNCTION OF THE ENDOCRINE PANCREAS

The pancreas functions as both an endocrine and an exocrine organ in the control of carbohydrate metabolism. As an exocrine gland, it produces and secretes an amylase responsible for the breakdown of ingested complex carbohydrates. Further digestion leads to the production of monosaccharides, which can be absorbed. Once absorbed, the monosaccharides signal the endocrine pancreas, which regulates hormones involved in energy homeostasis. Enteroendocrine cells in the gastrointestinal tract are also stimulated by nutrients to secrete incretins, peptide hormones that affect pancreatic function, gastric emptying, and intestinal motility.

The endocrine pancreas secretes four hormones from different cells residing in the islets of Langerhans. Insulin is produced by the beta cells, glucagon by the alpha cells, somatostatin by the delta cells, and pancreatic polypeptide (PP) by the PP or F cells. In insulin-sensitive tissues such as skeletal muscle, fat, and liver, insulin stimulates glucose uptake and the formation of glycogen and inhibits glucose production. Glucagon acts primarily in the liver, where it stimulates glucose production and, over time, ketogenesis. Somatostatin, on the other hand, inhibits insulin and glucagon secretion, as well as the secretion of several other hormones. Nutrient ingestion is the major stimulus for PP secretion. The physiologic significance of PP is not clear, but it can reduce appetite and food intake. In the rare reported cases of islet cell tumors producing excess PP, or in PP hyperplasia, some patients have been asymptomatic, whereas other cases are associated with watery diarrhea syndrome (Bellows, 1998; Pasiaka, 1999; Tomita, 1980).

The ratio of insulin to glucagon is important in the regulation of carbohydrate metabolism. Anabolism is favored when there is a relative increase in the insulin-to-glucagon ratio as in the postprandial state; catabolism is favored with a relative decrease in this ratio as in the fasting state. The ratio of insulin to glucagon is influenced by somatostatin, neural input, intestinal peptides, and the concentrations of glucose and other metabolites. The ratio of insulin to glucagon is tightly regulated to keep blood glucose concentrations within the normal range.

In addition to the hormones mentioned above, the pancreatic beta cell secretes a 37 amino acid protein called islet amyloid polypeptide (IAPP), or amylin. First discovered in 1987, amylin is colocalized and cosecreted with insulin in response to stimulation with nutrients. IAPP can inhibit insulin secretion, slow gastric emptying, and inhibit postprandial glucagon secretion. Oligomeric forms are associated with an increase in beta cell apoptosis. IAPP is first synthesized as a larger precursor peptide that is processed within the beta cell. High levels of IAPP have been observed in hyperinsulinemic, insulin-resistant states, such as impaired glucose tolerance and early type 2 diabetes, and low levels are seen in type 1 diabetes. Amyloid deposits, fibroid material derived from IAPP, are observed in islets in type 2 diabetes. IAPP levels can also be elevated in pancreatic cancer. Amylin assays are not used in clinical practice, but amylin analogs may be helpful in diabetes management by limiting postprandial glucose excursions. A synthetic analog of amylin, pramlintide acetate, is available for use by injection before major meals in patients with insulin-requiring diabetes.

INSULIN

Insulin is a peptide hormone with a mass of ≈ 5800 daltons (Da), secreted by the beta cells in the islets of Langerhans in the pancreas. It has a 21

Figure 16-1 Human proinsulin, with cleavage sites for the proprotein convertases PC1 and PC2 and for carboxypeptidase H (CPE). Orange circles represent the two pairs of basic amino acids used for proteolytic processing, and green circles represent cysteine residues that participate in disulfide bonding. (Diagnosis and classification of diabetes mellitus. Copyright © 2004 American Diabetes Association. From Mackin RB. Proinsulin: recent observations and controversies. *Cell Mol Life Sci* 1998;54:696–702, with permission.)

amino acid A chain and a 30 amino acid B chain that are linked by two disulfide bonds. Insulin is synthesized initially as a longer single-chain peptide precursor hormone, pre-proinsulin. Proinsulin (≈ 9000 Da), the immediate precursor of insulin, is processed into insulin in the secretory granules of the beta cells by enzymatic removal of the 31 amino acid peptide segment that connects the A and B chains, known as C-peptide (Figs. 16-1 and 16-2). This proteolytic processing is catalyzed by proprotein convertases PC2 and PC1/PC3, which first convert proinsulin into the intermediate metabolites 32,33 split proinsulin and 65,66 split proinsulin, and then, after cleavage by carboxypeptidase H, to des-31,32 split proinsulin and des-64,65 split proinsulin. In adults, small amounts of intact proinsulin and these metabolically active conversion intermediates, especially des-31,32 split proinsulin, are cosecreted with insulin. Healthy infants and preterm neonates have higher proinsulin and 32,33 split proinsulin levels than adults. Proinsulin and its metabolites may cross-react with insulin in some insulin radioimmunoassays. This can be significant, especially because the half-life of proinsulin is at least three times as long as that of insulin. In vivo studies of proinsulin have shown that it has 10%–15% of the biological activity of insulin.

Elevated proinsulin levels (intact and partially processed proinsulin) have been found in type 2 diabetes and are associated with decreased ability of the beta cells to secrete insulin (Roder, 1998). An increase in proinsulin levels has also been observed in pre-type 1 diabetes, where a reduction in beta cell function occurs, and may be the result of beta cell damage from cytokines produced by infiltrating immunocytes (Hostens, 1999). Less common conditions associated with high proinsulin levels include insulinomas. Familial hyperproinsulinemia is a rare condition caused by mutations in the proinsulin gene. In affected Japanese families, this genetic abnormality is associated with impaired glucose tolerance or type 2 diabetes, but in a three-generation Caucasian family with hyperproinsulinemia and mutant proinsulin (Arg65-His), glucose tolerance was normal (Roder, 1996).

C-peptide and insulin are secreted in equimolar amounts into the portal vein, but the ratio in serum is about 5:1 to 15:1. The molar concentration of C-peptide in blood is higher than that of insulin primarily because of the hepatic clearance of insulin. Approximately 50% of insulin is rapidly removed by its initial passage through the liver, but hepatic extraction of C-peptide is negligible. In cirrhosis, hyperinsulinemia is observed as the result of decreased hepatic insulin clearance. In healthy individuals, the half-life of both C-peptide and proinsulin is approximately 30 minutes, whereas it is only 4–9 minutes for insulin. In normal individuals, the molar ratio of C-peptide to insulin in the fasting state is 5:1. Whether C-peptide has any significant biological activity is unclear (Wojcikowski, 1990; Ido, 1997).

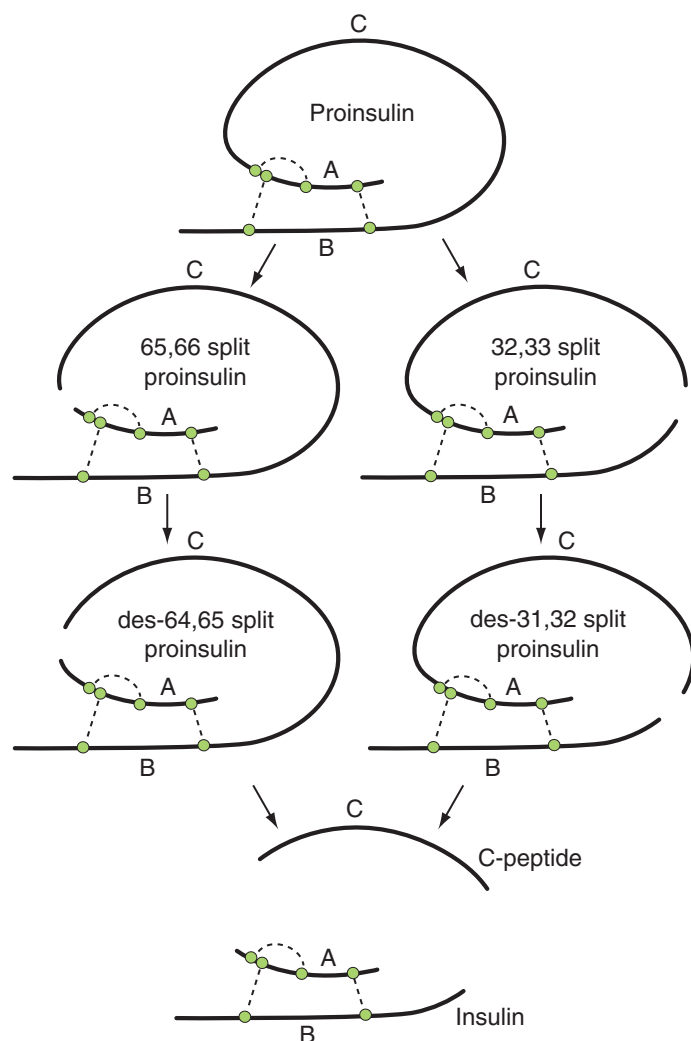

Figure 16-2 Processing of proinsulin to insulin. Green circles represent cysteine residues that participate in disulfide bonding. (Copyright John Wiley and Sons Ltd; reproduced with permission from Temple R, Clark PM, Hales CN. Measurement of insulin secretion in type 2 diabetes: problems and pitfalls. *Diabetic Med* 1992;9:503–512.)

Disease states occur when insulin concentrations are inappropriate for given blood glucose levels. Insulin deficiency, either absolute or relative, leads to diabetes mellitus. Serum insulin levels should be measured with a concomitant glucose level because insulin secretion is regulated primarily by glucose. Whereas a high insulin level in the presence of a low glucose level suggests inappropriate secretion or administration of insulin, high insulin levels can be observed in insulin-resistant individuals who need to secrete additional insulin to keep blood glucose levels normal.

Unregulated excess insulin secretion causes hypoglycemia. This is seen in insulin-secreting tumors, especially insulinomas, where patients have low serum glucose levels (<50 mg/dL), and elevated insulin and proinsulin levels with hypoglycemic symptoms (e.g., shakiness, palpitations, diaphoresis, confusion). C-peptide levels are measured in hypoglycemic states to help identify the cause of the hypoglycemia. Sera from insulinoma patients have high insulin and C-peptide levels, whereas hypoglycemia from injected or exogenous insulin is characterized by high insulin levels and low C-peptide levels. Commercially available insulin preparations are free of C-peptide and proinsulin. Because C-peptide is less stable than insulin, serum samples should be separated quickly and frozen.

In people with diabetes mellitus, C-peptide levels at baseline and after glucagon stimulation can be measured by immunoassay to help classify the cause of the diabetes and to provide information concerning beta cell secretory capacity. C-peptide and glucose can also be measured after an overnight 8-hour fast and 90 minutes after stimulation by an oral mixed meal. These tests usually are not performed in routine clinical practice, but they are used in research studies. Low C-peptide levels are characteristic of the absolute insulin deficiency of type 1 diabetes. C-peptide measurement can also be useful in follow-up evaluations after pancreatectomy

and postpancreatic transplantation. Unlike insulin, both C-peptide and proinsulin are primarily degraded in the kidneys, and so levels are elevated in renal failure.

Many commercial immunoassays for insulin, C-peptide, and proinsulin are now available. The American Diabetes Association Task Force on Standardization of the Insulin Assay reviewed 17 insulin assays and found significant variability (Robbins, 1996). It was recommended that all assays be standardized to one reference method. Manufacturers were encouraged to publish data concerning the performance of their assays, including accuracy, recovery, precision, specificity, linearity, and lowest measurable concentration statistically different from zero/limits of quantitation. Laboratory certification was also encouraged. In the United States, an external quality assessment program for insulin and C-peptide measurements is available through the College of American Pathologists (Northfield, Ill).

Serum insulin measurements may be falsely low in the presence of hemolysis. An insulin-degrading enzyme found in red blood cells as well as in other tissues is responsible for this problem. C-peptide and proinsulin measurements appear to be less affected by hemolysis. Insulin antibodies will also interfere with insulin immunoassays, with both falsely elevated and suppressed levels reported.

GLUCAGON

Proglucagon is synthesized in the pancreatic alpha cells and the L cells of the distal small bowel. Through differential processing, the glucagon family of gene products is formed. Fasting plasma glucagon concentrations are normally 25–50 pg/mL. Pancreatic glucagon stimulates glucose production. It is an important regulator of hepatic glycogenolysis, gluconeogenesis, and ketogenesis. In type 1 diabetes, over time, progressive glucagon deficiency develops. This deficiency of glucagon results in increased glycemic fluctuations and difficulty recovering from hypoglycemia.

Serum glucagon levels are rarely measured in clinical practice. Glucagonomas are rare islet cell tumors that produce excessive glucagon. Clinically, glucagonomas present with a characteristic necrotizing migratory erythematous rash, stomatitis, glossitis, weight loss, anemia, and mild diabetes mellitus. These tumors are usually associated with fasting glucagon levels greater than 120 pg/mL, but levels can range from 900–7800 pg/mL. The processing of proglucagon is impaired, and large molecular weight forms can be seen. Mild elevations in blood glucagon levels are seen in patients with multifunctional neuroendocrine tumors. Glucagon levels can also be mildly elevated in cirrhosis, diabetes, Cushing's syndrome, pancreatitis, acromegaly, and renal insufficiency. In familial hyperglucagonemia, an autosomal dominant disorder, glucagon levels are high in the absence of tumor. Family history is helpful in making this diagnosis.

INCRETINS

Oral nutrients stimulate the release of incretins from the intestines. The incretin effect refers to the greater and earlier insulin response to the oral administration of glucose compared with intravenous glucose. The most important incretins in the regulation of insulin secretion are glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic peptide (GIP), both of which are members of the glucagon superfamily. GIP, originally called gastric inhibitory polypeptide, exerts some beta cell effects in animal models but does not affect glucagon release or gastric emptying in physiologic doses.

In the intestine, GLP-1 is formed from proglucagon and functions mostly as an incretin to rapidly stimulate insulin secretion in response to a meal. Other effects include suppression of glucagon secretion and inhibition of gastric emptying. GLP-1 may reduce appetite and promote weight loss (Flint, 1998). In vitro and animal studies indicate that GLP-1 can inhibit beta cell apoptosis and stimulate beta cell proliferation and neogenesis from precursor duct cells (Drucker, 2003a). Plasma meal-stimulated GLP-1 levels are decreased in type 2 diabetes mellitus (Toft-Nielsen, 2001). GLP-1 (7–37), the most common active form, has a half-life of only 2–3 minutes. It is rapidly cleaved by circulating aminopeptidases to the inactive GLP-1 (9–37). This inactive form represents 80% of the circulating GLP-1. Both forms of GLP-1 are short-lived and cleared by the kidney. Dipeptidyl peptidase-4 (DPP-4), a serine peptidase present on the surface of endothelial cells, inactivates GLP-1 by removing two N-terminal

amino acids. Oral inhibitors of DPP-4 are used for the treatment of diabetes. Long-acting GLP-1 receptor agonists are available for use by injection in patients with type 2 diabetes.

SOMATOSTATIN

Somatostatin, a tetradecapeptide with a disulfide bond, was first isolated from the hypothalamus. Somatostatin was originally considered a hypothalamic hormone that inhibited growth hormone secretion, but the discovery of somatostatin in the islets of Langerhans prompted further investigation of its function in the endocrine pancreas. Subsequently, somatostatin was found in the gastrointestinal tract. It inhibits pituitary (growth hormone and thyrotropin), gastrointestinal (gastrin, secretin, vasointestinal peptide), and pancreatic (insulin, glucagon) hormones and possesses nonendocrine functions (e.g., inhibition of gastric acid secretion, gastric emptying time and, pancreatic enzyme release). The first isolated somatostatin peptide had 14 amino acids and is called somatostatin-14. Subsequently, somatostatin-28, which contains an N-terminal extension, was isolated and is a more potent inhibitor of other islet hormones.

In the pancreatic islets, somatostatin is produced in the delta cells, which make up 5%–10% of the islet cells. Rare islet cell tumors, somatostatinomas, secrete high levels of somatostatin. Elevated somatostatin levels can also be seen in small cell lung cancer, medullary thyroid cancer, and pheochromocytoma. Somatostatin has a very short half-life and is rarely measured in clinical practice. Two long-acting somatostatin analogs, octreotide and lanreotide, which bind primarily to the somatostatin receptor subtype 2 (SSTR2), are used to treat neuroendocrine tumors, as well as other disorders of the pancreas and gastrointestinal tract. Octreotide scintigraphy has also been used for tumor diagnosis, localization, and prediction for success of treatment with somatostatin analogs.

GLUCOSE MEASUREMENTS

SPECIMEN CONSIDERATIONS

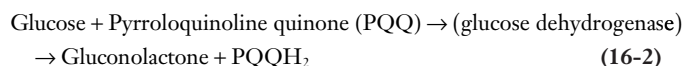

Measurements of glucose are critical to the diagnosis and management of diseases affecting carbohydrate metabolism. Glucose is measured in whole blood, plasma, serum, cerebrospinal fluid, pleural fluid, and urine for a variety of diagnostic and management purposes. In addition, devices can measure glucose from interstitial fluid for continuous monitoring of glucose levels in people with diabetes. How and when specimens are collected and handled and the site of collection affect the clinical interpretation of the analytic result.

The standard clinical specimen is venous plasma glucose. Glucose is metabolized at room temperature at a rate of 7 mg/dL/hour (0.4 mmol/L/hour); at 4° C, the loss is approximately 2 mg/dL/hour (Weissman, 1958). The rate of metabolism is higher with bacterial contamination or leukocytosis. A serum specimen is appropriate for glucose analysis if serum is separated from the cells within 30 minutes, but if serum is in contact with cells for longer than 30 minutes, a preservative such as sodium fluoride that inhibits glycolysis should be added. However, in serum specimens without bacterial contamination or leukocytosis, results remain clinically acceptable even after a delay of up to 90 minutes before separation of serum and cells. If whole blood is refrigerated, 2 mg of sodium fluoride per milliliter of whole blood prevents glycolysis for up to 48 hours (Chan, 1989). When refrigerated, glucose is stable in serum or plasma for 48 hours. With long-term specimen storage, even at –20° C, glucose values decrease significantly and progressively.

GLUCOSE MEASUREMENT METHODS

Most measurements of glucose employ enzymatic methods. These enzymatic methods provide specificity and can be packaged to furnish point-of-care determinations. Three enzyme systems are commonly used to measure glucose: glucose dehydrogenase, glucose oxidase, and hexokinase. These reactions produce an electrical current that is proportional to the initial glucose concentration, or a product that measured spectrophotometrically is proportional to the initial glucose concentration. The assays can be initial rate-of-change assays, where the velocity of the reaction is dependent on the initial glucose, or end-point assays.

When glucose is measured using a glucose dehydrogenase method, glucose is reduced to produce a chromophore that is measured spectrophotometrically (Equation 16-1) or an electrical current (Equation 16-2) (Kost, 1998).

Glucose oxidase, a flavoenzyme, catalyzes the reactions shown in Equation 16-3. The peroxidase reaction can be measured spectrophotometrically and can be inhibited by high concentrations of uric acid, ascorbic acid, bilirubin, glutathione, creatinine, L-cysteine, L-dopa, dopamine, methyl dopa, and citric acid (Zaloga, 1997). In addition, the glucose oxidase reaction can be coupled to the ferricyanide/ferricyanide couple to produce an electrical current, as shown in Equation 16-4. This system is dependent on the partial pressure of O₂ because oxygen will compete in the reaction to form hydrogen peroxide, so that the higher the partial pressure of O₂, the lower is the electrically measured glucose (Kurahashi, 1997). Glucose oxidase can be used in another electrical system, as shown in Equation 16-5.

The hexokinase system assay is the generally accepted reference method for measuring glucose. The reaction is shown in Equation 16-6. The glucose concentration is proportional to the rate of production of nicotinamide adenine dinucleotide phosphate (NADPH), which is followed spectrophotometrically. Depending on the source of the glucose-6-phosphate dehydrogenase, the enzyme can require specificity for NADP, or from some sources, it can use NAD as well. Hemolyzed samples can be problematic in that contents released from the erythrocytes may interfere with the stoichiometric relationship between glucose and NAD(P)H accumulation.

Whole blood glucose specimens can be analyzed with point-of-care devices. These monitoring devices are used in the home, in the physician's office, or at the bedside in the hospital to monitor for hypoglycemia and hyperglycemia. Most of these devices have been calibrated to give results similar to plasma levels and can report plasma or whole blood readings. Whole blood tends to give approximately 10%–15% lower glucose readings than plasma, but the percentage varies on the basis of hematocrit, analysis technique, and sample timing (fasting vs. postglucose load). Capillary blood is the source of most of these whole blood glucose measuring devices. Capillary blood glucose is similar to arterial glucose but can vary markedly from venous samples, depending on timing relative to food ingestion. For example, a postprandial specimen is higher in the capillary sample than in the venous sample. Capillary glucose tests, using point-of-care devices, should not be used to diagnose diabetes or hypoglycemic disorders. To establish these diagnoses, confirmation with laboratory measurements of plasma glucose is essential because of their greater accuracy.

Home blood glucose monitoring devices help people with diabetes better self-manage their disease. A wide variety of devices are available for home measurements. Proper training of patients in the use of individual meters is critical in avoiding operator errors, which, in one study, were reported in 12% of users (Schrot, 1999). Errors that may contribute to inaccurate readings in certain devices include the application of an insufficient volume of blood, milking the finger to acquire sufficient blood, the use of outdated test strips, environmental factors (humidity, heat, altitude), the use of a malfunctioning meter, the use of a dirty meter, hypertriglyceridemia, hypotension, and measurements outside of the hematocrit or temperature range. Some blood glucose monitoring devices are influenced by high levels of salicylate, acetaminophen, levodopa, uric acid, bilirubin, lipids, or low oxygen levels, and others are altered by touching the reaction area. Most are inaccurate at very high and low glucose values. The U.S. Food and Drug Administration has warned of the possibility of falsely elevated glucose readings using GDH-PQQ monitoring test strips with individuals who may have nonglucose sugars in their blood (i.e., use of Extraneal [icodextrin] peritoneal dialysis solution, maltose, and some immunoglobulins; <http://www.fda.gov/MedicalDevices/Safety/AlertsandNotices/PublicHealthNotifications/ucm176992.htm> [accessed January 5, 2010]). Desirable features of home blood glucose monitoring devices, aside from performance characteristics (precision and accuracy), include the following: ease of use, requirement of a small volume of blood, low maintenance, large print readout, rapid testing, appropriate alarms, minimal interfering substances, and memory storage and download capabilities. Some meters permit alternative site testing (such as forearm, upper arm, thigh), but results from alternative sites may be less accurate when rapid changes in glucose levels occur. Others incorporate electronic logbooks for recording events, insulin doses, and carbohydrate intake. This information can be downloaded to a computer to present the data in several displays such as logbooks, graphs, charts, and summary statistics.

Interstitial glucose measuring devices have been developed for continuous monitoring of glucose levels in people with diabetes. Most of these devices use electrochemical methods to automatically and frequently measure glucose levels in the interstitial fluid of dermis or subcutaneous fat tissue, and require repeated calibration to plasma or whole blood glucose levels. Examination of these data provides information about glucose patterns over hours to days. This glucose “trend analysis” can reveal useful findings for modifying treatment, such as unsuspected nocturnal hypoglycemia or postprandial hyperglycemia (Kaufman, 2002).

Interstitial glucose is in slow (5–30 min) equilibrium with capillary blood glucose and therefore is not equal to blood glucose, except in stable systems (Zierler, 1999; Cheyne, 2002). Particularly during times when glucose levels are rapidly changing, such as after meal ingestion or recovery from hypoglycemia, interstitial fluid readings will lag behind fingerstick glucose levels. Because the precision and accuracy of currently available portable continuous glucose monitors are not as high as for conventional home blood glucose monitoring devices, they may supplement but cannot replace conventional home blood glucose monitoring. Individual glucose readings obtained by fingersticks should be used primarily to direct therapy. Technologies currently under development for noninvasive glucose monitoring include impedance spectroscopy, thermal emission spectroscopy, near infrared spectroscopy, far infrared spectroscopy, ellipsometry, magnetic resonance imaging, and methods using electromagnetic waves.

DIABETES MELLITUS

Diabetes mellitus is a group of diseases in which blood glucose levels are elevated. Diabetes is the most common set of disorders of carbohydrate metabolism, affecting approximately 24 million Americans in 2009 and projected to increase to 44 million in 2034 (Huang, 2009). The prevalence of diabetes is increasing, with the prediction of an estimated 33% of males and 39% females born in 2000 in the United States being diagnosed with diabetes during their lifetime (Narayan, 2003). This chronic disease is responsible for significant morbidity, mortality, and cost. Diabetes is the leading cause of treated end-stage renal disease, the most common cause of nontraumatic amputations, and the foremost cause of new blindness in adults ages 20–74 years. Nerve damage, known as diabetic neuropathy, occurs in 60%–70% of people with diabetes. Most diabetes-related deaths, however, are related to the increased risk of developing atherosclerotic disease. People with diabetes are at least two to four times more likely to have heart disease and cerebrovascular disease than those without diabetes. In 2007, it was estimated that diabetes in the United States cost \$174

billion, representing \$116 billion in direct costs and \$58 billion in indirect costs (American Diabetes Association, 2008). Direct spending for diabetes was projected to increase from \$113 billion to \$336 billion from 2009 to 2034 (Huang, 2009).

The Expert Committee on the Diagnosis and Classification of Diabetes Mellitus revised the criteria for the diagnosis of diabetes in 1997, with recent modifications by the American Diabetes Association (2010a). A fasting plasma glucose level ≥ 126 mg/dL (7.0 mmol/L) on at least two occasions is diagnostic of diabetes (Table 16-1). The fasting glucose level should be obtained after an 8-hour fast. Symptoms of hyperglycemia (e.g., polyuria, polydipsia, polyphagia, unexplained weight loss) with a casual plasma glucose level ≥ 200 mg/dL (11.1 mmol/L) or $HbA_{1c} \geq 6.5\%$ is sufficient to diagnose diabetes. Pre-diabetes designates conditions in which glucose homeostasis is abnormal, but serum glucose levels are not high enough to be classified as diabetes. This group includes individuals with impaired fasting glucose and impaired glucose tolerance (see Table 16-1). They are also at increased risk for cardiovascular and cerebrovascular diseases.

Formal oral glucose tolerance tests are not generally recommended for routine clinical use in the diagnosis of diabetes. If used, the procedure described by the World Health Organization (1985) utilizing a 75 g glucose load should be followed. For children, 1.75 g glucose/kg up to 75 g is recommended. The exception to these criteria is the diagnosis of gestational diabetes (Table 16-2), the glucose intolerance that develops during approximately 7% of all pregnancies (American Diabetes Association, 2004). To detect gestational diabetes in high-risk individuals, an oral glucose tolerance test (OGTT) should be performed (the “one-step”

TABLE 16-1
Diagnosis of Pre-Diabetes and Diabetes Mellitus

	Fasting plasma glucose		2-hour plasma glucose level (after 75 g glucose load)		HbA _{1c}
	mg/dL	mmol/L	mg/dL	mmol/L	%
Normal	<100	<5.6	<140	<7.8

Diagnosis of Gestational Diabetes Mellitus

Initial Screening Test for Average-Risk Women				
1-hour plasma glucose level (after 50 g glucose load)			Detection of gestational diabetes	
≥130 mg/dL (7.2 mmol/L)			90%	
≥140 mg/dL (7.8 mmol/L)			80%	
Oral Glucose Tolerance Tests (OGTT) for High-Risk Women and Average-Risk Women With Abnormal Screening Test Results				
	100 g OGTT plasma glucose		75 g OGTT plasma glucose	
	mg/dL	mmol/L	mg/dL	mmol/L
Fasting	≥95	≥5.3	≥95	≥5.3
1 hour	≥180	≥10.0	≥180	≥10.0
2 hour	≥155	≥8.6	≥155	≥8.6
3 hour	≥140	≥7.8		

Gestational diabetes mellitus diagnosed if ≥ 2 plasma glucose levels are exceeded (American Diabetes Association, 2004).

approach). The “two-step” approach is recommended for women with average risk. This approach uses an initial screening test, followed by an OGTT if the screening test glucose level is elevated.

Before an OGTT is performed, individuals should ingest at least 150 g/day of carbohydrates for the 3 days preceding the test without limitation in physical activity, and the test should be performed after an overnight 8- to 14-hour fast. The individual should not eat food, drink tea, coffee, or alcohol, or smoke cigarettes during the test, and should be seated. Venous glucose samples are preferably collected in gray-top tubes containing fluoride and an anticoagulant.

Approximately 64 million adults in the United States in 2000 had the metabolic syndrome, and this number is increasing (Ford, 2004). Of great concern is the increasing prevalence of the metabolic syndrome in U.S. adolescents, affecting more than 2 million, with more than 30% of overweight adolescents having the metabolic syndrome phenotype (Duncan, 2004). The metabolic syndrome is associated with increased risk of cardiovascular disease and of developing diabetes. Criteria defining the metabolic syndrome according to the Third Report of the National Cholesterol Education Program Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults include the presence of three or more of the following: (1) impaired fasting glucose, (2) blood pressure $\geq 130/85$ mm Hg, (3) waist circumference >102 cm in men and >88 cm in women, (4) serum triglycerides ≥ 150 mg/dL (1.695 mmol/L), and (5) high-density lipoprotein (HDL) cholesterol <40 mg/dL (1.036 mmol/L) in men and <50 mg/dL (1.295 mmol/L) in women. Most commonly, these individuals are insulin resistant and have smaller, denser, more atherogenic low-density lipoprotein (LDL) cholesterol particles.

The classification of diabetes was revised in 1997 and is shown in Table 16-3 with recent minor modifications (American Diabetes Association,

2010a). The most common forms of diabetes are type 1 and type 2 diabetes (Table 16-4). Type 1 diabetes, characterized by absolute insulin deficiency and beta cell destruction, used to be called juvenile-onset diabetes or insulin-dependent diabetes, but these terms are no longer used. Although this disease is most commonly diagnosed in young people, its onset can occur at any age. Because people with other forms of diabetes also use insulin therapy, the term “insulin-dependent” is confusing and should not be utilized. Type 2 diabetes, characterized by insulin resistance and an insulin secretory defect, has been referred to in the past as adult-onset or non-insulin-dependent diabetes. These terms also are no longer used. Although the onset of type 2 diabetes is most common in older adults, it can occur at any age, including childhood. Many patients with type 2 diabetes use insulin therapy, so it is no longer referred to as non-insulin-dependent diabetes. Uncommon causes of diabetes include genetic defects of beta cell function and insulin action, pancreatic diseases, endocrinopathies such as Cushing’s syndrome, acromegaly and pheochromocytoma, and certain drugs, chemicals, and infections (see Table 16-3).

TYPE 1 DIABETES

Type 1 diabetes mellitus represents approximately 10% of all cases of diabetes. There usually is an autoimmune destruction of insulin-producing beta cells in the islets of the pancreas, causing an absolute deficiency in insulin production. The genetic susceptibility to develop type 1 diabetes is related, at least in part, to the inheritance of specific immune response genes associated with HLA-DR/DQ on chromosome 6, as well as other genes and genetic markers. It is then hypothesized that a precipitating event occurs, such as a viral infection, toxin exposure, or other environmental influence, which triggers the autoimmune destruction of the beta

From American Diabetes Association. Diagnosis and classification of diabetes mellitus. Diabetes Care 2010a;33:S62–S69.

TABLE 16-4

Characteristics of Type 1 and Type 2 Diabetes Mellitus

	Type 1 diabetes	Type 2 diabetes
Frequency	5%–10%	90%–95%
Age of onset	Any, but most common in children and young adults	More common with advancing age, but can occur in children and adolescents
Risk factors	Genetic, autoimmune, environmental	Genetic, obesity, sedentary lifestyle, race/ethnicity, hypertension, dyslipidemia, polycystic ovarian syndrome
Pathogenesis	Destruction of pancreatic beta cells, usually autoimmune	No autoimmunity
C-peptide levels	Very low or undetectable	Insulin resistance and progressive insulin deficiency
Pre-diabetes	Autoantibodies (GAD65, IA-2, IAA) may be present.	Detectable
Medication therapy	Insulin absolutely necessary; multiple daily injections or insulin pump	Autoantibodies absent
Therapy to prevent or delay onset of diabetes	None known	Oral agents
	Clinical trials in progress	Insulin commonly needed
		Lifestyle (weight loss and increased physical activity)
		Oral medications (metformin, acarbose) may be helpful.

cells. It is only after most of the beta cells are destroyed that hyperglycemia develops. Antibody markers of beta cell destruction are commonly present before and at the time of onset of diabetes. These include antibodies to antigens for which recombinant autoantibody assays are available: Antibodies to the 65 kDa isoform of glutamic acid decarboxylase (GAD65), insulin autoantibodies (IAA), and islet cell antigen 512 autoantibodies (ICA512). ICA512 are autoantibodies to parts of the tyrosine phosphatase IA-2 antigen. The tyrosine phosphate IA-2 β (phogrin) is a separate but partially homologous antigen to IA-2. ICA512 and IA-2 autoantibody assays are used more frequently than assays for IA-2 β autoantibodies because IA-2 β antibodies generally react with IA-2. Although the presence of antibodies may help in the differentiation of type 1 diabetes from other types of diabetes early in the course of the disease, the absence of antibodies does not exclude this diagnosis.

Those individuals at greatest risk of developing type 1 diabetes have high titers of multiple autoantibodies. In family, as well as in population studies, the detection of at least two autoantibodies is associated with increased risk of developing type 1 diabetes (Maclaren, 1999, 2003). GAD65 has the highest sensitivity (91%) as a single screening marker for detecting multiple antibody-positive individuals (Krischer, 2003). IAA are more common in young children who develop type 1 diabetes, whereas GAD65 is more common in adults. These antibody assays are being used in type 1 diabetes detection, treatment, and prevention research. Their use for routine screening of asymptomatic individuals is not recommended at the present time, in part because effective interventions have yet to be demonstrated (Verge, 1998).

In the past, the autoantibody assays have not been well standardized, and the cutoff values for these assays were not firmly established. Quality control programs are important, in that almost 50% of blinded samples that are considered “low positive” are found to be negative on repeat testing of a blinded duplicate aliquot (Eisenbarth, 2003). Fluid phase radioassays for GAD65 and IA-2 in general have better sensitivity and specificity than standard available enzyme-linked immunosorbent assays (Bingley, 2003). For IAA assays, the microradioassays perform best. These assays use a smaller volume of serum and utilize protein A precipitation (Williams, 1997). The Diabetes Antibody Standardization Program, a collaboration between the Immunology of Diabetes Society and the Centers for Disease Control and Prevention, has established a Proficiency Testing Service. This group has reported proficiency evaluations for different assays of GAD65, IA-2, and IAA (Bingley, 2003). Poorest performance (greatest variation) was observed in different IAA assays. In this study, GAD65 and IA-2 antibody values were expressed in common units, WHO units/mL, as suggested by the Immunology of Diabetes Society. Evaluation of assays for GAD and IA-2a in the Diabetes Antibody Standardization Program demonstrated improved performance from 2002–2005 (Torn, 2008).

The “pre-diabetes” period of gradual and progressive beta cell destruction can last for months, years, or decades. During this period, the acute insulin response to intravenous glucose, called the first-phase insulin release, becomes depressed or absent. The absence of first-phase insulin response is also found in other forms of diabetes. Eventually, in most people with type 1 diabetes, most or all of the beta cells are destroyed, resulting in inadequate or absent insulin secretion. C-peptide levels and endogenous insulin levels therefore are very low or undetectable. People

with untreated type 1 diabetes develop diabetic ketoacidosis. Insulin therapy is required for all patients with type 1 diabetes.

TYPE 2 DIABETES

Type 2 diabetes is the most common type of diabetes, affecting approximately 90% of Americans with diabetes. This disease is familial, but the underlying genetic defects for most of those affected have yet to be determined. Risk factors include overweight (body mass index [BMI] ≥ 25 kg/m²), sedentary lifestyle, family history of diabetes, advanced age (≥ 45 years), ethnicity (African Americans, Latinos, Native Americans, Asian Americans, and Pacific Islanders), and polycystic ovary disease, as well as history of gestational diabetes or delivery before diabetes of a baby weighing >9 lb, hypertension, vascular disease or dyslipidemia (HDL-cholesterol ≤ 35 mg/dL [0.90 mmol/L] and/or triglyceride level ≥ 250 mg/dL [2.82 mmol/L]), A1c $\geq 5.7\%$, impaired fasting glucose or impaired glucose tolerance, and other conditions associated with insulin resistance (i.e., acanthosis nigricans). This is not an autoimmune disease, so antibody testing is not worthwhile. C-peptide levels are measurable in type 2 diabetes. Of the estimated 24 million Americans with type 2 diabetes in 2009, 4–5 million are undiagnosed. Unlike undiagnosed type 1 diabetes, in which patients are usually symptomatic, people with new-onset type 2 diabetes can be free of symptoms. It is not unusual to diagnose type 2 diabetes after the onset of complications. Routine screening for high-risk individuals is therefore recommended.

The American Diabetes Association (2010b) recommends screening for type 2 diabetes by the individual's health care provider if one or more risk factors are present. Testing for diabetes should be considered in any overweight or obese adult. In general, it is recommended that adults ages 45 and older be screened for diabetes every 3 years, but screening should be performed earlier and more frequently if the individual is at high risk. The preferred test is a fasting plasma glucose or HbA_{1c} level. If a random plasma glucose level is ≥ 160 mg/dL (8.9 mmol/L), a fasting plasma glucose, HbA_{1c}, or 2 hour 75 g OGTT should be performed (see Table 16-1). It should be remembered that whole blood glucose values, which are measured on some home blood glucose monitoring devices, are 10%–15% lower than plasma glucose values. These devices should not be used to diagnose diabetes. If, however, an individual does have a capillary glucose test on one of these machines that reads ≥ 140 mg/dL (7.8 mmol/L), he or she should be rescreened with a fasting plasma glucose, HbA_{1c}, or OGTT using venous samples (see Table 16-1). Point-of-care A_{1c} assays are not recommended for use for diagnosis at this time.

In recent years, type 2 diabetes has been diagnosed in younger individuals, including children. The American Diabetes Association (2010b) recommends screening children and adolescents, beginning at age 10 or at onset of puberty, who are overweight (BMI >85 th percentile or weight $>120\%$ of ideal) with two of the following risk factors: Family history (type 2 diabetes in first- and second-degree relatives), high-risk race/ethnicity (Native Americans, African Americans, Hispanic Americans, Asians/South Pacific Islanders), signs of insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, polycystic ovary syndrome, or small for gestational age birth weight), or maternal history of diabetes or gestational diabetes during the child's gestation.

Most people with type 2 diabetes are insulin resistant and have a relative or absolute deficiency in insulin secretion. Most people with type 2 diabetes are also obese. Inappropriately high hepatic glucose production occurs, along with impaired glucose utilization peripherally. Decreased glucose transport can be demonstrated in muscle and adipose tissue. For glucose tolerance to remain normal, the pancreas has to secrete sufficient insulin. If the pancreas is unable to increase insulin secretion, impaired glucose homeostasis or type 2 diabetes results. Hyperglycemia is toxic to beta cell function and impairs insulin secretion. Over time, beta cell failure is usually progressive, and the beta cells produce lesser amounts of insulin, contributing to increasing insulin deficiency. Although many people with type 2 diabetes can be effectively treated with diet, exercise, and oral glycaemic control agents, others require insulin therapy.

MEASURES OF GLYCEMIC CONTROL

It has been established that improved glycaemic control is associated with preventing or delaying the progression of microvascular complications in diabetes. The Diabetes Control and Complications Trial (DCCT) demonstrated that lowering glucose levels in patients with type 1 diabetes slows or prevents the development of retinopathy, neuropathy, and nephropathy (DCCT Research Group, 1993). A 50%–75% decrease in complications was observed in the intensively treated group, in which a hemoglobin A_{1c} (HbA_{1c}) of 7.2% was achieved (compared with 9.0% in the conventionally treated group). In the DCCT follow-up Epidemiology of Diabetes Interventions and Complications study, reduction in cardiovascular disease was also found in the groups that had been intensively treated (Nathan, 2005). Reduction in microvascular complications in type 2 diabetes was reported in the United Kingdom Prospective Diabetes Study (UKPDS), as well as in a smaller Japanese study (UKPDS Study Group, 1998a,b; Ohkubo, 1995). In the UKPDS, microvascular complications were decreased by 25% in intensively treated patients by lowering the HbA_{1c} from 7.9% to 7.0%. In the UKPDS follow-up study, macrovascular disease was reduced as well. The standard of care is to measure HbA_{1c} levels every 3–6 months to monitor glycaemic control (American Association of Clinical Endocrinologists, 2007; American Diabetes Association, 2010b). Glycaemic goals are shown in Table 16-5.

Glycosylated hemoglobin (GHb) is formed nonenzymatically by the two-step reaction shown in Equation 16-7. The first reaction is rapid, reversible, and dependent on the ambient glucose concentration, and produces a labile aldimine or Schiff base. Over time, the aldimine slowly undergoes Amadori rearrangement and is converted to a stable ketoamine, glycosylated hemoglobin. Most HbA_{1c} assays measure this stable ketoamine, not the labile product, which is more prone to be influenced by recent dietary intake.

HbA_{1c} is now defined by the International Federation of Clinical Chemistry Working Group on HbA_{1c} as the hemoglobin A that is irreversibly glycosylated at one or both N-terminal valines of the β -chains of the tetrameric hemoglobin molecule, including hemoglobin that may also (but not solely) be glycosylated on lysine residues.

GHb testing provides an index of average blood glucose levels over the past 2–4 months. Although the life span of red blood cells is approximately 120 days, GHb levels represent a “weighted” average of glucose levels, with youngest erythrocytes contributing to a greater extent than older ones. Approximately 50% of the GHb level is determined by plasma glucose levels over the previous month, and 75% during the previous 2 months (Tahara, 1993). Testing methods have been standardized to the HbA_{1c} assay, which is now the preferred test to use to assess glycaemic

TABLE 16-5

Glycaemic Goals

	Hemoglobin A _{1c} (%)	Preprandial glucose		Postprandial glucose*	
		mg/dL	mmol/L	mg/dL	mmol/L
ADA†	<7.0‡	70–130	3.9–7.2	<180	<10.0
AAE§	≤6.5	≤110	≤6.1	≤140	<7.8

*1–2 hours after beginning a meal.

†ADA, American Diabetes Association, 2010b.

‡Lower goals may be appropriate for selected individuals if this can be accomplished safely (without significant hypoglycemia). Higher goals may be appropriate in some individuals (e.g., with a history of severe hypoglycemia, limited life expectancy, advanced complications, extensive comorbid conditions, or long-standing diabetes in whom the goal is difficult to achieve with appropriate education, monitoring and therapies including insulin).

§AAE, American Association of Clinical Endocrinologists, 2007.

control. To avoid confusion for the general public, the American Diabetes Association, the American College of Endocrinology, and the National Diabetes Education Program recommend using the term “A_{1c}” testing when referring to HbA_{1c} equivalent (GHb) or HbA_{1c} results.

The National Glycohemoglobin Standardization Program (NGSP) began in 1996, with the goal of standardizing GHb tests to the high-performance liquid chromatography (HPLC) method reported as HbA_{1c} or HbA_{1c} equivalent, as used in the DCCT. Several types of certified methods are available for measuring hemoglobin A_{1c}: immunoassay, ion-exchange HPLC, electrophoresis, boronate affinity HPLC, and enzyme methods. Reliable bench-top point-of-care analyzers, such as one that uses a cassette-based immunoassay method, also are now available (Guerci, 1997). Most U.S. laboratories use a certified method and the College of American Pathologists’ proficiency testing program, which utilizes whole blood and lyophilized samples (Little, 2001).

To obtain and retain a “Certificate of Traceability to the DCCT Reference Method” in the NGSP, the laboratory must annually satisfy precision criteria (CV ≤5%; ≤3% for Level 1 laboratories), bias criteria (95% confidence interval [CI] of differences between test method and Secondary Reference Laboratories [SRL] must fall within ±1% GHb of the SRL [±0.70% GHb for Level 1 laboratories]), and outlier criteria (greater than mean +3 standard deviation of absolute differences between pairs). Level 1 laboratories are usually large and involved in research studies. The NGSP website contains certification criteria and information on how to obtain certification and on assay interferences and hemoglobin variants (<http://www.ngsp.org/prog/index3.html>).

GHb assays vary in reliability in the presence of a variety of factors. Interference by carbamylated hemoglobin can occur with uremia, hypertriglyceridemia, and hyperbilirubinemia, and salicylates can cause interference by acetylated species. Hemoglobinopathies (HbSS, HbSC, HbCC) associated with high red blood cell turnover and the need for transfusions will adversely affect accuracy, as will chronic alcohol or opiate use, iron deficiency, and lead poisoning (Hoberman, 1982; Tarim, 1999). Vitamins C and E can falsely lower levels by inhibiting glycosylation, but vitamin C can also increase levels for some assays (Davie, 1992; Ceriello, 1991). Sample storage effects may occur. Any condition associated with shortened red blood cell survival or lower mean red blood cell age, such as hemolysis, recovery from acute blood loss, transfusions, or splenectomy, will lower the HbA_{1c} level as the result of reduced exposure to plasma glucose. Hyperglycemia has been associated with a decrease in erythrocyte survival, suggesting that HbA_{1c} levels in poorly controlled patients may underestimate their mean plasma glucose concentration (Virtue, 2004).

In 2007, a consensus statement on the international standardization of HbA_{1c} assays was issued by the American Diabetes Association, the European Association for the Study of Diabetes, the International Federation of Clinical and Laboratory Medicine, and the International Diabetes Federation (Consensus Committee, 2007). HbA_{1c} assays should be calibrated by a new reference measurement system (Weykamp, 2008). This reference method, developed by the International Federation of Clinical Chemistry and Laboratory Medicine, measures only HbA_{1c} (not non-A_{1c} components). The Consensus Committee also recommended that results be reported in a standardized manner (A_{1c} [%]; A_{1c} [mmol/mol]), and estimated average glucose). The correlation between HbA_{1c} and estimated average plasma glucose levels for clinical use is shown in Table 16-6 (Nathan, 2008). HbA_{1c} levels used for the diagnosis of diabetes and increased

diabetes risk are shown in Table 16-1. HbA_{1c} goals for use in diabetes management are shown in Table 16-5.

The turnover time of serum proteins, primarily albumin, is much shorter than that of erythrocytes (14–20 days), so their glycosylation reflects glycemic control over narrower periods of time. The nonenzymatic glycation of these serum proteins occurs similarly to that of hemoglobin, with the formation of ketoamine-linked glucose protein. Several methods are available for measuring glycosylated proteins or glycosylated albumin, including affinity chromatography and immunoassays. These assays may be useful in patients for whom HbA_{1c} assays are inaccurate, such as those with hemoglobinopathies and hemolytic anemias, but unlike HbA_{1c} levels, their clinical utility has not been firmly established.

Fructosamine assays are the most widely used to assess short-term (3–6 week) glycemic control because the average half-life of the proteins is 2–3 weeks. These assays have the advantage of using serum samples and automated equipment, so are simple to perform and low in cost. They are more reliable than other glycosylated protein assays but can be affected by alterations in serum protein levels that are present during acute illnesses and liver disease. Whether fructosamine values should be corrected for serum protein or albumin concentrations is controversial. The assay should not be performed if the serum albumin level is ≤ 3.0 mg/dL. High uric acid, triglyceride and bilirubin levels, and the presence of heparin or hemolysis can also affect the assay.

KETONE TESTING

The ketone bodies β -hydroxybutyric acid, acetoacetic acid, and acetone are products of fatty acid degradation. β -Hydroxybutyric acid and acetoacetic acid are normally present in a 1:1 ratio at concentrations of 0.5–1.0 mmol/L each. Ketone testing, using urine or blood, is particularly important for individuals with type 1 diabetes mellitus to detect ketosis. Diabetic ketoacidosis (DKA) is a serious and potentially fatal hyperglycemic condition requiring urgent treatment. It is frequently associated with nausea, vomiting, abdominal pain, electrolyte disturbances, and severe dehydration. Type 2 diabetes patients who are poorly controlled, particularly in the presence of extreme stress or severe acute illness, can also develop DKA. Ketone testing may be useful in pregnancy and in determining the cause of hypoglycemic disorders.

The ratio of β -hydroxybutyric acid to acetoacetic acid is greatly increased in DKA as a result of the altered redox state and elevated levels of NADH in the hepatic mitochondria. The most commonly used strips and tablets use sodium nitroprusside (sodium nitroferrocyanide) and turn purple in the presence of elevated levels of acetoacetic acid. Acetone is detected in the presence of glycine. False-negative results can occur with old strips and with strips that have had excessive contact with air, and after ingestion of large amounts of vitamin C. False-positive results have been observed with angiotensin-converting enzyme inhibitors and other sulphydryl medications. β -Hydroxybutyric acid is not detected by these methods. Because β -hydroxybutyric acid levels fall and acetoacetic acid and acetone levels rise during the treatment of DKA, these tests are not useful for the monitoring of therapy.

To specifically quantitate β -hydroxybutyric acid, enzymatic methods are available for use by hospitals, as well as by individuals at home, using point-of-care devices. β -Hydroxybutyric acid can also be measured using

electrochemical, chromatographic, electrophoretic, and colorimetric methods. For the monitoring of recovery from DKA in the hospital setting, serial measurements of β -hydroxybutyric acid can be followed, but more commonly, serum electrolytes, including bicarbonate with calculation of the anion gap, are used.

