Figure 44-16 Substrate-labeled fluorescent immunoassay (SLFIA). The substrate β -galactosylumbeliferone is conjugated with the antigen (analyte) and forms a nonfluorescent substrate. The substrate can be cleaved by the enzyme β -galactosidase to form a fluorescent product. However, when the substrate-antigen conjugate is allowed to react with specific antibody to the antigen, no cleavage of the substrate complex with the β -galactosidase enzyme occurs. In this assay, the concentration of the antigen (analyte) is directly proportional to the fluorescent intensity measured. (With permission from Nakamura RM, Kasahara Y, Rechnitz GA, editors. *Immunochemical assays and biosensor technology for the 1990s*. Washington, DC: American Society for Microbiology, ASM Press; 1992.)

Enzyme Inhibitory Homogeneous Immunoassay

The enzyme inhibitory homogeneous immunoassay (EIHIA), developed by Ashihara (1988), consists of antibody conjugated with enzyme and insoluble substrate. This assay is most suitable for the determination of large antigens (analytes). The EIHIA can be made to be homogeneous because the immunocomplex of conjugate with large antigen blocks the enzyme reaction with

the solid substrate (Fig. 44-18). α -Amylase has been used as a labeled enzyme for the determination of ferritin and AFP. The immunoreaction of analyte with enzyme-labeled antibody can reach a plateau within 10 minutes; thus, EIHIA based on a noncompetitive binding assay requires less incubation time to achieve a sensitive detection level. Using this method, the measuring range of ferritin in serum is 10–800 ng/mL,

Figure 44-17 Apoenzyme reactivation immunoassay (ARIS). Flavin adenine dinucleotide (FAD) attached to the antigen is used. The apoenzyme is apoglucose oxidase, which requires FAD cofactor for activity. In the assay, the concentration of antigen (analyte) is proportional to the enzyme activity generated. (With permission from Nakamura RM, Kasahara Y, Rechnitz GA, editors. *Immunochemical assays and biosensor technology for the 1990s*. Washington, DC: American Society for Microbiology; 1992.)

Figure 44-18 Enzyme inhibitory homogeneous immunoassay (EIHIA). The enzyme α -amylase from *Bacillus subtilis* or dextranase from *Chaetomium gracile* is conjugated to the specific antibody to the high-molecular-weight antigen. The high-molecular-weight antigen can be ferritin or α -fetoprotein. The α -amylase enzyme is inactive when the enzyme antibody conjugate reacts with specific antibody. The active enzyme form can react with the starch-insoluble substrate. The antigen concentration is directly proportional to the enzyme activity of the assay reaction. (With permission from Nakamura RM, Kasahara Y, Rechnitz GA, editors. *Immunochemical assays and biosensor technology for the 1990s*. Washington, DC: American Society for Microbiology; 1992.)

and for AFP it is 5–200 ng/mL. Dextranase has been used as an alternative enzyme (Nishizono, 1988). EIHIA has also been applied to a simple dry-film format (Ashihara, 1991). The dry film consists of three major layers, each containing a developing zone for immunologic and enzymatic reaction, a barrier zone, and a color-developing zone. An inhibitor specific to human amylase present in serum is used to prevent serum background. The assay for serum C-reactive protein is completed in only 6 minutes by simply

placing the specimen on the slide using dry chemistry instrumentation. Nevertheless, the sensitivity of the system remains inadequate for application to analytes such as tumor markers.

Cloned Enzyme Donor Immunoassay

The cloned enzyme donor immunoassay was first achieved through the application of recombinant DNA technology to homogeneous

Figure 44-19 Cloned enzyme donor immunoassay (CEDIA). Enzyme acceptors associate with enzyme donors to form an active β -galactosidase tetramer. The antibody inhibits the association of enzyme acceptor with enzyme donor–antigen conjugate. (With permission from Nakamura RM, Kasahara Y, Rechnitz GA, editors. *Immunochemical assay and biosensor technology for the 1990s*. Washington, DC: American Society for Microbiology; 1992.)

immunoassays by Henderson (1986). Microgenics Corp. (Concord, Calif.) was able to engineer β -galactosidase protein into a large polypeptide (an enzyme acceptor [EA]) and a small polypeptide (an enzyme donor [ED]). EAs and EDs assemble to form enzymatically active tetramers. In the assay (Fig. 44-19), a hapten antigen (analyte) is attached to an ED, and an analyte-specific antibody is used to inhibit spontaneous assembly of the active enzyme. The antigens (analytes) in patient serum compete with the analytes in the analyte–ED conjugate for antibody, modulating the amount of active β -galactosidase formed. The signal generated by enzyme substrates is directly proportional to the analyte concentration in the patient serum. The test for digoxin is a colorimetric assay that requires no serum pretreatment or predilution. The assay system is suitable for use with automated chemistry analyzers.

SUMMARY

EIAs can be applied to all Ag–Ab systems, including those involving serum protein, hormones, drugs, and other antigens and the antibodies directed against pathogens. Heterogeneous EIAs using chromogenic substrates can have a sensitivity comparable with that of RIAs, and they have gained wide acceptance for application in various immunoassays. Heterogeneous EIAs using sophisticated substrates that generate chemiluminescent light and small particles as the solid phase are sensitive enough to detect less than 1 pg/mL of analytes. Their sensitivity is thus much higher than that of RIAs. In addition, the assay manipulation is greatly simplified by fully automated instruments. Compared with heterogeneous EIAs, homogeneous EIAs have certain limitations in sensitivity, dynamic range, and large analyte application. Also, high background signals (noise) and relatively low assay signals are inevitable because of elimination of the washing steps for the separation of bound and free conjugates. Homogeneous EIAs are advantageous because they are based on a simple assay format and can be adapted to existing automatic instrumentation. At this time, heterogeneous EIAs with fully automated instruments remain the best choice in terms of sensitivity and simplicity, as well as for safety reasons, because they do not require the use of radioisotopes.

FLUORESCENT IMMUNOASSAY

BACKGROUND AND CLASSIFICATION

Coons (1941) first introduced the use of fluorescent compounds as immunochemical labels to detect antigens in tissue sections. Immunofluorescence assays on tissue sections are currently very well established in the

pathology laboratory. Over the past several years, many FIA procedures have been developed to detect the concentrations of drugs, hormones, and a wide variety of proteins and polypeptides (Nakamura, 1992). In the initial stages of development, analytic FIAs were hindered by a decrease in sensitivity caused by background fluorescence of biological samples. Gradually, the sensitivity of fluorometric methods improved, and detection of analytes at concentrations of 10^{-15} M became possible. Further advancements were achieved through improvements in instrumentation and the introduction of unique substrates with various immunochemical and enzymatic reactions.

Selection of the fluorochrome label is important. The label should be stable and should demonstrate high molar extinction coefficient and quantum yield. It should also emit at appropriate wavelengths without interference with ligand–antibody reactions. When most fluorophores or fluorescent molecules are irradiated with light at appropriate wavelengths, an electron in the ground state is transited into the excited state of the molecule. As the electron returns to the ground state, physical energy is released in the form of a photon of lower energy (longer wavelength) than the exciting light. The fluorescence spectrum reveals a wavelength of maximal emission, characteristic of a particular fluorescent compound. One of the typical labels, fluorescein isothiocyanate (FITC), has a less than 1 nanosecond time interval between excitation and emission, whereas other compounds (e.g., europium) exhibit delayed fluorescence with an interval of several hundred nanoseconds. The various FIAs may be classified as follows: (1) heterogeneous and homogeneous, (2) ligand or antibody labeled, (3) competitive or noncompetitive, and (4) solid or nonsolid phase. The most common methods are discussed here.

HETEROGENEOUS FLUORESCENT IMMUNOASSAY

Heterogeneous FIA procedures include a washing step to separate bound from free fluorescent labels. The assay procedure is similar to that of heterogeneous enzyme immunoassays and RIAs. Most commercially available assays use a solid-phase antigen or antibody system. The assay can be competitive or noncompetitive—a property shared by RIAs and EIAs.

FLUOROIMMUNOMETRIC METHOD

With the fluoroimmunometric method, the analyte reacts with excess labeled antibodies in the solution. Residual labeled antibodies bind to excess solid-phase bound antigens. The solid-phase matrix is washed, and

Figure 44-20 Assay principle of fluorescence polarization immunoassay (FPIA). **A**, A polarized beam can excite both an unbound conjugate and the conjugate bound to antibody (Ab) existing at the same angle as the irradiating beam. The conjugate consists of hapten (H) with a fluorescent molecule (F). **B**, Orientation of the molecules at the time of fluorescence emission. Small hapten conjugates free of antibody can quickly change their orientation and emit fluorescence at different angles that is not detected. However, the conjugate bound to the antibody still remains at the same angle because of its very slow movement, and it emits fluorescence that is detected.

fluorescence intensity is inversely related to the analyte concentration. This method can be adapted to the assay of haptens and complex proteins. Solid-phase FIA procedures were developed for the serologic assay of antibodies to rubella, toxoplasmosis, viral antigens, and antinuclear antibodies. Heterogeneous FIA methods for antigen determination were developed for serum proteins and hormones, including immunoglobulins, cortisol, progesterone, and thyroxine. The major advantage of heterogeneous FIAs is the significant reduction in interference by naturally fluorescent substances in patient samples, caused by the physical removal of interference factors during the separation step.

RADIAL PARTITION IMMUNOFUOROMETRIC ASSAY

In radial partition immunoassays, radial chromatography is used and the assay is carried out on glass-fiber filter papers (Giegel, 1982). This procedure has been automated for the assay of hCG and several other analytes in serum (Rogers, 1986).

TIME-RESOLVED FLUOROIMMUNOASSAY

This method makes use of special instrumentation and fluorescent labels to increase assay sensitivity. It involves the use of fluorescent labels exhibiting delayed fluorescence with a time period of 100 ns or longer between excitation and emission. Because most substances responsible for background fluorescence have a short decay period, measurement of the delayed fluorescence signal will significantly reduce the effects of background fluorescence. This is accomplished with the time-resolved fluorometer, a special instrument that produces a fast light pulse that excites the fluorophore. Fluorescence is measured a little while after excitation. Thus, the effect of nonspecific background, which generally decays in less than 10 nanoseconds, can be removed (Halonen, 1973; Soini, 1983). Fluorophores exhibiting delayed fluorescence that have been used in these assays include (Soini, 1979) the following:

- Pyrene derivatives with a decay time of almost 100 ns
- Rare earth metal chelate labels with a very long decay time of almost 50–100 μ s. These include europium (Eu^{3+}), samarium (Sm^{3+}), and terbium (Tb^{3+}).
- Time-resolved fluorimmunoassays have been developed to measure many analytes, including hCG, IgG, cortisol, insulin, and others.

HOMOGENEOUS FLUORESCENT IMMUNOASSAY

By definition, these immunoassays are performed on homogeneous specimen samples. They do not require the separation of bound from free conjugates and usually are not sensitive to background interference in the samples. Homogeneous FIAs also have the advantage of being quick to perform. However, when compared with heterogeneous assays, they show certain disadvantages. Homogeneous FIAs have a limited sensitivity near 10^{-10} m/L with standard instrumentation. Labeled impurities in the sample may increase background interference. The assays require relatively pure labeled antigen or specific antibody, as well as special instrumentation, to achieve higher sensitivity.

FLUORESCENCE POLARIZATION ASSAY

A polarizing lens or prism can resolve light into rays in a single plane. When viewed at the right angle of an excitation beam of vertically polarized light, fluorescent compounds in solutions emit partially polarized fluorescence. The fluorescence polarization principle was first applied to immunoassay procedures by Dandliker (1970, 1973). Polarized light transmitted through the sample can excite the fluorescent label, regardless of binding to antibody. However, as shown in Figure 44-20, random thermal motion causes small molecules labeled with a hapten to tumble freely in solution, losing their polarized orientation. When the labeled antigen is bound to antibody with a molecular mass greater than 160 kDa, the molecular motion is slowed enough to increase the polarized signal.

Studies using labeled antibody or antibody fragments showed no change in polarization upon mixing antigen and labeled antibody, even though immunoreaction had occurred. This method is most useful for the measurement of small antigens and haptens (Jolley, 1981). Abbott Laboratories has adapted this approach for the assay of many therapeutic and abused drugs on the TDx (Abbott Diagnostics, Abbott Park, IL). They developed a next generation analyzer, the IMx, to measure molecules with large masses such as tumor markers, hormones, and infection-related antigens or antibodies (Fiore, 1988). They combined two assay principles—fluorescence polarization and microparticle enzyme immunoassay. The demand for random access capabilities led Abbott to develop a fully automated, high-throughput random access analyzer named the AXSYM. This system is being used in clinical laboratories (Smith, 1993).

Figure 44-21 Chemiluminescent immunoassay mechanism with acridinium ester based on oxidative decomposition.

FLUORESCENCE EXCITATION TRANSFER IMMUNOASSAY

The fluorescence excitation transfer (FETI) method (Ullman, 1976) uses two labels: fluorescein as the donor fluorescent label and rhodamine as the acceptor or quencher. FITC has a maximum emission of 525 nm, and tetraethylrhodamine has a strong absorption peak at 525 nm. Therefore, when FITC-labeled antigen and rhodamine-labeled antibody bind, quenching of FITC fluorescence occurs. This phenomenon involves an energy transfer from an electronically excited fluorescent dye to an acceptor dye. The rate of energy transfer is inversely proportional to the sixth power of the distance between donor and acceptor molecules. For adequate reduction of fluorescence with quenching, the donor-acceptor distance between labels should be about 50–70 Å. This method is useful for the assay of antigen with multivalent antigenic determinants. Separate portions of specific antibody are labeled with fluorescein and rhodamine. The mixture of differently labeled fluorescein-tagged antibody and rhodamine-labeled antibody reduces the intensity of the fluorescein label by adjusting the ratio and amount of donor and acceptor molecules, so that they can react in close proximity to permit energy transfer. These problems have been overcome using new fluorescent compounds. The FETI method has been improved with the use of a fluorescence marker such as europium (III) (Eu(III)) trisbipyridine cryptate as a donor, and a fluorophore such as allopycocyanin as an acceptor (Alpha, 1987; Mathis, 1995). These transient compounds reveal a large Stokes shift in which the excited europium at 337 nm transfers energy through an acceptor molecule at an excitation of 620 nm and eventually emits fluorescent light at 665 nm, as in the time-resolved mode. Mathis (1993) has developed the fluorescence resonance energy transfer using cryptate-chelating rare metal and has applied it to the detection of AFP and carcinoembryonic antigen (CEA) in serum. CIS Bio International (Ceze, France) developed an automated homogeneous immunoassay system, KRYPTOR, for the detection of cancer markers such as CEA, CA 19-9, CA 125, and AFP, using the time-resolved amplified cryptate emission. The sensitivity for AFP was 0.25 ng/mL for 9 minutes' incubation.

FLUORESCENT PROTECTION IMMUNOASSAY

In this assay (Nargessi, 1979), the protein antigen is labeled with fluorescein and then is reacted with specific antibody to the antigen. The antigen-specific antibody will sterically inhibit the reaction of a second antibody specific to fluorescein, which functions to quench the fluorescence of fluorescein when it binds to the fluorophore. The ability of the specific anti-fluorescein antibody to interact with fluorescein coupled to the surface of the antigen will decrease. The procedure may be used to assay for antibody concentration or for antigen (analyte) concentration in a homogeneous system.

CHEMILUMINESCENT IMMUNOASSAY BACKGROUND

Chemiluminescent immunoassays (CLIAs) use chemiluminescence-generating molecules as labels, such as luminol derivatives, acridinium esters, or nitrophenyl oxalate derivatives and ruthenium tri-bipyridyl [$\text{Ru}(\text{bpy})_3^{2+}$] with tripropylamine for electrochemiluminescence. Basically, the assay method does not differ from that of heterogeneous immunoassays, RIAs, and FIAs. Light generation of luminol derivatives requires $\text{OH}^-/\text{H}_2\text{O}_2$ as a chemical trigger or H_2O_2 with peroxidase as an enhanced

chemiluminescent trigger. Acridinium esters chemically triggered with $\text{OH}^-/\text{H}_2\text{O}_2$ display a relatively high chemiluminescent quantum yield for light emission compared with luminol. Other chemiluminescent molecules include aequorin, a natural compound (Actor, 1998). Labels of chemiluminescent compounds produce light electrochemically on the surface of electrodes and can be applied to homogeneous assay formats. Both CLIAs using acridinium esters and electro-CLIAs are applicable for practical diagnostic testing. Their characteristics are described in the following section.

CHEMILUMINESCENT IMMUNOASSAY USING ACRIDINIUM ESTERS AS LABELS

In this method (Weeks, 1983), acridinium esters (Fig. 44-21) are directly conjugated with protein molecules. Acridinium esters can oxidatively react with H_2O_2 under alkaline conditions to produce high-energy intermediates that decompose to the excited fragment, generating light. The light emission of acridinium esters is extremely fast, within 5–10 seconds after initiation of the oxidation reaction. Flash-type chemiluminescence, as this process is called, has a much steeper spectrum of light emission to reactive time than glow-type chemiluminescence triggered by enzymes. The sensitivity of this assay is higher than that of RIA, and testing is less time consuming. The solubility of acridinium esters and the stability of conjugates with proteins in storage have been improved through modification of the molecule and conjugation chemistry. This technology is likely to bring improvements in the assay of haptens, such as hormones.

ELECTROCHEMILUMINESCENT IMMUNOASSAY

Electrochemiluminescent immunoassay (ECLIA) uses electrochemical compounds that generate light electrochemically, linked with the cycle reaction of the oxidative reduction. With optimization of reaction solutions, selection of appropriate conjugation method, and development of suitable compounds such as $\text{Ru}(\text{bpy})_3^{2+}$ and TPA, it became possible to apply electrochemiluminescent technology to immunoassays (Blackburn, 1991). $\text{Ru}(\text{bpy})_3^{2+}$ has a reaction site for the conjugation of analytes using activation reagent such as NHS. $\text{Ru}(\text{bpy})_3^{2+}$, thus conjugated with antibodies, can be applied to sandwich-type assays for large molecules. The conjugate generates light on the surface of gold electrodes. $\text{Ru}(\text{bpy})_3^{2+}$ on solid phase and TPA are oxidized on the surface of electrodes to form $\text{Ru}(\text{bpy})_3^{3+}$ and TPA^+ , respectively. TPA^+ spontaneously loses electrons. $\text{Ru}(\text{bpy})_3^{3+}$ can generate emission light at 620 nm when it returns to $\text{Ru}(\text{bpy})_3^{2+}$ as a ground state through reduction with TPA. The efficiency of light generation (quantum yield) depends on the proximity between the electrode and the conjugate, and thereby on the diffusion mobility of the conjugate. Free conjugates can generate more light than conjugates fixed on the solid phase as a result of immunoreaction. This allows easy access to the homogeneous assay format, but relatively high background noise interferes with assay sensitivity, as it does in other homogeneous assays. The assay protocol for the determination of analytes is as follows: Magnetic microparticles coated with antibody as the solid phase and sample mix together for immunoreaction. After washing for bound and free conjugates by magnetic separation according to the assay format, the solid-phase suspension is introduced into the detector with the electrode to measure chemiluminescence. The detection limit of ECLIA has been reported as 0.2–0.4 ng/mL for CEA and 0.4 ng/mL for AFP. This assay does not require complicated instruments. A further advantage is that ECLIA requires less time for signal detection, similar to FIAs and other CLIAs.

INSTRUMENT AUTOMATION AND MODULATION OF ASSAY SYSTEMS

HOMOGENEOUS ASSAY SYSTEMS

Although many homogeneous immunoassays have been developed for manual protocol as described in this chapter, most have not yet been automated. For the EMIT method, fully automated generic chemistry analyzers can be adapted to use these (Boyd, 1985). A few instruments are available for homogeneous FIAs, and these assay systems are not interchangeable with each other. The BRAHMS KRYPTOR system, which is the most recent system, has been developed with special features, including the use of a time-resolved fluorescence detector. It uses a two-wavelength method for internal standard correction of fluorescence intensity at 620 nm and 665 nm, making it possible to increase the sensitivity of the detection limit.

HETEROGENEOUS IMMUNOASSAY SYSTEMS

Until the early 1980s, most heterogeneous labeled immunoassays were manually performed. Then Boehringer Mannheim (which merged with Roche Diagnostics in 1998) developed a fully automated random access analyzer, the ES-600, based on colorimetric enzyme immunoassays, using horseradish peroxidase as the enzyme (Wu, 1987). From the late 1980s onward, many companies endeavored to develop fully automated EIA systems, which were high-throughput, sensitive, randomly accessible systems. Antigens associated with early onset of infectious disease, cytokines, growth factors, and hormones such as calcitonin exist at extremely low concentrations in serum, thus requiring a highly sensitive detection method for measuring these analytes (Nishizono, 1991; Isomura, 1994, 1999). Among the various methods, chemiluminescent immunoassays and their enzymes are the most sensitive assay systems capable of detecting analytes present at very low concentrations.

The fully automated instruments currently available are also capable of using fluorescent enzyme immunoassays. These assay systems are classified into several groups based on the generation and detection of signals and the type of solid phase. With respect to the detection signal, the AIA1200, 600 (Toso, Tokyo, Japan) and the AxSYM (Abbott, Abbott Park, Ind.) employ a fluorescent method of the EIA that uses alkaline phosphatase and a specific substrate, 4-methylumbelliferylphosphate. Three types of systems are available for chemiluminescent enzyme immunoassays. Lumi-pulse (Fujirebio, Tokyo, Japan), Access (Sanofi, Caska, Minn.), and Immulite (Diagnostic Products Corporation, Los Angeles) have used a stable chemiluminescent substrate, phenyl phosphoryl adamantyl dioxetane, for alkaline phosphatase (Babson, 1991; Nishizono, 1991; Patterson, 1994). Acridinium ester as a chemiluminescent label was applied to the ACS 180 (Bayer Diagnostics, Tarrytown, N.Y.) and later to the Centaur (Siemens, Tarrytown, N.Y.) In the ELECSYS 2010 (Roche Diagnostics, Indianapolis), Ru(bpy)₃²⁺ is used as an electrochemiluminescent label (Erler, 1998).

PRACTICAL FLOW OF THE IMMUNOASSAY IN THE ANALYTIC SYSTEM

The market demands that instrumentation be able to perform a large number of tests with random access capability. To meet these criteria, it is necessary to improve reagents and avoid tediousness in performing heterogeneous immunoassays. To simplify the system for application in a fully automated assay system, individual cartridges of prepackaged reagents or predispensed reaction cuvette reagents were designed. A generic system for heterogeneous labeled immunoassays is depicted schematically in Figure 44-22. The operator selects the desired test items by means of a computer program and loads reagent cartridges or bottles for each test. For a particular analyte, the cartridges and the reaction cuvette are fed automatically into the instrument. Samples are transported to the appropriate position for dispensing. The assay is designed to use reaction trays or carousels that automate mixing and separation steps that depend on performance through first and second immunoreactions and the signal generation reaction. All steps of the assay are carried out sequentially on the reaction line, and the signals generated are measured by a detector. Test results are printed out within 20–40 minutes and are sent automatically online to the host computer. The system can treat about 60–200 tests

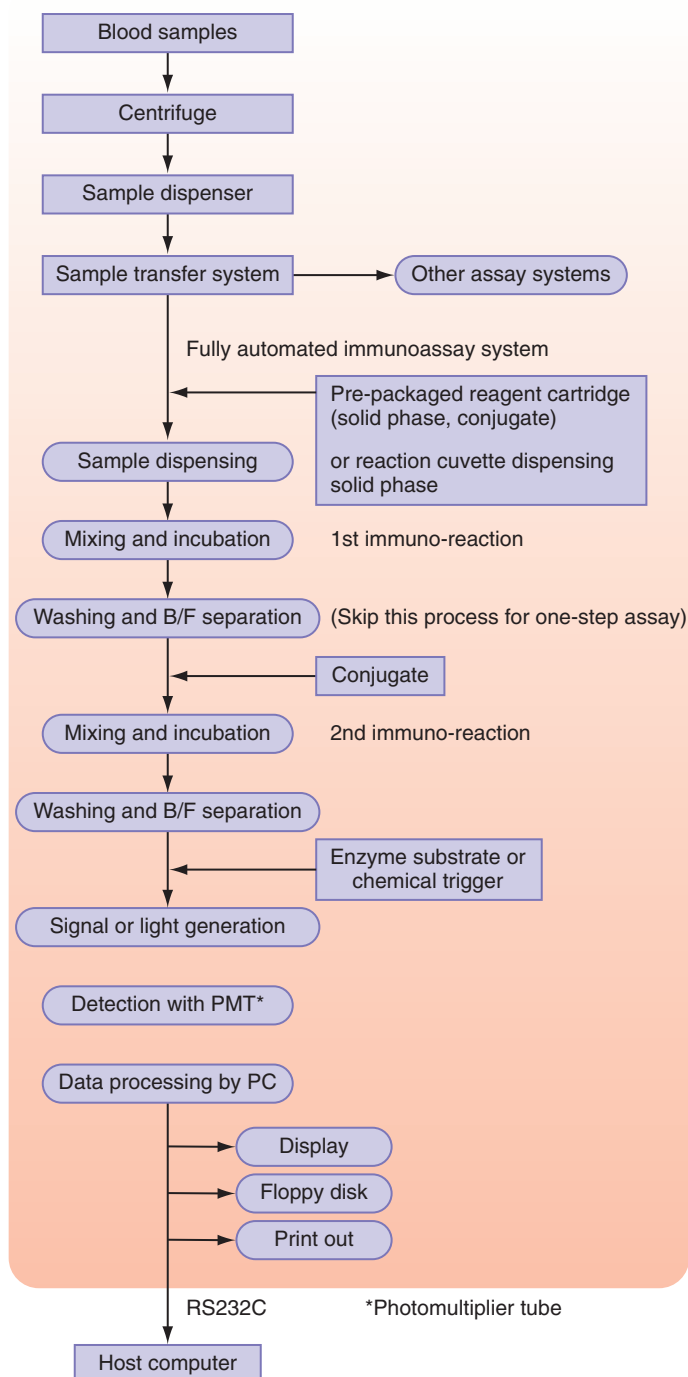

Figure 44-22 Brief diagram of fully automated immunoassay system in clinical laboratory automation.

per hour, processing 10–20 analytes in each sample specimen by the random access manner.

INSTRUMENTATION AND KEY POINTS FOR THE HETEROGENEOUS IMMUNOASSAY

Although the assay principle is similar in many instruments, big differences among instruments may be noted with respect to sampling format, heating control, B/F separation, carryover, waste flow, and so forth. Thus we should pay attention to how well the instrument performs after implementation.

Reaction Cuvette

In an immunoassay system, the design of cuvette features is very important to obtain reproducible data. Manufacturers use certain types of cuvettes to

achieve easy access and rapid handling of reagents. An all-in-one-type cuvette containing the reagents and the reaction cell has been introduced in the Lumipulse system. The Immulite system utilizes a unique reaction cell for B/F separation. The AxSYM (Abbott) uses another unique reaction vessel consisting of a reagent, an incubation well, and a sample well within a cuvette for B/F separation. The system combines the content of this assay cuvette into a matrix cell. The latter can be used to capture the solid latex phase followed by B/F separation and the second immunoreaction of the labeled antibody and the solid phase.

Sampling and Fluid Delivery Type

In general, fluid delivery is selected from two different types: a disposable chip or a fixed probe nozzle. Cross-contamination of samples should be avoided in all assay systems. The disposable chip can completely prevent cross-contamination. In the case of the fixed probe system, even though the original sample is divided into several small aliquots, cross-contamination still occurs. Therefore, the disposable chip system is the best way to avoid cross-contamination and to minimize biohazardous waste. On the other hand, the running cost of using chips for the assay is higher than that of the probe assay. Environmental effects of the disposable chips must be considered.

Carryover

Carryover from an extremely high concentration of analyte in one sample to the next sample sometimes causes misjudgment in clinical diagnosis. A disposable plastic tube is the simplest way to prevent this problem. On the other hand, the fixed probe nozzle has several cost advantages, as mentioned earlier. Thus, most of the technologies concerned with sample engineering have focused on minimizing sample carryover through washing and tip maintenance steps. Now, several fixed probe tips have made it possible to limit carryover to less than the order of 10^{-7} . Even with such low carryover, some samples still create problems (e.g., a hepatitis B surface antigen [HBsAg] strong positive sample followed by a negative). In this case, a software system can be used to check the subsequent result by automatically retesting weakly positive values following strong positive results.

Bound/Fixed Separation and Washing Systems

In a heterogeneous immunoassay, the bound conjugate has to be separated from the free label. This B/F separation depends on the characteristics of the solid phase. The IMx and AxSYM systems use latex microparticles as the solid phase and employ a porous membrane to entrap the latex for separation of particles of the solid phase from particles of the liquid phase. The Diagnostics Product Corporation has developed a unique cell for B/F separation systems, in which the reaction solution spins out from an inner cell to an outer waste cell, while the bound phase stays in a solid-phase bead ($\frac{1}{4}$ -inch bead). Advantages of this format are the avoidance of cross-contamination or carryover from one reaction mixture to the next and the fact that no excess washing process is required. All other systems use magnetic particles and magnetic beads, for which easy and rapid separation can be achieved by applying a magnetic field.

NEW SYSTEMS FOR THE NEXT GENERATION (MODULAR SYSTEMS)

Table 44-8 compares several of the commercial high-throughput immunoassay systems that have been introduced in the past few years. It shows the instrument specifications of each analyzer. By reducing the incubation and reaction times, a rapid result can be obtained in 10–25 minutes. Thus a high-throughput machine performing 120–200 tests/hour is possible. Furthermore, several manufacturers have demonstrated a new system concept that aligns the different analytic systems needed in a clinical laboratory. Many clinical laboratories have introduced an automated sample transporting line, which is connected to different analytic instruments controlled independently. However, several analyzers are not amenable to this approach because the speed of the instrument throughput or cycle time cannot be harmonized easily. To solve these problems, ARCHITECT (Abbott Laboratories) is an example of a new machine concept in which one system computer can control several immunoassay analyzers connected to one chemistry analyzer. Several other combinations still under development are based on this concept, which will make it possible to simplify the clinical laboratory and to lower total assay cost.

RAPID AND SIMPLE TEST DEVICES FOR POINT-OF-CARE TESTING

BACKGROUND

A strong demand for a home test (e.g., hCG for pregnancy diagnosis) has simplified the immunoassay format: The test must be simple, rapid, and reproducible. With these goals in mind, many hCG tests have been developed and have resulted in the first-generation test format with a flow-through enzyme immunoassay.

FLOW-THROUGH ASSAY DEVICES (IMMUNOFILTRATION ASSAY DEVICES)

Figure 44-23 illustrates schematically a typical flow-through-type device, the ICON hCG (Hybritech Incorporated, San Diego), which consists of

Figure 44-23 Flow-through immunoassay. Cross-section of Hybritech ICON and top view of the device. Capturing antibodies are immobilized at the center of a nylon membrane on which an absorbent bed is set to absorb unreacted sample fluid, labeled conjugate, and washing buffer. The assay can be performed sequentially, similar to a two-step enzyme immunoassay.

a porous membrane with immobilized anti-hCG antibody and an absorbent pad below the membrane (Valkirs, 1985). The assay principle and the procedure are as follows. Several drops of urine sample are applied to the membrane. Urine is absorbed into the absorbent pad, and washing buffer is applied dropwise, followed by a solution of alkaline phosphatase-labeled anti-hCG antibody.

DIPPING STRIP

A dipping strip format has also been developed to reduce the cost of materials as compared with the flow-through format. In this format, the test strip contains a spotting area with antibody at one end of the strip. The assay is performed as follows:

- The strip is dipped in a sample cup containing the sample.
- The strip is then dipped in a washing cup.
- The strip is dipped in labeling solution.
- Finally, the strip is dipped in color developer, if needed.

IMMUNOCHROMATOGRAPHIC DEVICES

To eliminate stepwise reagent additions in these two formats, further improvement has been accomplished with the use of immunochromatographic techniques that ensure a simpler and quicker immunoassay. Immunochromatography consists of simultaneous B/F separation and signal generation followed by lateral flow on porous materials such as a nitrocellulose membrane or a glass-fiber sheet. Through the capillary action of the membrane, the analyte in the sample can migrate from the proximal end to the distal end, where an absorbent pad is set to maintain constant capillary flow rate. The sample loading zone, labeling zone, and detection zone are set between the two ends. The immunochromatographic method is classified into several formats. Figure 44-24 shows the typical immunochromatographic formats. The proximal end is employed as the sample loading port connected to a pad containing labeled antigen or antibody, under which a nitrocellulose membrane is in contact with the pad, which serves as a fixed detection zone. The distal end of the membrane is attached to the absorbent pad as a source of capillary force. The sample, loaded by means of a dropper, reconstitutes the conjugate antibody or antigen labeled with colloidal gold or colored latex, which forms an immunocomplex with the analyte being detected, and the complex migrates to the detection zone. The antibody or antigen immobilized in the detection zone can capture the complex and form a positive red or blue line. Excess labeling substance migrates to the absorbent pad. The mobile phase for sample migration is the sample itself. Therefore, samples strongly colored owing to the presence of a high concentration of bilirubin or hemoglobin may

Figure 44-24 Typical immunochromatographic test strip by sample loading. Assay flows are illustrated in the lower part of the figure. In general, the proximal end of the lateral flow serves as the sample loading portion consisting of a pad containing antibody or antigen labeled with colored latex or colloidal gold. Analyte in the sample forms a complex with the conjugate and migrates to the detection zone, thereby immobilizing the capturing antibody to form a positive colored line. Excess amounts of conjugate and sample migrate to the distal end of the strip.

Figure 44-25 Immunochromatographic device using enzyme immunoassay (EIA). A sensitive amplification method is applied for immunochromatography using an enzyme. The sample is applied to the sample loading portion at the center of the strip. With this method, a developing solution is employed as the mobile phase and can serve as a washing buffer. The picture on the right part of the figure shows the plastic molded housing and assay results for *Treponema pallidum* (TP) antibody.

interfere with judgment in reading the results with the naked eye. In this format, the signal to be read is produced directly in the detection zone as a concentrated zone of colored particles.

Yamauchi (1997) established a novel platform format in which EIA can be performed automatically, including a washing procedure. The device is depicted schematically in Figure 44-25. In this format, the positioning of each of the zones is completely different from that of other immunochromatography formats mentioned previously. The proximal end has a developer solution, which makes it possible to carry out the washing process to take place spontaneously with capillary force. The sample is applied to a pad that is set in the center portion of the device and that contains the labeled conjugate in dry form. The distal end connects to an absorbent pad. Two drops of sample are dropped on the sample pad to react with the conjugate following reconstitution of the dried conjugate. The reaction mixture containing the immunocomplex formed between the analyte and the labeled antibody can spread to both ends. Once the reservoir of developing solution is ruptured, the dried substrate is reconstituted to become the soluble enzyme substrate in the detection zone. At this time, fluidic flow is directed toward the distal end. Serum components and excess nonreacted conjugate can be washed away to the absorbent. If the sample contains analyte, then the immobilized antibody captures the complex in the detection zone to form a colored line. This method has a number of advantages over other immunochromatographic devices developed by the sample. With such devices, hemolytic serum or lipemic serum may interfere with assay judgment by the naked eye owing to high background color. However, with this new device, which is equipped with a connected reservoir, interference by colored components does not occur. This device has been useful in detecting HBsAg, anti-HBs antibody (Yamauchi, 1997), and antibody to *T. pallidum* (Hasegawa, 1995). Most of its components, such as the membrane, the absorbent pad, and the sample compartment, have built-in molded plastic housing.

SUMMARY

Rapid and simple immunoassay devices are summarized in Table 44-9. These devices can be classified into three major types: flow-through,

dipping, and immunochromatography, along with combination formats of these three types. Most immunochromatographic devices employ direct-labeled conjugate, colloidal metal, or colored latex. These types of formats are actually well suited for direct migration of the immunocomplex, along with migration of the sample solution. However, many of these devices require a large volume of sample, in the range of 100–200 μL . On the other hand, the EIA-type device allows the assay to be carried out using a smaller amount of sample—25 μL —but a developer is required. The current stream of rapid tests for point-of-care testing (POCT) is strongly oriented toward devices using immunochromatography because, unlike other immunoassay devices, special skills are not required to perform the test correctly; one simply needs to follow the manufacturer's directions (Kasahara, 1997). By further improving the time performance and simplifying the procedure of genetic testing, a certain number of protein assays could be shifted to nucleic acid assays, even in the field of POCT, particularly for the diagnosis of infectious diseases.

SIMULTANEOUS MULTIPLE IMMUNOASSAYS

BACKGROUND

Recent immunoassay advancements have led to the development of novel technology concepts that allow simultaneous multiple detection as a way to reduce the reagent cost. This means that anywhere from 5 to 100 analytes can be detected simultaneously in an individual sample. These technologies are classified into two broad categories in terms of the type of solid phase used. The first, microsectioning technology, is adapted to immunoassays using a microchip as the solid phase, and the second uses microparticles as the solid phase. In the second, two technologies have been applied to the recognition of individual assay analyte parameters. One is direct recognition of the solid phase using fluorolabeled latex, and the other involves the use of particles of different sizes. In the latter case, limited recognition is possible because the resolution is dependent on particle size. Miniaturized technologies such as these are considered highly

advantageous for minimizing the cost of reagents, saving energy, and protecting the environment, because of the small mass of reagent and sample volumes required.

MICROSPOT ASSAY

The microchip solid surface is fractionated into small areas using micro-dotting technology. A total of 100–200 reaction sites are produced in a 3 mm diameter area of a polystyrene flat plate (Ekins, 1998). In each site,

a spotting area 80 μm in diameter receives a volume of less than 1 nL of solution ink-jetted automatically. With this method, the ambient assay theory established by Ekins has been applied, and the sensitivity and the detection limit depend on the antibody occupancy, but not on the surface area on the solid phase. The detection limit for TSH was found to be 0.01 mIU/L in an 18-hour assay, using this ambient analyte assay method. Therefore, it is evident that a highly sensitive assay can be achieved even on the microspot area. Boehringer Mannheim, which later merged with Roche Diagnostics, applied an avidin-coated solid phase uniformly to the

surface area and then ink-jetted biotin-binding antibody or antigen on the spot. Multiple parameters, including HIV antibody, HBsAg, anti-hepatitis C antigens, and rubella, can be detected simultaneously on the microchip made of polystyrene. The assay format is a three-step fluorescent immunoassay. Finally, a confocal laser scanner detects the fluorescent signal on the chip. This chip assay is also available for the application of DNA detection.

MULTIANALYTE MICROARRAY IMMUNOASSAY

Silzel has developed an analyte mass assay that measures total analyte mass within a sample (1998). Therefore, the basic concept of this method is different from that of the ambient assay, which measures analyte concentration. A polystyrene film was used as the solid phase. An 80 pL droplet was ink-jetted onto the film, and DBCY5 was adopted as the labeling marker because of the long Stokes shift from the excitation wavelength at 670 nm to the emission wavelength at 710 nm, with near-infrared fluorescence emission. The detection apparatus used in this method consists of a microscope attached to a Peltier-cooled charge-coupled device camera and a GaAlAs diode laser. In this format, 10^5 molecules of DBCY5 per 80 pL area could be detected in calibration solutions. The IgG subclass was applied to the present system for multiparameter detection. Four parameters—IgG1, 2, 3, and 4—were detected, and the sensitivity was shown to be comparable with that of ELISA, although a much smaller amount of antibody (100 times less) sufficed to cover the surface area as compared with an ELISA plate.

Protein chips microfabricated with highly dense spotting sites having 1250 reaction sites per 1×2 cm have been developed by Zyomyx (Hayward, Calif.) The protein chip is composed of silicon-based substrate as a solid phase and six lanes with a 5×50 array/lane (Peluso, 2003). Isomura has employed the chip and applied a simultaneous fluorescent sandwich immunoassay for some target proteins (e.g., AFP, interleukin [IL]-6, Erk-2, c-Jun, Grb2, c-Src, H-Ras) (Isomura, 2003). As shown in Figure 44-26, reaction sites are microfabricated to a pillar structure and then are coated with titanium oxide. The surface is coated with poly L-lysine polymer linking with polyethylene glycol-biotin. After binding of streptavidin to biotin, the solid streptavidin can bind to biotinylated antibodies. The assay can be performed in a flow device. The detection limit for IL-6 was found to be 5–50,000 ng/L in a 3-hour assay with the use of this protein biochip assay method.

Efforts to find better diagnostic markers are ongoing. The proteomics assay based on matrix-assisted laser desorption/ionization is expected to serve as a tool for the discovery of new markers. Advancements in glycomics (Finkelstein, 2007), the systematic study of the structure and physiologic function of carbohydrates, should lead to the development of new markers as well. The combination of these with existing markers will be evaluated for the enhancement of multiple marker assays.

Figure 44-26 Protein Biochip using fluorescence immunoassay (FIA). Sandwich FIA is applied for multiple detection using microfabricated silicon as a solid substrate. The surfaces of more than 1000 pillars are coated with organic polymer layer having biotin. Streptavidin bound to biotin binds to biotinylated antibody specific to analyte and reacts with antigen in the sample. The silicon device arraying different antibodies specific to different antigens is set in a molded plastic device.

FLOW CYTOMETRIC IMMUNOASSAY

Luminex (Austin, Tex.) has developed a simultaneous multiparameter fluorescent immunoassay using flow cytometric technology in which two types of fluorophores for recognition of the analyte serve to mark the latex particles used as solid phase (Fulton, 1997; Oliver, 1998). Two different types of fluorophores and fluorescence intensities mark the analyte mapping of each particle. More than 60 analytes can be detected simultaneously in principle. The assay procedure is as follows. The sample is mixed with antibody labeled with R-phycoerythrin and a second antibody immobilized on latex as the solid phase. The mixture is incubated for 10–30 minutes and then is injected into the flow system. A total of 1000 particles are separated as in flow cytometry, and both an enhanced fluorescence signal from the excited R-phycoerythrin as a result of the labeling and two fluorescence signals on the particle are detected simultaneously by laser scanner. Carson and colleagues have applied this approach to the simultaneous detection of 15 cytokines such as IL-1, IL-2, IL-4, and IL-6 (Carson, 1999). Simultaneous detection was less sensitive than the assay of individual cytokines. However, it is still a sensitive assay compared with conventional ELISA, and sensitivity was 100 pg/mL for IL-2, 10 pg/mL for IL-4, 100 pg/mL for granulocyte-macrophage colony stimulating factor, and 200 pg/mL for interferon- γ .

MICROCHANNEL ASSAY USING COMPACT DISK

Gyros AB (Uppsala, Sweden) has developed a simultaneous microfluidic fluorescent immunoassay using a compact disk (CD) as microlaboratory technology in which the microfluidic flow can be obtained by centrifugal force (Poulsen, 2004). On the CD, 104 assays can be performed simultaneously by fluorescent column immunoassay. The solid phase consists of plastic microparticles bound to streptavidin. Specific antibody binding with biotin is applied to the column. A total of 100 nL of sample can be automatically metered by separation of the hydrophobic breaking valve in which the wall has been coated with hydrophobic polymer. The valve can open by centrifugal force, and several types of break settings in the channel of the CD make it possible to perform a rapid and simple assay by changing the rpm to control reactions. This assay has been applied to the detection of human IgG, with a sensitivity of 1 ng/mL.

SUMMARY

Remarkable technological advancements in simultaneous assays have been achieved in the current decade. However, one of the tasks that remain to be achieved is miniaturization of the assay in all of its aspects. For instance, mechanical or physicochemical difficulties in handling microvolumes of fluid and sample evaporation during handling remain inevitable. Before the assay can be introduced successfully in routine clinical laboratories, both device technology and assay environment layout in the laboratory need to be improved.

From the point of view of clinical application, simultaneous multiple assays may not appear as attractive as might have been expected. In some cases, the sensitivity and specificity of this technique need to be assessed more carefully. However, simultaneous multiple assays based on miniaturization technology should be the ultimate goal for laboratory diagnostics, given the advantages they offer in terms of cost containment, reduction of burden on patients from phlebotomy, and clinical utility.

The logistic regression model, using multiple markers, has improved the sensitivity and accuracy of diagnostic immunology but has met with only limited success. Recent advancements in laboratory pharmacogenomic testing for selection of the appropriate therapeutic drug in the right dosage for the right patient require further statistical calculation to obtain additional valuable test results. Pharmacogenomic testing is useful for protein assay as well. The Multivariate Index Assay by Vermillion Inc. (Fremont, Calif.), which was approved by the FDA in 2009, is a multiple-protein assay that comprises five conventional biomarker assays developed with certain types of algorithms. Several genetic testing methods based on algorithms have been approved by the FDA for laboratory testing, but not as kits. Genetic testing for multiple markers, as well as protein or carbohydrate testing, is likely to provide reliable options for diagnostics and for selection of therapeutic drugs.

KEY POINTS

- Humoral immune tests assess production of specific antibody responses to past or recent infections, and cellular immune assays measure current immune responses.
- The immune system changes with age and nutritional status. Differences in immune responses of test subjects associated with immaturity, immunosenescence, or malnutrition should be taken into account when evaluating the results of specific tests.
- Primary immunodeficiency may be associated with an increased incidence of malignancy; malignancy, chemotherapy, and radiotherapy can significantly suppress the immune response and alter cellular immune assay results.
- Evaluation of the cellular immune response is undertaken in a graduated sequence of stages that may include both in vitro and in vivo testing to identify areas of immune deficiency.
- Measurement of lymphocyte activation may be accomplished in vitro by flow cytometry using activation-specific fluorescent-labeled monoclonal antibodies and vital dyes. The usefulness of this approach has increased significantly with the development of fluorochromes with different excitation spectra.

The understanding of the immune system is greatly enhanced by the detection of specific abnormalities in patients with suspected immune deficiency. These advances have come from studies of immune cell differentiation and function, experimental gene deletion, and detailed analysis of human immunodeficiency syndromes. New experimental approaches have helped to elucidate the mechanisms and functional basis of immune dysregulation in patients with primary (congenital) genetic mutations of the immune system or secondary (acquired) infections. Because some immune deficiencies cannot be accurately diagnosed by the combination of clinical symptoms and appropriate immune function assays, genetic information is becoming an increasingly important component of diagnostic testing and interpretation. The mission of the clinical immunology laboratory is to translate new research leads into highly standardized and clinically relevant tests for the individual patient.

Studies of the human cellular immune system have principally focused on three areas: (1) primary immune deficiency, which reveals the impact of congenital immune defects on host defense; (2) acquired immune deficiency, such as human immunodeficiency virus (HIV) infection, in which infection damages the immune system directly; and (3) autoimmune diseases, in which the effect of excessive or inappropriate immune activity is evident. In addition, cellular immune defects in patients with diseases with immune dysfunctional features, such as chronic infection, cancer, malnutrition, or traumatic injury, provide crucial insight into immune-mediated host defense.

The general concept of **immunity** is often equated with humoral immunity, because antibodies to infectious agents introduced by natural infection or by immunization have been studied for more than a century. Cellular immunology, as currently practiced in the clinical and research laboratory, is a relatively new science (Silverstein, 1979; Moulin, 1989; Good, 2002). The modern science of cellular immunology developed during the 1980s through a series of independent events and major research discoveries, including the use of monoclonal antibodies to identify immune cells, the development of analytic and sorting capabilities of the flow cytometer, the discovery of cytokine regulation of immune response, the birth of molecular immunology, and, above all, the tremendous need to understand and control the emerging HIV epidemic (Herzenberg, 2004). The appearance of HIV occurred virtually in parallel with the potential to identify CD4⁺ T cells. The first analyses of cellular immune functional deficiency in the acquired immunodeficiency syndrome (AIDS) were based on analysis of lymphocyte proliferative response (Masur, 1981; Siegal, 1981) and have since evolved into a range of functional approaches (Perfetto, 1997; Rosenberg, 1997; Zhou, 1998).

In contrast to humoral immunity, cellular immune function is both fundamentally complex and difficult to measure. Basic humoral immune tests measure the specific antibody product of a past response to a specific virus or microbe; by contrast, most cellular immune assays measure current responses. Because a majority of peripheral blood lymphocytes are resting cells, the cellular immune reaction must be re-created or generated freshly within the test system. The system must be capable of triggering the response, supporting the reaction by providing all needed elements available *in vivo*, and having a measurable endpoint.

This chapter presents current cellular immunologic tests in light of future trends. Cellular immune assessment is moving away from single assays and single-number fixed endpoints toward an integrated analysis of cell function at several levels that reflect cellular interactions as a dynamic process.

GENERAL PRINCIPLES OF CELLULAR IMMUNOLOGY

Two main immune cell types are known: (1) T lymphocytes (T cells), and (2) B lymphocytes (B cells) (Silverstein, 2003; Janeway, 2004; Chaplin, 2010). T lymphocytes are defined by expression of the T lymphocyte receptor, which binds to antigen and CD3, a surface determinant associated with the T cell receptor that is essential for activation. T lymphocytes have different, clonally variable receptors for a large range of antigens, require thymic maturation for normal function, and mediate cellular immunity. B lymphocytes are identified by surface immunoglobulin (detected by monoclonal antibodies such as CD19 or CD20) and upon appropriate activation develop into plasma cells secreting specific antibody and thus mediating humoral immunity. Loss of the normal thymus will compromise T lymphocyte function and affect T-dependent B lymphocyte activation. Failure at the bone marrow level can affect both T lymphocyte and B lymphocyte immune responses, although specific linkages may be involved.

The distinction between a specific and a nonspecific immune response is a fundamental necessity because the system must be able to distinguish between self and nonself (LeGuern, 2003; Smith, 2004). In general, self-recognition is accomplished by incorporating the molecular major histocompatibility complex (MHC) self-antigen system into the antigen recognition phase. Antigen must be processed and presented in the context of self-MHC to be recognized and to lead to response and development of immune memory. The antigen-processing function is carried out by antigen-presenting cells (APCs); the best studied is the monocyte. This response triggers lymphocyte activation and proliferation, and may include production of effector cells and triggering of B lymphocytes to produce antibody. This type of immunity, often termed adaptive immunity, is retained as “memory” and typically is elicited following immunization or natural infection (Owen, 1993; Sprent, 2002). Lack of expression of MHC class II antigen can be detected on lymphocytes by flow cytometry using monoclonal antibodies against human leukocyte antigen (HLA)-DR or HLA-DQ and is a hallmark of MHC class II deficiency.

A second fundamental type of immunity can be described as innate immunity. This type of immunity is an ancient host response to infectious agents or self cells with absent or altered self-recognition molecules; it is encoded within the genome, does not have memory, and is not improved by repeated contact (Janeway, 2002; Turvey, 2010). The innate immune

system consists of (1) external barriers (i.e., skin, mucosal surfaces) to prevent microorganisms from entering the body, and (2) a programmed, coordinated series of events to destroy microorganisms that penetrate the external barriers. These events include both chemically mediated (cytokines, complement, interferon) and cellular components (phagocytes, natural killer [NK] cells). The modern era of discovery about innate immunity began in 1989, when the late Charles Janeway, an immunologist at Yale University, predicted that sentinel cells (i.e., macrophages, dendritic cells) have nonclonal, germline “pattern recognition” receptors that directly recognize some invariant molecular signatures of microbes (pathogen-associated molecular patterns) not found in the host. In 1997, studies of *Drosophila melanogaster* (fruit fly) identified the toll-like receptor (TLR) as the major effector of the innate immune response in the fly, which has no adaptive immune system. Since that time, multiple TLRs have been found in humans, largely on macrophage and neutrophil membrane, as well as on epithelial cells lining the respiratory and gastrointestinal systems. TLRs can be thought of as a primitive, highly conserved alarm system that recognizes bacterial pathogens and stimulates the expression of molecules that initiate the local inflammatory response and phagocytosis (Beutler, 2009; Kumar, 2009). TLRs are highly conserved molecules characterized by an extracellular domain of leucine-rich repeats and an intracellular signaling domain with homology to that of the interleukin (IL)-1 and IL-18 receptor family. TLR signaling initiates the transcriptional expression of genes that constitute a core inflammatory response, including proinflammatory cytokines, such as IL-1 α , IL- β , tumor necrosis factor (TNF)- α , and IL-6, as well as numerous chemokines and cell surface receptors that regulate T and B cell immune responses (Iwasaki, 2010; Kawai, 2010).

Other pattern recognition receptors are believed to play a less important role in the binding of bacteria and fungi by phagocytes in preparation for phagocytosis. These include a large family of lectin receptors (including the mannose receptor), some integrins, CD14, and scavenger receptors. Lectin receptors are carbohydrate receptors that specifically bind sugar residues found in the cell walls of certain bacteria. Scavenger receptors bind many anionic bacterial ligands.

Unlike phagocytic cells, NK cells are not functionally developed at birth, probably because the key cytokine, interferon (IFN)- γ , which is needed for development and maturation of this system, is also downregulated at birth. The NK cell, once called the “K” cell, “null” cell, or “third population,” has neither surface immunoglobulin nor a rearranged T cell receptor (Cooper, 2009). The NK system is constitutively active and does not have to be primed by antigen to kill (Yokoyama, 2004; Hamerman, 2005). NK cells make up a diverse population that has eluded conventional classification by cell lineage analysis. However, CD56 is currently considered the most definitive immunophenotypic marker for the NK cell (Trinchieri, 1995). NK cells have been best known as cells that can kill nonspecifically (naturally) virus-infected cells and bacteria, and can prevent tumor cell metastasis. However, NK cells also regulate T and B cell functions, as well as hematopoiesis. These functions of NK cells are probably dependent on their ability to produce lymphokines, particularly IFN- γ . NK cells are important for antigen-independent activation of phagocytic cells early in infection and for favoring the development of antigen-specific T-helper type 1 (Th1) cells. When armed with specific antibody, however, these cells can kill specifically.

LYMPHOCYTE ACTIVATION AND PROLIFERATION

Although the immune system is classically divided into humoral and cellular components, this separation is in no way absolute, in that considerable interdependence is seen between B and T cells. The most commonly measured functional cellular immune parameter is lymphocyte proliferation (Perfetto, 2002). Measurement of lymphocyte activation/proliferation has evolved substantially since the late 1950s and early 1960s, when cell division was determined by counting the number of lymphocytes that had transformed into blasts. The latter method was later replaced by the quantitation of incorporated radiolabeled nucleic acid precursors (tritiated thymidine) into newly synthesized deoxyribonucleic acid (DNA). Although this “bulk assay” remains the most commonly used laboratory procedure for measuring cellular proliferation, new reagents and new procedures have recently become available to assess lymphocyte activation and proliferation. These include commercially available cell surface proliferation markers, the ability to measure the percentages of cells in specific phases of the cell cycle, the quantitation of cell-associated and secreted cytokines/

cytokine receptors, and the ability to assess the number of cell divisions in lymphocytes labeled with “tracking dyes.” In this section, we review the molecular events involved in T lymphocyte activation and proliferation, and review some of the new methods that have been developed to assess the functions of the cellular immune system.

Unraveling the Biochemical Pathways of Lymphocyte Activation

Specific interaction of mitogen or antigen/MHC with the appropriate lymphocyte receptors leads to a cascade of cellular processes that include changes in membrane transport, rearrangement of the cytoskeletal system (polarizing the lymphocyte toward APC), and activation of several signaling pathways (Harding, 2005). These changes ultimately lead to a number of outcomes, including T cell differentiation, cytokine secretion, proliferation, anergy, or apoptosis. Ongoing investigations are unraveling the complex molecular and biochemical pathways that drive the activated T cell down these pathways. Specific abnormalities in these pathways are constantly being discovered and underlie many of the primary immunodeficiency diseases. Unfortunately, abnormalities in a bulk proliferation assay indicate only that there is limited or no cell division and provide no information regarding the underlying abnormality in lymphocyte activation. Therefore, more sophisticated assays are required to investigate underlying T cell abnormalities.

Antigen-Induced Activation of T Lymphocytes

Antigen/MHC-induced activation of T lymphocytes involves a series of complex and defined events that differ slightly between the activation of a naive T cell versus the activation of a memory T cell. Antigen is processed by B cells or monocytes, leading to the assembly of immunogenic peptides into class I or class II products of MHC genes (van der Merwe, 2003). The peptide-MHC complex is presented to T cells bearing the appropriate T cell receptor. In addition, the APC expresses a series of adhesion and costimulatory molecules that interact with appropriate ligand/counterreceptors on the T cell surface. Ligation of the T cell receptor alone is not sufficient for activation of the T cell, which has led to the development of the “two-signal model” for T cell activation (Bretscher, 1992, 2004). The first signal delivered via the T cell antigen receptor (TCR)/CD4/CD8 modulates transition of the T cell from the early stages of activation (i.e., G_0 to G_1). Signal two is delivered via the costimulatory pathways, most notably CD28, and to lesser extents, LFA-3, CD2, CD5, and CD7, and leads to the induction of IL-2 and other cytokine genes required for T cell proliferation and differentiation to effector cells.

T CELL RECOGNITION, ACTIVATION, AND SIGNAL TRANSDUCTION

Lymphocytes are unique in that they express surface receptors able to identify virtually any molecule or foreign substance (antigen). Structural diversity within these receptors is created by the differential rearrangement of T cell receptor genes. In general, only a limited number of circulating lymphocytes are able to recognize any single antigen. When a lymphocyte recognizes a foreign antigen *in vivo*, cells proliferate rapidly in a clonal manner to generate a large number of both effector and memory cells.

The TCR complex is composed of a both a heterodimeric antigen recognition structure (i.e., the TCR) and a noncovalently bound transducing complex referred to as CD3 (Malissen, 2003). The TCR cannot be expressed on the cell surface without CD3 (Weiss, 1991) and has no inherent signaling capabilities of its own. The antigen recognition structure is composed of structurally divergent α and β chains (or, less frequently, γ and δ chains), and the CD3-transducing complex is composed of five invariant polypeptide chains: α , β , ϵ , η , and a ζ chain dimer. Each of the CD3 proteins contains a motif called the immune tyrosine activation motif (ITAM), which binds the SH2 domains of protein tyrosine kinases. The ζ chain (which exists as a ζ homodimer, a ζ with an η , or a ζ with an Fc ϵ RI γ chain) contains three ITAMs and is the most significant component of the TCR complex involved in signal transduction from the TCR (Weiss, 1994; Alarcon, 2003). Originally described by Reth, these motifs play an essential role in early events following T cell activation (Reth, 1989; Irving, 1991). CD4 and CD8 molecules on the surfaces of T cells are also noncovalently attached to the TCR complex. They bind to HLA class II and class I molecules, respectively, on the APC and are also involved in transduction of activation signals (Fig. 45-1). Processed antigen is presented to T cells in the context of the MHC antigens. In general, CD4⁺ T cells

respond to exogenously processed antigens presented in the context of MHC class II, and CD8⁺ T cells respond to endogenously processed antigens presented in the context of MHC class I. CD4 and CD8 are also associated with tyrosine kinases involved in the early events following T cell activation. In addition to these interactions and the costimulatory molecular interactions, another group of molecules present (adhesion molecules) on both the APC and the responding T cell bind to each other and serve to increase the avidity of the binding.

Costimulatory molecules identified on APCs include B7 (CD80) (Linsley, 1991), B7.2 (Azuma, 1993), and heat-stable antigen (HSA) (Liu, 1992), among others (Wingren, 1995; Foletta, 1998). On T cells, CD28 is the primary costimulatory molecule and binds B7; CTLA-4, on the other hand, binds both B7 and B7.2 and is involved in downmodulating T cell activation (Linsley, 1991). The receptor on T cells for HSA has not been identified. Antigen presentation in the presence of reagents that block the costimulatory molecules leads to anergic response (tolerance) on subsequent exposure to that specific antigen but does not affect the responses to other antigens (Tan, 1993). The ability to make nonimmunogenic transplantable tumors immunogenic by transfecting them with the B7 gene (Chen, 1992; Baskar, 1993; Townsend, 1993; Janeway, 1994) suggests that costimulatory molecules play an important role in T cell activation *in vivo*.

SIGNAL TRANSDUCTION FOLLOWING ANTIGEN-SPECIFIC STIMULATION

The presentation of antigen to T cells leads to aggregation of the TCR-CD3 complexes and activation of protein tyrosine kinases (PTKs). The TCR itself has a small cytoplasmic tail with no known transducing activity. It is the associated ζ chains of the CD3 complex that contain the ITAM motifs and that have been shown to coprecipitate PTK activity. Two well-known classes of cytoplasmic PTK families are involved in the very early events following T cell receptor aggregation: Src and Syk/ZAP-70. Signaling cascades downstream from the TCR-CD3 complex and the CD28 costimulatory pathway are fairly well understood (Foletta, 1998; Samelson, 2002). Activation of TCR-associated tyrosine kinases ZAP70, p59^{lyn}, and p56^{lck} leads to activation of three pathways: p21^{ras}, calcium/calcineurin, and protein kinase C (PKC). Activation of p21^{ras} activates mitogen-activated protein kinases, which, in turn, phosphorylate several transcription factors, thereby regulating gene expression. Activation of the PTKs also activates phospholipase C, which hydrolyzes phosphatidyl inositol and leads to generation of the second messengers diacyl glycerol (DAG) and inositol triphosphate (IP₃). DAG activates PKC, and IP₃ leads to rapid and sustained increases in cytoplasmic calcium. The increase in free calcium activates the calmodulin-dependent phosphatase calcineurin. These events also lead to the induction of DNA-binding proteins and the transcription of numerous genes, including IL-2 and the IL-2 receptor required for T cell proliferation.

Understanding the pathways leading to T cell activation has led to the discovery of molecular defects in several acquired immunodeficiency diseases and may ultimately help provide therapeutic strategies to correct these deficiencies (Rosen, 2000). For example, mutations in the protein tyrosine kinase ZAP-70 have been reported and are associated with the autosomal form of severe combined immunodeficiency (SCID) syndrome in humans (Elder, 1998). Mutations in the common γ chain of the interleukin receptors IL-2, IL-4, IL-7, IL-9, and IL-15 lead to transduction abnormalities and are associated with the X-linked form of SCID (Noguchi, 1993). It is interesting to note that another form of autosomally inherited SCID is associated with mutations in the downstream Janus family protein tyrosine Jak3, the only signaling molecule associated with the common γ chain (Pesu, 2005). As more and more of the underlying abnormalities leading to T cell immunodeficiency are discovered, including at least 10 different molecular defects for SCID alone (Fischer, 2005), it has been proposed that these disorders be classified using a comprehensive system that would identify the disorders according to abnormalities in differentiation, maturation, and function (Gelfand, 1993). These designations would begin to focus on the actual physiologic or biochemical defect and may ultimately provide new options for therapy, including gene therapy (Buckley, 2004; Conley, 2005).

T CELL RESPONSES

Recently, the designation of T cell type I versus type II cytokine responses has been preferred for those T cell responses that lead to cytokine secretion patterns known to be involved in cellular immunity versus cytokine

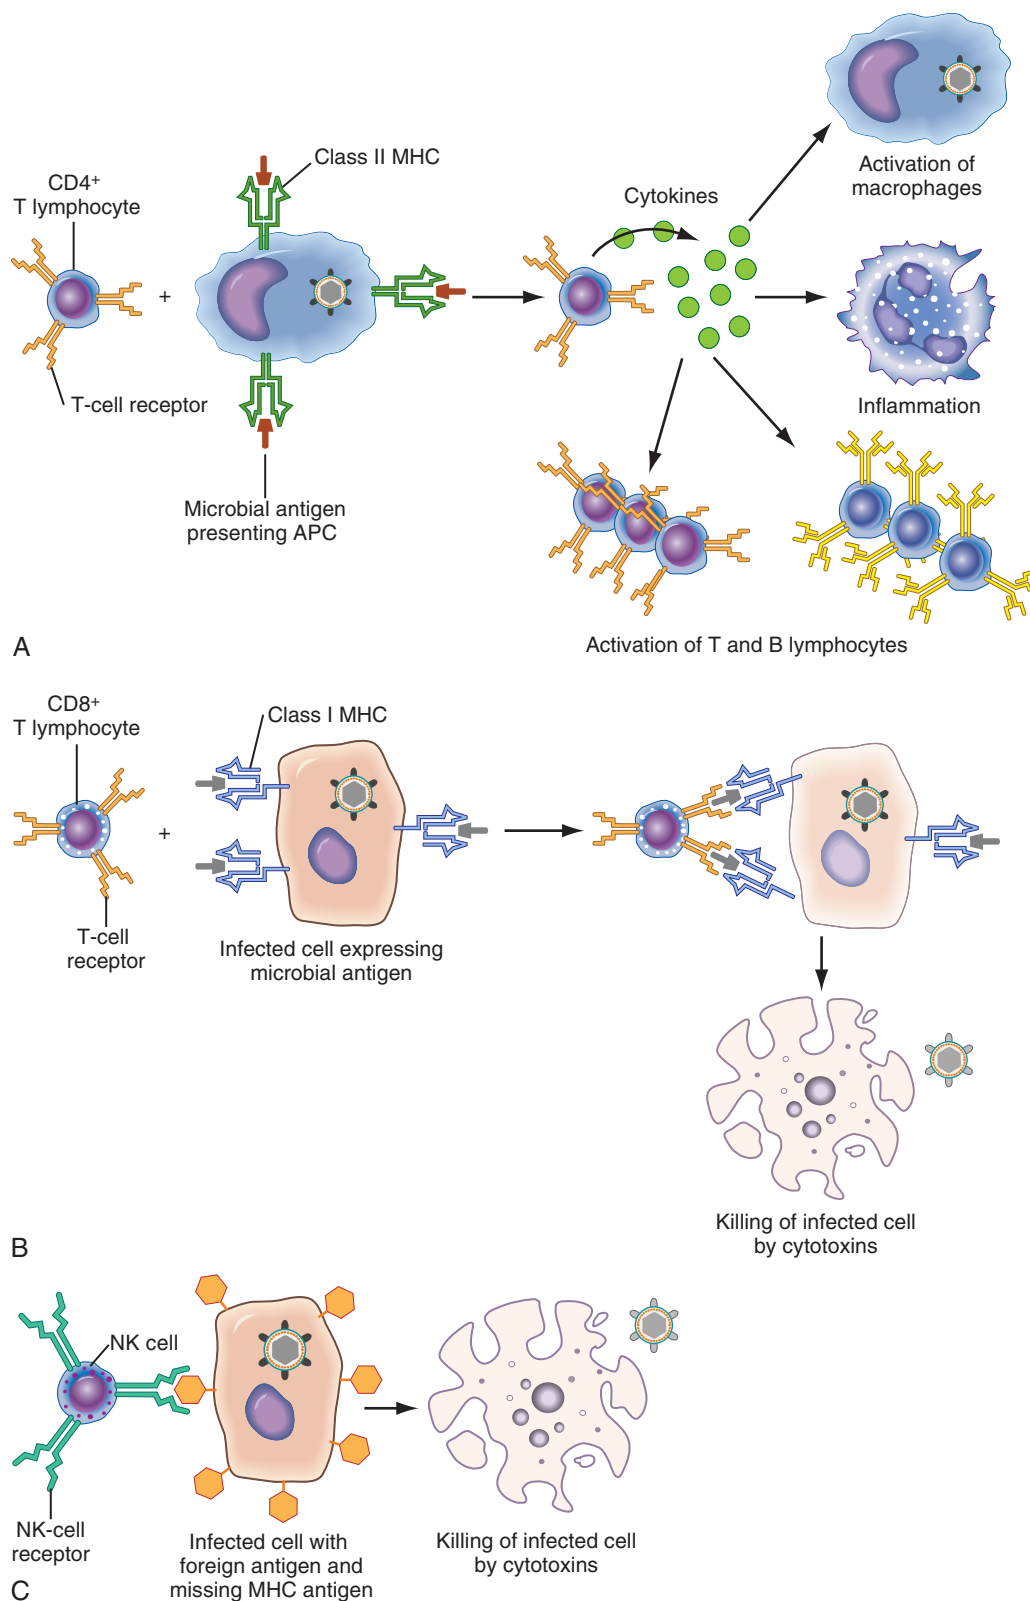

Figure 45-1 A schematic illustration of immune cell function. **A**, Function of helper T lymphocytes. Helper T cells are activated by contact with an antigen-processing cell (APC) that has ingested and processed a foreign or altered self substance and displays processed antigen fragments bound to a class II self-major histocompatibility complex (MHC) receptor. Simultaneous binding of the T cell receptor complex (TCR) in conjunction with a CD4 coreceptor activates the T cell primarily through a complex signaling mechanism involving the SRC kinase family. Activated T cell coordinates the immune response by secreting cytokines that have a multitude of effects, including recruitment and activation of macrophages, activation of the inflammatory system, and activation of cytotoxic T lymphocytes and other helper T lymphocytes. **B**, Function of cytotoxic T lymphocytes. Cytotoxic, CD8-positive cells are activated primarily by contact with infected, damaged, dysplastic, or neoplastic self-cells expressing processed microbial or abnormal self-antigens bound to the class I MHC. Activation of the cell occurs via the TCR in conjunction with the CD8 coreceptor that is specific for the class I MHC. The target cell is killed by the release of cytotoxic chemicals, including perforin, granzymes, and granulysin. **C**, Function of natural killer (NK) cells. NK cells are activated by cytokines or interferons and directly recognize “missing-self” virally infected or tumor cells that have only low levels of MHC I self-antigen. Unlike cytotoxic T cells, prior sensitization is not required. Killing of the target cell occurs via the release of cytotoxic chemicals, similar to cytotoxic T lymphocytes. (Diagrams courtesy Dr. Peter Ping, Motifolio, Inc., Ellicott City, Md.)

Figure 45-2 Function of B lymphocytes. Each B lymphocyte has a unique variable domain in its surface immunoglobulin molecules (B cell receptor) that permits it to recognize a specific antigen. An encounter with this specific antigen, in conjunction with a cytokine signal from a T helper cell, results in activation of the B cell. An activated B cell can differentiate into an antibody-producing plasma cell or a memory T cell. In the lymph node, the activated B cell may also undergo a germinal center reaction, resulting in hypermutation of the variable region of the immunoglobulin gene. (Diagram courtesy Dr. Peter Ping, Motifolio, Ellicott City, Md.)

secretion patterns observed in humoral immunity, respectively. Type I responses are characterized by the secretion of cytokines known to enhance inflammation (proinflammatory) and induce activation and proliferation of T cells and monocytes, namely, IL-2, IFN- γ , and IL-12. Type II responses are characterized by the secretion of cytokines that suppress inflammation (anti-inflammatory) and stimulate B cells to divide and differentiate into immunoglobulin-secreting cells (i.e., IL-4, IL-5, IL-10, and IL-13). Evidence suggests that secretion of type I cytokines regulates the secretion of type II cytokines and vice versa (Paul, 1993). For example, in the presence of IL-4 both in vivo (Chatelain, 1992) and in vitro (Seder, 1992, 1993), T cells will not develop into IFN- γ -secreting cells (i.e., this environment favors the development of a humoral immune response). It has been suggested that the relative amounts of IL-4 and IL-12 that are present during stimulation of naive T cells will shift the response one way or the other (Paul, 1994).

Several factors are involved in regulating the type of T cell response that ensues following antigenic stimulation. In addition to the cytokine environment, evidence suggests that the dose of antigen influences the type of response (Bretscher, 1992; Madrenas, 1995). The predominant response that develops following T cell activation has significant clinical implications. It has been postulated that the development of a type I response to HIV infection may lead to protective immunity (Clerici, 1994). Clearly, a type II response is not protective, as most infected persons seroconvert and eventually succumb to profound immunosuppression. Clerici and Shearer (1993, 1994) argue that repeated exposure to low-dose HIV-1 may lead to protective type I cellular immunity. Results reported by this group indicate that between 39% and 75% of peripheral blood mononuclear cells of HIV-1-seronegative and polymerase chain reaction-negative high-risk individuals (i.e., homosexual men, intravenous drug users, and infants born to HIV-1-positive mothers) secreted IL-2 in response to the env protein in vitro. These scientists propose that seronegative high-risk individuals develop protective cell-mediated immunity as a result of low-dose immunization or infection.

B CELL RESPONSES IN CELLULAR IMMUNITY

Antibody-producing B cells govern the humoral immune response to contain and eliminate primarily extracellular pathogens and, to a lesser extent, intracellular threats. Initiation of B cell activation involves initial antigen binding and requires costimulatory signals. These signals, in some cases, as in nonpeptide antigens for example, may be delivered by the antigen itself, by TLRs, by surface immunoglobulin cross-linking, or by

other mechanisms (Mond, 1995). Alternatively, the Th2 subset of CD4⁺ helper T cells provides important costimulatory triggers to activate B cells in response to peptide antigens (Fig. 45-2).

Surface immunoglobulin on naive B cells binds antigen and transmits intracellular signals. It also delivers antigen into the cell, where it is processed into peptide fragments and then distributed and bound to MHC class II surface receptors. Epitopes of these fragments are recognized by specific Th2 class helper T cells primed by related antigen exposure, and costimulatory signals are transmitted between CD40-ligand (CD154) on T cells and CD40 receptor molecules on B cells (Jones, 1981). These interactions generate T cell cytoskeletal changes and subsequent release of cytokines, including IL-4, which binds to B cells to favor cell cycle progression and hence clonal expansion, and also promotes isotype switching to immunoglobulin (Ig)G1 and IgE. These engaged T cells also release transforming growth factor (TGF)- β , which has been shown to induce isotype switching to IgG2B and IgA, along with IL-5 and IL-6, which promote B cell differentiation into plasma cells (Isakson, 1982). These cellular interactions occur in the T cell/B cell zone borders of primary lymphoid organs. Differentiation into effectors/plasma cells with antibody secretion appears to be sentinel for the primary/early focus of humoral immune response. Some activated B cells migrate into germinal centers and undergo further enhancement, including affinity maturation, IgH variable gene alteration, and isotype switching, to provide what is thought of as a more durable, prolonged response. A subset of memory cells is also produced that provide low-level surveillance with an associated rapid amnestic response upon antigen reexposure.