HYPOLYCEMIA

Hypoglycemia results from an imbalance between glucose utilization (by brain, erythrocytes, muscle tissue, and kidneys) and production (endogenous glucose production by liver and kidneys and from ingestion of carbohydrates) in such a manner that the rate of glucose utilization exceeds the rate at which glucose is being produced (Guettier, 2006). The symptoms of hypoglycemia can be divided into two categories: neurogenic and neuroglycopenic. Neurogenic symptoms are triggered by the autonomic nervous system. Tremulousness, palpitations, and anxiety are catecholamine mediated, and diaphoresis, hunger, and paresthesias are related to acetylcholine release. The neuroglycopenic symptoms are due to diminished glucose supply to the central nervous system and include dizziness, tingling, difficulty concentrating, blurred vision, confusion, behavioral changes, seizure and coma (Towler, 1993; Schwartz, 1987; Mitakou, 1991). Severe hypoglycemia if not corrected in a timely fashion can lead to brain death (Cryer, 2007).

Treatment of diabetes mellitus with insulin or agents that increase insulin secretion (insulin secretagogue drugs) such as sulfonylureas is the major cause of hypoglycemia. A number of drugs and medical conditions can also cause hypoglycemia (Table 16-7). Pancreatic hyperinsulinemic hypoglycemia can be diagnosed by demonstrating that insulin secretion is not suppressed normally when the individual develops hypoglycemia. Measurements of insulin, C-peptide, proinsulin, insulin and insulin receptor autoantibodies, β -hydroxybutyrate, and drugs (i.e., sulfonylurea/meglitinide levels) are recommended to determine the correct diagnosis. Insulin and proinsulin autoantibodies may interfere with the immunoassays for insulin, proinsulin, and C-peptide.

“Whipple’s triad,” initially proposed by Whipple for the diagnosis of hypoglycemic disorders, continues to be an important tool in assessing patients with episodes suggestive of low plasma glucose levels. Whipple’s triad refers to symptoms consistent with hypoglycemia associated with a documented low plasma glucose level and relief of symptoms with correction of hypoglycemia (Whipple, 1938). Further evaluation is indicated if a person in good health presents with symptoms of hypoglycemia and a laboratory plasma glucose level ≤ 55 mg/dL (3.0 mmol/L) in the absence of treatment of diabetes mellitus (Cryer, 2009). A blood glucose level ≤ 50 mg/dL (2.8 mmol/L) in infants is considered abnormal and warrants diagnostic assessment (Sperling, 2004; Haymond, 1989).

HYPOLYCEMIC DISORDERS

Drugs

Several drugs can cause hypoglycemia that may manifest as altered mental status. Most cases of drug-induced hypoglycemia have been described in patients with diabetes mellitus who are on glucose-lowering medication such as insulin and insulin secretagogue drugs (sulfonylureas, repaglinide, and nateglinide). Elevated insulin with low C-peptide levels is observed when exogenous insulin has been administered. High insulin and C-peptide levels with a positive drug screen for an insulin secretagogue would be expected when these oral agents have been used surreptitiously. It is important that these blood tests be drawn during the hypoglycemic episode. The assays for sulfonylureas and meglitinides should be sent to a laboratory that has the capability to measure very low levels of these drugs, as assays using higher detection limits can lead to an inaccurate diagnosis (Manning, 2003).

Pentamidine used for the treatment of *Pneumocystis pneumonia* causes hypoglycemia by damaging pancreatic beta cells. Hypoglycemia can occur within a few hours to days of administration of pentamidine. Plasma insulin levels are high despite low glucose concentrations, indicating excessive insulin leakage (Bouchard, 1982; Assan, 1995). Sulfonamide-induced hypoglycemia is also associated with increased insulin and C-peptide levels in susceptible individuals (Hekimsoy, 1997). Salicylate-induced hypoglycemia may be due to increased peripheral glucose utilization secondary to uncoupling of oxidative phosphorylation, decreased hepatic glycconeogenesis, and increased insulin release (Marks, 1999). Beta blockers, such as propranolol, can cause hypoglycemia by antagonizing catecholamine-mediated glycogenolysis (Chavez, 1999).

Drug-induced hypoglycemia: a systematic review. *J Clin Endocrinol Metab* 2009;94(3):741–745.

Adenosine triphosphate (ATP)–sensitive potassium (K_{ATP}) channels play a major role in the regulation of insulin secretion from pancreatic beta cells. Blockage of these channels causes depolarization of the beta cell membrane, opening of voltage-dependent calcium channels, and increased influx of calcium that causes release of insulin from the beta cell and lowering of blood glucose. Gatifloxacin, a fluoroquinolone, causes hypoglycemia by blocking the ATP-sensitive potassium channels of pancreatic islet cells, leading to increased insulin release. The K_{ATP} channel consists of eight subunits (four Kir6.0 and four SUR). Saraya et al. showed that the Kir6.2 subunit of the pancreatic beta cell is blocked by gatifloxacin and to a lesser extent by levofloxacin and temafloxacin (Saraya, 2004; Park-Wyllie, 2006). Gatifloxacin has been withdrawn (*Federal Register*, Vol. 73, No. 175/September 9, 2008/Notices accessed on June 21, 2009, at <http://edocket.access.gpo.gov/2008/E8-20938.htm>).

Alcohol consumption can inhibit hepatic gluconeogenesis and increase glycogen phosphorylase activity, depleting hepatic glycogen stores and resulting in hypoglycemia. Alcohol-induced hypoglycemia is usually seen in the setting of a history of alcohol intake of 50–300 g without food intake for the preceding 6 to greater than 36 hours. Alcohol can be detected in the blood or breath. Plasma β -hydroxybutyrate levels are elevated and plasma insulin and C-peptide levels are low during the hypoglycemic episode (Arky, 1989; Marks, 1999).

Severe Medical Illnesses

Widespread hepatic disease and severe cardiac failure can result in hypoglycemia. Pathogenic mechanisms can include impaired gluconeogenesis,

hepatic congestion with decreased oxygen delivery to hepatocytes, impaired insulin degradation, and shunting of portal blood into the systemic circulation (Khoury, 1998). A decrease in glycogen reserves coupled with failure of gluconeogenesis and enhanced glucose utilization may be the cause of hypoglycemia in patients with severe sepsis (Miller, 1980). In addition, patients with very low muscle mass, such as those with spinal muscular atrophy and congenital myopathy, are at risk for hypoglycemia during prolonged fasting (23 hours), presumably related to poor availability of the gluconeogenic substrate alanine. Low plasma insulin and high plasma glucagon levels are observed during the hypoglycemia (Orngreen, 2003).

Hypoglycemia in end-stage renal disease (ESRD) can be related to defective gluconeogenesis, as well as impaired hepatic glycogenolysis due to poor nutritional status (Arem, 1989). Alcohol use, use of insulin or sulfonylurea drugs, sepsis, malnutrition, liver disease, and cardiac failure can increase the likelihood of hypoglycemic events in a patient with renal failure (Haviv, 2000). Gabapentin has been associated with hypoglycemia in a patient with ESRD on peritoneal dialysis. Plasma insulin and C-peptide levels were elevated during the hypoglycemic episode (Penumalee, 2003).

Hormone Deficiencies

Glucose counterregulation, mediated by glucagon, catecholamines, cortisol, and growth hormone, is important in preventing hypoglycemia. Glucagon initially stimulates glycogenolysis and later gluconeogenesis to increase plasma glucose levels. Catecholamines increase glycogenolysis, gluconeogenesis, and lipolysis, decrease insulin-mediated glucose uptake, and inhibit insulin release. Both growth hormone and cortisol decrease

insulin-mediated tissue glucose uptake and increase release of glucose into the circulation. A deficiency in the secretion of these counterregulatory hormones can contribute to low blood glucose levels. Hypoglycemia in adults is rarely attributable to deficiencies of glucagon or catecholamines, but poor glucagon and epinephrine responses to hypoglycemia are common in patients with long-standing diabetes mellitus and are associated with prolonged hypoglycemic episodes. Infants and children with a deficiency of cortisol and growth hormone are prone to develop hypoglycemia, especially during an acute illness. Adults with glucocorticoid or growth hormone deficiency can also develop hypoglycemia, usually after a prolonged fast (Smallridge, 1980; Zuker, 1995; Bunch, 2002).

Non-Beta Cell Tumors

Non-islet cell tumor hypoglycemia (NICTH) originates from non-beta cell tumors, which cause hypoglycemia without producing insulin. Tumors of mesenchymal origin (mesothelioma, hemangiopericytoma, solitary fibrous tumors) and epithelial origin (hepatocellular, gastrointestinal stromal tumor) are commonly associated with NICTH. These tumors are associated with increased paraneoplastic production of insulin-like growth factor-II (IGF-II). Normally, IGF-II is produced by liver and is relatively independent of growth hormone (GH) action. The primary transcription product is pre-proIGF-II. Post-translational processing of pre-proIGF-II leads to the formation of proIGF-II that is cleaved to form IGF-II. The intermediate product proIGF-II may be secreted. Non-islet cell tumor hypoglycemia is associated with aberrant paraneoplastic production of proIGF-II, also known as “big” IGF-II (Fukuda, 2006; de Groot, 2007). It is believed that elevated levels of IGF-II increase glucose utilization and suppress endogenous glucose production (Chung, 1996; Daughaday, 1989). The diagnosis of NICTH can usually be made by the presence of fasting hypoglycemia, low insulin, proinsulin, and C-peptide levels, an elevated IGF-II-to-IGF-I ratio, and low growth hormone and β -hydroxybutyrate levels. The glucagon level is usually within the normal range despite hypoglycemia because of the suppressive effect of “big” IGF-II on glucagon secretion. Hypokalemia is frequently associated with hypoglycemia due to insulin-like activity of big IGF-II. Levels of “big” IGF-II and IGF-BP 2 (IGF binding protein 2) can be determined by immunometric assays and are usually elevated (van Doorn, 2002). Size-exclusion acid chromatography is considered the gold standard method for detecting “big” IGF-II in NICTH. However, this is a time-consuming procedure. Determination of “big” IGF-II by immunoblot analysis after 16.5% tricine sodium dodecyl sulphate-polyacrylamide gels is a rapid, reproducible, and sensitive method (Miraki-Moud, 2005). The tumor is usually detected on physical examination and is confirmed by radiologic diagnostic studies.

Endogenous Hyperinsulinism

Hypoglycemia from endogenous insulin secretion can be due to (1) insulin-secreting beta cell tumors (insulinomas), (2) congenital hyperinsulinism (also called nesidioblastosis/islet hypertrophy or noninsulinoma pancreatogenous hypoglycemia syndrome), and (3) autoantibodies to insulin in patients who have never been treated with insulin (Hirata, 1994). A supervised 72-hour fast is recommended for the diagnosis of insulinoma with frequent clinical and biochemical monitoring for signs of hypoglycemia. During the hypoglycemic episode, blood is drawn for glucose, insulin, proinsulin, C-peptide, and β -hydroxybutyrate levels. Blood or urine screening tests for sulfonylurea/meglitinide drugs are also performed.

Insulinomas are the most common tumors of islet cells, with an incidence of 2–4 patients per million of the population per year (Oberg, 2005). The diagnostic criteria for an insulinoma are as follows: Presence of signs and symptoms of hypoglycemia with plasma glucose level ≤ 55 mg/dL (3.0 mmol/L), insulin level ≥ 3 μ U/mL (18 pmol/L) by immunochemiluminometric assay, C-peptide concentration ≥ 0.6 ng/mL (0.2 nmol/L), proinsulin concentration ≥ 5.0 pmol/L, β -hydroxybutyrate ≤ 2.7 mmol/L, an increase in the plasma glucose concentration of at least 25 mg/dL (1.4 mmol/L) in response to a 1 mg glucagon injection given intravenously, and a negative sulfonylurea/meglitinide blood/urine screen (Cryer, 2009). Those patients who are found to have endogenous hyperinsulinemic hypoglycemia with negative screening for oral antihyperglycemic agents and no evidence of insulin antibodies need further diagnostic tests to localize the insulinoma. These tests may include computed tomography (CT) or magnetic resonance imaging (MRI), as well as transabdominal and endoscopic ultrasonography (USG). Selective pancreatic arterial calcium injections with measurement of hepatic venous insulin levels can be used when conventional noninvasive means (CT, MRI, USG) have failed to localize the insulin-producing islet cell tumors (Guettier, 2009).

Autoimmune

Hypoglycemia can be due to antibodies directed against endogenous insulin or the insulin receptor. Hypoglycemia associated with autoantibodies to insulin in patients who have not received insulin injections is a rare condition called the autoimmune insulin syndrome (AIS). Individuals with autoimmune diseases or recent ingestion of sulfhydryl-containing medications (i.e., methimazole, penicillamine, captopril, imipenem, hydralazine, procainamide, isoniazid, penicillin G) are at increased risk for AIS. These patients commonly experience episodes of postprandial hypoglycemia. In some patients, fasting hypoglycemia, as well as hypoglycemia precipitated by increased physical activity, has been reported. Excessive amounts of insulin secreted after a meal are bound to antibodies, and as a result insulin becomes unavailable to target tissues. Hours later, insulin dissociates from the antibodies, resulting in hyperinsulinemia and hypoglycemia. Insulin levels are extremely elevated and distinctly higher than in insulinoma. C-peptide levels are incompletely suppressed, and a high insulin-to-C-peptide molar ratio is present. Serum insulin antibodies are elevated (Hirata, 1994; Dozio, 1998; Lidar, 1999; Cavaco, 2001; Vogeser, 2001; Yaturu, 2004; Lupsa, 2009).

Antibodies directed against the insulin receptor can cause hypoglycemia or hyperglycemia with extreme insulin resistance (type B insulin resistance). Type B insulin resistance is a rare condition that occurs in the third to fifth decades of life. It is more common in women and in persons of African heritage. Hyperglycemia may be the initial metabolic derangement in 80% of these patients; however, 20% may present with hypoglycemia. Hypoglycemia may develop some time later in 14% of patients who initially present with hyperglycemia (Fareau, 2007). Other autoimmune diseases, such as systemic lupus erythematosus and Hashimoto's thyroiditis, may also be present in these patients (Qing, 2009; Kato, 2008; Bao, 2007). In this condition, insulin receptor antibodies block insulin from attaching to the insulin receptor. In some patients, hyperglycemia is due to receptor degradation or downregulation leading to insulin resistance. Hyperglycemia and hypoglycemia sometimes can be seen in the same patient. Plasma glucose, β -hydroxybutyrate, and proinsulin levels are low, and insulin and the insulin-to-C-peptide ratio are inappropriately high. Insulin receptor antibodies can be detected by immunoprecipitation assays (Redmon, 1999; Taylor, 1989). Mutations in the insulin receptor gene are another rare cause of hypoglycemia.

Infancy and Childhood

Endocrine adaptive responses at birth help ensure neonatal nutrition. These include a decrease in insulin levels and an increase in glucagon and catecholamine levels. Glycogenolysis, gluconeogenesis, lipolysis, and beta-oxidation of fatty acids occur during this period of metabolic transition in early neonates. Blood glucose concentrations are usually lower than those observed in older infants and children. However, because of increased production and use of alternative fuels such as lactate and ketone bodies and differences in functional and metabolic requirements of neonatal brain, this “transitional hypoglycemia” is not associated with adverse effects. Hypoglycemia can be detrimental during the neonatal phase if the production of alternate fuels is impaired. Neonatal hyperinsulinism seen in infants of women with poorly controlled diabetes mellitus increases the risk of hypoglycemia during the few days after birth. A blunted glucagon surge (possibly mediated by intravenous glucose or formula feeds) or insufficient catecholamine release (due to maternal beta-blocker medication use) can lead to hypoglycemia requiring treatment (Hawdon, 2008). Other possible causes of hypoglycemia in infants include pituitary and adrenal disorders. Ketogenic hypoglycemia can be seen in children between 18 months and 5 years of age. Alanine, a gluconeogenic substrate, is found to be low in these patients. Usually, an episode of illness or prolonged fasting is associated with the hypoglycemia (Haymond, 1983).

Congenital Hyperinsulinism

Congenital hyperinsulinism (CHI) is associated with inappropriate secretion of insulin in relation to blood glucose concentration, leading to hyperinsulinemic hypoglycemia (HH). Genetic mutations in beta cells have been identified that result in dysregulated insulin release. Mutations in ATP-binding cassette, subfamily C, member 8; potassium inwardly rectifying channel, subfamily J, member 11; glutamate dehydrogenase; glucokinase; hydroxyacyl-coenzyme A dehydrogenase; solute carrier family 16, member 1; and hepatocyte nuclear factor 4 alpha have been linked to HH seen in CHI. Hyperinsulinemic hypoglycemia is characterized by a low blood glucose level with inappropriate insulin and C-peptide concentrations (Hussain, 2008; Kapoor, 2009).

The enzyme glucokinase (GCK) functions as a glucose sensor in the pancreatic beta cell and mediates glucose-stimulated insulin secretion. Activating mutations of GCK are inherited in an autosomal dominant manner and have been associated with familial hyperinsulinemic hypoglycemia. The hypoglycemia is usually mild (as compared with the autosomal recessive form) and is not limited to infancy. De novo mutations in the GCK gene resulting in hypoglycemia have also been described. In the hyperinsulinism hyperammonia syndrome, hypoglycemia is caused by an activating mutation of the glutamate dehydrogenase gene (*GLUD1*) located on chromosome 10. It is an autosomal dominant disorder characterized by hypoglycemia and elevated ammonia levels (three to eight times normal). Less severe hypoglycemia has been reported in sporadic cases (Sunehag, 2002; Straub, 2001; Cuesta-Munoz, 2004; Stanley, 1998). Hypoglycemia and lactic acidosis have been described in a child with mutation in a subunit of the mitochondrial respiratory chain complex III (Haut, 2003). In addition, mutations in enzymes involved in mitochondrial fatty acid oxidation can cause hyperinsulinemic hypoglycemia (Molven, 2004). Elevated plasma levels of hydroxybutyrylcarnitine and urinary 3-hydroxyglutarate are seen in hydroxyacyl-coenzyme A dehydrogenase (HADH) deficiency (Clayton, 2001).

The noninsulinoma pancreatogenous hypoglycemia syndrome reported in adults is not associated with mutations in the *SURI* or *Kir6.2* gene. These patients usually present with postprandial hypoglycemia. Serum insulin and C-peptide levels are elevated, and the drug screen for sulfonylureas and meglitinides is negative (Service, 1999).

Alimentary

Alimentary (reactive) hypoglycemia occurs usually within 4 hours after eating a meal. The OGTT is unreliable in diagnosing this condition. Individuals who have had gastric surgery are at risk. The dumping syndrome is characterized by vasomotor symptoms such as sweating, dizziness, and weakness, which usually occur less than an hour after ingestion of a meal. Hypoglycemia is not a characteristic of early dumping syndrome.

Hypoglycemia has been reported in patients who have undergone bariatric surgery for obesity. Hypoglycemia in the setting of gastric bypass surgery may be caused by trophic factors such as GLP-1 that cause endogenous hyperinsulinemia (Gebhard, 2001). These patients usually have a history of “spells” of postprandial hypoglycemia that fulfill Whipple’s triad. An insulin level $>3.0 \mu\text{U/mL}$ (18 pmol/L) with C-peptide $>0.6 \text{ ng/mL}$ (0.2 nmol/L) in the presence of plasma glucose $<55 \text{ mg/dL}$ (3.0 mmol/L)

and negative sulfonylurea/meglitinide screen with normal adrenal, pituitary, and thyroid functions is important for diagnosis. Imaging studies are negative for pancreatic tumor.

Some individuals without gastrointestinal pathology report spontaneous symptoms suggestive of hypoglycemia 1–4 hours after intake of carbohydrate-rich meals but have a normal laboratory evaluation. These patients are believed to have idiopathic reactive hypoglycemia. The OGTT is also not useful for the diagnosis of this condition (Lefebvre, 1988). Increased insulin sensitivity has been seen in some patients exhibiting features of postprandial hypoglycemia (Tamburrano, 1989). Contributing factors may also include delayed release of insulin in response to a meal and concomitant alcohol ingestion (Flanagan, 1998).

INBORN ERRORS OF CARBOHYDRATE METABOLISM

Normal plasma glucose levels are maintained by absorption of glucose from the diet, synthesis of glucose during gluconeogenesis, and the release of glucose from glycogen, the principal storage form of glucose. Glycogen storage diseases or glycogenoses result from defects in glycogen metabolism. These diseases are the consequence of inherited deficiencies of enzymes that control the synthesis or breakdown of glycogen. Abnormal quality or quantity of glycogen is found in these disorders. Liver and muscle are most commonly affected by defects in glycogen metabolism, as these tissues have abundant quantities of glycogen. Glycogen storage diseases that primarily affect the liver (hepatic glycogenoses) usually manifest with hypoglycemia and hepatomegaly. Muscle cramps, exercise intolerance, fatigue, and weakness are common complaints in glycogen storage diseases affecting muscles (muscle glycogenoses). Glycogen storage disease types I (glucose-6-phosphatase deficiency), III (debrancher deficiency), IV (brancher deficiency), VI (liver phosphorylase deficiency), IX (phosphorylase kinase deficiency), and 0 (glycogen synthase deficiency) and glucose transporter-2 (GLUT-2) deficiency mainly affect the liver. Table 16-8 shows the various characteristics of hepatic glycogenoses (Wolfsdorf, 1999; Chen, 2001). Muscle glycogenoses or glycogen storage diseases affecting the muscles (Table 16-9) include type V (muscle phosphorylase deficiency), type VII (muscle phosphofructokinase deficiency), and glycogen storage diseases secondary to defects in phosphoglycerate kinase, phosphoglycerate mutase, lactate dehydrogenase, fructose 1,6-bisphosphate aldolase A, pyruvate kinase, muscle phosphorylase kinase, lysosomal acid

alpha-glucosidase (type II, Pompe disease), and cardiac-specific phosphorylase kinase (Tsujino, 2000; Chen, 2001; Weinstein, 2002).

DEFECTS IN GALACTOSE METABOLISM

Galactose is a monosaccharide constituent, together with glucose, of the disaccharide lactose. Milk and milk products are the main sources of galactose. Enzymatic defects of galactokinase, galactose-1-phosphate uridyl transferase, and uridine diphosphate galactose-4-epimerase result in the defective metabolism and accumulation of galactose and its metabolites causing galactosemia (Holton, 2001).

Galactosemia with Uridyl Transferase Deficiency

Galactose-1-phosphate uridyl transferase (GALT) deficiency (classic galactosemia) has an autosomal recessive mode of inheritance. The most common mutation of the *GALT* gene is the *Q188R* mutation on chromosome 9. GALT deficiency presents early in infancy with symptoms of hypoglycemia, vomiting, diarrhea, irritability, feeding difficulties, and

failure to thrive. These infants may have jaundice, hepatomegaly, and easy bruisability. Initial diagnostic tests may reveal hyperbilirubinemia, elevated liver transaminases, metabolic acidosis, galactosuria, glycosuria, hypoglycemia, and abnormal clotting measurements. These patients are at risk of developing cerebral edema. Vitreous hemorrhage and *Escherichia coli* sepsis have also been reported in affected individuals. Long-term complications in GALT deficiency include impaired cognition, ovarian failure in females, and ataxic neurologic disease. Microbiological and fluorometric assays are used in the screening of the newborn to detect galactosemia. A fluorescent spot screening test for GALT activity (Beutler test) is available. An abnormal test is followed by biochemical or molecular confirmation of the diagnosis. The quantitative assays can give false-negative results after blood transfusion. A milder form of galactosemia known as the “Duarte variant” is also caused by a mutation within the *GALT* gene and is characterized by decreased red cell enzyme activity, which generally is of no clinical significance. Treatment of GALT deficiency consists of restriction of galactose in the diet (Holton, 2001; Leslie, 2003).

Galactokinase Deficiency

In galactokinase (GALK) deficiency, galactose cannot be converted into galactose-1-phosphate, and this leads to cataract formation. Pseudotumor cerebri is another rare complication observed in this disorder. The diagnosis is made by demonstrating an elevated blood galactose level with normal uridyl transferase activity and absence of galactokinase activity in erythrocytes. A galactose-free diet can reverse cataracts if started in early infancy (Holton, 2001; Bosch, 2002).

Uridine Diphosphate Galactose-4-Epimerase Deficiency

The benign form is associated with enzyme deficiency limited to erythrocytes and leukocytes. These affected individuals are healthy, and no treatment is required. In the severe form, clinical findings are similar to those seen in GALT deficiency, with additional findings of hypotonia and sensorineural deafness. Treatment consists of dietary restriction of galactose (Walter, 1999; Holton, 2001).

DEFECTS IN FRUCTOSE METABOLISM

Essential fructosuria, hereditary fructose intolerance, and fructose-1,6-diphosphatase deficiency are the clinical conditions resulting from defects in fructose metabolism.

Essential Fructosuria

This autosomal recessive disorder results from fructokinase deficiency. Fructokinase catalyzes the conversion of fructose to fructose-1-phosphate. The condition is asymptomatic and usually is diagnosed incidentally by the detection of fructose in urine as a reducing substance. No treatment is necessary.

Hereditary Fructose Intolerance

A defect of fructose-1,6-biphosphate aldolase B activity in the liver, kidney, and intestine results in failure of conversion of fructose-1-phosphate and fructose-1,6-biphosphate into dihydroxyacetone phosphate, glyceraldehyde-3-phosphate, and glyceraldehydes. Fructose intake leads to accumulation of fructose-1-phosphate and causes symptoms of hypoglycemia and nausea followed by vomiting. Symptoms occur only when fructose-containing foods are ingested. Prolonged exposure to fructose-containing foods can cause frequent hypoglycemic episodes, hepatomegaly, irritability, lethargy, seizures, and proximal tubular dysfunction. Hepatic dysfunction can result in prolonged clotting time, elevated transaminases with elevated bilirubin levels, and hypoalbuminemia. The diagnosis is supported by clinical suspicion followed by an intravenous fructose tolerance test. Definitive diagnosis can be made by assay of aldolase B activity in a liver biopsy specimen.

Fructose-1,6-Biphosphatase Deficiency

This autosomal recessive defect in fructose-1,6-biphosphatase results in failure of hepatic glucose generation by gluconeogenic precursors such as lactate, glycerol, and alanine. Life-threatening episodes of hypoglycemia, hyperventilation, lactic acidosis, convulsions, and coma can be seen in affected patients. The diagnosis is established by demonstrating enzyme deficiency in a liver or intestinal biopsy specimen. Correction of hypoglycemia and acidosis by intravenous fluids is the treatment of choice during acute attacks. Prolonged fasting can cause symptoms in affected individuals if glycogen stores are depleted. Fructose and sucrose need to be limited in the diet (Steinman, 2001).

LACTIC ACIDOSIS

Lactic acid is a product of pyruvic acid metabolism. Approximately 1400 mmol of lactic acid is produced daily in healthy individuals, most of which is derived from glucose via the glycolytic pathway and deamination of alanine (Marko, 2004; Kreisberg, 1980). This enormous amount of lactic acid is eliminated by several mechanisms, including buffering by extracellular buffers and removal by the liver and kidneys. Under normal circumstances, the rates of lactate entry and exit from the blood are in equilibrium, and net lactate accumulation is zero. Excessive accumulation of L-lactic acid is caused by overproduction and/or underutilization of L-lactate (the levorotary form of lactic acid).

Selected causes of lactic acidosis are shown in Table 16-10. Lactic acid production increases during ischemia, seizures, vigorous exercise, and some leukemic conditions. High levels of lactic acid produced during

MILS (maternally inherited Leigh's syndrome)

strenuous exercise are rapidly cleared by both renal and hepatic mechanisms, as well as by aerobic metabolism in muscle (half-life approximately 60 minutes). A decrease in lactic acid utilization can also lead to accumulation of lactic acid. This is generally seen in diseases of the liver and kidneys. Defects in the removal of lactic acid have been associated with hepatic insufficiency, specific enzymatic defects, and severe acidosis. Metformin, which is widely prescribed for the treatment of type 2 diabetes, rarely causes lactic acidosis. Risk factors for metformin-related lactic acidosis include congestive heart failure, tissue hypoxia, renal insufficiency, and sepsis (Salpeter, 2003; Misbin, 2004). Nucleoside reverse transcriptase inhibitors used in the treatment of human immunodeficiency virus infection can also induce lactic acidosis (John, 2002; Ogedegbe, 2003).

Lactic acidosis is diagnosed by the presence of high blood lactate levels (>45 mg/dL or >5.0 mmol/L), an elevated anion gap, and a low blood pH (<7.35). For accurate measurements of lactate, tourniquet use should be minimal, and the patient should not clench his or her fist at the time of the blood draw. A gray-top tube containing fluoride oxalate should be used for sample collection, as it blocks further glycolysis.

Treatment of lactic acidosis consists of correction of underlying conditions that initiated the disruption in normal lactate metabolism. Tissue oxygenation, improved fluid status, amplification of cardiac status, and treatment of sepsis play important roles in the treatment of lactic acidosis. Dialysis is sometimes necessary for removal of lactate. D-Lactic acidosis results from excessive accumulation of D-lactic acid (the dextrorotary form of lactic acid). It has been described in patients with jejunoileal bypass or small bowel resection. In these conditions, glucose and other carbohydrates are converted into D-lactic acid in the colon by bacteria. The D-lactic acid is absorbed into the systemic circulation and is slowly metabolized. Affected patients present with episodes of metabolic acidosis and encephalopathy. D-Lactate levels can be measured using D-lactate dehydrogenase enzymatic assays (Luft, 2001; Zhang, 2003).

KEY POINTS

- Although ultracentrifugation and electrophoretic techniques are of historical significance, most useful lipid and lipoprotein testing methods are now enzymatic.
- Low-density lipoprotein cholesterol can be measured directly but is usually calculated using the Friedewald formula. Calculated values require evaluation of fasting samples.
- Low-density lipoprotein cholesterol is currently considered the most important value in assessing cardiac risk and directing therapy.

- The profile currently recommended for initial screening in adults, age 20 or older, includes total cholesterol, low- and high-density lipoprotein cholesterol, and triglycerides. Testing should be repeated at least once every 5 years.
- Other tests, including apolipoprotein levels and lipoprotein subclasses, may prove valuable in fine-tuning risk assessment and evaluating response to therapy.
- New guidelines elevate the perceived atherosclerotic risk of diabetes and support aggressive intervention in diabetic patients and patients with metabolic syndrome.

OVERVIEW

Disorders of lipid metabolism play a major role in atherosclerosis and coronary heart disease (CHD). A clear-cut relationship is evident between elevated serum cholesterol and myocardial infarction. At the tissue level, cholesterol deposits occur in areas of endothelial cell damage and are a prominent part of atherosclerotic lesions. Although cholesterol may be considered “bad” because of the previous association, it is actually a vital structural component of cell membranes and a precursor of steroid hormones and bile acids. Another lipid, triglyceride, is a major source of energy for cells. Cholesterol and triglycerides are the most important lipids in the study and management of CHD risk.

Lipids are soluble in nonpolar organic solvents, such as chloroform and ether, but relatively insoluble in polar solvents such as water. Thus, cholesterol and triglycerides travel in plasma not as free-floating molecules, but as part of water-soluble complexes called *lipoproteins*. These particles contain cholesterol in two forms: free cholesterol, a polar nonesterified alcohol (about 30%), and cholesterol ester, a hydrophobic form wherein cholesterol is linked to a fatty acid (about 70%). The lipoprotein is arranged like a micelle (Fig. 17-1). The most hydrophobic lipids, such as cholesterol esters and triglycerides, are located in the core of the particle. Lipids with some hydrophilicity, such as free cholesterol and phospholipids, are arranged on the surface with polar groups pointing outward. *Apolipoproteins* (apo) the protein moiety of lipoproteins, are also arrayed on the surface. They show amphiphilic characteristics; hydrophobic residues interact with the hydrophobic core, whereas hydrophilic residues interact outside the aqueous environment.

Four major lipoprotein classes have been identified: Chylomicrons (CMs), very-low-density lipoprotein (VLDL), low-density lipoprotein (LDL), and high-density lipoprotein (HDL). The classification is based on the buoyant density of the particles (see later). Several minor lipoproteins have also been identified, including intermediate-density lipoprotein (IDL) and lipoprotein(a) (Lp[a]) (Tables 17-1 and 17-2). Lipoproteins can

be differentiated by density, particle size, chemical composition, and electrophoretic mobility. These physical properties are due to differences in protein, triglyceride, and cholesterol content and reflect the role of each lipoprotein in lipid metabolism (see later). Each lipoprotein is associated with specific apolipoproteins that play important roles in lipid transport, such as activating or inhibiting the enzymes involved in lipid metabolism, and binding lipoproteins to cell surface receptors. The apo composition of the lipoprotein classes is summarized in Table 17-1.

Lipoproteins are commonly differentiated from one another on the basis of their buoyant density and electrophoretic mobility (Fig. 17-2). Ultracentrifugation separates lipoproteins by buoyant density. Lipids and proteins have average densities of 1.0 and 1.4 g/mL, respectively. If centrifuged in solutions of different densities, these particles band at characteristic densities. The density of a lipoprotein particle is determined mostly by its protein and triglyceride content. As illustrated in the diagram, the higher the lipid content, the less dense is the lipoprotein particle; therefore, the closer they migrate to the top of the tube. Lipoproteins with high triglyceride and low protein content (CM and VLDL) are less dense than those with high protein and low triglyceride content (HDL). LDL and IDL are more dense than VLDL but less dense than HDL. When plasma lipoproteins are separated by agarose gel electrophoresis, CM remains at the origin and HDL migrates fastest in the α -region, followed by VLDL in the “pre- β ” region and IDL and LDL in the β region.

Based on the presence and absence of apoB, lipoproteins can be classified as apoB-containing (CM, VLDL, IDL, LDL) and non-apoB-containing (HDL) lipoproteins. This classification is important because apoB is a nonexchangeable apolipoprotein, and only one molecule of apoB is present per lipoprotein. ApoB-containing lipoproteins may or may not contain additional apolipoproteins such as apoA-I, apoC, and apoE. ApoB serves as a structural protein for these lipoproteins and is always associated with these particles. They are synthesized mainly by hepatocytes and enterocytes.

Figure 17-1 Lipoprotein structure. Lipoproteins are spherical particles with a hydrophobic core and an amphiphilic surface. The surface consists of a single layer of phospholipids. This surface layer also contains proteins and free cholesterol. The hydrophobic core mainly contains triglycerides and cholesterol esters.

TABLE 17-1

Major Classes of Human Plasma Lipoproteins: Physicochemical Characteristics

Particle	Electrophoretic mobility*	Major apolipoproteins	Diameter (Å)	Density (kg/L)	Sf†
Chylomicrons	Origin	ApoA-I, A-IV, B-48, C-I, C-II, C-III, E	750–12,000	<0.95	>400
VLDL	Pre- β	ApoB-100, C-I, C-II, C-III, E	300–700	0.95–1.006	20–400
IDL	β or pre- β	ApoB-100, E		1.006–1.019	12–20
LDL	β	ApoB-100	180–300	1.019–1.063	0–12
HDL ₂	α	ApoA-I, A-II, E	50–120	1.063–1.125	
HDL ₃	α	ApoA-II, A-I, E	50–120	1.125–1.210	
Lp(a)	Pre- β	ApoB-100, Apo(a)		1.045–1.080

Figure 17-2 Lipoprotein classification. Lipoproteins are classified on the basis of buoyant density or electrophoretic mobility. Separation of lipoproteins based on buoyant density depends on the ratio between lipids and proteins present in them. Lipoproteins that contain higher amounts of lipids have lower buoyant density and are collected on top of the centrifuge tube. Separations based on electrophoretic mobility are based on the number of charges present on lipoproteins and are independent of their size and buoyant density.

This group of lipoproteins is mainly involved in delivering lipids to tissues for storage or use in energy production. CM (formed in the intestine from dietary fat) and VLDL (formed in the liver) are triglyceride-rich particles that are metabolized after entering the circulation. Through the action of lipoprotein lipase (LPL), these particles shed triglycerides and cholesterol esters and are transformed into denser lipoproteins with a higher percentage of cholesterol. LDL is the densest of these particles, and elevated serum LDL-cholesterol (LDL-C) is a primary cardiac risk factor. Treatment of CHD-causing dyslipidemia is generally aimed at lowering LDL.

One way to understand heterogeneity in apoB-containing lipoproteins is to view them as a metabolic progression in which CM and VLDL release triglycerides to tissues via interaction with LPL. As a result of this interaction, CM and VLDL become triglyceride depleted, denser, and relatively protein and cholesterol rich, giving rise to CM remnants and LDL. These particles are internalized and metabolized by cells—CM by liver and bone marrow cells and LDL by liver cells and by cells throughout the body. LDL serves as the major source of cholesterol for tissues. This metabolic progression is presented in Figure 17-3.

A block in any step of the pathway leads to the accumulation of one or more lipoproteins. The number over each step in the pathway represents the functional hyperlipoproteinemia (originally described by Fredrickson [1967]) caused by a block between two intermediates. For example, a block in the progression from CM to CM remnants results in the accumulation of CM—Type 1 or 5 disease—and presents with high triglycerides and normal cholesterol. A block in the conversion of VLDL to IDL and LDL results in Type 4 disease (i.e., VLDL accumulation with elevated triglycerides and frequently elevated cholesterol). Often the cause of Types 1, 5, and 4 disease is LPL deficiency and the resulting inability to break down triglycerides. Type 2 disease results from a block in LDL metabolism and

Figure 17-3 Metabolism of lipoprotein particles. The figure depicts successive shrinkage in the size of lipoproteins as a consequence of the lipolysis of triglycerides present in the particles. The number over each step in the pathway represents the functional hyperlipoproteinemia caused by a block between two intermediates (see Table 17-3). CM, Chylomicrons; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

may have a genetic basis: a defective apoB protein that does not bind to the LDL receptor, or a mutant LDL receptor that does not recognize apoB. Type 2 is further subcategorized on the basis of triglyceride level. Note that other studies (see later) may be necessary to distinguish Type 2B and Type 3 because both present with elevated cholesterol and triglycerides. This functional classification is presented in Table 17-3. No ideal system is known for classifying lipid disorders. They can be categorized in many different ways: primary versus secondary, hereditary versus acquired, as well as by lipoprotein fraction phenotypes. In general, each category is heterogeneous with respect to genetic, clinical, and pathologic factors. These are discussed in greater detail at the end of the chapter.

The major protein present in non-apoB-containing HDL is apoA-I, which makes up about 70% of the HDL protein. HDL is formed in the liver and plays a key role in reverse cholesterol transport, the process by which excess cholesterol is returned from tissues to the liver, where it is reused or excreted in bile. Besides apoA-I, HDL contains several proteins. In addition to reverse cholesterol transport, other functions of HDL have been described on the basis of in vitro assays, including anti-inflammatory, antioxidant, antithrombotic, and nitric oxide-inducing mechanisms. Although the role of reverse cholesterol transport has been suggested as a protective mechanism against atherosclerosis, these other properties of HDL might also contribute to the “protective” effect. Consequently, such protection may stem from HDL function rather than from increased plasma levels of HDL. Nonetheless, therapies targeting increased HDL levels in plasma remain an active area of research.

LIPOPROTEINS, APOLIPOPROTEINS, AND RELATED PROTEINS

Lipoprotein particles are dynamic entities that acquire and shed protein and lipid components as they circulate in the body. As mentioned earlier,

TABLE 17-3

Classical Hyperlipidemia Phenotypes

WHO ICD and OMIM numbers	Type	Particle	Triglycerides	Cholesterol	Comments
E78.3 238600	1 (familial chylomicronemia or LPL deficiency)	CM	High	Normal	Low cardiac risk; hereditary, found mostly in pediatric patients and young adults; autosomal recessive mutation in <i>LPL</i> or <i>APOC2</i> ; <i>APOA5</i> , <i>LMF-1</i> , and <i>GPIHBP1</i> mutations are linked to this phenotype.
E78.0 143890	2A (heterozygous and homozygous familial hypercholesterolemia)	LDL	Normal	High	High cardiac risk; mostly polygenic disease; about 10% are monogenic; heterozygous form is due to mutations in <i>LDLR</i> , <i>APOB</i> , or <i>PCSK9</i> ; homozygous form is due to mutations in <i>LDLR</i> or <i>LDLRAP1</i> (ARH)
E78.4 144250	2B (combined hyperlipoproteinemia)	VLDL, LDL	High	High	High cardiac risk; polygenic disease; links to mutations in <i>USF1</i> , <i>APOB</i> , and <i>LPL</i>
E78.2 107741	3 (dysbetalipoproteinemia)	IDL	High	High	High cardiac risk; mutations in <i>APOE</i> gene or homozygous for E2 allele of <i>APOE</i>
E78.1 144600, 145750	4 (primary hypertriglyceridemia)	VLDL	High	Normal	Lower cardiac risk than type 2 or 3; polygenic disease
E78.3 144650	5 (mixed hyperlipidemia)	VLDL, CM	High	High	Low cardiac risk; polygenic disease; 10% of patients have mutations in <i>LPL</i> , <i>APOC2</i> , and <i>APOA5</i> ; mutations in <i>APOE</i> , <i>TRIB1</i> , <i>CHREBP</i> , <i>GALNT2</i> , <i>GCKR</i> , and <i>ANGPTL3</i> are thought to contribute to this disease.

ANGPTL3, Angiopoietin-like 3; *APOA5*, apolipoprotein A-V; *APOB*, apolipoprotein B; *APOC2*, apolipoprotein C-II; *APOE*, apolipoprotein E; *CHREBP*, carbohydrate response element binding protein (or *MLXIP*); *CM*, chylomicron; *GALNT2*, UDP-N'-acetyl-alpha-D-galactosamine-polypeptide N-acetylglucosaminyltransferase 2; *GCKR*, glucokinase regulator; *ICD*, International Classification of Diseases; *IDL*, intermediate-density lipoprotein; *LDL*, low-density lipoprotein; *LDLRAP1*, LDL receptor adaptor protein 1 (also known as ARH); *OMIM*, Online Mendelian Inheritance in Man; *TRIB1*, tribbles homologue 1; *USF1*, upstream transcription factor 1; *VLDL*, very-low-density lipoprotein; *WHO*, World Health Organization.

CM and VLDL particles lose triglycerides and become smaller as they are metabolized. Thus, young VLDL and CM particles are larger and less dense than their more mature counterparts. For this reason, it is best to view each of the lipoprotein classes not as a collection of identical particles, but as a heterogeneous group. In fact, distinct lipoprotein subfractions or subclasses have been well described.

MAJOR LIPOPROTEINS

Chylomicrons

CMs are large particles produced by the intestine that transport lipids of dietary origin to the tissues of the body. They are very rich in triglycerides, but relatively poor in free cholesterol, phospholipids, and protein. These particles are secreted into mesenteric lymphatics and reach circulation at the thoracic duct. These lipoproteins acquire apoC-II, a cofactor for lipoprotein lipase, from plasma. The interaction of chylomicrons with lipoprotein lipase at the luminal surface of capillary endothelium results in the depletion of triglycerides and surface elements. The resulting smaller particles, called chylomicron remnants, are removed from circulation by the liver (Hussain, 1996), primarily through the interaction of apoE with receptors such as proteoglycans, the LDL receptor, and the LDL receptor-related protein (LRP). Because of the very high lipid/protein ratio, chylomicrons are considerably less dense than water and float without centrifugation. When present at high levels, chylomicrons result in "milky" plasma and accumulate as a floating creamy layer when left undisturbed for several hours. The apolipoproteins in chylomicrons include apoB-48, apoA-I, apoA-IV, apoC-I, apoC-II, apoC-III, and apoE.

Very-Low-Density Lipoproteins

VLDL particles are produced by the liver and supply the tissues of the body with triglycerides of endogenous, primarily hepatic, origin and cholesterol. As compared with chylomicrons, VLDL particles are smaller and produce turbid plasma when present in excessive amounts. They are rich in triglycerides, although to a lesser extent than chylomicrons, and have a higher buoyant density because of their lower lipid/protein ratio. By mass, VLDL particles contain approximately 50% triglyceride, 40% cholesterol and phospholipid, and 10% protein, mostly apoB-100 and apoC-I, apoC-II, and apoC-III, but also apoE. VLDL particles vary widely in size and chemical composition. Larger particles are rich in triglycerides and apoC. Smaller particles have less of these two components. Lipoprotein lipase hydrolyzes VLDL, and this produces highly atherogenic, smaller

triglyceride and surface material-depleted particles called VLDL remnants and IDL. These particles can be removed from plasma by LDL receptors or further metabolized to LDL.

Low-Density Lipoproteins

LDL is produced through the metabolism of VLDL in circulation and constitutes about 50% of the total lipoprotein mass in human plasma. The particles are much smaller than the triglyceride-rich lipoproteins (VLDL and CM) and do not scatter light or alter the clarity of plasma even at greatly increased concentrations. LDL consists of approximately 50% cholesterol, mostly esterified, 25% protein, mostly apoB-100 with traces of apoC, 20% phospholipid, and some triglycerides. Although each VLDL and LDL particle is thought to contain only one apoB-100 molecule, the extraordinary size of this protein allows it to be the largest protein component of these particles. The liver takes up most of the LDL in circulation (approximately 75%), with apoB-100 serving as a ligand for the hepatic receptor. The remaining LDL is delivered to other tissues. Some LDL is modified and is removed from the circulation by scavenger cells such as those found in atheromatous plaque. Small LDL particles contain less cholesterol ester and have a lower cholesterol/apoB ratio. Increased amounts of the small particles have been found in patients with several common forms of dyslipoproteinemia that are associated with CHD.

High-Density Lipoprotein

HDL is a small particle, consisting mostly of protein, cholesterol, and phospholipids, with only traces of triglycerides. Produced by the liver and intestine, HDL is involved in reverse cholesterol transport. In vitro studies suggest that HDL is involved in anti-inflammatory, antioxidant, anti-thrombotic, and nitric oxide-inducing mechanisms. The major site for the clearance of HDL cholesterol is the liver, and the best understood mechanism is the selective uptake of cholesterol esters from HDL by the SR-B1 receptor expressed in the liver. In the selective uptake process, SR-B1 promotes cholesterol uptake without apolipoprotein degradation. Cholesterol esters are removed from the internalized HDL particles and cholesterol-depleted HDLs are re-secreted. Mouse models that lack SR-B1 exhibit increased plasma HDL, slower HDL uptake by the liver, and increased atherosclerosis. Reverse cholesterol transport is reduced. In contrast, mouse models overexpressing SR-B1 in the liver show increased reverse cholesterol transport with reduced HDL plasma levels; however, these same mice also exhibit reduced atherosclerosis. In studies done on humans who maintain normal lipid profiles, the contribution of SR-B1 to HDL uptake is minimal. The cholesterol ester transfer protein (CETP)

TABLE 17-4

Significant Human Apolipoproteins

Apolipoprotein	Major lipoproteins	Mr* (kDa)	Amino acids	Chromosome	PLASMA CONCENTRATION	
					(mmol/L)	(mg/dL)
A-I	HDL	29	243–245	11	32–46	90–130
A-II	HDL	17.4	154	1	18–29	30–50
A-IV	HDL, LDL	44.5	396	11		
(a)	Lp(a)	350–700	Variable	6		
B-100	VLDL, IDL, LDL	512.7	4536	2	1.5–1.8	80–100

pathway is considered to be an alternative pathway for HDL metabolism. CETP transfers triglycerides from apoB lipoproteins in exchange for cholesterol esters in HDL. The result is an HDL particle depleted of cholesterol esters but enriched with triglycerides. Cholesterol transferred to apoB-lipoproteins is then cleared by LDL receptors.

HDLs are also heterogeneous particles. Discrete HDL particle subpopulations have been identified on the basis of differences in size or charge, including two major ultracentrifugation subclasses, HDL₂ and HDL₃ (Blanche, 1981; MacKenzie, 1973; Sundaram, 1974). The distinction is significant because HDL₂ is thought to be more cardioprotective than HDL₃, and people with low levels of HDL₂ are thought to be at increased risk for premature CHD. Additionally, HDL has been subfractionated into particles that contain apoA-I but not apoA-II, and those that contain both apoA-I and apoA-II (Fruchart, 1992; von Eckardstein, 1994). ApoA-I is present on virtually all HDL particles and makes up 70% of the protein content. ApoA-II makes up about 20% of the HDL lipoprotein and is present on about two thirds of all HDL particles in humans. The physiologic function of apoA-II is not fully understood; however, both apoA-I and apoA-II are required for normal HDL biosynthesis and metabolism. Studies have shown that apoA-II plays an important role in maintaining levels of HDL in plasma. A high percentage of HDL₂ particles fall into the apoA-I-only category. ApoE also associates with HDL particles. Laboratory measurement of such particles eventually may prove clinically useful.

MINOR AND ABNORMAL LIPOPROTEINS

Intermediate-Density Lipoproteins

Formed through the metabolism of VLDL in circulation, IDL can be removed from circulation quickly through interaction with the LDL receptor, or can be further metabolized to LDL. As expected, the lipid content, size, and density of IDL is intermediate between VLDL and LDL.

Lipoprotein(a)

Lp(a) is similar to LDL in terms of density and overall composition, and can be thought of as an LDL particle to which apo(a) has been added, linked to apoB-100 via a disulfide bond (Fless, 1984, 1985; Gaubatz, 1983). The electrophoretic mobility of Lp(a) is usually pre- β but can vary between that of LDL (β) and albumin (pre- α). Lp(a) is generally present in much lower concentrations than LDL; however, in normal subjects, values can range from <20–1500 mg/L or more. Increased levels can be familial, showing an autosomal dominant pattern of inheritance, and have been associated with an increased risk of CHD, cerebrovascular disease, and

stroke. When concentrations in the plasma are increased to above 200–300 mg/L, Lp(a) appears electrophoretically as a lipid-staining pre- β band in the plasma fraction containing lipoproteins of density >1.006 g/mL.

Lp(a) is synthesized in the liver, but the details of its metabolism are not well understood. It binds to the LDL receptor by virtue of its apoB-100 component, albeit with lower affinity than LDL (Floren, 1981). The removal of apo(a) from Lp(a) increases the affinity of the residual apoB-containing particle for the LDL receptor (Armstrong, 1985), and it has been suggested that apo(a) may interfere with the uptake of apoB-100-containing particles (Scanu, 1988). At present, neither the function of Lp(a) nor its atherogenic properties are well understood. It has been speculated that Lp(a) or apo(a) might interfere with normal thrombolysis by virtue of their similarity to plasminogen.

LpX Lipoprotein

LpX is an abnormal lipoprotein found in patients with obstructive biliary disease, and in patients with familial lecithin/cholesterol acyltransferase (LCAT) deficiency. Lipids account for more than 90% of its weight (mostly phospholipids, unesterified cholesterol, and very little esterified cholesterol). Proteins, primarily apoC and smaller amounts of albumin, constitute <10% of LpX by weight.

β -VLDL (“Floating β ” Lipoprotein)

β -VLDL (“floating β ” lipoprotein) is an abnormal lipoprotein that accumulates in type 3 hyperlipoproteinemia. It is richer in cholesterol than VLDL and apparently results from the defective catabolism of VLDL. The particle is found in the VLDL density range but migrates electrophoretically with or near LDL.

IMPORTANT PROTEINS IN LIPOPROTEIN METABOLISM

Apolipoproteins

As mentioned previously, apos constitute the major protein component of lipoproteins. They are commonly referred to using the nomenclature introduced by Alaupovic (1971). Some significant properties of the apos are outlined in Tables 17-4 and 17-5.

Lipolytic Enzymes and Other Proteins

The major enzymatic systems that are known to participate in plasma lipoprotein metabolism are the LCAT and the lipolytic enzymes, lipoprotein lipase (LPL), hepatic triglyceride lipase (HL), and endothelial lipase (EL). Many other proteins are also involved in lipoprotein

TABLE 17-5

Apolipoprotein Functions and Significant Characteristics

Apolipoprotein	Main distribution	Function (if known)	Comments
A-I	HDL	Activates LCAT that esterifies cholesterol in plasma Ligand for <i>ABCA1</i>	Synthesized in liver and intestine; HDL biosynthesis
A-II	HDL		May inhibit lipoprotein and hepatic lipases and increases plasma triglyceride
A-IV	HDL, CM, and free in plasma		May be a cofactor for LCAT; increased during fat absorption; HDL biosynthesis
B-100	VLDL and LDL	Carboxy-terminal recognition signal targets LDL to the LDL (apoB, E) receptor	Very large structural protein, synthesized in liver with lipids of endogenous origin (i.e., not chylomicrons)
B-48	CM	Not recognized by LDL receptor	Synthesized in intestine, encoded by same gene and same amino terminus as apoB-100. Differential production of the two proteins involves RNA editing.
C-I	CM and VLDL		May inhibit hepatic uptake of VLDL and cholesterol ester transfer protein
C-II	CM and VLDL	Activates lipoprotein lipase	Deficiency causes reduced clearance of triglyceride-rich lipoproteins.
C-III	VLDL, HDL	Inhibits lipolysis of triglyceride-rich lipoproteins; decreases clearance rate of remnant particles	Deficiency causes reduced clearance of triglyceride-rich lipoproteins.
D	HDL	Activates LCAT	
E	CM, VLDL, IDL, remnants and HDL	Recognition factor that targets CM and VLDL remnants to hepatic receptor; also binds to cell surface LDL receptors and proteoglycans	E-2, E-3, and E-4 isoforms; E-4 is associated with high LDL-C, higher risk of CHD and Alzheimer's disease; E-2 associated with type 3 hyperlipoproteinemia
F	HDL, LDL, VLDL	Regulates CETP function	
H	VLDL	Related to activation of LPL; triglyceride metabolism	Antibodies against apoH or β_2 -glycoprotein-I are a subset of antiphospholipid antibodies, and may be associated with hyperthrombosis and stroke.
J		Cell-aggregating factor in Sertoli cells; inhibitor of the C5b*7 complement complex; beta-amyloid clearance in glial cells; cholesterol trafficking in brain	Involved in apoptosis; linked to neurologic diseases like Pick's and Alzheimer's; also known as clusterin
L	HDL		May be linked to reverse cholesterol transport
M	HDL, CM, LDL, VLDL		May be linked to HDL remodeling
Apo(a)	Lp(a)		Homologous to plasminogen, may be prothrombotic; bound to apoB-100 by disulfide linkage

ABCA1, ATP-binding cassette transporter; *CETP*, cholesterol ester transfer protein pathway; *CHD*, congenital heart disease; *CM*, chylomicron; *HDL*, high-density lipoprotein; *IDL*, intermediate-density lipoprotein; *LCAT*, lecithin/cholesterol acyltransferase; *LDL*, low-density lipoprotein; *LDL-C*, low-density lipoprotein cholesterol; *Lp(a)*, lipoprotein A; *LPL*, lipoprotein lipase; *VLDL*, very-low-density lipoprotein.

metabolism. Some significant attributes of these proteins are summarized in Table 17-6.

LIPID TRANSPORT AND LIPOPROTEIN METABOLISM

Triglycerides and cholesterol enter circulation as part of triglyceride-rich lipoprotein particles, CMs produced in the intestine, and VLDLs produced primarily by the liver. Their synthesis requires an intracellular chaperone microsomal triglyceride transfer protein (MTP) that transfers different lipids in *in vitro* systems (Hussain, 2003). In addition, MTP physically interacts with apoB. These two properties of MTP play a critical role in the biosynthesis of apoB-containing lipoproteins. It is believed that MTP physically associates with nascent apoB and lipidates it, forming a lipoprotein particle that is further matured and secreted. Enterocytes synthesize chylomicrons under postprandial conditions. In fasting conditions, they synthesize VLDL and smaller lipoproteins (Hussain, 1996). These lipoproteins are concentrated into mesenteric lymphatics and are delivered to blood at the thoracic duct. Hepatocytes synthesize VLDL and are directly secreted into the circulation. Their synthesis is also dependent on MTP activity. The main function of apoB-containing lipoproteins is to deliver cholesterol and triglyceride to different tissues. CMs are primarily involved in the absorption and delivery of dietary fat and fat-soluble vitamins, whereas VLDLs deliver endogenous lipids to other tissues.

Only one *APOB* gene is present in the human genome. Nevertheless, enterocytes and hepatocytes make two different forms of apoB to synthesize CMs and VLDL, respectively. In both tissues, the human

APOB gene is transcribed into mRNA that is 15 kilobases long. This transcript is translated into a single polypeptide in the liver, called apoB-100. In the intestine, however, *APOB* mRNA undergoes a post-transcriptional change. One cytosine residue (at position 6666) is deaminated to a uracil. This changes a glutamine codon into a stop codon. Translation of the edited mRNA gives rise to a polypeptide of 2152 amino acids that is 48% of the apoB-100 (synthesized by the liver). This editing enzyme is not expressed in the liver; therefore, the liver synthesizes only full-length apoB-100.

These lipoprotein particles begin to undergo intravascular change almost immediately after entry into the circulation through the action of LPL. This enzyme hydrolyzes triglycerides and diglycerides, releasing fatty acids and monoglycerides, which are taken up by cells and used as a source of energy. ApoC-II stimulates the hydrolysis of triglycerides. In addition to losing triglycerides by LPL-mediated hydrolysis, CM lose surface lipids and apos by transfer of these components to HDL. Overall, CMs lose significant mass in the form of triglyceride and the A and C apolipoproteins. The depleted CM remnant particle contains apoB-48 and apoE as its major apolipoproteins. These particles are rapidly removed from plasma and are sequestered in the space of Disse by binding to proteoglycans. These particles can undergo further hydrolysis by hepatic lipase and are enriched with apoE. Eventually, they are internalized and degraded by means of a rapid and specific receptor-mediated endocytic process involving LDL receptors, LDL receptor-related protein, and proteoglycans. C apos inhibit the uptake of CMs, allowing them to remain in the circulation long enough to complete the hydrolysis of triglycerides. In the fasting state, the intestine continues to make apoB and secretes "intestinal VLDL" (small CMs). These particles may constitute up to 10%

TABLE 17-6

Enzymes and Other Proteins Important for Lipoprotein Metabolism

Enzyme	Gene location	Function	Deficiency	Tissue expression
ABCG5	2p21	Forms heterodimers with ABCG8 to pump out plant sterols back into the intestinal lumen	Increased plant sterol levels in plasma that can disrupt cell membranes and cause sitosterolemia; influences cholesterol levels in plasma	Tissue expression in liver, colon, and intestines
ABCG8	2p21	Forms heterodimers with ABCG5 to pump out plant sterols back into intestinal lumen; also associated with cholesterol and sterol excretion in bile	Increased plant sterol levels in plasma that can disrupt cell membranes and cause sitosterolemia; influences cholesterol levels in plasma	Tissue expression in the liver, intestines, and gallbladder
ABCA1	9q22-31	Efflux of cholesterol from peripheral cells into HDL	Tangier disease, with very low HDL and accumulation of lipids in peripheral cells	Many cell types, prominently in the liver, testis, and adrenal
CETP	16q21	Transfers CE, PL, and TG among lipoproteins, esp. the transfer of CE from HDL to apoB-100-containing lipoproteins in exchange for TG	Deficiency results in large cholesterol-laden HDL	Produced in liver and circulates with HDL
EL	18q21.1	Hydrolysis of PL and TG in lipoproteins, esp. PL in HDL. Homologous to LPL and EL and pancreatic lipase	Increased levels of HDL ₂ , and large buoyant LDL. Overexpression in mice, decreased TC, PL, and HDL-C	Expressed in many tissues, including liver. Synthesized by endothelium
HL	15q22-23	Hydrolysis of TG and PL, esp. from HDL ₂ , and may be necessary for HDL metabolism. Also active on lipids in VLDL remnants and IDL. Not very active on newly released VLDL or CM	Increased TC, TG, and HDL-C in deficiency	Associates with nonparenchymal liver cells
LCAT	16q22.1	Catalyzes the esterification of cholesterol, esp. in HDL, by promoting transfer of fatty acids from lecithin to cholesterol. Enables HDL to accumulate cholesterol as CE. Activated by apoA-I	Deficiency results in decreased HDL.	Produced in liver and circulates with HDL
LPL	8q22	Hydrolysis of TG in lipoproteins (esp. VLDL and CM), releasing free fatty acids and glycerol to tissues. ApoC-II are essential cofactors.	Large CM and VLDL with very high TG levels	Present on surface of capillary endothelial cells in adipose tissue and skeletal and heart muscle, but not produced by endothelial cells
LDLR	19p13.2	Binds apoE and apoB-100 and mediates endocytosis of lipoproteins, mostly LDL, but also VLDL, IDL, and CM remnants	Familial hypercholesterolemia results primarily in elevated LDL	Expressed on most cell types, but hepatic receptors clear 70% of LDL
MTP	4q24	Lipidates and regulates secretion of ApoB particles from the liver and intestines	Deficiency of MTP function leads to abetalipoproteinemia where ApoB lipoproteins are virtually undetectable in plasma.	Expression is seen in liver, intestines, heart, kidney, and eye.
PLTP	20q12	Transfer of PL to and from HDL. Important for HDL growth and remodeling	Deficiency in mice results in low HDL.	Expressed on many cell types
PCSK9	1p32.3	Influences the number of LDLRs expressed on cell surface	Depending on mutation—either gain of function or loss of function—the presence of PCSK9 affects availability of LDLR on cell surface and, consequently, the levels of LDL in plasma; gain of function leads to more LDL in plasma; loss of function associates with increased LDLR expression and thus less LDL in plasma.	Secreted protein by the liver cells; expressed in pancreatic islet beta cells and neuronal cells
SR-B1	12q24.31	Binds HDL on cell surface. Plays a role in selective uptake of CE from HDL in liver and steroidogenic tissues. May also enable macrophages to bind oxidized LDL	Accumulation of large CE-rich HDL, and accelerated atherosclerosis in mice	Macrophage, adrenal, liver and testis

ABCA1, ATP-binding cassette protein A1; Apo, apolipoprotein; CE, capillary electrophoresis; CETP, cholesterol ester transfer protein; CM, chylomicron; EL, endothelial lipase; HDL, high-density lipoprotein; HDL₂, ultracentrifugation subclass of HDL; HDL-C, high-density lipoprotein cholesterol; HL, hepatic lipase; IDL, intermediate-density lipoprotein; LCAT, lecithin cholesterol acyltransferase; LDL, low-density lipoprotein; LDLR, LDL receptor; LPL, lipoprotein lipase; MTP, microsomal triglyceride transfer protein; PL, phospholipid; PLTP, phospholipid transfer protein; SR-B1, scavenger receptor class B, member 1; TC, total cholesterol; TG, triglycerides; VLDL, very-low-density lipoprotein.

Figure 17-4 The low-density lipoprotein (LDL) receptor pathway and regulation of cholesterol metabolism.

or 20% of the circulating “VLDL,” but are probably metabolized as CMs (Byers, 1960; Cenedella, 1974; Green, 1981; Risser, 1978).

VLDL is synthesized in the liver. Similar to CMs, VLDL is catabolized upon entry into the circulation, in part by lipoprotein lipase, and is converted to cholesterol-enriched VLDL remnants. Some of these remnants are removed from circulation by the liver via receptor-mediated endocytosis; others are further catabolized to LDL (Bachorik, 1988). LDL carries most of the circulating cholesterol and transports cholesterol to hepatic and extrahepatic tissues, where it is taken up by LDL-receptor-mediated endocytosis (Brown, 1981). LDL binds to the LDL receptor (i.e., via apoB-100) and is subsequently internalized and directed to the lysosome, where apoB-100 is degraded and cholesteryl ester and other lipids are hydrolyzed. LDL-receptors are recycled back to the cell membrane (Fig. 17-4).

The unesterified cholesterol produced via lysosomal hydrolysis becomes available for membrane, hormone, and bile acid synthesis. Excess cholesterol is re-esterified by the microsomal enzyme acyl:cholesterol acyl transferase (ACAT) and is stored until it is needed. Cellular cholesterol, when present in sufficient quantity, downregulates the LDL receptor, reducing the number of cell membrane receptors and consequently the uptake of LDL. About two thirds of LDL is removed from plasma via hepatic LDL receptors. Although most tissues use cholesterol only for membrane synthesis or store it as cholesteryl ester, the liver can utilize cholesterol in other ways. The liver excretes cholesterol into the bile both as unesterified cholesterol and after conversion to bile acids, and reuses cholesterol for lipoprotein synthesis, as when it secretes VLDL into the circulation. Steroid-secreting tissues use cholesterol as a precursor of the steroid hormones.

Although LDL and CM remnants deliver lipids to the tissues, HDL is thought to be the vehicle for reverse cholesterol transport, the process by which excess cholesterol is removed from peripheral tissues and transported back to the liver. HDL is secreted from both the liver and the intestine as nascent, disk-shaped particles that contain apolipoproteins, cholesterol, and phospholipid (Havel, 1980; Oppenheimer, 1987; Oram, 1986; Scanu, 1982). The formation of nascent HDL particles is almost exclusively

dependent on the synthesis and release of apoA-I. Some HDL also seems to arise *de novo* in circulation from excess surface material (e.g., free cholesterol, apoA-I, apoA-II, apoC, phospholipid) removed from the triglyceride-rich lipoproteins as they are catabolized. In peripheral tissues, excess cholesterol is exported from cells (including macrophages) in part through the action of the protein ABCA1. This free cholesterol is accumulated by nascent HDL particles and esterified by LCAT. As cholesterol esters move into the hydrophobic core, the particle becomes spherical and larger, developing eventually into HDL₃ and then HDL₂. Several plasma enzymes and proteins are involved in this remodeling process, including phospholipid transfer protein (PLTP) and cholesterol ester transfer protein (CETP). CETP catalyzes the transfer of cholesterol esters to apoB-100-containing particles in exchange for triglycerides (Tall, 1990). PLTP facilitates the transfer of phospholipids from other lipoproteins to HDL, allowing the particle to grow by acquiring surface phospholipid as it accumulates esterified cholesterol and triglyceride in its core. Once formed, HDL delivers excess lipids, especially cholesterol, to the liver and other tissues (Bachorik, 1987; Glass, 1983; Stein, 1984). This may occur directly when HDL is taken up by the hepatocytes via specific receptors or through the action of cell surface receptors and lipases (HL and EL) that deplete phospholipid and triglyceride without internalizing the HDL particles. Lipids may also return to the liver indirectly or be directed to peripheral tissues via apoB-lipoproteins to which they are transferred from HDL by CETP.

Although HDL particles may return to the liver soon after formation, the bulk of HDL seems to remain in circulation for several days, continuously exchanging lipids and apolipoproteins with other lipoprotein particles, retrieving additional cholesterol from peripheral tissues, and delivering those lipids to the liver and steroid-producing tissues. This is supported by the fact that apoA-I has a half-life of several days in circulation. Eventually, HDL may be internalized by the liver (probably via the LDL receptor), or small lipid-depleted HDL may be catabolized in the kidney following filtration and cubulin-mediated reuptake in the proximal tubule.

LIPID AND LIPOPROTEIN MEASUREMENT

Lipoprotein concentrations have been measured and described in several ways. Some of these measurements, including particle mass and mass concentration (the mass of each lipoprotein particle as solute per liter of solution), are not easily applied for screening or routine clinical purposes. Fortunately, other methods may be used to describe the lipoprotein content of blood. Because the cholesterol composition of each lipoprotein class is similar from individual to individual, lipoprotein cholesterol is commonly used to evaluate lipoprotein concentration. For example, it is easier to determine the amount of LDL-C in a specimen than it is to determine the mass of LDL (cholesterol + triglyceride + protein) in solution, yet both measurements provide similar information about the LDL content of plasma. Lipoprotein-cholesterol concentrations correlate well with analytic ultracentrifugation values. Also, because these values have been used in most population studies of cardiovascular risk, they have documented predictive value.

When various methods of lipid analysis are considered, several issues should be kept in mind. First, the more complicated the analytic procedures, the greater is the variability of the analyses (Bookstein, 1990; Brown, 1990). For example, the measurement of plasma lipoproteins usually requires two steps: separating lipoprotein classes and measuring the class of interest. Both steps contribute to the error in the measurements. Consistent with this, lipoprotein cholesterol analyses are generally more variable than total cholesterol (TC) analyses because of the additional manipulations required to prepare the lipoprotein-containing fractions. Second, in addition to analytic sources of error, significant preanalytic variables may affect measured lipid and lipoprotein levels. In fact, plasma lipoprotein concentrations can change dramatically as a result of normal physiologic variation. In this section, issues of sampling and storage are considered, along with methods for measuring lipids and lipoproteins.

BLOOD SAMPLING AND STORAGE

Variation and error can be introduced before or during venipuncture, or when the samples are handled and stored before analysis. Therefore, it is important to standardize conditions under which blood specimens are drawn and prepared for analysis.

Biological Variation

Physiologic variations in cholesterol, triglyceride, and lipoproteins have been examined in a number of studies (Bookstein, 1990; Brown, 1990; Demacker, 1982; Kafonek, 1992; Warnick, 1979). For cholesterol, the coefficient of physiologic variation within an individual averages about 6.5%, but it can be higher in certain individuals (Table 17-7). When measured in serial samples from the same person, cholesterol levels in 95% of samples will vary by about 13% above or below that person's mean level. As a result, physiologic variation can be several times greater than analytic error, and measurements must be made in several blood samples taken at least a week apart to establish the individual's usual lipoprotein concentration.

A variety of biological factors can affect lipid and lipoprotein levels. Cholesterol levels rise with age, starting in early adulthood, in both sexes.

TABLE 17-7

Physiologic Variation of Plasma Lipids, Lipoproteins, and Apolipoproteins

Component	CVP (%) [*]	CVP (%) [†]
Total cholesterol	5.0	6.4
Triglycerides	17.8	23.7
LDL-cholesterol	7.8	8.2
HDL-cholesterol	7.1	7.5
ApoA-I	7.1	—
ApoB	6.4	—

CVP, Coefficient of physiologic variation; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

^{*}Data from patients of a lipid clinic (Kafonek, 1992).

[†]Data from the National Cholesterol Education Program 1995 Working Group on Lipoprotein Measurement.

Women have lower levels than men, except in childhood and after the early fifties. Age-related variation forms the basis for the National Cholesterol Education Program (NCEP) recommendation that cholesterol screening should be repeated every 5 years. Seasonal variation also occurs, such that cholesterol levels are slightly higher in the winter (Robinson, 1992). Also, dietary intake of saturated fat and cholesterol significantly influences plasma lipid levels. The effects of dietary modification take several weeks to become apparent; thus, before individuals' cholesterol levels are ascertained, it is important that they be on their usual diet for 2 weeks and are neither gaining nor losing weight. Several common medications, including oral contraceptives, postmenopausal estrogens, and some antihypertensive drugs, significantly alter lipid levels. Medical disorders that lead to secondary dyslipoproteinemia include thyroid, hepatic, and kidney disease (see Table 17-15, later). In such cases, management of hyperlipidemia is predominantly a function of treating the underlying disorder. Lifestyle and biological factors that produce short-term deviations from baseline lipid values include fasting, posture, venous occlusion, anticoagulants, recent myocardial infarction, stroke, cardiac catheterization, trauma, acute infection, and pregnancy. It is recommended that lipoprotein measurements be made no sooner than 8 weeks after any form of trauma or acute bacterial or viral infection, and 3–4 months after childbirth.

Fasting

Ideally, patients should fast for 12 hours before venipuncture. CMs are usually present in postprandial plasma and, depending on the type and amount of food ingested, can markedly increase the plasma triglyceride (TG) concentration. Concentrations of LDL- and HDL-cholesterol (LDL-C and HDL-C) also decline transiently after eating, in part as a consequence of CETP-mediated compositional changes that occur during the catabolism of CMs (Cohn, 1988). CMs are almost completely cleared within 6–9 hours, and their presence after a 12-hour fast is considered abnormal. Generally, TC and HDL-C levels can be measured in nonfasting individuals, greatly facilitating screening and monitoring. Fasting has little effect on plasma TC levels, and although nonfasting HDL-C levels can be a few mg/dL lower than fasting levels, this should not lead to misclassification of patients with low HDL levels. When TG and LDL-C are being measured, fasting becomes a requirement. The postprandial appearance of CMs and compositional changes in LDL lead to the underestimation of LDL-C and can result in the misclassification of truly affected patients. The NCEP Adult Treatment Panel III (ATP III) (NCEP, 2002) has recommended that patients fast for at least 9 hours before blood specimens are taken for lipid and lipoprotein analysis. This is an accommodation for patients who may be unable or unwilling to fast for 12 hours. The shorter fasting period should produce only minor and clinically insignificant errors in the estimation of the patient's usual TG, LDL-C, and HDL-C levels. A 12-hour fasting period is still considered appropriate when lipoprotein measurements are made in clinical and epidemiologic studies.

Posture

When a standing patient reclines, extravascular water transfers to the vascular system and dilutes nondiffusible plasma constituents. Decreases of as much as 10% in the concentrations of TC, LDL-C, HDL-C, apoA-I, and apoB (Miller, 1992) have been observed after a 20-minute period of recumbence. The decrease in TG is about 50% greater, suggesting that factors other than simple hemodilution may also operate. These effects are about half as great in a standing subject who sits (Miller, 1992). Postural changes are reversible when the patient resumes the standing position. The position of the patient therefore should be standardized for venipuncture, preferably to the sitting position, which is most commonly used. Current NCEP guidelines recommend that patients be seated for 5 minutes before sampling to prevent hemoconcentration. If it is necessary to use the recumbent position, this position should be used each time the patient is sampled to minimize postural change. Prolonged venous occlusion can lead to hemoconcentration and cholesterol increases of 10%–15%. Tourniquets should not be applied for longer than a minute or two, if possible.

Venous vs. Capillary Samples

Although it is generally assumed that venous and capillary samples are equivalent, the available information at present is limited and somewhat contradictory. Some investigators have found that cholesterol measurements in the two kinds of samples agreed in about 4% (Koch, 1987) or less (Law, 1997; Lunz, 1987), but others have reported differences of 8%–12% (Bachorik, 1990). In general, measurements in capillary blood

samples seem to be a little lower than in venous samples. Additionally, measurements in fingerstick samples tend to be more variable than in venous samples obtained at the same time, probably as the result of pre-analytic sources of error. Estimates for the biological component of within-subject variations have been made for lipid and lipoprotein in venous and fingerstick samples, and are similar in both kinds of samples for cholesterol, TG, HDL, and LDL (Kafonek, 1996). Although the use of capillary samples may be unavoidable under some conditions, it is good to keep in mind first that the epidemiologic data from which risk levels for lipids and lipoproteins are derived are based on measurements in venous samples, and second, that for various physiologic and methodologic reasons, the measurements in the two kinds of samples may differ.

Plasma vs. Serum

Plasma or serum can be used when only cholesterol, TG, and HDL-C are measured, and LDL-C is calculated from these three measurements (see later); however, plasma is preferred when the lipoproteins are measured by ultracentrifugal or electrophoretic methods because the samples can be cooled to 4° C immediately to retard changes that can occur in the lipoproteins at room temperature. When plasma is to be used, blood is cooled in an ice bath as soon as it is drawn, and the cells are removed as soon as possible, generally within 3 hours. The plasma is then stored at 4° C until it is analyzed. Plasma should not remain in contact with the cells overnight. Even in the presence of the anticoagulant, protein aggregation can occur in plasma that is stored in the refrigerator for a few days or frozen for longer periods. This can make it difficult to obtain a homogeneous aliquot for analysis and can interfere with the flow of sample in automated analyzers, resulting in inaccurate or variable results. Protein aggregation occurs less frequently in serum.

The choice of anticoagulant is also important. Some anticoagulants, such as citrate, exert rather large osmotic effects that result in falsely low plasma lipid and lipoprotein concentrations. Heparin, because of its relatively high molecular weight, has little effect on plasma volume but can alter the electrophoretic mobilities of the lipoproteins. Ethylenediaminetetraacetic acid (EDTA) is the preferred anticoagulant even though cholesterol and triglyceride concentrations in EDTA plasma are about 3% lower than in serum (Laboratory Methods Committee of the Lipid Research Clinics Program, 1977). This anticoagulant retards certain kinds of oxidative and enzymatic alterations that occur in the lipoproteins during storage.

Storage

Generally, TC, triglycerides, and HDL-C can be satisfactorily analyzed in frozen samples, and LDL-C concentrations can be estimated with the Friedewald equation (Friedewald, 1972). Apolipoproteins can also be measured in frozen samples (see later). Frozen samples are not appropriate for ultracentrifugal analysis because the triglyceride-rich lipoproteins do not withstand freezing. When serum or plasma must be stored for long periods, it should be maintained at temperatures of -70° C or lower. For short-term storage (up to a month or two), the samples can be kept at -20° C, but they should not be stored in a self-defrosting freezer. The temperature in a self-defrosting freezer actually cycles between about -20° C and 2° C during the defrost cycle and effectively subjects the samples to daily freeze-thaw cycles, which can hasten their deterioration and cause the lipid and lipoprotein measurements to become variable (i.e., less reproducible).

ESTIMATION OF PLASMA LIPIDS

Cholesterol and triglycerides are the plasma lipids of greatest interest in the diagnosis and management of lipoprotein disorders. Phospholipid analyses generally provide little additional information and are seldom required. Occasionally, they may be requested in cases of obstructive liver disease or disorders associated with abnormally low lipoprotein levels.

Cholesterol

Cholesterol accounts for almost all of the sterol in plasma. It exists as a mixture of unesterified (30%–40%) and esterified (60%–70%) forms; the proportion of the two forms is fairly constant among normal individuals. TC and lipoprotein-cholesterol concentrations are usually expressed in terms of the sterol nucleus without distinguishing the esterified and unesterified fractions. In general, it is not necessary to distinguish the two forms, except in cases where the contribution of the fatty acid moiety to cholesteryl ester mass must be accounted for, or when the cholesterol/cholesteryl ester mass ratio is of interest.

This discussion considers primarily the enzymatic methods of cholesterol quantification, which have virtually replaced the chemical methods that were used for most clinical and research purposes (Bachorik, 1976; Lipid Research Clinics Program, 1982; Wood, 1980). However, one chemical method, a modification of the Abell-Kendall method (Abell, 1952), continues as the reference method for cholesterol used by the Centers for Disease Control and Prevention (CDC) and a network of secondary reference laboratories (Myers, 1989). In the Abell-Kendall method, cholesteryl esters are hydrolyzed with alcoholic potassium hydroxide (KOH), and the unesterified cholesterol is extracted with petroleum ether and measured with the Liebermann-Burchard reagent using purified cholesterol standards. This method can be accurate within about 0.5% of true value.

Enzymatic Methods

These methods measure TC directly in plasma or serum through a series of reactions in which cholesteryl esters are hydrolyzed. The 3-OH group of cholesterol is oxidized, and hydrogen peroxide, one of the reaction products, is quantified enzymatically:

To complete the enzymatic measurement of TC, there must be a way to quantify the byproducts of the reaction. One method is the measurement of oxygen consumption; a benefit of this method is that interference by some components within serum/plasma is minimized (Rifai, 2000). Interference will be discussed further later. However, oxygen consumption methods are not easily automated and generally require a lot of cholesterol oxidase. For this reason, this method has not been widely used.

Another approach is to measure cholest-4-en-3-one during the dehydrogenase reaction (Reaction 17-2). This compound can be measured at 240 nm. However, the procedure to measure the compound is time-consuming and very difficult to perform, and has thus fell out of favor for use clinically or in a purely research setting (Rifai, 2000). Currently, the most common method of quantifying the cholesterol oxidase reaction is to measure the amount of hydrogen peroxide produced (Reaction 17-3). The hydrogen peroxide produced in the cholesterol oxidase reaction can be oxidatively coupled to two chromogenic substrates by catalysis with a peroxidase, most commonly horseradish peroxidase (HRP). The chromogens used are usually phenol and 4-aminoantipyrine. When coupled with hydrogen peroxide, they produce a quinoneimine dye that can be read photometrically at 500 nm. The catalytic properties of HRP are very nonspecific; therefore, this step is most subject to interference from other components of serum/plasma.

Interfering Substances

Enzymatic methods are less subject to interference by nonsterol substances that react in the chemical methods; however, they are not absolutely specific for cholesterol. Cholesterol oxidase (Reaction 17-2) can react with sterols other than cholesterol that are present in plasma such as plant sterols, which are present in appreciable concentrations in the circulation of patients with β -sitosterolemia. These sterols also contribute to the cholesterol values measured via most chemical methods. Another type of interfering agent is ascorbic acid. Ascorbic acid is known for its properties as a reducing agent. These properties allow it to compete with the chromogenic substrates of Reaction 17-3 for hydrogen peroxide. Therefore, plasma/serum samples with elevated levels of ascorbic acid can result in lower measured levels of TC. It is currently accepted that ascorbic acid levels >30 mg/dL should be accounted for in TC measurements, although levels that high are infrequent (Rifai, 2000). Another interfering agent that acts in a similar manner is bilirubin. Bilirubin can interfere with TC measurements because of its own spectral properties; bilirubin absorbs light at 500 nm (Rifai, 2000). This tends to increase measured cholesterol values. However, bilirubin is also oxidized by H_2O_2 , and as a result loses its absorbance at 500 nm. This complicates the application of a serum blank to correct for bilirubin absorbance. On the whole, interference by bilirubin seems to be significant only at concentrations exceeding 5 mg/dL, at which level it has been reported to decrease apparent cholesterol values by

5%–15% (Deacon, 1979; Naito, 1984; Pesce, 1977). Sample turbidity as a result of hypertriglyceridemia can also interfere with enzymatic methods (Pesce, 1977). Hemoglobin is another possible interfering agent in the measurement of TC. It has a pseudo-peroxidase activity that can consume the hydrogen peroxide produced in Reaction 17-2. More important, however, is that hemoglobin has an inherent color that can falsely elevate TC levels. Just as hemoglobin is a product of red blood cell hemolysis, other products of hemolysis such as catalase can compete with the peroxidase for hydrogen peroxide. However, hemolyzed products do not significantly affect cholesterol measurements even at abnormally high plasma concentrations (Deacon, 1979; Pesce, 1977).

In addition to their relative resistance to interference, enzymatic methods have other significant benefits. They consume only microliter quantities of sample and do not require a preliminary extraction step. They are rapid, and if the cholesteryl ester hydrolase step is omitted, they can be used to measure unesterified cholesterol. Finally, enzymatic methods are precise with coefficients of variation generally in the range of 1%–2%. For the most part, they use stabilized pure cholesterol standards or serum calibration standards for which the stated values are traceable to the CDC reference method for cholesterol (Pesce, 1977). Enzymatic values generally agree with reference values within 1%–2% when measured in a laboratory setting with modern equipment. Serum-based calibrators are inherently preferable to pure cholesterol, as they are subject to all analytic reactions undergone by patient samples.

Triglycerides

A wide variety of methods has been used to measure plasma triglycerides (Bachorik, 1977), but the methods most commonly used for clinical or epidemiologic purposes are based on the hydrolysis of triglycerides and the measurement of glycerol that is released in the reaction:

Because each glycerol molecule is calculated to represent a triglyceride molecule, TG concentrations are often overestimated if endogenous unesterified glycerol is not subtracted. Even so, TG levels will still remain an overestimation because of the presence of monoglyceride and diglyceride molecules. Despite this knowledge and the availability of reagents and methods to correct for endogenous glycerol, only about 5% of American clinical laboratories actually correct for endogenous glycerol. The reason for this is that in most normal individuals, endogenous glycerol levels are negligible.

TG measurements are almost universally performed enzymatically; as with cholesterol, the enzymatic methods have replaced earlier chemical methods (Kessler, 1966; Lipid Research Clinics Program, 1982).

One chemical method still used is the CDC reference method for triglycerides. The CDC-reference method uses a chloroform extraction procedure followed by silicic acid chromatography to isolate TG. Glycerol is released by saponification (alkaline hydrolysis of triglycerides) and is oxidized with sodium periodate:

The formaldehyde produced is measured by reaction with a sulfuric acid solution of chromotropic acid to produce a pink chromophore. This method is not specific for glycerol. Formaldehyde is also produced indirectly from glycerol-containing phospholipids; however, these and other interfering substances are removed during the extraction (with chloroform) and adsorption (silicic acid chromatography) steps and do not interfere with TG measurements made using the CDC reference method.

Enzymatic Methods

(Bucolo, 1973)

These are now universally used for TG analysis in the clinical laboratory. They are relatively specific, rapid, and easy to use. The analyses are performed directly in plasma or serum, and are not subject to interference by phospholipids or glucose.

Common to most enzymatic methods is the hydrolysis of triglycerides to free fatty acids and glycerol, followed by the phosphorylation of glycerol to glycerophosphate.

However, several methods may be used to quantify the amount of glycerol formed, and therefore the amount of triglyceride in plasma. In one approach, glycerophosphate reacts as follows:

NADH formation can be measured spectrophotometrically at 340 nm. In other methods, Reaction 17-9 has been added so that absorbance readings can be made in the 500 to 600 nm region of the spectrum, using instruments that are more commonly available in the clinical laboratory.

In a common variation, the glycerophosphate formed in Reaction 17-7 is oxidized by the action of glycerophosphate oxidase:

The resulting H_2O_2 is measured as described previously for cholesterol methods (Reaction 17-3).

In a third approach, adenosine diphosphate (ADP), rather than glycerophosphate is formed in Reaction 17-7, is quantified:

In this method, the disappearance of NADH is measured at 340 nm.

Enzymatic TG methods generally perform well. The reagents are available commercially as lyophilized preparations that need only be reconstituted before use. Based on recent College of American Pathologists (CAP) surveys, the interlaboratory coefficients of variation (CVs) for TG measurement using a variety of enzymatic methods were on the order of 5%–6%. It is prudent before selecting an enzymatic method to evaluate its accuracy and precision over the range of triglyceride concentrations likely to be encountered most frequently (1.299–12.987 mmol/L; 50–500 mg/dL).

Triglyceride Blanks

Enzymatic measurements of triglyceride involve the generation and measurement of glycerol. Although phospholipids and glucose do not interfere with enzymatic methods, free glycerol does. Glycerol is normally present in plasma in concentrations below 0.163 mmol/L (1.5 mg/dL), equivalent to a triglyceride concentration of about 14 mg/dL. However, concentrations can be higher in the following circumstances: after extremely vigorous exercise; in patients with uncontrolled diabetes; after chance contamination with the glycerol lubricant used on the stoppers of some blood collection tubes; after recent ingestion of glycerol-containing medications; or in a relatively rare disorder, hyperglycerolemia, which arises secondary to a mutation in the glycerol kinase gene on chromosome Xp21.3. A blank assay, without the addition of lipase, provides a measure of preexisting glycerol. Increased readings in the blank indicate the presence of glycerol, and measured TG values can be corrected accordingly. In an alternative procedure, free glycerol is consumed in a preliminary reaction before triglyceride hydrolysis is initiated. In this case, the measured value is the equivalent of a blanked triglyceride.

The blanking procedures described earlier are satisfactory for correcting spurious measurements that arise from many glycerol sources, but not for those that result from partial glycerides (diglycerides and monoglycerides). Partial glycerides are generally present at very low concentrations in fresh plasma or serum but can form through the slow hydrolysis of triglycerides when samples are stored. It is not clear whether partial glycerides in fresh plasma should be subtracted, but those that form during storage probably should not be subtracted because they arise from triglycerides that were originally present in the sample.

Fortunately, as complex as the blanking problem is, it is usually of little practical importance. Blanks are not determined routinely in many laboratories, and their use continues to be a matter of uncertainty. When measured, the magnitude of the blanks encountered in most fresh samples is on the order of 0.056–0.112 mmol/L (5–10 mg/dL), expressed as triglyceride, although they can be higher in samples with high triglyceride concentrations. However, blanks can assume importance in the standardization and quality control of triglyceride measurements because they can be on the order of 0.226–0.339 mmol/L (20–30 mg/dL) or greater in

serum pools used for these purposes. This is probably a result of the partial hydrolysis of triglycerides during preparation of the pools.

Interfering Substances

As with cholesterol measurement interference, TG measurement is subjected to similar interference by the same substances. Plasma ascorbic acid is an antioxidant that can interfere with the oxidation/reduction reactions involved in the measurement of TG. Bilirubin can also cause interference, both spectrally and chemically. Significant plasma hemolysis can spectrally interfere with TG measurements and may cause the dilution of lipid constituents.

Phospholipids

Most of the phospholipid in human plasma is phosphatidylcholine (70%–75%) or sphingomyelin (18%–20%). Remaining phospholipids include phosphatidylserine, phosphatidylethanolamine (3%–6%), and lysophosphatidylcholine (4%–9%). Phospholipid measurement is not routinely performed in the clinical laboratory. The reason for this is that phospholipid analysis usually provides little additional information in cases of dyslipoproteinemia. Another reason is that the phospholipid concentration in plasma is not altered as markedly as that of cholesterol and TG in various pathologic conditions. However, estimation of lipoprotein phospholipids provides information that at times can be more important than cholesterol or TG concentrations. For example, only 10%–20% of the total weight of HDL is cholesterol, but almost 25%–30% of it is phospholipid, making it a far more accurate reflection of HDL content (Rifai, 2000). Furthermore, the phospholipid content of HDL is more important than cholesterol or even apolipoprotein A-I in reverse cholesterol transport; abnormalities in HDL phospholipid composition have been noted to have a greater effect on HDL function than cholesterol concentration. Phospholipids are also important substrates for a number of lipoprotein metabolizing enzymes (e.g., LCAT, LPL, HL); therefore changes in the composition could adversely affect the function of these enzymes. Most important, the dietary status of essential fatty acids is more accurately assessed by the fatty acid composition of phospholipids rather than total lipids. It has also been noted that the saturated fatty acid content of plasma phospholipids is reported to be an independent risk factor for atherosclerosis.

The only unique structural feature common to all phospholipids is the presence of lipid-bound phosphate. Therefore most of the methods originally designed to determine plasma phospholipids depend on the estimation of lipid phosphorus. Lipids are extracted from the sample and are oxidized completely to convert phospholipid phosphorus to inorganic phosphate, which is then determined colorimetrically. These procedures are reproducible and sensitive and can be adapted to measure total phospholipid phosphorus in 100 μ L or less of plasma or serum. Each mole of phosphorus contributes about 4% to the total phospholipid mass; thus phospholipid mass can be determined by multiplying the phospholipid phosphorus concentration (expressed in mg/dL) by 25.

Serum or plasma phospholipids can also be measured enzymatically using commercially available methods. In the method available from WAKO Pure Chemical Industries, Ltd. (Osaka, Japan), lecithin (phosphatidylcholine), sphingomyelin, and lysolecithin are hydrolyzed using phospholipase D, and the choline liberated is oxidized.

The resulting H_2O_2 produced is measured in a manner similar to that shown in Reaction 17-3. Analysis of individual phospholipid classes is seldom required for evaluation of dyslipoproteinemia and is not discussed in this chapter.

ESTIMATION OF LIPOPROTEINS AND LIPOPROTEIN CHOLESTEROL

Because lipoproteins share common lipid and apolipoprotein components, the central problem in lipoprotein analysis is the separation of different lipoprotein classes from one another. Many methods have been applied to lipoprotein separation, including ultracentrifugation, adsorption, gel filtration, affinity chromatography, electrophoresis in various media, polyanion and alcohol precipitation, immunochemical procedures, and various combinations of methods. Some of these methods require special skills and equipment and are not easily adapted for clinical or epidemiologic

purposes. This discussion is limited to several procedures that have been used by clinical laboratories.

Ultracentrifugation Methods

These take advantage of two properties of the lipoproteins. First, by virtue of their lipid content, lipoproteins have lower densities than the other plasma macromolecules. Second, each class of lipoproteins has a different density. Thus, lipoproteins can be readily separated on the basis of their densities by using ultracentrifugation techniques. The proportion of lipids, in particular TG, associated with appropriate proteins determines the density of a particular lipoprotein class. VLDL and chylomicrons are the most lipid-rich lipoprotein classes in human blood. This fact leaves them as the most buoyant in plasma. These lipoproteins have a density <1.006 kg/L (density measurement). LDL particles are smaller in size and in lipoprotein content, causing their density to range from 1.006–1.063 kg/L. HDL, the densest lipoprotein, ranges from 1.063–1.210 kg/L (Rifai, 2000). Ultracentrifugation methods are largely considered the best means to compare lipoprotein classes; however, the technique is difficult, time-consuming, and expensive, leaving it for research settings rather than clinical measurement.

Electrophoretic Methods

In the past, electrophoresis was widely used in the clinical laboratory to separate and measure lipoproteins. However, because the method has significant limitations (described later), it generally is not required for the diagnosis of dyslipoproteinemia, and its use in routine clinical practice has diminished in recent years. In general, the cost of the procedure, in terms of both time and money, is rarely justified by the information provided.

The most commonly used support medium for lipoprotein electrophoresis is agarose gel because of its speed, sensitivity, and ability to resolve the lipoprotein classes. Chylomicrons, if present, remain at the origin. Of the remaining major lipoproteins, HDL migrates the fastest, LDL the slowest, and VLDL at a rate intermediate between HDL and LDL. The electrophoretically separated lipoproteins have been named according to their mobilities: HDL (α -lipoprotein) moves with the α_1 -globulins; LDL (β -lipoprotein) migrates with the β -globulins, and VLDL (pre- β lipoprotein) migrates with the β_2 -globulins. Different properties of lipoproteins form the basis for electrophoretic and ultracentrifugal separation, and analogous fractions separated by the two techniques may not be identical. For example, β -VLDL (found in type 3 hyperlipidemia, see later) is isolated with VLDL by ultracentrifugation but moves electrophoretically with LDL. In the absence of additional information, a sample containing β -VLDL would appear to have an elevated VLDL concentration by ultracentrifugation and an increased LDL concentration by electrophoresis. Another example is that Lp(a) is isolated in the LDL–HDL density range by ultracentrifugation, but it has an electrophoretic mobility similar to that of VLDL. This dichotomy is responsible for naming Lp(a) “sinking pre- β -lipoprotein.”

Electrophoresis can be performed using unfractionated plasma or in plasma fractions that contain other serum proteins. Lipoprotein electrophoretograms are usually visualized with a lipid-staining dye such as Oil Red O, Fat Red 7B, or Sudan Black B. These lipid stains react primarily with the ester bonds in triglycerides and cholesteryl esters. Lipoproteins rich in free cholesterol and phospholipids (such as LpX) stain very poorly and thus are grossly underestimated by electrophoretic techniques.

Attempts have been made to quantify the lipoproteins by densitometry. Lipoprotein levels have been expressed in terms of the percentage distribution of lipid-staining material in β -, pre- β -, and α -lipoproteins, or have been converted to lipoprotein–cholesterol concentrations according to calculations that incorporate assumptions about cholesterol content and dye uptake of the lipoproteins. In general, these approaches have not been successful for reasons that include incomplete resolution of β - and pre- β -lipoproteins, the presence of minor or unusual lipoproteins, and differences in the intensity of staining. Electrophoresis has been used most successfully in conjunction with other methods.

Polyanion Precipitation Methods

Some lipoproteins are precipitated with polyanions such as heparin sulfate, dextran sulfate, phosphotungstate, and others in the presence of divalent cations such as Ca^{++} , Mg^{++} and Mn^{++} . Conditions have been established in which the major classes of lipoproteins can be precipitated in stepwise fashion beginning with the lower-density, lipid-rich lipoproteins (Burstein, 1982). The more dissimilar the lipoproteins are from one another, the better is the separation. Thus, it is easier to separate apoB-containing lipoproteins from HDL than it is to separate VLDL from LDL or HDL₂ from HDL₃. Historically, polyanion precipitation was most commonly

used to remove apoB-containing lipoproteins before analysis of HDL-C. This required a sample pretreatment and was not fully automated. Most clinical laboratories have replaced precipitation techniques with automated homogeneous assays for HDL-C and LDL-C.

Determining HDL-C Values

The NCEP recognizes HDL-C as an independent risk factor for CHD and recommends its measurement in conjunction with TC measurements. An HDL-C concentration of <35 mg/dL is considered high risk for CHD, while levels >60 mg/dL are considered protective. Historically, HDL-C has been measured in the supernatant of samples following the precipitation of apoB-containing lipoproteins by polyanion-divalent cations. Several combinations of polyanion-divalent cations have been used, and not all of them give precisely the same results. HDL-C values determined with heparan sulfate-Mn⁺⁺ procedures agree closely with those obtained using analytic or preparative ultracentrifugation (Bachorik, 1976; Warnick, 1979). This method was widely used in epidemiologic studies. Dextran sulfate (relative molecular mass 50000 Da)-Mg⁺⁺ and sodium phosphotungstate-Mg⁺⁺ methods gained popularity because they do not interfere with enzymatic cholesterol studies. However, they give results about 5% lower than ultracentrifugation. Heparin-Ca⁺⁺ appears to give results that are about 10% higher. These differences arise, in part, from the underprecipitation of apoB-containing lipoproteins, which leads to overestimation of HDL-C, or the overprecipitation of HDL, which can lead to underestimation of HDL-C. Increased triglycerides interfere with precipitation methods and overestimate HDL-C. Attempts were made to simplify precipitation methods by using dextran sulfate-coated magnetic beads to achieve selective separation of HDL from the apoB-containing lipoproteins (Naito, 1995).

Currently, homogeneous assays are the most popular method for measuring HDL-C. Unlike precipitation methods, these fully automated two-reagent procedures do not require off-line pretreatment and separation (hence the term "homogeneous") and can be adapted to most chemistry analyzers. Thus, they reduce hands-on time and overall assay costs. Test kits distributed in the United States are based on a variety of methods. Usually, the first reagent forms a stable complex with non-HDL lipoproteins, preventing them from participating in the reaction, and the second reagent releases HDL-C that is then measured enzymatically. According to CAP 2005 surveys, the most common method uses a synthetic polymer together with a polyanion to block non-HDL lipoproteins, followed by a selective detergent to release HDL-C (Genzyme Diagnostics, Cambridge, Mass.; Beckman Coulter, Inc). Other methods use polyethylene glycol-modified enzyme (Roche Diagnostics, Indianapolis), or immunoinhibition (Wako Chemicals USA, Inc, Richmond, Va.) to block non-HDL lipoproteins. A fourth method (Polymedco Inc, Cortlandt Manor, N.Y.) uses a special reagent to selectively eliminate cholesterol in non-HDL lipoproteins, followed by a second reagent that releases cholesterol from HDL (Denka Seiken Co, Niigata, Japan). These methods generally are not affected by high triglycerides, bilirubin, and globulins.

In a comprehensive review (Warnick, 2001), multiple HDL-C homogeneous assays were compared with traditional precipitation and ultracentrifugation procedures. The authors concluded that the new procedures simplify the determination of HDL-C and are accurate, precise, and meet NCEP criteria for total error. However, atypical lipoproteins evaluated by homogeneous assay may show discrepant results when compared with the established precipitation method. These differences are seen in patients with hyperlipidemia or liver or kidney disease when abnormal lipoprotein forms occur. Laboratories that encounter a high proportion of atypical lipoproteins (e.g., lipid clinics or research settings) should thoroughly validate a homogeneous assay for use with their patient population.

LDL-C Measurement

LDL cholesterol plays a causal role in the development of atherosclerosis. LDL-C >160 mg/dL with no risk factors is an indication for therapy (Rifai, 2000). With two or more CHD risk factors, the upper limit is lowered to 130 mg/dL for initiation of therapy. Several methods have been used to measure LDL-C. The first, a reference laboratory procedure, involves ultracentrifugation to separate LDL from other lipoproteins, followed by analysis as described previously to measure cholesterol. This method is not extensively discussed here. A much more common second method uses the Friedewald formula to calculate LDL-C. Finally, more recently developed homogeneous methods for measuring LDL-C are now available.

Friedewald Calculation

LDL-C can be determined by using the Friedewald formula, originally described by Friedewald, Levy, and Fredrickson (Friedewald, 1972).