FLOW AND IMAGE CYTOMETRY IN EVALUATION OF CELLULAR IMMUNITY

Since its development three decades ago, laser-based single-cell analysis (flow and image cytometry) has become an essential tool for the medical research laboratory and the standard of laboratory clinical practice in the study of the cellular immune response (Goetzman, 1993; Lamb, 2002; Herzenberg, 2004; Shapiro, 2004). Measures of immune competence and immune modulation of specific surface markers and receptors, characterization of lineage by the immunophenotyping of lymphomas and leukemias, the definition of malignancy using specific chromosome probes, and the study of tumor heterogeneity by multiparameter DNA measures are analyses that are commonly performed in many laboratories, as detailed by many authors (Good, 2002; Goolsby, 2004; Herzenberg, 2004). Classification of cell types by these means enables the definition of biological and effector functions on a molecular basis, and allows these measures to

be related to disease process and definition. These are but a few of the applications that are possible when laser-based technologies are applied.

Two major technologies are used. The first is flow-through, in which the particles that are being counted and their physical and chemical characteristics are measured by particles passing in a fluid stream in a single-cell suspension (Keren, 1989; Givan, 2004; Stewart, 2004). In the second, known as static analysis, the particles are stationary and the stage or the laser moves as in image analysis (Martin-Reay, 1994). Image analysis technology is slowly making its mark in the laboratory in the evaluation of touch preparations or cytospins, chromosome preparations, and tissue sections for certain applications, such as DNA and fluorescent *in situ* hybridization (FISH). Advances in recent years in the availability of fluorescent probes for use in FISH and chromosome painting will make these analyses more relevant and useful tools in the clinical laboratory (Weinberg, 1993; Stewart, 2002). As with many techniques, including cell cycle analysis in DNA, each of the new markers and new techniques must be defined and evaluated and correlated with patient outcomes before absolute clinical utility is imparted, or not. Development of instrumentation that combines the strengths of flow cytometry and the static advantages of image analysis has begun. These instruments, known as scanning laser cytometers, use the traditional flow cytometry measures of forward scatter, side scatter, and fluorescence on cells in suspension or fixed onto a glass slide. Experience with these systems will reveal whether this approach offers measurement advantages not available with the current flow cytometric and image system configurations (Martin-Reay, 1994). Scanning image cytometers and image analysis are not discussed further in this chapter.

Combined advances in electronic pulse processing, optics, and data storage, along with advances in computer technology and software, have allowed flow cytometry technology to become routine in the laboratory. Furthermore, the wide availability of workshop-clustered monoclonal antibodies now numbering 339 (Zola, 2002), labeled in multicolor, directly conjugated, and in premixed formats, has allowed the simultaneous detection of multiple surface antigens, as well as cytoplasmic and nuclear constituents. The ability to perform multiparameter analysis is the greatest strength of flow cytometry. Measurement of both phenotypic and intracellular markers is now done routinely in many laboratories. The major manufacturers have turned the art of flow cytometry into a routine laboratory measurement—a “black box” science—much to the dismay of many (Chapman, 2000). As described, this black box approach phenomenon is largely the result of the use of flow cytometry in the phenotyping of T cell subsets in monitoring patients with HIV (Mandy, 2004; H.M. Shapiro, 1993). Before the onset of the HIV epidemic, flow cytometry was used in the laboratory primarily for the characterization of leukemias and other hematologic malignancies, and for DNA analysis of tumors for synthesis phase (S phase) and DNA index (DI). Although flow cytometry technology may be more toward black box, the HIV epidemic has brought the power of the flow cytometer to a much larger number of institutions and laboratories. This has allowed the technology to become an integral part of many diagnoses, and to be used as an important adjunct in the treatment of patients. Despite its simplification, many issues with regard to U.S. Food and Drug Administration (FDA) regulation, proficiency testing, data management, and reproducibility of data remain. This is particularly true in the area of DNA analysis. It is not the purview of this chapter to describe all the nuances of a flow cytometer or an image cytometer. Current flow cytometers all can adequately perform routine immunophenotyping and other assays. Most laboratory problems are related to the nonavailability of standard quality control reagents and calibrators, and the lack of reliable, rapid methods for data transfer and storage that are compatible with laboratory information systems. More important for clinicians is an understanding of the technology, along with its strengths and pitfalls, and how it can be used for quality control and quality assurance, specimen preparation, and data interpretation.

THE FLOW CYTOMETER AND OTHER TOOLS

The Light Source and Signal Processing

Today's clinical flow cytometer is rarely used for cell separation (i.e., cell sorting); this property continues to be associated with research instruments in the highly specialized laboratory. Most multifaceted clinical flow cytometers use a single argon ion–air cooled laser with a minimum of four photomultiplier tubes to perform three- or five-color immunophenotypic analysis (Fig. 45-3) (Shapiro, 1993; Chapman, 2000; Snow, 2004). Research laboratories interested in performing more than five colors of analyses with

Figure 45-3 Structural components and function of the flow cytometer. **A**, Fluorochrome-labeled monoclonal antibody solutions are added to a cell suspension from peripheral blood, bone marrow aspirate, or a lymph node. The tubes are incubated at room temperature for a short time. **B**, Labeled cell suspensions are passed through the flow cell of a flow cytometer. Many flow cytometers are automated, but some models require the operator to process the tubes individually. More than 10,000 cells from each tube are typically analyzed to produce statistically valid information. **C**, Each cell passes individually through the highly focused laser beam of the flow cytometer, a process termed single cell analysis. The fluorochrome of each labeled monoclonal antibody attached to the cell is excited by the laser light and emits light of a certain wavelength. The cells also scatter light at multiple angles. Photodetectors placed at forward and right angles to the axis of the laser beam collect the emitted or scattered light. Forward and right angle scatter signals, and as many as five fluorochrome signals, can be detected from each cell (multiparametric analysis). **D**, The signals from each photodiode are digitized and passed to a computer for storage, display, and analysis. Typically, all data recorded from each cell are stored for possible later recall for further analysis (list mode data storage). **E**, A variety of histograms for visual display can be generated automatically or at the discretion of the operator. List mode data can also be transferred to a separate computer for analysis. Presently, most commercial flow cytometers utilize a standardized file format for list mode storage, and a variety of computer programs are commercially available for data analysis and display.

Hoescht's ultraviolet-stimulated probes use larger water-cooled 5W lasers in combination with air-cooled lasers, although new instrument systems with new lasers are eliminating the need for water-cooled lasers. At present, commercial manufacturers of flow cytometers include Becton Dickinson (San Jose, Calif.), Beckman Coulter (Fullerton, Calif.), and Partec GmbH (Munster, Germany). Analytic software is provided by the instrument manufacturers, as well as by several independent software companies, including Tree Star, Inc. (Ashland, Ore.), Verity Software House (Topsham, Maine), De Novo Software (Los Angeles), CyFlo Ltd. (Turku, Finland), Walter and Eliza Hall Institute of Medical Research (Melbourne, Australia), and Applied Cytometry (Sheffield, United Kingdom).

The Flow Cell

Two common flow cells are used in the clinical laboratory, but because most clinical instruments are used in the measurement of CD4 cells in the monitoring of HIV disease, a closed system is used as a biohazard precaution (Bogh, 1993; Chapman, 2000; McCoy, 2002). The first, known as a stream-in-air or flow-in-air flow cell, allows the optical measurement point to be directly on the sample stream. This type of flow cell minimizes the distance between the flow chamber and the sample injector tip and thus minimizes carryover between specimens and the sample wash time necessary between samples. This chamber allows greater sample flow rate

TABLE 45-1

Representative Fluorochromes Used in Flow Cytometric Analysis

Fluorochrome	Ex, nm	Em, nm	Excitation laser lines, nm	Comment
Hoechst 33342	343	461	355	Nucleic acid probe, AT-selective
DAPI	359	461	355	Nucleic acid probe, AT-selective
Pacific Blue	410	455	360, 405, 407	
Pacific Orange	400	551	360, 405, 407	
CFSE		517	488	
Fluorescein isothiocyanate (FITC)	493	525	488	pH sensitive
Alexa Fluor 488	495	519	488	Good photostability
Acridine Orange (AO)	510	530	488	Nucleic acid probe
R-Phycoerythrin (PE)	496, 565	575	488, 532, 561	High quantum yield, poor photostability
PE/Texas Red (Red 613)	496, 565	613	488, 532, 561	
Propidium iodide (PI)	305, 540	620	325, 360, 488	Nucleic acid probe, DNA intercalating, used as viability dye
Thiazole orange (TO)	510	530	488	Nucleic acid probe
7-Amino actinomycin D (7-ADD)	546	647	488	Nucleic acid probe, GC-selective, used as viability dye
PE/Cy5 conjugates	496, 565	670	488	Tandem dyes, Cychrome, R670, Tri-Color, Quantum Red
Peridinin chlorophyll protein (PerCP)	482	675	488	
PerCP/Cy 5.5	482	690	488	Tandem dye
PE/Cy 5.5	496, 565	695	488	Tandem dye
PE/Cy 7	496, 565	774	488	Tandem dye
Texas Red	589	615	595, 633	Sulfonyl chloride
Allophycocyanin (APC)	645	660	595, 633, 635, 647	
Alexa Fluor 647	650	668	595, 633, 635, 647	
APC/Cy7 (PharRed)	650, 755	785	595, 633, 635, 647	

Em (nm), Emission wavelength in nanometers; Ex (nm), excitation wavelength in nanometers.

variability than a closed system. Other advantages of the stream-in-air tips are important in cell sorting and are not considered here. With the closed system, often referred to as a quartz tip flow cell, the focal point is within the chamber. Disadvantages of these quartz systems include the thickness of the quartz and thus the diffraction of the laser beam or the scattering of the signal. Additionally, the relatively large cross-section (200 μm^2) makes the flow rate more difficult to control. The success of these quartz flow cells in the clinical system depends on illumination and collection optics. The major manufacturers have made many advances in these systems to provide both safety and maximum sensitivity with the use of low-power, laser-based systems (Bogh, 1993).

Many terms are used in the definition of flow cytometry systems, which include flow rate, sheath pressure, core size, resulting particle velocity, resulting coefficients of variation (CVs), and so forth. However, the most important factor for a laboratory worker to understand is that in DNA analysis, the cells are analyzed at a slow flow rate to increase the time a particle spends in the beam, allowing greater sensitivity and better CVs. In immunophenotyping, sensitivity typically is not an issue, and the particle flow rate can be increased. Most clinical systems were developed with compromises, to accommodate the most common application of immunophenotypic analysis (Baumgarth, 2000). Research flow cytometers offer much greater flexibility and operator control over sample flow rate, differential pressure, and time.

Colors and More Colors: Applications of Fluorochromes

Most laboratories are still using the most common fluorochromes, fluorescein isothiocyanate (FITC; 530-nm emission) and phycoerythrin (PE; 575-nm emission) for immunophenotyping, and propidium iodide (PI) (625-nm emission) in the measurement of DNA (McCoy, 2002). FITC and PE are directly conjugated by the antibody of interest and are simultaneously added to a patient's sample. Use of a secondary antibody such as a goat antimouse (GAM) IgG labeled with fluorescein is no longer necessary for extra sensitivity; therefore, the background fluorescence is minimized. Most clinically used antibodies in the study of HIV are premixed and prediluted for use in whole blood technologies. PI can be used simultaneously with cell surfaces made in multiparameter DNA

analysis, although this requires preservation of the cell membrane (Clevenger, 1993).

New dyes that have become available to the clinical laboratory allow the simultaneous measurement of five or more colors with directly labeled monoclonal antibodies excited with a single 488-nm laser. This availability is revolutionizing the current performance of flow cytometry in laboratory practice. These dyes with a red and far red emission include PE Texas Red tandems (625-nm emission), PE-Cy-5 tandems (675-nm emission), and allophycocyanin (675-nm emission), to name a few (Table 45-1). The early tandems were problematic because of excess free PE in solution, leading to excess background fluorescence. New technologies for the synthesis of these dyes are exploding, solving most of the technical issues, and new dyes are constantly being added for use in the clinical laboratory (Clevenger, 1993). With the availability of the red and far red dyes, an HIV subset analysis can be performed in a single tube with greater surety (Nicholson, 1993). A single tube with 100 μL of whole blood is simultaneously stained with CD45 PE-Cy-5, CD3 PE-Texas Red, CD8 FITC, and CD4 PE. With the new digitized signal processing, compensation (vide infra) is easily performed, and the analysis is completed using CD45 as a gating agent with side scatter (SSC) and the simultaneous analysis of CD3, CD4, and CD8 (Fig. 45-4). Another interesting phenomenon is that these new dyes have allowed the use of fluorescence as a trigger in place of the usual forward light scatter parameter. This is possible because the far red dye spectra are not found in components of most cells, or they do not have autofluorescence competition in nature, as was found with FITC. Furthermore, they can be excited at wavelengths that minimize the autofluorescence from cell constituents such as riboflavin. Therefore, when performing a rare event (cells present at <0.1% of total population) analysis using a fluorescent trigger, many cells can be analyzed very rapidly. This method is also used to label leukocytes in unlysed blood using fluorescence as a trigger. A dye that marks the nuclei or cytoplasm of the leukocytes, and not the erythrocytes, is used.

The use of multicolor fluorescence has allowed the concept of multiparameter analysis to become a reality in most laboratories. The parameters can evaluate (1) different functional subsets of a particular cell population using an intracellular fluorescent probe; (2) use of several colors to identify small clusters of otherwise unidentifiable events (as in detection of minimal residual disease, MRD); (3) the activation status of cells at a

Figure 45-4 Flow cytometric immunophenotypic lymphocyte subset analysis. Use of four-color flow cytometry for the performance of peripheral blood lymphocyte subset enumeration. **A**, A dot-plot histogram of CD45 fluorescence intensity (CD45-FITC) versus side scatter (SS) as a gating strategy to discriminate lymphocytes (gated area) from other peripheral blood cells in a normal control individual. **B** and **C**, Dot-plot histograms of CD3⁺CD4⁺ and CD3⁺CD8⁺ cell populations. **D** through **F**, Corresponding histograms from a human immunodeficiency virus (HIV)-infected individual, demonstrating a marked decrease in CD4⁺ lymphocytes and the corresponding relative increase in CD8⁺ lymphocytes. Directly conjugated monoclonal antibodies were conjugated with fluorescein isothiocyanate (FITC), phycoerythrin (PE), energy-coupled dye (ECD), or a PE-Cy5 tandem (PC5).

particular disease stage (e.g., use of HLA-DR and CD38 on CD4 and CD8s in HIV staging using an anchor gate approach); and (4) cell surface expression and the DI or S phase of a particular cell population, as in defining the CD19 S phase in acute leukemia. Obviously, the possible combinations are nearly infinite and their sophistication is enhanced by the specific dyes and DNA/ribonucleic acid (RNA) probes that are now available. A discussion of some of these approaches and techniques follows.

GATING AND DATA ANALYSIS

IMMUNOPHENOTYPIC ANALYSIS

Analysis of cell populations with the flow cytometer uses a combination of parameters that, when applied, define a specific cell population. Flow cytometry uses parameters similar to those that have been used for many years in hematology, including size (forward light scatter), cytoplasmic granularity (side scatter), and affinities for specific dyes, and combines them with the immunologic tools already mentioned. These include multiple fluorescent dyes bound to antibodies or probes, DNA measurements as obtained using PI or 4'-6-diamidino-2-phenylindole, and other nuclear markers. The key is the simultaneous detection of these parameters with today's analytic systems. For many years, the clinical laboratory flow cytometer could use only three simultaneous measurements. Staining of cell populations was limited by the unavailability of directly conjugated monoclonal antibodies, necessitating the use of a secondary GAM reagent or the use of biotin-labeled antibodies. Definitions of positive and negative populations in high-background cases made it necessary to use a subtraction channel-by-channel algorithm to differentiate positive from negative (Bagwell, 1993). In cases in which the cell population had a defined boundary between negative and positive, a cursor was set so that no more than 2% of the events considered negative fell to the right of the cursor, thereby defining the positive events when a matched isotypic control was used. Although this approach seemed reasonable at the time (Lewis, 1993) and worked well with bright cell clusters, it has become cumbersome when identifying leukemic cells or performing analyses of cell activation markers. Leukemic cells are particularly problematic because each leukemia has its own "relative" fluorescent intensity, and isotype controls may have little relevance. Applying hard and fast rules to cursor settings led to the underestimation of positive clusters. The failure of this approach is especially

dramatic in the analysis of monoclonality by κ and λ light chain expression where small, but significant differences were often lost.

Use of isotype controls in certain situations has been challenged on many fronts, both from technical aberrations associated with their use and from added costs to the laboratory. New software algorithms have the capability of making intensity measurements and defining clusters based on population means intensities, including relative fluorescent intensities, as well as actual molecules of equivalent soluble fluorochrome quantitation (vide infra). Clearly, the need to remember what we are measuring and an understanding of the biology of the population of interest need to be considered in designing an analysis protocol. Fortunately, some sophisticated software approaches and better reagents have allowed us to use multiparameter gating to define populations, rather than trying to make estimates of fluorescence expression using cursor values. Many investigators have used the multiparameter approach in defining cluster and other populations of interest (Loken, 1990; Baumgarth, 2000; Kraan, 2003; Stewart, 2004). These approaches take many forms, a few of which are reviewed here.

With the arrival of multicolor fluorescence came the need to analyze the numbers of cells expressing one or more colors at the same time in a particular cell population defined by forward angle light scatter (FALS) and SSC regions (Loken, 1976, 1977). When this method was first developed, scientists were thinking basically about the mathematics and the accounting of all cells and the numbers of these cells expressing one or more colors. A binary approach to this analysis was developed, known as Prism (Coulter, Hialeah, Fla). These analysis regions were hard-gated and were set into the instrument by the operator. They could not be redefined at a later time using list mode analysis, which caused a lot of frustration. This approach was later modified to allow some regating, and other manufacturers, as well as third-party software, made this Prism binary approach work on a postanalysis basis. Loken then defined bone marrow populations using CD45 versus SSC gating—a unique approach to defining the heterogeneous populations found in bone marrow (Loken, 1990; Stelzer, 1993). They and others (Borowitz, 1992) developed the concept of patterns defining specific leukemic states. Loken further promoted the use of CD45 and CD14 dual-parameter analysis gated on the lymphocyte region of FALS versus SSC for peripheral blood. Many agencies embraced and promoted this approach for most of the HIV flow cytometry panels to minimize the effects of contaminating monocytes in the lymphocyte

population, because they might interfere with a true CD4 lymphocyte count, as monocytes have CD4 receptors on their surface (Passlick, 1989). Agencies that promoted this type of analysis included the Centers for Disease Control and Prevention (CDC, 1992), the National Institute of Allergy and Infectious Disease, Division of AIDS (DAIDS) (Calvelli, 1993), the National Committee for Clinical Laboratory Standards (NCCLS) (Standards, 1992), and the College of American Pathologists (CAP).

Unfortunately, even though this approach solved a lot of problems, it did not ensure that each tube in the panel had the same contents as the tubes containing CD45 and CD14, and the required purity correction might be overestimated, leading to incorrect values for CD4. These issues were reviewed during a conference held by the CDC a year after the HIV guidelines for the performance of CD4 counts were published (Stelzer, 1993). Other analyses of this approach have been performed by the AIDS Clinical Trial Group (ACTG) Flow Advisory Committee in the DAIDS Proficiency CD4/CD8 program (Kagan, 1993) and by CAP in its proficiency testing program (Homburger, 1993).

A new approach to gating was evaluated in HIV panels that followed from Loken's original approach to a bone marrow definition of clusters (Loken, 1990). The use of CD45 as a gating parameter has simplified the analysis of bone marrow, leukemias, and HIV panels. In bone marrow and leukemia workups, CD45 is usually set as the third or fourth color and is paired with forward light scatter or side scatter; this allows the definition of a blast (potentially malignant) population. The blast population is then defined using a panel of monoclonals and the three available color parameters. In the HIV, one-tube, four-color method, CD45 allows the definition of a large lymphocyte-gated region, which is secondarily gated for CD45. This can also be done without the use of light scatter parameters, as was previously described, or with the use of a two-tube, three-color panel. Newer analytic reagent products from some manufacturers include precounted beads in the monoclonal antibody-containing tube, thus permitting an absolute lymphocyte count, known as a flow differential, to be performed at the same time as the lymphocyte subset enumeration. This removes the requirement of needing a hematology counter when performing T cell enumerations and avoids the problems of white cell deterioration with shipping and the performance of an accurate differential to get accurate T cell numbers. These methods are just becoming incorporated into ACTG HIV trial work and that of other laboratories.

Another gating strategy is the use of two- or three-color definition of a particular subset of interest. This approach, commonly referred to now as an anchor gate, uses the particular properties of some cells to investigate another set of parameters. When applied specifically to T lymphocytes, it is referred to as a T gate (Mandy, 1992). An anchor gate (Paxton, 1995) is especially useful when looking at activation markers, as in the HIV subsets of CD3/CD8 expressing CD38 and HLA-DR, or when looking at the expression of CD45Ra and CD45Ro against CD3/CD4 or CD3/CD8. The advantage of this method is that it is intuitive, and each color acts as a quality control check for the other subset. Furthermore, one has the choice to define the expression of biologically relevant markers in relation to functional or biologically relevant populations. This approach lends itself well to quantitative fluorescence. Although the concept of quantitative fluorescence is not new, the techniques used to measure fluorescence equivalents or fluorescence thresholds or other similar designations are new. Quantitative fluorescence measurements will be described after DNA gating and analysis.

Another approach to anchor gating involves CD34 harvesting, which uses CD34 and CD45 staining with or without 7-amino-actinomycin D (7-AAD) as a viability assessment in the identification and enumeration of CD34 progenitor cells. With these methods, beads can also be used to obtain the number of cells recovered. These methods have great utility in bone marrow transplantation protocols in which progenitor cells are harvested from cord blood, bone marrow, or peripheral blood (e.g., the International Society for Hematotherapy and Graft Engineering) and reinfused. This approach has become the standard for most laboratories performing transplants. A commercial system called ProCount (Becton Dickinson) uses a similar approach and reagents to automate the process. Complex immunophenotypic analysis with five or more monoclonal antibodies is becoming more common in clinical and research laboratories for the detection of (1) minor lymphocyte subpopulations of clinical relevance in patients with autoimmune and immunodeficiency diseases, (2) small, immunologically aberrant subpopulations, and (3) minimal residual disease in patients with hematologic malignancy. In this regard, multiparametric flow cytometric analysis using 17 fluorescent colors was recently reported (Perfetto, 2004).

DNA ANALYSIS

General Aspects

Conceptually, DNA analysis should be less complex than immunophenotyping analysis, but a review of the literature and its prognostic capabilities, as well as performance by laboratories on proficiency tests, indicates otherwise (Nicholson, 1993; Coon, 1994; Tirindelli Danesi, 1997). Because publication of several thousand reports in the 1980s and the early 1990s yielded conflicting findings regarding the diagnostic and prognostic significance of ploidy and S phase activity in various human tumors, a DNA consensus conference was held and the proceedings published in *Cytometry* (Shankey, 1993). This report was a historical review of major tumor types (in fresh, frozen, and paraffin samples) and the clinical value of the performance of ploidy by DI and the value of the S phase. These parameters were analyzed in terms of their effectiveness as prognostic markers. The 1994 CAP Conference looked at the previous markers and some additional potential tumor surrogates. In each case, the DI and the S phase were less predictable as prognostic markers than was hoped. This was largely attributed to the variability in technical performance and analysis of these assays (both instrument and samples preparation) and the inherent risk of tumor heterogeneity and therefore of appropriate sampling of the tumor. Specific recommendations were made with each tumor type for appropriate quality control measures that should be taken and for proper deconvolution of the histograms. Since that time, the routine utilization of DNA analysis in the clinical laboratory has considerably declined. Because of the high degree of variability and the lack of prognostic significance, it was suggested by some that clinical DNA measurements be performed only by expert laboratories or be completely eliminated (ASCO, 1996). The FDA to date has not cleared any methods and still considers this a research test. However, several groups have made significant inroads into solving some of the issues associated with DNA analysis (Fig. 45-5) (Shankey, 2002). The future of this technique in clinical medicine is further discussed later in the chapter.

Sample Preparation

DNA preparative methods are reasonably simple and inexpensive to perform. Many references for the original methods exist, as do many modifications. The most common methods are those used on fresh and frozen tissues and developed by Krishan, Vindelov, Crissman, Steinkamp, and others (Rabinovitch, 1993; Vindelov, 1994), and those used on paraffin blocks (Hedley, 1983). In each case, whether the cells are enucleated or the cell membrane is preserved, the DNA dye PI is used most commonly in the majority of clinical laboratories and has already been described. PI staining is straightforward as long as timing, saturation, and removal of RNA parameters are followed. Measures of gross karyotypic abnormalities are made by comparing the peak (fluorescence intensity, PI uptake) of the tumor versus a diploid calibrator. Factors affecting this measurement include the CVs of the peaks for both the calibrator and the suspected tumor, the G₂/G₁ ratio, the linearity of the instrument, and linearity as measured by the deconvolution software package and the percent of tumor present (sampling) in the sample (Shankey, 2002). It is common to find laboratories reporting out a diploid tumor result on a sample containing "no" tumor. Tumors with near diploid values need stringent rules of interpretation, as does the definition of tetraploidy. Additional problems are associated with the definitions of aggregates, doublets, and debris; the treatment of sliced and cut nuclei; and the S phase population. The descriptive and semiquantitative acronym BAD is used by software analysis packages to model the effects of background, aggregates, and doublets (Rabinovitch, 1993, 1994). The impact of this parameter on the analysis is controversial.

The resulting S phase and DI measurements based on a single-parameter mode of analysis (PI only) are subject to these deconvolution algorithms, leading to great interlaboratory variability (Coon, 1994). These deconvolution algorithms for DNA have been studied extensively (Wheless, 1991; Rabinovitch, 1993, 1994; Shankey, 1993; Coon, 1994), but many models used for analysis need further study. The DNA consensus document makes specific recommendations applicable to certain tumor types and suggests that laboratories perform their analyses accordingly, but even with these guidelines, a level of ambiguity remains in the interpretation and performance of the clinical laboratory that contributes to the discordance of results in comparative studies and in proficiency tests (Coon, 1988; Wheless, 1991; Coon, 1994). Difficulty in achieving consensus makes interpretation of results more difficult for the novice laboratory, as well as for clinicians who are trying to compare their laboratory results with recent literature on the treatment of their patients. This is

Figure 45-5 The cell cycle. **A**, Schematic illustration of the cell cycle of an asynchronous cell population. Most cells are in the resting (G₀) or early proliferative (G₁) stage of the cell cycle, and have diploid (2N or 2C) DNA content. Cells that are actively synthesizing DNA (S phase) have increased DNA content (2N–4N), and cells in the second gap (G₂) phase or undergoing mitosis (M) contain precisely twice the diploid amount of DNA (4N or 4C). **B**, Flow cytometric DNA histogram of a normal proliferating cell population stained with propidium iodide. Cells in the G_{0/1}, S, and G₂M phases of the cell cycle can be differentiated by this technique. Resolution of DNA analysis depends on the fluorochrome utilized for staining DNA, resolution of the instrument, and other factors. Mathematical modeling is required for analysis of cell cycle data because of “overlap” of the S phase curve into the G_{0/1} and G₂M regions. (Reprinted with permission from Riley RS, Mahin EJ, Ross W. *Clinical applications of flow cytometry*. New York: Igaku-Shoin Medical Publishers, 1993.)

especially true in the classification of S phase values. S phase measures are subject to the effects of debris and aggregate modeling as described by Rabinovitch and others (Coon, 1988; Bagwell, 1993; Rabinovitch, 1993, 1994; Shankey, 1993). Furthermore, it is critical that decisions made with regard to which mathematical model is used for a particular tumor be kept constant, and that the list mode data be retained without modeling in case further analysis is necessary.

Other approaches using DNA and RNA probes, such as thymidine derivatives, bromodeoxyuridine and acridine orange (RNA), are used to improve the quality of the models in the estimation of proliferative and kinetic properties of a specific tumor. It is important to remember that proliferation measures are not the same as measures of S phase quantitation, which provide a static model or a picture in time of all cells being analyzed. Integration of the area for the number of cells between 2C and 4C in a DNA histogram is not capable of giving any information with regard to cells “stuck” in S₀ (cells actually stop DNA synthesis) nor of measuring the number of infiltrating normal cells that also might be proliferating. The S phase value may often be higher than the actual proliferative capacity owing to artifacts of tumor heterogeneity. The single-parameter histogram yields reasonable results when dealing with an asynchronous, relatively homogeneous cell population. Pulse labeling is most commonly used in larger academic settings and to measure the effectiveness of radiation and chemotherapy by obtaining true measures of G₀/G₁ cells and G₂ + M compartments, which are not possible to attain using single-parameter measures of S phase.

Other approaches using nuclear and cytoplasmic probes as well as surface markers can be used to separate a population of interest from a mixture of cell types. This type of multiparameter analysis is especially useful in the measure of S phase in hematologic malignancy. Specific blast populations can be identified by FITC fluorescence and FALS, and those events analyzed for DNA content and S phase using PI. Staining methods are altered to preserve cell surface properties or nuclear properties (Clevenger, 1993; Ramaekers, 1993; Bauer, 1994; Carothers, 1994). These methods usually involve staining the surface marker of interest (e.g., KI-67, cyclin B1, cytokeratin, CD10) with the monoclonal antibody, fixing it in an alcohol (or commercial fixation and permeabilization reagent), then treating it with a detergent to allow penetration of PI or another nuclear dye. Staining methods are selectively modified to preserve specific membrane and nuclear properties specific to the probe of interest (Bauer, 1994).

DNA Studies of Interest in Cellular Immunology

There has been an explosion of literature on the subject of apoptosis (i.e., programmed cell death) and its relevance to traditional DNA parameters and other phenotypic considerations. It is not within the scope of this chapter to handle this topic. Although many studies are ongoing, apoptotic measurements are still not part of the routine clinical laboratory.

As mentioned earlier, laboratory DNA analysis has recently come under much scrutiny, and in some regions, these studies are no longer being reimbursed. Several investigators in the field had challenged the wholesale expulsion of this test from the laboratory, as it is useful in certain

tumors. The reexamination of a set of retrospective breast cases is being studied by Bagwell and others (2004) to attempt to develop a unified prognostic model for node-negative breast cancer patients. It is hoped that these studies and others will resurrect what could be a useful prognostic and diagnostic tool that perhaps was previously underestimated in its complexity.

QUANTITATIVE FLOW CYTOMETRY

The definition of cell types in immunologic terms such as effector cells implies the property of these cells to regulate, whether up or down, specific molecular functions through surface receptors. Known as immunologic phenotypes (Poncellet, 1993), these cells need other measurable properties to define their biological roles in maturation and in disease processes. One of the observed phenomena is the differential expression of cell surface antigens (CDs) in relative terms and in absolute quantitative terms. Before the availability of absolute measures, descriptive terms such as bright or dim, bimodal, and so forth, were used in the literature to describe a visual phenomenon of antigen density differences. Although descriptive, these terms are difficult to define and to standardize between laboratories and between patients. They also lack precision in defining an event and cannot be objectively used to monitor patients' treatment or cell definition (cell type) by measures of CD expression and overlapping expression. Evidence suggests that quantitative differences in antigen expression in chronic lymphocytic leukemia and other leukemias may be important in determining the prognosis (Poncellet, 1985). These measures are also used in the definition of MRD and in the investigation of a viral effect or activation in HIV disease (Poncellet, 1991). The percent of a specific cell present often does not give the true clinical picture. This is particularly true in leukopenic cases and when the blast population represents a relatively small percentage of total cells present.

Quantitative flow cytometry is defined as the quantitation of fluorescence intensity (FI) as determined by the antibody-binding capacity of a given fluorochrome antibody conjugate; it is an indirect measure of the amount of cell surface antigen present per individual cell (Stelzer, 1997; Marti, 2003). Investigators (Poncellet, 1985, 1986; Vogt, 1991, 1994) have described the use of polystyrene beads or cell lines coated with saturating amounts of antibody to determine the absolute numbers of receptors or antigenic sites per cell, also referred to as antigen density (Poncellet, 1993). ABC units are defined as a measure of relative antibody-binding capacity. This method does not need to match the fluorescein/protein ratio, as both the cells and the standards are being stained with the same antibody. Use of FI measurements should give the user a means to avoid this situation. More information can be obtained by referring to the 1997 U.S./Canadian consensus document that reviews the necessary parameters for standardization (Stelzer, 1997).

Although early in its development, quantitative phenotypes will help us define cluster analysis software programs for cell quantification and identification by establishing mean channel FI as a means of separating cells of different functional phenotypes.

CLINICAL SIGNIFICANCE OF CELLULAR IMMUNE TESTING

The decision to test the immune response is usually made in the context of the patient's clinical presentation, as described in Table 45-2. The most common reasons for the initiation of a clinical laboratory request include increased or unexplained susceptibility to infection, increased severity of common infections, or an unusual reaction to immunization. Unusual infections, especially those caused by opportunistic agents or severe infections that are unresponsive to treatment, and certain allergic or atopic states may also prompt immune testing. In recent years, potential HIV infection has replaced possible primary immune deficiency as the leading

presumptive diagnosis. Because few, if any, cellular immune tests are totally and specifically diagnostic, and because they may be expensive and time consuming, the request for laboratory evaluation should be approached with caution and a clear understanding of how the result will lead to improved management of the patient. Under these circumstances, the responsibility of the clinical immunology laboratory is to establish a sufficient range of tests to enable judicious testing for determination of the nature and extent of the immune alteration, as well as interpretation of the results in the context of the current clinical presentation and past medical history.

The principal task of the clinical immunologist, aided by the laboratory, is often to distinguish the features of primary immune deficiency, or suspected acquired immune deficiency due to HIV infection, from immune changes associated with other clinical conditions that may produce immune changes that could appear phenotypically identical to primary immunodeficiency. In this regard, immune changes may accompany many clinical entities such as malignancy, traumatic injury such as burns or accidents resulting in major blood loss or organ damage, hematologic disease such as Fanconi's anemia, hemophilia, immune thrombocytopenia, lymphoproliferative disorders such as histiocytosis, the hemoglobinopathies such as sickle cell anemia, thalassemia, and a fairly wide range of chromosomal abnormalities such as DiGeorge syndrome, Down syndrome, Bloom syndrome, William congenital dyskeratosis, epidermolysis bullosa, and Duncan syndrome (X-linked lymphoproliferative disorder). Autoimmune diseases such as rheumatic disease, mixed connective tissue disease, type 1 diabetes mellitus, systemic lupus erythematosus, amyotrophic lateral sclerosis, multiple sclerosis, and myasthenia gravis may be associated with cellular immune changes and are discussed further elsewhere in this textbook.

Primary immune deficiency disorders nearly always present in the context of infection or hematologic change. Laboratory evaluation of these disorders requires a stepwise approach to minimize blood drawing and to logically choose among available tests for the purpose of differential diagnosis. Some presumptive diagnoses may appear to be too frequently suspected, for example, Wiskott-Aldrich syndrome, although this does need to be ruled out in cases of unexplained thrombocytopenia. However, Wiskott-Aldrich syndrome may be missed if response to mitogens alone rather than to antigens as well is not tested, and the immune defect may become more marked with time, so that follow-up testing may be needed.

HIV infection can be readily diagnosed by direct testing, but the clinical immunology laboratory is sometimes used as a proving ground before the patient or guardian is approached for informed consent for HIV testing. This is based on the observation that an inverted CD4/CD8 ratio is virtually always found among HIV-positive adults. Thus, as a result of the current AIDS epidemic, the inverted CD4/CD8 ratio has become identified as a marker of HIV infection. However, a number of diseases other than HIV involve the immune system and can produce an inverted CD4/CD8 ratio, or extremely low CD4 cell numbers. These include, but are not limited to, DiGeorge syndrome, benign thymoma, the early phase of hepatitis C virus infection, Kawasaki disease, protein-calorie malnutrition, and malignancy.

CLINICAL INTERPRETATION OF CELLULAR IMMUNE TESTING

The clinician or laboratorian interpreting cellular immune function assays is often confronted by the issue of how to evaluate the potential clinical significance of an impaired in vitro immune response. Studies of even relatively well-defined disorders have shown that very significant differences in clinical symptoms may occur. However, newer testing strategies can be helpful in subclassifying patients by the level and extent of the defect.