Generally, in fasting plasma samples, LDL contains the cholesterol that is not present in HDL or VLDL. Thus LDL-C can be determined by the following equation in which concentrations are expressed in mmol/L, and the term [Plasma TG]/2.175 is used to represent VLDL-C:

$$[\text{LDL-cholesterol}] = [\text{Total cholesterol}] - [\text{HDL-cholesterol}] - \frac{[\text{Plasma TG}]}{2.175}$$

The term [Plasma TG]/5 is used when concentrations are expressed in mg/dL. In this method, the plasma TC, TG, and HDL-C concentrations are determined as described. Because VLDL carries most plasma triglyceride, VLDL-C concentration is estimated from the ratio of triglyceride to cholesterol in VLDL:

$$\text{VLDL-C} = \frac{\text{Plasma TG}}{2.175}$$

It has been reported that the factor [Plasma TG]/2.825 gives a more accurate estimate of VLDL-C (DeLong, 1986). This is equivalent to Plasma TG/6.5, when concentrations are expressed in mg/dL. However, the factor that gives the best estimate of VLDL-C, and therefore the best estimate of LDL-C, varies among populations and depends on the triglyceride method used; the NCEP Working Group on Lipoprotein Measurement prefers the unmodified Friedewald equation (NCEP Working Group on Lipoprotein Measurement, 1995).

The Friedewald formula has significant limitations (Sniderman, 2003). These limitations arise largely from two assumptions on which the method is based. First, the calculation assumes that essentially all plasma triglycerides are carried in VLDL. Second, the method assumes that the triglyceride/cholesterol ratio of VLDL is invariant. Neither assumption is entirely true; as a result, this method is unsuitable for nonfasting samples that contain chylomicrons or samples that contain β -VLDL. As compared with VLDL, the ratio of triglycerides to cholesterol in chylomicrons is much higher. Thus, when CM is present, the use of the factor TG/2.175 to account for non-HDL, non-LDL cholesterol can overestimate the amount of cholesterol in VLDL, leading to underestimation of LDL-C. Similarly the ratio of triglyceride to cholesterol in β -VLDL is much lower than in VLDL; use of the factor TG/2.175 in the presence of β -VLDL can underestimate VLDL-C and thus overestimate LDL-C. A patient with type 3 hyperlipoproteinemia can be misclassified as having an elevated LDL-C. It is important to distinguish the two conditions because their treatments differ.

Even in CM-free samples, the ratio of VLDL-C to triglyceride changes as triglyceride levels increase, and this can lead to errors in estimates of VLDL-C. Because VLDL generally carries only about 25% of the TC in plasma, resulting errors in LDL-C are usually less than 5–10 mg/dL (0.130–0.260 mmol/L). However, the calculation is not suitable for samples with high triglyceride concentrations. Errors in LDL-C become noticeable at triglyceride levels >2.26 mmol/L (200 mg/dL) and become unacceptably large at triglyceride levels >4.52 mmol/L (400 mg/dL). The accuracy of LDL-C calculation also suffers at low LDL-C levels, indicating that calculated LDL-C values may not provide the best assessment of cardiac risk in patients who already are receiving cholesterol-lowering therapy (Sniderman, 2003). Provided that its limitations are appreciated, the Friedewald equation has broad utility, both as a screening tool and for following patients.

Another issue to consider is non-LDL lipoproteins. Generally, LDL contributes most of the cholesterol to the measurement, and IDL and Lp(a) contribute only a few mg/dL each. However, these lipoproteins can contribute significantly to cholesterol measurements in some hyperlipidemia patients. Because Lp(a) levels are not lowered by a number of treatments that effectively lower LDL levels, Lp(a) measurements can, in some circumstances, reveal why a patient does not respond well to LDL-lowering therapy.

Selective Chemical Precipitation

LDL-C is calculated as the difference between TC and the amount remaining after precipitation of LDL-C. Such methods are reasonably accurate if TG concentrations are low enough. However, this method allows only for the separation of apoB-containing lipoproteins, separating HDL from non-HDL particles.

Beta Quantification

Beta quantification assumes that virtually all cholesterol is contained in the three major lipoprotein classes (i.e., VLDL, LDL, and HDL). In this method, plasma is ultracentrifuged for at least 18 hours at 105 K \times g. VLDL and CMs accumulate as a floating layer, leaving predominantly LDL and HDL in solution (Rifai, 2000). The solution is measured for cholesterol and is precipitated for LDL lipoproteins. LDL-C is calculated according

to the difference between these two measurements. Because TG-rich lipoproteins are removed from this sample, measurement of LDL-C is more reflective of actual concentration. The resulting difference also reflects contributions of IDL-C and Lp(a) cholesterol, both of which are considered pro-atherogenic. Therefore, measurement of LDL-C by this method represents the amount of cholesterol being transported in pro-atherogenic particles (Rifai, 2000).

Direct LDL-C Measurement

To a large extent, the ability to calculate LDL-C has eliminated the need for direct measurements. However, homogeneous direct LDL-C methods are useful when triglycerides are elevated because they are not subject to interference by triglycerides even at relatively high concentrations (600 mg/dL) (Bachorik, 2000). Direct assays have been adapted for use on a variety of analyzers and have been extensively reviewed elsewhere (Nauck, 2002; Miller, 2002). Although these methods differ significantly, in general, they use a combination of two reagents. The first reagent usually selectively removes non-LDL lipoproteins (and/or stabilizes or inhibits LDL from reacting with enzymes), and the second reagent releases cholesterol from LDL so that it can be measured enzymatically.

In one method (Equal Diagnostics, Exton, Pa.; Genzyme Diagnostics), the first reagent uses a detergent polymer mixture to disrupt non-LDL lipoproteins, releasing their cholesterol. The cholesterol is then de-esterified and reacts with cholesterol oxidase to generate hydrogen peroxide, which reacts to form a colorless compound. The second reagent contains a detergent that releases cholesterol from LDL. After de-esterification, the LDL-C proceeds through a similar set of reactions, except that the final step generates a colored compound. The intensity of the color is proportional to the concentration of LDL-C. Another method (Roche Diagnostics) is based on selective micellar solubilization of LDL by a nonionic detergent, as well as the interaction of a sugar compound with HDL, VLDL, and chylomicrons to inhibit participation in the measurement assay (Sugiuchi, 1998). A third method exploits the fact that reactivity of cholesterol in the different lipoproteins is affected by the hydrophile:lipophile balance (HLB) of solubilizing detergents. In this method, non-LDL-C is reacted with cholesterol esterase and cholesterol oxidase in conditions where LDL-C is inhibited, and the resulting peroxide is eliminated by catalase. A second reagent then alters the HLB of the detergent, creating conditions where LDL-C reacts. This reagent also contains an azide that inhibits catalase and allows the colorimetric detection of peroxide (see [Reaction 17-3](#)) (Polymedco Inc; Reference Diagnostics, Bedford, Mass.). In a fourth method, the first reagent contains amphoteric surfactants that protect LDL, allowing the elimination of non-LDL-C and resulting peroxide as described earlier. The second reagent contains nonionic surfactants that displace the protecting surfactants and allow measurement of LDL-C (Sigma Diagnostics, St Louis).

Although these methods are precise, they produce discrepancies in comparison with the reference ultracentrifugation procedures in a number of circumstances, including the presence of abnormal lipoproteins. When the triglyceride level is <400 mg/dL, homogeneous methods perform no better than the Friedewald calculation for classifying patients into treatment groups (Miller, 2002). However, unlike the calculation, homogeneous assays can provide clinically useful results when triglycerides >400 mg/dL. Another potential benefit is the convenience of measuring LDL-C in nonfasting individuals, although some have recommended against this practice (Miller, 2002). ATP III recommendations do not favor replacing calculated LDL-C with direct LDL-C because the constituents of the calculation have to be measured in any case. Running direct LDL-C would only add to the expense.

ADDITIONAL METHODS IN THE STUDY OF DYSLIPIDEMIA

Measurement of Lipoprotein Subclasses

Subpopulations or subclasses have been identified in VLDL, LDL, and HDL by techniques such as analytic ultracentrifugation, gradient gel electrophoresis, and nuclear magnetic resonance (NMR) spectroscopy (Krauss, 1992, 1987; Otvos, 1992). Some subclass distinctions are of clinical significance, yet the number of subclasses identified varies between methods of separation, and the nomenclature for subclasses is less than uniform. For example, when NMR technology is used to identify lipoprotein subclasses, particle subclass numbers tend to increase with increasing particle size; thus LDL particles of the L2 subclass are larger than L1 particles. When electrophoresis or ultracentrifugation is used, the opposite is true, and

particles tend to decrease in size with higher numbers. Thus, in segmented gradient gel electrophoresis, LDL subclass IV (or LDL4) particles are smaller than subclass II (LDL2) particles; in gradient ultracentrifugation, subclass LDL4 particles are smaller than LDL3 particles.

Recent interest has focused on the role of subclasses in the development of atherosclerosis, specifically the smallest and least dense LDL particles. This fraction is thought to be more atherogenic than large LDL. Small HDL and large VLDL subclasses have also been associated with an increased incidence of atherosclerosis. The NMR Lipoprofile (LipoScience, Raleigh, NC) allows the quantification of lipoprotein particles by subclass based on their unique NMR-spectral characteristics. This profile provides information about CHD risk by quantifying the subclass distribution of lipoprotein particles (Otvos, 2002). At least partially, the appeal of this technique arises from the idea that the migration of LDL particles into the artery wall is gradient driven based on LDL particle number. When large numbers of small LDL particles are present, LDL-C measurements tend to underestimate the number of LDL particles, and thus the atherosclerotic effects of LDL. Triglyceride levels >100 mg/dL and HDL-C <60 mg/dL are associated with high levels of small LDL particles; when these conditions are present, NMR profiling may be a useful technique for assessing CHD risk. Sensitive electrophoretic methods should provide similar results. These methods are not currently viewed as screening tools. They are more appropriate for refining risk assessment and treatment in patients with previously identified CHD risk: those under treatment, and patients who have LDL-C values at or close to treatment goals. This is consistent with most accepted guidelines that stress the importance of LDL-C as the primary goal of therapy in most types of dyslipidemia.

Standing Plasma Test

Chylomicrons, if present in appreciable quantities, are detected using the “standing plasma” test. An aliquot of plasma (2 mL) is placed into a 10 × 75-mm test tube and allowed to stand in the refrigerator at 4° C undisturbed overnight. Chylomicrons accumulate as a floating “cream” layer and can be detected visually. The presence of chylomicrons in fasting plasma is considered to be abnormal. A plasma sample that remains turbid after standing overnight contains excessive amounts of VLDL; if a floating “cream” layer also forms, chylomicrons are present as well.

Detection of β -VLDL and Lp(a)

As mentioned earlier, the abnormal lipoprotein β -VLDL has the density of VLDL but migrates electrophoretically with LDL in the β -region. It can be detected when the ultracentrifugal fraction of $d < 1.006$ kg/L is examined electrophoretically. In practice, unfractionated plasma and both ultracentrifugal fractions ($<$ and >1.006 kg/L) are examined at the same time; each sample thus serves as its own control to establish the relative migration of the lipoprotein bands. In normal plasma, the β (LDL and IDL), pre- β (VLDL), and α (HDL) lipoprotein bands are visible in unfractionated plasma; only the pre- β band is present in the $d < 1.006$ kg/L fraction, and the β - and α -lipoprotein bands are seen in the $d > 1.006$ kg/L fraction. When present, β -VLDL is observed as a band with β -mobility in the $d < 1.006$ kg/L fraction. Its presence is abnormal and is usually associated with dysbetalipoproteinemia (type 3 hyperlipoproteinemia), although occasionally it is seen in other disorders. Chylomicrons, which often are seen in type 3 patients, remain at the origin on agarose gel.

Lp(a) has a density similar to LDL but migrates similarly to VLDL on electrophoresis. Thus it can be detected when the $d > 1.006$ g/mL protein is examined electrophoretically. When Lp(a) is present in concentrations exceeding 20–30 mg/dL (i.e., when it contributes more than about 10 mg/dL to the LDL-C measurement), an additional band with pre- β mobility is observed in the $d > 1.006$ kg/L fraction (hence the name sinking pre- β -lipoprotein). Under these conditions, the physician may wish to request a quantitative Lp(a) measurement. Lp(a) can now be measured using immunoturbidimetric methods. When the Lp(a) level is very high, it may be necessary to correct LDL-C for the contribution of Lp(a)-cholesterol. The following relationship has been used to estimate the contribution of Lp(a)-cholesterol to the measured LDL-C value, where the values are given in mg/dL:

$$\text{Lp(a)-cholesterol} = 0.3 \times [\text{Lp(a) mass}]$$

$$\text{LDL-C} = \text{TC} - [\text{HDL-cholesterol}] - [\text{Plasma TG}/5 - (0.3[\text{Lp(a) mass}])]$$

VLDL-C/Plasma Triglyceride Ratio

The ratio of VLDL-C to plasma triglycerides may be useful in the evaluation of type 3 hyperlipoproteinemia. This ratio, expressed in mol/mol or

(mass/mass), is generally in the range of 0.230–0.575 (0.1–0.25) in samples without β -VLDL, depending on the relative amounts of VLDL, LDL, and HDL present, and on the errors inherent in the VLDL-C and plasma triglyceride measurements. Type 3 subjects have ratios >0.689 (0.3), usually in the range of 0.689–0.919 (0.3–0.4), and higher ratios can be observed. Again, because of errors in the measurements, the observation of a ratio of 0.689 (0.3) on a single occasion may or may not be significant. Overt type 3 patients manifest both β -VLDL and a VLDL-C/plasma triglyceride ratio of 0.689 (0.3) or greater. Occasionally, a lipid disorder treatment clinic may request the assessment of apoE phenotype to supplement the diagnosis of type 3 hyperlipoproteinemia (see later), because homozygosity for apoE-2 is associated with this disorder. However, not all homozygous patients have type 3 hyperlipoproteinemia, and ultracentrifugation is still required for assessing the presence of β -VLDL.

Apolipoprotein Analysis

Studies have indicated that apoA-I and apoB may be better discriminators of atherosclerotic disease than lipid or lipoprotein determinations. Because apoA-I is present primarily in HDL, while apoB (in fasting samples) is present in VLDL, IDL, and LDL, it stands to reason that low apoB and high apoA-I levels, as well as a low apoB-to-apoA-I ratio would be a good thing. In general, the evidence for this has been more consistent for apoB than for apoA-I, but the reason for this is not clear. A large-scale, placebo-controlled intervention trial, AFCAPS (Gotto, 2000), found that apoB was the best single lipid, lipoprotein, or apolipoprotein measurement to predict both baseline and on-treatment CAD risk, followed by apoA-I. ApoB:A-I ratios may also be useful in assessing risk.

Apolipoproteins are usually measured by immunoassay or immunonephelometry. These techniques rely on measurement of the turbidity caused by apolipoprotein-antibody complexes (Lopes-Virella, 1980). A potential limitation of this method stems from the inherent turbidity of lipemic samples or even nonlipemic samples after repeated freezing and thawing. To some extent, automated systems can correct for such turbidity.

THE NCEP GUIDELINES

The Third Report of the NCEP Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III, or ATP III) was published in 2002 (NCEP, 2002). It presents the updated NCEP evidence-based guidelines for cholesterol testing and management, and provides detailed information on other topics, including the classification of lipids and lipoprotein particles, CHD risk assessment, lifestyle intervention, drug treatment, specific dyslipidemias, and treatment adherence issues. More recently, the NCEP recommendations have been updated in consideration of new clinical trial data (Grundy, 2004).

RELIABILITY OF MEASUREMENTS

NCEP guidelines have shifted the focus from recognizing abnormal and normal cholesterol values to assessing overall cardiovascular risk based on cutoffs for cholesterol, triglycerides, HDL-C, and LDL-C. The adoption of a single set of cutoffs imposes a mandate on clinical laboratories to measure lipids and lipoproteins accurately and precisely. The Laboratory Standardization Panel of NCEP (NCEP, 1995) guidelines are presented in Table 17-8. Note that each test has a single maximum acceptable value for total error that includes assay bias (i.e., a measure of accuracy) and CV (i.e., a measure of imprecision). Total error is calculated as follows:

$$\% \text{ total error} = \% \text{ bias} + 1.96 (\% \text{ CV})$$

For each test, Table 17-8 provides an example of a target bias and CV that, when considered together, would yield the maximum acceptable total error. Note that by using total error, a laboratory can slightly exceed the limit for bias, provided that the CV is sufficiently small to maintain the total error within the guideline (the opposite is also true). For example, cholesterol has a target bias of 3% and a target CV of 3%. A laboratory with a bias of 3.5% and a CV of 2% exceeds the target for bias, even though it still meets the target for CV. However, the total error of 7.5% (i.e., $3.5\% + 1.96 \times 2\%$) is acceptable because it is less than the 9% target.

TESTING AND TREATMENT

ATP III introduced several new concepts for the evaluation of hyperlipidemia. Diabetes mellitus is now considered a risk equivalent because it

confers a high risk of new CHD within 10 years. This means that for evaluation of elevated cholesterol levels, diabetic patients are treated like patients who already have CHD. Also, ATP III recognized patients with metabolic syndrome (described later) and patients with a high 10-year risk for CHD based on the Framingham risk projections as candidates for intensive intervention and therapy.

Cholesterol Goals

ATP III recommends a complete lipoprotein profile (TC, LDL-C, HDL-C, and triglycerides) as the initial test for evaluating blood cholesterol. Testing should be performed in all adults age 20 and older and should be repeated at least once every 5 years. If testing is performed in the non-fasting state, then only TC and HDL-C can be used. In such circumstances, if the TC is 200 mg/dL or the HDL is <40 mg/dL, then a follow-up profile should be performed. ATP III provides guidelines for acceptable test values and uses LDL-C as the primary target for cholesterol-lowering therapy (Table 17-9). Note that major risk factors (Table 17-10) can modify LDL cholesterol goals (Table 17-11). Therapeutic lifestyle change (TLC) and drug therapy are the two approaches used to reach the LDL-C goal. TLC involves dietary change and increased physical activity, combined with regular follow-up. Regardless of a patient's risk category or LDL goal, TLC represents the first line of therapy, although it may be combined initially with drug therapy when high-risk patients are treated. Note that patients in the moderate-risk category are further subdivided (for drug therapy) based on a Framingham Risk Score, which estimates the 10-year risk of cardiac events based on factors in Table 17-10, as well as

TABLE 17-8

NCEP Guidelines for Acceptable Measurement Error

Analyte	Total error	Bias	CV*
Cholesterol	$\leq 9\%$	$\leq 3\%$	$\leq 3\%$
Triglyceride	$\leq 15\%$	$\leq 5\%$	$\leq 5\%$
HDL-cholesterol	$\leq 13\%$	$\leq 5\%$	$\leq 4\%^\dagger$
LDL-cholesterol	$\leq 12\%$	$\leq 4\%$	$\leq 4\%$

HDL, High-density lipoprotein; LDL, low-density lipoprotein.

*Coefficient of variation defined as standard deviation/mean $\times 100$.

† Precision criteria applied to HDL-cholesterol levels of 42 mg/dL (1.09 mmol/L) and higher. At lower levels, CV is not used; rather, standard deviation should not exceed 1.7 mg/dL (0.044 mmol/L).

TABLE 17-9

ATP III Classification for LDL, Total and HDL Cholesterol, and Triglyceride Values

LDL Cholesterol	
<100	Optimal
100–129	Near optimal/above optimal
130–159	Borderline high
160–189	High
≥ 190	Very high
Total Cholesterol	
<200	Desirable
200–239	Borderline high
≥ 240	High
HDL Cholesterol	
<40	Low
≥ 60	High
Triglycerides	
<150	Normal
150–199	Borderline high
200–499	High
≥ 500	Very high

Data from National Cholesterol Education Program Expert Panel: Third Report of the National Cholesterol Education Program Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III): final report. *Circulation* 2002;106:3143–3421.

HDL, High-density lipoprotein; LDL, low-density lipoprotein.

other factors such as TC and HDL-C (Wilson, 1998). Drug therapy for hyperlipidemia usually consists of four types of medications: statins, fibric acid derivatives, bile acid resins, and nicotinic acid. Some relevant characteristics of these medications are briefly summarized in Table 17-12.

Metabolic Syndrome

This physiologic syndrome is characterized by a constellation of known and emerging risk factors for CHD. Several organizations, including the World Health Organization (WHO) and NCEP, have proposed different definitions for this syndrome; however, risk factors generally include abdominal obesity, atherogenic dyslipidemia (elevated triglycerides, small LDL particles, and low HDL-C), raised blood pressure, insulin resistance (with or without glucose intolerance), and prothrombotic and proinflammatory states. First described as “syndrome X” in the late 1980s, this condition may be present in 20%–25% of adult Americans. In patients with metabolic syndrome, LDL-C is the primary target of therapy; however, patients are usually candidates for more intensive cholesterol-lowering therapy than might be suggested by their LDL-C alone. Other objectives include treatment of the underlying causes (i.e., obesity and physical inactivity) and treatment of associated nonlipid and lipid risk factors (Garber, 2004).

Hypertriglyceridemia

Supported by data from recent meta-analyses, ATP III identifies elevated triglycerides as an independent risk factor for CHD. Factors associated with a high triglyceride level include obesity, physical inactivity, cigarette smoking, excess alcohol intake, high-carbohydrate diets (>60% of energy intake), several diseases (e.g., type 2 diabetes, chronic renal failure,

nephritic syndrome), certain drugs (e.g., corticosteroids, estrogens, retinoids, higher doses of β -adrenergic blocking agents), and genetic disorders (e.g., familial combined hyperlipidemia, familial hypertriglyceridemia, familial dysbetalipoproteinemia). In persons with elevated triglycerides, the primary aim of therapy is to achieve the target for LDL-C. In the fasting state, most circulating triglyceride is in VLDL remnant lipoproteins, so non-HDL cholesterol (TC-HDL cholesterol) can be used as a secondary target for therapy. Non-HDL cholesterol includes all apoB-containing lipoproteins but in the fasting state provides a combined assessment of LDL-C and VLDL-C. Treatment plans for hypertriglyceridemia emphasize weight reduction and increased physical activity with borderline high elevations, but include LDL-lowering medications and triglyceride-lowering drugs (nicotinic acid or fibrates) at higher levels. In rare patients with very high triglyceride levels (>500 mg/dL), the initial aim of therapy is to prevent acute pancreatitis.

Emerging Risk Factors

ATP III recognizes additional positive risk factors for CHD, including elevations in Lp(a), remnant lipoproteins, small LDL particles, fibrinogen,

TABLE 17-12
Hyperlipidemia Drugs

Drug class	Primary effects	Secondary effects	Mechanism	Side effects	Examples
Statins	Lower LDL-cholesterol (20%–60%)	Small decreases in elevated triglyceride; modest increase in HDL-cholesterol	Inhibit HMG-CoA reductase	Rare GI disturbances, liver problems, rhabdomyolysis	Lovastatin Simvastatin Pravastatin Atorvastatin
Fibric acid derivatives	Lower triglycerides (20%–50%)	Small increases in HDL (10%–15%)	Not clearly defined; may decrease the catabolism of HDL, increase the activity of LPL, and inhibit the hepatic synthesis of VLDL	GI disturbances, increased likelihood of cholesterol gallstones, may increase effects of warfarin, and tendency of statins to cause rhabdomyolysis	Gemfibrozil Fenofibrate
Bile acid resins	Lower LDL-cholesterol (10%–20%)	Bind bile acids in intestine, leading to excretion	Mild GI disturbances	Cholestyramine	Colestipol Colestevlam
Niacin (nicotinic acid)	Lowers triglycerides (20%–50%)	Raises HDL-cholesterol (15%–35%)	May inhibit mobilization of fatty acids in adipocytes via G-protein–coupled receptor, HM74A, leading to decreased VLDL production by liver; reduce LDL-cholesterol (10%–20% decrease)	GI disturbances, flushing, chills, pruritus, liver problems, gout, elevated blood sugar	Niacin

homocysteine, high-sensitivity C-reactive protein (hs-CRP), impaired fasting plasma glucose (110–125 mg/dL), and preexisting subclinical atherosclerosis (as evidenced by myocardial ischemia on exercise testing, carotid intimal–medial thickening, and/or coronary artery calcium deposition). The links between some of these factors and CHD are obvious or are discussed elsewhere; however, others require expanded consideration. For example, elevated homocysteine levels have been linked to medications, as well as to genetic, disease and lifestyle conditions, and may contribute to CHD at least partially by exerting toxic effects on the endothelium. The links between hs-CRP (a marker of chronic inflammation) and fibrinogen (a marker of prothrombotic states) and CHD at this point remain largely statistical; clear mechanisms have not been established. Elevation of apoB (present in chylomicrons, VLDL, IDL, and LDL), decreases in apoA-I (present mostly in HDL), and increases in the apoB/apoA-I ratio have also been associated with increased risk of CHD (Walldius, 2004). Although these risk factors are not used widely for screening purposes, they may be useful in defining risk status and refining treatment in patients already known to be at risk.

Children

Current evidence indicates that atherosclerotic lesions can begin in childhood; children with high blood cholesterol levels typically maintain high blood cholesterol through adulthood. In an effort to intervene early in children with an atherosclerotic predisposition, guidelines for assessing CHD risk in children and adolescents have been promulgated by organizations such as the NCEP (NCEP Expert Panel on Children and Adolescents) (NCEP, 1992) and the American Heart Association (Kavey, 2003). Current recommendations support selective screening (starting at 2 years of age) of children and adolescents with a family history of premature cardiovascular disease or those with at least one parent with high blood cholesterol. Table 17-13 classifies these children by total and LDL-C levels. These recommendations do not support the universal laboratory screening of children and adolescents.

Intervention aimed at reducing risk is recommended when the averaged results of three fasting lipid profiles are above the cutoffs for TC and LDL described earlier, with elevated triglycerides (>150 mg/dL) or decreased HDL-C (<35 mg/dL). As in adults, intervention focuses on a search for medical causes of lipid abnormalities, TLC, and pharmacologic intervention when necessary.

LIPIDS, LIPOPROTEINS, AND DISEASE

Lipoprotein and lipid levels are used to predict CHD and form the basis of the NCEP guidelines discussed earlier. However, for many years, the Fredrickson Classification (alluded to in Table 17-3) was used to characterize lipid disorders (Hansen, 1998). The Fredrickson Classification used electrophoresis and a standing plasma test for CM to correlate clinical disease syndromes with laboratory phenotypes (Fredrickson, 1967). Note that each phenotype is not a specific disease but rather a variety of disorders that affect the same lipoproteins and therefore express the same lipid pattern. Thus treatment is usually the same for all disorders falling within the same phenotype. One limitation of this system is that it does not consider low HDL as a risk factor for CHD. In recent years, the Fredrickson Classification has proved less useful given modern analytic techniques and an evolving understanding of the genetics of these disorders. Nevertheless, the nomenclature for a few pathognomonic syndromes (e.g., Type 1 and Type 3 hyperlipidemias) has remained in use. Some pertinent details of the Fredrickson Classification are presented in Table 17-14.

As our understanding of lipids, lipoprotein metabolism, and genetics has evolved, far more complex systems for describing clinical lipid disorders have been conceived. Presently, no ideal scheme to categorize these disorders is available. They can arise from lifestyle or secondary causes, as

TABLE 17-13

Classification of Total and LDL-Cholesterol in Children: Targeted Fasting Screen in Children >2 Years of Age With Family History of Dyslipidemia or Premature CHD

Category	Total cholesterol (mg/dL)	LDL-cholesterol (mg/dL)
Acceptable	<170	<110
Borderline	171–199	111–129
High	≥200	≥130

TABLE 17-14

Pertinent Details of the Fredrickson Classification

Type	Refrigerator test	Gel electrophoresis	Clinical presentation
1	Positive; clear plasma	Normal	Eruptive xanthoma; acute, recurrent pancreatitis in early childhood; lipids improve on low-fat diet
2a	Negative; clear plasma	Increased β band	Xanthelasma, tendon xanthoma; premature coronary disease; autosomal dominant familial inheritance; commonly known as familial hypercholesterolemia
2b	Negative; cloudy plasma; increased β and pre- β band	Isolated xanthelasma may be present; premature coronary disease; autosomal dominant pattern; affected family members must have varied patterns (e.g., isolated hypertriglyceridemia, isolated hypercholesterolemia, combined hyperlipidemia) to meet diagnostic criteria for familial combined hyperlipidemia	
3	Occasional cloudy plasma; increased pre- β band; eruptive xanthoma and palmar xanthoma; premature coronary disease; autosomal recessive pattern; a secondary cause of dyslipidemia, such as hypothyroidism, can unmask type 3, and treatment of the secondary condition can return lipids to normal		
4	Negative; cloudy plasma; increased α_2 band	May or may not be associated with premature coronary disease	
5	Positive; cloudy plasma; increased α_2 band	Eruptive xanthoma; may be associated with pancreatitis; may be associated with premature coronary disease	

well as from mutations in genes encoding apolipoproteins, apolipoprotein receptors, or enzymes of lipoprotein metabolism. Some genes (e.g., apoA-I, apoC-III, apoA-IV) are in close proximity and share similar response elements, allowing a single mutation to alter multiple aspects of lipoprotein metabolism. The following disorders of lipoprotein metabolism are categorized on the basis of laboratory findings. Lifestyle factors affecting lipid profiles and causes of secondary hyperlipidemia are listed in Table 17-15 in association with their most common laboratory presentation. As with the genetic dyslipidemias, these factors can produce overlapping and somewhat variable lipoprotein profiles. In Figures 17-5 and 17-6, some of the disorders described later are incorporated into the schemes of forward and reverse cholesterol transport, so that their cause and pathogenesis may be more readily understood.

HIGH CHOLESTEROL WITH HIGH LDL-C

These disorders share one feature—hyperbetalipoproteinemia (Fredrickson Type 2A), characterized by elevated LDL-C and normal triglycerides. It is associated with a high cardiac risk that is not surprising given the elevations in LDL, a highly atherogenic particle. This is a commonly encountered laboratory presentation.

Polygenic (Nonfamilial) Hypercholesterolemia

Polygenic (nonfamilial) hypercholesterolemia is a general term used to describe individuals for whom the cause of hypercholesterolemia is likely multifactorial (Soutar, 1998). Although some of the causative factors in this disease are thought to be genetic, before a patient's hypercholesterolemia

TABLE 17-15

Lifestyle Factors and Causes of Secondary Dyslipidemia

Lipoprotein profile	Secondary causes	Lifestyle factors
High cholesterol and high LDL-C with or without low HDL-C	Hypothyroidism and nephrotic syndrome Medications such as thiazide diuretics and steroids Chronic obstructive liver disease Cholestatic liver disease (primary biliary cirrhosis and related diseases)	Obesity Excess dietary cholesterol and/or saturated fat ApoE-4 may increase susceptibility
High triglycerides with normal total and LDL-C with or without low HDL-C	Medications such as thiazide diuretics, estrogens, corticosteroids, retinoids, cyclosporine, and beta-blockers (without intrinsic sympathomimetic) Insulin resistance/diabetes Chronic renal failure and nephrotic syndrome Antipsychotic drugs (clozapine/olanzapine)	Obesity Physical inactivity Cigarette smoking Excess alcohol intake High-carbohydrate diets
High cholesterol and high triglycerides with or without low HDL-C	Medications, notably high-dose steroids or cyclosporine Severe hypothyroidism, diabetes/insulin resistance, and nephrotic syndrome	Obesity HIV antiretroviral drugs
Isolated low HDL-C	Medications such as isotretinoin, probucol, anabolic steroids, beta blockers, and certain progestogens	Physical inactivity Increased body weight High-carbohydrate, low-fat diets
Isolated high HDL-C	Medications such as phenytoin, phenobarbital, rifampicin, griseofulvin, and estrogens	Alcohol intake

is labeled “polygenic,” secondary and familial hypercholesterolemia (autosomal dominant) must be ruled out. Approximately 85% of the hypercholesterolemia in the population may fall into this category. Some clinicians use this term to describe patients who develop age-related increases in cholesterol that do not respond to lifestyle modification.

Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is an autosomal dominant disorder caused by one of several mutations in the LDL-receptor gene on chromosome 19. The resulting defective receptors cannot bind or clear LDL from the circulation (Hobbs, 1992). Several hundred mutations have been identified in the LDL receptor gene, and they affect most aspects of receptor synthesis, transport, and function (Fig. 17-7). This genetic heterogeneity has led to variability in presentation and responsiveness to therapy. Heterozygous FH occurs in 1 in 500 individuals and is associated with premature atherosclerotic disease. Affected heterozygous men usually present in their fourth decade and women 10–15 years later. Untreated LDL-C levels are typically >220 mg/dL. Further, FH heterozygotes exhibit LDL-C levels that vary with environmental factors and genetics. Homozygous FH presents in childhood with LDL levels >400 mg/dL. Vascular deposition of lipid results in premature symptomatic CHD. In addition, homozygotes are less affected by environmental factors in terms of LDL-C levels. Large valvular and supralvalvular cholesterol deposits can produce symptomatic aortic stenosis. Other stigmata of the disease include corneal arcus, tendinous xanthomata, and xanthelasma. These stigmata generally develop in early childhood in homozygotes, and by adulthood in heterozygotes. Statins, which inhibit 3-hydroxy-3-methylglutaryl-CoA (HmG-CoA) reductase, may be effective; however, because these drugs may act indirectly by increasing LDL receptor activity, not all heterozygous patients will normalize their LDL-C despite receiving maximum doses of statins. Homozygous patients have two abnormal LDL receptor genes, making statin drugs ineffective unless combined with apheresis (Ose, 1999). Patients with homozygous FH are classified into two groups on the basis of tests for LDL receptor (LDLR) activity in skin fibroblasts: patients with less than 2% of normal LDLR activity are receptor-negative; patients with 2%–25% of normal LDLR activity are receptor-defective. Receptor-negative patients rarely live past the second decade; receptor-defective patients often develop significant atherosclerotic disease by the age of 30 years.

Figure 17-7 Classification of low-density lipoprotein (LDL) receptor mutations based on abnormal function of the mutant protein. These mutations disrupt the receptor’s synthesis in the endoplasmic reticulum, transport to the Golgi complex, binding of apoprotein ligands, clustering in coated pits, and recycling in endosomes. Each class is heterogeneous at the DNA level. (Modified with permission from Hobbs HH, Russell DW, Brown MS, Goldstein JL. The LDL receptor locus in familial hypercholesterolemia: mutational analysis of a membrane protein. *Annu Rev Genet* 1990;24:133–170. Copyright 1990 by Annual Reviews.)

Familial Defective ApoB

Familial defective ApoB is an autosomal dominant disorder of the apoB gene on chromosome 2 that interferes with the recognition of apoB-100 by the LDL receptor (Hansen, 1998). The disease results from a missense mutation (*Arg3500Gln*) in the LDLR-binding domain of ApoB-100, although other mutations that occur less frequently can cause this disease. Estimated frequency in the population is 1 in 750. Patients with familial defective apoB have similar physical stigmata to those of FH: tendinous xanthomata, xanthelasma, and premature coronary disease. Untreated LDL-C levels can overlap those seen in FH but tend to be slightly lower. Further, patients with familial defective ApoB have levels of plasma LDL-C comparable with those in FH heterozygotes. Statin drugs are effective.

Sitosterolemia

Sitosterolemia is an extremely rare autosomal recessive disorder wherein phytosterols (plant sterols) are absorbed and accumulate in plasma and peripheral tissues. This disease results from mutations in the *ABCG8* or *ABCG5* gene, both of which are located at chromosome 2p21. Mutations in these genes disrupt the ABCG5 or 8 proteins from forming the proper channel to pump back absorbed plant sterols into the intestinal lumen, as well as the ability of liver to secrete absorbed phytosterols into bile. Most patients identified with sitosterolemia have had high plasma LDL-C levels during childhood. Children present with tendinous xanthomata and normal to high levels of LDL. Premature CHD is present. Cholesterol levels may be normal or elevated. Many common assays do not differentiate between cholesterol and plant sterols, and measurement of plasma phytosterols is necessary to confirm the diagnosis. Phytosterols are positively identified using gas-liquid chromatography in lipids extracted from plasma. A distinctive clinical presentation of sitosterolemia is the occurrence of low-level hemolysis. Red blood cells may be incorporating the plant sterols into their membranes. Diagnosis of sitosterolemia should be considered if the patient presents with xanthomatosis and hypercholesterolemia yet has parents who have normal levels of cholesterol. Treatment consists of restricting dietary phytosterol intake (Patel, 1998) and using ezetimibe and a bile acid sequestrant to limit sterol accumulation.

Autosomal Dominant Hypercholesterolemia

Autosomal dominant hypercholesterolemia (ADH) is an autosomal dominant disorder of the *PCSK9* gene on chromosome 1 that is involved in cholesterol homeostasis in the liver (Abifadel, 2003). Two known mutations of the gene may lead to gain of function of *PCSK9* (*S127R* and *F216L*). Individuals with gain-of-function mutations present clinically with increased plasma levels of LDL-C and exhibit higher risk of coronary heart disease. Relatively little is known about the frequency of ADH since the discovery of the mutation in three families in 2003. However, more gain-of-function *PCSK9* patients have been reported (*D374Y*). *PCSK9* is a member of the proprotein convertase family of proteins. Although the mechanism of action is still unclear, it is known that *PCSK9* is secreted into plasma and binds to LDLR on the cell surface. This leads to endocytosis and intracellular degradation of the LDLR. Consequently, gain of function of *PCSK9* is thought to be involved in decreasing levels of LDLR protein. In addition to the gain-of-function mutations, loss-of-function mutations have been found. These missense (*R46L*) and nonsense (*Y142X* and *C697X*) mutations have led to hypocholesterolemia in patients.

Autosomal Recessive Hypercholesterolemia

Autosomal recessive hypercholesterolemia (ARH) involves the ARH gene found on chromosome 1. ARH is also known as *LDLRAP1*. In these patients, LDLR expression is normal, but LDL clearance rates are low and comparable with those of patients with homozygous FH. ARH is thought to express a protein that is involved in internalization of the LDLR-LDL complex. Plasma levels of LDL-C in ARH patients tend to be between FH heterozygotes and FH homozygotes. The onset of atherosclerotic disease presents later than in homozygous FH patients. ARH patients can present with large, bulk xanthomas. Patients with ARH respond to lipid-lowering medications. However, most ARH patients are maintained on LDL apheresis as part of their treatment.

HIGH TRIGLYCERIDES WITH NORMAL CHOLESTEROL

These disorders are related to elevations of triglyceride-rich particles, namely, chylomicrons or VLDL (Fredrickson Types 1 and 4).

This commonly encountered laboratory presentation is usually due to hyperprebetalipoproteinemia (VLDL) and may be due to secondary causes such as excess alcohol or a high-carbohydrate diet. LDL and LDL-C are typically normal.

Diabetic Dyslipidemia

Diabetic dyslipidemia consists of atherogenic dyslipidemia (high triglycerides, low HDL, and small dense LDL) in persons with type 2 diabetes. Current evidence supports the treatment of LDL-C as the primary target in patients with this disorder. Although cholesterol levels may be within the “normal” range, treatment is often directed at LDL-C because diabetes is viewed as a CHD risk equivalent and thus is associated with a lower than “normal” target cholesterol value (see Table 17-11).

Familial Hypertriglyceridemia

Familial hypertriglyceridemia occurs along with other lipoprotein abnormalities as part of a number of familial hyperlipidemia syndromes. Isolated hypertriglyceridemia (or Type 4 hyperlipidemia) is a relatively common autosomal dominant disorder, affecting approximately 1:300 to 1:50 people in the United States, depending on the criteria used for diagnosis. The disorder usually presents in adulthood with fasting triglyceride levels in the 200–500 mg/dL range. The pathophysiology remains elusive, but VLDL triglyceride production is increased in the setting of normal apoB production, resulting in the formation of “fluffy,” triglyceride-rich VLDL particles. Some kindreds have premature CHD; however, it is unclear whether the CHD results from hypertriglyceridemia or from the frequently coexisting exacerbating factors, obesity and insulin resistance (Brunzell, 1983).

Lipoprotein Lipase Deficiency (Hyperlipoproteinemia Type 1 or Hyperchylomicronemia)

Lipoprotein lipase deficiency is a rare, autosomal recessive disorder that presents in childhood with abdominal pain and pancreatitis. Defective or absent LPL creates an inability to clear chylomicrons, creating the classic “type 1” chylomicronemia syndrome (see Tables 17-3 and 17-14). Fasting triglyceride levels may be >100 mg/dL and may rise to >10,000 mg/dL postprandially. Patients with LPL deficiency do not develop premature CHD, implying that chylomicrons themselves are not atherogenic. Treatment with a low fat diet to reduce chylomicron input is effective; fat-soluble vitamins should be supplemented, and drug therapy can be considered to lower endogenous VLDL production (Brunzell, 1995). Heterozygotes have half-normal LPL activity and occur in the general population at a frequency of 1 in 500. It has been speculated that heterozygous individuals with the defective *LPL* gene constitute a subset of families with familial combined hyperlipidemia (Babirak, 1989).

ApoC-II Deficiency

ApoC-II is an activating cofactor for LPL. Thus, the absence of apoC-II creates a functional LPL deficiency, which presents similarly to LPL deficiency as a rare autosomal recessive form of familial hyperchylomicronemia. The disorder presents in children and young adults as recurrent bouts of abdominal pain and pancreatitis. Several defects in the apoC-II gene have been described (Fojo, 1992). Patients can be treated with plasma transfusions during severe hypertriglyceridemia providing apoC-II, which will activate endogenous LPL.

ApoC-III Excess

ApoC-III excess interferes with the activity of lipoprotein lipase and binds to the carboxy-terminal portion of apolipoprotein B, preventing the binding of lipoproteins to the LDL receptor. Excess apoC-III, especially within the apoB-containing lipoproteins LDL and VLDL, may be an independent risk factor for CHD. ApoC-III levels can be increased in patients with diabetes type 2, hyperbilirubinemia, kidney deficiency, and thyroid dysfunction; further, genetic mutations in the apoC-III gene are known. In addition to genetic factors, serum apoC-III is affected by age and alcohol consumption in men and women; oral contraceptive use in women has also been associated with high levels of apoC-III. For males and females in their youth, post-pubescent status and oral contraceptive use have been shown to affect apoC-III levels. Several genetic polymorphisms of the apoC-III gene are known. They include point mutations at -641T/C, -482C/T, -455T/C, 1100C/T, 3175C/G, and 3026T/G of the start site of the apoC-III gene. The mutations at -455T/C and 1100C/T are more common in Caucasian males and boys. It is thought that the point

mutation at -455T/C affects a transcription factor-binding site associated with insulin response. Consequently, lack of response to insulin at the apoC-III promoter, which downregulates apoC-III transcription, is thought to contribute to high levels of triglycerides in plasma. Genetic mutations at other genes such as *APOA4* or carrying APOE E4 alleles have been suggested to influence serum apoC-III levels as well.

ApoA-V

ApoA-V is a highly hydrophobic protein that has a preference for binding to lipids and HDL particles. The function of ApoA-V has been hypothesized as being involved in VLDL assembly; in addition, it has been postulated that ApoA-V may be involved in activation of LPL-mediated triglyceride hydrolysis. Consequently, low levels of ApoA-V may promote hypertriglyceridemia, whereas high levels of ApoA-V would have the opposite effect. One variant of ApoA-V has been found in humans that has a strong correlation with hypertriglyceridemic patients. The actual function of ApoA-V and its role in triglyceride metabolism require further investigation.

HIGH CHOLESTEROL WITH HIGH TRIGLYCERIDES

These disorders are related to elevations of LDL and triglycerides (Fredrickson Types 2B and 3). Familial combined hyperlipidemia (2B) is the most common primary hyperlipoproteinemia and presents with a variety of lipoprotein phenotypes within a family. The relatively rare dysbetalipoproteinemia (Type 3) is characterized by an abnormal LDL (IDL) that appears as a broad beta electrophoretic band and distinguishes it from familial combined hyperlipidemia. These disorders are associated with increased cardiac risk because of the elevated LDL.

Familial Combined Hyperlipidemia (Type 2B)

Familial combined hyperlipidemia (Type 2B) is a relatively common disorder wherein affected individuals may have simple hypercholesterolemia, simple hypertriglyceridemia, or a mixed defect. Because of the disorder's phenotypic heterogeneity and the lack of a definitive biochemical marker for the disorder, considerable overlap and confusion with other forms of hyperlipidemia have occurred. Estimated frequency in the population is 1 in 100. Affected families must have more than one pattern of lipid disorder to meet diagnostic criteria for familial combined. The genetic basis is unknown (deGraaf, 1998) and appears to be multifactorial, although inheritance was thought initially to be autosomal codominant. The specific gene or genes explaining the defect have not been fully elucidated.

Acquired Combined Hyperlipidemia

Acquired combined hyperlipidemia is common in patients who have metabolic syndrome. As the name suggests, the disease stems from a syndrome of conditions that include type 2 diabetes mellitus, hypertension, central obesity, and coronary heart disease. It is thought that the liver increases the production of VLDL through high levels of free fatty acids in plasma. As a result, the increased VLDL levels mature to LDL until this process is saturated. When LDL levels get high enough, VLDL levels follow, causing both hypercholesterolemia and hypertriglyceridemia.

Dysbetalipoproteinemia (Type 3)

ApoE is present on chylomicrons, VLDL, IDL, and chylomicron remnants. By binding to the LDL receptor, and probably other receptors, apoE helps to clear these lipoproteins from circulation. Three common electrophoretic isoforms of apoE are known, each form attributable to several different genetic mutations. The most common isoform is E-3, followed by E-4 and E-2. ApoE-2 has lower affinity for the LDL receptor (less than 2% of binding ability of E-3), thus lipoprotein particles accumulate in the blood of patients who are homozygous for E-2. However, although individuals with this genotype are relatively common in the Caucasian population (1 in 100), expression of an overt Type 3 phenotype occurs in 1 to 5 per 5000 individuals. Thus, the manifestation of the Type 3 hyperlipidemia phenotype is thought to contribute to the disease. Secondary factors implicated in the manifestation of disease include obesity, diabetes mellitus, hypothyroidism, and medications such as protease inhibitors.

Type 3 hyperlipidemia primarily affects adults and men more commonly than women. Symptomatic individuals typically have roughly equal elevations of cholesterol and triglycerides, presence of β -VLDL or cholesterol-enriched remnants of intestinal chylomicrons, and hepatic

VLDL, xanthomas, and premature vascular disease such as coronary heart disease and peripheral artery disease. Type 3 has a pathognomonic feature: a broad abnormal band between VLDL and LDL known as "abnormally migrating beta lipoprotein," or β -VLDL. The cholesterol content in VLDL is also increased, and measurement of the VLDL-C/triglyceride ratio is a useful screen. Normally, the VLDL-C/triglyceride ratio is 0.2; typical Type 3 patients have a ratio >0.3 . Day-to-day variation in lipid levels is more pronounced than usual. Other clinical stigmata include palmar xanthoma and tuberoeruptive xanthoma on elbows, knees, and buttocks. Premature atherosclerosis is highly prevalent and, unlike familial hypercholesterolemia, more often involves abdominal and femoral arteries. The atherosclerosis appears reversible with treatment of the lipid disorder (Kuo, 1988). Patients are responsive to low fat diets, weight loss, and most classes of lipid-lowering drugs.

Hepatic Lipase Deficiency

Generally resulting from mutations of the HL gene, this rare familial disorder is associated with combined hyperlipidemia characterized by TC levels of 250–1500 mg/dL and TG levels of 400–8000 mg/dL. Levels of HDL-C are normal or increased. Physical stigmata include palmar and tuberoeruptive xanthoma; the risk of atherosclerosis is thought to be increased. In contrast to Type 3 hyperlipidemia, although β -VLDL is increased, the TC/TG ratio is not increased. The triglyceride content of all lipoproteins is increased 3-fold to 5-fold. Families with compound heterozygous mutations have been described (Connelly, 1998). Patients with hepatic lipase deficiency are able to convert large VLDL to smaller VLDL particles; however, they are unable to convert VLDL to IDL and also LDL from IDL. HDL and LDL particles from hepatic lipase deficiency patients are large and enriched with triglycerides.

Cholesterol 7-Alpha-Hydroxylase Deficiency

Cholesterol 7-alpha-hydroxylase deficiency is a recessive disorder of the *CYP7A1* gene that encodes cholesterol 7-alpha-hydroxylase protein. *CYP7A1* encodes an enzyme that is involved in the first step of the classical pathway for bile acid biosynthesis. The few patients who present with this rare disease exhibit not only high cholesterol, but also high triglycerides in plasma. Very little is known about the disease. However, it has been reported that the few patients diagnosed with this disease are resistant to statin therapy, although the same patients managed to lower their plasma cholesterol with atorvastatin and niacin therapy. Lack of cholesterol 7-alpha-hydroxylase is thought to reduce hepatic LDLR activity; however, because so few patients have been identified with this condition, more information and patients will be necessary to confirm the relationship between the deficiency and its clinical presentation.

LOW TOTAL CHOLESTEROL AND TRIGLYCERIDE

These uncommon disorders are associated with defective apoB synthesis or metabolism, leading to low or nonexistent levels of apo-B lipoproteins such as CM, VLDL, and LDL. Triglycerides and cholesterol are low. Fat-soluble vitamin deficiencies are common. Low fat diet therapy is required.

Abetalipoproteinemia

Abetalipoproteinemia (also known as Bassen-Kornzweig syndrome) is a rare, autosomal recessive disorder involving mutations in the *MTTP* gene located on chromosome 4. *MTTP* encodes an 894 amino acid protein called MTP, or microsomal triglyceride transfer protein (MTP). MTP protein forms a heterodimer with a chaperone protein called protein disulfide isomerase (PDI) in the endoplasmic reticulum. Mutations in *MTTP* affect its binding to PDI and its ability to transfer lipids. Clinically, abetalipoproteinemia patients present with undetectable plasma apoB containing lipoproteins. During apoB translation, MTP incorporates lipids onto the nascent apoB protein and prevents it from proteasomal degradation. Consequently, the lack of functional MTP still allows for apoB protein production; however, the protein ends up misfolded and destroyed by endoplasmic reticulum (ER)-associated degradation mechanisms. Neither apoB-48 nor apoB-100 is present in plasma. Patients present in childhood or early adolescence with fat malabsorption, hypolipidemia, retinitis pigmentosa, cerebellar ataxia, and acanthocytosis. Laboratory testing usually shows decreased apoB, triglycerides, and TC (typically <50 mg/dL). Patients develop fat-soluble vitamin deficiencies caused by malabsorption of vitamins A, K, and E. Vitamin D does not require chylomicrons for

absorption and therefore is typically not deficient. Because both vitamin A and vitamin K have transport systems independent of lipoproteins, clinical deficiency is not as severe as that seen with vitamin E, which not only depends upon chylomicrons for absorption but relies upon VLDL and LDL for delivery to tissues. Children with this disorder respond to a low-fat diet rich in medium-chain fatty acids and supplemented with high-dose fat-soluble vitamins, especially vitamin E. Replacing vitamin E stores improves the retinal and peripheral neuropathic symptoms. Heterozygotes have no symptoms and no evidence of abnormal plasma lipid levels.

Hypobetalipoproteinemia

Hypobetalipoproteinemia is an autosomal dominant disorder explained by nonsense or missense mutations in the *apoB* gene, leading to synthesis of various truncated forms of apoB. Severity of disease depends on the type of apoB synthesized. Generally, patients have very low LDL-C levels (Wu, 1999). The familial form is associated with a decreased risk for cardiovascular disease. Homozygous individuals have TC levels <50 mg/dL and present at an early age with fat malabsorption and low plasma cholesterol levels. Heterozygous individuals are usually asymptomatic and have low plasma LDL concentrations. They develop progressive neurologic degenerative disease, retinitis pigmentosa, and acanthocytosis, similar to patients with abetalipoproteinemia. Complications from vitamin E deficiency can be prevented by treatment with very high doses of vitamin E (100–300 mg/kg/day). Heterozygous individuals have LDL-C levels approximately half that of age- and sex-matched controls, but are otherwise asymptomatic.

Chylomicron Retention Disease

Chylomicron retention disease (Anderson's disease) presents in childhood with fat malabsorption and low levels of plasma lipids. This syndrome is distinct from abetalipoproteinemia, as only apoB-48 appears to be affected. Further, the disease is characterized by hypocholesterolemia, chronic diarrhea, failure to thrive, and deficiency of fat-soluble vitamins (vitamin E in particular); the latter can lead to neurologic deficits. The genetic abnormality associated with this disorder is linked to the *SARA2* gene on chromosome 5q3 that encodes the Sar1 GTPase protein. This protein belongs to a family of GTPases that govern the intracellular trafficking of proteins in protein-coated vesicles (Jones, 2003). Sar1 GTPase most likely plays a role in the steps involving intracellular trafficking of newly synthesized apoB-48-containing lipoproteins in the enterocytes. After proper folding and lipidation in the ER by the MTP, apoB-48 lipoproteins leave the ER through pre-chylomicron transfer vesicles (PCTVs). These vesicles fuse with a recipient Golgi membrane and are ultimately secreted. The precise role of Sar1 GTPase in intracellular trafficking has not been elucidated.

ISOLATED LOW HDL-C

Low HDL levels are associated with CHD, presumably because insufficient HDL is available to participate in reverse cholesterol transport, the process by which cholesterol is eliminated from peripheral tissues.

Familial Hypoalphalipoproteinemia

Familial hypoalphalipoproteinemia is a common autosomal dominant disorder that occurs in 1 in 400 people. Affected men have HDL-C levels <30 mg/dL, and women have HDL-C levels <40 mg/dL. The criteria for familial hypoalphalipoproteinemia include the following: (1) low HDL cholesterol in the presence of normal VLDL cholesterol and LDL cholesterol levels; (2) absence of diseases or factors that lead to secondary effects of hypoalphalipoproteinemia; and (3) the presence of a similar lipoprotein pattern in a first-degree relative. Half of affected families appear to have hepatic lipase or apoA-I/C-III/A-IV gene defects (Breslow, 1995). Mutations in the *ABCA1* gene, the same gene that is mutated in Tangier disease, have been associated with some cases of hypoalphalipoproteinemia. Premature CHD is typically present.

ApoA-I Deficiency and ApoC-III Deficiency

ApoA-I deficiency with ApoC-III deficiency is a rare autosomal recessive condition characterized by a reduction in the formation of HDL. It has

been linked to point mutations in the *apoA-I* gene and to deletions/gene rearrangements at the *apoA-I/C-III/A-IV* gene locus on the long arm of chromosome 11 (Assman, 1995). HDL-C levels are <5 mg/dL; both corneal opacification and premature coronary disease are seen in some patients.

ApoA-I Variants

ApoA-I variants are rare, specific amino acid substitutions in the *apoA-I* gene. They have been shown to increase catabolism of HDL and apoA-I (Breslow, 1995). Homozygous patients generally present with autosomal recessive inheritance of low HDL-C levels (approximately 10 mg/dL), corneal opacifications, xanthomata, and premature coronary disease. Heterozygous individuals may present with low HDL-C. One mutation, *apoA-I-Milano*, shows autosomal dominant inheritance and is associated with low HDL-C levels but is not associated with premature coronary disease (Calabresi, 1997).

Tangier Disease

Tangier disease is a rare autosomal recessive disorder characterized by complete absence of HDL due to a mutation in the *ABCA1* gene on chromosome 9. The mutation leads to an inability to effectively transfer cholesterol and phospholipids from within the cell onto nascent apoA1 proteins in plasma. The resulting buildup of cholesterol within the cell becomes toxic. LDL cholesterol is reduced. In the homozygous state, patients present with low or undetectable HDL in plasma, hepatosplenomegaly, peripheral neuropathy, orange tonsils, and premature coronary disease (Rust, 1999). In normal cells, the ABCA1 protein enables cholesterol to exit the cell, upon which it combines with apoA-I to form the HDL. The small amount of HDL that is present in patients with this disorder differs qualitatively from normal HDL.

Lecithin : Cholesterol Acyltransferase Deficiency

Lecithin : cholesterol acyltransferase (LCAT) deficiency is characterized by corneal opacities, normochromic anemia, and renal failure in young adults. It is a very rare autosomal recessive disorder. The disease occurs in two forms: a classic (or complete) familial LCAT deficiency and a milder partial deficiency phenotype known as fish-eye disease (Peelman, 1999). In complete deficiency, HDL-C levels are typically <10 mg/dL, but total cholesterol levels are normal or high. Without LCAT, most cholesterol remains unesterified and HDL synthesis is impeded. Patients with complete LCAT deficiency have anemia, increased proteinuria, and renal failure. Diagnosis is made by LCAT quantification and cholesterol esterification activity in the plasma. Partial LCAT deficiency exhibits progressive corneal opacification, low plasma HDL levels (<10 mg/dL), and variable hypertriglyceridemia (also seen in complete LCAT deficiency). Premature CHD has been reported even in cases of partial LCAT deficiency (Kuivenhoven, 1997). No treatment can be given to raise LCAT levels; however, therapies for this condition involve dietary restriction of fat and management of complications from this disease.

ISOLATED HIGH HDL-C

Cholesteryl Ester Transfer Protein Gene Defects

HDL is involved in the reverse transport of cholesterol from peripheral tissues to the liver. An important step in this process involves CETP, the plasma protein that facilitates the transfer of cholesteryl esters from HDL to apoB-100-rich proteins (VLDL and LDL) in exchange for triglycerides. CETP deficiency is an autosomal recessive disorder in which the transfer of cholesterol esters is inhibited. As a result, HDL particles are large and laden with cholesterol ester, and apoA-I is increased, as is HDL-C (typically >100 mg/dL). The association of higher HDL-C plasma levels with risk of coronary heart disease is still unclear based on genetic studies of humans with *CETP* mutations. Heterozygotes have moderately increased HDL-C levels. Inhibition of CETP is an active area of research given the potential to raise HDL-C levels.

KEY POINTS

- The most important disease affecting the heart is coronary heart disease (CHD), which is atherosclerosis affecting the coronary arteries. CHD can lead to thrombotic occlusion of coronary blood flow, causing an acute coronary syndrome (ACS). ACS with frank necrosis of any amount of myocardium is known as myocardial infarction (MI).
- The primary tests for diagnosing ACS are electrocardiography and laboratory measurement of cardiac markers. Cardiac markers are proteins released into the circulation from damaged heart muscle. The most important cardiac marker today is cardiac troponin (cTn), which derives only from heart muscle.
- Troponin is a complex of three proteins, two of which are suitable as specific cardiac marker tests: cTnI and cTnT. These two proteins have different properties, but their clinical applications are similar. Clinically, MI is now essentially defined as an ACS that causes release of troponin.
- There is a delay of a few hours following MI before cTn is detected in the circulation; it peaks in about 24 hours and then declines over several days.
- Patients presenting to an emergency department with symptoms suggesting ACS must be processed rapidly and precisely to provide life-saving interventions as needed, yet avoid wasting resources. Rapid measurements of cTn, and possibly other laboratory markers, play a critical role.
- The clinical laboratory also measures risk factors associated with the development and progression of CHD. Significant laboratory markers of risk include lipids (cholesterol, triglycerides, and specific lipoprotein fractions—see Chapter 17), homocysteine (Hcy), and C-reactive protein (CRP). Hcy is an amino acid that exacerbates thrombosis. CRP is an inflammatory marker that appears to reflect the severity of CHD and may contribute to its pathogenesis.
- CHD and other heart diseases can impair the heart's ability to pump blood, causing the clinical syndrome of heart failure (HF). B-type natriuretic peptide (BNP), a 32 amino acid peptide secreted by the cardiac ventricles in response to wall-stretch stimuli, is a marker of the presence and severity of HF. BNP testing is particularly useful for aiding the differential diagnosis of patients who present to an emergency department with shortness of breath.

- Atherosclerosis affecting the carotid arteries or brain vasculature can lead to ischemic or hemorrhagic stroke. Some biomarkers show promise for the diagnosis or evaluation of stroke, but none are sufficiently discriminatory for routine use at present.
- Measurement of D-dimer, a degradation product of fibrin, has good sensitivity but poor specificity for the diagnosis of pulmonary embolism and venous thrombotic disease in general.

OVERVIEW

Heart disease is an affliction intimately tied to high technology. Technology has had a causal role, in part by allowing people to live longer, and in part by enabling a sedentary and overly consumptive lifestyle. During the twentieth century, heart disease rose from obscurity to become the leading cause of morbidity and mortality in developed nations (Table 18-1). Diagnosis and treatment of heart disease also depend heavily on advanced technology, including electrophysiologic, imaging, catheterization, surgical, and clinical laboratory modalities. The following major laboratory applications will be the subject of this chapter:

1. Measurement of proteins present in cardiac myocytes indicates recent damage to cardiac muscle. These tests are used mainly for the diagnosis and management of ischemic events (acute coronary syndromes). Although many different markers of ischemic damage have been used in the past, at the time of writing the most important markers by far are *cardiac troponin I* and *cardiac troponin T*.
2. Measurement of substances that are damaging to the coronary arteries, or at least have proven association with coronary heart disease, is used to assess risk and select appropriate preventive measures. The most important laboratory risk factors are lipids, which are discussed in Chapter 17. Of the many other substances that could be discussed, this chapter will focus on two: homocysteine (Hcy) and C-reactive protein (CRP).
3. Measurement of natriuretic peptides released from myocardium, particularly *B-type natriuretic peptide* (BNP) and the related inactive fragment, *NT-pro-BNP*, reflects the presence and severity of heart failure.
4. Laboratory testing has been less applicable to cerebrovascular disease, but some new biomarkers may be considered promising. Measurement of D-dimer is useful in ruling out pulmonary embolus.

TABLE 18-1
Heart Disease Statistics for the United States

- An estimated 80 million American adults, or about 1 in 3, has some form of cardiovascular disease (including hypertension).
- 16.8 million Americans have a history of CHD—of these, 7.9 million have had an MI and 9.8 million have had angina pectoris.
- 5.7 million Americans have HF.
- 6.5 million Americans have experienced a stroke.
- Cardiovascular disease is the underlying cause in 35.3% of all deaths in the United States, about 860,000 deaths per year. It claims about as many deaths as cancer, chronic lower respiratory diseases, accidents, and diabetes mellitus combined.
- The estimated annual direct and indirect cost of cardiovascular disease is \$475 billion.
- Although some trends in cardiovascular disease are favorable, other factors, including an alarming increase in the prevalence of obesity and type 2 diabetes, will fuel the epidemic for many years to come.

Clinical Abbreviations

ACS	Acute coronary syndrome
CHD	Coronary heart disease (also referred to as ischemic heart disease [IHD], atherosclerotic heart disease [ASHD])
HF	(Congestive) heart failure
MI	(Acute) myocardial infarction
NSTEMI	Non–ST-elevation myocardial infarction
STEMI	ST-elevation myocardial infarction
UA	Unstable angina

BACKGROUND (Table 18-2)

It is ironic that for the heart, an organ that pumps several liters of blood each minute, the most important disease process is ischemia—the lack of an adequate blood supply. This is so because heart muscle depends on constant nutrition through a system of coronary arteries, which are highly vulnerable to the process of atherosclerosis. Atherosclerosis is a chronic process involving damage to endothelium and the buildup of vessel-occluding lesions called plaque. In the early stages of atherosclerosis, as coronary blood flow is gradually reduced, there are typically no symptoms or laboratory evidence of cardiac injury. Once the diameter of a coronary artery is reduced to less than 10%–20% of its original size, chest pain (angina pectoris) often develops when demand for oxygen increases, particularly during exercise (exertional angina). More rapid reduction in blood flow can occur when plaque stimulates formation of a thrombus in a coronary artery, leading to an acute coronary syndrome (ACS). When a thrombus completely cuts off blood flow, the supplied muscle will develop irreversible ischemic damage, and the syndrome is a myocardial infarction (MI). When the blockage is not complete, irreversible muscle damage may be avoided, but the patient will experience severe angina, even at rest, and this syndrome is known as unstable angina. The broad spectrum of heart disease resulting from impaired coronary blood flow is referred to as coronary heart disease (CHD).

MI's can be categorized by whether they are accompanied by characteristic changes on the electrocardiogram (ECG). More severe MI's, generally involving transmural damage to the myocardium, typically cause the rapid appearance of ST-segment elevations and the later appearance of Q-waves. These are categorized as ST-elevation MI's (STEMI's). MI's without these changes (non-Q-wave MI's, or non-ST elevation MI's [NSTEMI's]) typically involve lesser degrees of muscle damage, possibly only to the subendocardium, but any ACS event carries serious risk for possibly lethal arrhythmias and for future events. Damage to a sizable quantity of cardiac muscle carries the additional risk of compromising the heart's ability to pump blood, leading to the clinical syndrome of heart failure (HF), which is discussed later.

Cardiac muscle is relatively resistant to ischemia, compared with other cells such as neurons and renal tubular epithelial cells, in which even short duration of ischemia can lead to cell death. In experimental animals, complete blockage of blood flow to an area of the heart does not cause cell death (MI) until after at least 20–30 minutes of ischemia; if blood flow had been previously restricted, cell death often is delayed for up to an hour. With complete coronary artery occlusion, there is typically a gradient of ischemia, with oxygen deprivation worst in areas receiving blood flow last (the subendocardial portions of the ventricular wall). Cells near the border between ischemic myocardium and normally perfused myocardium may receive some oxygen supply, and thus may remain viable for several hours. The longer the duration of ischemia, the higher is the percentage of cells at risk that will die; 3 hours of ischemia increases cell death to 80% of cells at risk, and 6 hours of ischemia causes the death of almost 100% of cells at risk. For this reason, early recognition of persistent ischemia and intervention to restore blood flow are needed to minimize cell death. Blood flow is most commonly restored by manipulating the plaque (usually by inflating a balloon) via a catheter inserted into a peripheral vein and then threaded into the coronary circulation (percutaneous coronary intervention). A mesh tube, or stent, may be inserted at the same time to maintain the patency of the coronary artery. When flow is blocked at multiple sites, it may be necessary to perform a coronary artery bypass graft.

The pathobiology of atherosclerosis and ACS remains incompletely understood. Formation of obstructive plaques probably begins with non-obstructive lesions known as fatty streaks, which have been observed in the coronary arteries of young individuals dying in combat or in accidents (Enos, 1953; Berenson, 1992; Strong, 1999). The lesions are likely triggered by uptake of oxidized low-density lipoprotein (LDL) particles by macrophages, which then invade the coronary endothelium (Ross, 1993; Witztum, 1994; Adams, 2000; Zaman, 2000). Inflammatory cells and mediators play a role in the evolution of the lesion, which eventually becomes a structure containing a lipid core (mainly cholesterol esters) surrounded by numerous macrophages and other inflammatory cells, and covered with a cap of endothelialized connective tissue (Davies, 2000; Weissberg, 2000; Hansson, 2005). Advanced lesions also contain new blood vessels and calcium deposits. Plaques in coronary arteries were formerly regarded as passive, physiologically irreversible barriers to blood flow. In recent years, their more dynamic role in ACS has been appreciated. A balance of inflammatory mediators, shear forces, and other factors can cause the fibrous cap of the plaque to strengthen or weaken. Erosion of the cap can expose thrombogenic material, leading to deposition of platelets and eventually enlargement of the lesion. More ominous is actual rupture of the plaque, causing thrombosis with sufficient occlusion to result in ACS. A major contributor to this concept of plaque vulnerability has been the finding that cholesterol-lowering statin drugs can diminish the risk of ACS substantially without causing appreciable diminution of the degree of stenosis caused by atherosclerotic lesions (see Chapter 17). Unfortunately, no good test is available at present to assess plaque vulnerability.

The severity of coronary atherosclerotic disease has traditionally been evaluated by coronary angiography, which uses a radiopaque “dye” to image blood flow through the coronary arteries. Besides being invasive, this test has the limitation that it can only identify restrictions to coronary blood flow; it says nothing about the biology of the plaque lesions. Electron beam computed tomography can noninvasively image the accumulation of calcium in atherosclerotic lesions, but ability to predict the future behavior of lesions is still limited (Fusconi, 2003). Blood tests that reflect the actual extent of atherosclerotic disease may be available in the future, for example, measurement of microparticles shed by plaque has been proposed (Heloire, 2003). At present, however, risk of CHD in individuals is mainly assessed indirectly through the measurement of risk factors, each of which appears to play a contributory but not necessarily definitive role (Stampfer, 2004). Several clinical parameters, summarized in Table 18-3, have been established as important risk factors. Additionally, hundreds of laboratory tests have been studied in relation to CHD risk. Of these, several lipid tests, as discussed in Chapter 17, have the best established role in risk assessment. Two newer markers, homocysteine and C-reactive protein, are discussed later.

Next to CHD, and often as a direct consequence of it, the most important heart disease is HF. HF is a clinical syndrome with prominent symptoms, including fatigue, shortness of breath, and pulmonary edema, resulting from impairment in the heart's pumping ability. It is most commonly caused by damage to the myocardium, as results from CHD. Because of the high incidence of CHD and the improving survival of people who suffer from it, HF is a rapidly increasing problem, especially

TABLE 18-3

Clinical (Nonlaboratory) Risk Factors for CHD

- Cigarette smoking (any smoking in the past month)
- Hypertension (blood pressure >140/90 mm Hg or on antihypertensive medication)
- Family history of premature CHD (CHD in male first-degree relative <55 years, or in female first-degree relative <65 years)
- Age (men >45 years; women >55 years)
- Obesity
- Diabetes mellitus
- Sedentary lifestyle

The definitions given in parentheses are used, along with the HDL-cholesterol level, in a risk estimate formula for targeting a desirable LDL-cholesterol level (National Cholesterol Education Program Expert Panel, 2002) (see Chapter 17).

CHD, Coronary heart disease; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

in the elderly. HF can also be caused by mechanical problems, such as valvular disease, which interfere with the pump function of the heart. When the problem is related to filling of the left ventricle during diastole, it is often referred to as diastolic HF.

Diagnosing HF and monitoring its progression can be difficult. A defining parameter for systolic HF is the left ventricular ejection fraction (LVEF), which is the fraction of the left ventricle's blood volume that is ejected during systole. It can be measured by echocardiography or by radionuclide ventriculography. Symptomatic HF is usually associated with LVEF <40%, but correlation between LVEF and subjective symptoms is poor. Until recently, no clinical laboratory test had specific utility in disclosing the presence or severity of HF. This situation has changed with the introduction of testing for cardiac natriuretic peptides, which is discussed later.

Of the myriad other diseases that can affect the heart, brief mention should be made of genetic diseases that, although relatively uncommon, have disproportionate importance because of their potentially life-threatening consequences. The syndrome of hypertrophic cardiomyopathy, described more than a century ago, occurs in 1 in 500 individuals and is the most common cause of sudden death in the young (Taylor, 2004). More than 240 mutations have been tied to this disorder (Gomes, 2004); they affect various proteins of the contractile apparatus, including the troponins, actin, and myosin, and generally are inherited in autosomal dominant fashion. The long-QT syndrome, an abnormality in ventricular repolarization that can cause sudden death, has several distinct variants caused by both autosomal dominant and recessive mutations in ion channels and other proteins (Priori, 2004). Application of molecular diagnostics to these disorders is in its infancy, but evidence already indicates that identifying the genotype not only is useful for confirming the diagnosis but may play an important role in guiding specific therapy.

MARKERS OF MYOCARDIAL DAMAGE

HISTORICAL DEVELOPMENT

Biochemical markers of myocardial damage were essentially a serendipitous discovery in the early 1950s, when LaDue and coworkers were investigating the transaminase enzymes then known as glutamate-oxaloacetate transaminase; now aspartate transaminase, and glutamate-pyruvate transaminase; now alanine transaminase (LaDue, 1954). While surveying various hospital patients, investigators noted that serum transaminase levels rose sharply after an MI, and thus was born the era of "cardiac enzymes." The simple underlying principle, as with other organ markers, is that cell death will cause release of cellular proteins into the circulation. (A more difficult question, still not fully resolved, is the extent to which reversible cell damage can cause protein leakage.)

Transaminases have not endured as cardiac markers because of their abundance in liver, skeletal muscle, and other tissues. They were soon superseded for cardiac diagnosis by two other enzymes, lactate dehydrogenase (LD) and creatine kinase (CK) (Hess, 1963; Roe, 1977). LD is a zinc-containing enzyme that is part of the glycolytic pathway and is found in virtually all cells in the body. It utilizes reduced nicotinamide adenine dinucleotide (NADH) in catalyzing the reduction of pyruvate to lactate and nicotinamide adenine dinucleotide in catalyzing the reverse reaction, making it simple to assay this enzyme because the appearance or disappearance of NADH can be easily monitored at 340 nm (see Chapter 20).

CK transfers high-energy phosphate between creatine and adenosine diphosphate, mainly in muscle cells, but it is found in all types of muscle and in brain and other tissues. With both of these enzymes, improved cardiac specificity was achieved through separation of isoenzymes. LD is a tetramer of two active subunits, H (for heart) and M (for muscle), with a molecular weight of 134 kDa. Combinations of subunits produce five isoenzymes ranging from LD₁ (HHHH) to LD₅ (MMMM); the intermediate isoenzymes contain differing combinations of H and M subunits (LD₂, HHMM; LD₃, HHMM; LD₄, HMMM). As the subunit names imply, LD₁ is relatively abundant in cardiac muscle, whereas LD₅ is more abundant in skeletal muscle. Patients with MI exhibit a characteristic pattern of "flipped" LD, where the normal finding LD₂ > LD₁ is reversed.

CK is predominantly found as a dimer of catalytic subunits, each with a molecular weight of about 40 kDa; the two subunits are termed M (for muscle) and B (for brain). The three resulting isoenzymes are CK₁ (BB), CK₂ (MB), and CK₃ (MM). CK is found in small amounts throughout the body, but is found in high concentrations only in muscle and brain, although CK from brain virtually never crosses the blood-brain barrier to reach plasma. In skeletal muscle, creatine kinase-MB fraction (CK-MB) accounts for 0% to 1% of the total CK in type 1 fibers and 2%–6% of CK in type 2 fibers. During regeneration of skeletal muscle, increased amounts of CK-MB are produced relative to CK-MM, similar to the pattern seen in fetal muscle (Tzvetanova, 1971). In the normal heart, an average of 15%–20% of the CK is CK-MB; its distribution is not uniform, with CK-MB percentage greater in the right heart than in the left heart (Marmor, 1980). A single study, however, suggests that CK-MB is not found in normal myocardium, but appears only when the muscle becomes diseased (Ingwall, 1985). CK-BB is the dominant isoenzyme of CK found in brain, intestine, and smooth muscle.

In the past, clinical laboratories would commonly analyze both CK and LD isoenzymes to improve overall diagnostic performance, especially because the two enzymes exhibit different kinetics, with changes in LD observable for a much longer time than changes in CK. Isoenzyme analyses were relatively lengthy and tedious, generally involving electrophoretic separation, followed by development of color or fluorescence using suitable substrates, followed by densitometric scanning. Hence these tests could be performed only about once per day—a situation that was acceptable at a time when "rule out MI" patients were generally admitted to hospital for at least a several-day period of observation. A major advance was the development of sensitive immunometric assays for proteins using monoclonal antibody technology (see Chapter 44). With this technology, it was possible to develop a CK-MB "mass assay" that did not depend on the protein's enzymatic activity (el Allaf, 1986; Mair, 1991). More important, it provided the opportunity to develop organ markers that were not traditional enzymes, leading to the advent of troponin testing.

High-resolution electrophoresis of serum CK discloses that the MM and MB isoenzymes are heterogeneous, with MB having two sub-bands, and MM three sub-bands. These species, known as isoforms, arise through the action of carboxypeptidase in serum cleaving the terminal lysine off of the M-subunit (Wevers, 1978; George, 1984). Thus the MB isoenzyme can be unmodified (MB₀) or can have one lysine cleaved (MB₁), whereas the MM isoenzyme can be unmodified (MM₀) or can have one (MM₁) or two (MM₂) lysines cleaved. Because enzymatic cleavage occurs over a period of hours following the release of unmodified enzyme into the blood, a relatively high fraction of the unmodified isoform can serve as an indicator of recent tissue damage, as in an acute MI. This test offers improved early sensitivity for detection of acute MI over CK-MB mass assay (Puleo, 1994; Bock, 1999), but it requires a dedicated electrophoresis workstation, and for this reason had somewhat limited use even before the troponin era.

CARDIAC TROPONIN

Troponin (Tn) is a regulatory complex of three proteins that resides at regular intervals in the thin filament of striated muscle. The three individual proteins are tropomyosin-binding subunit (TnT, 37 kDa), inhibitory subunit (TnI, 24 kDa), and calcium-binding subunit (TnC, 18 kDa). The Ca²⁺ trigger for muscle contraction is transmitted via the Tn complex, which causes a conformational change in another thin-filament component, tropomyosin, allowing interaction between actin and myosin to proceed. In contrast to nearly all other muscle proteins, the forms of Tn found in skeletal and cardiac muscle differ. For TnC, the forms found in type 2 fibers and cardiac muscle are identical, obviating its use as a differential marker. TnI has a cardiospecific form (cTnI), as well as distinct forms in types 1 and 2 skeletal muscle fibers, each coded by a separate gene. The presence of the cardiospecific form in tissue other than cardiac

muscle has never been documented (Bodor, 1995). TnT also has distinct forms in myocardium (cTnT) and in fast-twitch and slow-twitch skeletal muscle, but here the situation is more complicated, because cTnT has been detected in fetal skeletal muscle and diseased skeletal muscle. However, post-translational modifications cause detectable differences between cTnT produced in myocardium and cTnT produced in diseased skeletal muscle (Apple, 1998; Apple, 1999). Hence an immunochemical test for cTnT with carefully chosen antibodies, such as the current generation (but not earlier generations) of commercial cTnT assays, should have myocardial specificity approaching 100%. Nevertheless, small increases in circulating cTnT, even with newer assays, have been reported in patients with muscular dystrophy and renal failure who have no other evidence of cardiac disease (Muller-Bardorff, 1997; Hammerer-Lercher, 2001a).

Within the cardiac myocytes, cTnT and cTnI are bound predominantly to muscle fibers, as described earlier, and this bound form is released slowly over the course of 1 to 2 weeks following myocardial infarction. Thus, although cTnI and cTnT are relatively small proteins that are rapidly cleared, their plasma levels fall slowly after cardiac injury. A small fraction of cTn in the myocardial cell is free within the cytoplasm; this averages 6% for cTnT and slightly lower (2%–5%) for cTnI. The free fraction allows early leakage from injured myocardial cells and detection in a time frame similar to that of CK-MB, with cTn reaching a peak at about 24 hours after MI. Because of the slow release of fiber-bound cTn, the rapid decline in circulating cTn right after its peak is typically followed by a plateau or even a small secondary increase. It is important that such an increase *not* be interpreted as evidence of reinfarction. Circulating cTn declines to baseline levels in about 5–10 days, depending on infarct size (Mair, 1997) (Fig. 18-1).

In contrast to other cardiac markers, cTnT and cTnI are nearly absent from normal serum. With the best assays in wide use at present, which have detection limits around 0.01 ng/mL, many healthy individuals have undetectable levels, so the normal range is not well defined. The 99th percentile of the healthy population is around 0.04 ng/mL, depending on the assay. Levels above this threshold are almost certainly indicative of myocyte damage but possibly reveal a much lesser amount of damage than was detectable with earlier cardiac markers such as CK-MB. With the advent of cTn testing, it has become clear that myocyte damage can occur in many circumstances other than coronary artery obstruction: cTn elevations are observed in pericarditis, myocarditis, pulmonary embolism, renal failure, sepsis, and other critical illness (Roongsritong, 2004). Prolonged intense exercise, such as running a marathon, can cause small elevations (Mingels, 2009). Healthy newborns were found to have levels as high as 3.0 ng/mL (Araújo, 2004). Small measured elevations in cTn may also be analytic artifacts (see Assay Procedures later).

OTHER MARKERS

Myoglobin

Myoglobin is a heme-containing protein that binds oxygen within cardiac and skeletal muscle; only a single form is common to both muscle types. Having a molecular weight of only 18 kDa, myoglobin apparently leaks from damaged cells more rapidly than other proteins. Following MI,

elevated myoglobin may be detectable in plasma before CK-MB or cTn. However, with the newest and most sensitive cTn assays, it is not clear how often this may occur. Typically, myoglobin peaks about 6 hours after MI and returns to baseline after 24 hours. Although myoglobin may offer some advantage in early detection of myocardial damage, its value is limited by its lack of specificity.

Carbonic Anhydrase III

Carbonic anhydrase III (CA III) is an enzyme present in skeletal but not in cardiac muscle, hence it can serve as a sort of “negative” cardiac marker. It is released from damaged muscle at a fairly fixed ratio to myoglobin. Thus myoglobin is a more specific indicator of myocardial damage when its ratio to CA III is also elevated (Väänänen, 1990; Brogan, 1996; Beuerle, 2000).

Glycogen Phosphorylase

Glycogen phosphorylase (GP) is a widely distributed enzyme that catalyzes the first step in glycogenolysis. A dimer of identical subunits, it has three characterized isoenzymes, named for the tissue in which they are most expressed: GPLL (liver), GPMM (muscle), and GPBB (brain). GPBB is also expressed in myocardium, as well as other tissues, but it is not found in skeletal muscle, which contains only GPMM. The potential usefulness of GPBB is that it appears to be released earlier than other markers, and may in fact be released under conditions of reversible ischemia that do not give rise to comparable elevations in other markers (Rabitzsch, 1995; Krause, 1996). However, comparisons with modern cTn assays have been limited and not particularly encouraging (Lang, 2000).

Heart Fatty Acid-Binding Protein

Heart fatty acid-binding protein (HFABP) is a low-molecular-weight (15 kDa) protein that is a relatively early marker of myocardial damage, with kinetics similar to that of myoglobin. It is not cardiac specific and therefore does not seem to offer advantages over myoglobin. However, the ratio of myoglobin to HFABP is much lower in heart than in skeletal muscle and may have diagnostic applicability (Van Nieuwenhoven, 1995; Zanotti, 1999).

Myosin

Myosin makes up the thick filament of the muscle contractile apparatus and is composed of a pair of heavy chains (200 kDa) and one pair each of type I and type II light chains (20–26 kDa). Several of these components have been examined as cardiac markers (Katus, 1988; Uji, 1991; Ravkilde, 1994; Ravkilde, 1995). It has not been possible to achieve complete cardiac specificity with myosin, and it is not clear that it would offer any important advantages.

Ischemia-Modified Albumin

Ischemia-modified albumin (IMA) is a unique type of cardiac marker (FDA approved in 2003) that is *not* a protein released from damaged myocytes (Bar-Or, 2000; Bar-Or, 2001; Christenson, 2001; Bhagavan, 2003). Rather, the test detects a variant form of albumin with a reduced affinity for metal ions near the N-terminus. The variant is measured by a spectrophotometric determination of Co⁺⁺ binding. It is postulated to arise from interaction of albumin with free radicals at sites of tissue ischemia. The theoretical advantage of this test is that it detects ischemia before irreversible cell damage occurs. The change in albumin appears to occur within minutes of ischemia and lasts for about 6 hours. The test clearly is not specific for cardiac ischemia, but appears to have a clinical sensitivity of 80%–90% for ACS at the time of presentation—greater than that of the ECG (Roy, 2004; Sinha, 2004). Clinical specificity, in the context of emergency diagnosis of ACS, may be around 50%. Taking any one of elevated IMA, positive ECG, or elevated cTn as a positive result, a test for ACS with very high negative predictive value, but poor positive predictive value, is achieved. More prospective data will be needed to establish the clinical role of this unusual test.

ASSAY PROCEDURES

The measurement of cardiac markers has evolved from measurement of total enzyme activity, to electrophoretic or chromatographic isoenzyme separations, to the current era of sophisticated immunoassay technology. cTn and other protein markers are universally measured by sensitive immunometric assays employing monoclonal antibodies. These can be automated for high volume and round-the-clock availability, or alternatively adapted to point-of-care testing. In contrast, the IMA test is a

Figure 18-1 Schematic depiction of the kinetics of several cardiac markers following a myocardial infarction. CK, Creatine kinase; CK-MB, creatine kinase-MB fraction; cTnI, cardiospecific form of TnI; cTnT, myocardium form of TnT; LD-1, lactate dehydrogenase-1.

colorimetric assay that is commercially available on high-throughput standard chemistry analyzers.

Despite the impressively high sensitivity and specificity of modern immunometric assays, they have intrinsic limitations that must be well recognized in the case of cTn. All proteins, because of post-translational modifications, are heterogeneous analytes, but cTn, which originates in a protein complex that degrades as it is released into the circulation, is especially so. Circulating forms that have been identified include a ternary cTnT-I-C complex, binary cTnI-C, free cTnT (but not free cTnI), oxidized forms (cTnI but not cTnT that contains cysteine residues that can be oxidized to form an intramolecular disulfide bond), phosphorylated forms, and degraded forms (Gao, 1997; Katrukha, 1998; Morjana, 1998; Wu, 1998b; Shi, 1999; Bunk, 2000; Labugger, 2000). Evidently certain epitopes are blocked or modified in some of these forms, because differences greater than 20-fold have been observed in their reactivity with different commercial assays for cTnI (Wu, 1998a; Datta, 1999; Newman, 1999; Shi, 1999; Tate, 1999; Kao, 2001). The problem does not arise in the same way for cTnT because assays are at this time marketed by only one manufacturer. A certified reference material for cTn has been prepared (Bunk, 2006), but it has demonstrated commutability only with plasma cTn specimens for half of the commercial assays (Christenson, 2006). cTn I results will always demonstrate some inconsistency among methods, unless manufacturers adopt the use of very similar antibodies.

Another problem is that because the normal level of plasma cTn is very low, even a minuscule degree of assay interference can elevate a result to the abnormal range, suggesting a strong possibility of ischemic disease to the caregiver. This may lead to unnecessary invasive procedures such as coronary angiography. Various cTnI assays have in fact been found susceptible to interferences from heterophilic antibodies, fibrin, and other substances (Roberts, 1997; Fitzmaurice, 1998; Dasgupta, 1999; Nosanchuk, 1999; Parry, 1999; Galambos, 2000; Dasgupta, 2001). Negative interference due to autoantibodies has also been reported (Eriksson, 2005).

Reference ranges and decision points have been a matter of some confusion (Jaffe, 2004), but in keeping with recent guidelines, there has been a general trend toward use of the 99th percentile of the healthy population as the cutpoint for elevated cTn. It is desirable that the precision of the assay be within a 10% coefficient of variation at this cutpoint, and this is achievable with the newest assays. As the low-end accuracy of cTn assays improves, it is becoming increasingly apparent that the 99th percentile can vary, depending on the reference population chosen, and that levels below the 99th percentile may have clinical significance (Latini, 2007; Eggers, 2009).

CLINICAL PROTOCOLS

Diagnosis of ACS

Diagnosis of MI has evolved from a somewhat leisurely process spanning several days of a hospital stay to an urgent task carried out largely in the emergency department (ED), sometimes within a specialized chest pain center (Zalenski, 1998). Approximately 8 million ED visits in the United States each year are related to chest pain or other symptoms, including shortness of breath, dizziness, or loss of consciousness, which may suggest ACS (Storrow, 2000; Fig. 18-2). Although diagnosis is often straightforward, the challenge is to achieve a very high level of accuracy. Missed diagnosis of ACS, which may occur in about 2% of cases, carries an increased risk of mortality and is the leading cause of malpractice payout for emergency physicians (Karcz, 1996; Pope, 2000). On the other hand, the conservative practice of hospital admission for most patients with suspected ACS spends billions of dollars unnecessarily, because two thirds of these patients turn out not to have ACS.

Biochemical markers play a secondary role in the initial management of patients with suspected ACS. The earliest decision-making, which ideally should take place within 10 minutes of the patient's arrival in the ED, is based on history, physical examination, and 12-lead ECG (Anderson, 2007) (Fig. 18-3). The ECG may establish the diagnosis of STEMI, at which point the patient is a candidate for immediate intervention to restore coronary blood flow (Antman, 2008). Biochemical marker results are not necessary before these interventions are provided, and in fact are likely to be negative at this early time.

If the initial ECG is negative for STEMI, biochemical markers assume increasing importance. Choice of markers and time points for testing has varied among institutions, but it is now generally agreed that cTn is the preferred marker, with little to choose between I and T (Anderson, 2007; Morrow, 2007). cTn does not rise until several hours after the onset of myocyte necrosis, so a specimen obtained at the time of presentation is likely to be negative, and an additional one or two specimens should be drawn at intervals of 6 to 9 hours. The diagnosis of NSTEMI is established by positive biomarker results with appropriate changes over time. Negative biomarker results with ischemic ECG changes (ST depression or T-wave inversions) or other evidence may establish the diagnosis of UA. These two diagnoses are managed similarly, possibly with invasive artery-opening therapy (Anderson, 2007).

If, after several hours, the patient's presenting symptoms have resolved, and ECG and biochemical findings have been consistently negative, then an ACS has been effectively ruled out. For increased safety, before such a

Figure 18-2 Mortality rates of acute coronary syndrome patients as a function of cardiospecific troponin (cTnI) level. The 1441 patients in the TIMI IIIB study were from 21 to 76 years of age, had episodes of pain at rest that were presumed to be ischemic in origin and had lasted for at least 5 minutes (but less than 6 hours) within the preceding 24 hours, and had documented evidence of coronary heart disease. Patients were excluded from the study if left bundle-branch block was noted on presentation, a documented myocardial infarction had occurred within the previous 21 days, a treatable cause of angina was present, thrombolytic therapy had been administered within the previous 72 hours, or angioplasty had been performed in the previous 6 months. Mortality rates at 42 days are shown for ranges of cTnI measured at enrollment. The numbers at the bottom of each bar are the numbers of patients with cTnI in each range, and the numbers above the bars are percentages. $p < 0.001$ for the increase in mortality rate (and the risk ratio for mortality) with increasing levels of cTnI at enrollment. (From Antman EM, Tanasijevic MJ, Thompson B, et al. Cardiac-specific troponin I levels to predict the risk of mortality in patients with acute coronary syndromes. *N Engl J Med* 1996;335:1342–1349, with permission).

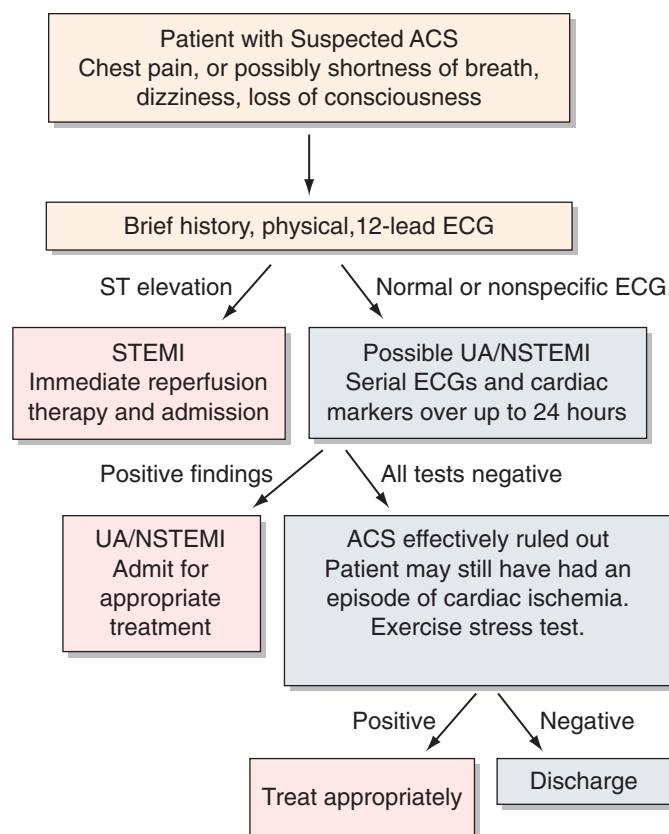

Figure 18-3 Outline of a clinical algorithm for treating patients presenting to an emergency department with symptoms suggesting acute coronary syndrome (ACS). The protocol is general and has to be customized to particular institutions and used with proper clinical judgment. (Adapted from Pearson TA, Mensah GA, Alexander RW, et al. Markers of inflammation and cardiovascular disease: application to clinical and public health practice. A statement for healthcare professionals from the Centers for Disease Control and Prevention and the American Heart Association. *Circulation* 2003;107:499–511). ECG, Electrocardiogram; NSTEMI, non-ST-elevation MI; STEMI, ST-elevation MI; UA, unstable angina.

patient is discharged, a provocative test for CHD is commonly performed, such as a simple exercise ECG test or a more elaborate nuclear imaging or echocardiography stress test (Farkouh, 1998; Lindsay, 1998; Storrow, 2000). These tests must be rapidly and continuously available if the ED is to achieve the desired rapid discharge of low-risk patients. They have the drawbacks of expense and significant numbers of false-positive and false-negative results, depending on the test modality chosen.

Because both clinical care and patient flow through the ED require rapid risk assessment, cardiac marker test results must be available quickly. It is commonly advocated that point-of-care testing be considered when the central laboratory cannot reliably provide results within about 1 hour. Both qualitative and quantitative tests for cardiac markers that are suitable for point-of-care testing are now available and have demonstrated effectiveness (Antman, 1997; Brogan, 1998; Bock, 2008).

Other Applications

Besides ruling in or ruling out the diagnosis of MI, cTn testing can be useful in determining prognosis and adjusting treatment. Higher cTn levels indicate a larger volume of infarcted muscle and a worse prognosis (Böhmer, 2009; Kurz, 2009). A single specimen obtained 72 to 96 hours after the event appears to be most useful for assessment of infarct size (Younger, 2007; Giannitsis, 2008). Although more experience has been acquired in testing for reinfarction using CK-MB, which declines more rapidly after an uncomplicated MI than cTn, it appears that the latter can be equally effective in diagnosing reinfarction (Apple, 2005). When reinfarction is clinically suspected, a blood specimen should be drawn immediately and 3–6 hours later. An increase in cTn of >20%, with an absolute value exceeding the 99th percentile, confirms the diagnosis (Thygesen, 2007).

cTn measurements can usefully suggest adverse outcomes after procedures such as percutaneous coronary intervention (PCI) and cardiac surgery. Because these procedures may be intrinsically associated with

some degree of myocyte damage, it is difficult to justify firm guidelines for defining periprocedural MI. General recommendations that have been advanced include the following: An increase of more than three times the 99th percentile indicates a PCI-related MI; and an increase of more than five times the 99th percentile during the first 72 hours following a coronary artery bypass graft, when associated with other clinical evidence, indicates a periprocedural MI (Thygesen, 2007). Cardioversion, whether external or internal, causes minimal to no elevation in cTn (Allan, 1997; Greaves, 1998; Rao, 1998; Gorenek, 2004).

Transaminases, LD, and LD isoenzymes are no longer recommended as cardiac markers (Apple, 2007). CK-MB testing has persisted to some degree in the troponin era, but because there are few if any situations where it clearly provides additional information, it generally is not regarded as a cost-effective addition to cTn testing (Saenger, 2008).

MARKERS OF CORONARY RISK

CHD is a chronic disease of aging, and obviously, the most desirable approach to management is to prevent or minimize its development. As summarized earlier in the Background section, our understanding of the causation of CHD is still incomplete, so definitive preventive measures are not foreseeable at this time. However, many lines of evidence, the most important being large epidemiology studies, have identified several risk factors associated with CHD. Most of these risk factors pertain not just to the heart but to the general processes of atherosclerosis and/or thrombosis. Hence they have important implications for stroke and peripheral vascular disease as well.

The major clinical risk factors for CHD (not related to laboratory tests) are summarized in Table 18-3. Of risk factors that can be identified by the clinical laboratory, the earliest identified, and still one of the most important, is serum cholesterol. It is actually the LDL fraction of cholesterol, which generally contains about 70% of the total circulating cholesterol, that is directly associated with risk; the high-density lipoprotein fraction is in fact a negative risk factor. The other major lipid class commonly measured in plasma, triglyceride, has been an issue of controversy but now is generally accepted as a significant risk factor. Lipid testing and its relationship to CHD risk assessment are discussed in Chapter 17.

Aside from the lipids, a wide array of plasma constituents have been related to CHD risk. These include various nutrients, hormones, clotting factors, drugs, toxins, oxidants, antioxidants, and markers of inflammation or infection. In this chapter, only two markers that appear to be relatively important will be discussed: CRP and Hcy.

C-REACTIVE PROTEIN

First isolated in 1930 from the plasma of patients with pneumococcal pneumonia, CRP was so named because it binds to the C-polysaccharide of the pneumococcus. It was later found that the protein appeared in plasma during many infectious or inflammatory conditions, and CRP was the original acute phase reactant. CRP has now been characterized as a member of the pentraxin family of proteins. It comprises five protomers, each of 206 amino acids and molecular weight 23 kDa, arranged in cyclic symmetry. With the participation of Ca^{++} ions, it binds various proteins and phospholipids, particularly phosphocholine. It opsonizes particles and activates complement via the classical pathway, but its actual biological function is unknown (Szalai, 1999; Black, 2004).

In plasma from normal individuals, the median CRP concentration is about 1 mg/L, and the 99th percentile is about 10 mg/L. In individuals with acute illness, cytokines, chiefly interleukin-6, stimulate hepatic production of CRP, and plasma levels increase to 300 mg/L or more. Plasma CRP is increased in a variety of disorders, including most bacterial (but usually not viral) infections. MI is among the acute illnesses associated with elevation of plasma CRP (de Beer, 1982).

Epidemiologic studies have established that individuals with higher baseline levels of plasma CRP are at increased risk for CHD and stroke. In the relatively early Physicians Health Study, which enrolled 22 000 male U.S. physicians to examine the cardioprotective effects of aspirin and beta-carotene, plasma CRP averaged 1.51 mg/L in participants who developed MI, 1.38 mg/L in those who developed stroke, and 1.13 mg/L in controls who did not suffer vascular events (Ridker, 1997). In the larger and more recent Reykjavik study, the average baseline CRP was 1.75 mg/L in participants who developed MI, versus 1.25 in those without vascular events (Danesh, 2004). Similar findings, as summarized in a 2004 meta-analysis, have been reported from some 20 other epidemiology studies, although the degree of independent risk associated with CRP has varied (Danesh,

Figure 18-4 Chemical structure of homocysteine and related compounds.

2004). A report on the Women's Health Study suggested that CRP was actually more predictive than LDL cholesterol (Ridker, 2002), whereas investigators for the Reykjavik study reported that CRP is less predictive than total cholesterol, cigarette smoking, or systolic blood pressure. Differences may relate to the nature of the population studied and the means of correction used for traditional risk factors.

Elevation of plasma CRP (as indicated earlier) that confers excess coronary risk is minute compared with the hundred- to thousand-fold increases that occur with overt inflammatory or infectious diseases. For this reason, testing of CRP related to cardiac risk has been given the somewhat misleading name of high-sensitivity CRP (hs-CRP). Actually, even at concentrations around 1 mg/L or less, CRP is a relatively abundant plasma protein, which does not require the most sensitive (or expensive) techniques for accurate measurement. Methods such as nephelometry, which had been established for measuring CRP as an inflammatory marker, have been readily adapted to hs-CRP assays; the main differences involve degree of dilution and calibration. Commercial hs-CRP assays have adequate precision, and the long-term stability of hs-CRP in individual patients appears to be comparable with that of other risk factors, such as blood pressure and cholesterol (Danesh, 2004).