For example, the DiGeorge syndrome (DiGeorge, 1974) is classically a triad of thymic and parathyroid aplasia and conotruncal defects. Patients with the DiGeorge syndrome show marked differences in severity of infection in spite of relatively similar findings of reduced numbers of mature T lymphocytes and a poor response to mitogens. Initially, a very high degree of fatality was associated with this syndrome. Improved surgical and anesthesia methods have led to a significant decrease in the incidence of severe infection, although some infants still develop intractable and ultimately fatal infection (Bastian, 1989). Recently, it has been possible to use more exact lymphocyte phenotype analysis to determine the severity of the immune defect and to more accurately predict clinical outcome. Using longitudinal testing over several months and a multiple parametric approach, it now seems that severity may be predictable from consistently

TABLE 45-2

Presentation of Possible Immunodeficiency

low CD4⁺ T cell numbers, an inverted CD4/CD8 ratio, and reduced lymphokine IL-2 production (Cunningham-Rundles, 1994). Investigation into the significance of monosomic deletions of chromosome 22q11.2, which are the leading causes of DiGeorge syndrome, velocardiofacial syndrome, and conotruncal anomaly face syndrome, illustrates the importance of new genetic information. Although only DiGeorge syndrome was originally described as an immunodeficiency disorder, new studies looking at the frequency of immunodeficiency in the other clinical syndromes associated with the chromosome 22q11.2 microdeletion have shown that more than 75% of patients have evidence of immunocompromise, the severity of which does not correlate with any particular phenotypic feature (Sullivan, 1998).

T cell function may be as important, or more important, in HIV infection than the loss of CD4⁺ T cells or the rate of loss. In some viral-associated illnesses, considerable uncertainty exists as to how close the association is between an immune deficit detected *ex vivo* and the patient's *in vivo* immune function (Landay, 1991; Lloyd, 1992). In other diseases, immune abnormalities have been identified as disease markers, but there is no clear understanding of cause and effect. An example is seen in some forms of chronic fatigue syndrome associated with altered orthostatic response (Rowe, 1999) and increased plasma levels of TNF- α (Moss, 1999).

AGE AND THE IMMUNE RESPONSE

Current studies demonstrate that the immune system changes as part of the aging process (Weiskopf, 2009). Although considerable variation in this is seen, and much is a consequence of altered nutritional status (Mazari, 1998; Lesourd, 2004; Gorczynski, 2008), it is essential that the clinical laboratory provide relevant laboratory values for age-matched controls.

The study of pediatric patients presents particular issues for the laboratory diagnosis of immune deficiency. Development of the immune system in the child is not complete at birth; in addition, children have not been exposed to a wide variety of abnormal environmental agents and may have vulnerability to infection (Zola, 1996). Congenital viral exposure or prematurity alone may be associated with immune abnormalities. Key differences in the pediatric immune response include marked lymphocytosis at birth, elevated B cells, increased CD4⁺/CD8⁺ T cell ratio, few NK cells, and oligoclonal T cell expansions (Yabuhara, 1990; Fletcher, 1992; Cunningham-Rundles, 1993; Wedderburn, 2001). These differences are reflected in marked differences in the normal range of lymphocyte subsets and must be taken into account during evaluation of results (Denny, 1992; Bonilla, 1997). Also, marked differences in response to various activators have been noted as compared with adults. The neonatal response of premature infants to certain microbial activators may be stronger than that of adults or full-term infants because of rapid changes in immune regulation (Cunningham-Rundles, 1991, 2000), or because of fundamental differences in perinatal programming (Prescott, 1998). The immune system of elderly individuals also shows changes in comparison with that of younger adults. In particular, cumulative alterations in critical B and T cell subpopulations, altered cell signaling and cytokine production, and other changes may contribute to the increased incidence of autoimmune disease and cancer in this group (Ginaldi, 2000; Fulop, 2003; Hakim, 2004). The deterioration of immune responses with increasing age has been designated **immunosenescence** (Malaguarnera, 2001).

MALNUTRITION AND THE IMMUNE RESPONSE

Although it is generally believed that malnutrition is relatively rare in developed countries, growing evidence suggests that malnutrition is fairly common, especially in certain age groups (Pennington, 1996). Malnutrition is associated with immune deficiency and causes significant vulnerability to infection (Cunningham-Rundles, 1996; Keusch, 2003). For example, zinc deficiency can present as a profound immune deficiency that may be related to the primary lack of zinc uptake at the gastrointestinal tract, to acrodermatitis enteropathica, or to lack of adequate zinc in the diet (Moynahan, 1974; Prasad, 2009; Tuerk, 2009). Persons with hypogammaglobulinemia and associated malabsorption affecting zinc levels may show poor proliferative response *in vitro* and infections that resolve with zinc repletion (Cunningham-Rundles, 1981). This is associated with the fact that zinc is required for the biological activity of thymic hormone, is needed for the production of functionally mature T cells and for activation of T cells, and may play a role in intercellular signaling within the immune

system (Cunningham-Rundles, 1998; Prasad, 1998; Haase, 2008; Hirano, 2008). Increasing evidence suggests that micronutrient imbalance will alter immune response through specific effects on the immune response (Amati, 2003). In many clinical settings, malnutrition may be a complicating factor. The interaction of infection with altered metabolism secondary to the acute phase response can cause temporal shifts in trace elements, leading to transient suppression of the immune response. Physical stress may have a similar effect and may lead to enhanced vulnerability to infection in the context of immune suppression (Cunningham-Rundles, 1999). This is a two-way process. Growth failure may be the first sign of HIV infection in an HIV-positive child (Peters, 1998). For this and other reasons, immune evaluation should be an ongoing process in the context of continuing treatment or other testing.

CANCER AND THE IMMUNE RESPONSE

Primary immunodeficiency is associated with an increased incidence of cancer (Cunningham-Rundles, 1987), and it is increasingly clear that tumors develop in association with HIV infection (Krown, 1996; Aoki, 2004; Engels, 2008). In the patient with cancer, generalized immune deficiency or reduction in response to antigenic challenge may appear in association with the development of primary malignancy, may occur during metastasis, or may be caused by the side effects of therapeutic intervention. Reduced immune response to nonspecific activators studied *ex vivo* in proliferation assays does correlate with stage of disease and has prognostic significance for survival (Heimdal, 1999). An inverted CD4/CD8 ratio and increased suppressor cell activity are often observed in untreated cancer patients, and changes in cytokine production have been observed (Livingston, 1987; Smyth, 2004). Experimental studies have shown that tumors may be surprisingly immunogenic but may drive the immune response toward a nonprotective response (Loose, 2009).

The development of new immunotherapeutic approaches is increasing, suggesting that response to tumor-specific antigens will be used more in the future (Schultes, 2004; Steinman, 2004; Waller, 2004). Immune response assays may also be used to track and evaluate response to treatments such as IL-2 (Lissoni, 1999) and cancer vaccines (Yannelli, 2004). In many patients, chemotherapy will produce transient suppression of immune response that resolves within a short time, and radiation may have longer-term effects (Katz, 1993). Assessment of immune response in the cancer patient requires highly selective and discriminating use of tests and activators, which reflect relevant processes, as well as specificity of response.

METHODOLOGIC APPROACH TO CELLULAR IMMUNE TESTING

Human studies have been based on observation of peripheral blood immune cells because the peripheral compartment is most accessible and readily measured, but this approach may not reflect regional events. Knowledge of the differences between systemic and mucosal immune response may ultimately explain many current paradoxes that arise when immune response measured *in vitro* or *ex vivo* is compared with host defense *in vivo* (Xu-Amano, 1993). Systemic cellular immune function appears to be regulated through functionally distinct T-helper-type cytokine patterns ("the cytokine network"), such that when Th1 cytokines, IL-2, and IFN- γ are produced, cellular immune host defense is favored. When Th2 cytokines, IL-4, IL-5, IL-6, and IL-10 are produced, B lymphocyte response is induced (Balkwill, 1989; Yamamura, 1991).

In contrast to systemic immunity, the primary activity of the mucosal immune response is to protect the mucosa by blocking microbial, toxin, and antigen entry through secretion and transport of IgA to the lumen of the gut—a process mediated by the innate immune system and a special type of memory T lymphocyte with reduced proliferative capacity capable of providing B cell help (Tlaskalova-Hogenova, 2002; Cheroutre, 2004; Nochi, 2006). Both lamina propria T lymphocytes and intraepithelial T lymphocytes develop in relative independence of the thymus and function differently from peripheral blood T cells in using the CD2 signal transduction pathway rather than the T cell receptor/CD3 pathway.

At present, tests of mucosal immunity usually are not performed in the clinical immunology laboratory, and, with rare exceptions, the immune cells under study are from the peripheral blood compartment. For this reason, use of *in vivo* skin testing and examination of humoral immune response to previously encountered vaccines are useful to the cellular immunologist, as these provide other means of assessment. In all cases, the use of a stepwise approach and repeated testing is highly informative.

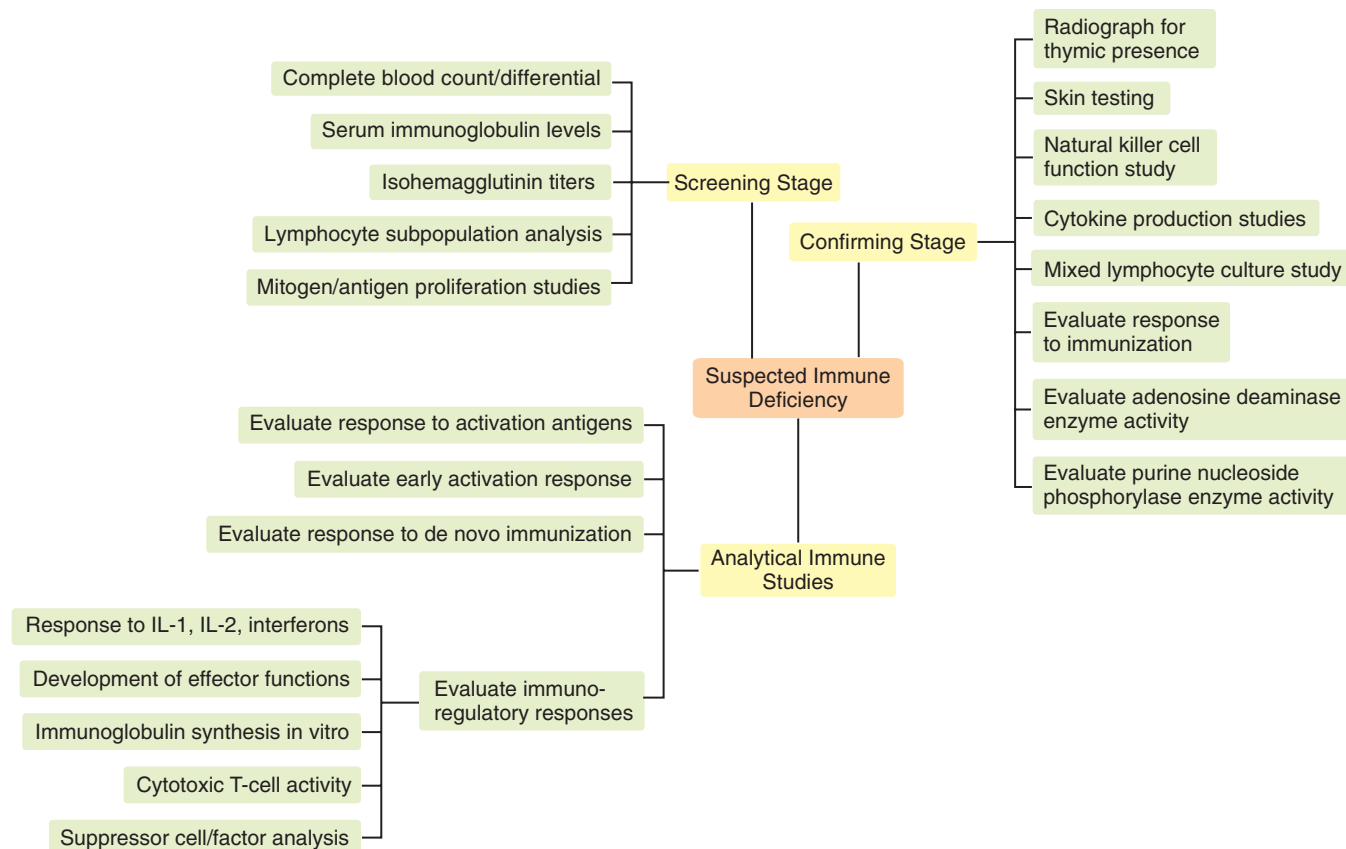

Figure 45-6 The three phases of the clinical evaluation of a suspected deficiency of cellular immunity.

TABLE 45-3

Basic Screening Immunology Studies

- Complete blood count with leukocyte differential count
- Isohemagglutinin titers
- Lymphocyte subpopulation analysis (numbers and percentages of T and B cells) by flow cytometry
- Lymphocyte activation in vitro to mitogens and microbial activators
- Serum immunoglobulins, including immunoglobulin subclasses if evidence of clinical infection with encapsulated bacteria. In some cases, immunoglobulin levels are normal but heterogeneous non-binding antibodies are produced; thus, additional studies are needed.

STAGES OF STUDY: THE SCREENING STAGE

Evaluation of immune function in a patient with a possible immune deficiency is normally achieved in stages (Fig. 45-6). The first stage is a screening analysis of possible areas of deficiency in correlation with the medical history, the family history, and physical examination findings (Table 45-3). A complete blood count and leukocyte differential count must be obtained in all patients, and the peripheral blood film reviewed. Other critical assays include serum immunoglobulin levels (IgG, IgA, IgM, IgD, IgE), complement levels, and isohemagglutinin titers (Cassimos, 2009). These screening studies should be accompanied by appropriate flow cytometric analysis of lymphocyte subpopulations, and in children must include the use of a B cell marker to assess possible B cell shifts, which may occur transiently in the neonate and may be reflected in low T cell populations. The use of an NK cell marker is also strongly recommended in young children older than 3 months of age, because NK cell levels in this population may be reduced or absent at birth (Zola, 1983).

Although there is frequently a limitation on the quantity of blood to be drawn for such studies, it is essential that the first evaluation be performed on blood specimens obtained at the same time. Functional studies need to be performed on fresh anticoagulated blood whenever possible (or blood stored at room temperature in the dark for less than 24 hours) before

mononuclear cells are isolated. When blood is being sent by air or transport to a distant laboratory, it is extremely important to include a control specimen drawn in parallel from a healthy person to serve as an internal standard for the shipping process. The type of tube chosen to draw the blood is important. The use of lithium heparin- or ethylenediaminetetraacetic acid-containing tubes is not recommended for any lymphocyte functional studies. Sodium heparin (preservative free) or acid citrate dextrose tubes must be used. Blood collected in heparinized tubes can also be used for flow cytometric analysis, although the timing of specimen preparation and analysis is critical (Standards, 1992; Nicholson, 1993).

The question of when the blood should be drawn is important. In general, most data have been obtained from blood drawn in the morning, and circadian effects may influence results. When this cannot be done, it is helpful to continue to maintain uniformity of drawing time for an individual patient. This is most critical when measuring absolute numbers of T lymphocyte subsets in the monitoring of HIV disease, or as part of a clinical trial (Malone, 1990).

The screening stage also includes a panel approach to assess mitogenic and antigenic proliferative response. The proliferative response of lymphocytes to a range of activators continues to be one of the most sensitive tools to assess normal function, and, when this includes an appropriate T cell and B cell activator, it can be useful in defining the areas of defect. Although this is not always done, the use of multiple concentrations of each activator is strongly recommended.

STAGES OF STUDY: THE CONFIRMING STAGE

General Aspects

Once the screening of the individual has been achieved and evidence of a potential immune deficiency has been observed, initial findings should be confirmed by repeated tests. Minimally, a positive and a negative (normal range and abnormal range) test should be carried out. Additional tests sometimes may be added to the panel; this may provide the beginning phase of analytic studies.

It is important to make appropriate arrangements to draw blood when the patient is in the most clinically stable state. Double baseline studies are

recommended before intervention is undertaken, and these can encompass the confirming phase. In some cases of apparent immune deficiency, sequestration of immune cells is reflected in low percentages of T lymphocytes in the peripheral compartment. The confirmation stage should also include a careful reevaluation of the patient's medical history and family history. Studies that may be used at this confirming stage are shown in Table 45-4.

Thymic Presence

The roentgenogram for thymic shadow may be inadequate because the thymus is highly prone to stress depletion (Haynes, 1998; Chen, 2000). Although it is difficult to determine with accuracy, the actual size of the thymus assessed by magnetic resonance imaging has been found to correlate with CD4⁺ T lymphocyte number in HIV infection (Vigano, 1999). Recent studies suggest that the human thymus can be thought of as a chimeric organ that comprises both central and peripheral lymphoid tissues. Haynes (1998, 2000) has postulated that thymic epithelial atrophy may derive in part from cytokines or other factors produced by peripheral immune cells within the thymic perivascular space. As described in the subsequent specific section on flow cytometric evaluation of T lymphocyte subsets, expression of normal maturation antigens acquired during thymic development will suffice to identify the presence of a working thymus.

Skin Testing

The use of a skin test panel can be important at this point. This approach to cellular immune assessment originally served as the departure point for the development of the cellular immune functional tests because it measures delayed-type hypersensitivity directly in vivo (McCormick, 2006). Experience with the delayed-type hypersensitivity skin test has shown good overall correlation between lack of reactivity, termed anergy, and immune deficiency (Deodhar, 1983; Maas, 1998), but it has not been useful as an analytic tool to dissect out the reason for lack of response. In addition, the skin test is not very quantifiable. Use of the purified protein derivative skin test to assess the possible presence of *Mycobacterium tuberculosis* is an exception, although anergic individuals do not respond; in addition, false-positives are seen in persons who have been vaccinated with bacille Calmette-Guérin (Huebner, 1993). The relative effectiveness of a standardized *Candida albicans* skin test product in children has been reported (Ohri, 2004).

Reasons for lack of skin test response are shown in Table 45-5. Some studies have been based on a de novo immunization skin test using dinitrofluorobenzene. Although this once was used rather extensively, the approach is no longer considered useful because of ambiguities in the underlying mechanism of reaction. The introduction of the "skin window" test may ultimately provide a more quantitative and informative measure of in vivo immune response because the reaction can be used to test autologous tumor response (Black, 1988). However, despite some reservations, the importance of the skin test as a convincing demonstration that

immune defects noted in vitro may have prognostic significance in vivo should not be underestimated.

STAGES OF STUDY: ANALYTIC IMMUNE STUDIES

Analytic studies are outlined generally in Table 45-6. Although a complete description of these approaches is beyond the scope of this discussion, in general these studies attempt to identify the underlying mechanism of immune defect by proceeding through a series of steps. Although there are different possible ways of doing this, one good way is to assess the general level of defect by following the general plan of assessing the presence of cell types and the relative proportions of all in light of areas of diminished general function, and then to perform studies of effector function.

If cell populations have been determined to be essentially intact in the absence of activation, the issue of intrinsic failure may be studied by many different approaches, including the use of expanded lymphocyte surface marker analysis, framework determinants to the TCR, and activation antigens such as CD25, CD38, and HLA-DR (Table 45-7). Absence of MHC class II upregulation in response to IFN- γ is one example. Although cell populations may express a reference normal differentiation antigen, they may also coexpress others inappropriately, and this may be a key to functional abnormality. For example, CD8⁺ T cells coexpressing CD38 are not functionally the same as CD8 cells that do not express this marker and are expanded in HIV disease (Giorgi, 1989). Absence of expression of certain molecules, such as CD28, is another important indicator. In some primary immune deficiency syndromes, upregulation of the IL-2 receptor in response to IL-2 may be abnormal. Receptors may

not be translocated normally, or receptors may be shed prematurely (Cunningham-Rundles, 1990).

Development of the immune response may be kinetically abnormal because of delayed secondary recruitment during the amplification phase. This should be tested by doing time course studies. In some cases, cytokines may not be made, or they may be functionally altered. Effector functions may be missing or impaired. Evaluation of this may require a detailed approach. Attempts to restore response by addition of cytokine may be useful, although this may circumvent the lesion through compensation rather than fill in the actual deficiency. New testing strategies may utilize whole blood rather than isolated mononuclear cells (Bocchieri, 1995). This system provides an excellent *ex vivo* mirror of immune response, because the actual relationships among cells are not altered. Furthermore, this system can be used to measure cytokine production (Petrovsky, 1995; Suni, 1998).

The cellular immunology laboratory is advised to choose basic analytic studies that are normally done on a routine basis, so a basis for comparison is available. Establishment of laboratory normal ranges and maintenance of reagent quality control, especially for certain variable elements, are essential for the accuracy and sensitivity of these tests.

LABORATORY EVALUATION OF LYMPHOCYTE FUNCTION

Developmental defects, inherited genetic abnormalities, and acquired infections cause profound immunodeficiency states. Additionally, severe burns, trauma, and therapeutic intervention may lead to immunodeficiency. Bulk assays can be used to ascertain whether or not an individual has a decreased T cell proliferative response and have been available for some time, but they are limited both by poor reproducibility and by the limited information garnered from bulk assays. Recent technological developments have allowed for the production of a variety of reagents that can be used to assess multiple activities along the pathway of T cell activation. These reagents include monoclonal antibodies specific for T cell activation markers, reagents and systems for the detection of intracellular cytokines, and tracking dyes and nonradioactive DNA precursors developed to assess lymphocyte proliferation.

LYMPHOCYTE TRANSFORMATION ASSAYS

Principles of Lymphocyte Transformation

The most common *in vivo* procedure used to assess cellular immunity is a simple skin test. A positive skin test for the detection of a delayed-type hypersensitivity response implies intact cellular immunity, as well as intact monocyte chemotaxis (Borut, 1980; Ananworanich, 2002). Although skin testing is easily performed, negative results are difficult to interpret, especially in young children, and skin testing is not as sensitive as *in vitro* lymphocyte stimulation assays (Borut, 1980). Other *in vivo* correlates of cell-mediated immunity include contact sensitivity, granuloma formation, and allograft rejection.

Mitogen-Induced Blastogenesis

Most laboratories assess the proliferative capacity of lymphocytes by measuring the rate of incorporation of radiolabeled DNA nucleosides (tritiated thymidine) following prolonged incubation of peripheral blood mononuclear cell cultures with mitogens (3–4 days) or antigens (5–10 days) (Maluish, 1986). In general, only a limited number of T cells respond to any one antigen *in vitro*; therefore, cells must be cultured from 5–10 days to detect a response. *In vitro* lymphocyte transformation in response to a mitogen was first reported by Nowell (1960). Mitogens and IL-2 in general are the most potent stimuli, as they induce the rapid proliferation of the largest proportion of lymphocytes. For this reason, proliferation can be detected in 3–4 days and thus provides an effective screening tool. Of the mitogens, phytohemagglutinin and concanavalin A (Con A) induce T cell blastogenesis, and pokeweed mitogen and staphylococcal protein A trigger B cell activation.

In the standard mitogen-induced blastogenesis procedure, lymphocytes are isolated with Ficoll-Hypaque density gradient centrifugation and cultured for several days with a mitogen or a specific soluble antigen in media enriched with human AB serum. Tritiated thymidine is added to the culture media, and the plates are incubated for an additional 4–24 hours. The cells are isolated (harvested) from the plates using a special device (cell harvester) and are transferred to disks of filter paper (Fig. 45-7). These

Figure 45-7 Principle of lymphocyte stimulation assay. Lymphocytes are cultured with antigen or mitogen. If stimulation occurs, a proliferative reaction takes place, with the formation of daughter cells. The amount of proliferation can be determined from tritiated thymidine ($^3\text{H}\text{-TdR}$) incorporation, by flow cytometric cell cycle kinetic analysis, or by measuring a cell proliferation antigen such as Ki-67. (Reprinted with permission from Riley RS, Mahin EJ, Ross W. *Clinical applications of flow cytometry*. New York: Igaku-Shoin Medical Publishers; 1993.)

disks are placed in scintillation fluid, and radioactive emissions are measured in a liquid scintillation counter. This technique is classified as a **bulk assay method** because the response of the entire cell population is measured.

Several controls are necessary in bulk assays of lymphocyte proliferation because the assays may be influenced by the number of cultured cells, incubation time and temperature, mitogen concentration, and various inhibitory factors that may be present. The results are expressed as a stimulation index, which is the ratio of radioisotope incorporation into the test versus control cells. The relative proliferation index is the ratio of the Δcpm per minute (cpm) of the test subject (cpm of stimulated cells minus unstimulated control cells) to the Δcpm of a panel of normal individuals tested simultaneously.

Bulk assays, in addition to their inherent technical problems, provide no information on the specific cell subsets that are responding. Cram and collaborators (1976) were among the first to resolve this problem through analysis of blastogenesis at the single cell level by flow cytometry. Since that time, flow cytometry with its inherent multiparameter potential has become the instrument of choice for analysis of lymphocyte transformation and other aspects of the cellular immune response. Comprehensive reviews of flow cytometry and methods used to assess lymphocyte activation and proliferation have been published by Maluish and Perfetto (Maluish, 1986; Perfetto, 2002).

Precise measurement of the proportion of lymphocytes in the various phases of the cell cycle (i.e., cell cycle analysis) is critical for flow cytometric studies of blastogenesis and lymphocyte proliferation. In general, two distinct approaches are used in cell cycle analysis. In the past, the preferred approach was to measure the level of fluorescence intensity emitted by DNA staining dyes. The most commonly used dye was propidium iodide, a phenanthridinium-based compound that intercalates stoichiometrically into DNA (i.e., the amount or intensity of fluorescence is proportional to the amount of DNA in a cell). Using complex mathematical modeling, the percentages of cells in the G_0/G_1 , S, and G_2 phases can be determined from the distribution of FI. Most peripheral blood lymphocytes are in the resting phase of the cell cycle, with fewer than 5% of cells in the S phase. Many fluorescent dyes with different DNA binding affinities and spectral properties have also been used, including ethidium bromide, DAPI, Hoechst 33258, and Hoechst 33342. Bromodeoxyuridine

(5-bromo-2-deoxyuridine, BrdU) is another substance used to measure the proliferation of lymphocytes and other cells. BrdU is a synthetic analog of thymidine that is incorporated into the DNA of replicating cells, while substituting for thymidine. Fluorochrome-labeled antibodies specific for BrdU are used to measure BrdU incorporation and cell proliferation. The quantitation of cell cycle-related nuclear proliferation antigens is another approach for the measurement of cell cycling and proliferation in lymphocyte and other cell populations. Ki-67 antigen is a nuclear protein expressed by proliferating cells in all phases of the cell cycle, but not by resting cells (Sawhney, 1992). Labeled monoclonal antibodies specific for Ki-67 can be measured by flow cytometric or immunohistochemical techniques to obtain the **Ki-67 proliferation index**.

The use of dyes that stably integrate into the membranes of live lymphocytes or other cells is the most recently described means of measuring lymphocyte proliferation. After washing away excess dye, the lymphocytes are stimulated to divide. With each successive division, the amount of dye per cell is halved. The fluorescence emitted from the cells after culture can be modeled, and the number of cell divisions can be estimated. This method has been standardized into a kit that includes both the software required for analyses and the tracking dye (Sigma Immunochemicals, St Louis). An evaluation of 14 of the most commonly utilized tracking dyes reported that two of the dyes, PKH26 and carboxyfluorescein diacetate succinimidyl ester (CFSE), were most suitable for their ability to quantify lymphocyte proliferation (Hasbold, 1999; Parish, 1999, 2002; Hawkins, 2007; Quah, 2007; Gil, 2009). This assay may provide the most accurate assessment of cell proliferative response in *in vitro* culture systems with the substantial advantage over standard bulk assays of allowing the measurement of specific lymphocyte subsets. CFSE indices appear to correlate more closely with TdR assays than measurement of CD69⁺ cells (Angulo, 1998). Measurements of lymphocyte proliferation using the tracking dyes PKH26 and CFSE have been developed, optimized, and tested for their utility in clinical applications (Allsopp, 1998; Angulo, 1998).

Some laboratories have replaced the tritiated thymidine incorporation assays with a combination of cell surface marker induction assays and measurement of the percentage of cells at various phases of the cell cycle following activation (Cost, 1993).

The recently developed ability to measure the production of cell-associated cytokines at the single-cell level also has significant potential as a clinical tool for evaluation of the cellular immune response. Cytokine flow cytometry (intracellular cytokine staining) is performed by stimulating target cells for 4 to 6 hours in the presence of membrane transport blocking reagents (brefeldin A or monensin) to prevent the secretion of cytokines (Ghanekar, 2006). Cells are then labeled with subset-specific monoclonal antibodies, fixed, permeabilized, and labeled with fluorescently tagged monoclonal antibodies specific for the cytokine of interest (Jung, 1993; Prussin, 1995; Maino, 2004; Maecker, 2005; Nomura, 2008). The assay has been developed with the presence of costimulatory antibodies for the sensitive detection of antigen responses in whole blood cultures after relatively short incubation periods (Suni, 1998). Special attention is being focused on the development of antibodies that recognize the nascent forms of the cytokines (within the Golgi) and optimization of the timing of culture to detect maximal cytokine response (Mascher, 1999). Clinical studies have begun to demonstrate the potential utility of this technique. For example, patients suffering very severe burns who show a shift to a Th2 cytokine response may be at increased risk for the development of multiple organ dysfunction syndrome (Zedler, 1999), and clinically active multiple sclerosis patients may show increased production of IL-10 (Inoges, 1999). Expansion of this technique to incorporate the ability to simultaneously measure proliferation and specific cytokine synthesis at the single-cell level has been reported but has not yet been evaluated in a clinical setting (Mehta, 1997).

Clearly, new assays are being developed that measure different events involved in T cell activation. Methods and reagents are available to measure the earliest phosphorylation/dephosphorylation events through signal transduction, gene transcription, and cell division. As these methods are adapted for routine clinical use, we will have a veritable armamentarium of methods to assess many of the processes involved in lymphocyte activation and proliferation. Although many of these new technologies are still within the domain of research laboratories, the methods are constantly being simplified and adapted for use and evaluation in clinical laboratories.

Mixed Lymphocyte Culture

The mixed lymphocyte culture assay (MLC) is a special type of lymphocyte stimulation assay based on the ability of histoincompatible lymphocytes

Figure 45-8 The one-way mixed lymphocyte culture assay (MLC). Irradiated stimulator cells, which are incapable of cell division, are mixed with nonirradiated responder cells, which can proliferate and divide. After incubation under cell culture conditions for approximately 1 week, responder cells proliferate in the presence of a disparity in the human leukocyte antigen (HLA)-D locus (*right side of diagram*), but no proliferation occurs if the responder and stimulator cells are HLA-D compatible (*left side of diagram*). Tritiated thymidine is added to the reaction mixture, and the degree of proliferation is determined by liquid scintillation counting. (Reprinted with permission from Riley RS. *Basic principles of immunodiagnosis*. In: McClatchey KD, editor. *Clinical laboratory medicine*. Baltimore: Williams and Wilkins, 1994.)

from one individual to stimulate the lymphocytes of another individual (mixed lymphocyte reaction) (Bach, 1974; Dupont, 1976; Mickelson, 1990). Although complex in origin, the D locus of the HLA system is the major determinant of the MLC phenomenon. When two cells share common D loci, they are not able to stimulate each other, but when the D loci are different, the cells are stimulated. The MLC is unilateral (one way) when one group of cells are made incapable of responding (by treatment with radiation or mithromycin); it is bidirectional (two way) when no radiation or mithromycin is utilized. In the one-way MLC, untreated cells are termed the responder population, and treated cells are the stimulator population (Fig. 45-8).

Numerous factors must be considered in performance and interpretation of the MLC. Because the reaction is complex, lack of stimulation between two cell types cannot be considered as conclusive evidence of histocompatibility at the HLA-D locus. Other minor histocompatibility loci may also be involved, as well as some non-HLA loci. In addition, specific and nonspecific serum factors can inhibit the assay, and lymphocytes from diseased individuals may not perform well. Numerous controls (including autologous controls) must be included, and the assay must be

performed as expected for the results to be accepted as valid. The principal clinical use of the MLC assay is to assist in the selection of a compatible donor for a bone marrow transplant, because the MLC is a predictor of host response to a transplanted organ. To prevent graft rejection or graft-versus-host disease, donor and recipient cells must be mutually nonstimulatory (El-Agroudy, 2004).

Flow cytometric quantitation of the mixed lymphocyte reaction has been reported. In the method reported by Cram and by Kanda, nuclear DNA content during lymphocyte blastogenesis was determined with a DNA-specific fluorochrome (PI) (Cram, 1976; Kanda, 1985). With this technique, the proliferative index (percentages of cells in the S phase and G₂M phase of the cell cycle) is a direct measurement of de novo DNA synthesis. A good correlation ($r = 0.9493$) was observed between the flow cytometric measurement of the mixed lymphocyte reaction and the results using a traditional MLC with ³H-thymidine incorporation. Other investigators have utilized BrdU, Ki-67, or CFSE for the flow cytometric quantitation of T cell proliferation in the MLR (Palutke, 1987, 1989; Bontadini, 1990; Marin, 2003; Onoe, 2003; Tanaka, 2005). Multiparametric analysis has also been used to measure nuclear DNA content in conjunction with T cell subsets, activation antigens, apoptosis, cytokine secretion, and other parameters during the MLR (Williams, 1984; Uchida, 1987, 1988; Lavergne, 1990; Nguyen, 2003).

CYTOTOXICITY ASSAYS

Cell death (cytotoxicity) is the endpoint commonly used in functional assays of the cellular immune system. In these assays, cell cytotoxicity may occur as the result of complement activity (complement-mediated cytotoxicity) or may be due to the direct effect of one cell on another (cell-mediated cytotoxicity). Conventionally, target cell lysis is determined by the release of a substance such as ⁵¹chromium (⁵¹Cr) from the target cell upon death, or by the incorporation of a vital dye such as eosin or trypan blue. A variation of these assays, the microlymphocytotoxicity assay, is widely used in the clinical histocompatibility laboratory for human organ transplantation. However, the accuracy and reproducibility of these assays are often compromised by the length and technical complexity of the assays, technical problems such as poor uptake or nonspecific release of the marker, or the need for subjective interpretation of the results. The advent of new markers, in combination with the quantitative and multiparametric abilities of the flow cytometer, has made cytotoxicity assays much more practical for biomedical research studies. Other than in histocompatibility testing, these assays have not achieved widespread utilization in patient care.

Cytotoxic T Cell (CTL) Assays

Cytotoxic T cells (CTLs, T killer cells, cytolytic T cells, CD8⁺ T cells, killer T cells) constitute a subset of T cells important in the host defense against altered class I MHC-positive self cells, especially cells infected with a virus or other pathogen. CTLs recognize altered target cells by the presence of peptide fragments produced by processing of the foreign antigen and presented by the class I MHC receptor to the T cell antigen receptor. Recognition of an MHC complex on a target cell by a CTL induces cell death by apoptosis by the granule-exocytosis pathway (granule endocytosis) or the FAS-FAS ligand pathway (Barry, 2002; Lieberman, 2003).

Transfused ⁵¹Cr-labeled cells, especially red blood cells, have been used since the early 1950s to study cellular in vivo distribution and kinetics. In the mid-1960s, Goodman (1961), Sanderson (1964), and Wigzell (1965) independently described the use of ⁵¹Cr-labeled mouse tumor of lymph node cells to study antibody-dependent complement-mediated cytotoxicity. Since that time, the **chromium release assay** has become the standard technique for the measurement of complement- or cell-mediated cytotoxicity. In the chromium release assay for cytotoxic T cell activity, the binding of CTLs to infected ⁵¹Cr-labeled target cells with virus peptide on syngeneic class I MHC induces apoptosis with the proportional release of ⁵¹Cr into the supernatant (Fig. 45-9) (Levin, 1978). Alternatives for the chromium release assay were developed because of the disadvantages of the assay, including its relatively limited sensitivity and use of a radioisotope. The most widely employed alternative techniques include flow cytometry and variations of the enzyme-linked immunosorbent assay (ELISA).

Measurement of antibody- or cell-mediated cytotoxicity by flow cytometry is based on the discrimination of viable and nonviable cells with fluorescent dyes. In addition to relatively high sensitivity, flow cytometry permits multiparametric analysis, with simultaneous detection of up to 12 markers at the single-cell level. The permeability of the cell membrane is

Figure 45-9 Principle of the antibody-dependent cell-mediated cytotoxicity (ADCC) assay. This assay is performed with mononuclear cells from a kidney organ donor or from several unrelated individuals (panel cells), which are stimulated with phytohemagglutinin (PHA) and labeled with ⁵¹Cr. Following incubation with eluate from another nephrectomy specimen or from normal human serum, labeled cells are washed and incubated with effector cells from a normal unrelated individual. Radioactivity (γ -emissions) in the cells at the end of the experiment represents unlysed cells. The results are expressed as % cytotoxicity. (Reprinted with permission from Riley RS. *Basic principles of immunodiagnosis*. In: McClatchey KD, editor. *Clinical laboratory medicine*. Baltimore: Williams and Wilkins, 1994.)

the most widely used parameter of cell viability measured by flow cytometry. Damaged or nonviable cells have altered membrane permeability, and many leak some intracellular substances into the supernatant, while losing the ability to prevent other dyes from penetrating the cell membrane. PI and 7-AAD were the first fluorescent dyes to be used for flow cytometric measurements of cell viability because they are excluded by live cells but rapidly penetrate cells with damaged membranes. Fluorescein diacetate, carboxyfluorescein diacetate (CFDA), and calcein are lipid-soluble, non-fluorescent probes that are metabolized by cytoplasmic esterases to produce a charged, fluorescent product that is retained within the cell if the cell membrane is intact (Zarcone, 1986; Talbot, 1987). Other dyes used for viability determination include PKH-1 (Slezak, 1989), hydroxystilbamide methanesulfonate (Fluoro-Gold [FG]) (Barber, 1999), SYTO13 (Shenkin, 2007), Cell Tracker Orange (Kim, 2007), and calcofluor white M2R (Berghlund, 1987). In many cases, the simultaneous use of two or more markers permits the most accurate measurement of cytotoxicity. One example is the use of PKH-1 in conjunction with PI. PKH-1 is a fluorochrome that emits light in the green region of the spectrum, binds avidly to the cytoplasmic membrane, and is not transferred to other cells. In one

Figure 45-10 Principle of the enzyme-linked immunosorbent spot (ELISPOT) assay. ELISPOT assays bear many similarities to conventional sandwich enzyme-linked immunosorbent assays. A polyvinylidene difluoride (PVDF)-backed microplate is immobilized with an antibody specific for the analyte under evaluation. Immune cells are stimulated with an appropriate antigen or mitogen and then are pipetted into the wells of the microplate. The microplate is incubated in a humidified carbon dioxide (CO_2) chamber at 37°C for a specified period of time, during which stimulated immune products, such as cytokines and antibodies, are secreted. The secreted analyte binds to the immobilized antibody on the microplate. The microplate is washed to remove cells and unbound substances, and a biotinylated polyclonal antibody specific for the chosen analyte is added. Unbound biotinylated antibody is removed by washing, and streptavidin conjugated with alkaline-phosphatase conjugate is added. Following another wash to remove unbound enzyme, the reaction is completed by the addition of the enzyme substrate solution (BCIP/NBT). Dark, blue-black precipitate spots mark the original locations of analyte-secreting cells. The spots can be counted manually under a stereomicroscope, or automatically with a commercial automated ELISPOT reader system.

application, PKH-1 is used to label the target cells, while a second fluorochrome with a red emission signal (PI) is used to detect nonviable cells (Slezak, 1989). This combination of markers allows statistically valid quantitation of both dead and live effectors and targets, permitting the simultaneous determination of percent target lysis, effector-to-target ratio, viability of the effector cells at the termination of the assay, and viable effector-to-target cell ratios.

The enzyme-linked immunosorbent spot (ELISPOT) assay is a very sensitive, extremely versatile adaptation of sandwich ELISA (Shacklett, 2006). Originally described by Czerkinsky and coworkers in 1983 to detect individual B cells secreting antigen-specific antibodies, the ELISPOT was rapidly adapted to detect T cell cytokine excretion (Czerkinsky, 1983; Stott, 2000; Sedgwick, 2005; Kalyuzhny, 2009). Because the ELISPOT assay can reproducibly detect the proportion of antigen-specific or cytokine-secreting cells at a sensitivity of 1/100,000 to 1/1,000,000, it has

achieved widespread use in research involving cancer, infectious disease, and immune disease. Clinically, the ELISPOT is used in immune monitoring and the detection of latent tuberculosis infection. The ELISPOT utilizes polyvinylidene fluoride (PVDF)-backed microplates coated with a monoclonal or polyclonal capture antibody specific for the desired analyte, usually $\text{IFN-}\gamma$ (Kalyuzhny, 2005). A cell suspension and appropriate antigens or mitogens are added to the microplates, and they are incubated in a humidified carbon dioxide (CO_2) incubator at 37°C for a specified time. The plates are washed to remove cells and debris, a biotinylated polyclonal antibody specific for the analyte is added, the plates are washed a second time to remove unbound antibody, and avidin-horseradish peroxidase and a precipitating substrate is added to develop the assay. Colored spots on the plate represent individual analyte-producing cells (Fig. 45-10). The spots can be manually or automatically detected and counted. A variation of this assay using fluorochrome-labeled antibodies (Fluorospot assay)

permits the simultaneous detection of two or three cytokines. A variation of the ELISPOT for the detection of granzyme B, rather than IFN- γ , has shown better correlation with the chromium release assay for the measurement of cytotoxic T cell activity (Shafer-Weaver, 2003; Malyguine, 2007).

Natural Killer Cell-Mediated Cytotoxicity

NK cells are critical members of the innate immune system characterized by their capability to lyse target cells without prior sensitization, termed **spontaneous cell-mediated cytotoxicity** (Sinkovics, 2005). NK cells can be subdivided into two functional and immunophenotypically distinct groups defined by the surface density of CD56 (i.e., CD56bright, CD56dim) (Cooper, 2001; Batoni, 2005; Whiteside, 2006; Morice, 2007; Milush, 2009; Poli, 2009; Bryceson, 2010). Release of ^{51}Cr from labeled target cells is the standard method for the characterization of NK cells. The chronic myeloid leukemia cell line K562 has been used as the standard target in these assays. A variety of other techniques are under evaluation because the ^{51}Cr -release technique has many disadvantages, including the use of radioisotopes, low sensitivity, and the spontaneous release of ^{51}Cr . These methods include the incorporation of radioactive nucleotides during cell proliferation, dye exclusion, target cell enzyme release, and flow cytometry (Bryceson, 2010). Flow cytometric analysis has been performed using a wide variety of markers to differentiate live and dead target cells, including CFDA, PI, Hoechst 33342, fluorochrome octadecylamine-fluorescein isothiocyanate (F-18), usually in combination with multiparametric analysis of cell surface makers, degranulation, cytokine production, and other parameters (McGinnes, 1986; Zarcone, 1986; Vitale, 1989; Kim, 2007; Chung, 2009; Bryceson, 2010).

Microlymphocytotoxicity Assay

The dye exclusion lymphocytotoxicity assay is the standard technique for the detection of an antibody-antigen interaction on a cell surface. The lymphocytotoxicity assay was introduced by Terasaki and McClelland in 1964, and was later accepted as the National Institutes of Health standard procedure for histocompatibility testing (Terasaki, 1964). In the histocompatibility laboratory, variations of the lymphocytotoxicity assay are used for HLA typing, detection of anti-HLA antibodies, and crossmatch testing.

In the lymphocytotoxicity procedure, viable cells (usually lymphocytes) are incubated with serum-containing antisera. If a cell surface antigen is present that is recognized by antibodies in the sera, an antigen-antibody complex will form on the surface. These complexes are detected by the sequential addition of rabbit complement and a vital dye, such as eosin, to the reaction mixture. The occurrence of complement fixation on the cell membrane leads to activation of the terminal complement components, and eventually to cell lysis and death. Dead cells are detected and counted by phase microscopy after differential uptake of the eosin dye and fixation with formalin. Antibody-bound lymphocytes will die, take up the eosin dye, and give a positive reaction; unbound lymphocytes will remain viable, exclude the eosin dye, and give a negative reaction (dye exclusion) (Fig. 45-11).

LABORATORY EVALUATION OF GRANULOCYTE AND MONOCYTE FUNCTION

Monocytes and granulocytes are extremely important in the early inflammatory response, and abnormalities in their functions lead to profound deficiencies in cellular immunity. The activity of neutrophils and macrophages is complex and involves activation of the cell, margination and passage through the vessel wall (diapedesis), movement toward an inflammatory stimulus (chemotaxis, chemokinesis), opsonization, engulfment of the offending agent (phagocytosis), and intracellular killing via the generation of toxic oxygen radicals (Seely, 2003; Zarbock, 2009). Until the modern era of flow cytometry, laboratory analysis of these nonspecific immune parameters was difficult to measure, with available assays being subjective and lacking standardized methods and quality control. In contrast to the subjective assays, many flow cytometric studies are rapid, reproducible, and statistically valid. In addition, the multiparametric capabilities of the flow cytometer permit the simultaneous determination of several cell functions, as well as an assessment of the interrelationship between cell function and other parameters. Flow cytometric assays have been described for the measurement of phagocytosis of microorganisms,

Figure 45-11 Principle of microlymphocytotoxicity by dye exclusion. Cells and serum are incubated together in the wells of a microtiter tray. Mineral oil at the top of the wells prevents fluid evaporation. Complement is added, and a second incubation is performed. The cells are washed, eosin is added, and the cells are fixed with formalin. Cells that fixed antibody and were killed through the action of complement take up eosin and appear dark and nonrefractive under a phase-contrast microscope. In contrast, living cells are refractive and are easily identified by phase-contrast microscopy. Variations of the microlymphocytotoxicity assay are used for human leukocyte antigen (HLA) typing, HLA crossmatch, and detection of anti-HLA antibodies. (Reprinted with permission from Riley RS, Mahin EJ, Ross W. *Clinical applications of flow cytometry*. New York: Igaku-Shoin Medical Publishers; 1993.)

degranulation and enzymatic activity, intracellular killing and degradation of microorganisms, exocytosis, osponization, oxidative metabolism, membrane potential, phagosomal pH, calcium mobilization, F-actin assembly, cell volume, apoptosis, receptor expression, adhesion and aggregation, and other parameters (Duque, 1987; Stelzer, 1988; Bjerknes, 1989; van Eeden, 1999; Elbim, 2009; Zarbock, 2009).

ASSAYS OF NEUTROPHILIC ACTIVATION

Neutrophil activation results when stimulatory substances (e.g., chemotactic factors, immune complexes, opsonized particles) bind to surface receptors to initiate metabolic and structural changes in the cell that result in locomotion, degranulation, phagocytosis, the oxidative burst, and other processes. Early studies of neutrophil activation utilized 7-nitrobenz-2-oxa-1,3-diazole-phalloidin, a fluorescent derivative of an acidic phallo-toxin isolated from mushrooms of the *Amanita* genus, to measure changes in the equilibrium of F-actin that occur during cell activation (Belloc, 1990; Packman, 1990). However, the flow cytometric detection of neutrophil activation antigens, especially CD11b, CD13, and CD64, has become the standard technique for studies of neutrophil activation, usually performed in conjunction with other measurements of intercellular neutrophil function, such as the oxidative burst and measurement of the production and release of neutrophil secretion products such as myeloperoxidase, neutrophil elastase, and lactoferrin (Alvarez-Larran, 2005).

ASSAYS OF PHAGOCYTOSIS AND ENDOCYTOSIS

Conventional analysis of phagocytosis uses particles that are visible within the cell and can be counted after ingestion, or an ingestible substance that can be extracted from the cell and measured. Live or heat-killed *Candida albicans* or staphylococci fulfill the first criterion and permit a simple, convenient means of measuring phagocytosis. Target cells (i.e., neutrophils and monocytes) are incubated with yeast particles in the fresh serum, Giemsa-stained cell preparations are made, and 200 cells are examined and counted for the presence of ingested microorganisms (Lehrer, 1969, 1970). The results are expressed as the percentage of target cells showing phagocytosis and the number of particles per phagocytic neutrophil. Oil droplets containing dissolved oil red O stain and coated with *Escherichia coli* liposaccharide and C3 complement have also been used for the measurement of phagocytosis.

Flow cytometric assays of phagocytosis are quantitative and more accurate than subjective studies using visual counting of phagocytosed microorganisms. Different investigators have used a variety of labeled targets to study phagocytosis by both neutrophils and monocytes. Labeled targets have included fluorescent beads coated with opsonins (Bassøe, 1983a, 1983b, 1984a, 1984b, 1985; Bjerknes, 1983, 1984a, 1984b; Dunn, 1981; Steinkamp, 1982; Ogle, 1988), fluorescein-labeled *C. albicans* (Busetto, 2004), FITC-labeled zymosan particles (Nuutila, 2005), fluorescein-labeled *Staphylococcus aureus* (Carvalho, 2009), fluorescein-labeled *E. coli* (Hirt, 1994; Cacciapuoti, 2007; Danikas, 2008), enhanced green fluorescent protein (EGFP)-expressing *E. coli* (Gille, 2006; Bicker, 2008), and bis-carboxyethyl-carboxyfluorescein pentaacetoxymethylester-labeled *C. albicans* (Pattanapanyasat, 2007). For example, green fluorescent microspheres coated with C3b, iC3b, IgG, mixtures of these substances, bovine serum albumin, or human F(ab')₂ are utilized in the technique developed by Ogle and collaborators (1988). In this assay, neutrophils are incubated with coated microspheres alone or in the presence of cytochalasin D to inhibit phagocytosis. Externally bound microspheres are then stained with a red-labeled antibody against the immobilized ligand(s), and flow cytometric analysis is performed. The ratio of red-to-green fluorescence in the cytochalasin D-inhibited mixtures is used to correct the uninhibited mixtures for externally bound, nonphagocytosed particles. Net phagocytosis is thus represented by the corrected green fluorescence. The specificity of this technique was confirmed with the use of fluid phase C3b and iC3b and monoclonal antibodies to the receptors.

Receptor-mediated endocytosis is a common method for the cellular uptake of viruses, hormones, proteins, toxins, and other ligands. Endocytosis is a complex process that involves capping, internalization of the ligand, intracellular movement, and entry of the ligand into a subcellular compartment. Fluorescent dyes were first used to study endocytosis by Ohkuma and Poole (1978), who studied intralysosomal pH in living cells using a fluorometer and FITC-dextran. Subsequent investigators have used flow cytometry and fluorescent-labeled ligands or liposomes to follow the internalization of various ligands, while others have utilized changes in pH sensitivity to study internalization and/or intracellular movement (Metzeau, 1982; Murphy, 1982a, 1982b; Finney, 1983; Trunch, 1983; Murphy, 1984a, 1984b, 1984c, 1984d; van Deurs, 1984; Elguindi, 1985; Murphy, 1986; Ruud, 1986; Becker, 1997; Ruud, 1989). A different technique was utilized by Wang Yang (1988), who utilized flow cytometric pulse profiles to study capping and endocytosis by mouse B lymphocytes and BCL₁ cells. In this assay, the cells were stained with FITC-labeled anti-immunoglobulin, and were permitted to undergo changes in a temperature-controlled flow cytometer sample compartment. Cap formation resulted in decreases in area values from pH-dependent quenching as the internalized antibody entered the acidic subcellular compartments. Fattorossi (1989) described a related procedure utilizing FITC-conjugated, heat-killed *C. albicans* (F-Ca) opsonized with purified antibodies, or normal human serum. Neutrophils were first incubated with the labeled, opsonized *Candida* particles, and subsequently with ethidium bromide. Although ethidium bromide does not penetrate intact cell membranes, it binds to membrane-bound particles and causes a shift from green to red fluorescence through resonance energy transfer. Because internalized particles retain green fluorescence, the number of internalized or surface-bound particles can be ascertained by contour plot analysis. Fluoresceinated derivatives of α -fetoprotein and transferrin were used by Torres (1990) to study the endocytosis of these substances, and Fibach (1988) studied the uptake of a fluorescent fatty acid derivative [12-(1-pyrene) dodecanoic acid] by a variety of peripheral blood cells. Flow cytometry and electron microscopy were used by

Figure 45-12 Principle of the nitroblue tetrazolium (NBT) reduction assay. Neutrophils are incubated with NBT. Enzymatic activity in the activated neutrophil converts NBT into an insoluble brownish-black precipitate (formazan), which is visible under the microscope. The proportion of neutrophils with intracytoplasmic precipitated material is determined. (Reprinted with permission from Riley RS. *Basic principles of immunodiagnosis*. Kershaw (2009) to study the endocytosis and intracellular trafficking of chemokine CCR5.

ASSAYS OF ENZYMATIC ACTIVITY AND INTRACELLULAR KILLING

Intracellular killing of microorganisms is mediated by complex enzymatic mechanisms. Oxygen-dependent mechanisms of cell killing are the most important, although oxygen-independent mechanisms have also been described. The increase in oxidative metabolism during phagocytosis is referred to as the **oxidative burst**. During this process, the key event is the activation of a membrane-bound pyridine nucleotide-dependent oxidase (NADPH oxidase), which reduces oxygen to O₂⁻ (superoxide anion) and oxidizes NAD(P)H to NAD(P)⁺. Subsequently, hydrogen peroxide (H₂O₂), hydroxyl radical (OH[•]), and singlet oxygen are generated. All of these compounds are directly toxic to the cell, with the H₂O₂-halide-myeloperoxidase system being the most important mechanism of bacterial killing. In the presence of H₂O₂ and halide ions (F⁻, Cl⁻), myeloperoxidase catalyzes direct halogenation of the bacterial cell wall and causes damage to the cell wall by converting amino acids into aldehydes.

In the clinical laboratory, the nitroblue tetrazolium (NBT) reduction assay is the conventional method for determination of the oxidative capacity of the neutrophil. NBT is a yellow dye in its oxidized state, but when reduced, it forms formazan, a crystalline substance that has a deep blue color (Fig. 45-12) (Urban, 1979). NBT can be attached to latex particles or microorganisms to permit phagocytosis, or it can be ingested in soluble form by neutrophils that have been stimulated by endotoxin or other means. If the normal oxidizing environment in the phagolysosome is present, the resultant blue particles can be detected microscopically, or the formazan can be extracted and measured spectrophotometrically. Approximately 10% of normal unstimulated neutrophils ingest and reduce NBT, but this is increased to 80% with stimulated neutrophils.

A flow cytometric variation of the NBT assay has been described. With this technique, neutrophils are incubated for a short time with FITC-labeled Con A, rendering the cell membrane fluorescent (Fattorossi, 1990). The cells are then incubated with NBT and an agent to trigger respiratory activity, such as phorbol myristate acetate. The formazan that is subsequently produced has a distinct fluorescent peak at 520nm that corresponds with the peak emission of fluorescein, and fluorescence quenching of surface fluorescence by formazan is proportional to the intensity of the respiratory burst. In addition, simultaneous changes in cell size and forward light scatter occur.

Bass (1983) described one of the first non-NBT-based flow cytometric-based assays to measure neutrophil oxidative metabolism and oxidative burst at the single-cell level. This technique uses the fluorogenic substrate dichlorofluorescein-diacetate (DCFH-DA) to quantitate H₂O₂ production during the oxidative burst (Bass, 1983). DCFH-DA is a small, nonpolar substance that is actively taken up by the cell and deacetylated by intracellular esterases into a nonfluorescent compound (2',7'-dichlorofluorescein [DCFH]), which is trapped within the cell. In the presence of H₂O₂ and peroxidase, DCFH is oxidized into dichlorofluorescein, which is highly fluorescent in the green region of the spectrum (Fig. 45-13) (Bass, 1983). Other fluorochromes that have been used to directly measure the oxidative burst include dihydrorhodamine 123, dihydrotetramethylrosamine,

Figure 45-13 Flow cytometric analysis of the oxidative burst of polymorphonuclear leukocytes. In this assay, dichlorofluorescein-diacetate (DCFH-DA) is taken up by the cell and is trapped by deacetylation, with the formation of 2',7'-dichlorofluorescein. During the oxidative burst, nonfluorescent 2',7'-dichlorofluorescein is converted into the fluorescent product dichlorofluorescein. The fluorescent intensity in the green region of the spectrum is proportional to the oxidative capacity of the cell. (Reprinted with permission from Bass DA, Parce JW, Dechatelet LR, et al. Flow cytometric studies of oxidative product formation by neutrophils: a graded response to membrane stimulation. *J Immunol* 1983;130:1910–17.)

4-carboxydihydro-tetramethylrosamine succinimidyl ester, and hydroethidine (Smith, 1993; Model, 1997; Walrand, 2003; Elbim, 2009).

Flow cytometric measurements of the oxidative burst have been combined with the quantitation of other metabolic or antigenic changes in the phagocytic cell to fully utilize the multiparametric power of the flow cytometer. In particular, several investigators have described flow cytometric techniques for the simultaneous measurement of phagocytosis and intracellular killing. In one of the earliest studies, phagocytic activity was determined by the internalization of viable, FITC-labeled *C. albicans* (Bjerknes, 1984). At selected intervals, fungi were extracted from the cells, and the fraction of killed fungi was measured by the uptake of PI. Later variations of this technique were developed to simultaneously measure phagocytosis and the oxidative burst (Trinkle, 1987; Prodan, 1995; Lehmann, 1998; McCloskey, 2000; Carvalho, 2009).

A technique for the assessment of surface antigen expression, phagocytosis, and cell proliferation in human bone marrow cells was described by Lund-Johansen (1990). With this technique, incubation of leukocytes with ethidium monoazide-labeled *C. albicans*, followed by staining with an FITC-labeled monoclonal antibody, permitted correlation of surface antigen expression with phagocytic capacity. After incubation with the labeled *C. albicans*, aliquots of the cells were fixed and stained with PI for cell cycle analysis. Haynes (1990) reported a novel method to measure protein digestion within the phagocytic vacuole based on the fluorescent quenching that occurs when rhodamine is attached to albumin at a high molar ratio. In the phagocytic vacuole, digestion of albumin releases free rhodamine and restores fluorescence. This method was affected less by

vacuole pH than fluorescein-based methods and measured digestion even in the presence of abnormal phagocytosis.

ASSAYS OF OPSONIZATION

Phagocytosis of microorganisms and other foreign bodies is greatly enhanced by the presence of certain chemical substances (opsonins) on the surface of the foreign body. In patients with certain immunoglobulin and complement deficiencies, increased susceptibility to infection results in part from decreased opsonization. Opsonins in the serum can be detected by incubating the serum with normal neutrophils and yeast particles, and by visually quantitating phagocytosis of yeast particles by normal neutrophils. In addition, flow cytometric methods have been used for the measurement of serum opsonin function (Bassøe, 1984; Sjørnsen, 1987a, 1987b, 1989). In this assay, live FITC-labeled *Neisseria meningitidis* organisms were preopsonized by incubation with serum for 7.5 minutes, and then were incubated with human polymorphonuclear neutrophilic leukocytes (PMNLs) for 5 minutes at a bacteria-to-PMNL ratio of 20:1. Results were expressed in the number of bacteria incubated per phagocyte.

ASSAYS OF MEMBRANE PERMEABILITY

Fluorescein diacetate has been extensively utilized to monitor changes in membrane permeability. In this regard, fluorescein diacetate is enzymatically hydrolyzed within the cell, with the production of fluorescein. Free fluorescein is released into the extracellular environment across the cell membrane through a process that follows energy-dependent, first-order kinetics, and that is dependent on membrane integrity and permeability. The efflux of fluorescein is inhibited by metabolic poisons and glucose depletion, and has been used to study the effects of a variety of agents on the cell membrane (Prosperi, 1985, 1986). Prosperi (1990) showed that the fluorescein efflux is also related to the ionic gradient (membrane potential) of the cell.

QUALITY CONTROL AND QUALITY ASSURANCE IN THE CELLULAR LABORATORY

Throughout this chapter, we have tried to point out areas where the clinician and laboratory staff must pay particular attention to the methods used and the interpretations made in evaluation of the cellular response. Quality assurance and quality control parameters are not well defined in this area of the laboratory, and few absolute standards exist as compared with chemistry analytes or humoral antibody measures. The success of the cellular laboratory rests in its approach to the problem and the longitudinal assessment of the condition being diagnosed. It was clearly pointed out that baseline studies need to be repeated if the original evaluation is performed at a time of immunologic stress.

Basic parameters of diurnal variations in lymphocyte subsets are obvious but are often forgotten or overlooked. Malone (1990) pointed out that variability in CD4 measures of absolute counts is 50% owing to biology, with the other 50% related to other technical issues. Factors affecting the longitudinal evaluation of CD4 absolute counts in a clinical trial setting have been reviewed by Fei (1993). Furthermore, Fahey (1990) reviewed the prognostic value of both humoral and cellular assays in HIV. With other clinical cellular assays, variability is inherent in the assay owing to lack of standard formats and methods, as well as reagents. Furthermore, instrument calibration and sensitivity are not well monitored. Cytotoxic T lymphocyte assays are particularly difficult to standardize. Historic assays such as mitogen proliferation are also fraught with variability between laboratories. Therefore, laboratories that offer these immunologic tests must have an extensive database by which they can interpret an individual patient's result. Cellular laboratories must establish normal ranges for their assays and must be aware that adult normal ranges are not applicable to pediatric assays. This is particularly problematic because pediatric normal ranges are difficult to determine owing to lack of available subjects in the first year of life, and correct interpretation of laboratory results depends on these normal values. Data between laboratories should be compared carefully.

When available, a cellular immunology laboratory must use available standards in the performance of flow cytometry and DNA analysis, and should be aware of state and federal regulations with regard to the laboratory, including the Human Health and Services Clinical Laboratory

Improvement Act of 1988. Furthermore, laboratory staff should participate in proficiency testing, when available, and should be involved in continuing education seminars, including competency evaluations for all personnel involved in testing. All assays performed in the laboratory must include a normal control and, when possible, in-process controls to establish the validity of the assay. Shipped samples must be carefully monitored for exposure to heat and cold and time since patient procurement. A clinical history should accompany the samples for particular studies being ordered, so that the laboratory director can take the correct approach to testing.

A consensus document with recommendations on the immunophenotypic analysis of hematologic neoplasia by flow cytometry has been published (Braylan, 1997). This document was painstakingly developed by concerned providers in the medical community to cover laboratory procedures, selection of antibodies for identification of neoplasms, data analysis and interpretation, medical reporting, and indications in the absence of standardized kits and other devices. The FDA has put into effect the Analyte Specific Regulation (Analyte Specific Regulation, 1997), which moves reagents such as monoclonals from research use status to ASRs.

This rule does not allow manufacturers to tell laboratory users how to use their reagents. They cannot specify intended use. The ASR rule does provide for stable, well-defined reagents manufactured under good manufacturing practices. All laboratories using these reagents as a "home brew test" must perform their own clinical trial and validation studies and must use a disclaimer in the final report. The consensus document allows a laboratory to perform its assays in a consistent manner and in keeping with the definition of clinical significance used across a large number of laboratories and institutions. The document is not a standard but is consistent with other published standards from NCCLS that are already in use.

The cellular laboratory is faced with a more difficult job of interpretation because the data are not easily standardized. Furthermore, quality assurance of the sample and the evaluation being performed depends on careful documentation of biological and logical parameters that may influence the results. The future of tests used in evaluation of the cellular component of the immune response resides in the development of new methods that may lend themselves to better standardization.

KEY POINTS

- Five different classes of antibody are known—immunoglobulin (Ig)M, IgG, IgA, IgD, and IgE—each with a distinct heavy chain.
- Two different light chain types have been identified: κ and λ .
- Antigens react with antibodies at the Fab region, which contains variable regions of both heavy and light chains.
- The Fc region on the heavy chains determines what other proteins will bind to the antibody (e.g., complement).
- IgG is prevalent in blood and tissue fluids; IgM is found mainly in the blood; secretory IgA is found primarily on epithelial surfaces; IgD is bound mostly to B cells; and IgE is bound largely to basophils and mast cells.
- Polyclonal increases in immunoglobulins occur as part of the immune response and may be found in chronic disease.
- Monoclonal increases in immunoglobulins suggest a plasma cell dyscrasia.
- Diagnosis of disorders of immunoglobulins is aided by their quantitative measurement, in addition to qualitative measures of their clonality by immunofixation electrophoresis and by determination of free light chain concentrations.
- Cryoglobulins can arise as excess monoclonal immunoglobulin (type I), which causes hyperviscosity, or as an IgM autoantibody against IgG (types II and III), which forms circulating immune complexes and causes vasculitis.
- Oligoclonal bands of immunoglobulin in cerebrospinal fluid suggest autoimmune disorders such as demyelinating disease or infection.

Antibodies are the effector molecules of humoral (B cell–mediated) immunity. They are immunoglobulins that react specifically and bind with the antigens that stimulated their production. By mass, immunoglobulins make up about 20% of plasma proteins in healthy individuals. Antibody activity is associated with the slowest migrating proteins on electrophoresis—the γ -globulins. The focus of this chapter is to discuss the general structural and functional properties of immunoglobulins, their laboratory evaluation, and their clinical significance.

STRUCTURAL PROPERTIES OF ANTIBODIES

ANTIBODY MOLECULES

The molecular structure of antibodies has been well elucidated (Padlan, 1991; Poljak, 1991; Tedford, 1991). An immunoglobulin molecule is a Y-shaped glycoprotein. It has two identical antigen-binding sites at the tips of the Y (Fab region) and binding sites for complement components and/or various cell surface receptors on the tail of the Y (Fc region). Each immunoglobulin molecule is composed of two identical heavy (H) chains and two identical light (L) chains. These polypeptide chains are held together by noncovalent interactions that are stabilized by disulfide bonds. Parts of both the H and L chains form the antigen-binding sites. Each immunoglobulin L and H chain consists of a variable region of about 110 amino acid residues at its amino-terminal end (the tips of the Y), which forms the antigen-binding site, linked to a constant region. The H constant region is three or four times larger than that of the L chain. Each chain is composed of repeating, similarly folded domains: An L chain has one variable region (VL) and one constant region (CL) domain, whereas an H chain has one variable region (VH) and three or four constant region (CH) domains (Fig. 46-1). The amino acid sequence variation in the variable regions of both L and H chains is for the most part confined to three small hypervariable regions that come together at the amino-terminal end of the molecule to form the antigen-binding site. Each antigen-binding site is only large enough to bind an antigenic determinant the size of five or six sugar residues.

Five different heavy chain isotypes (γ , α , μ , δ , ϵ) and two light chain isotypes (κ and λ) have been identified, with some of the isotypes having further subtypes. For example, γ has subtypes $\gamma 1$, $\gamma 2$, $\gamma 3$, and $\gamma 4$. The isotypes are formed as a result of variations in the constant regions of the heavy and light chains. These isotypic designations are the basis for the nomenclature of antibodies. Because the heavy chain alone determines effector functions, immunoglobulins are conveniently referred to by their heavy chain isotype (class) using an English letter terminology (IgG, IgA, IgM, IgD, and IgE).

Antibodies have two identical antigen-binding sites. An antigen-binding site is made up of amino acids from one H chain class and one L chain class. Thus, the four-chain Y monomer molecules (see Fig. 46-1) possess two identical antigen-combining sites and are said to be **bivalent**.

Figure 46-1 Schematic representation of immunoglobulin G molecule. The relative positions of the interchain disulfide bonds and the intrachain disulfide bonds that form the loop regions are shown. Each of the loops delineates the domain of the light and heavy chain labeled accordingly. Probable sites of enzymatic cleavage in the “hinge” region by papain or pepsin are indicated. The papain fragments are designated Fab and Fc. The pepsin fragments are Fc' and Fab'2 (2 Fab fragments disulfide-linked). Digestion of Fab with pepsin under proper conditions yields the fragment Fv (VH and VL noncovalently associated). The part of the heavy chain that contributes to the Fab fragment is designated Fd.

Such antibody molecules can cross-link antigen molecules into a large lattice if the antigen molecules each have three or more antigenic determinants. Once the lattice reaches a certain size, it precipitates out of solution (Davies, 1983). This cross-linking is physiologically important because it enhances the engulfment of antigen, such as that expressed by bacteria and by phagocytic leukocytes. It is also involved in activation of the complement system. In addition, cross-linking may be required for the triggering of antibody-producing cells (B lymphocytes) by antigen. The efficiency of antigen-binding and cross-linking reactions by antibodies is greatly increased by a flexible hinge region, where the arms of the Y join the tail, allowing the distance between the two antigen-binding sites to vary.

Multivalence affects the avidity with which an antibody can bind certain types of antigens. A particulate antigen (such as a bacterium or virus) has repeating antigenic determinants on its surface. An antibody molecule may interact with a single particle in such a manner that both of its antigen-combining sites are bound to antigenic determinants on that particle rather than to antigenic determinants on two adjacent particles. When this type of binding occurs, the effective energy of interaction or avidity is greatly increased compared with that associated with monovalent attachments to two particles. This mechanism has been shown to be physiologically important in the neutralization of viruses by antibodies of relatively low binding affinity.

The protective effect of immunoglobulins is not due simply to their ability to bind antigen. They engage in a variety of biological activities mediated by the tail of the Y, the Fc region of the molecule. This part of the antibody molecule determines what will happen to the antigen once it

is bound. Immunoglobulins with the same antigen-binding capacity can have a variety of different Fc regions and therefore different functional properties, such as activating the complement system and attaching to Fc receptors on macrophages, thereby aiding phagocytosis of antigens.

Because of its exposed location and loosely folded structure, the **hinge region** is readily attacked by various proteolytic enzymes. As the name suggests, the hinge region confers a certain amount of flexibility on the molecule, allowing it to assume the Y-shaped structure. This permits an antibody to become attached to a single particle (e.g., a bacterium) through both of its antigen-combining sites or, alternatively, to stretch out to its full length to join two particles. The unique properties conferred by the hinge region on Ig molecules are related to its rich content of proline and hydrophilic amino acid residues. The inter-H chain disulfide bonds of IgG, IgA, and IgD molecules are located in the hinge region (see Fig. 46-1).

The proteolytic enzymes papain and pepsin cleave antibody molecules into different characteristic fragments that lead to an understanding of the structure-function relationship of the protein. Papain cleavage produces two separate and identical Fab (fragment antigen-binding) fragments, each with one antigen-binding site, and one Fc fragment (so-called because in nonhuman primates, it readily crystallizes). On the other hand, pepsin cleavage produces one F(ab')₂ fragment, so-called because it consists of two covalently linked F(ab') fragments (each slightly larger than a Fab fragment); the rest of the molecule is broken down into smaller fragments of various sizes (see Fig. 46-1). Because F(ab')₂ fragments are bivalent, they can still cross-link antigens and form precipitates. This is not true of the univalent Fab fragments. Neither of these fragments (subunits of

antibodies) has the other biological properties of intact antibody molecules because they lack the tail (the Fc region) that mediates these properties. However, monovalent Fab is the form of postimmunization monospecific, affinity-purified ovine antibody that is used therapeutically in patients for such applications as removing toxic levels of digoxin (Digibind) or neutralizing crotalid snake venoms (CroFab).

Each B cell clone makes antibody molecules with a unique antigen-binding site. Initially, the molecules are inserted into the plasma membrane, where they serve as cell surface receptors for antigen. When antigen binds to the membrane-bound antibodies, B cells are activated to multiply, differentiate to a plasma cell, and synthesize a large amount of soluble antibody with the same antigen-binding site, which is secreted into the blood. Humoral antibodies defend humans and animals against infection by inactivating viruses and bacterial toxins via VH/VL domains and by recruiting complement and various cells to kill and ingest invading microorganisms via CL domains in the Fc region of the molecule. The biological properties of the various immunoglobulin domains are summarized in Table 46-1.

ANTIBODY-ANTIGEN INTERACTION

The binding of an antigen to antibody is reversible. The affinity and the number of binding sites contribute to the strength of an antibody-antigen interaction. This reversible binding is a result of many relatively weak noncovalent forces, including hydrophobic and hydrogen bonds, van der Waals forces, and ionic interactions. These weak forces are effective only when the antigen molecule is close enough to allow some of its atoms to fit into complementary recesses (regions) on the antibody surface. The complementary regions of a four-chain antibody unit are its two identical antigen-binding sites, whereas the corresponding region on the antigen is an antigenic determinant. Most antigenic macromolecules have many different antigenic determinants; if two or more of them are identical, the antigen is said to be multivalent.

The **affinity** of an antibody molecule reflects the tightness of fit of an antigenic determinant to a single antigen-binding site, and it is independent of the number of antigenic sites. However, the total **avidity** of an antibody for a multivalent antigen, such as a polymer with repeating subunits, is defined as the total binding strength of all of its binding sites together. A typical IgG molecule binds at least 10,000 times more strongly to a multivalent antigen if both antigen-binding sites are engaged than if only one site is involved.

For the same reason, if the affinity of the antigen-binding sites in an IgG and an IgM molecule is the same, the IgM molecule (because it is a pentamer and thus has 10 binding sites) will have much greater avidity for a multivalent antigen than an IgG molecule (which has two binding sites). This difference in avidity is important in view of the fact that antibodies produced early in an immune response usually have much lower affinities than those produced later. The increase in the average affinity of antibodies produced as time passes after immunization is called **affinity maturation**. This occurs because the antibody response to an antigen is heterogeneous, that is, antibodies with different antigen-combining sites are elicited against the antigen by the responding clones of B lymphocytes. Because

Figure 46-2 Antibody and antigen concentrations influence the size of antigen-antibody complexes formed. The largest complexes are formed when both molecules are present at approximately the same molar concentration (zone of equivalence), whereas the smallest complexes are formed when the antigen is present in great excess. Note that the small complexes formed in antigen excess have only a few antibody molecules per complex; for this reason, they are inefficiently cleared from the extracellular fluids by macrophages.

of its high total avidity, IgM (the major Ig class produced early in immune responses) can function even when each of its binding sites has only low affinity.