Although diverse evidence points to a role of inflammation in CHD (Paoletti, 2004; Hansson, 2005), a precise mechanism for the relationship of plasma CRP to CHD risk is lacking at this point. A key question still unresolved is whether the elevation in CRP is a cause or a consequence of the disease (or possibly both) (Hingorani, 2009). The inflammatory response associated with atheromatous lesions may trigger enough cytokine production to be associated with a measurable rise in plasma CRP. CRP may, in turn, through its proinflammatory effects, increase plaque vulnerability or have other effects that worsen the severity of CHD. The presence of CRP in human atheromatous lesions has been demonstrated (Reynolds, 1987), and in rats it has been shown that injection of human CRP after ligation of the coronary artery enhances infarct size (Griselli, 1999). Another intriguing possibility is that the risk associated with CRP relates to cytokine production by adipocytes, and that CRP is essentially a biochemical marker of the recently recognized metabolic syndrome (Yudkin, 1999; Ridker, 2004).

Given the variations in quantitative risk estimates, the unclear role of CRP in the pathogenesis of vascular disease, and the lack of specific treatment for high CRP, the usefulness of the hs-CRP test in individual patients has been controversial. A joint committee of the Centers for Disease Control and Prevention and the American Heart Association issued recommendations in 2003, some of which are listed in Table 18-4. Following a recent trial in which benefits of statin therapy were demonstrated in individuals with relatively low LDL cholesterol but high hs-CRP, it has been suggested that asymptomatic men older than 50 years and asymptomatic women older than 60 years be screened by hs-CRP when LDL cholesterol is not elevated and a decision to treat with statins is not otherwise clear (Ridker, 2008; Mora, 2009).

HOMOCYSTEINE

Hcy (Fig. 18-4) is a sulfur-containing amino acid that is not incorporated into protein but is a metabolic intermediate; it can be methylated to form methionine, or it can be converted through the transsulfuration pathway to cystathionine and then to cysteine. Hcy can exist in plasma as the species

TABLE 18-4

Recommendations of a Joint Committee of the American Heart Association and the Centers for Disease Control and Prevention on CRP Testing to Assess CHD Risk

(Pearson, 2003)

- If inflammatory markers are to be used in assessment of CHD risk, hs-CRP is the current analyte of choice.
- Optimally, hs-CRP results should be averaged from two specimens drawn about 2 weeks apart. If a level >10 mg/L is identified, there should be a search for an obvious cause of infection or inflammation; this result should then be discarded, and another test done 2 weeks later.
- Decision intervals are as follows: <1 mg/L, low risk; 1–3 mg/L, intermediate risk; >3 mg/L, high risk (approximately corresponding to tertiles in the adult population).
- Patients most likely to benefit from an hs-CRP test would be those in whom the risk estimate from established factors is moderate (i.e., approximately 10%–20% risk of CHD in the next 10 years), and the physician desires additional information to guide preventive therapy.
- The role of hs-CRP in secondary prevention (i.e., prevention of disease progression in patients with established CHD) is limited, because it is not likely to alter management (which needs to be aggressive, regardless of additional information provided by CRP or other markers).
- Universal hs-CRP screening of the adult population is *not* warranted.

CHD, Coronary heart disease; CRP, C-reactive protein; hs-CRP, high-sensitivity C-reactive protein.

with a free sulfhydryl group, as a disulfide (homocystine), or as a mixed disulfide, linked to a plasma protein via one of its cysteine residues. It is the sum of these, which may be referred to as “total homocystine,” “homocyst(e)ine,” or simply “homocysteine” that is generally measured.

Excessive levels of circulating Hcy generally reflect a diminished activity of one of the enzymes involved in its metabolism. The classical syndrome of homocystinuria, first described in 1962 (Carson, 1962; Gerritsen, 1962), is due to a homozygous defect in the enzyme cystathionine-β-synthase (CBS). It results in very high circulating levels of the various forms of Hcy and methionine. Clinical manifestations include dislocation of the optical lens, osteoporosis with associated skeletal abnormalities, mental retardation, psychiatric disturbance, and thromboembolic disease, such as CHD (Yap, 2003).

The basis of the damaging effects of Hcy is uncertain. At a biochemical level, oxidant stress and inhibition of transmethylation reactions are likely possibilities. Cellular effects that have been documented in experimental systems include endothelial injury, alteration of nitric oxide metabolism, platelet activation, and smooth muscle proliferation (Thambyrajah, 2000). Some of the toxicity of Hcy may derive from its enzymatic conversion to Hcy thiolactone (see Fig. 18-4), which can modify LDL and enhance its uptake by macrophages (McCully, 1993; Vignini, 2004).

The development of Hcy as a CHD risk marker in some ways parallels that of cholesterol: The regular occurrence of atherosclerosis in persons with massive elevation, due to an inborn error of metabolism, led to the hypothesis of increased risk in individuals with more moderate elevations. Experimentally induced hyperhomocysteinemia in animals lent support to the hypothesis (McCully, 1993). In humans, mild to moderate elevations

in Hcy can have many causes. Genetic causes include a heterozygous defect in CBS, a defect in methionine synthase (rare), or a defect in 5,10-methylenetetrahydrofolate reductase (generally rare, except for a temperature-sensitive form that is relatively common). Nutritional causes include a deficiency of any of the vitamin cofactors involved in metabolism of Hcy: folate, B₁₂, or pyridoxine (B₆).

Many of the earlier epidemiology studies seemed to confirm a correlation between moderate Hcy levels and CHD. For example, in the Physicians Health Study, it was initially reported that having a Hcy level in the upper 5% of the population conferred a 3- to 4-fold higher risk (Stampfer, 1992). However, other studies, including a longer-term follow-up in the Physicians Health Study (Chasan-Taber, 1996) and many of the larger and more recent studies, have shown little or no association between moderate elevations of Hcy and CHD risk. A recent meta-analysis has supported a moderate association between Hcy and CHD risk (Humphrey, 2008). Widespread folate supplementation of food has probably tended to diminish average circulating Hcy in the U.S. population, and sparse data support the cardioprotective effects of Hcy-lowering therapy. For these reasons, no general advice regarding widespread Hcy screening is available (Kaul, 2006). However, measurement of Hcy may be warranted in individuals who develop CHD despite being at relatively low risk according to traditional risk factors.

Hcy has traditionally been measured by chromatographic techniques (Vester, 1991; Ubbink, 1999; Frick, 2003; Arndt, 2004). A method using enzymatic adenosylation followed by immunoassay has been automated on the Abbott IMx analyzer (Shipchandler, 1995), and purely enzymatic methods suitable for automation have also been introduced (Tan, 2000; Huijgen, 2004; Roberts, 2004). Attention must be paid to proper sample collection and storage to prevent an artifactual increase in measured Hcy (Willems, 2004).

MARKERS OF CONGESTIVE HEART FAILURE

CARDIAC NATRIURETIC PEPTIDES

The heretical concept that the heart could be an endocrine organ was enforced by two reports in 1956: (1) that inflating a balloon inside the left atrium of a dog caused an increase in urine flow (Henry, 1956); and (2) that structures resembling secretory granules were visible on electron micrographs of guinea pig atrial cells (Kisch, 1956). In 1981, extracts of rat heart atria (but not ventricles) were found to have a natriuretic effect (de Bold, 1981), and in 1984, a peptide named atrial natriuretic peptide (ANP) was isolated from human heart (Kangawa, 1984). A short time later, a similar peptide named brain natriuretic peptide (BNP) was isolated from porcine brain (Sudoh, 1988). It turns out that in humans, BNP is produced mainly in the cardiac ventricle (Mukoyama, 1991), so the hormone now is commonly referred to as B-type natriuretic peptide.

Members of the natriuretic peptide family are illustrated in Figure 18-5. Their notable common feature is a 17 amino acid ring structure, closed by a cystine bridge, with substantial homology among the family members. C-type natriuretic peptide (CNP), described in 1990, is produced not in the heart but rather in endothelial cells (Sudoh, 1990). D-type natriuretic peptide (DNP) was isolated in 1992 from the green mamba snake, *Dendroaspis angusticeps* (Schweitz, 1992). DNP immunoreactivity was later reported in human plasma (Schirger, 1999), but this peptide has not been definitively demonstrated in humans (Richards, 2002). Finally, urodilatin is a form of ANP with four additional amino acids at the N-terminus; it is likely produced in the kidney by alternative splicing of the same gene product (Schulz-Knappe, 1988). Both ANP and BNP have been investigated regarding testing for HF; the latter has proved more useful, so further discussion will be confined to the BNP system.

Circulating BNP derives from a 108 amino acid prohormone, proBNP, which is cleaved within the cardiac myocyte by the endoprotease furin to a 32 amino acid C-terminal fragment, the active BNP, and an inactive N-terminal fragment, N-BNP or NT-proBNP (Sawada, 1997). Secretion of both fragments is enhanced by ventricular wall stretch and volume overload, as occur in HF (Tabbibizar, 2002). BNP is removed from the circulation by binding to a clearance receptor and also through the action of endopeptidases; its circulating half-life is approximately 22 minutes. The circulating half-life of N-BNP is considerably longer (60–120 min), and its mechanism of clearance is not well understood.

BNP and the other natriuretic peptides exert their effects through two types of G-protein-coupled receptors, resulting in release of the second

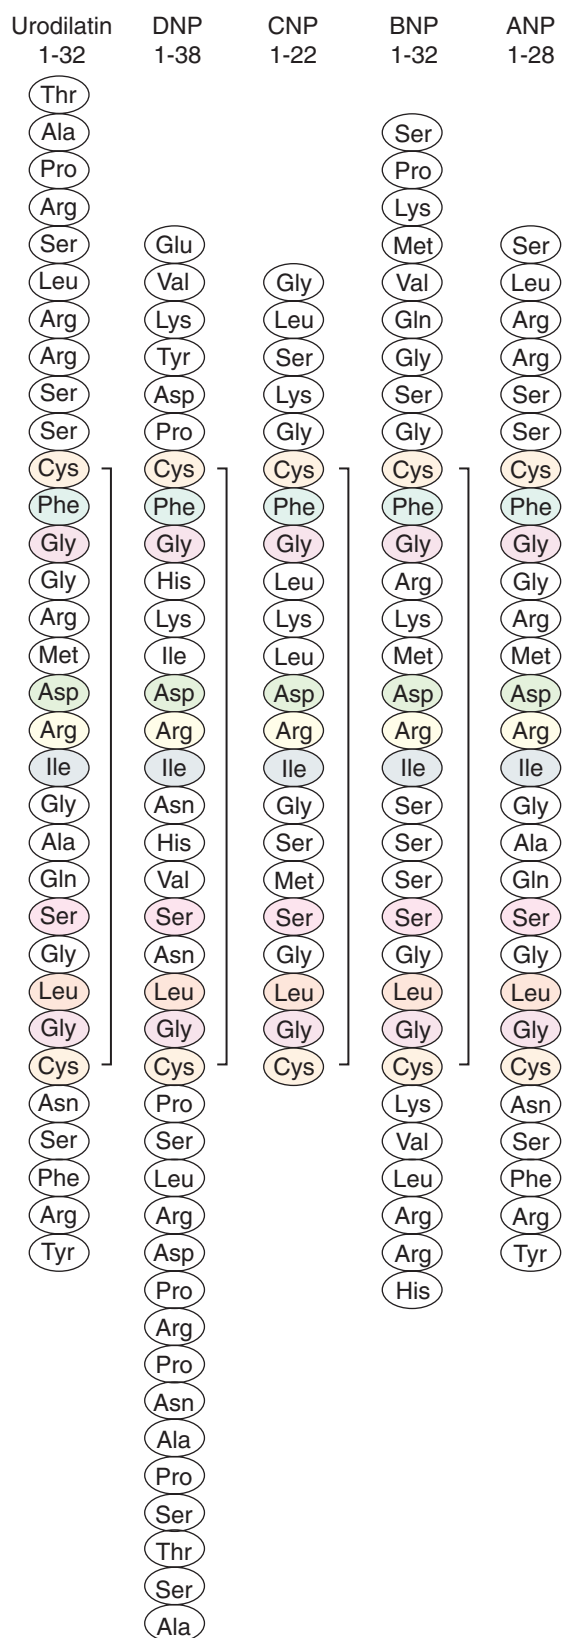

Figure 18-5 Amino acid sequences of the natriuretic peptides. Amino acids preserved through the family are indicated in color. ANP, Atrial natriuretic peptide; BNP, B-type natriuretic peptide; CNP, C-type natriuretic peptide; DNP, D-type natriuretic peptide.

messenger cyclic guanosine monophosphate. They downregulate the renin-angiotensin-aldosterone system, decrease sympathetic nerve activity in the heart and kidney, increase renal blood flow, and increase sodium excretion via a direct effect on the renal collecting duct (Beltowski, 2002; Spevack, 2004).

Plasma levels of BNP are less than 100 pg/mL in most healthy individuals; reference ranges depend on age and gender. The best established application of BNP measurement is for diagnosing acutely ill patients presenting to emergency service with shortness of breath. Distinguishing HF from lung disease, such as emphysema, in these patients is occasionally difficult, and until now no laboratory test has been specifically applicable. The multinational Breathing Not Properly study enrolled patients who presented to emergency centers with dyspnea and used a point-of-care method for measurement of BNP. At a decision point of 100 pg/mL, the BNP test had the following characteristics for diagnosis of HF: sensitivity 90%, specificity 76%, positive predictive value 79%, and negative predictive value 89% (Maisel, 2002). Among patients with a history of ventricular dysfunction, BNP was higher in those whose current symptoms were thought to be caused by HF; it was also higher in patients with more severe failure (see <http://www.americanheart.org/presenter.jhtml?identifier=4569>) (Fig. 18-6).

BNP levels decline when effective therapy for HF is instituted, and so the test may be used to monitor the course of treatment (Cheng, 2001; Faggiano, 2009; Novo, 2009). Other proposed applications include risk stratification of patients with ACS (de Lemos, 2001; Omland, 2002; Jernberg, 2004; Wiviott, 2004); monitoring disease severity in patients with stable CHD (Weber, 2004); screening for ventricular dysfunction

in selected populations (Bay, 2003; Nielsen, 2003); and testing for drug cardiotoxicity (Okumura, 2000). However, the test is relatively expensive, so routine application that leads to a large volume of testing needs to be carefully considered. Some medical centers have introduced restrictions to limit the use of BNP for monitoring inpatients (Lum, 2006).

A major limitation of BNP is that a wide range of values is observed in patients with and without HF, and all of the determinants of the circulating BNP level have not yet been well established. BNP is increased in conditions of fluid imbalance other than HF, particularly renal insufficiency, which commonly coexists with HF (McCullough, 2004). In individuals without HF, higher levels are associated with female gender, advanced age, and lower body mass index (Chiong, 2009). Also, patients with symptomatic HF, especially when it is chronic and stable, can have “normal” levels (Tang, 2003). Intraindividual variability is relatively high; in a group of patients with stable, chronic HF, week-to-week variability for BNP and N-BNP was 30%–40% (Bruins, 2004). At this time, it appears that the most appropriate use of the BNP test is as an adjunctive test to rule out HF in the acute setting; it must *not* be used as a sole criterion for establishing the diagnosis of HF (Jessup, 2009). In other contexts, it should be used judiciously as more information becomes available.

The earliest assay for BNP commercially available in the United States was an immunoassay using an instrument most suitable for point-of-care measurement. Recently, the test has become available on large, automated immunoassay platforms. Assays for both BNP and N-BNP are available; a clear advantage of one biomarker over the other for any particular application has not been established (Hammerer-Lercher, 2001b).

Besides being a biomarker for HF, BNP has natriuretic, vasodilatory, and other effects that are ameliorative for the syndrome, and in fact is available as the drug nesiritide (Natrecor) for the treatment of HF. Because of the short half-life of BNP, measured levels several hours after its administration would reflect endogenous secretion. However, the utility of BNP measurement in the context of its therapeutic administration has not been established at this time.

OTHER CONDITIONS ASSOCIATED WITH ATHEROSCLEROSIS OR THROMBOSIS

A cerebrovascular accident, or stroke, is another dreaded complication of atherosclerotic disease. About 795,000 Americans suffered a stroke in 2009, versus about 1,250,000 who suffered an ACS (Lloyd-Jones, 2009). Many strokes are presumably caused by a mechanism similar to the usual ACS, where atherosclerotic plaque eventually becomes unstable and ruptures, resulting in thrombotic occlusion. However, additional mechanisms can cause ischemic stroke, and 20% of strokes result from hemorrhage rather than from vascular occlusion. Considerable effort has been directed at finding biomarkers for stroke that might rival the utility of troponin and other markers for cardiac disease. Candidate markers have included neurotransmitters; proteins produced in neurons or glia such as tau, S100b, and neuron-specific enolase; inflammatory mediators such as CRP, interleukins, and matrix metalloproteinases; and others. At the time of writing, none has been shown to have sufficient sensitivity and specificity for incorporation into routine practice (Whiteley, 2009). Possibly a multiple marker approach will eventually be successful, but at present, the diagnosis and management of stroke rests on clinical findings and imaging studies.

Thrombosis in peripheral veins can result in dislodging of part of the thrombus—embolization—which, after passing through the right side of the heart, will lodge in the lung, causing the syndrome of a pulmonary embolus (PE). Depending on the size of the PE, consequences can range from minimal to sudden death. PE can cause chest pain, ECG abnormalities, and increased cTn levels, and thus may be confused with an ACS. Measurement of D-dimer, a specific degradation product of fibrin (see Chapter 39), has become a useful laboratory test for ruling out PE and venous thrombotic disease in general. Almost any activation of the coagulation cascade, anywhere in the body, leads to production of D-dimer; hence elevated levels are widespread, especially in hospitalized patients, and have little meaning. When pre-test probability of thrombotic disease is low, however, low levels of D-dimer have high negative predictive value in excluding the diagnosis of PE (as well as any venous thrombosis). Sensitive immunoassay measurements of D-dimer for this purpose are now available (Adam, 2009).

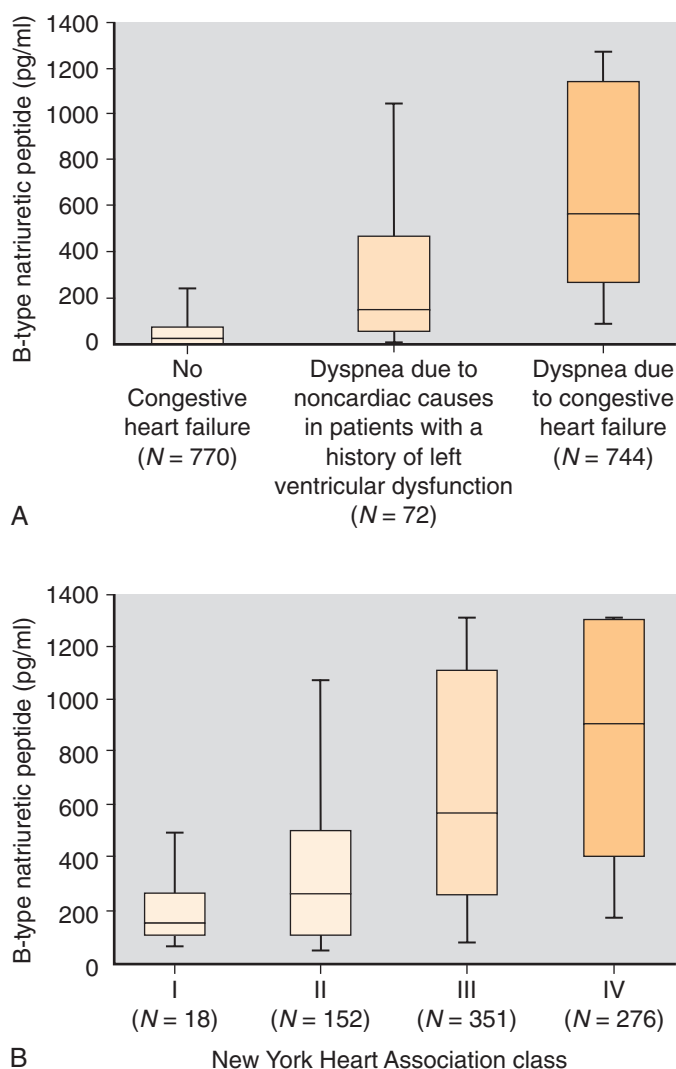

Figure 18-6 Box plots showing median levels of B-type natriuretic peptide in patients presenting to an emergency department with dyspnea, in the Breathing Not Properly study. **A**, Patients in different diagnostic categories. **B**, Patients with heart failure, classified according to the New York Heart Association criteria. A higher class indicates more severe disease, as evidenced by a lesser amount of activity needed to provoke symptoms. Boxes show interquartile ranges, and I bars represent highest and lowest values. KEY POINTS

- The primary structure of a protein is its linear sequence of amino acids with different side groups, which determine how the protein folds on itself (secondary and tertiary structures) and how it reacts with other molecules and cells (i.e., its molecular identity).
- Methods to quantitate and fractionate proteins are based on turbidimetry, colorimetry, absorption spectrophotometry, dye binding, column chromatography, electrophoresis, and immunoassays.
- Protein electrophoresis separates proteins according to their electrical charges (usually at pH 8.6).
- The major proteins in plasma that contribute to the electrophoretic pattern are albumin, α_1 -antitrypsin, α_2 -macroglobulin, haptoglobin, β -lipoprotein, transferrin, complement C3, fibrinogen, and immunoglobulins.
- Several minor components of plasma proteins, such as ceruloplasmin, C-reactive protein, prealbumin, and protease inhibitors, have clinical utility in diagnosing and monitoring diseases and are quantitated by immunoassays.
- Patterns of protein electrophoresis in serum and urine are characteristic of specific diseases primarily involving changes in synthetic rates (liver), loss (renal), or inflammatory states.
- Hereditary deficiency of some plasma proteins leads to significant diseases (e.g., α_1 -antitrypsin).
- Proteins in plasma play several roles, including maintaining oncotic pressure, transporting small molecules, and promoting or inhibiting inflammatory reactions.
- The major clinical use of serum and urine protein electrophoresis is to screen for monoclonal gammopathies.

Examination of the proteins in plasma can provide information reflecting disease states in many different organ systems. The most frequently performed measurement—that for total protein—is usually performed on serum, which has no fibrinogen and no anticoagulant that may slightly dilute proteins in plasma. Although total protein determination gives the physician some information as to a patient's general status regarding nutrition or severe organ disease (as in protein-losing states), further fractionations yield far more clinically useful information.

Additional quantitation of albumin, for example, is more informative regarding nutritional status, liver synthetic capacity, and protein-losing

nephropathy or enteropathy. It allows the clinician to interpret high or low calcium and magnesium levels, because albumin binds about one half of each of those ions on a molar basis. Calculated differences between total protein and albumin represent the value of all globulins, a composite of the other fractions that individually may rise several-fold in severe disorders.

Protein electrophoresis separates the globulins from albumin and resolves the major proteins of serum into patterns that may be highly specific for some diseases. High-resolution techniques can provide a display of all components in concentrations down to about 1 g/L (0.1 g/dL in traditional units); however, at that level, quantitation by scanning of stained proteins is not highly reliable, and alternative methods should be employed. Such techniques, involving immunologic detection of individual proteins, have the dual advantages of specificity and sensitivity over electrophoresis (see Chapter 44).

Yet there is much to be appreciated from visual inspection of an electrophoretogram of proteins, because the human eye is highly efficient at detecting subtle variations in individual proteins, as well as alterations in protein patterns. Identification of these patterns is a useful screening method to be followed by more specific confirmatory procedures to identify and quantitate aberrant protein bands. Protein electrophoresis also can be a useful tool for monitoring patients over long periods of time when marked alterations are noted in levels of particular proteins, such as in myeloma, nephrotic syndrome, cirrhosis, or extensive body burn.

This chapter will review protein structure, methods of measurement and separation, the major plasma proteins (except coagulation factors, immunoglobulins, and the complement system, which are covered in Chapters 39, 46, and 47), and some of the patterns encountered in particular disease states.

PROTEIN STRUCTURE

The backbone of all protein molecules is a continuous chain of carbon and nitrogen atoms joined together through peptide bonds between adjacent amino acids. At one end (the amino-terminus) is a free amino group, and at the other end (the carboxy-terminus) is a free carboxyl group. Whereas the peptide backbone is qualitatively invariant between different proteins (its total length is equivalent to the total number of amino acids in a particular protein), proteins have structural identity by virtue of the side groups or residues of the constituent amino acids. The average molecular weight of an amino acid is 120 Da. Serum proteins range in size from roughly 66 kDa to over 700 kDa. These amino acid side chains are conventionally grouped according to chemical nature: hydrogen (glycine), aliphatic (alanine, valine, leucine, and isoleucine), hydroxymethylamino (serine and threonine), aromatic (tyrosine, phenylalanine, and tryptophan),

imino (proline and hydroxyproline), acidic (aspartate and glutamate), basic (arginine, histidine, and lysine), amides (asparagine and glutamine), and sulfur-containing (cysteine and methionine). These different side chains may be charged, polar, or hydrophobic, resulting in the tendency for them to be relatively soluble or insoluble in water, respectively.

The linear sequence of amino acids in a protein is called its *primary structure*; this sequence of amino acids determines the identity of a protein, what its molecular structure is, what functions it can perform, how it can bind to other molecules, and how it can participate in the processes of recognition between molecules and cells. These biological interactions are guided by reactivities between charged groups on one molecule and those on another, and similarly by hydrophobic interactions between molecules. Analytic processes such as chromatography, electrophoresis, dye binding, light absorbance, and others also depend on the primary amino acid sequence.

The *secondary structure* refers to specific regular three-dimensional conformations into which portions of the polypeptide chain fold. Three such structures have been identified (Branden, 1991). First is the α -helix, in which the chain forms a regular helix such that the backbone C=O of the i th peptide group participates in a hydrogen bond with the N-H of the $(i+4)$ th peptide unit. The second is β -pleated sheets in fully extended structures, in which the chain forms a flat structure such that the side chains of adjacent amino acids point in opposite directions; in this conformation, two or more extended chains can associate so that the maximum number of C=O...H-N bonds form between them. β -Pleated sheets can have their individual β -strands in parallel or antiparallel orientations. Finally, a third grouping of structures is the bend conformation, in which the direction of the polypeptide chain reverses itself, thereby allowing long primary structures to bend back on themselves and assume compact conformations.

The core of a protein molecule typically consists of combinations of α -helices and β -strands linked by loops of various lengths and shape. This inner core generally contains hydrophobic amino acids, whereas the loops and other surface portions of the protein molecule are richer in polar and charged amino acids that are hydrophilic. Upon degradation, some proteins (e.g., serum amyloid-associated protein, immunoglobulin light chains, prealbumin) release fragments rich in β -regions. These fragments are capable of coming together spontaneously in vivo to form deposits of β -sheets in fibrils that constitute amyloid. Recent work has shown an association between the genotype of apolipoprotein E (especially the allele apoE-4) and the progression of late-onset Alzheimer's disease, in which cerebral plaques of amyloid form within the brain. These genetic findings suggest that Alzheimer's disease may be understood and treated as a disease that has a biochemical basis in β -pleated sheet generation (Roses, 1994; Hayashi, 2004).

Molecular regions with clusters of hydrophobic side groups tend to remain on the interior of a protein that is soluble in water, whereas those regions with clusters of charges or other hydrophilic moieties tend to appear on the protein's surface. Conversely, proteins that are membrane bound usually have a distinct hydrophobic segment that protrudes to anchor the protein molecule in the lipid phase of the membrane. The actual three-dimensional structure or folding pattern of the protein, uniquely determined by its amino acid sequence, is termed its *tertiary structure*. Individual proteins or monomeric subunits may form more stable complexes, such as dimers, trimers, and tetramers; this is termed *quaternary structure*.

The sulfhydryl group on a cysteine residue can form a disulfide (covalent) bond with another cysteine within the same protein to hold different segments tightly together. This action helps stabilize the whole structure from disruption by mechanical, thermal, or other forces. These intramolecular disulfide bonds most likely form after spontaneous protein folding along the linear amino acid sequence into most thermodynamically stable conformations. Disulfide bonds can also form between cysteine residues on different molecules, thereby stabilizing multimeric molecular structures (e.g., haptoglobin, von Willebrand antigen).

The acidic and basic amino acids determine the net charge on a protein and hence its electrophoretic mobility. The charge on carboxyl and amino groups is a function of pH (i.e., whether a hydrogen ion is bound to or dissociated from the group). Combining all the different side groups and their different degrees of dissociation, the pH at which a particular protein has net charge equal to zero is called its isoelectric point (pI). Proteins with pI less than 7 are acidic and tend to have carboxyl side groups exposed, whereas those with pI greater than 7 are basic (e.g., histones that, in turn, bind to the external helical structure of DNA that is negatively charged with phosphate groups).

Proteins are synthesized from the amino end to the carboxyl end by ribosomes translating from the information encoded in messenger RNA. The initial translation product of some proteins is acted on before secretion by proteolytic enzymes that convert a preform to the mature protein by removal of a signal peptide (generally hydrophobic) that otherwise holds the new protein molecule to the endoplasmic reticulum. Release of a preprotein from the endoplasmic reticulum entails passage through a membrane pore with the participation of various translocation factors (Brodsky, 1998). The correct assembly of a protein may critically depend on the function of so-called molecular chaperones, which are other proteins that guide the folding of nascent proteins in concert with proteases that remove selective segments to achieve functional conformations (Wickner, 1999). Many genetic diseases are due to harmful mutations in DNA, leading to alterations in the amino acid sequence of a protein that may block this complex assembly process or that may render any assembled protein molecules nonfunctional (Kuznetsov, 1998).

Additional modifications to protein structures occur post-translationally (i.e., after joining of the amino acids is complete) (Harding, 1985). Phosphorylation consists of the enzymatically regulated attachment of phosphate groups to serine and threonine groups as well as tyrosine (e.g., by tyrosine kinases) in the peptide backbone, thereby forming phosphoproteins with a more negative charge that can alter protein functions and state of activation. Glycosylation may occur spontaneously, in the presence of sugar molecules, or in a directed manner under enzymatic control, in which oligosaccharides, frequently terminating with sialic acid (which carries a negative charge), are attached to the protein (Van den Steen, 1998). These species of molecules are termed glycoproteins. Linkages are generally to asparagine residues through *N*-acetylglucosamine or to serine and threonine residues through *N*-acetylgalactosamine. Proteolysis results in the cleavage or removal of short segments of the peptide backbone that can open up catalytic sites of a zymogen (e.g., plasminogen to plasmin) or facilitate recognition by a receptor molecule (e.g., proinsulin to insulin). Many of these post-translational steps are unique to eukaryotic cells and do not occur in prokaryotic cells; this point is very important to the biotechnology industry, which uses cloned genes to produce human proteins in bacteria, yeast, or other artificial cell types, and so must take additional steps to synthesize accurate molecules (Jenkins, 1996). Post-translational changes in the structure of proteins influence their antigenicity, specific chemical or catalytic activities, abilities to bind to receptors, and electrophoretic mobilities.

TECHNIQUES OF PROTEIN SEPARATION

ELECTROPHORESIS

Modern understanding of the protein composition of serum and plasma derives from the electrophoretic techniques introduced by Tiselius. He separated proteins dissolved in an electrolyte solution by application of an electric current through a U-shaped quartz tube that held the protein solution. At pH 7.6, four serum protein fractions, designated albumin, α , β , and γ , were identified and quantified optically by change in refractive index at the boundaries among these bands. Because separation was achieved in a homogeneous solution without solid support medium, convective forces prevented resolution into distinct zones. Hence, this technique has been termed moving boundary or frontal electrophoresis. Introduction of filter paper as an anticonvection support medium permitted separation of the protein fractions into discrete bands or zones in a process termed *zonal electrophoresis*. On solid support medium and at pH 8.6, the α fraction further splits into two groups of proteins, α_1 and α_2 . Other support media, such as cellulose acetate membrane, agarose gel, starch gel, and polyacrylamide gel, have been used. Cellulose acetate and agarose have predominated in the clinical laboratory because of ease of use, low cost, and commercial availability (Jeppsson, 1979).

Application of samples can be done in wells that are cut into the gel, but this process typically leaves an artifact that can interfere with the scan. A method to get around this problem involves soaking the sample into the gel by means of an overlying template. Each end of the gel is then immersed into separate buffer chambers in which electrodes are mounted. A voltage is applied between the electrodes, generating a current that passes through the gel, usually for a period of about 30 minutes, to achieve desired resolution. The ionic strength of the buffer determines the amount of current and the movement of the proteins for a fixed voltage. If ionic strength is low, relatively more current is carried by the charged proteins. If ionic strength is high, less current is carried by the proteins, which move a shorter distance. If the electrodes are not properly aligned, the current

Figure 19-1 Positions of major serum proteins in a normal person using electrophoresis in agarose. Individual proteins separate according to their electrical charge between the anode (positive pole) and the cathode (negative pole).

may be denser on one side of the gel than on the other; proteins will migrate farther on the side with more current. If electrophoresis proceeds too long, the proteins may migrate off the gel into the buffer. If there is a break in the electrical circuit and no current passes, the proteins will not move from the point of application. Frequently, gels show the “smile artifact,” in which samples at the center of the gel migrate farther than those at the edges.

After electrophoresis, the gel is treated with a mild fixative, such as acetic acid, that precipitates the proteins at the positions to which they have migrated. They are then stained, and the gel is dried and cleared of excess stain. Protein patterns can be inspected visually for qualitative identification of abnormal proteins. Densitometric scanners are used to generate tracings and to quantitate the relative percentages of protein in each fraction. Those percentages are then multiplied by the total protein (separately measured) in the sample to yield the concentration of protein in each fraction.

When an electrophoretic support medium has a negative charge, the electromotive force to which it is subjected tends to move it toward the anode (positive pole; Fig. 19-1). However, the solid support medium is fixed, and so it cannot move. The complementary positively charged ions in the surrounding buffer are free to move under the electromotive force, and they carry with them molecules of the solvent water, which are clustered around their charges. The net result is flow of buffer toward the cathode. This buffer flow is termed electro-osmosis or endosmosis, which also carries the proteins with it to some extent by mechanical flow, not by charge. The actual distance traveled by a particular protein migrating in an electrical field is determined by the combined magnitudes of the electromotive force (a feature of the protein itself and the pH) and the electro-osmotic force (a function primarily of the support medium). When the electro-osmotic force is greater than the electrophoretic force acting on weakly anionic proteins (e.g., γ -globulins), those proteins move from the application point toward the cathode, even though their charge is slightly negative.

Through critical manipulations of buffer salt composition, endosmotic properties of the medium, and means of sample application, commercially available electrophoretic agarose plates now achieve consistently high-resolution quality that allows routine separation of all major serum protein species (Fig. 19-2). Because of variability in the chemical formulations of gels, it should not necessarily be expected that each manufacturer's electrophoretic system will yield identical protein separation patterns. Furthermore, optimal separation of isoenzymes generally requires different buffer and gel composition compared with the conditions for best resolution of serum proteins versus lipoproteins versus hemoglobins. A significant variation in conditions for protein electrophoresis is that for optimizing the separation of the γ -region to resolve and detect oligoclonal bands of

Figure 19-2 Plasma protein electrophoresis pattern in agarose gel is composed of five fractions, each composed of many individual species. Some of the major proteins are shown here in an artist's rendition for clarity. (Adapted from Laurell CB. *Electrophoresis, specific protein assays, or both in measurement of plasma proteins?* Clin Chem 1973;19:99, with permission.) α_1 Ac, α_1 -Antichymotrypsin; α_1 Ag, α_1 -acid glycoprotein; α_1 At, α_1 -antitrypsin; α_2 M, α_2 -macroglobulin; α -Lp, α -lipoprotein; Alb, albumin; AT3, antithrombin III; β -Lp, β -lipoprotein; complement components C1q, C1r, C1s, C3, C4, C5, as designated; C11nh, C1 esterase inhibitor; Cer, Ceruloplasmin; CRP, C-reactive protein; Gc, Gc-globulin (vitamin D-binding protein); FB, factor B; Fibr, fibrinogen; Hpt, haptoglobin; Hpx, hemopexin; immunoglobulins IgA, IgD, IgE, IgG, IgM, as designated; IaTI, Inter- α -trypsin inhibitor; Pl, plasminogen; Pre A, prealbumin; Tf, transferrin.

immunoglobulin in cerebrospinal fluid (CSF). In this case, the endosmosis is set high to maximize the cathodal movement of immunoglobulins from the point of application over a span of the gel that is convenient for visual inspection.

Polyacrylamide is an inert support medium whose porosity is easily adjusted by changing the composition of acrylamide before polymerization. Although polyacrylamide gel electrophoresis (PAGE) is applicable to standard separation of native proteins, it can also be used for separating proteins according to molecular weight when they are denatured in the presence of sodium dodecyl sulfate (SDS). SDS-PAGE is at present the most widely used protein electrophoretic technique for research in molecular biology. However, its very power for resolving proteins and separating them into multitudinous subunits has virtually excluded it from routine use in the clinical laboratory. Nevertheless, there is promise for clinical application of two-dimensional electrophoresis (2-DE), which uses standard separation in one direction followed by SDS-PAGE in the perpendicular direction. 2-DE results in perhaps hundreds of identifiable protein peaks, from which it may be possible to obtain important diagnostic information by sophisticated pattern analysis.

Isoelectric focusing affords superior resolution of closely migrating proteins or various forms of a single protein that differ in charge owing to minor modification (e.g., post-translational) (see Chapter 4). By this technique, proteins migrate through a gel containing a gradient of pH established with a mixture of ampholytes. As each protein reaches the gel location where the pH is equal to its pI, the net charge on it becomes zero. It no longer has electromotive force acting on it, and it comes to rest. Thus the final pattern is strictly according to pI.

PRECIPITATION

Chemical precipitations of serum proteins have been devised to resolve albumin and the globulins into two or more fractions that can then be measured for protein content. With the addition of sodium sulfate, sodium sulfite, ammonium sulfate, or methanol, the globulins tend to precipitate, leaving albumin in solution. By measuring total protein in the original serum and protein in the precipitate or the supernatant, values for albumin and globulin can be derived. The ratio of these values (A/G ratio) has been used extensively because it accentuates abnormalities in serum protein

composition, which in disease generally involve depression of albumin and elevation of one or more globulin fractions. Albumin may be depressed owing to decreased synthesis (malnutrition, malabsorption, liver failure, diversion to synthesis of other proteins) or increased loss (proteinuria, accumulation of ascites fluid, enteropathy). Globulins may be elevated owing to increased synthesis of many different proteins as part of acute or chronic reactions to disease. Lowering of albumin and elevation of globulins tend to occur simultaneously in disease, thus leading to exaggerated changes in the A/G ratio as the numerator and denominator move in opposite directions. Precipitation methods are not as accurate as zonal electrophoresis, because some α -globulins may fail to precipitate, thus leading to an overestimate of the albumin fraction.

Preparative procedures for the isolation of a single minor protein constituent usually begin with a precipitation step to remove the bulk of other undesired serum proteins. The next step in protein isolation typically involves a column that separates on the basis of molecular size (gel filtration) or charge (ion exchange).

COLUMN SEPARATIONS

Gel filtration media such as Sephadex or agarose beads are rated according to pore size, which in turn determines what size molecules can pass through the interior of each bead or particle of the column. After application of a sample composed of various-sized proteins in aqueous solvent containing buffer and salt, more of the buffer is applied to drive the sample through the column. Very large molecules tend to flow through interstices of the column without entering the beads and emerge first from the bottom of the column in the void volume. Slightly smaller molecules enter the largest pores before being washed through and so are slightly retarded in passing through the column. Small protein molecules pass into still smaller pores and are retained still longer. Finally, particles the size of dissolved salt penetrate farthest into the interior of gel filtration beads and come out after all the proteins have emerged in an amount of applied buffer called the salt volume. Thus, in gel filtration the order of protein elution is by molecular weight or size, from largest first to smallest last. Because all protein species continuously move through a gel filtration column all at the same time but at different rates, it is necessary to apply the sample in a small and uniform volume to optimize separation between peaks. Gel filtration requires that the medium be inert and not interact chemically or by charge with the proteins. It is not a method to be employed for high-resolution separation.

Ion-exchange chromatography, on the other hand, takes advantage of the charge on proteins to bind them to beads of a support medium with positively charged components such as diethylaminoethyl or quaternary aminoethyl. In anion-exchange chromatography, proteins are usually applied at a basic pH such as 8.6, at which they may be negatively charged (albumin and α_1 -, α_2 -, and β -globulins are anions) or may have no net charge (γ -globulins). The neutral proteins pass immediately through an anion-exchange column, whereas the anionic ones stick to the positively charged column matrix. If a buffer with a higher salt concentration is washed through, anions of the salt displace the anionic proteins and exchange for them by binding to the support medium. The proteins then elute from the column. By using a steadily increasing gradient of salt concentration in the eluting buffer, the proteins can be resolved according to charge. The ones with a small amount of charge will elute first, whereas those with the greatest charge (e.g., albumin) elute only when displaced by higher salt levels.

Alternatively, if pH is lowered while salt concentration is held low, anionic proteins acquire a net neutral or slightly positive charge and pass through the column. A gradient of falling pH can be used to resolve anionic proteins, with the order of elution being roughly β -, α_2 -, and α_1 -globulins, and albumin. Note that this order of elution is the reverse order of electrophoretic migration at pH 8.6, because in anion-exchange chromatography, mobility is retarded according to net negative charge, whereas in electrophoresis, mobility is enhanced by that charge.

Cation-exchange chromatography begins at an acid pH, with the proteins having positive charge (cations) and adhering to a negatively charged column matrix such as carboxymethylcellulose. They can be displaced by the cations of high salt in an eluting buffer or by increasing the pH, which will reverse the charge on the proteins to negative. By cation exchange, albumin should elute first, followed by α_1 -, α_2 -, β -, and γ -globulins.

Another separation modality by column is hydrophobic chromatography, in which samples are applied at high salt and are eluted with low salt. The support medium interacts with proteins with a hydrophobic nature;

this is a good complementary technique to follow ion-exchange chromatography, in which the sample was eluted with high salt.

Affinity chromatography is based on specific binding between a protein of interest and another protein that has been covalently linked to the solid support medium of a column. For example, coagulation factor VIII complexed with von Willebrand factor (vWF) can be selectively removed from the other plasma proteins by passing plasma through a column that contains monoclonal anti-vWF antibody linked to the solid phase matrix. The factor VIII-vWF complex selectively binds to the column as other plasma proteins wash through. The factor VIII is then dissociated from the vWF, thereby allowing it to elute in a purified fraction suitable for transfusion therapy. Such antigen-antibody interactions may be disrupted by high salt concentration, change in pH, or a chemical denaturant, such as urea, in different applications. Other affinity chromatography gels use a binding phenomenon that mimics naturally occurring molecular interactions. Thus, some dyes coupled to agarose are able to bind albumin, thereby removing it selectively from serum. Therapeutic antibodies or their Fab portions are concentrated with affinity columns containing their intended target antigens (e.g., Digibind for digoxin, CroFab for crotalid snake venom). Immunoglobulins can also be absorbed from a sample by staphylococcal protein A coupled to the gel matrix. Many other separation schemes can effect a high degree of purification in a single step with affinity chromatography medium coupled to dyes, drugs, nucleotide cofactors, and sugars. A clinical test using affinity chromatography is quantitation of glycosylated hemoglobin using a dihydroxyboronate affinity matrix that selectively binds molecular species of hemoglobin to which glucose has been covalently attached, while allowing the nonglycosylated forms to pass through the column. The glycosylated hemoglobin is then separately eluted and quantitated.

Capillary electrophoresis is a separation method based on flow through a capillary tube that can be tailored to resolution of different molecules based on size, hydrophobicity, or stereospecificity. It is applicable to large molecules such as DNA or proteins, as well as to small ones such as hormones or therapeutic drugs. Physically, the method is similar to high-performance liquid chromatography (HPLC), in which solvent is pumped through a column that retains or passes solutes according to chemical interactions. Capillary electrophoresis for serum proteins employs a column with properties similar to agarose, so the separation of proteins is comparable with that from electrophoresis. This analysis can be automated with a detector at the effluent end that detects and quantitates protein bands without the need for staining and separate scanning. Although equipment costs are relatively high for capillary electrophoresis, reagent and labor costs are low and the procedure is fast and very quantitative, leading to the promise of more widespread clinical applications in the future (Chen, 1991; Brinkman, 2004).

PROTEIN DETECTION AND QUANTITATION

The ultimate reference method for determining concentration of protein is the analysis for nitrogen content. Nitrogen is present uniformly along the peptide bonds throughout the length of a protein and more irregularly in the side groups, wherever tryptophan, arginine, lysine, histidine, asparagine, or glutamine is present. The Kjeldahl technique consists of acid digestion to release ammonium ions from nitrogen-containing compounds. The ammonium can then be quantitated by conversion to ammonia gas and titration as a base, or by nesslerization, in which double iodides (potassium and mercuric) form a colored complex with ammonia in alkali. Although determination of nitrogen content can be extremely precise, its use for calculation of protein concentration depends on the exact protein composition of a sample, because each protein has a somewhat different nitrogen content according to amino acid composition. However, for a sample of a purified protein, nitrogen content is highly accurate for estimating protein concentration when the nitrogen content on a molar basis is already known for that purified protein. Knowledge of a protein's exact amino acid sequence allows an accurate calculation of what the nitrogen content should be. Because clinical samples consist of unpredictable mixtures of different proteins, and measurement of nitrogen content is not a simple procedure, it is not commonly used in clinical laboratories.

Refractive index can be accurate for measuring serum protein concentration as dissolved solute for levels above 2.5 g/dL. Hemolysis, lipemia, icterus, and azotemia produce erroneously high results. Refractive index cannot be used for urine protein measurements because of excess amounts of solutes in relation to the protein.

Specific gravity (and thus, by inference, protein content) can be estimated by pipetting drops of serum or blood into a graded series of copper sulfate solutions. A protein-copper shell forms about the drop to prevent dissolution for a short interval, during which time the drop falls to the bottom, remains stationary, or rises to the top. The protein concentration of a sample is estimated from the specific gravity of the copper sulfate solution in which the drop remains stationary. This technique is simple and has been used widely as a screening test for hemoglobin concentration in whole blood.

Proteins in solution absorb ultraviolet light at 280 nm (A_{280}), owing mostly to tryptophan but also to tyrosine and phenylalanine (Layne, 1957). For accurate conversion of A_{280} readings to protein concentration, the molar absorptivity must be used, because each protein contains a different amount of these three amino acids. However, the A_{280} of a mixture of proteins is not a perfect measure of protein content because molar absorptivities vary greatly between different proteins. Because nucleic acids (which absorb strongly at 260 nm and also somewhat at 280 nm) may be present in protein preparations, a better estimate of protein concentration in the presence of nucleic acids is given by the formula:

$$\text{Protein concentration (mg/mL)} = 1.55 \times A_{280} - 0.76 \times A_{260}$$

Direct measurements of absorbance can be used for quantitating proteins in the range of 0.05–1.5 mg/mL.

Turbidimetric methods are often used for a similar concentration range in CSF or urine. Protein forms precipitate on the addition of trichloroacetic acid, sulfosalicylic acid, or other acid reagent. The resulting turbidity can be used for protein quantitation by increment in optical density in comparison with similarly treated standards. However, these techniques are not specific to proteins, because other acid-insoluble substances such as nucleic acids can also precipitate.

A colorimetric technique highly specific for proteins and peptides is the Biuret method, by which copper salts in alkaline solution form a purple complex with substances containing two or more peptide bonds. Interferences are minimal, although ammonium ion may acidify the reaction, while hemoglobin and bilirubin absorb in the same region as the Biuret complex (540–560 nm). The Biuret method is extensively used in clinical laboratories, particularly in automated analyzers in which protein concentration can be measured down to 10 or 15 mg/dL.

Greater sensitivity can be obtained using the Folin-Ciocalteu reagent (or phenol reagent, phosphotungstomolybdic acid), which oxidizes phenolic compounds such as tyrosine and, in addition, tryptophan and histidine to give a deep blue color.

Lowry (1951) used the Biuret method followed by the phenol reagent, which greatly enhanced color formation, because the phenol reagent can react with Biuret complexes involving all peptide bonds. The Lowry assay has been extensively used for consistently accurate determinations of protein concentration.

Further sensitivity for detection down to 1 μ g of protein can be obtained using Coomassie brilliant blue dye, which is free of interferences from a very wide range of substances.

Comparable sensitivity is obtained with ninhydrin, which develops a violet color by reacting with primary amines. This reagent is widely used for detection of peptides and amino acids after paper chromatography and amino acid analyses from ion-exchange columns, as well as for detection of drugs on toxicology screens using thin-layer chromatography (see Chapter 23).

Quantitation of albumin in the presence of other proteins is possible by virtue of the specific binding of albumin to certain dyes such as bromophenol blue, methyl orange, hydroxybenzeneazobenzoic acid, bromocresol purple, and bromocresol green (BCG). BCG is used extensively in automatic analyzers for determining serum albumin in parallel with Biuret reagent for total protein. Dyes bound to albumin absorb maximally at slightly different wavelengths, thus allowing direct spectrophotometric quantitation of the albumin.

The standard dyes used for staining electrophoresis are Coomassie brilliant blue, Ponceau S, and amido black. For detection of minor components in high-resolution gels, silver staining is very sensitive down to nanogram quantities (Merril, 1981).

In addition, special dyes, such as Oil Red O and Sudan black, stain lipoproteins, and periodic acid-Schiff stains glycoproteins separated in special electrophoretic applications.

Because electrophoresis followed by staining does not afford explicit identification of serum proteins, immunologic measurements have been instituted for quantitation of individual proteins (Laurell, 1966). Nephelometry detects the turbidity produced usually within minutes or less by the precipitation of a reagent antibody with its target protein in a serum sample (Maachi, 2004). The major serum proteins are now widely measured by this method on automated immunochemistry analyzers that have supplanted former measurements by radial immunodiffusion. Owing to the specificity of the antibody reagent, nephelometry has great specificity for quantitating individual proteins even in the presence of others. Proteins present in lower concentrations may be quantitated by immunologic methods, such as radioimmunoassay (RIA) or enzyme-linked immunosorbent assay.