The size of the antigen-antibody complex is determined by the valence of the antigen and the relative concentrations of the antigen and the antibody. The antigen-antibody precipitation reaction is based on cross-linking of multivalent antigens by bivalent antibodies. If only one species of antibody (a monoclonal response) is present, molecules with only one antigenic determinant cannot be cross-linked. If an antigen is bivalent, it can form small cyclic complexes or linear chains with antibody, whereas an antigen with three or more antigenic determinants can form large three-dimensional lattices that readily precipitate. However, most antisera elicited against an antigen contain a variety of different antibodies (a polyclonal response) that react with different determinants on the antigen and can cooperate in cross-linking the antigen. By contrast, homogeneous (monoclonal) antibodies can precipitate molecules only if they contain repeating identical antigenic determinants.

Given valence conditions that allow the formation of large aggregates, the size of the antigen-antibody complexes that form depends critically on the relative molar concentrations of the two reactants. If an excess of antigen or antibody is present, large complexes are unlikely to form (Fig. 46-2). This property is crucial to understanding seemingly paradoxical reactions in some immunoassays that depend on antigen-antibody complex formation. For example, a vast excess of antigen can completely saturate all antibody-binding sites, leading to a negative signal (i.e., no agglutination). This phenomenon is sometimes referred to as the **prozone effect**. The prozone effect remains a potential problem for modern assay systems, including syphilis testing, in which extremely high titer antibodies can be missed unless the specimen is tested at dilutions (Smith, 2004) and even in immunofixation electrophoresis (see later, Fig. 46-6, E).

The size and composition of antibody-antigen complexes are not only important in influencing precipitation reactions in vitro, they are crucial in determining the fate of the complexes in the body. Complexes formed at equivalence or in antibody excess have multiple protruding Fc regions and therefore bind strongly to Fc receptors in macrophages, which ingest and degrade them. Small complexes, formed in antigen excess, have only one Fc region per complex. Therefore, they bind poorly to Fc receptors

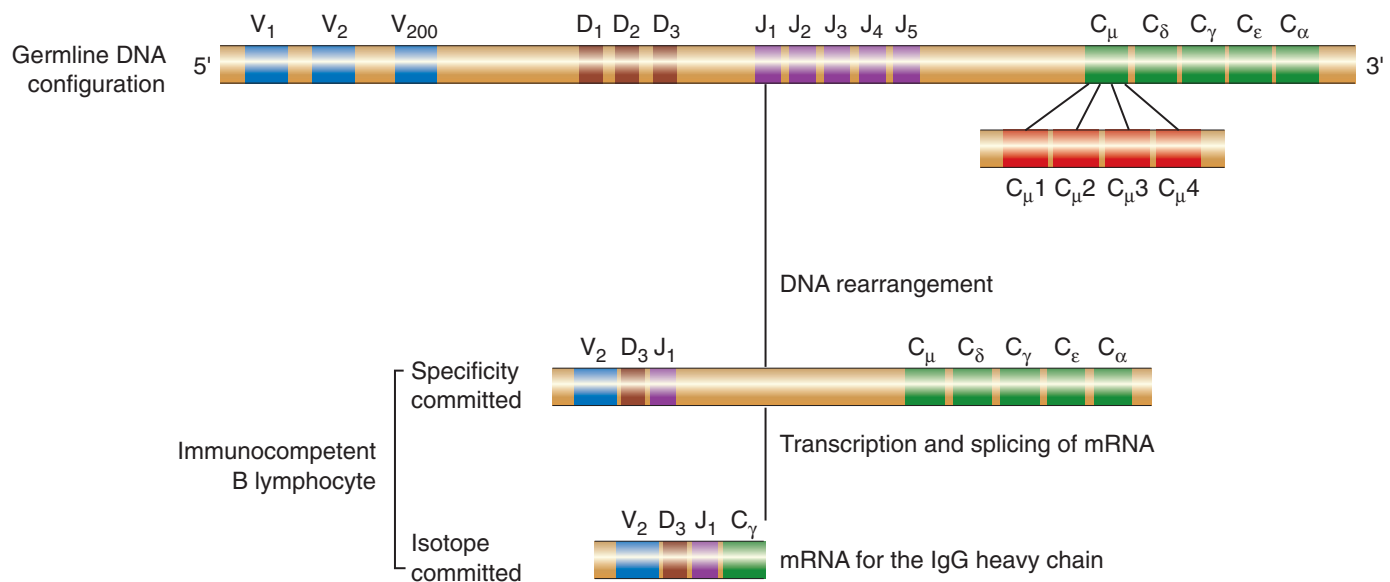

Figure 46-3 Organization and rearrangement of heavy chain immunoglobulin (Ig) genes (exons) on the mouse 12 chromosome. Each VH gene also has a leader sequence, which is not shown. The constant region genes are identified by the heavy chain isotype, and more than one gene exists for the C γ and C α isotypes. Unlike C γ and C α genes, CH genes are composed of multiple exons, as illustrated for the C μ gene (C μ 1–C μ 4 domains). The switch sites are located at the 5' end of each of the CH genes and are not shown. The solid line represents the intervening sequences (introns) between genes or gene segments. Each heavy chain is encoded by four distinct gene segments: V, D, J, and C. (Redrawn with permission from Marcu KB. Immunoglobulin heavy-chain constant region genes. *Cell* 1982;29:719. Copyright © by Cell Press.)

on macrophages and are less efficiently destroyed. Instead, they may be deposited in small blood vessels in the skin, kidneys, joints, and brain, where they may activate the complement system, causing inflammation and the destruction of tissue.

Although it appears that antigen–antibody complexes have a rigid “lock-and-key” appearance, antibodies are dynamic entities that undergo structural fluctuations (Karplus, 1983; Wilson, 1991). Conformational changes may even be required for binding. These adjustments include side chain shifts of up to 20–30 nm, aromatic ring rotations, conformational changes, and even small rotations between VH and VL domains (Bhat, 1990; Standfield, 1990; Herron, 1991).

THE GENETIC BASIS OF ANTIBODY DIVERSITY

It is estimated that a human is able to make at least 10^6 – 10^9 different antibody molecules. Special genetic mechanisms have evolved to produce the very large number of immunoglobulin molecules that develop in response to antigen stimulation without the need for an excessive number of genes (Max, 2003).

Immunoglobulin molecules are produced by three separate gene pools encoding the κ , λ , and H chains, respectively. The gene pools for light and heavy chains reside on different chromosomes. In each pool, separate gene segments that encode for different parts of the variable regions of light and heavy chains can be brought together by site-specific recombination events during B cell differentiation. The light chain gene pools contain one or more constant (C) genes and sets of variable (V) and joining (J) gene segments. The H chain gene pool contains a set of C genes and sets of V, diversity (D), and J gene segments. To make an antibody molecule, a VL gene segment is recombined with a JL gene segment to produce a V gene for the light chain; and a VH gene segment is recombined with D and JH segments to produce a V gene for the heavy chain (Fig. 46-3). Each of the assembled gene segments is then cotranscribed with the appropriate constant region sequence to produce a messenger RNA molecule that encodes for the complete polypeptide chain. By variously combining inherited gene segments encoding for VL and VH regions, vertebrates can make thousands of different light chains and thousands of different H chains that can associate to form millions of different antibody molecules.

The baseline repertoire of antibody molecules can be expanded still farther by somatic hypermutation, which seems to be activated by exposure to antigen. Thus, the selective role of antigen in the presence of somatic mutation appears to lead to fine tuning of the immune response and to a virtually unlimited diversity of antibody molecules. Somatic point

mutations in immunoglobulin genes occur in B cells (not germ cells) during the lifetime of the animal or of humans (Tonegawa, 1983). The somatic hypermutations are largely confined to the H chain and L chain variable region genes and the introns immediately surrounding them. It is estimated that close to one mutation will occur in the H or L chain V region of an individual cell with each cell division. This not only increases antibody diversity but may cause a change in the affinity with which the antibody binds its ligand. Those emerging B cells that can bind the antigen more avidly have an advantage over other B cells that do not bind the antigen as avidly. As the concentration of antigen falls, those B cells that have more avid receptors dominate the population of responding cells. This results in greater affinity of the antibodies being produced on rechallenge than in the initial response. Thus, this process of somatic hypermutation can result in the presence in immunized individuals of high affinity antibodies that are much more effective on a weight basis.

All B cells initially make IgM antibodies. Some later switch to make antibodies of other classes (isotypes: IgG, IgA, etc.) that have the same antigen-binding site (idiotype) as the original IgM antibodies (**allelic exclusion**) (Table 46-2). Such class switching in combination with allelic exclusion allows the same antigen-binding sites (same VH and light chain) to be distributed among antibodies with many different biological properties (secondary effector functions) (Corcoran, 2005).

Thus, the gene organization mechanism permits the assembly of immunoglobulin molecules with a variety of specificities. Antibody diversity depends on the presence of multiple gene segments, their rearrangement into different sequences, the combination of different light and heavy chains in the assembly of immunoglobulin molecules, and somatic mutations.

GENERAL PROPERTIES OF IMMUNOGLOBULINS

The various classes of human immunoglobulins and their properties (Spiegelberg, 1974; Kolar, 2003) are summarized in Tables 46-3 and 46-4.

IMMUNOGLOBULIN M

This glycoprotein is the major class of antibody secreted into the blood in the early stages of a **primary** antibody response. Normally, the secreted form of IgM is a pentamer composed of five four-chain units, a macroglobulin with a 19S sedimentation rate, and a molecular weight of 900 kDa. However, in human autoimmune disorders, such as systemic lupus erythematosus (SLE), the monomeric 7S form may be detected in appreciable amounts in serum. Selective IgM deficiency is a rare disorder associated

TABLE 46-2

Summary of Immunoglobulin Variants

Type of variation	Distribution	Variant	Location	Examples
Isotypic	All variants present in serum of a normal individual	Classes Subclasses Types Subtypes Subgroups	C _H C _H C _L C _L V _L , V _H	IgM, IgE IgA1, IgA2 κ, λ λOz+, λOz- V _{κ1} , V _{κ1b} , V _{H1} , V _{H1b}
Allotypic	Allelic forms not present in all individuals	Allotypes	Mainly C _H /C _L Occasionally V _H /V _L	Gm group (human γ chain; e.g., IgG1, G1m3, G1m17) b ₄ , b ₅ , b ₆ , b ₉ (rabbit light chain)
Idiotypic	Antigenic individuality specific to each Ig molecule	Idiotypes	V _H /V _L	Determinant identified by antibody specific to an individual immunoglobulin

with the absence of IgM and normal levels of other immunoglobulin classes. The cause of this disorder is unknown.

Because pentameric IgM has a total of 10 antigen-binding sites, it is more efficient than 7S monomeric IgM or IgG molecules in cross-linking antigen and in activating the complement system when bound to antigen. Thus, this high efficiency in binding and activating complement, coupled with its early appearance during the course of infection, makes IgM a particularly potent agent in combating microbial invasions.

Each IgM pentamer contains one copy of another polypeptide chain, called a **J (joining) chain**, which has a molecular weight of 15kDa. This accessory polypeptide is produced by IgM-secreting cells. It is an acidic glycoprotein with a high content of cysteine residues and thus is disulfide linked between two adjacent IgM monomeric Fc regions at the carboxy-terminal end. Presumably, oligomerization is initiated at this site.

IgM is also the first class of antibody to be produced by developing B cells. The immediate precursors of B cells, called pre-B cells, make μ chains but not light chains, which accumulate in the cells. Pre-B cells then begin to synthesize light chains, which combine with μ chains to form four-chain monomer IgM molecules. The two μ-chain and two light-chain component is inserted into the plasma membrane, where it functions as a receptor for antigen. At this point, the cells have become B lymphocytes and can respond to antigen.

Perhaps because of its large size, secreted pentamer IgM is not found to any significant extent in tissue spaces; it is confined to the blood circulation and does not cross the placenta. IgM is a minor component of secretory immunoglobulins at mucosal surfaces and in breast milk.

IgM is phylogenetically the most primitive of the immunoglobulins, and most variants of the genes from the μ chain appear to have evolved into heavy chain genes for the other immunoglobulin classes. Additional

physical and biological properties of IgM, as well as the other classes of immunoglobulin, are given in Tables 46-3 and 46-4.

IMMUNOGLOBULIN G

IgG is the best studied isotype at both structural and functional levels (Burton, 1985). Antibodies of this class constitute the major immunoglobulin in the blood. They are copiously produced during the **secondary** immune response. The Fc region of IgG molecules binds to specific receptors on phagocytic cells, such as macrophages and polymorphonuclear leukocytes, thereby increasing the efficiency with which the phagocytic cells can ingest and destroy infecting microorganisms that have become coated with IgG antibodies in response to infection. These receptors on antibodies attached to target cells also guide natural killer (NK) lymphocytes to destroy them through the process of antibody-dependent cell-mediated cytotoxicity (ADCC). The best known function of IgG is complement activation via the classical cascade. The Fc region of IgG can bind to and thereby activate the first component of the complement system, which unleashes a biochemical attack that kills the microorganisms. At least two molecules of IgG are required for complement activation compared with one molecule of IgM, which has five Fc regions.

IgG molecules are the only antibodies that can pass from mother to fetus. Cells of the placenta that are in contact with maternal blood have receptors that bind the Fc region of IgG molecules and mediate their passage to the fetus. The antibodies first are ingested by receptor-mediated endocytosis and then are transported across the cell and released by exocytosis into the fetal blood. Other classes of antibodies do not bind to these receptors and therefore cannot pass across the placenta. The ability of IgG to cross the placenta provides a major line of defense against infection for

IgG—Combats microorganisms and their toxins in extravascular fluids					
IgA—Defends external body surfaces					
IgD—Present on lymphocyte surface of immunocompetent cells, important for B cell activation and/or immunoregulation					

the first weeks of an infant's life. Normally, the human fetus begins to receive significant quantities of maternal IgG transplacentally at around 12 weeks' gestation. The quantity increases steadily until, at birth, cord serum contains a concentration of IgG comparable with that of maternal serum. Barring any immunologic disorders, adult levels of IgG are reached by the seventh year of life and remain relatively constant thereafter.

IgG antibodies have a high diffusion coefficient, which enables them to diffuse into the extravascular body spaces more readily than other Ig classes. IgG, being the predominant immunoglobulin in these spaces, carries the major burden of neutralizing bacterial toxins and of binding microorganisms to enhance their phagocytosis. Furthermore, only IgG antibodies coating target cells, such as tumor cells, can sensitize them for extracellular killing by ADCC; the NK cells responsible for ADCC also possess Fc receptors for IgG.

There are four subclasses of human IgG. These four subclasses reflect the existence of four antigenetically distinct H chains ($\gamma 1$ – $\gamma 4$), which are similar but not identical in amino acid sequence and general properties. For example, IgG1 is the dominant subclass in adult humans. IgG3 is the most effective binder of complement, followed by IgG1 and IgG2. IgG4 in most cases fails completely to bind complement by the classical pathway. All the subclasses except IgG2 have been demonstrated to cross the placenta. A summary of the physical and biological properties of IgG is given in Tables 46-3 and 46-4, and for the subclasses in Table 46-5.

IMMUNOGLOBULIN A

Antibodies of this class constitute the major class of antibody in secretions (milk, saliva, tears, and respiratory and intestinal secretions). It exists as a four-chain monomer (like IgG) or as a dimer of two such monomer units. IgA molecules in secretions are dimers that carry a single J chain, similar to the one associated with pentameric IgM, and an additional glycopoly-peptide chain of 70kDa called **secretory component (SC)**. IgA dimers pick up SC from the surface of the epithelial cells lining the intestine, the bronchi, or the milk, salivary, or tear ducts. Secretory component is synthesized by the epithelial cells and is initially exposed on the nonluminal (external) surface of these cells, where it serves as a receptor for binding dimer IgA. The resulting dimer IgA–receptor complexes are ingested by receptor-mediated endocytosis and are transferred across the epithelial cell

cytoplasm in the form of a membrane vesicle, which fuses with the plasma membrane on the luminal side of the epithelial cell. The extramembrane portion of the IgA receptor is then enzymatically cleaved and released as part of the secretory IgA molecule ($(\alpha_2, L_2)_2 - J\alpha$) into the lumen. The amino-terminus of the dimer IgA receptor remaining attached to dimer IgA is the SC (Fig. 46-4). Thus, the fully assembled dimeric secretory IgA molecule is the synthetic product of two distinct types of cells: plasma cells and epithelial cells. In addition to this transport role, SC may protect the dimer IgA molecules from being digested by proteolytic enzymes in secretions.

In humans it has been possible to classify IgA antibodies into two subclasses—IgA1 and IgA2—based on differences in antigenic structure and variation in the arrangement of interchain disulfide bridges. Whereas IgA2 is a minor component of serum IgA, this subclass is the dominant form in secretions. Furthermore, secretory IgA reaches adult levels sooner than serum IgA. The IgA system in the intestinal tract of humans, for example, may be fully developed by 2 years of age, whereas serum IgA levels do not normally reach adult concentrations until 12 years of age.

Because of its presence near external membranes, secretory IgA constitutes a first line of defense against microorganisms in the external environment. It has been postulated that IgA inhibits the adherence of microorganisms to the surface of mucosal cells, thereby preventing their entry into body tissues. One property of secretory IgA that is important in this respect is its multivalence, which is associated with high avidity of binding to antigens; this may be especially relevant in the neutralization of viruses. Antiviral activity by IgA antibodies has been demonstrated in individuals given either of the polio vaccines. Secretory IgA may also combine with certain antigens in food, preventing their absorption into the bloodstream and thus reducing the incidence of allergic reactions. For example, IgA immunodeficiencies can lead to increased levels and incidence of humoral antibodies directed against antigens derived from food and intestinal organisms.

IgA possesses the following effective properties: It fixes complement through the alternative pathway; through a specific Fc receptor on macrophages it can serve as an opsonin for phagocytosis; and it can induce eosinophil degranulation through a specific receptor, which has implicated IgA in antiparasitic responses. The physical and biological properties of IgA are listed in Tables 46-3 and 46-4.

TABLE 46-5

Properties of Human Immunoglobulin G Subclasses

	IgG1	IgG2	IgG3	IgG4
Physiologic				
Percentage distribution of total normal serum IgG	66 ± 8	23 ± 8	7.3 ± 3.8	4.2 ± 2.6
Synthetic rate, mg/kg/day in serum	25	?	3.4	?
Fraction catabolic rate, % per day (half-life, day)	8 (23)	6.9 (23)	16.8 (7)	6.9 (23)
Ratio of κ/λ	1.4–2.4	1.0–1.1	1.1–1.3	5.0–7.0

Figure 46-4 The mechanism by which the secretory component mediates the transport of a dimeric immunoglobulin (IgA) molecule across an epithelial cell. The entire complex is transported from the extracellular fluid into the lumen of the epithelial tube. The secretory component is synthesized by the epithelial cell as a transmembrane glycoprotein and serves as a receptor on its basolateral surface for binding the IgA dimer. The receptor-IgA complex enters the cell in an endocytotic vesicle, which crosses the cell and is exocytosed at the apical surface. Cleavage of the receptor frees the dimer IgA for discharge at the exterior surface (lumen side). The portion of the receptor that remains attached to the IgA dimer is called the secretory component. This transport mechanism is responsible for depositing IgA in various exocrine secretions (e.g., saliva, milk, bile, tears, sweat), as well as in the mucous layer that protects the inner lining of the nasopharyngeal passages, intestine, and genitourinary tract.

IMMUNOGLOBULIN D

Although only a minor component of the serum, IgD is a major membrane immunoglobulin found on the surface of a high proportion of B lymphocytes, especially in newborns. During the course of B cell differentiation, these cells synthesize and display IgD molecules, as well as IgM molecules. Whereas this appears to contradict the “one-cell-one-immunoglobulin” rule, the antigen-binding sites (idiotype) of the two types of molecules and their light chains are identical. Only their CH regions differ. The membrane-bound IgD may serve as one of the receptors with which B cells bind antigen and are stimulated to undergo clonal proliferation. Some evidence suggests that IgM-bearing B cells can respond to certain T-independent antigens, and that the acquisition of IgD is needed for B cells (IgM- and IgD-bearing) to respond to the T cell help required for T-dependent antigen responsiveness.

Furthermore, if IgD molecules are selectively removed from IgM- and IgD-bearing B cells by taking advantage of the much greater sensitivity of the δ chain to papain, these cells are rendered susceptible to becoming tolerant. The precise role played by surface IgD in an immune response remains unknown, but the generally held view is that it turns on, turns off, or modulates (controls) B cell division or differentiation.

IgD usually is detected in serum at about 6 months of age, and its concentration throughout life is always very low. In disease states, however, IgD concentration can vary greatly. In chronic infection, IgD serum levels increase, as do those of the other immunoglobulins. To date, no specific increase in IgD has been associated with a particular disease. Patients with allergies and autoimmune diseases do not show an abnormal IgD concentration. IgD is usually absent in hypogammaglobulinemic individuals.

To date, IgD has not been assigned a specific biological role as a humoral antibody. IgD activity against a number of antigens has been reported on occasion. Surface IgD, which has proteins similar to those of surface IgM, is a marker for mature B cells, and its role as a receptor is generally accepted even though the nature and purpose of the signal it transmits remains controversial (Carsetti, 1993; Roes, 1993). IgD does not bind complement, does not cross the placenta, and does not bind to cells through its Fc region. The secreted form of IgD as well as that of the other immunoglobulins lacks the carboxy-terminal transmembrane peptide that anchors it to the surface of B cells. Tables 46-3 and 46-4 list additional properties of IgD.

IMMUNOGLOBULIN E

Of the various classes of immunoglobulin, IgE is present at the lowest serum concentration (see Table 46-4). It has the ability to attach to human skin (homocytotropic antibody) and to initiate aspects of the allergic reaction (reaginic antibody). The biological activity of IgE is accounted for by its property of binding through the Fc region to basophils and to their tissue equivalent—mast cells. IgE may also be important in the humoral immune response to parasitic disease because it is often found at high levels in the serum of patients with helminthic infection. IgE may play a part in allowing white blood cells (WBCs), antibodies, and complement components to enter sites of inflammation, leading to an immediate hypersensitivity reaction. IgE antibodies provide a striking example of the **bifunctional** nature of antibody molecules. The Fc portion of the molecule binds to the target cells, whereas the Fab portion binds the allergen (see Chapter 54 for the role of IgE in allergic diseases and related assays).

As with IgA, IgE is produced mainly in the linings of the respiratory and intestinal tracts and is part of the external secretory system of antibody. A deficiency of IgE has been inconsistently associated with deficiency of IgA in individuals with impaired immunity, who present with undue susceptibility to infection. IgE does not cross the placenta, and IgE-antigen complexes do not bind complement by the classical pathway (see Table 46-4).

SUMMARY

Five different classes of antibody (IgM, IgG, IgA, IgD, and IgE), four subclasses of IgG antibody (IgG1, IgG2, IgG3, and IgG4), and two subclasses of IgA antibody (IgA1 and IgA2) are present in humans. Each of these antibody isotypes possesses a distinct H chain (μ , γ , α , δ , ϵ , $\gamma 1$, $\gamma 2$, $\gamma 3$, $\gamma 4$; and $\alpha 1$, $\alpha 2$, respectively). The H chains contain the Fc region of the antibody, which determines what other proteins will bind to the antibody and therefore the biological properties of the class and subclass. Either type of L chain (κ or λ) can be associated with any class of H chain.

Structural differences among the five classes of immunoglobulins correspond to functional differences in their sites of production and action, their relative levels of production in primary and secondary immune responses, and their roles as physiologic effectors. For example, IgG is prevalent in both blood and tissue fluids, whereas IgM is chiefly confined to the blood, and secretory IgA is found primarily on epithelial surfaces. IgD and IgE are principally bound to cells, IgD to B cells, and IgE to basophils and mast cells.

CLINICAL SIGNIFICANCE OF IMMUNOGLOBULINS

Immunoglobulins play important roles in disease pathogenesis, diagnosis, prevention, and therapy.

DISEASE PATHOGENESIS

Monoclonal hyperimmunoglobulinemia is a prominent feature of multiple myeloma and Waldenström's macroglobulinemia. Antibodies against native antigens may result in autoimmune disease, as discussed in Chapters 51 and 53. Hypoglobulinemia or agammaglobulinemia is often the prime characteristic of some immunodeficiency disorders (see Chapter 50). Polyclonal hypergammaglobulinemia can result from chronic inflammation or other disorders such as cirrhosis of the liver due to excess pan-B cell stimulation.

Hyperimmunoglobulinemia

Serum Immunoglobulin Levels

Valid interpretation of serum immunoglobulin levels requires recognition of biological variations that exist throughout the life span of individuals. The most important of these variables are age, sex, and race. In neonates, levels of circulating immunoglobulins are much lower than at all other ages, as essentially all immunoglobulins at that stage were passively transferred from mother to fetus in utero. Immunoglobulin levels rise through childhood to more stable concentrations in mature adults. Normal IgG, IgA, and IgM concentrations at any particular age can vary as much as tenfold from lower to upper limits of the reference ranges. A very large study of immunoglobulin concentrations in a northern New England (99% Caucasian) population of 115,017 serum samples demonstrated the expected rise from infancy, more stable values after adolescence, and then in older individuals further slight increase in IgA, nearly stable IgG, and slight reduction in IgM (Ritchie, 1998). Little difference was noted between males and females in terms of IgA and IgG median levels, whereas males exhibited lower IgM than females at all ages except the very young. That study might be considered definitive for age and gender through the sheer number of subjects, although the population was not racially diverse.

A smaller but still reasonably large group of healthy white subjects (3213) from a single community (Tecumseh, MI) showed that mean concentrations of IgG and IgA increased with age, with slight but significant differences between the sexes. Females had higher serum levels of IgG and lower levels of IgA. Although these sex differences for IgG and IgA are statistically significant, their biological meaning is not apparent. IgM levels in these subjects remained relatively constant with age. However, females had higher mean levels of IgM (1.06 mg/mL) than males (0.77 mg/mL) (Cassidy, 1974).

Several studies have reported that immunoglobulin levels are higher in persons with pigmented skin. A study of a healthy biracial population in Evans County, Georgia, demonstrated that black people had higher levels of the three major immunoglobulins (IgM, IgG, and IgA) when compared with white people (Lichtman, 1967). The most prominent difference was seen in IgG. No urban-rural difference in immunoglobulin levels was noted in this study. White subjects in Rochester, New York, had serum levels of IgM and IgG similar to those of white subjects in rural Georgia. A triracial study in Durban, Natal, South Africa, showed that Bantu male adults had significantly higher levels of IgM (32% more), IgG (40% more), and IgA (32% more) in their sera than comparable white male adults in this community who were born in the same year and had the same ABO blood group. Healthy Asiatic male adults had about 20% more IgG, 23% more IgA, and 7% more IgM than comparable white male adults. A study of subjects in the Washington, DC, metropolitan area revealed that black people had significantly higher IgG levels than white people but similar IgA and IgM levels (Tollerud, 1995). Control groups used in these studies were matched for age, sex, and race, as well as for several environmental

TABLE 46-6

Polyclonal Hyperimmunoglobulinemias: Some Associated Disease States

Condition	Immunoglobulin (Ig) classes
Immunodeficiency Diseases	
Hyperimmunoglobulin E and recurrent infections	IgE
Wiskott-Aldrich syndrome	IgA, IgE
"Dysgammaglobulinemia type I"	IgM
Hyperimmunoglobulin A and recurrent infections	IgA
Acquired immune deficiency syndrome (AIDS)	All classes
Infections	
Congenital infections (syphilis, toxoplasmosis, rubella, cytomegalovirus)	IgM
Infectious mononucleosis	IgM or all
Trypanosomiasis	IgM or all
Intestinal parasitism	All classes
Several helminthic infections	IgE
Visceral larva migrans	All classes
Chronic granulomatous disease of childhood	All classes
Leprosy	All classes
Chronic infection in general	All classes, with a preference for IgG
Liver Diseases	
Chronic active hepatitis	IgG predominates
Acute hepatitis	IgG predominates
Biliary cirrhosis	IgM predominates
Lupoid hepatitis	All classes
Pulmonary Disorders	
Pulmonary hypersensitivity syndrome	All classes
Sarcoidosis	All classes
Berylliosis	All classes
"Autoimmune" Disorders	
Systemic lupus erythematosus	All classes
Rheumatoid arthritis	IgA or all
Many "autoimmune" states such as thyroiditis	All classes
Scleroderma	All classes
Cold agglutinin disease	IgM
Anaphylactoid purpura	IgA
Miscellaneous	
Down syndrome	All classes
Amyloidosis	All classes
Narcotic addiction	IgM
Renal tubular disease	All classes

factors. Increases in gammaglobulin often are first noted after serum protein electrophoresis, measurement of total protein, or measurements of albumin and γ -globulin fractions.

Increases in immunoglobulins are referred to as monoclonal or polyclonal. Monoclonal immunoglobulins from any one individual are structurally identical and are believed to result from the clonal expansion of a single immunoglobulin-producing lymphoid cell, and hence are specific for a particular antigen. Polyclonal immunoglobulins in the same individual are structurally different from each other in one or more important ways—by class, as polyclonal IgG, IgA, or IgM; by light chain; or by antigen specificity. Polyclonal immunoglobulins arise from the expansion of several to many different immunoglobulin-producing lymphoid cells.

Polyclonal Immunoglobulins

Polyclonal increases in immunoglobulins have been associated with many disease states (Table 46-6) (Cushman, 1973; Buckley, 1977). Serum protein

TABLE 46-7

Selected Conditions Associated With Monoclonal Immunoglobulins

- Multiple myeloma
- Macroglobulinemia of Waldenström
- Chronic lymphocytic leukemia
- Other leukemias
- Lymphomas
- "Benign" monoclonal gammopathy
- Systemic capillary leak syndrome
- Amyloidosis
- Chronic liver disease such as chronic active hepatitis, primary biliary cirrhosis
- Autoimmune disorders, including rheumatoid arthritis, systemic lupus erythematosus, thyroiditis, pernicious anemia, polyarteritis nodosa, Sjögren's syndrome
- Gaucher's disease
- Malignancies of various types
- Hereditary spherocytosis
- HIV infection, including AIDS

AIDS, Acquired immune deficiency syndrome; HIV, human immunodeficiency virus.

Figure 46-5 Serum protein electrophoresis performed in agarose gel. This gel demonstrates the variation in electrophoretic migration of monoclonal bands as typically encountered in diagnosing and monitoring patients with plasma cell disorders such as multiple myeloma. This routine analysis of serum specimens from 2 controls and 28 patients included 14 individuals with monoclonal bands.

electrophoresis is often sufficient to establish this condition. Immunoelectrophoresis, immunofixation, and determination of individual immunoglobulins or immunoglobulin light chains may be helpful at times to confirm a polyclonal distribution or an increased concentration in one or more immunoglobulin classes. Increases in serum immunoglobulins may result from decreased catabolism and increased synthesis. The control mechanisms for these events are not well understood. The implications of elevated immunoglobulins are unknown. Most immunoglobulins appear not to be directed toward a definable specific antigenic determinant, or set of specific antigenic determinants. It should also be noted that most autoantibodies are not monoclonal but polyclonal. In general, persistent polyclonal increases in gammaglobulin are thought to be related to antigenic stimulation of a chronic nature or loss of immunoglobulin regulation.

Monoclonal Immunoglobulins

Monoclonal immunoglobulins or fragments of immunoglobulins have been associated with a number of disease conditions (Table 46-7) (Wells, 1974; Benbassat, 1976; Atkinson, 1977; Schaefer, 1978; Kelly, 1985). These immunoglobulins have also been referred to as immunoglobulins with restricted heterogeneity. Protein electrophoresis of serum and urine (Fig. 46-5) is commonly used to screen for monoclonal gammopathy.

The incidence of monoclonal immunoglobulins (M components) in unselected population studies is estimated to be 0.9% (Bachman, 1965; Axelsson, 1968; Cohen, 1985). Of course, a much higher percentage of positive results is found in clinical laboratories where the sera to be tested are preselected. Multiple myeloma, Waldenström's macroglobulinemia, and B cell neoplasms are some of the diseases that are associated with elevated levels of monoclonal immunoglobulins. It was earlier believed that monoclonal gammopathies were rare in cases of chronic lymphocytic leukemia or well-differentiated lymphocytic lymphoma. It has now been shown that when high-resolution electrophoresis and immunofixation are combined to study samples from these patients, most are found to have a

monoclonal gammopathy (Keren, 1988). Monoclonal gammopathies have also been demonstrated in patients with Burkitt lymphoma and B cell acute lymphocytic leukemia.

Although the antigen-combining specificities of monoclonal gammopathies generally are not known, some result in paraproteinemic neuropathies. This clinical syndrome is generally due to the interaction of an IgM paraprotein with myelin-associated glycoprotein (MAG), gangliosides (e.g., GM1 in motor neuropathy, GD1b in sensory neuropathy), or other glycosphingolipids (Ropper, 1998).

The term *monoclonal gammopathy of undetermined significance* (MGUS) was coined by Kyle to categorize individuals in whom a monoclonal component is demonstrated in the serum but who lack other key features for diagnosing a malignant condition (Kyle, 1982). As many as 3% of individuals over the age of 70 have an MGUS (Kyle, 2003). Subjects with MGUS may have as many as 10% plasma cells in the bone marrow. This is considerably less than the bone marrow plasmacytosis associated with multiple myeloma. About 20% of individuals with MGUS will develop a malignant B cell lymphoproliferative disorder, most commonly multiple myeloma, over a 10-year period. Some of the other cases develop into chronic lymphocytic leukemia, amyloidosis, well-differentiated lymphocytic lymphoma, and other B cell proliferative diseases. Subjects with MGUS have quantities of M component ranging from 300 mg/dL to greater than 3000 mg/dL and usually do not have Bence Jones protein in the urine. It is recommended that such patients be followed with serum protein electrophoresis every 6–12 months to determine whether the process is progressing or regressing.

The risk of progression with MGUS is about 1% per year even after 25 years of a stable condition (Kyle, 2003). A 31-year follow-up study of MGUS in New Zealand showed progression to hematologic malignancy in 64% of 11 patients originally detected by screening 2192 subjects in a town in 1967 (Colls, 1999).

A special consideration is MGUS that is observed in organ transplant patients who have received immunosuppressive drugs that alter T lymphocyte functions, including the modulation of B cell responsiveness. These monoclonal gammopathies may be transient in up to 75% of cases (Radl, 1985). They may occur in both monoclonal and oligoclonal forms (Stanko, 1989), and they may coincide with infections of cytomegalovirus or Epstein-Barr virus (Drouet, 1999). Their progression is likely stimulated by high circulating levels of interleukin-6 (Nickerson, 1994).

Cryoglobulins

Cryoglobulins are immunoglobulins that precipitate upon storage at refrigerated temperatures (4° C), and as a group, are associated with hematologic, autoimmune, and chronic infections such as hepatitis C. Type I cryoglobulins consist of a single monoclonal immunoglobulin that precipitates in the cold without binding other proteins. This type of molecule is typically IgM encountered in Waldenström's macroglobulinemia, where it can produce a hyperviscosity syndrome due to very thick consistency of the circulating blood that can be exacerbated by cold ambient temperatures encountered by the patient.

Type II cryoglobulins are distinctly different from type I. The abnormality in type II is a monoclonal IgM autoantibody that is directed at the Fc region of normal polyclonal IgG (Cacoub, 2002). This autoantibody is the same as rheumatoid factor. It is also referred to as mixed cryoglobulin containing both IgM and IgG. It is commonly encountered in rheumatoid arthritis and in chronic hepatitis C virus infection for unknown reasons. The presence of IgM anti-IgG leads to formation of circulating immune complexes (CICs), with IgG normally occurring in the blood. These CICs then deposit in small blood vessels, causing vasculitis, glomerulonephritis, arthritis, and so forth.

Type III cryoglobulins have been described as a variant of type II in which the IgM autoantibody against IgG is polyclonal. Type III can be found in chronic infections and inflammatory states. Many such cases in the past could have been confused with type II because of methods that would not permit sensitive typing of the light chains in a minor band of IgM in the presence of large amounts of IgG, because both light chain types would appear in the cryoprecipitate.

DISEASE DIAGNOSIS

Laboratory evaluation of immunoglobulin levels and functions may be helpful in the diagnosis and management of disease. Complement fixation tests, hemagglutination assays, and other immunoassays can detect an increased or changing titer of antibodies against specific antigens such as those present on microorganisms.

Requests to examine sera for the presence of a monoclonal protein usually are generated by a physician who recognizes that a patient has clinical symptoms and signs of such a disorder, or by laboratory examination of a serum protein electrophoresis that suggests a monoclonal protein. Many times, the physician's suspicion of a plasma cell dyscrasia is triggered by findings of anemia (with one or more cytopenias), elevated total serum protein with elevated globulins, and proteinuria; other findings may include hyperuricemia, hypercalcemia, elevated alkaline phosphatase, bone pain, or lytic lesions of bone on x-ray. If indeed an M component is present in a serum protein electrophoresis, quantitative measurement of immunoglobulins by radial immunodiffusion, nephelometry, or another suitable technique can identify the specific immunoglobulin if only one of the major three classes is increased. Of course, this neither determines the light chain of a monoclonal immunoglobulin nor detects light chain myelomas. Biclinal gammopathies may be confusing.

Quantitative immunoglobulins are useful in monitoring the course of the disease and its treatment and may be helpful in separating a benign from a malignant condition. Monoclonal IgG levels of 2 g/100 mL or IgA levels of 1 g/100 mL (Isobe, 1971) or greater suggest a malignant condition. In many malignant immunocytopathies, the concentration of non-monoclonal immunoglobulins is reduced. Thus, a deficiency of polyclonal immunoglobulins is suggestive of malignancy. Paradoxically, the patient with a malignant immunocytopathy is immunodeficient even though he possesses large quantities of a "nonsense" immunoglobulin produced by a poorly controlled clone of lymphoid cells.

Immunofixation

Confirmation of heavy chain and light chain types of a monoclonal band today is done almost exclusively by immunofixation electrophoresis (IFE). Immunoelectrophoresis (IEP) was an older procedure in which patient and normal serum specimens were electrophoresed in adjacent lanes, followed by diffusion of individual antisera against light and heavy chains from a trough cut into the agarose support medium. After overnight incubation, the pattern of precipitin arcs formed by the antisera with their target immunoglobulins was interpreted as monoclonal or polyclonal distribution. Readers are referred to earlier editions of this textbook for more information about IEP and pictures of the gels, which are no longer commonly used in modern clinical laboratories. IFE has virtually replaced IEP in the clinical laboratory because of its speed, sensitivity, and ease of interpretation. IFE has greater sensitivity for detecting small monoclonal bands in the presence of polyclonal immunoglobulins. IFE also has the advantage of a more rapid readout because diffusion through gel is not required. Replicate samples of patient serum are subjected to electrophoresis through high-resolution gel before monospecific antisera are applied directly to the separated serum proteins. The gel is washed, and the protein-antibody conjugates are stained and read directly (Fig. 46-6). One lane is treated with a precipitating reagent that fixes all proteins in the same pattern as the serum protein electrophoresis. Maintaining all serum proteins in register with the immunofixed immunoglobulins adds to the ease of confirming and identifying monoclonal paraproteins.

Occasionally, the concentration of the monoclonal protein in a patient's serum is so high that it exceeds the capacity of the reagent antibodies to form precipitating complexes by IFE. This phenomenon corresponds to the zone of antigen excess depicted in Figure 46-2. The result is a halo of precipitated complexes (where the concentrations are nearer to equivalence) with a clear central zone of antigen excess (see Fig. 46-6, E). Although this result appears atypical, it is straightforward to interpret and to confirm by repeating the IFE with a greater dilution of patient serum (Keren, 1999).

Either technique may be applied to other body fluids, most commonly urine. Monoclonal light chains in the urine (Bence Jones protein) may be detected in more than half of patients with multiple myeloma (Isobe, 1971; Wells, 1974). Polyclonal light chains may be detected in patients with other disorders, usually as part of complete immunoglobulin molecules. The original method to detect Bence Jones protein was based on precipitation in urine heated to 40°–60° C and then redissolution when further heated to 100° C. IFE of urine is more specific and more sensitive than the older Bence Jones assay. IFE may be performed on urine samples with sufficient protein or subsequent to concentration by lyophilization or by selective membranes (Minicon, Millipore Corporation, Billerica, Mass.).

Immunoglobulins at very high concentrations can significantly increase the viscosity of blood, leading to problems with organ perfusion. Measurements of the viscosity of serum have been done to assess this effect, but they are rarely used today because other methods for quantifying

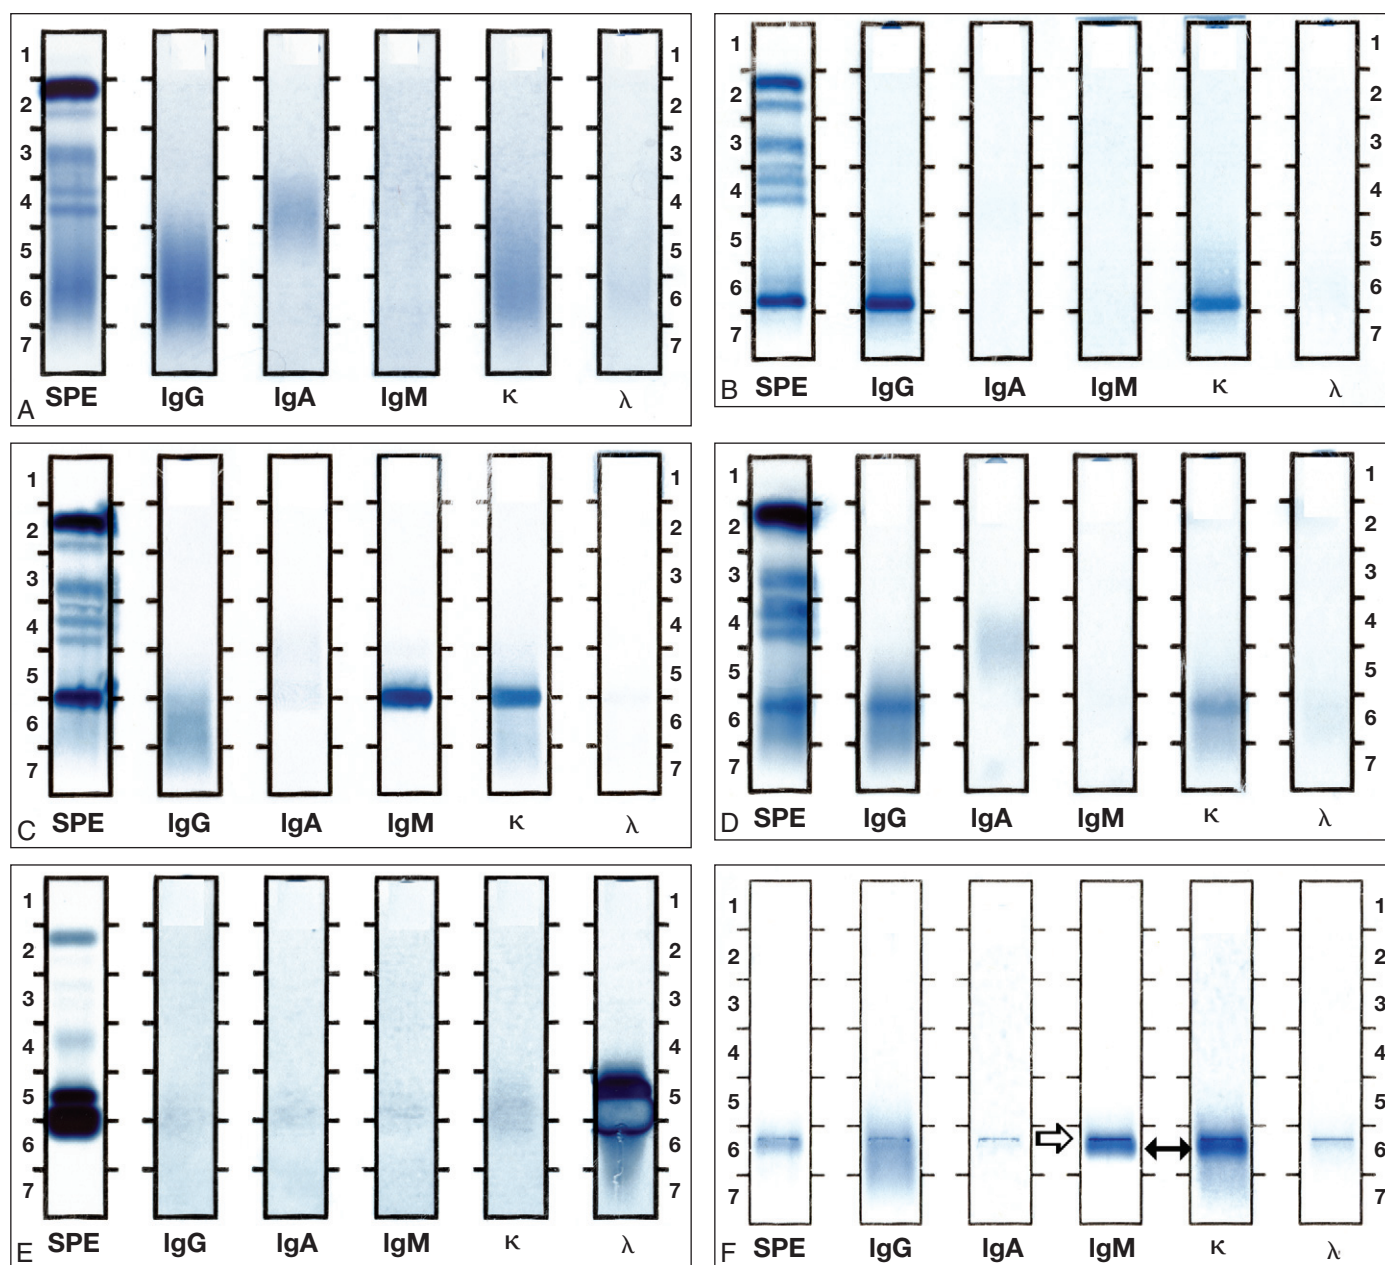

Figure 46-6 Monoclonal immunoglobulins (Ig) demonstrated by serum immunofixation. Replicate samples of patient serum were subjected to electrophoresis through agarose at pH 8.6. The separated proteins were allowed to react with monospecific antisera, and the gels were washed, fixed, and stained. **A**, Normal polyclonal pattern of immunoglobulins. **B**, Monoclonal IgG- κ immunoglobulin (M protein) in serum with loss of most normal polyclonal immunoglobulins. **C**, Monoclonal IgM- κ immunoglobulin in serum. **D**, Minor band of IgG- κ immunoglobulin in serum, along with normal appearing immunoglobulins—possible monoclonal gammopathy of undetermined significance (MGUS). **E**, Two bands of λ light chains in urine. The lower band demonstrates antigen excess with artifactual clearing in its central region surrounded by a ring of immunofixed protein. The upper smaller band sometimes results from dimerization of free light chains through disulfide bonds. **F**, Type II mixed cryoglobulin precipitated from serum containing monoclonal IgM κ (solid arrow) and polyclonal IgG. Some undissolved cryoglobulin (open arrow) remained at the application point of each lane. IgA, sample reacted with anti-IgA (α -heavy chain specific); G or IgG, sample reacted with anti-IgG (γ -heavy chain specific); κ , sample reacted with anti- κ ; λ , sample reacted with anti- λ ; IgM, sample reacted with anti-IgM (μ -heavy chain specific); SPE, all proteins in sample precipitated with acid reagent (serum protein electrophoresis).

immunoglobulin concentrations such as nephelometry are widely practiced. Furthermore, serum viscosity by itself is a poor indicator of whole blood viscosity with cellular elements present, which is really the crucial factor clinically in the patient.

Immunoglobulin Free Light Chain Analysis

The synthesis of immunoglobulin heavy chains and light chains is regulated differently by virtue of their genes being on different chromosomes (heavy chain genes on chromosome 14; κ light chain genes on chromosome 2; λ light chain genes on chromosome 22). Light chains are normally synthesized in slight excess and are cleared from the circulation in a few hours so they do not accumulate in the blood; however, in some monoclonal plasma cell disorders, light chain synthesis can greatly exceed heavy chain production with the resultant release of variable quantities of free light chains. Because of the relatively rapid renal clearance of small light

chains compared with that of an intact immunoglobulin, measurement of free light chains in serum or urine has been used to assess plasma cell mass and growth in monoclonal disorders. Although the concentration of the intact immunoglobulin of an M-spike has long been used in monitoring myelomas, this new and more rapidly responsive marker of light chain release has recently been introduced for clinical use.

Reagent anti-light chain antibodies used for IFE react with κ or λ light chains both as part of intact immunoglobulins and as free light chains. The principle of specifically measuring free light chains is to use reagent antibodies that react with epitopes on the light chains that are normally hidden by association with heavy chains. Consequently, the free light chain assay gives quantitative information that is complementary to results of quantitative immunoglobulin measurement, as well as protein electrophoresis (PEL) and IFE. One operational advantage of free light chain (FLC) analysis is its automation (Jaskowski, 2006).

Analysis of FLCs entails measurement of both κ and λ light chains in serum and/or urine. Results are abnormal if the κ or λ value is very high and the other is low. To accentuate differences, the ratio of κ to λ measurements is calculated (rFLC). If rFLC is abnormally high, the interpretation is that of plasma cell proliferation with a κ light chain type (i.e., a high κ value in the numerator). If rFLC is below the normal cutoff value, the interpretation is that of proliferation with a λ light chain type (i.e., high λ value in the denominator). Use of rFLC also allows application to patients who have renal disease and do not clear light chains from plasma normally, and so might have elevations of both κ and λ light chains.

Consensus guidelines for use of serum free light chain analysis have recently been developed by the International Myeloma Working Group (Dispenzieri, 2009). They include the following:

1. Serum screening for plasma cell disorders. The serum FLC assay combined with serum PEL and IFE is sufficient to screen for pathologic monoclonal plasmacproliferative disorders except for AL amyloidosis (light chain amyloidosis), for which the additional test of 24-hour urine IFE is essential. This recommendation allows FLC to replace the 24-hour urine IFE for all plasma cell disorders but AL. Avoiding 24-hour collections of urine is considered positively by many physicians and patients.
2. Serum FLC for prognosis. This assay should be performed at the time of diagnosis for MGUS, smoldering or active multiple myeloma, solitary plasmacytoma, and AL amyloidosis. The baseline values of FLC predict progression of these disorders and so can help to frame therapy or at least to make recommendations for frequency of monitoring and helping patients to understand the risks of their disease.
3. FLC for quantitative monitoring of response. The only recommended indications for routine serial use of FLC are seen in oligosecretory multiple myeloma and in AL amyloidosis. Other potential uses for which data were not sufficient to recommend use include light chain myeloma and measurable intact immunoglobulin disease. Also recommended is use in patients who have achieved a complete response to determine whether it is a stringent complete response.

The availability of FLC assays is an issue because the reagents have been provided by only one manufacturer, and they are not adaptable to a wide range of immunoassay instruments commonly found in clinical laboratories. Accordingly, these assays typically are sent out to reference laboratories. The commercial promotion of FLC assays has resulted in their use in far more situations than are covered by the recent consensus guidelines. Much more clinical outcome information needs to be accrued before it can be recommended that FLC assays should be used routinely for both diagnosis and monitoring of virtually any plasma cell disorder.

Cryoglobulin Testing

Accurate laboratory test results for cryoglobulins are especially sensitive to improper preanalytic handling, and clinicians must be aware of specimen temperature requirements when ordering these studies to avoid false-negative results (Shihabi, 2006; Chan, 2008). Testing for cryoglobulins in serum begins with a period of incubation in the cold (4° C) to detect turbidity or precipitate after 24 or 72 hours compared with an aliquot of the patient's serum kept at 37° C as a control for other precipitating substances not related to cold phenomena. Any cryoprecipitate is sedimented by centrifugation, washed briefly with cold saline to remove other serum proteins, and then redissolved (and dissociated) in warm saline for electrophoresis and immunofixation to identify immunoglobulin components (i.e., heavy and light chains).

Type I cryoglobulins typically form a relatively large volume of cryoprecipitate (e.g., up to 10% or even 20% of the serum volume—sometimes referred to as the “cryocrit”) (Fig. 46-7). Upon immunofixation electrophoresis, type I cryoglobulins exhibit a single heavy chain and a single light chain type, often monoclonal IgM. The whole serum usually not treated with cryoprecipitation usually demonstrates a large amount of the same monoclonal band. The concentration of the band should fall after successful plasma exchange.

Type II cryoglobulins typically show only a small amount of cryoprecipitate that is less than 1% of the serum volume, and so quantitating the percentage of cryocrit is not analytically valid for serial measurements to monitor a patient's progress. IFE shows a monoclonal band of IgM plus polyclonal IgG (see Fig. 46-6, F). This pattern is observed frequently because of its association with chronic hepatitis C.

Figure 46-7 Type I cryoglobulin in the plasma of a patient undergoing plasmapheresis for hyperviscosity syndrome due to monoclonal immunoglobulin (Ig)M- κ . Plasma removed during plasma exchange was stored at 4° C in a 50-mL tube. The cryoglobulins that precipitated in the cold occupied approximately 20% of this patient's plasma volume. The arrow indicates the top of the cryoglobulin that settled in the tube.

IFE findings in type III cryoglobulin would be similar to those in type II with a relatively small amount of cryoprecipitate that demonstrates both polyclonal IgM and polyclonal IgG.

Oligoclonal Immunoglobulin Bands in Cerebrospinal Fluid

Evaluation of intrathecal synthesis of immunoglobulin is aided by high-resolution electrophoresis of cerebrospinal fluid protein that spreads out the γ region to display individual bands of different immunoglobulin clones. The interpretation of cerebrospinal fluid (CSF) protein electrophoresis requires simultaneous electrophoresis of the patient's serum to ensure that findings in the CSF are unique and do not just reflect the passive transfer of clonal immunoglobulins from the blood. Oligoclonal bands as a marker of synthesis of immunoglobulins in the central nervous system suggest the possibility of an autoimmune process such as a demyelinating disease. Another possibility is an immunologic response to central nervous system infection, so the interpretation of oligoclonal bands in CSF must be made in the context of other diagnostic findings such as cell counts, viral serologies, bacterial cultures, syphilis testing, nucleic acid amplification tests for viruses, and so forth.

The protein electrophoretic pattern of CSF and serum from a patient with multiple sclerosis is shown in Figure 46-8, A. The CSF was concentrated and the serum was diluted to achieve comparable amounts of stainable protein in each application. CSF has a relatively higher concentration of prealbumin than does serum. Albumin is the predominant band in both fluids. The other significant band in CSF is transferrin, because of its small molecular size that permits ultrafiltration from blood into CSF. The higher molecular weight proteins in serum (α_2 plus β -lipoprotein) are absent from CSF. C3 is also identifiable in CSF, along with a band of asialotransferrin in the β_2 region. After all these landmark proteins of CSF are recognized, oligoclonal bands should be evaluated in the γ region, which normally has only a small quantity of polyclonal immunoglobulins. The oligoclonal bands in Figure 46-8, A, are discrete and clearly separate from one another.

Examination of serum and CSF sometimes shows a clonal band of immunoglobulin present in both (Fig. 46-8, B); however, this finding is

Figure 46-8 Protein electrophoretic patterns in serum and cerebrospinal fluid (CSF). **A**, Serum and CSF from the same patient showing positive oligoclonal bands in the γ region of the CSF but not in the patient's serum. **B**, Monoclonal band of immunoglobulin in both serum and CSF interpreted as negative for oligoclonal bands in CSF. **C**, Artifact of hemoglobin (Hb) in CSF (left lane) adjacent to the position of transferrin (Tf) (right lane).

not indicative of intrathecal synthesis and so is not a positive result for oligoclonal bands. Presumably, it represents clonal proliferation of plasma cells in the body with passive movement of the monoclonal antibody from blood into CSF.

Another distortion of the electrophoretic pattern occurs with release of hemoglobin (Hb) into the CSF, resulting in a major band in the β region close to transferrin (Fig. 46-8, C). This band of Hb should not be confused with clonal immunoglobulin in CSF. Confirmation that this band is Hb depends on visual examination of the CSF for blood or hemolysis (red color). A band of red Hb can also be seen in the β region before staining of the electrophoretic gel.

A consensus statement on analysis of CSF was commissioned from experts in multiple sclerosis by the Consortium of Multiple Sclerosis Clinics (Freedman, 2005). That group recommended qualitative assessment of CSF for IgG using IEF on unconcentrated CSF compared directly with a serum specimen from the same patient. Interpretation of the pattern should consist of one of the following:

Type 1: No bands in CSF and serum

Type 2: Oligoclonal bands in CSF, not in serum; indicates intrathecal IgG synthesis

Type 3: Oligoclonal bands in CSF plus other oligoclonal bands in CSF and serum; indicates intrathecal IgG synthesis

Type 4: Identical oligoclonal bands in CSF and serum; indicates systemic immune reaction with passive transfer to CSF; no intrathecal IgG synthesis

Type 5: Monoclonal band in CSF and serum; paraprotein; no intrathecal IgG synthesis

Problems in Detecting Monoclonal Bands

Clearly demarcated monoclonal bands are straightforward to identify when they are at high concentration and migrate separately from other serum proteins, particularly when the γ fraction is clear of normal polyclonal immunoglobulins owing to replacement of normal plasma cells with the malignant clone. Several examples of clear-cut monoclonal bands are presented in Figure 46-5. The area under the tracing for such bands can be readily integrated to calculate concentration of a monoclonal protein for monitoring in serial specimens.

Sometimes the monoclonal bands are much less pronounced and may be difficult to distinguish within a background of normal proteins. Figure 46-6, D, shows such a minor band of IgM- κ that can still be readily identified by IFE. However, when small monoclonal proteins migrate in the β or even α_2 region, they can escape detection because of overlap with normal proteins such as transferrin or C3 (Fig. 46-9, B). A monoclonal band migrating between normal serum proteins may also be mistakenly disregarded (Fig. 46-9, D), so it is very important to interpret such electrophoreses with a firm expectation of where normal bands migrate and what their intensities should be.

False-positive interpretations of monoclonal bands can occur owing to the presence of fibrinogen from an unclotted specimen (Fig. 46-9, C), or when hemolysis occurs as the result of improper specimen collection

Figure 46-9 Low-intensity bands of monoclonal and other proteins migrating about the β region. **A**, Normal serum protein electrophoresis pattern. **B**, Minor band of immunoglobulin (Ig)A- κ (arrow) overlapping C3. **C**, Fibrinogen (arrow), not to be confused with a monoclonal band. **D**, Minor band of IgA- κ (arrow) migrating between transferrin and C3. **E**, Hemolysed specimen with a minor band of hemoglobin-haptoglobin (arrow). **F**, Redraw of serum without hemolysis from same patient as in **E**. **E** and **F** were electrophoresed on a different gel system from **A** through **D**; relative mobilities of normal serum proteins can vary in different systems.

(Fig. 46-9, *E* and *F*). Confirmation that a small band is a monoclonal paraprotein is typically done with IFE.

DISEASE PREVENTION AND THERAPY

Passive immunization is the administration of pre-formed antibodies obtained from another individual of the same species (homologous γ -globulins) or a different species (heterologous γ -globulins); it results in immediate protection against infection. The immunity is short-lived and decays as the antibodies are used and catabolized. Passive protection in neonatal life is based on transfer of maternal antibodies across the placenta or through colostrum (Pennington, 1991).

Pooled human γ -globulin is useful for temporary protection against several viral and bacterial infections (Berkman, 1990; Hammarström, 1990; Desai, 1991). Depending on the dose used and the time of administration, the disease may be modified to a mild form or entirely prevented. The effect is more complete and more predictable if one uses hyperimmune preparations made from the plasma of individuals who are convalescing from the disease in question, or who have recently been immunized against it. Such preparations contain a higher concentration of specific antibodies. Antibodies may also be produced in animals, such as horses, and in the past these antibodies found widespread use. However, prior sensitization to foreign proteins may lead to clinical reactions such as anaphylaxis, serum sickness, pyrexia, and local Arthus reactions.

Monoclonal antibodies have revolutionized many areas of medicine, including research, diagnostics, and therapy. Murine, human, and

humanized monoclonal antibodies have been developed (Lefrano, 1990; Morrison, 1992; Mountain, 1992; Ward, 1992; Shin, 1993). Many monoclonal antibodies, often replacing polyclonal antisera, are used for diagnostic purposes (see Chapter 43). Perhaps the most important therapeutic applications of monoclonal antibodies are seen in the fields of transplantation and oncology (Stevenson, 1990; Vitetta, 1993; Neame, 1994). OKT3, a murine monoclonal antibody against the CD3 receptor on lymphocytes, is often used as an antirejection therapy to block the activity of cytotoxic T lymphocytes in renal transplant recipients (Ortho Multicenter Transplant Study Group, 1985). Many potential clinical applications of monoclonal antibodies are being evaluated. A recent example is the use of a monoclonal antibody against tumor necrosis factor- α to prevent Jarisch-Herxheimer reactions resulting from antibiotic treatment of *Borrelia* infection in sheep (Fekade, 1996). Anticytokine and antineutrophil adhesion molecule monoclonal antibodies may be effective in conditions associated with acute inflammation and cytokine release such as acid aspiration, ischemia, or reperfusion injury (myocardial infarction, hemorrhagic shock, aortic aneurysm repair); antibodies inhibiting neutrophil adhesion may be effective in asthma, pulmonary fibrosis, meningitis, and cerebral malaria; and recently, a monoclonal antibody directed against a component of the complement cascade suggests the possibility of eventual therapeutic regulation of specific arms of the inflammatory response (DiLillo, 2006). It seems reasonable to expect that a multitude of therapeutic applications will become available in the future, in which monoclonal antibodies will be designed to modulate the actions of one or more naturally occurring mediators of inflammation, infection, or malignant proliferation.

KEY POINTS

- The complement system is a group of circulating proteins that promote inflammation and host defense.
- Unregulated tissue damage is a possible complication of complement activation, and a large variety of circulating and membrane-bound proteins exist to regulate complement activity.
- Complement component C3 is the central convergence point for all complement activation pathways.
- It is frequently necessary to measure serum complement levels to track disease activity, but it is important to recognize that serum complement measurements are snapshots of a dynamic process involving variable rates of complement consumption and production.
- Methods are available that allow accurate determination of serum levels of complement components.
- Functional complement assays are sensitive and precise tools for providing information about the activity and integrity of a complement component or pathway.
- The simplest functional assay of the classical pathway (CH50) measures total hemolytic complement activity.
- Cytokines are soluble proteins released by cells over short distances to facilitate communication between cells, to assist in upregulation or downregulation of the immune response, to direct cell differentiation, and to orchestrate associated inflammatory and reparative activities.
- Adhesion molecules are complex glycoproteins that bind living tissues together and mediate cell migration during embryogenesis, wound healing, and the inflammation response.

STRUCTURE AND FUNCTION OF THE COMPLEMENT SYSTEM

The term **complement** refers to a group of more than 30 circulating and membrane-bound regulatory and constitutive component glycoproteins that function to promote host defense against infectious agents, to promote the clearance of apoptotic cell debris and immune complexes, and to regulate the immune response. Unregulated tissue damage is a possible complication of complement activation, and a large variety of circulating glycoproteins, as well as tissue membrane-bound proteins, function to regulate complement activity and downregulate complement attack. The existence of this system of proteins was inferred late in the 19th century, when it became clear that fresh serum had the ability to lyse gram-negative bacteria and cholera vibrios in the presence of specific antibody. As techniques for protein purification and identification became more sophisticated over the years, it was recognized that complement is a very complex system with many interacting proteins.

In general, the system functions to identify foreign cells and microorganisms and destroy them. This may occur by direct lysis, by opsonization (the process of coating them with specific complement peptides recognized by specific receptors on phagocytes to aid ingestion), or by inflammation produced by the attraction of phagocytic cells. It also has become clear that complement plays a role in facilitating the immune response.

The complement system of proteins is phylogenetically older than the proteins associated with acquired immunity (immunoglobulin) and is present in primitive organisms that lack immunoglobulin. Complement is presumed to provide a level of innate or natural immunity and host defense, even in the absence of an antibody response. It accomplishes this via the mannan-binding lectin (MBL) pathway and the alternative

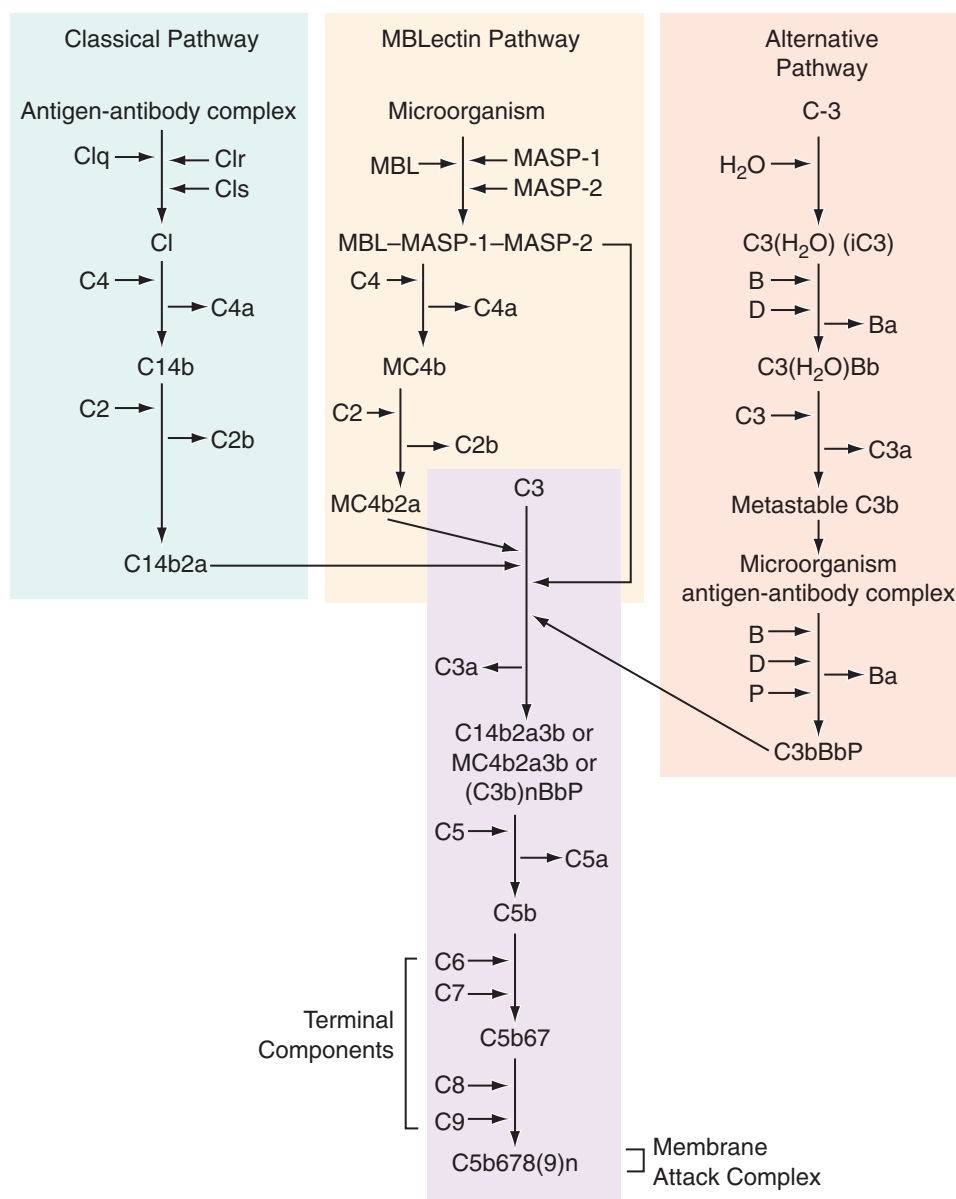

Figure 47-1 Components of the classical, MBLectin, and alternative pathways converge to form a convertase that cleaves C3. In the classical pathway, antigen-antibody complexes sequentially bind and activate C1, C4, and C2. In the MBLectin pathway, interaction of MBL with a carbohydrate on the surface of a microorganism leads to the formation of an enzymatic complex (MBL-MASP-1-MASP-2, termed M in the figure) that binds and activates C4 and C2. In the alternative pathway, C3 undergoes hydrolysis of its thioester bond, which induces a change in conformation. It then binds factor B (B), which is cleaved by factor D (D) to form a convertase that is stabilized by properdin (P). C3b, the cleavage product of C3, also has a cleaved thioester bond and is capable of activating the alternative pathway. The C3b-containing convertase of all pathways continues sequentially by binding the late-acting component until the sequence of activation is complete.

complement pathway, both discussed later. Antibody provides a level of increased specificity and increased efficiency in mediating host defense. A detailed history of the discovery of complement and of the various complement pathways is provided elsewhere (Frank, 1998).

NOMENCLATURE

Three major complement activation pathways are present in human serum: the classical pathway, the alternative pathway, and the MBL pathway (or MBLectin pathway). Figure 47-1 illustrates the reaction sequence of each pathway. The nomenclature for proteins of the complement system generally follows two conventions (World Health Organization, 1968; IUIS-WHO, 1981). For historical reasons, the nine proteins of the classical pathway are designated by the upper case letter C, which is then followed by the number that relates to their order of appearance in the reaction sequence. A notable exception is C4, which acts before C2. Molecules that are part of the C1 complex are termed C1q, C1r, and C1s. Proteins reacting solely in the alternative pathway are called factors and are referred to by an upper case letter (e.g., factor B, factor D). Fragments of complement proteins resulting from proteolytic cleavage are designated by an appended

lowercase letter (e.g., C4a, C4b), where “a” represents the smaller fragment, and “b” represents the larger fragment. The exception to this rule is C2, where C2a is the larger fragment and C2b is the smaller fragment. Further degradation fragments of the large complement fragment of one component are designated by lowercase letters (e.g., C3c, C3d). Components that have lost activity (i.e., are inactive) are usually designated by a prefixed lowercase “i” (e.g., iC3b, iC4b). Polypeptide chains of a native complement protein are designated by Greek lowercase letters (α , β , γ); with the exception of C1q, these chains are termed A, B, and C. Single components or multicomponent complexes that have enzymatic activity are designated by a bar over the component(s). Proteins of the MBLectin pathway are designated by abbreviations of the names of the proteins (e.g., MBL for mannan-binding lectin, MASP for MBL-associated serine protease). Regulatory proteins are designated by a descriptive title or letter (e.g., C4-binding protein, factor H). Membrane-bound regulatory proteins have been assigned CD numbers and descriptive titles (e.g., CD46 for membrane cofactor protein), and complement receptors are designated by numbers following the prefix CR (for complement receptors 1 to 4). The other complement receptors are designated by the component’s symbol followed by the uppercase letter R.

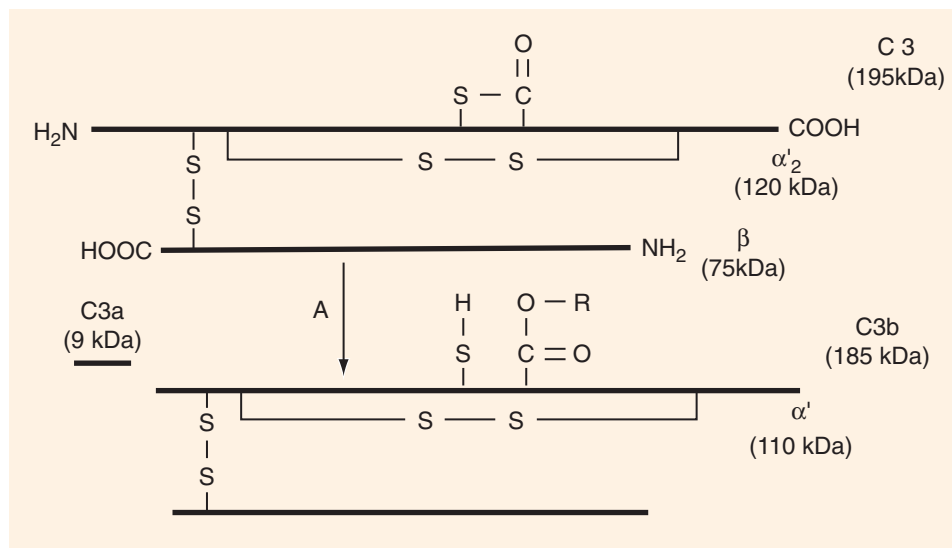

Figure 47-2 C3 cleavage by C3 convertase: The approximate molecular weight of each chain or fragment is given in kilodaltons (C3 convertase is represented by A).

C3: CENTRAL MOLECULE OF COMPLEMENT ACTIVATION PATHWAYS

The protein known as C3 is the central convergence point for the three complement activation pathways (the MBLectin pathway, the alternative pathway, and the classical pathway), which all proceed to lysis, phagocytosis, or regulation of the inflammatory response farther down the cascade.

C3 is a two-chain molecule synthesized in many cells, particularly hepatocytes, formed from a single-chain molecule, pro-C3, and released into the circulation, where it binds to foreign target surfaces. The α and β chains are stabilized by intrachain disulfide bonds; an interchain disulfide bond stabilizes α and β chain interaction (Fig. 47-2). The α chain contains a thiolester that imparts an unstable structure to the molecule. Although it is in the hydrophobic center of C3, the thiolester can be cleaved by gradual hydrolysis as water penetrates the molecule, activating the alternative complement pathway. C3 may also be cleaved rapidly by the action of C3 convertase in releasing the 9-kDa C3a fragment from the α chain amino-terminus, from the larger C3b. C3b will go on to coat target proteins, thereby marking them for destruction, and C3a in the role of anaphylatoxin activates nearby cells to release mediators of inflammation (Wen, 2004). Either avenue results in marked conformational alteration of C3 (now termed C3b) that permits it to interact with cells expressing C3b receptors, in particular CR1 (C3b/C4b receptor, CD35). (Native C3 will not interact with C3b receptors.)