SPECIFIC PLASMA PROTEINS

MAJOR COMPONENTS

The major serum proteins are those components that are readily resolved and detected on electrophoretic gels stained by conventional clinical laboratory techniques (Table 19-1 and Fig. 19-1).

Prealbumin

Prealbumin is defined electrophoretically as the fraction that migrates in a position faster than albumin toward the anode. Prealbumin has a tetrameric structure with a total molecular weight of 62,000 Da, making it one of the smaller serum proteins. Each monomer can bind a molecule of thyroxine. As such, it is also called thyroxine-binding prealbumin (TBPA) or transthyretin (TTR), although only a small fraction of thyroxine is

TABLE 19-1

Characteristics of Major Plasma Proteins

Protein	Concentration range (g/L)	Molecular weight	Actions
Prealbumin	0.15–0.36	62,000	Binds thyroxine; transports vitamin A
Albumin	39–51	66,000	Oncotic pressure; amino acid reservoir; carries small molecules
α_1 -Antitrypsin	2.0–4.0	54,000	Protease inhibitor
α_2 -Macroglobulin	1.5–3.5	725,000	Protease inhibitor
Haptoglobin	0.4–2.9	100,000 (Type 1-1)	Binds hemoglobin
β -Lipoprotein	2.7–7.4	380,000	Lipid transport
Transferrin	2.0–4.0	80,000	Transports iron
C3	0.6–1.4	185,000	Component of complement system
Fibrinogen	1.0–4.0	340,000	Clot formation
Immunoglobulin A	0.4–3.5	160,000	Surface immunity
Immunoglobulin D	0.1–0.4	180,000	
Immunoglobulin E	50–600 (μ g/L)	180,000	Binds to mast cells; hypersensitivity reactions
Immunoglobulin G	7–15	150,000	Humoral immunity
Immunoglobulin M	0.25–2.0	850,000	Humoral immunity primary response

actually bound to TBPA in normal individuals, because thyroxine-binding globulin has a 100-fold greater affinity for thyroxine (Oppenheimer, 1968). However, at least one molecular variant of prealbumin, inherited in a familial pattern, has a greatly increased affinity for thyroxine, resulting in elevated serum thyroxine content, although those individuals have normal free thyroxine concentrations and so are euthyroid (Moses, 1982).

Prealbumin plays a significant role in the metabolism of vitamin A by complexing with the retinol-binding protein (RBP), which, in turn, complexes with vitamin A to transport it through the body (Peterson, 1971). RBP is a small protein of only 182 amino acids, and so it would be rapidly removed from the circulation by filtration through the kidney if it were not held in the plasma by the larger protein prealbumin, which is not cleared into the glomerular filtrate. The complex of retinol, RBP, and transthyretin appears to be assembled in the endoplasmic reticulum of hepatocytes (Gaetani, 2002).

Prealbumin is rich in tryptophan (sometimes called tryptophan-rich prealbumin) and has considerable β -pleated sheet conformation. A portion of prealbumin is the source of the β -fibrillar amyloid component in type I familial amyloidotic polyneuropathy (Glennner, 1980). This hereditary amyloidosis derives from a mutation in the prealbumin gene that produces a protein (e.g., TTR Met 30 variant) susceptible to proteolytic cleavage to create the β -structured fragments that are the building blocks of amyloid in nerve fibers (Li, 1991; Saraiva, 1989). More than 80 different mutations in transthyretin have been recognized, mostly affecting nerve or heart with amyloid. These pathogenetic variants of prealbumin cannot be distinguished from normal by standard protein electrophoresis. Current diagnosis is based on analysis at the DNA level.

Prealbumin has a relatively short half-life in the circulation (roughly 2 days) compared with other major serum proteins. Its synthetic rate is also exquisitely sensitive to intake of adequate nutrition and to alterations in hepatic function where it is produced. Therefore, prealbumin concentrations in serum fluctuate more rapidly in response to alterations in synthetic rate than do those of other proteins such as albumin. For this reason, quantitation of serum prealbumin has major clinical utility as a marker for nutritional status (Gofferje, 1978). Because of the rapid dynamics of its synthesis and clearance, prealbumin is considered to be a better early indicator of change in nutritional status than other commonly used markers, such as albumin and transferrin, which are more abundant, but whose levels respond to other factors as well and at slower time scales. In a study of 7815 hemodialysis patients, low levels of prealbumin were associated with greater risks of mortality and hospitalization for infection that were independent of other risk factors, including serum albumin (Chertow, 2005). Thus prealbumin measurements can be very important for planning patient management.

Because of its compactness, prealbumin crosses more easily into the CSF than do the other serum proteins. Therefore, concentrating CSF before electrophoresis allows visualization of a distinct prealbumin band in CSF. CSF normally contains a major peak of albumin plus prealbumin and a small amount of transferrin. Electrophoresis of CSF is usually requested for detection of oligoclonal bands of immunoglobulin, and the presence of a distinct band of prealbumin is used only as a landmark to confirm that the specimen was likely CSF. True prealbumin is generally below the level of detection by serum electrophoresis; instead it is best quantified by immunologic measurements such as nephelometry. A protein band frequently appears in the prealbumin position of serum from patients who have had heparin therapy. In the circulation, heparin activates and releases lipoprotein lipase activity, which attacks triglycerides in lipoprotein fractions, thereby greatly enhancing their electrophoretic migration anodally. Protein stain reveals apolipoproteins in the prealbumin position but no β -lipoprotein fraction. This is an *in vivo* effect that does not occur if heparin is added to samples already collected.

Albumin

The single most abundant protein in normal plasma is albumin, usually constituting up to two thirds of total plasma protein (Peters, 1975). For this reason, depressions in albumin level due to impaired synthesis (e.g., malnutrition, malabsorption, hepatic dysfunction) (Rothschild, 1972) or to losses (e.g., ascites, protein-losing nephropathy or enteropathy) result in serious imbalance of intravascular oncotic pressure. This loss is manifested clinically by the development of peripheral edema (Slater, 1975). However, the congenital absence of albumin (albuminemia) generally does not lead to such problems, presumably because of lifelong compensatory mechanisms that control hydrostatic pressures (Waldman, 1964). Albumin also serves as a mobile repository of amino acids for incorporation into other proteins. A third function ascribed to albumin is that of a general transport

Figure 19-3 Bisalbuminemia. Serum protein electrophoresis with normal pattern in left lane and bisalbuminemia consisting of two equal intensity bands of albumin in right lane. The additional band of albumin in this patient migrated more slowly than normal albumin into the α_1 -region.

or carrier protein. Many organic and inorganic ligands (e.g., thyroxine, bilirubin, penicillin, cortisol, estrogen, free fatty acids, warfarin [Coumadin], calcium, magnesium, heme) are complexed with different regions of the albumin molecule in covalent (e.g., δ -bilirubin) (Lauff, 1982) or dissociable binding (Koch-Weser, 1976). These binding interactions with very different ligands are possible because of a wide variety of binding sites on the albumin molecule, which consists of 585 amino acids arranged in nine loops held together by the disulfide bonds between cysteine residues (Meloun, 1975). The primary sequence of albumin contains three major regions with three peptide loops each, suggesting that it arose from gene duplication of some ancestral gene in a tandem rearrangement process (Peters, 1977; Sevall, 1986). It is also interesting to note that α -fetoprotein has regions of homology with serum albumin, which may indicate a common ancestral gene origin for these two proteins.

In addition to the genetic abnormality of albuminemia, many hereditary variants of albumin differ from the most common allotype, albumin A, by single amino acid substitutions. These variants can be rapid or slow migrating compared with albumin A, leading to two distinct albumin peaks (bisalbuminemia) in the heterozygous state (Fig. 19-3). None of the variant albumins appears to affect health, but one variant does have greatly enhanced affinity for thyroxine, which leads to elevated thyroxine content in the serum of such persons, who nevertheless remain euthyroid (Ruiz, 1982). At least 77 different mutations in albumin are recognized, 65 of which lead to bisalbuminemia; 12 cause albuminemia, and 3 have strong binding of thyroid hormones, while others show variations due to frame-shifts, with modifications near the carboxy terminus of the albumin molecule (Minchiotti, 2008).

Up to 8% of albumin circulating in normal persons becomes glycosylated nonenzymatically, whereas up to 25% becomes glycosylated during hyperglycemia in analogy with glycosylated hemoglobin (Guthrow, 1979). The half-life of circulating albumin is about 17 days, so that measurements of the glycosylated form may be useful in monitoring diabetic control during an interval of a few weeks. Measurement of glycosylated albumin (also called fructosamine) can be very useful for assessing diabetic control in patients with hemolytic anemias (e.g., sickle cell disease, thalassemia, autoimmune hemolysis), whose red cell survival is greatly shortened and in whom measurement of glycosylated hemoglobin is unreliable. Glycosylated albumin measurements may not be reliable for assessing diabetic

control in patients with protein-losing nephropathy, in which albumin clearance is accelerated. Diabetic patients on hemodialysis can be monitored with glycosylated hemoglobin or glycosylated albumin (Ghacha, 2001).

Analysis of newly synthesized albumin from intracellular sites has revealed the existence of a precursor proalbumin, which has an additional hexapeptide at its amino-terminal end. The primary structure of albumin consists of 35 cysteine residues, of which 34 form intramolecular disulfide bonds and one remains free. On storage for many days, albumin forms covalently linked dimers through the free cysteines, resulting occasionally in an extra band of albumin on electrophoresis.

Clinical measurements of albumin are very frequent, with determinations of total protein and albumin often included in chemistry panel profiles. Organ- or disease-oriented panels of chemistry tests in current use include the following measurements: comprehensive metabolic panel has albumin and total protein; renal function panel has albumin; hepatic function panel has albumin and total protein.

Elevations of serum albumin concentration are infrequent, although they do occur in dehydration as the plasma water phase shrinks. Following rehydration, the albumin level should fall to within the normal reference range. Elevation of serum albumin may also occur artifactually as the result of prolonged application of a tourniquet for venipuncture. In this instance, increased hydrodynamic pressure from venous backup forces water and small solutes out of the intravascular space, thereby concentrating cellular elements, micellar forms of lipoproteins, and proteins such as albumin.

Depression of albumin concentrations is frequent in sick individuals, and a review of hospitalized patients reveals that a substantial proportion of albumin measurements are below healthy reference ranges (see Fig. 9-7). Although some of these decreases are likely dilutional, owing to the administration of intravenous fluids, others are caused by loss of albumin into urine, ascitic fluid, or the gastrointestinal tract in enteropathies, or by decreased synthesis in the liver caused by hepatic disease such as cirrhosis or by secondary effects on synthesis resulting from compromised nutrition or diversion of synthetic capacity to other proteins. This sensitive but nonspecific reduction of albumin in so many different conditions has led to its being termed a “negative acute phase reactant” (Post, 1991). Measurements of albumin concentrations are vital to the understanding and interpretation of calcium and magnesium levels because these ions are bound to albumin, and so decreases in albumin are directly responsible for depression of their concentrations, too. In some disease states, decreases in albumin are at least partially compensated for by increases in other serum proteins, thereby stabilizing oncotic pressures intravascularly. In particular, cirrhosis shows a major polyclonal increase of immunoglobulins in the γ -fraction (Fig. 19-4, *A*) and nephrotic syndrome shows high levels of α_2 -macroglobulin (Fig. 19-4, *B*).

Body fluids that form normally, such as CSF, or pathologically, such as filtrates of plasma (e.g., ascites), contain albumin as the major component, with very little contribution from other plasma proteins. The presence of albumin in the urine is generally considered abnormal even in trace amounts, although some healthy individuals exhibit albuminuria following intense exercise. Progression of diabetic nephropathy can be assessed by the quantitative measurement of albuminuria, as it tends to appear ahead of the other serum proteins in urine during the course of renal glomerular damage. Immunologic measurement of microalbumin in urine is now considered a standard of care for management of diabetes mellitus and the early detection of diabetic complications. The nephrotic syndrome, which is marked by extensive hypoalbuminemia, is often due to diabetic nephropathy or one of several other primary glomerular diseases (Orth, 1998).

α_1 -Antitrypsin

The major component of the α_1 -globulins is the protease inhibitor α_1 -antitrypsin (AAT), which has the capacity to combine with and inactivate trypsin (Eriksson, 1965; Berninger, 1985a). The first clue to this function came with the discovery that the serum of some young adults with pulmonary emphysema was deficient in α_1 -globulin. Further investigation revealed a similar deficiency of AAT in children with cirrhosis (Sveger, 1976). Usually, no appreciable circulating levels of trypsin are found in blood, but other related proteases, such as elastase, are released from leukocytes responding to irritants or inflammation. AAT is able to neutralize the activity of these proteases, too, and hence is an intrinsic factor in the homeostatic mechanism modulating endogenous proteolysis within the body and preventing inappropriately severe biochemical response to inflammation (Cox, 1986).

AAT is coded for by the gene *SERPINA1* on chromosome 14. A majority of people are homozygous for the normal fully active *M* allele of AAT,

Figure 19-4 **A**, Serum protein electrophoresis in cirrhosis (Cir) shows more rapidly migrating albumin compared with normal serum (Nor) because of the additional negative charge from covalently linked conjugated bilirubin (i.e., δ -bilirubin). The γ -globulins are broadly increased in the polyclonal elevation characteristic of cirrhosis of the liver. **B**, Protein electrophoretic patterns of serum (Ser) and concentrated urine (Ur) in a patient with nephrotic syndrome. Smaller molecular-sized proteins such as albumin are preferentially lost from blood into urine. Larger proteins such as α_2 -macroglobulin and β -lipoprotein are retained in the blood and constitute major bands in the serum pattern.

or phenotype MM (Lieberman, 1972). About 10% of white people (and fewer of other races) are heterozygous for *M* and some other allele of the protease inhibitor or Pi system. More than 2% carry the *PiZ* allele and exhibit the phenotype MZ. Although these individuals have somewhat reduced levels of trypsin inhibitory capacity in serum, they are generally asymptomatic; however, their homozygous ZZ offspring (who have very low levels of AAT) are susceptible to pulmonary or hepatic disease. The ZZ phenotype occurs in about 1 in 4000 individuals. Another common variant is the *PiS* allele, which shows moderate reduction in synthesis. Although the MS phenotype does not show related disease, both SS and SZ phenotypes are suspected to have increased risk of lung or liver disease. Another allele that may need special attention to detect is the null variant that produces no AAT protein.

Although AAT deficiency can be recognized on serum protein electrophoresis, an efficient diagnostic algorithm employs measurement of AAT concentration followed by phenotyping with isoelectric focusing electrophoresis and genotyping with molecular assays designed to detect specific mutations (Snyder, 2006; Bornhorst, 2007). Definitive typing may require analysis of the DNA sequence for the *AAT* gene. At least 75 different alleles exist for *AAT*. About 17 alleles have sufficiently low protein production to lead to pulmonary disease, and only a few are responsible for liver disease (Cox, 1986).

Therapy for pulmonary emphysema secondary to AAT deficiency has been greatly advanced by intravenous replacement of AAT, using concentrates or recombinant protein to bring circulating levels into ranges sufficient for antielastase protection to the lungs (Snider, 1989). Further replacement has also been successful with AAT inhalation for patients in whom pulmonary disease has not yet become extensive (Hubbard, 1989). Avoidance of cigarette smoking by homozygous individuals is essential, because cigarette smoke is a major source of irritants that trigger leukocytes in the lung to release proteases (Gelb, 1977). The cirrhosis in young children is treated by hepatic transplant, because the liver is the site of AAT synthesis. An interesting aspect of cirrhosis and the ZZ phenotype is the presence of unsialylated mutant-type AAT granules in the hepatocytes,

Figure 19-5 Phenotyping of haptoglobin. Patient serum specimens were mixed with free hemoglobin from erythrocytes lysed in vitro and electrophoresed in a polyacrylamide gel with high resolution of different molecular weight proteins. After electrophoresis, the gel was developed in a solution of substrate 3,3',5,5'-tetramethylbenzidine and hydrogen peroxide. Hemoglobin exhibits pseudoperoxidase activity that converts substrate to a blue product wherever it has migrated including complexes with haptoglobin. Bubbles of oxygen formed in the gel at the location of catalase, which is also present in the lysate. Type 1-1 haptoglobin (arrow in left lane) migrated deeply into the gel (from top to bottom), although unbound hemoglobin migrated even farther. Type 2-2 haptoglobin showed no band in the 1-1 position but migrated as a series of high molecular weight polymers, each binding hemoglobin (bar next to right lane). Type 1-2 haptoglobin (middle lane) showed a minor band of 1-1 plus a series of high molecular weight polymers different from the bands observed with 2-2.

implying a defect of secretion in those alleles. Cirrhosis secondary to AAT abnormality has not been improved by replacement therapy. Children with this disorder can develop progressive, severe cholestasis, prompting liver transplantation. Following transplant, the recipient takes the AAT phenotype of the donor.

AAT is one of the serum glycoproteins that rise in response to acute inflammation, but such elevations lack clinical specificity. The α_1 -fraction never appears completely empty in AAT deficiency, because other proteins (e.g., α -lipoprotein, α_1 -acid glycoprotein) migrate there but do not resolve into distinct bands.

Genetic screening for AAT deficiency may be useful in targeted populations, resulting in early diagnosis, improved outcomes, and guidance for affected kindreds (Aboussouan, 2009).

α_2 -Macroglobulin

α_2 -Macroglobulin (AMG) is the largest major nonimmunoglobulin protein in plasma, with a molecular weight of 725,000 Da (Roberts, 1985). The serum concentration in normal individuals is comparable with that of the other major protease inhibitor, AAT, although women have higher levels than men in response to estrogen (Horne, 1970). The concentration of AMG rises 10-fold or more in the nephrotic syndrome when other lower molecular weight proteins are lost (Beetham, 1993). The loss of AMG into urine is prevented by its large size. The net result is that AMG reaches serum levels equal to or greater than those of albumin ($\approx 2-3$ g/dL) in the nephrotic syndrome, which has the effect of maintaining oncotic pressure (see Fig. 19-4, B). Synthesis of AMG in nephrotic syndrome may also be enhanced, which accounts for its absolute increase in concentration. AMG inactivates proteases by complexing with them and forming covalent bonds to them. Its own conformation is thereby altered, which enhances clearance by the reticuloendothelial system. At least four molecular forms of AMG differ in sialic acid, mannose, and galactose content and can be separated by isoelectric focusing. Other molecular variations probably are the result of proteases linked to AMG before removal from the circulation. The spectrum of inhibition by AMG is very wide, including virtually all types of serine, carboxyl, thiol, and metal proteases. AMG complexes with prostate-specific antigen (PSA) in a form that is not detected by immunoassay for PSA (see Chapter 73). Although AMG function is certainly important for maintaining balance in the ebb and flow of proteolysis, no specific deficiency with associated disease has been recognized, and no disease state is generally attributed to low concentrations of AMG. Mild

but distinct elevations of AMG can be observed on serum protein electrophoresis early in the course of diabetic nephropathy.

AMG inactivates proteases through a molecular trap mechanism using a bait region to bind proteases that then are bound to AMG and cleared by macrophage receptors (Armstrong, 2006). AMG also has separate binding sites for β -amyloid peptide, transforming growth factor- β , nerve growth factor- β , and platelet-derived growth factor-BB. Polymorphisms of AMG may be important in the modulation and clearance of these substances, leading to varying risk for disorders such as Alzheimer's disease (Mettenberg, 2005).

Haptoglobin

The other major protein migrating in the α_2 -region is haptoglobin, which has the function of combining with hemoglobin released by lysis of red cells to preserve body iron and protein stores. The circulating half-life of haptoglobin, free of hemoglobin, is roughly 4 days. Hemoglobin-haptoglobin complexes are removed from the circulation within minutes by the reticuloendothelial system, where the hemoglobin is broken down into globin and heme, which further degrades to iron and bilirubin. When the hemoglobin-binding capacity of haptoglobin is exceeded, free hemoglobin enters the glomerular filtrate as α -chain- β -chain dimers that are subsequently reabsorbed in the proximal renal tubules and converted to hemosiderin.

Haptoglobin has two heavy chains and two light chains linked by disulfide bonds in analogy to the basic structure of immunoglobulins. Some persons have a light chain gene that is duplicated in a head-to-tail arrangement (Type 2). Normal haptoglobin (Type 1-1) gives rise to a single molecular species of molecular weight 100,000. Heterozygous individuals (1-2) have, in addition to Type 1-1 haptoglobin, a series of multimers (e.g., dimers, trimers) by virtue of intermolecular disulfide linkages through the duplicated light chain. Type 2-2 haptoglobin consists of a different series of multimers, because the Type 2 light chain has a different molecular weight from the Type 1 light chain (Konigsberg, 1974). These different forms of haptoglobin can be distinguished by high-resolution electrophoresis (Fig. 19-5).

Haptoglobin can be quantitated in terms of its hemoglobin-binding capacity or by immunologic means, especially nephelometry. Owing to steric hindrance between molecular sites on the multimers, the different phenotypes of haptoglobin yield measurements of antigen- or hemoglobin-binding capacity that may be discrepant with the absolute amount of

haptoglobin protein present in a sample. Accordingly, the reference range for haptoglobin is broader for an entire population of different phenotypes than within individual phenotypes. For this reason, interpretation of haptoglobin concentrations is soundest for serial measurements in the same individual. However, very high levels can readily be distinguished from very low ones, which can be important in the first-time evaluation of a patient for hemolysis. Congenital deficiency of haptoglobin appears not to have clinical consequences (Manoharan, 1997).

In diabetes mellitus, patients with Type 2-2 haptoglobin have shown higher risk for vascular complications, perhaps owing to different ability to clear hemoglobin, thus leading to altered iron handling and heightened oxidative load (Van Vlierberghe, 2004; Levy, 2010).

Serum haptoglobin rises in response to stress, infection, acute inflammation, or tissue necrosis, probably by stimulation of synthesis (see later under *Acute Phase Reactants*). After a hemolytic episode, haptoglobin concentrations fall as the complexes with hemoglobin are cleared from the circulation. This effect is dramatic following massive hemolysis in situations of hemolytic transfusion reaction, thermal burns, or autoimmune hemolytic anemia. It is also a useful measurement for serially monitoring patients who have a slow but steady rate of red cell breakdown such as by mechanical heart valves, hemoglobinopathies, or exercise-associated trauma. Low haptoglobin concentrations may accompany liver disease when hepatic synthetic capacity is impaired. There are also individuals with congenital deficiency of haptoglobin who apparently use other mechanisms to conserve body iron stores. Serum samples from blood hemolyzed in vitro during phlebotomy or processing show a displaced band of haptoglobin-hemoglobin complex on protein electrophoresis.

It should be noted that myoglobin does not bind to haptoglobin; therefore, release of large amounts of myoglobin by rhabdomyolysis does not diminish haptoglobin levels in serum. This difference can be useful in the workup of a positive dipstick test for blood (actually a test for pseudoperoxidase activity of heme in hemoglobin or myoglobin) in urine with no coexisting red cells. In this case, low serum haptoglobin suggests hemoglobinuria (hemolysis), whereas high serum haptoglobin suggests myoglobinuria. Lactate dehydrogenase (LD) isoenzyme 1 in serum is also associated with hemolysis, whereas LD5 and creatine kinase are released in rhabdomyolysis.

β-Lipoprotein

β-Lipoprotein (low-density lipoprotein [LDL]) migrates with a characteristic sharp leading cathodal edge and feathery trailing region more anodally. Although it is better quantitated by stains for lipid, apoprotein content is sufficient to be a distinct band on staining for protein. The exact position of the β-lipoprotein band is sensitive to recent ingestion of fatty foods; thus, samples from fasting versus postprandial collections will show the β-lipoprotein in slightly different positions. The other lipoproteins (very-low-density lipoprotein, high-density lipoprotein, and chylomicrons) are relatively small in intensity, and they occur in overlapping electrophoretic positions with other serum proteins, so that these fractions generally are not appreciated on protein stain. Administration of heparin activates post-heparin lipoprotein lipase, which degrades triglycerides in the circulating lipoprotein fractions. Consequently, heparinized patients transiently demonstrate an anomalous band of β-lipoprotein that can migrate very rapidly and unevenly across the electrophoretic path, even into the prealbumin region. Elevations of LDL, with greater staining intensity to the β-lipoprotein band, occur in hypercholesterolemia. Lipoproteins are discussed more thoroughly in Chapter 17.

Transferrin

The major β-globulin is transferrin (siderophilin), which transports ferric ions from the iron stores of intracellular or mucosal ferritin to bone marrow, where erythrocyte precursors and lymphocytes have transferrin receptors on their surfaces (Irie, 1987).

Transferrin consists of 687 amino acids with a calculated molecular weight of 79,550 Da (MacGillivray, 1982). Analysis of the amino acid sequence shows that transferrin has two homologous domains that may have arisen by contiguous duplication of an ancestral transferrin gene. Each domain has a binding site with very high affinity for iron. Transcription of mRNA for transferrin synthesis in the liver is regulated by the concentration of iron in the circulation and surrounding the hepatocytes.

In normal serum, transferrin ranges in concentration from 200–400 mg/dL, which is conveniently measured as iron-binding capacity (IBC) (Tsung, 1975). In response to short-term iron deficiency, transferrin levels rise markedly to twice normal levels or higher. Because transferrin is a single molecular species with a tight electrophoretic mobility, an elevated level

can have the appearance of a paraprotein (pseudoparaproteinemia) in cases of severe iron deficiency (Zawadzki, 1970). At least some iron deficiency and elevation of transferrin should be expected with pregnancy (Mendenhall, 1970). Administration of iron to deficient patients increases saturation; this is followed by return of transferrin to normal.

Chronic saturation of transferrin occurs in idiopathic hemochromatosis and transfusional hemosiderosis. Because almost no unsaturated IBC is found in those syndromes, iron cannot be mobilized normally for excretion, resulting in excess deposition in tissues that is toxic. Current strategies to screen for hemochromatosis include measurement of serum iron and serum transferrin (usually by nephelometric immunoassay), with the calculation of percent saturation as the best index for identifying previously unrecognized cases. Hemochromatosis is a hereditary disorder that results in cirrhosis, diabetes, cardiomyopathy, arthritis, and other endocrine disorders owing to the toxic effects of excess free iron. Screening for hemochromatosis is desirable because disease progression can be halted by lowering the body burden of iron by such means as phlebotomy or chelation therapy.

Transferrin may also demonstrate an antibacterial effect by complexing iron and removing it from bacteria that require iron for growth (Reddy, 1970; Weinberg, 1978).

Congenital deficiency of transferrin (atransferrinemia) is a rare disorder characterized by microcytic anemia and iron overload (Aslan, 2007). In protein-losing nephropathy of sufficient severity, transferrin is lost from the circulation into the urine, carrying iron with it. This loss may contribute to the development of hypochromic anemia.

Electrophoretic variants of transferrin occur occasionally in serum owing to allotypic variation in the amino acid sequence, and hence have a different charge on the molecule. In this case, the heterozygous state shows a doublet in place of a single electrophoretic band for transferrin (Kamboh, 1987).

Transferrin is a glycoprotein in which various sugar molecules are added to newly synthesized protein molecules in the liver. Persons who engage in heavy alcohol consumption demonstrate abnormal carbohydrate-deficient transferrin (CDT) in their serum (Stibler, 1991). These aberrant molecules of disialo- and asialotransferrin as opposed to normally glycosylated tetrasialotransferrin may be due to failure of glycosyltransferases in hepatocytes, to increased sialidase activity in serum, or to a combination of the two (Xin, 1995). CDT can be detected by anion-exchange chromatography or isoelectric focusing of isoforms in serum followed by immunoblotting. Other methods include HPLC, capillary zone electrophoresis, mass spectrometry, and turbidimetric immunoassay (Bean, 2001). Although CDT is generally considered to be a highly specific marker for chronic alcohol abuse (Arndt, 2001), false negatives can occur in women, in non-smokers, and in persons who have a high body mass index (both overweight and obese) (Whitfield, 2008).

A variant of transferrin has been recognized in CSF (Zaret, 1992), aqueous and vitreous humor of the eye (Tripathi, 1990), and perilymph of the ear (Thalmann, 1994). Chemically, it lacks sialic acid in glycosylation compared with the transferrin found in plasma (Hoffman, 1995); it is called asialotransferrin, τ protein, or β_2 -transferrin because of slightly different electrophoretic migration (toward the cathode), because it carries less negative charge than plasma transferrin (Blennow, 1995). CSF contains both forms of plasma transferrin and asialotransferrin, whereas plasma contains only one form. Consequently, detection of asialotransferrin in fluid from a fistula or drainage is presumptive evidence for the presence of CSF in cases of skull fracture or other head trauma with nasal drainage (Solomon, 1999), or for the presence of perilymph in fistula fluid from otologic procedures such as cochlear implants (Delaroche, 1996). Asialotransferrin reacts immunologically as transferrin, and so it can be readily detected by immunoblotting following electrophoresis (Roelandse, 1998). This procedure is easily done by adapting commercially available agarose gel electrophoresis systems already used in many laboratories for direct immunofixation of immunoglobulins (Normansell, 1994); using an anti-transferrin antibody demonstrates a single band of transferrin in serum samples, but two bands if the specimen contains CSF (Fig. 19-6). It is necessary to include serum in addition to test fluid from the patient to rule out allelic variants of transferrin that could cause false positives if not recognized (Sloman, 1993). The presence of CSF in drainage fluid may require surgical repair or antibiotic therapy, so detection of asialotransferrin as a marker for CSF can have a substantial clinical impact.

Complement

A separate fraction of β-globulin consists of the C3 component of complement. Although this protein can be resolved easily with a fresh serum

Figure 19-6 Immunofixation with transferrin antibody to test for presence of cerebrospinal fluid (CSF). *Ser*, Normal serum showing position of transferrin (Tf; double-headed arrow); *CSF*, normal position of Tf and asialotransferrin (aTf, single-headed arrow); *Pt Ser*, patient serum included to rule out electrophoretic variant of Tf; *Pt FI*, unknown fluid from patient demonstrating bands of both Tf and aTf that confirm the presence of CSF in that fluid.

Figure 19-7 Comparison of serum (*Ser*) and citrated plasma (*PI*) from the same individual demonstrates the position of fibrinogen (arrow) in plasma that should not be confused with a monoclonal immunoglobulin.

sample, in stored specimens and commercial control serum that has been lyophilized, C3 is cleaved to form C3c, which migrates anodally to native C3 as a band nondistinct from other β -globulins. Depression of C3 occurs in autoimmune disorders when the complement system is activated and C3 becomes bound to immune complexes deposited in tissues, thereby removing them from plasma. Thus, C3 (and also C4) concentration is a convenient marker for assessing disease activity in rheumatic disorders such as lupus erythematosus and rheumatoid arthritis. C4 is not appreciated on serum protein electrophoresis because its concentration is normally only about one-fifth that of C3. Both C3 and C4 are now easily quantitated by nephelometry for monitoring rheumatic disease activity. No particular diagnostic significance is ascribed to higher than normal levels of C3 or C4, except as mild indicators of an acute phase response. The complement system and its inhibitors are discussed further in Chapter 47.

Fibrinogen

Plasma contains 100–400 mg/dL of fibrinogen, which is the most abundant of the coagulation factors and which forms the fibrin clot. With an overall molecular weight of 340,000 Da, fibrinogen is a dimer consisting of three pairs of peptide chains (A- α , B- β , and γ) linked with multiple disulfide bonds near their amino-terminal ends (Doolittle, 1975, 2001). This region of the molecule is termed the E domain or disulfide knot. The chains extend outward into two other identical domains (D) at their carboxyl ends, where all three chains are intertwined. Thrombin cleaves fibrinopeptides A and B from the amino ends of the A- α and B- β chains, thereby resulting in a fibrin monomer that polymerizes into fibrils that macroscopically form a fibrin clot. Factor XIII then produces covalent bonds between lysine and glutamine residues on adjacent γ -chains of different fibrin molecules, making the fibrin clot essentially a single molecule. A cross-linked clot is refractory to dissolution by chemical denaturants and is mechanically very stable.

Numerous hereditary variants of fibrinogen (dysfibrinogenemias) have been identified, in which a functionally abnormal fibrinogen molecule is synthesized with altered amino acid sequence owing to genetic mutation. Some dysfibrinogenemias exhibit impairment of clotting and a hemorrhagic diathesis, whereas others show increased tendency to thrombosis (Menache, 1973). Congenital afibrinogenemia, in which essentially no fibrinogen is synthesized, results in a hemorrhagic disorder that paradoxically is not as severe as the hemophilias in terms of joint abnormalities secondary to hemorrhage (hemarthroses).

Fibrinogen levels become elevated with the other acute phase reactants, occasionally to over 1.0 g/L. In such instances, the erythrocyte sedimentation rate (ESR) is also markedly elevated owing to fibrinogen content directly. Fibrinogen levels also rise with pregnancy and use of contraceptive medications. Low levels generally indicate extensive activation of coagulation with consumption of fibrinogen. During this process,

plasminogen is also activated into plasmin, which degrades fibrin and fibrinogen into split products that are measured for the assessment of intravascular coagulation. Normally, clots that form are removed by the action of plasmin, which, in turn, is inactivated by antiplasmin and the other protease inhibitors.

Fibrinogen is absent from normal serum but should appear in plasma electrophoresis as a distinct band between the β - and γ -globulins (Fig. 19-7). Not infrequently, blood drawn from heparinized patients does not fully clot, so that a fibrinogen band is present on electrophoresis. It can be distinguished by examining the specimen for a fine clot and by repeat electrophoresis of a thoroughly clotted sample. This maneuver is important to distinguish a residual fibrinogen band from a monoclonal spike of immunoglobulin that can migrate in the same electrophoretic position.

MINOR COMPONENTS

The next group of individual proteins are those not usually detected by standard protein electrophoresis owing to low levels in serum. Their quantitation is typically performed by immunologic methods.

Ceruloplasmin

Migrating with the α_2 -globulins is a copper-binding protein, ceruloplasmin, which contains most of the copper in plasma and exhibits ferroxidase activity that is important in iron metabolism (Hellman, 2002). Synthesized in the liver, it has a molecular weight of 132,000 Da and consists of a single polypeptide chain. Although lower at birth (Al-Rashid, 1971), serum levels are 20–40 mg/dL in normal adults, with 2-fold elevations found in oral contraceptive therapy and pregnancy (Burrows, 1971), or as an acute phase reactant. Each molecule of ceruloplasmin can bind six atoms of copper, which imparts a blue color to the protein. The combination of this blue with the yellow from other chromogens of plasma imparts a greenish color to plasma with elevated ceruloplasmin concentrations (Schenker, 1971); this green appearance is frequently noted in bags of plasma donated for transfusions. Iron is oxidized from ferrous to ferric ions by ceruloplasmin, which may be a means of releasing iron from ferritin for binding to transferrin (Roeser, 1970).

Wilson's disease (hepatolenticular degeneration) results from disordered copper metabolism, in which hepatic excretion of copper into the

bile is impaired, leading to toxic deposition of copper in tissues. Normal metabolism of copper includes incorporation by the liver into ceruloplasmin (about six to seven copper atoms per molecule), which is then secreted into the plasma. In Wilson's disease, this process is impaired, and copper that has been absorbed by the body and transported to the liver fails to re-enter the circulation as part of ceruloplasmin. Normal excretion of copper through the bile is diminished, with an overall increase in body copper deposits that are toxic to liver, brain, cornea, kidneys, bones, and parathyroids. Diagnosis is usually made in childhood or adolescence, when damage to the liver is first noticed. Other affected persons may present later in life when neurologic changes also occur. Treatment is long-term chelation with penicillamine or, in severe cases, liver transplantation, which may be curative.

Diagnosis of Wilson's disease is based on physical findings (liver disease, neurologic signs, Kayser-Fleischer ring in the cornea), measurement of low serum ceruloplasmin level, and increased copper concentrations in urine and on liver biopsy. The oxidase activity of ceruloplasmin can be used in a colorimetric assay, with *p*-phenylenediamine as substrate, for quantitation. Additionally, immunochemical methods are used, because the band is too faint to be used reliably on protein electrophoresis. Because no single clinical or laboratory finding is sufficient to make the diagnosis of Wilson's disease, a combination of them is necessary (Ferenci, 2004). Mutations in the ceruloplasmin gene leading to aceruloplasminemia result in iron overload affecting pancreas, liver, and brain with a spectrum of neurologic disease (McNeill, 2008).

Gc-Globulin

Vitamin D binds to the group-specific component (Gc) globulin (vitamin D-binding protein [DBP]) (Daiger, 1975; Bikle, 1986), which migrates as an α_1 -globulin and has a molecular weight of about 51,000 Da. Normal serum concentration is 20–55 mg/dL. It may be decreased in severe liver disease. Gc-globulin has two autosomal codominant alleles expressed as three phenotypes: 1-1, 2-2, and 1-2 (Giblett, 1969). Congenital absence of this protein may be a lethal mutation, owing to impairment of vitamin D transport, because vitamin D has low solubility in aqueous media. Gc-globulin binds vitamin D and its metabolites on a mole-per-mole basis, but in plasma, it probably is not fully saturated. Nephrotic syndrome results in urinary loss of DBP, some of which is complexed with vitamin D. This loss of vitamin D may contribute to subsequent problems of calcium metabolism encountered in nephrotic syndrome (Goldstein, 1981). As a minor component of plasma proteins, Gc-globulin can be quantitated by radioimmunoassay, radioimmunodiffusion, or rocket immunoelectrophoresis (Walsh, 1982; Westwood, 1986). More recent studies with immunonephelometry have shown lower levels of Gc-globulin in trauma patients who develop organ dysfunction and sepsis (Dahl, 2003). Plasma concentrations of 25-hydroxyvitamin D are affected by polymorphisms of the vitamin D-binding protein (Sinotte, 2009) presumably caused by varying levels of this protein associated with the different phenotypes (Lauridsen, 2001).

Hemopexin

The β -migrating globulin hemopexin binds heme released by degradation of hemoglobin (Muller-Eberhard, 1970). By this means, this small porphyrin molecule with its iron atom is protected from excretion, thereby contributing to the preservation of body iron stores. Among plasma proteins, hemopexin has the strongest binding affinity for heme, which probably helps to limit the toxicity of free heme (Tolosano, 2002). Normal serum concentration is 50–120 mg/dL, so that it must be quantitated by immunologic means. It has a molecular weight of 70,000 Da, of which 20% is carbohydrate and consists of a single polypeptide chain. Although low levels of hemopexin can occur with nonspecific urinary loss or as the result of decreased synthesis in liver failure, the most profound decreases occur following intravascular hemolysis, when the amount of free hemoglobin exceeds the binding capacity of haptoglobin. The circulating plasma hemoglobin can then degrade to release heme, which is bound molecule per molecule by hemopexin. Heme-hemopexin complexes are cleared from the circulation by hepatocytes, which markedly lowers hemopexin concentration in serum. Excess heme then binds to albumin as methemalbumin. As more hemopexin is made available by new synthesis, heme passes from methemalbumin to hemopexin, which continues to depress the hemopexin level. As such, this can be an additional aid for diagnosing hemolysis at an earlier time, after haptoglobin levels have returned to normal but before full clearance of the heme (Wochner, 1974). Hemopexin can also be decreased in porphyrias and in rhabdomyolysis and chronic neuromuscular disease (Delanghe, 2001).

α_1 -Acid Glycoprotein

This protein, also known as orosomucoid, has a very high carbohydrate content, which minimizes its visualization by standard protein stains (Alvan, 1986). With a molecular weight of roughly 44,000 Da, it passes into the glomerular filtrate to a large extent, resulting in a half-life of only about 5 days in the circulation. Serum levels are normally 40–105 mg/dL, with elevations during pregnancy (Schmid, 1975). It is an acute phase reactant, but its biological function is not known. As a binder of progesterone, it may be important in the transport or metabolism of that steroid hormone. It also binds some drugs (e.g., lidocaine) and keeps them in an inactive circulating pool. Measurements of this protein have clinical utility in interpreting levels of drugs, such as lidocaine, that may achieve high serum concentrations without expected therapeutic effect owing to being complexed in inactive form to higher than normal amounts of α_1 -acid glycoprotein. Some genetic polymorphisms of this protein may be additionally complicated by isomorphous forms from specific tissue sources, although the primary site of its synthesis appears to be the liver. Although measurements of this protein have not been widely employed, its ability to bind various drugs such as the tyrosine kinase inhibitor STI571 (Gleevec, used in chronic myeloid leukemia) has led to concerns over possible drug-refractory states through binding and drug inactivation (Jorgensen, 2002; Le Coutre, 2002).

C-Reactive Protein

This serum constituent was discovered by mixing the serum of patients who had recovered from pneumococcal infections, with C-polysaccharide of that bacterium. Visible flocculates formed, which allowed extensive study and purification of the C-reactive protein (CRP) from serum in the 1940s. It was found that CRP is present in the serum of patients with disorders other than pneumococcal infection, but that it rises strikingly whenever there is tissue necrosis. Many other substances react with CRP, such as DNA, nucleotides, various lipids, and other polysaccharides (Hokama, 1982). Thus, it appears to serve as a general scavenger molecule. Its molecular weight is between 118,000 and 144,000 Da, with substantial carbohydrate content. The normal serum concentrations are about 100 ng/mL at birth, 170 ng/mL in children, and 470–1340 ng/mL in adults. Despite these low concentrations, CRP has major significance as a highly sensitive acute phase reactant (Deodhar, 1989). It is generally measured by its capacity to precipitate C-substance or by immunologic methods, including nephelometry, precipitations, RIA, and enzyme immunoassay (Saxstad, 1970; Claus, 1976). By electrophoresis, CRP is a γ -migrating protein that may form a minor but distinct monoclonal-appearing band in patients having a severe inflammatory response. CRP levels are sometimes used as a rapid test for presumptive diagnosis of bacterial infection (high CRP) versus viral infection (low CRP) (Clyne, 1999). CRP is often used by rheumatologists to monitor the progression or remission of autoimmune disease. The gene for CRP has been localized to human chromosome 1 (Whitehead, 1983). Recent epidemiologic studies have shown that a high-sensitivity assay for CRP can add to the predictive value of serum lipids for identifying individuals at risk of cardiovascular events, presumably owing to the role that inflammation plays in atherogenesis (Ridker, 2000). Persons with high normal CRP concentrations are at greater risk for stroke or myocardial infarction than those with low normal values (discussed in greater detail in Chapter 18).

PROTEASE INHIBITORS

In addition to α_1 -antitrypsin and α_2 -macroglobulin, which have already been considered, other distinct inhibitors of different proteases are present in plasma. They include α_1 -antichymotrypsin (AAC) (Berninger, 1985b), inter- α -trypsin inhibitor (IATI) (Daniels, 1975), antithrombin III (AT3), antiplasmin, C1 esterase inhibitor (Prograis, 1985), protein C (Stenflo, 1984), and plasminogen activator inhibitor-1 (PAI-1) (Nilsson, 1984). None of these proteins attains plasma concentrations appreciable on stained protein electrophoresis. Whereas the other inhibitors show inhibition over a rather wide range of proteases, AAC is highly specific for neutralizing chymotrypsin, which cleaves peptide bonds at the carboxyl side of tyrosine and phenylalanine residues. AAC has a molecular weight of 68,000 Da with about 25% carbohydrate content. Normal serum concentration is 40–60 mg/dL, but AAC can rise rapidly to five times normal as an acute phase reactant that remains elevated throughout a period of inflammation (Kosaka, 1976). AAC complexes with prostate-specific antigen, measured as the bound form of PSA by immunoassay (see Chapter 73). It can be lost along with other low molecular weight serum proteins in the proteinuria of nephrotic syndrome.

IAT1 is a glycoprotein of molecular weight 160,000 Da. Its concentration normally is about 50 mg/dL. IAT1 does not rise appreciably as an acute phase reactant. Its role in disease states is probably similar to that of the major protease inhibitors in preventing autodigestion of tissues by endogenous cellular enzymes (Daniels, 1975).

AT3 is of special clinical interest because of the role it plays in neutralizing thrombin, which normally becomes activated intravascularly from prothrombin during clot formation. This 62,000-Da protein forms a covalently bonded complex with thrombin over a period of several minutes when mixed in solution. On addition of heparin, the complex formation occurs almost instantaneously (Rosenberg, 1975, 1985, 1987). Although AT3 is probably essential for successful therapeutic administration of heparin, only those rare individuals with marked deficiencies seem to have thrombotic disorders (Carvalho, 1976). The action of AT3 extends to other coagulation factors (IX, X, XI, XII, and kallikrein). Serum levels of AT3 may be depressed in severe liver disease or in protein-losing disorders when the similar-sized molecule albumin is lost, and also in disseminated intravascular coagulopathy (DIC). A new experimental protocol for treating DIC involves replacing AT3 by infusion of concentrates when the patient's AT3 level falls to very low concentrations as part of the consumptive coagulopathy. Presumably, return to normal levels of AT3 has the effect of blocking further thrombosis systemically. AT3 levels are lower in heparin therapy and slightly elevated in oral anticoagulant therapy owing to increased and reduced turnover, respectively.

Although AAT, AMG, and AT3 provide the bulk of plasmin-neutralizing activity in serum (Harpel, 1976), a distinct antiplasmin migrates as an α_2 -globulin (Lijnen, 1985). This cross-reactivity of serum protease inhibitors for plasmin illustrates the difficulty in sorting out the precise physiologic function of each molecular species, because each one appears capable of substituting for another in different instances. However, antiplasmin binds quantitatively to the majority of plasmin that is generated from plasminogen in human plasma that undergoes clotting. Antiplasmin thus serves as one of the critical checks within the joint coagulation-fibrinolytic system, which maintains hemostasis by balancing clot formation against dissolution. By this mechanism, clot formation and breakdown are generally contained within local regions of the vasculature without extending to the entire circulation. Hereditary deficiency of antiplasmin results in a bleeding disorder due to relatively unlimited fibrinolysis.

PAI-1 acts to prevent activation of plasminogen, thereby blocking fibrinolysis at an early step. Deficiency of PAI-1 results in less inhibition, leading to greater fibrinolysis and potentially a bleeding disorder. Elevated levels of PAI-1 prevent fibrinolysis, leading to thrombotic disorders and to the progression of atherosclerosis. Protein C (with its cofactor protein S) inactivates activated coagulation factors V and VIII. Deficiency of protein C or S (Griffin, 1987) allows prolonged activity in vivo of procoagulant factors leading to thrombotic disorders.

The C1 esterase inhibitor is capable of inhibiting activated complement components C1r and C1s plus some other coagulation and fibrinolytic factors. It rises as an acute phase reactant. Hereditary deficiency of C1 esterase inhibitor allows activation of complement to proceed relatively unabated, a disorder termed hereditary angioedema. The complement system and its inhibitors are described in depth in Chapter 47.

ACUTE PHASE REACTANTS

The acute phase reactant proteins share the property of showing elevations in concentrations in response to stressful or inflammatory states that occur with infection, injury, surgery, trauma, or other tissue necrosis (Daniels, 1974; Laurell, 1975; Dowton, 1988). They include AAT, α_1 -acid glycoprotein, haptoglobin, ceruloplasmin, fibrinogen, serum amyloid A protein, and CRP. Others are factor VIII, ferritin, lipoproteins, complement proteins, and immunoglobulins. It is easy to see how such a response of the plasma proteins would be advantageous to the body: Inflammation causes release from leukocytes of proteolytic enzymes in tissue that must be neutralized by enzyme inhibitors to limit their extent of destruction; scavenger proteins (haptoglobin, CRP) help collect and transport cellular debris and breakdown products to phagocytic cells (reticuloendothelial system) to process them and conserve vital substances (e.g., iron); and healing of wounds requires a large amount of fibrin, which arrives via the circulation as fibrinogen. Thus, the humoral response of the acute phase reactants can be viewed as a phenomenon that is geared to handle extensive insult each time it is triggered, even though not all components will be needed on every occasion. The elevation of acute phase reactants is likely a response to the cytokines, including interleukin-1, tumor necrosis factor, interferon- γ , and interleukin-6. The total physiologic response includes

induction of fever, recruitment of leukocytes, catabolism of muscle, and a shift in protein synthesis patterns with reduction in albumin production.

For clinical use in diagnosis, other parameters in fact may be as sensitive as these and far easier to measure (e.g., fever, leukocytosis, ESR). However, these proteins provide another dimension of quantitation that can be useful for monitoring the course of a patient by serial determinations (van Oss, 1975). Of course, those patients with congenital deficiencies (Gitlin, 1975), those with other impairment of synthesis due to drugs or organ disease, and newborns who normally have lower levels of many constituents (Gitlin, 1969) may not show the dramatic increases expected. However, a generally useful acute phase reactant for monitoring response is CRP, which is the fastest rising acute phase reactant and one that returns to normal quickly following successful therapies (Fischer, 1976). CRP is frequently applied to the detection and preliminary classification of occult infections, because bacterial infections can stimulate much higher levels of CRP than viral ones. It is also widely used for assessing disease activity in autoimmune disorders, because it is rarely elevated persistently without continued inflammatory response. Elevations of CRP can be up to 1000 times normal levels, which greatly assists in detecting abnormal states compared with the other acute phase reactants, which may rise at most only several-fold in such responses, although ferritin levels may occasionally rise to values greater than 20,000 ng/mL.

PATTERNS OF PROTEIN ABNORMALITIES

Some of the most frequently encountered patterns of protein abnormalities in electrophoresis are shown as densitometric scans in Figure 19-8. Scanning allows quantitation of each fraction, but visual inspection of the electrophoretic strip provides more detailed information about individual proteins separated in high-resolution systems (Ritzman, 1975). Interpretation of electrophoretic results depends on visual inspection to identify abnormal patterns or aberrant bands, and on quantitation by scan to gauge the relative quantities of individual fractions.

Patterns of hypoproteinemia due to malnutrition or gross loss of protein show decreases in all fractions, but the most dramatic reduction is often seen in albumin compared with its normally high value as the most abundant serum protein (Fig. 19-9, lane 3). Severe starvation, malabsorption, or inanition associated with severe chronic disease will show marked reduction in albumin to levels below 20 g/L. The other serum proteins, including AAT, AMG, haptoglobin, transferrin, and C3, appear even fainter on electrophoresis. Reduction in staining intensity for the β -lipoprotein parallels a marked decrease in serum cholesterol concentration. The immune system is strongly affected by severe starvation, with decreased synthesis of immunoglobulins resulting in hypogammaglobulinemia and impaired resistance to bacterial and other infections. Protein-losing enteropathy (Fig. 19-8, H) shows a variation in the hypoproteinemia pattern, in which most fractions are diminished owing to the combination of decreased synthesis and increased loss, although α_2 may be relatively higher owing to a coexisting acute phase response (haptoglobin) or to preferential retention of larger molecules (α_2 -macroglobulin).

Specific loss of proteins into the urine as in nephrotic syndrome occurs on a molecular weight basis, with smaller proteins being lost more rapidly than larger ones. Accordingly, albumin appears early in the course of protein-losing nephropathies, followed by smaller quantities of AAT, transferrin, and, ultimately, immunoglobulins (Fig. 19-10, lanes 1 and 2). The very large molecule AMG is retained, as are the large micelles of β -lipoprotein. The result is complementary patterns of proteins in the serum (decreases in albumin and α_1 -, β -, and γ -globulins; increased α_2 -macroglobulin and elevated β -lipoprotein) versus those in urine (see Fig. 19-4, B) (glomerular proteinuria with albumin, α_1 -, β -, and γ -fractions present but without α_2 -macroglobulin in the urine sample). Tubular proteinuria that is due to impaired renal tubular reabsorption of small proteins shows a pattern of α , β , and γ in the urine with only minimal albumin loss into the urine (Killingsworth, 1982) (see Fig. 19-10, lane 4). In addition to glomerular and tubular patterns of proteinuria (Maachi, 2004), it is important to recognize the important pattern of a monoclonal gammopathy in urine (see Fig. 19-10, lane 3, and Fig. 19-11). A similar pattern of a single large band occurs in hemoglobinuria (see Fig. 19-10, lane 5), which must be distinguished from a monoclonal immunoglobulin or free light chains.

Acute phase or immediate response patterns have greatest effect on serum protein electrophoresis by increasing the amount of haptoglobin while slightly decreasing the concentration of albumin. Increases in haptoglobin usually indicate some form of response, whether acute or chronic,

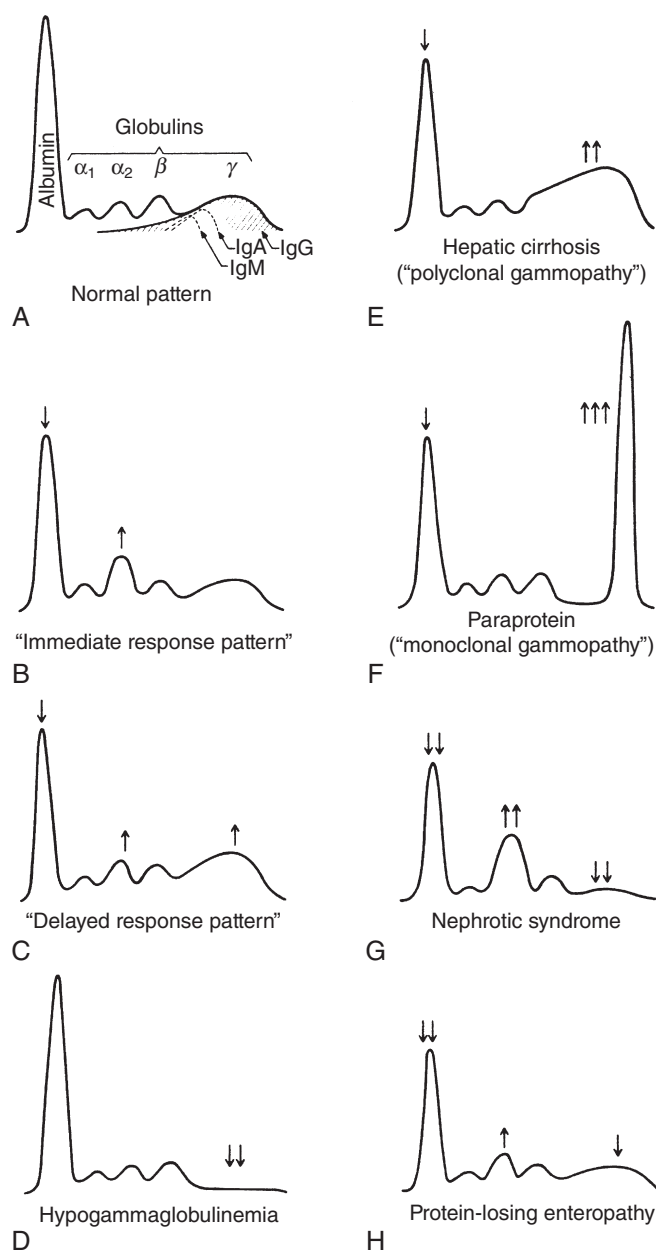

Figure 19-8 Serum protein electrophoresis: clinicopathologic correlations. (Courtesy of Dr. A. E. Krieg.)

to stressful stimuli (Fig. 19-9). Other proteins such as AAT can contribute to this response; minor components such as CRP do not contribute significantly to this protein stain pattern, although immunologic measurement of CRP may show up to 1000-fold elevations. If the haptoglobin has been depleted in a patient as a result of active hemolysis, an independent band of hemoglobin may be migrating in the β - or α_2 -region. Hemolysis of a sample in vitro may show a red band (on the unstained gel) of the haptoglobin-hemoglobin complex that migrates differently from hemoglobin alone. The pattern of delayed response or chronic pattern is an extension of the acute phase response (high haptoglobin, slight reduction in albumin) with greater decrease in albumin and polyclonal increase in immunoglobulins broadening the γ -region.

A striking elevation of transferrin in the β -region sometimes occurs in patients suffering from iron deficiency anemia. The increase in transferrin corresponds to increased IBC, and the percent saturation is low (Koerper, 1977). This variation may be confused with a myeloma protein because the transferrin band forms a narrow, clonal-appearing band.

Cirrhosis of the liver creates a protein pattern that is recognizable (Fig. 19-4, A). Hepatocellular damage from cirrhosis results in diminished capacity to synthesize albumin. Furthermore, the imbalance of hemodynamic pressures in portal hypertension secondary to cirrhosis leads to the formation of ascitic fluid, which contains almost exclusively albumin. This

Figure 19-9 Serum protein patterns in (1) chronic inflammation with decreased albumin and increased γ -globulins; (2) acute inflammation with increased α_2 -fraction (haptoglobin) and decreased C3 due to activation and consumption of complement; (3) inanition post-spinal cord injury with hypoproteinemia of several fractions.

Figure 19-10 Patterns of urine protein electrophoresis in different disorders. (1) Severe glomerular proteinuria with a major band of albumin plus a secondary one of transferrin (*). (2) Trace proteinuria with a faint band of albumin and other diffuse proteins. (3) Immunoglobulin light chains (*). (4) Tubular proteinuria with multiple bands that do not correspond to major serum proteins. (5) Hematuria with a major band of hemoglobin (not to be confused with monoclonal gammopathy), in addition to albumin.

decreased synthesis, coupled with increased loss, greatly reduces serum albumin concentrations. The loss of albumin is balanced to some extent by marked polyclonal increase in immunoglobulins with a γ -fraction that may contribute significantly to oncotic pressures. The increase in γ -globulin involves all immunoglobulins; the increase in immunoglobulin A (IgA) in the slow β -region shows a continuum with the γ (also termed β - γ bridging).

In contrast to polyclonal increases, oligoclonal bands consist of only a few clones of distinct immunoglobulins that migrate in defined positions. This pattern is seen in serum in cases in which an immunologic disorder is present, or in some patients treated with chronic immunosuppression for organ transplantation (Myara, 1991). Oligoclonal bands in the CSF are used to indicate immunologic activity in the central nervous system and occur in infectious diseases or autoimmune or demyelinating disorders (see Chapter 46).

Figure 19-11 Serum and urine protein electrophoretic patterns in a patient with multiple myeloma. Serum demonstrates a predominance of the larger complete immunoglobulin; the urine has a large amount of the smaller-sized light chains with only a small amount of the whole immunoglobulin.

Hypogammaglobulinemia is manifested as a nearly to completely absent γ -fraction. It occurs normally in neonates before maturation of the immune system. It also occurs in some congenital immunodeficiency states such as Bruton's agammaglobulinemia and other states involving B cell function. Perhaps more commonly, this pattern is seen in adults with lymphoreticular disorders in whom normal plasma cells have been displaced by lymphocytic proliferations, and to some extent after chemotherapy for eradication of malignancies, as well as in hypoproteinemic states (see Fig. 19-9, lane 3).

The single most important and widespread clinical application of serum protein electrophoresis is used for the detection of monoclonal gammopathies. This very explicit pattern comes from a paraprotein (immunoglobulin) secreted by a monoclonal proliferation of plasma cells and is generally found without normal amounts of polyclonal γ as normal plasma cells are replaced by the malignant clone (see Fig. 19-11). The presence of a paraprotein with normal polyclonal γ suggests a possible plasmacytoma that has not yet spread throughout the bone marrow. Laboratory evaluation of myeloma should include serum and urine protein electrophoreses to detect aberrant clonal bands, immunoelectrophoresis or immunofixation to type the heavy and light chains of the paraprotein, and quantitation of immunoglobulins to provide a baseline for monitoring the patient's response to therapy or disease progression. Other proteins that may sometimes be mistaken for monoclonal bands of immunoglobulin on serum protein electrophoresis include haptoglobin-hemoglobin complexes, C3 and its variants, β -lipoprotein, transferrin, fibrinogen, immune complexes, CRP, and occasionally, α_2 -macroglobulin.

Immunoglobulins, disorders of the immune system, and abnormalities of complement are discussed further in Chapters 46, 47, and 50.

KEY POINTS

- Enzymes are protein catalysts utilized by essentially all mammalian cells in specific biochemical reactions in different organs of the body, which may also be physically located in different organelles and structures within a cell.
- Enzymes lower the activation energies of the chemical reactions that they catalyze, so as to cause greatly enhanced rates of reaction. They do not become modified in these reactions and do not affect the equilibrium between reactants and products in the reaction.
- Most enzymes have a practical or trivial name as well as a name based on standardized nomenclature of the International Union of Biochemistry; the latter is based on the type of reaction catalyzed by the enzyme.
- Along with certain narrow ranges of pH, temperature, and protein and salt concentrations, most enzymes require additional organic molecules and/or inorganic ions for optimal enzyme function.
- An understanding of enzyme kinetics allows for laboratory measurement of serum and other body fluid enzyme levels, as well as determination of possible enzyme inhibition.
- Transition state theory of enzyme action has resulted in major breakthroughs in drug design.
- Damaged or dying cells within organs can release enzymes into the circulation; these plasma enzyme levels can be used clinically to develop a differential diagnosis of a patient with respect to specific organ disease and dysfunction.
- In addition, many enzymes have isozymes (i.e., polypeptide chains that differ in sequence but have similar enzymatic activity). Some enzymes are composed of two or more different polypeptide chains, such as the M and B chains of creatine phosphokinase, giving rise to isozymes that differ in chain composition (e.g., the MM, MB, and BB forms of creatine phosphokinase). In a number of diseases, specific isozymes become elevated in serum, facilitating diagnosis.

GENERAL PROPERTIES OF ENZYMES

All enzymes are proteins and function as catalysts. This means that they accelerate the rates of chemical reactions in the body but do not become chemically altered themselves in these reactions. Virtually every reaction that occurs in the body, both intracellularly and extracellularly, is catalyzed by an enzyme. The molecule for which a particular enzyme catalyzes a reaction is called the substrate. As will be explained further later, enzymes interact very specifically with their substrates and, with the possible exceptions of closely related molecules, do not interact with any molecules other than their substrates. The concentrations and/or activities of different enzymes in blood give vital information about the functioning of specific tissues. Furthermore, many enzymes exist predominantly in specific tissues and not in other tissues. Thus certain enzymes can serve as biomarkers for diseases in specific tissues. Therefore, a vital focus of the medical laboratory is determination of the concentrations and/or activities of specific enzymes in blood and other body fluids. The fact that an enzyme interacts selectively with only specific substrates facilitates determination of enzyme concentrations. Simply by adding a specific substrate to serum or other body fluid and observing the rate at which the substrate disappears, or the product of the reaction forms, the concentration of an enzyme can be determined. This chapter is concerned with the principles of how enzyme concentrations are determined.

CATALYSIS

A catalyst accelerates the rate of a chemical reaction. The acceleration may occur in solution, and the process is called homogeneous catalysis. Catalysis on an insoluble surface is termed heterogeneous catalysis. Biological catalysts are called enzymes and for the most part are proteins that exhibit homogeneous catalysis. However, some enzymes are embedded in membrane structures and should be considered insoluble, heterogeneous catalysts.

ENZYME SPECIFICITY

Enzyme specificity defines the capacity of protein catalysts to recognize and bind only one or a few molecules, the substrate(s), excluding all others,

Figure 20-1 The **lock and key** model of substrate binding to the enzyme active site. The enzyme exhibits preformed steric and electronic complementarity to the shape and charge distribution of the substrate. No shape changes or electronic redistributions in the enzyme or the substrate are necessary for optimal binding. (By permission of W.H. Freeman and Company, San Francisco; Stryer L. *Biochemistry*, 2nd ed. Stanford, Calif.: Stanford University; 1981.)

a process referred to as binding specificity. An enzyme catalyzes a unique chemical process (i.e., a solitary type of covalent bond is broken or formed). This is called reaction specificity. Most enzymes exhibit absolute reaction specificity, that is, no minor byproducts are formed. Binding specificity permits many biochemical reactions to occur simultaneously within the same biological space. Absolute reaction specificity saves energy because it reduces the pool of unwanted metabolites.

Enzymes are stereoselective because of the asymmetry of their active sites. They recognize only one enantiomeric form (i.e., one of a pair of compounds having a mirror image relationship) of a chiral substrate. Hence, proteases exclusively bind polypeptides made up of L-amino acids (and not D-amino acids) and catalyze their hydrolysis. Enzymes exhibit geometric specificity exemplified by the fumarase reaction, in which the Krebs cycle intermediate, fumarate (the *trans* isomer), but not maleate (the *cis* isomer), undergoes hydration.

ENZYME CONCENTRATION AND ACTIVITY

The concentration of enzyme molecules within a given intracellular or extracellular space depends on their rate of synthesis and degradation. Control of enzyme synthesis occurs at both transcriptional and translational levels. In eukaryotes, cells of different organs express different isoforms, called isozymes (discussed later), of the same enzyme, which alters rates and specificity suitable for selective cellular homeostasis. The presence of substrate, or other inducing molecule, can cause a sudden increase in enzyme levels.

Enzymatic activity is also subject to control through the binding of small molecules that produce conformational changes in the structure of the enzyme. This binding can alter substrate affinity for the enzyme, or change the enzyme's catalytic activity, or both. Generally, enzymes that catalyze rate-determining steps in metabolic pathways are subject to this type of regulation.

Enzymes do not affect the value of the equilibrium constant between reactants and products. In a reversible reaction, they accelerate forward and reverse reactions by the same relative amount. The equilibrium distribution of reactants and products is unchanged whether the equilibrium state has been achieved in the presence or absence of an enzyme.

As noted previously, almost all known enzymes are proteins or conjugated proteins. A few enzymes are nucleoproteins, which are ribonucleic acid (RNA) molecules complexed to proteins. Enzymes contain a surface region referred to as the active site, where binding and catalysis occur. It is a cleft or crevice in which are embedded specific groups, suitably oriented, which carry out the roles of binding and bond-making, or bond cleavage. The three-dimensional shape of the active site is a vital determinant in the recognition and specificity process. The enzyme-substrate complex is the adduct formed by the physical adsorption of the substrate to the active site. Enzyme-substrate complex formation requires specific alignment of atoms in the active site with atoms in the substrate molecule. This complementary arrangement is referred to as the lock-and-key fit of the substrate in the active site and is illustrated in Figure 20-1. Sometimes the shape of the substrate molecule does not exactly match the contour of

Figure 20-2 The **induced fit** model of substrate binding to the enzyme active site. The induced fit model postulates an initial weak, flexible interaction of the substrate with groups in the enzyme's substrate (ES) binding site. This is sufficient to trigger a conformational rearrangement of the enzyme's surface that exposes additional ligand binding groups that enhance the binding affinity of the substrate for the enzyme. (By permission of W.H. Freeman and Company, San Francisco; Stryer L. *Biochemistry*. 2nd ed. Stanford, Calif.: Stanford University; 1981.)

the active site. Yet the substrate binds tightly because of its capacity to reshape the active site to a conformation that binds the substrate with high affinity. This type of substrate adsorption is described as **induced fit**. It is illustrated in **Figure 20-2**. Active sites of induced fit enzymes become complementary only after the substrate is bound. Some of the favorable binding energy is used in reorganizing the shape of the active site.

MOLECULAR BASIS FOR ENZYME CATALYSIS

The free energy of activation is the energy absorbed by reactant molecules before they have a chance to convert to products. The free energy of activation is a barrier to chemical reactivity. When this barrier is large, the rate of a chemical reaction is very slow. The lower the barrier, the faster is the reaction rate. The barrier exists for almost all chemical reactions because, for bonds to be broken, they must be stretched and sometimes bent away from their equilibrium positions. These deformations require energy. Enzymes lower the free energy of activation. Most metabolic reactions have very high activation barriers, and in the absence of enzymes, reaction rates are imperceptibly slow. Cells can selectively reduce metabolic reaction rates to near zero by abolishing enzyme activity. This feature of metabolism allows cells to "turn on" and "turn off" metabolic pathways during different stages of the cell cycle. Enzymes lower the free energy of activation in various ways. Binding and appropriate orientation of the substrate in the active site increase its proximity to the catalytic groups. Various types of catalysis are used by enzymes. The major types of catalysis are acid-base, electrophilic, nucleophilic, elimination reactions, decarboxylation reactions, and metal ion and electrostatic catalysis. Reductions in the free energy of activation occur through preferential binding of the transition state (or intermediate enzyme-substrate complex) to active site groups. The side chains of different amino acids participate in catalysis. The side chain of histidine is an effective acid-base catalyst, and the side chains of serine, cysteine, lysine, histidine, and aspartic acid participate in covalent catalysis. The side chains of lysine and arginine, as well as metal ions, can act as electrostatic catalysts by stabilizing negative charges that develop during catalysis. Conversely, the side chains of aspartate and glutamate residues can stabilize the positive charges that develop during catalysis.

The rate of the reaction is proportional to the concentration of molecules that have attained energy equal to the free energy of activation, ΔG^\ddagger . This energy is higher for the uncatalyzed reaction. The idea that enzymes accelerate chemical reactions by lowering G^\ddagger is illustrated in **Figure 20-3**, where the free energy needed for a productive reaction is compared for an uncatalyzed and an enzyme-catalyzed reaction. As shown in this figure, enzymes lower the activation energy. As explained later, an enzyme binds to its substrate to form an enzyme-substrate complex in an initial recognition step. In the subsequent step, the substrate is converted to product. The enzyme-substrate complex is more stable than the two separated species (i.e., has a lower free energy). However, this

Figure 20-3 The free energy path of a reactant molecule through its transition state on its way to becoming a product molecule. The energy trajectory followed by a molecule undergoing a chemical reaction is the minimum free energy pathway known as the **reaction coordinate**. The transition state, the state of highest free energy, is the point where there is an equal probability that a reaction will take place, or that the **activated complex** will decompose back to the reactant. The free energy change, ΔG^\ddagger , is the energy that the substrate molecule must acquire to reach the activated complex, also called the activation energy barrier. **A**, The uncatalyzed reaction. The reactant, called S, must acquire the necessary energy, ΔG^\ddagger , to become converted into the product, P. This energy is the difference between the energy of the transition state and the ground-state energy of S. **B**, The enzyme-catalyzed reaction. In this case, the enzyme binds noncovalently to the substrate, resulting in a stable enzyme-substrate (ES) complex. In most textbooks, the ES complex is shown as having slightly higher energy than that for free E and S. This is because the energy of the substrate increases when it binds to the enzyme because the enzyme recognizes the transition state of the substrate (discussed later), which is a higher energy form for the substrate. However, overall, the energy of the ES complex is lower than for the free enzyme and free substrate, as reflected in the favorable affinity constant (usually measured as $1/K_M$) for the binding of S to E. This is why the energy of ES is shown as lower than for the two isolated species. However, although this complex has a lower free energy than that for the two separated species (S and E), it should not be too much lower, as discussed later. The energy of activation, ΔG^\ddagger , now becomes the difference in energy between that of the transition state in the ES complex, and not for S alone, and that of the ground state ES complex. This energy is less than that for the uncatalyzed reaction. A major reason why ΔG^\ddagger for the enzyme-catalyzed reaction is less than for the uncatalyzed reaction in **A** is that the enzyme has a high affinity for the transition state, lowering its energy relative to that for the ground state ES complex. Note in **B** what would happen if the enzyme had a very high affinity for **ground state ES** (broken line). If the same transition state is assumed, the energy barrier to reach this transition state, instead of just being ΔG^\ddagger , will now be $\Delta G^\ddagger + \Delta G^\ddagger$, resulting in a slower rate of reaction.

energy cannot be too low, as in the case of the dotted lines in **Figure 20-3**, because in this case, the activation energy would be raised, and the reaction rate would be slower. As explained later, an enzyme binds to what is called the transition state on the reaction pathway. This is the reactive form of the substrate that is of relatively high free energy compared with the free energy of the ground state of the substrate. Thus, although the energy of the substrate is raised in the transition state complex, the enzyme provides stabilizing interactions with the transition state that result in overall stabilization of the complex and in an enhanced rate of reaction.

Enzymes have developed as extremely efficient catalysts because their active sites have evolved to bind transition states very tightly. It is this tight binding that stabilizes the transition state and lowers the free energy of activation. Enzymes do not alter the ground state energies of reactants and products of a chemical reaction. The equilibrium state is characterized as a state of lowest energy, and the composition of the reactant and product mixture at equilibrium is a reflection of these ground state energies. Enzymes emerge from the catalytic process unaltered, although some undergo transient chemical modification during the reaction.

NOMENCLATURE OF ENZYMES

The nomenclature of commonly measured enzymes was standardized by the Enzyme Commission (EC) of the International Union of Biochemistry

(1979, 1992). Each enzyme has two names: a practical or trivial name, and a systematic name. The latter consists of a unique numeric code designation and the nature of the catalytic reaction, as follows: Enzymes are named by citing the name of the substrate molecule and by following that with the suffix, -ase; sometimes the name also includes a designation of the type of reaction catalyzed.

Examples

1. RNA is hydrolyzed by an enzyme called ribonuclease.
2. Lactic acid is oxidized to pyruvic acid by an enzyme called lactic acid dehydrogenase.

Older trivial names persist in the literature. Examples are trypsin, a protein-hydrolyzing enzyme secreted into the gut, and papain, a plant enzyme that also hydrolyzes proteins. A more systematic classification of enzymes has been implemented in the biochemical literature (International Union of Biochemistry, 1979, 1992). Enzymes have been organized by reaction type into six major classes, as shown in Table 20-1.

ISOZYMES

Many enzymes have isoenzymes, called isozymes, of different forms that catalyze the same reaction. These different forms occur because of differences in the amino acid sequences of enzymes. Despite these differences in sequence, the enzymes fold to the same three-dimensional structures and frequently exhibit similar affinities for and catalytic rates with substrates. Often, isozymes occur as the result of differences in the chain composition of enzymes, as discussed later. Most commonly, different isoenzymes are found in specific organs or tissues; determination of the type of isoenzyme present can then be of use in identifying the damaged tissue and releasing the enzyme. The standard nomenclature of isoenzymes

is based on their electrophoretic migration, with the isoenzyme migrating farthest toward the anode designated **isoenzyme 1**. The most widely recognized isoenzymes are those that are composed of varying combinations of subunits; common examples are creatine kinase (CK), a dimer of muscle (M) and brain (B) subunits, and lactate dehydrogenase (LD), a tetramer of heart (H) and M subunits. In other cases, isoenzymes may have the same protein component but may differ based on modifications made by the cell of origin. For example, the bone, renal, and liver isoenzymes of alkaline phosphatase (ALP) have identical amino acid sequences but differ in carbohydrate composition.

In some cases, isoenzymes may have completely different protein structures. Distinct cytoplasmic and mitochondrial isoenzymes of both CK and aspartate aminotransferase (AST) have markedly differing structures. Placental and intestinal ALP isoenzymes have a different protein structure compared with that of the tissue-nonspecific forms found in liver, bone, and other organs.

Finally, enzymes can be modified by proteases present in serum to produce forms that differ slightly from each other; these are termed isoforms. As an example, CK-M subunits are partially metabolized by carboxypeptidase N, removing a lysine residue from the carboxy-terminal end of the molecule and converting the tissue isoform to a differently charged plasma isoform. The relative amounts of the tissue and plasma isoforms can be used as a marker of duration of injury to CK-containing cells. The official names and EC numbers of the commonly measured, clinically useful enzymes are given in Table 20-2 (Zollner, 1989).

ENZYME COFACTORS

Two thirds of all enzymes contain cofactors that are a group of heat-stable substances required for catalysis. They are low molecular weight organic molecules and inorganic ions. The combination of cofactor plus the protein portion, the apoenzyme, forms the complete catalytic entity and is known as the holoenzyme. Organic cofactors are bound covalently or noncovalently to the apoenzyme. Covalently bound cofactors are sometimes referred to as prosthetic groups. Cofactors are observed in oxidation-reduction, group transfer, and isomerization reactions, and in reactions that form covalent bonds. Hydrolytic reactions generally do not require cofactors. Organic cofactors are listed in Table 20-3. Inorganic cofactors that include mainly metal ions are listed in Table 20-4. A cosubstrate is an organic cofactor that behaves as a second substrate in an enzyme-catalyzed reaction. Cofactors such as nicotinamide adenine dinucleotide (NAD^+) can serve as cosubstrates for many oxidoreductases. A single molecule of NAD^+ may act as a cosubstrate many thousands of times. The product, NADH (reducing agent derived from NAD^+), must first be oxidized back to NAD^+ before it can participate again as an electron and H atom acceptor. The recycling of the NAD-NADH oxidation-reduction couple depends on the ready availability of a chemical system capable of regenerating NAD^+ from

TABLE 20-1
Enzyme Classification

Class	Type of reaction catalyzed
1. Oxidoreductases	Oxidation-reduction reactions
2. Transferases	Transfer of functional groups
3. Hydrolases	Hydrolysis reactions
4. Lyases	Group elimination to form double bonds
5. Isomerases	Isomerizations
6. Ligases	Bond formation coupled with ATP hydrolysis

ATP, Adenosine triphosphate.

TABLE 20-2
Names, Enzyme Numbers, Substrates for Enzymes

Enzyme (IUB group, EC number)	Substrate	Comments
AChE (hydrolase, EC 3.1.1.7)	Acetylcholine, acetyl thiocholine; hydrolyzes acetyl- β -methylcholine	Choline is $\text{HO-CH}_2\text{-CH}_2\text{-N}^+(\text{CH}_3)_3$, a quaternary amine; many esters with the OH group are substrates. Critical in regulating acetylcholine neurotransmission
PChE (hydrolase, EC 3.1.1.8)	Many aliphatic esters of choline; unlike AChE, does not hydrolyze acetyl- β -methylcholine but, also unlike AChE, does hydrolyze butyryl- and benzoylcholine	Largely unknown function; it is critical in hydrolyzing the muscle relaxant, succinyl choline
ACP (hydrolase, EC 3.1.3.2)	G6P, phenyl-P, 3-glycerophosphate, phenolphthalein-P, thymolphthalein-P, naphthol-P	Cleaves phosphate esters like ALP (see next entry) but at pH values around 5.0
ALP (hydrolase, EC 3.1.3.1)	See ACP	ALP has unusual pH optimum of about 9. Optimum pH varies with substrate and buffer
ACE (bradykinin, hydrolase, EC 3.4.15.1)	Splits C-terminal His-Leu dipeptide of angiotensin 1 to yield angiotensin 2; also splits hippuryl-His-Leu to hippurate + His-Leu	Considered a nonspecific hydrolase; acts on Met- and Leu-enkephalin
LD (oxido reductase, 1.1.1.27)	Pyruvate and other keto acids + NADH Also lactate and other 2-hydroxy acids + NAD^+	Moderately specific
5'-Nucleotidase (hydrolase, EC 3.1.3.5)	5'-Monoribonucleotides	Wide specificity for 5'-monoribonucleotides

ACE, Angiotensin-converting enzyme; AChE, acetylcholinesterase; ACP, acid phosphatase; ADP, adenosine diphosphate; ALP, alkaline phosphatase; ATP, adenosine triphosphate; EC, Enzyme Commission; G6P, glucose-6-phosphate; IUB, International Union of Biochemistry; LD, lactate dehydrogenase; NAD^+ , nicotinamide-adenine dinucleotide; NADH, the reduced form of NAD^+ ; P, phosphate; PChE, pseudocholinesterase; pNPP, p-nitrophenylphosphate.

NADH. A substrate molecule is usually irreversibly changed in a reaction. In contrast, cosubstrate molecules are recycled.

FACTORS AFFECTING PLASMA ENZYME ACTIVITIES

Plasma levels of enzymes may be increased by several mechanisms. Because enzymes are high molecular weight compounds, the most common cause for increased plasma enzymes is death of enzyme-containing cells. As cells die, activation of phospholipases leads to development of holes in the plasma membrane, allowing leakage of cytoplasmic macromolecules such as proteins. Enzymes are also released in the process of normal cell turnover; this is thought to be the source of normal plasma levels of various enzymes. Increased synthesis of enzymes by cells also leads to increased plasma enzyme levels. With increased activity of osteoblasts, plasma levels of the bone isoenzyme of ALP increase. This may be responsible for the increase in muscle-related enzymes seen with increased exercise (Dickerman, 1999). Many drugs that stimulate microsomal enzymes, including ethanol and antiepileptic agents, lead to increased plasma γ -glutamyl transferase (GGT). In some cases, release of enzyme from cells occurs without cell death or increased synthesis.

As discussed in Chapter 21 on liver function, ethanol causes expression of the mitochondrial isoenzyme of AST on the surface of hepatocytes and increased plasma levels. Ischemia of myocardial cells leads to loss of glycogen phosphorylase BB isoenzyme and the MB isozyme of CK into plasma. Ingestion of food leads to release of intestinal ALP into lymphatic fluid, and may transiently increase plasma levels of ALP. A number of liver enzymes (ALP, GGT, leucine aminopeptidase, 5'-nucleotidase [5'-NT]) are bound to the canalicular surface of the hepatocyte. Increased concentrations of bile salts with canalicular obstruction may release fragments of membrane with enzyme attached into the circulation, or may solubilize the membrane-binding domain (Van Hoof, 1997). Finally, increased plasma enzyme levels may be due to decreased clearance of enzymes from the circulation. Some smaller enzymes, such as amylase and lipase, are partially cleared by glomerular filtration; renal failure increases their plasma levels. For many enzymes, autoantibodies against one or more isoenzymes may cause the development of enzyme-antibody complexes (often termed macroenzymes) (Sosolick, 1997), which result in enzyme half-lives similar to the 3-week half-life of immunoglobulin G (Remaley, 1989). Most commonly, no specific clinical feature is associated with such macroenzymes; however, it is common to see antibodies against the intestinal isoenzyme of ALP in persons with bacterial infection (Mader, 1994). A similar phenomenon can occur when enzymes are bound to antibodies directed against other antigens, such as LD complexes with antibodies to streptokinase (Podlasek, 1989).

FACTORS AFFECTING THE LIFETIME OF ENZYMES IN BLOOD

The time course of appearance and disappearance of enzymes with cell injury is dependent on a number of factors. With cell death, defects in cellular membranes enlarge gradually over time; thus, smaller cytoplasmic enzymes will leak from damaged cells sooner than larger ones. For example, with myocardial injury, CK and AST are smaller than LD and appear in plasma sooner. Some enzymes are not cytoplasmic, but may be within mitochondria (isoenzymes of CK and AST) or bound to plasma membranes (such as ALP and GGT); cell death typically does not lead to release of such enzymes. If cell death is due to infarction caused by interruption of blood flow to a portion of an organ, enzymes released from damaged cells must diffuse away from the nonperfused region before appearing in the circulation. For example, in myocardial infarction, CK peaks later in persons whose coronary arteries are not successfully reperfused by the use of thrombolytic agents. The degree of elevation of an enzyme is related to the number of cells injured, the gradient in concentration between cell and plasma, and the rates of enzyme entry into and clearance from plasma. In myocardial infarction, the amount of CK released is strongly correlated to size of infarction; thus, enzyme levels with one-time injury are related to the amount of cell injury occurring. If injury is ongoing, plasma enzyme levels will continue to be elevated for a longer time period. For example, in acute hepatic injury, the time course of enzyme changes can be used to differentiate viral hepatitis, in which immunologic damage causes ongoing cell death and prolonged enzyme elevation, from ischemic and toxic injury, in which damage is immediate but short-lived and enzyme elevations rapidly return to normal.

Other important determinants of the time course of enzyme changes include the relative gradient in enzyme levels between cells and serum and the rate of clearance of enzyme from plasma. For any given amount of cell damage, the enzyme with the higher gradient between cells and serum will show greater elevation of plasma levels. For example, with hepatocyte injury, AST levels in hepatocytes are higher than those of alanine aminotransferase (ALT), and both are many times higher than levels of LD. Immediately after injury, therefore, AST will show a greater degree of elevation than will ALT, and LD will show the least degree of increase. In cardiac tissue, the gradient of CK between myocardial cells and plasma is several times higher than that for LD, leading to higher peak CK than LD levels. Once enzyme reaches plasma, the rate of clearance also becomes important; for example, the half-life of AST is much shorter than that of ALT, and the half-life of CK is shorter than that of the cardiac isoenzymes of LD. With hepatic injury, therefore, plasma ALT often becomes higher than AST within a short time after injury. Following myocardial infarction, CK returns to normal several days earlier than does LD.

ENZYME KINETICS: DETERMINATION OF TOTAL ENZYME CONCENTRATIONS IN SERUM AND OTHER BODY FLUIDS

The basic objective of clinical enzymology is the determination of the total concentrations of specific enzymes in serum and other body fluids. Qualitatively, detecting the presence of enzymes in body fluids is fortunately quite simple because each enzyme has almost total specificity for one or at most a few substrate(s). By adding the substrate, say, to serum, and observing either its disappearance or the appearance of the product, the presence of the enzyme can be ascertained. As is now explained, the rate at which substrate disappears or product appears can be directly used to determine the concentration of enzyme present (Cleland, 1970, 1990; Dixon, 1979; Cornish-Bowden, 1995; Fersht, 1999; Segel, 2009).

THE MICHAELIS-MENTEN EQUATION GIVES THE MEANS TO DETERMINE TOTAL ENZYME CONCENTRATION IN SERUM AND OTHER BODY FLUIDS

Enzymes exhibit saturation, which occurs when the rate becomes unresponsive to further increases in substrate concentration. Ordinary chemical reactions occur with rates proportional to the entire range of reactant concentrations. In an enzyme-catalyzed reaction, at low substrate concentrations rates are proportional to substrate concentration. At higher concentrations, the rate does not increase in direct proportion. At still higher

TABLE 20-3
Enzyme Cofactors

Coenzyme	Reaction type	Deficiency
Coenzyme A	Acyl transfer	
Thiamine pyrophosphate	Aldehyde transfer	Beriberi
Folic acid coenzymes	One-carbon transfer	Megaloblastic anemia
Cobamide (B ₁₂) coenzymes	Alkylation	Pernicious anemia
Nicotinamide coenzymes	Oxidation-reduction	Pellagra
Flavin coenzymes	Oxidation-reduction	
Biotin	Carboxylation	
Lipoic acid	Acyl transfer	
Pyridoxal phosphate	Amino group transfer	
Coenzyme Q	Electron transfer

substrate concentrations, the rate becomes constant and unresponsive to any further change in substrate concentration. This led to the proposal that enzyme catalysis is a two-step process that consists of an initial adsorption whereby the substrate combines with the enzyme to form a noncovalent enzyme-substrate (ES) complex, followed by a second step in which the ES complex decomposes into product (P) and free enzyme (E).

The formation of enzyme-substrate may be regarded as the step in which the enzyme recognizes the substrate. This process involves the formation of specific *noncovalent* interactions between enzyme and substrate. These interactions include ionic interactions, hydrophobic interactions, hydrogen bonding, and van der Waals interactions.

The physical explanation for saturation is that binding reduces the number of active sites available to form the enzyme-substrate complex. When all sites are filled, no further binding can occur until an active site discharges its contents. The step that determines the overall rate is the k_2 step. Adding additional substrate molecules under saturating conditions does not change the rate because all unbound substrate molecules must wait until an active site becomes vacant. This kinetic model is now used to derive the Michaelis-Menten equation that enables direct determination of total enzyme concentration or activity.

Derivation of the Michaelis-Menten Equation

The velocity, v , the rate at which product forms, of an enzyme-catalyzed reaction is defined as:

$$v = v_0 = d[P]/dt = k_2[ES] \quad (20-2)$$

where t is time. Note that v is the *initial* velocity of the reaction, referred to as v_0 , where we know the concentration of the substrate. It is important to measure initial velocities to ensure the absence of product inhibition (when time $[t] = 0$, $[P] = 0$) and the loss of enzyme due to proteolysis, denaturation, or time-dependent adsorption onto glass or plastic surfaces.

The differential rate law, which gives the rate of change of $[ES]$ with time, is the difference between the rate of the k_1 step leading to formation of the complex and the rates of the steps leading to the disappearance of $[ES]$ and k_1 and k_2 steps.

$$d[ES]/dt = k_1[E][S] - k_{-1}[ES] - k_2[ES] \quad (20-3)$$

For a wide variety of enzyme-catalyzed reactions, it has been found that, over long periods of time, after an initial transient phase lasting a few milliseconds, the concentration of the ES complex remains constant (i.e., does not change in time), especially when $S \gg E$. This is the steady-state assumption. Therefore,

$$d[ES]/dt = 0 = k_1[E][S] - k_{-1}[ES] - k_2[ES] = k_1[E][S] - (k_1 + k_2)[ES] \quad (20-4)$$

and

$$[ES] = k_1[E][S]/(k_{-1} + k_2) = [E][S]/K_M \quad (20-5)$$

where the ratio of the rate constants $k_1/(k_{-1} + k_2)$ is defined as $1/K_M$. K_M is termed the Michaelis constant, whose significance is discussed later.

If E_T is the total concentration of enzyme, it is equal to free enzyme plus enzyme bound to substrate, that is,

$$[E_T] = [E] + [ES] \quad (20-6)$$

Then, using Equation 20-5,

$$[E_T] = [E] + [E][S]/K_M \quad (20-7)$$

and

$$[E] = [E_T]/(1 + [S]/K_M) \quad (20-8)$$

and substituting for $[E]$ in Equation 20-5,

$$\begin{aligned} [ES] &= [E][S]/K_M \\ &= [E_T]/(1 + [S]/K_M) \times [S]/K_M \\ &= [E_T][S]/(K_M + [S]) \end{aligned} \quad (20-9)$$

Combining Equation 20-9 with Equation 20-2, we have

$$\frac{d[P]}{dt} = V_0 = k_2[ES] = \frac{k_2[E_T][S]}{(K_M + [S])} \quad (20-10)$$

Figure 20-4 The effect of substrate concentration $[S]$ on the velocity (V) of an enzyme-catalyzed reaction. The plot is for an enzyme that obeys Michaelis-Menten kinetics, where the maximal velocity is V_{max} and $[S]$ equals K_M where (v) equals $V_{max}/2$.

Equation 20-10, termed the **Michaelis-Menten equation**, accurately describes virtually all single-substrate enzyme-catalyzed reactions and many bisubstrate reactions in which the concentration of one substrate is constant throughout the course of the reaction.

Total Enzyme Concentration Can Be Determined From the Initial Rate at Saturation

A typical plot of v_0 versus initial substrate concentration is shown in Figure 20-4. The curve is a rectangular hyperbola, and the initial rate increases up to a particular substrate concentration beyond which the rate remains constant. This occurs on the curve where $[S] \gg K_M$. This is referred to as saturation, where all of the enzyme molecules are bound to substrate, making it impossible to increase the rate any further by increasing $[S]$. Note that, where saturation occurs, that is, where $[S] \gg K_M$, Equation 20-10 reduces to

$$d[P]/dt = v_0 = k_2[E_T] \quad (20-11)$$

Because the rate is constant at saturation, the rate is zero order with respect to substrate; the rate does not depend on the concentration of reactants. There is a dependence on E_T , which, however, is not consumed in the reaction. At saturation, the initial velocity of the reaction is referred to as the maximal velocity, or $V_{max} = k_2E_T$. Under this saturating condition, the initial rate of the reaction is directly proportional to the total enzyme concentration. If k_2 is known, then E_T can be directly computed as the observed initial rate divided by k_2 . This equation solves the problem of determining the total enzyme concentration from measurements of the rate of the enzyme-catalyzed reaction where $[S] \gg K_M$.

Knowledge of k_2 and K_M Allows Determination of $[S]$ Values That Will Saturate the Enzyme

To fulfill the conditions of Equation 20-11, it is necessary to know both K_M and k_2 . These can be estimated from plots similar to the one shown in Figure 20-4. To generate these plots, the purified enzyme is dissolved in aqueous solution in a series of tubes at the same concentration. To each of these tubes, a different concentration of substrate is added, and the initial rate of reaction for each tube is determined using a suitable (mostly spectrophotometric) technique. The value of v_0 vs initial substrate concentration $[S]$ can be plotted; the value of S at which the rate levels off (i.e., becomes constant) can be estimated from the plot.

The Lineweaver-Burk Plot Gives k_2 and K_M

The problem with this approach is that, in the v_0 versus $[S]$ plot, the rate approaches V_{max} asymptotically. Therefore, V_{max} can only be estimated, often inaccurately, from such a plot. A more accurate method by which to accomplish this goal is to linearize the Michaelis-Menten equation (20-10) by taking the reciprocal of both sides of the equation and rearranging the terms, that is,

Figure 20-5 A typical Lineweaver-Burk ($1/v_0$ vs. $1/[S]$) plot, from Equation 20-12, for an enzyme-catalyzed reaction. v_0 is the initial velocity of the reaction at time $t = 0$, where the substrate concentration, $[S]$, is known. The figure shows that $[S]$ must cover a range from where it is significantly less than K_M ($0.5 K_M$) to where it is significantly greater than K_M ($5 K_M$) to obtain reliable values for K_M and V_{\max} . The Y-intercept is $1/V_{\max}$, and the X-intercept is $-1/K_M$. The slope is K_M/V_{\max} .

$$\frac{1}{v_0} = \frac{K_M}{V_{\max}} \cdot \frac{1}{[S]} + \frac{1}{V_{\max}} \quad (20-12)$$

As can be seen from Equation 20-12, a plot of $1/v_0$ versus $1/[S]$, called the double reciprocal plot, also called the Lineweaver-Burk plot, should be linear; the Y-intercept should be $1/V_{\max}$, and the slope should be K_M/V_{\max} . Because $1/V_{\max}$ is the intercept, K_M can be computed as the slope/Y-intercept. Because from Equation 20-12, the X-intercept is $-1/K_M$, K_M can also be computed directly from this relationship. K_M can be computed directly from the Michaelis-Menten equation (20-10) from V_{\max} . When $[S] = K_M$, from Equation 20-10, $v_0 = V_{\max}/2$. Thus the K_M is the substrate concentration necessary to reach $V_{\max}/2$. A typical Lineweaver-Burk plot is shown in Figure 20-5.

Practically, after the points are obtained from the double reciprocal plot, the least squares best line is drawn through the points from which the slope and X- and Y-intercepts are directly determined. The correlation coefficient, which is a measure of the closeness-of-fit of the experimental points to the best line, is also calculated and should be greater than 0.9, that is, a high correlation.

Note in the above procedure and as is illustrated in Figure 20-5 that substrate concentrations must span a range that brackets K_M . Measurements of v_0 at low $[S]$ have relatively large errors, as illustrated in the upper right portion of the line in Figure 20-5, yet it is these estimates which are critical in determining accurate values of K_M and V_{\max} . Modern computer programs provide reasonably accurate values for K_M and V_{\max} based on weighted values of the initial velocities. Weights are assigned based on the magnitude of v_0 . In addition, other computer programs use nonlinear regression analysis to fit the weighted data to a hyperbolic v_0 versus $[S]$ curve, as in Equation 20-10, and a Lineweaver-Burk plot is used only for visual display of the kinetic data.

Once K_M is known, saturating concentrations of substrate can be used such that $[S] \gg K_M$. So, for example, if $K_M = 1 \times 10^{-5}$ M for a certain enzyme for which an assay is desired, we can use a substrate concentration of 1×10^{-3} M (1 mM) and be assured that $[S] \gg K_M$, here by a factor of 100, so that Equation 20-11 applies. The substrate at this concentration is added to a patient sample (most often, serum), and the rate is observed and then divided by k_2 to obtain the total concentration of enzyme. As discussed later, because many enzymes exist as different isozymes with different k_2 and K_M values, division by k_2 is not performed, and the results are reported directly as $k_2 E_T$, referred to as total activity units.

A Word About K_M

Equation 20-1 shows that the ES complex is in equilibrium with free E and free S. We can write an equilibrium constant for this process as a dissociation constant, K_s , as k_{-1}/k_1 , which is equal to $[E][S]/[ES]$. The reciprocal of this constant, or the association constant, K_A , is $k_1/k_{-1} = [ES]/[E][S]$. From Equation 20-5, K_M is defined as $(k_{-1} + k_2)/k_1$. Note that when $k_{-1} \gg k_2$, K_M is the same as K_s . This condition actually pertains to most enzyme-catalyzed reactions; k_{-1} is the rate of dissociation for the

enzyme-substrate complex that almost always involves the breaking of noncovalent bonds, and k_2 is the rate for the breaking and/or making of covalent bonds. Usually, the energy necessary for the former process is much less than for the latter; therefore, the rate of dissociation, k_{-1} , of the noncovalent ES complex is higher than the rate, k_2 , for the covalent catalysis step. Thus K_M is the dissociation constant for the ES complex. The reciprocal of this is K_A , the association constant, and it is the affinity of the substrate for the enzyme.

However, in some cases, the rate for the covalent catalytic step is greatly enhanced. Examples include carbonic anhydrase ($k_2 = 10^6 \text{ sec}^{-1}$; carbon dioxide is the substrate) and catalase ($k_2 = 10^7 \text{ sec}^{-1}$; hydrogen peroxide is the substrate). For these enzymes, because k_2 is large, K_M is not a dissociation constant, but rather a steady-state constant, equal to k_2/k_1 .

Enzyme Activity

As noted previously, computation of total enzyme concentration using Equation 20-11 is often not performed because many enzymes have multiple isozymes. For example, at least five isozymes of LD are known, each having a different set of values for K_M and k_2 . In this case, the total enzyme activity of LD is given, that is, $k_2 \times [E_T]$. In these cases, enzyme activities are all reported in units called international units, defined originally in 1964 by the International Commission on Enzymes. One international unit (IU) is the amount of enzyme that catalyzes the formation of one micromole of product (or the disappearance of 1 micromole of substrate) in 1 minute. It applies only under specified conditions of pH, temperature, and ionic strength, all factors which influence enzyme activity, as discussed later.

With development of the Système International d'Unités system and the use of moles and seconds as base units, a second definition for the unit of enzyme activity was developed, the katal: 1 katal is defined as the amount of enzyme that catalyzes the conversion of 1 mol of substrate to product in 1 second, under the conditions used in the assay. One IU is equal to 16.7 nanokatal (nkat), and 1 katal is equal to 6×10^7 IU. Both definitions unfortunately omit volume. Generally, 1 IU is reported per liter (L); the right side of Equation 20-11 has the units of concentration per time so that IU/L conforms to these units. It is vital that, if total enzyme activity is reported, the substrate used in the assay for the enzyme also be reported because the k_2 value differs for different substrates.

As discussed later, many factors affect enzymatic activity, including pH, temperature, ionic strength, concentration of cofactors of an enzyme, presence of inhibitors, use of other enzyme reactions as indicators, and whether the forward or backward reaction is used to measure the enzyme concentration. For example, LD measured using the forward reaction has approximately one third the activity of LD measured using the reverse reaction, and lipase measured with colipase present has 5 to 10 times the activity of lipase measured without its cofactor.

Therefore, even if the same substrate is used by different laboratories, the reference ranges of enzymes may differ dramatically among these laboratories. Furthermore, differences in reference ranges between two different laboratories can still exist even if the above factors are the same for both, because of different assay conditions.

To attempt to standardize enzyme activities, one approach is to have each laboratory set the upper boundary of the reference range to 100 (Langdon, 1994). Then all other values are expressed as percentages or ratios. A result indicating that an enzyme level was 10 times normal is useful to a physician. If the result is 10X U/L, then the physician must hunt the value of X and calculate the ratio. As long as the assays are performed with internal consistency in a highly reproducible manner, quantitative results are comparable between one laboratory and another if relative activities are reported. More commonly, the results of enzyme assays are now expressed in IU along with the reference ranges for each enzyme, allowing for evaluation of the patient's condition, progression of disease, or efficacy of therapy.

Measuring Enzyme Activity