C3 activation and conversion to C3b (with thiolester cleavage) lead to covalent binding of C3b to the surface of a target such as a microorganism. The target becomes coated with C3b capable of interacting with cells expressing C3b receptors, including all phagocytes, all B lymphocytes, and a subset of T lymphocytes. It is C3b that continues the complement cascade leading to lysis.

THE CLASSICAL PATHWAY

The classical pathway of complement activation, described around the year 1900, was the first to be studied, and for this reason is called “classical.” It is evolutionarily the most recent of the three pathways described. The classical pathway is responsible for complement activation on most antibody-sensitized cells. Details of this pathway are published elsewhere (Fries, 1987; Volanakis, 1998). Nine numbered proteins make up the classical pathway. Activation of the classical pathway usually requires interaction between an antigen and a C1-binding **complementing** antibody. In humans, only immunoglobulin (Ig)M and IgG are effective at activating the classical pathway, except IgG4, which is unable to activate complement. A number of molecules other than immunoglobulins have the ability to activate the classical pathway via direct interaction with C1q. These include C-reactive protein, serum amyloid P component, β-amyloid, some gram-negative bacteria, certain viruses, mycoplasmas, protozoa, and intracellular components such as DNA, mitochondrial membranes, cytoskeletal filaments (Gewurz, 1993), and apoptotic cells (Korb, 1997). The latter might be of critical importance in the elimination of apoptotic cells and

debris from the circulation. In some instances, infectious agents may exploit complement to their advantage, as with prion diseases such as transmissible spongiform encephalopathy, which may use complement components such as C3 and C1q to facilitate its localization within target cells (Mabbott, 2004).

Upon binding of immunoglobulin to a target, C1 binds to that immunoglobulin and becomes activated. C1 is a macromolecule of 740 kDa that comprises a single molecule of C1q complexed with two C1r and two C1s chains held together in the presence of calcium ions. Once bound to immunoglobulin, C1q adopts a conformational change that leads to auto-activation of the two C1r chains. Activated C1s₂ cleaves the next component in the cascade, C4. The larger fragment, C4b, becomes attached to the activator surface, whereas the smaller fragment, C4a, is released in the fluid phase. C4a is an anaphylatoxin and is described in a subsequent section of this chapter. Most of the generated C4b is hydrolyzed and remains in the fluid phase. Nevertheless, some of the generated C4b molecules bind to the activator surface as a cluster around the antigen-antibody-C1 site. A single antibody-antigen-C1 site thus can lead to the deposition of many C4b molecules.

In the presence of magnesium ions, C4b acts as a site for the binding and subsequent cleavage of C2. C1s₂, in association with C4b, cleaves C2 into two fragments. The larger fragment, C2a, remains bound to C4b, whereas the smaller one, C2b, is released in the fluid phase. This molecular complex, C4b2a, is unstable and has a relatively short half-life because of decay that results from the tendency of C2a to break away from the complex in an inactive form. The C4b2a complex is the classical pathway C3 convertase required for C3 binding and cleavage (see Fig. 47-2). It is C2a as part of the C4b2a complex that enzymatically cleaves C3 in the next step of the activation cascade, and cleaves C5 in a later step. C2a cleaves C3 into a large fragment, C3b, which binds to the activator surface, and a smaller fragment, C3a, which is released into the fluid phase, where it serves as an anaphylatoxin. The newly generated C4b2a3b complex is the C5 convertase of the classical pathway that triggers deposition of terminal complement components on the target surface.

IgM and IgG differ in their ability to activate the classical pathway of complement. It appears that a single molecule of most IgM antibodies bound by multiple antibody sites to an antigen can bind one molecule of C1 and trigger a complete complement activation sequence. IgM, with its five antigen-binding sites, adopts a functionally active conformation on an antigenic surface that allows multiple interactions with antigens.

In contrast, C1 binding to IgG requires two molecules of IgG side by side in most experimental studies (Borsos, 1965). Because IgG antibodies bind to a target surface in a random fashion, and because antigens may not be evenly distributed on a target organism, the attachment of hundreds or thousands of IgG antibodies may be required to generate a C1-binding site. Classical pathway activation by IgG-antigen complexes is also shown to facilitate the alternative pathway (see next section) on the activator surface (Moore, 1981).

The ability of aggregated immunoglobulin to bind C1q has provided the basis for a number of tests designed to detect the presence of soluble

immune complexes in patient blood samples. Radiolabeled C1q is added to the serum or plasma sample, and one of a number of techniques (e.g., polyethylene glycol precipitation) is used to separate free C1q from that bound to protein components of serum. The binding of C1q suggests the presence of immunoglobulin complexes in the serum or plasma sample (Zubler, 1976). Soluble immune complexes may also be measured by identification of C1q- or C3-bound immune complexes using enzyme-linked immunosorbent assay (ELISA) techniques (Stanilova, 2001). Detection of the presence of C1q in tissue specimens by direct visualization with immunofluorescently labeled anti-C1q antibodies may be used to identify immune complexes in biopsy specimens.

THE ALTERNATIVE PATHWAY

The presence of a second pathway of complement activation was first proposed by Pillemer in 1954 and was accepted by the scientific community almost two decades later. This complement activation pathway appears to be important in early defense against pathogenic microorganisms (Pangburn, 1984). Although antibodies can also activate this system, neither antibody nor lectin is required for activation. Initiation of the alternative pathway on an acceptor surface begins with deposition of active C3 on a surface that has no regulators of complement present on it, leading to the generation of C3b fragments and allowing the process to continue as an unimpeded amplification loop (Wen, 2004). This event depends on the ability of the carbonyl group of the exposed thiolester group of C3b to interact with an amide or a hydroxyl group of a protein or a carbohydrate present on the surface of a target (Law, 1979). In serum, C3 is hydrolyzed at a rate of 0.2%–0.4% of plasma pool per hour (Pangburn, 1981). C3 with a hydrolyzed thiolester undergoes a conformational change that allows it to interact with proteins that do not interact with native C3, and is termed C3(H₂O) (also termed iC3). C3(H₂O) then has the ability to interact with factor B in the presence of magnesium ions. Factor B, upon binding to C3(H₂O), can interact with factor D and is cleaved to generate the so-called initiation C3 convertase C3(H₂O)Bb and liberate a small fragment, Ba. This cleavage is mediated by factor D, a serine protease that adopts an active conformation upon recognition of its substrate and returns to an inactive conformation once proteolytic cleavage is accomplished (Volanakis, 1996).

The initiation C3 convertase cleaves C3 to generate metastable C3b at a continuously slow rate in the circulation. Metastable C3b can bind covalently to the activator surface and then, like C3(H₂O), can bind factor B. As in the initiation C3 convertase, factor D then cleaves factor B to generate the cell-bound C3 convertase C3bBb. This complex decays rapidly but is stabilized upon binding of properdin, which prolongs the half-life of the C3 convertase from 1 to 18 minutes (Fearon, 1975). This stabilized C3 convertase rapidly cleaves yet more C3, which can bind to the activator surface and therefore is referred to as the amplification C3 convertase of the alternative pathway. Amplification of C3b deposition to the activator surface leads to the formation of a C5 convertase (C3b2BbP) (Kinoshita, 1988), which has the ability to trigger activation of the terminal components of the complement system.

THE MANNAN-BINDING LECTIN PATHWAY

A third pathway of complement activation has been described recently that utilizes the serum protein MBL (also called mannan-binding lectin, or mannan-binding protein), which is present in serum at about 1.5 µg/mL. Formed in the liver, MBL is found in all mammals and birds and belongs to a family of molecules termed collectins (Epstein, 1996; Turner, 1996). The collectin family includes, in addition to MBL, lung surfactant proteins A and D (SP-A, SP-D), bovine conglutinin, bovine CL-43, and the ficolins (Epstein, 1996; Thiel, 2007). MBL and the ficolins are complement-activating soluble pattern recognition molecules, that is, they recognize pathogen-associated molecular patterns (PAMPs) on the surfaces of microbes. Once they bind their specific PAMP, these proteins undergo a conformational change that permits them to associate with the three MBL-associated serine proteases, MASP-1, MASP-2, and MASP-3, to activate the complement cascade (Thiel, 2007). MBL is structurally related to C1q and recognizes certain **pathogenic** carbohydrates expressed on the surface of microorganisms, but does not recognize carbohydrates such as galactose and sialic acid, which are the terminal sugars expressed on mammalian glycoproteins (Epstein, 1996). This allows MBL to discriminate between self and nonself, and it is reported that MBL may react with a wide range of acapsular gram-positive and gram-negative bacteria, viruses, yeasts, mycobacteria, parasites, and protozoa (Epstein, 1996).

The MASPs share structural homology with C1r and C1s, suggesting similarity with the C1 complex (C1qr₂s₂). After activation, MASP-2 cleaves C4 to generate the classical pathway C3 convertase C4b2a (Vorup-Jensen, 1998). MASP-1 has the ability to cleave C3 (Matsushita, 1998), suggesting that it might trigger alternative pathway activation directly (Schweinkle, 1989). Following generation of the classical pathway C3 convertase C4b2a by the MBL–MASP-1–MASP-2–MASP-3 complex, complement activation proceeds as in the classical pathway, with possible recruitment of the alternative pathway as well (Suankratay, 1998). Specific antibody–antigen complexes can also trigger the MBLectin pathway. It was demonstrated that a fraction of IgG molecules that lack terminal galactose residues (termed IgG-G0), as found in the plasma of patients with pathologic conditions such as rheumatoid arthritis, have the ability to interact with MBL and activate the classical pathway (Malhotra, 1995). MBL may also play a role in the elimination of target organisms by phagocytes through interaction with a specific receptor present on those phagocytes (Tenner, 1995; Hansen, 1998). It may modulate inflammatory and allergic responses, affect apoptotic cell clearance, and modulate the adaptive immune system (van de Wetering, 2004; Thiel, 2007). Regulation of the MBLectin pathway appears to be mediated by C1 inhibitor (Matsushita, 1996) and α₂-macroglobulin (Terai, 1995).

TERMINAL COMPLEMENT COMPONENTS

The three complement activation pathways converge on the activation of C3 and the assembly of the membrane attack complex (MAC), formed by components C5 to C9. Upon formation of the classical, MBLectin (C4b2a3b), and alternative (C3b2Bb) pathway C5 convertases, C5 is cleaved. The larger fragment (C5b) can associate with the cell membrane and interact with C6. The next step involves the interaction of the C5b–6 complex with fluid-phase C7, forming a trimeric complex with amphiphilic properties (high affinity for the lipid constituents of the cell membrane) (Podack, 1979). C5b–7 inserts in the lipid bilayer of the cell membrane but is not sufficient for cell lysis to occur. C8 associates with this trimolecular complex via an interaction with exposed C5b. The C5b–8 complex penetrates the lipid bilayer further to form a small transmembrane pore that causes slow lysis of erythrocytes (Ramm, 1982). However, insertion of multiple copies of C9 through the lipid bilayer via an initial interaction with the α chain of C8 is needed to produce the full cytolytic activity of the MAC (Plumb, 1998). It is believed that the C5b–8 complex serves as an initiator of C9 polymerization within the cell membrane.

The MAC, by electron microscopy, has a hollow, cylinder-like structure formed by the assembly of its components in the presence of excess C9 (Podack, 1984). The mechanism by which the MAC disrupts the cell membrane is still controversial and may include distortion of the lipid bilayer to form **leaky patches** (Esser, 1991) or, more likely, formation of a transmembrane pore with a hydrophilic center through which ions can pass freely (Bhakdi, 1991). Formation of the MAC induces lysis of certain bacteria and viruses, and of heterologous erythrocytes. Most nucleated cells resist MAC-induced cytotoxicity. This protection, especially from attack by one's own complement proteins, is mediated by membrane-associated regulatory molecules that prevent MAC formation (see later, under “[Regulation of Complement Activation](#)”), as well as by shedding of the activated complement proteins by blebbing of the cell surface. Lysis of nucleated cells mediated by the MAC may occur but requires multiple MAC lesions to take effect (Koski, 1983).

It has been proposed that the deposition of sublytic amounts of the MAC might protect the cell from subsequent complement attack (Reiter, 1992). Nucleated cells are protected from the effects of the MAC in part because of its active elimination from the cell surface by membrane repair linked to lipid turnover (Mold, 1998). MAC formation has a stimulating effect on several nucleated cell types. Among others, these effects include production of reactive oxygen radicals from neutrophils and macrophages, release of eicosanoids from phagocytic cells, induction of procoagulant activity in platelets and endothelial cells, proinflammatory activity in endothelial cells and smooth muscle cells, proliferation of smooth muscle cells and endothelial cells, and triggering of signal transduction pathways (Niculescu, 1993, 1999; Benzaquen, 1994; Sims, 1995; Kilgore, 1996; Tedesco, 1997; Mold, 1998).

ANAPHYLATOXINS

Activation of complement via the classical, alternative, or MBLectin pathway leads to the generation of complement protein fragments that have important roles in various biological functions, including

TABLE 47-1

Complement Regulatory Proteins

Protein	Molecular weight, kDa	Target	Mechanism of action
Fluid Phases			
C1 inhibitor	105	C1	Dissociates the C1 complex by binding to C1r and C1s
Factor H	150	C3b	Cofactor for C3b inactivation by factor I
C4-binding protein	550	C4	Cofactor for C4b inactivation by factor I
S protein (vitronectin)	84	C5b-7	Inhibits insertion of the MAC into cell membranes
Clusterin	70	C5b-7	Inhibits insertion of the MAC into cell membranes
Factor J	20	C1, C3, B	Inhibits C1 complex formation, inhibits cleavage of C3 by Bb
Cell Associated			
CR1	190*	C3b, C4b	Dissociation of C3/C5 convertases, cofactor for C3b and C4b inactivation by factor I
DAF (CD55)	70	C3bBb, C4b2a	Dissociation of C3/C5 convertases
MCP (CD46)	45-70	C3b (C4b)	Cofactor for C3b inactivation by factor I
CD59 (protectin)	18-20	C8, C9	Inhibition of formation of the MAC
HRF	65	C8, C9	Inhibition of formation of the MAC

*Most common isoform of CR1.

opsonization, phagocytosis, immunomodulation, and generation of inflammatory reactions.

Complement activation leads to proteolytic cleavage of many complement proteins with the subsequent release of small biologically active fragments into the fluid phase. Three of these released fragments—C4a, C3a, and C5a—are called anaphylatoxins. The structural and functional characteristics of these molecules are described in an excellent review on the subject (Ember, 1998). C3a is a 9-kDa peptide fragment released during selective proteolytic cleavage of the C3 α chain by C2a (as a component of C3 convertase) in the classical and MBlectin activation pathways. It is also released by proteolytic cleavage of C3 by the enzymatically active peptide Bb, a component of the alternative pathway C3 convertase. C4a is an 8.7-kDa peptide released from C4 upon cleavage by C1s2. C5a is an 11-kDa peptide released from the α chain of C5 by cleavage induced by C2a in the classical and MBlectin pathway C5 convertase, or by Bb in the alternative (and perhaps MBlectin) pathway C5 convertase. In general, anaphylatoxins are defined by their biological effects on smooth muscle cells, mast cells, small blood vessels, and peripheral blood leukocytes. Specific effects mediated by these peptides include degranulation of mast cells and basophils, with subsequent release of various mediators such as histamine and serotonin. They also induce human neutrophil aggregation and smooth muscle contraction, enhance vascular permeability, induce thromboxane release from guinea pig macrophages, and stimulate release of mucus from goblet cells (Marom, 1985). An especially important effect of the anaphylatoxins on basophils is vasodilation caused by histamine release, leading to increased blood flow to sites of inflammation.

The function of C4a is generally similar to that of C3a, but C4a is far less effective in its biological effects on a molar basis. C5a is by far the most potent of the human anaphylatoxins, having an effect 200-fold greater than C3a and 3000-fold greater than C4a in causing smooth muscle contraction of guinea pig ileum. It should be noted, however, that the relative effectiveness of these peptides is both tissue- and species-specific. For instance, C3a may be selectively effective in eosinophil localization to allergic sites, whereas C5a has an effect on many other cell types (DiScipio, 1999).

In addition to its role as an anaphylatoxin, C5a has many important biological properties. The binding of C5a to neutrophils produces an increase in adhesion and aggregation, induction of an oxidative response, and release of lysosomal enzymes. C5a is strongly chemotactic for monocytes and neutrophils, inducing the migration of these cells toward the source of complement activation in the tissues. Thus, a local complement-activating inflammatory reaction can induce increased blood flow to the affected tissue, adherence of neutrophils to a locally activated endothelium, and directed migration of phagocytes to inflamed sites along a chemotactic gradient. Neutrophils aggregated by C5a can embolize to the lung, causing changes in pulmonary gas exchange and even death. It is thought that C5a mediates much of the pulmonary inflammation caused by immune complex formation (Ward, 1997). In a rat experimental sepsis model, it has been

demonstrated that C5a may block the bactericidal functions of neutrophils if produced in excessive amounts, suggesting a role for complement activation in the high mortality rates observed in sepsis (Czermak, 1999). The biological effects of anaphylatoxins are mediated via specific cell surface receptors described in the section on complement receptors.

REGULATION OF COMPLEMENT ACTIVATION

Complement activation, although important to host defense, may produce profound tissue damage. Organisms have evolved with internal control mechanisms to (1) limit overly widespread inflammation, (2) avoid excessive activation, and (3) protect host cells from inadvertent injury. A potent regulatory system consisting of fluid-phase and membrane-associated proteins controls complement activation at almost every step of the activation cascade (Table 47-1).

Fluid-Phase Regulators

Control of the first component of the classical pathway (C1) is mediated by C1 inhibitor (C1-Inh). C1-Inh blocks C1 autoactivation, C1 activation in the fluid phase, and C1 activation on weak activators of the classical pathway; it does not block activation on most immune complexes (Doekes, 1983). It is thought that C1-Inh has the ability to dislodge the entire C1q₂s₂ complex from immunoglobulin with low binding affinity for C1q (Chen, 1998), and from targets sensitized with low doses of human IgG (Chen, 1998). In vitro, C1-Inh inactivates MASP (mannan-binding lectin-associated serine proteases) (Matsushita, 1996). C4b activity is regulated by factor I (formerly referred to as the C3b/C4b inactivator) (Fries, 1987), which cleaves the C4b α chain to generate two fragments, C4c and C4d; the latter fragment remains cell-bound. For proteolysis, a cofactor, C4-binding protein (C4BP), is required. C4BP is a 570-kDa protein that can also bind particle-bound and fluid-phase C4b and can displace C2a from the classical pathway C3 convertase C4b2a (Gigli, 1979). Because of its pivotal role in the three complement activation pathways, C3 is under rigid control. Fluid-phase C3b and C3(H₂O) are rapidly inactivated by factor I, which cleaves three peptide bonds on the α chain of C3b (Davis, 1982), thus generating an inactive form of the molecule, iC3b, which is incapable of engaging C5 or factor B. This factor I-mediated cleavage requires factor H as a cofactor. Factor H is a 150-kDa protein that binds C3b and has decay-accelerating activity toward the alternative pathway C3 convertase, in addition to its cofactor activity for factor I-mediated cleavage of C3b. In addition to regulating C3b in the fluid phase, factor H binds to cell-bound C3b and triggers cleavage by factor I, thus limiting classical pathway activation (Ollert, 1995). Once C3b is cleaved into iC3b, which then remains bound to the target surface, it is free to interact with complement receptor type 3 (CR3) present on phagocytic cells, thereby promoting phagocytosis.

A number of fluid-phase inhibitors of the terminal complement components can prevent insertion of the MAC into cell membranes. S protein

TABLE 47-2

Cell Receptors for Complement Protein Fragments

Receptor	Molecular weight, kDa	Ligand	Physiologic role
CR1	190 (most common isoform)	C3b, C4b, iC3b	Phagocytosis, immune complex clearance
CR2	140	C3d, C3dg, iC3b	B cell activation
CR3	165 (α chain) 95 (β chain)	iC3b, C3d, C3b	Phagocytosis, cellular adhesion
CR4	150 (α chain) 95 (β chain)	iC3b, C3b	Cellular adhesion
C1qRp*	126	C1q, MBL, SP-A	Phagocytosis
C3aR	48	C3a	Chemotaxis, degranulation of serosal-type mast cells, increase in vascular permeability
C5aR	43	C5a, C5a desArg	Chemotaxis, degranulation of serosal-type mast cells, cellular adhesion, increase in vascular permeability

*Other C1q receptors have also been described.

(not identical to protein S), also called vitronectin, binds the C5b-7 complex, thereby preventing its insertion in the cell membrane (Podack, 1977) and inhibiting C9 polymerization (Johnson, 1994). S protein binds C5b and C8 within the sC5b-9 complex (Su, 1996) and binds to the receptor C1q (Lim, 1996). Although the full role of S protein in regulating complement activation *in vivo* is uncertain, Peake (1996) showed that S protein forms a complex with sC5b-9 when complement is activated in rabbits, and that this complex still has the ability to block C9-mediated lysis of sensitized sheep erythrocytes bearing complement components 1-7. Clusterin (also called Sp-40, or apolipoprotein J) is another fluid-phase inhibitor of the terminal complement components. Similar to vitronectin, clusterin prevents insertion of the C5b-7 complex into the cell membrane (Choi, 1989) and regulates the MAC at both C5b-7 and C9 levels (Berge, 1997).

Cell-Associated Regulatory Proteins

Regulation of complement activation must occur on host cell surfaces to limit inadvertent injury to those cells. Many of these regulatory proteins also act as complement receptors. One such protein is complement receptor type 1 (CR1), which binds activated C4b and C3b and serves as a cofactor for their factor I-mediated cleavages (see next section for more). Control of cell membrane-deposited C4b and C3b is also achieved by membrane cofactor protein (MCP, CD46). This protein is expressed by almost every cell, with the notable exception of erythrocytes, and serves as a cofactor for factor I-mediated cleavage of C4b and C3b into C4c and C4d, and iC3b, respectively (Seya, 1986, 1989).

Another cell membrane-associated protein that controls complement activation at the level of the C3 and C5 convertases is decay-accelerating factor (DAF, CD55). DAF is expressed by all circulating cells, all endothelial cells, and a number of epithelial cells (Morgan, 1994b), and accelerates the decay of C3 and C5 convertases of both the classical and alternative pathways.

Regulatory control of terminal complement components of the MAC is achieved by homologous restriction factor (HRF), or C8-binding protein, and CD59 (also referred to as protectin, HRF-20, membrane inhibitor of reactive lysis, and P-18). HRF is expressed on erythrocytes, platelets, T lymphocytes, B lymphocytes, neutrophils, and monocytes (Morgan, 1994b), where it binds C8 and inhibits C9 polymerization (Morgan, 1994b). The second regulatory protein, CD59, is found on all circulating cells, endothelial cells, epithelial cells, spermatozoa, and glomerular podocytes (Morgan, 1994b), and on some cells of the central nervous system (Morgan, 1996). CD59 binds both the β chain of C8 and the b domain of C9 (Chang, 1994), inhibiting MAC formation on host cells. Because of their glycosyl phosphatidylinositol linkage to cell membranes, DAF, HRF, and CD59 are absent from the cells of patients with paroxysmal nocturnal hemoglobinuria (PNH) (Volanakis, 1988).

COMPLEMENT RECEPTORS

Receptors that bind activated complement components have been described in various cell types. These receptors control the biological effects of complement activation peptides and are linked to several other cellular

functions as well (Table 47-2). The complement receptors that have been best studied are those that bind the degradation fragments of C3.

Complement receptor type 1 (CR1, CD35, C3b/C4b receptor) is a single-chain glycoprotein expressed on erythrocytes, mononuclear phagocytes, eosinophils, B lymphocytes, a subset of T lymphocytes, glomerular podocytes, follicular dendritic cells (Ahearn, 1998), and astrocytes (Morgan, 1996). It binds both C3b and C4b, to a lesser extent iC3b, and C1q as well (Klickstein, 1997). CR1 serves as a cofactor for factor I-mediated cleavage of C3b, iC3b, and C4b and has decay-accelerating activity for the classical and alternative pathway C3 and C5 convertases. A major physiologic role of CR1 is related to phagocytosis of complement-coated particles (opsonized particles). It is believed that erythrocyte CR1 has a major role in sequestering C3b- and iC3b-bearing immune complexes, removing them from the plasma and facilitating their transfer to degradation sites in the liver and the spleen (Birmingham, 1995). Decreased expression of erythrocyte CR1 may be associated with increased susceptibility to chronic forms of infection (Teixeira, 2001).

A receptor for the C3d fragment of C3 is found on human B cells, B cell lines, follicular dendritic cells, some peripheral T cells, some T cell lines, thymocytes (Ahearn, 1998), and astrocytes (Morgan, 1996), and is termed CR2 (CD21). CR2 has the ability to serve as a cofactor for factor I-mediated cleavage of iC3b bound to targets (Mitomo, 1987), and is the receptor for Epstein-Barr virus on B cells causing infectious mononucleosis (Fingerth, 1984). The major function of CR2 is thought to be the regulation of B cell immune responses to antigen (Carroll, 1998).

A third complement receptor, CR3 (also referred to as Mac-1, CD11b/CD18) is a member of the β 2 leukocyte integrin family of adhesion molecules. CR3 is expressed on mononuclear phagocytes, granulocytes, natural killer (NK) cells (Ahearn, 1998), and microglial cells (Morgan, 1996), and binds iC3b, C3b, and C3d (Brown, 1991). On phagocytes, CR3 triggers the phagocytic process in a fashion that parallels that of CR1. Another important role for CR3 is seen in the adhesion of monocytes and neutrophils to endothelial cells via interaction with its ligand, intercellular adhesion molecule type 1 (ICAM-1). This allows accumulation of phagocytes at sites of tissue injury where endothelial cells become activated. CR3 may serve as a receptor for both human immunodeficiency virus (HIV)-1 and *Neisseria gonorrhoeae* infection of follicular dendritic cells and cervical epithelial cells, respectively (Edwards, 2001; Batjaj, 2004).

Complement receptor type 4 (CR4, CD11c/CD18) is a glycoprotein that shares characteristics with CR3. It is also a member of the integrin family of adhesion molecules and is expressed on myeloid cells, dendritic cells, NK cells, activated B cells, some activated T cells, platelets (Ahearn, 1998), and microglial cells (Morgan, 1996). CR4 binds iC3b, and C3b to a lesser extent (Brown, 1991). The exact role of CR4 in terms of complement activation is unknown, but because this glycoprotein is an adhesion molecule, it may serve to "assist" neutrophil adhesion to the endothelium during inflammatory processes (Sengelov, 1995).

A receptor for the anaphylatoxin C5a (C5aR) is expressed on neutrophils, monocytes, basophils, eosinophils, platelets, mast cells, liver parenchymal cells, lung vascular smooth muscle cells, lung and umbilical vascular endothelial cells, bronchial and alveolar epithelial cells, astrocytes, microglial cells (Ember, 1998), and human T cells (Nataf, 1999). C5a binding

to C5aR induces a wide variety of events, including chemotaxis of inflammatory cells; degranulation of mast cells; production of oxygen radicals; promotion of cell adhesion; production of leukotrienes and prostaglandins in neutrophils and eosinophils; and induction of acute phase proteins, cytokines, and antibodies (Ember, 1998).

COMPLEMENT BIOSYNTHESIS

It is estimated that about 90% of plasma complement components are synthesized in the liver and are acute phase proteins (i.e., their synthesis by the liver increases during inflammatory reactions to increase plasma levels). The hepatocyte produces the vast majority of complement components, with the exception of C1q, factor D, properdin, and C7 (Morgan, 1997a). C1q appears to be synthesized by epithelial cells, monocytes/macrophages, and fibroblasts. The main source of factor D is the adipocyte. Properdin is synthesized mainly by monocytes and macrophages, with some synthesis occurring in lymphocytes and granulocytes. Most plasma C7 also appears to originate from monocytes and macrophages, although neutrophils were shown to store C7. Monocytes, macrophages, cells of the synovial tissues, and astrocytes have the ability to synthesize all components of the classical and alternative pathways. This may have important implications in tissue-specific inflammation, where a localized mechanism of host defense must be present to eliminate foreign particles efficiently. Production of complement components usually synthesized by hepatocytes or by extrahepatic cells often requires stimuli generated in inflammatory reactions such as interleukin-1 α , interleukin-6, or interferon- γ . A good description of the regulation of complement protein synthesis by various cells is provided elsewhere (Colten, 1998).

COMPLEMENT GENETICS

Most of the complement components are inherited in an autosomal codominant fashion. Genes that encode complement proteins, receptors, and regulatory molecules have been cloned and assigned a chromosome location (Table 47-3). Linkage exists for many of the genes that code for complement-related molecules. These linkage groups include major histocompatibility complex (MHC) class III genes (C2, factor B, and C4), genes for the regulators of complement activation (C4-binding protein, CR1, CR2, DAF, MCP, and factor H), and genes for proteins of the MACx (C6, C7, and C9) (Schneider, 1999). Molecules within each of these three groups share structural homology, suggesting that complement proteins may have arisen from gene duplication of a limited number of ancestral genes. Almost all complement-related proteins show polymorphism. The most polymorphic complement component is C4, with more than 35 identified alleles. Point mutations, insertions, or deletions of nucleic acids are usually linked to deficiencies in complement proteins (Schneider, 1997). Complement protein polymorphism is assessed by both phenotypic and genotypic analysis. Details of these methods will not be discussed in this chapter, and the reader is referred to Chapter 49 in this book, "The Major Histocompatibility Complex and Disease," as well as to other authors (Mauff, 1996; Schneider, 1997) for further reading.

COMPLEMENT AND ACQUIRED IMMUNITY

The complement system plays an important role in the establishment of acquired immune responses (Carroll, 2004). Evidence of this role came to light when depressed antibody responses to antigen stimulation were noted in animals transiently depleted in C3 (Pepys, 1974); in animals with genetic deficiencies in C2, C4, or C3 (Ochs, 1983; Böttger, 1985; O’Neil, 1988); and in patients who were genetically deficient in C2, C4, C3, or CR3 (Ochs, 1986). Studies of knockout mice lacking C4, C3, or CR1, and CR2, have furthered our understanding of the role that complement plays in the acquired immune response.

Complement may influence the antibody response to antigen in several ways. CR2 is present on the surface of B cells in association with CD19 and TAPA-1. When the B cell antigen receptor and CR2 are coligated (as would occur when antigen is complexed with C3d), the threshold for B cell activation and ultimately antibody production is dramatically lowered. Complement may also assist in the trapping of immune complexes by follicular dendritic cells, thereby facilitating the formation of lymphoid germinal centers, where B cells acquire the memory phenotype. Lack of one of the early components of the classical pathway of complement activation, or lack of CR1 and/or CR2, leads to an impaired immune response to antigen, and in some cases, to an inability to mount a secondary antibody response. Complement appears to play a role in the generation

TABLE 47-3 Complement Proteins in Human Plasma

of CD5-positive B cells, which give rise to so-called **natural** antibodies (Carroll, 1998). Along with complement activation, these natural antibodies are important in proper B cell activation in response to antigenic challenge (Boes, 1998; Lutz, 1999).

Complement components C4, CR1, and CR2 play an important role in the maintenance of B cell tolerance to self-antigens (Prodeus, 1998). Complement, especially C3, is important in the generation of the acquired immune response to antigen via antigen-presenting cells (APCs). The presence of C3 cleavage products on antigen enhances uptake of that antigen by APCs (B cells and other professional APCs expressing CR1 and/or CR2), thereby increasing the efficiency of antigen presentation to T cells with enhancement of subsequent T cell–mediated responses (Boackle, 1998; Kerekes, 1998). Evidence suggests direct complement modulation of T cell immune response through interaction with complement receptors variably expressed on some T cell populations (Kemper, 2007). The role of complement in negatively regulating host immunity is also becoming apparent. For instance, cross-linking of C5a, C3b, and C1q receptors on macrophages and dendritic cells induces suppression of toll-like receptor mediated proinflammatory signaling, thereby contributing to induction of tolerance (Cummings, 2007). It thus appears that complement plays both inductive and inhibitory roles in acquired immunity.

GENETIC COMPLEMENT DEFICIENCIES

Identification of individuals with complement deficiencies has contributed much to our understanding of the role that complement plays in host defense, especially against infectious agents, and in the development of autoimmune disease. Genetically controlled complement deficiencies are very rare but are estimated to account for as many as 6% of primary immunodeficiencies (Notarangelo, 2004). These deficiencies are

TABLE 47-4

Inherited Deficiencies in Complement and Complement-Related Proteins

Protein	Pattern of inheritance	Major clinical correlates*
Common to All Pathways		
C3	Autosomal recessive	Recurrent pyogenic infections, glomerulonephritis
Classical Pathway

DAF/CD59/HRF	Acquired	Paroxysmal nocturnal hemoglobinuria

dAF, Decay-accelerating factor; DLE, disseminated lupus erythematosus; MBL, mannan-binding lectin; SLE, systemic lupus erythematosus.

*Note that some people with complement deficiencies, especially C2 and components of the membrane attack complex, are clinically well. A substantial number of patients with defects in C5–C9 have had autoimmune disease. Deficiencies of C1–C9 are associated with a CH50 of 0. Deficiencies of C1, C4, and C2 are associated with SLE, and patients often have negative LE preps. Deficiencies of C3–C9 are associated with absent or low bactericidal activity in serum. Deficiency of C3 or C5 is associated with absent or diminished chemotactic activity of serum and may be associated with absent leukocyte response to infection.

†Deficiency in C4 genes (C4A and C4B) is referred to as “q0,” for quantity zero. Such deficiency is designated C4Aq0 or C4Bq0. Patients with such deficiencies have a higher than normal incidence of autoimmune disease. Heterozygous C2-deficient individuals also have an increased incidence of autoimmune disease.

‡Approximately 85% of cases involve silent alleles, and 15% involve alleles encoding for acquired dysfunctional variant C1 inhibitor protein. In hereditary angioedema, the C1 level is normal or depressed, the C3 level is always normal, and the C4 level is depressed. In the acquired disease, C1 and C4 levels are depressed, the antigenic C1 inhibitor level usually is normal or high, and the functional C1 inhibitor level is very low.

§Homozygosity for low (not absent) numeric expression of CR1 on erythrocytes is detectable in vitro and may be associated with SLE. An acquired defect in the number of CR1 may also be operative. Low, but not absent, levels of leukocyte CR3 are detectable in both parents of most CR3-deficient children.

of interest because they allow us to determine the role of complement components in various biological phenomena and in various disease states. Knowledge of a specific genetic mutation associated with a deficiency would permit confirmation of the heritable nature of the complement deficiency and enable screening for carriers of the mutation within the family. Even so, because genetic analyses are difficult to undertake routinely and are generally more expensive to use for screening purposes, they are rarely used during the primary workup of complement component deficiencies (Mollnes, 2007). The absence of a complement component usually follows simple mendelian genetic principles and is most often inherited as an autosomal recessive trait, with some exceptions noted here. Heterozygous patients tend to have half the expected normal complement level or less, and homozygous (deficient) patients have little or no detectable complement component activity. Deficiencies are known for every protein linked to complement activation (Table 47-4). The incidence of complete complement deficiency is estimated to be 0.03% of the general population (Wen, 2004), but with the discovery of the MBL pathway came the surprising finding that deficiency in serum MBL is fairly common. In fact it is estimated that as much as 5% of the population has one of the three recognized gene mutations that lead to MBL deficiency (Sumiya, 1997).

A correlation between MBL deficiency (autosomal codominant) and upper respiratory tract infection, especially between the ages of 6 and 18 months, has been reported, demonstrating the importance of the MBL pathway in early childhood (Turner, 1996). One study suggested that variant MBL genes might be associated with as many as one third of all meningococcal infections in children (Hibberd, 1999). Purified MBL infusions are reported to correct the defect and susceptibility to infection in children with MBL deficiencies (Valdimarsson, 1998). Not surprisingly, the same tendency to acquire clinically significant infections is associated with MBL deficiency in those immunocompromised by chemotherapy. Furthermore, it has been suggested that MBL deficiency leads to autoimmune diseases such as systemic lupus erythematosus (SLE) (Turner, 1996) and is a risk factor for recurrent miscarriage (Christiansen, 1999). In contrast, deficiencies of early components of the classical pathway are rare, but are strongly associated with lupus-like disease with rash and glomerulonephritis (Botto, 2009).

Because complement is important in the clearance of immune complexes from the circulation, it may be true that early complement component deficiency leads to improper handling of immune complexes, along with their accumulation in tissues such as the kidney. Deficiencies of terminal complement components and alternate pathway components such

as factor B, factor D, and properdin (X-linked) are well described and are associated with elevated risk of recurrent infection with gram-negative cocci such as *Neisseria meningitidis* and septic shock. Deficiency in C1 inhibitor (autosomal dominant) leads to hereditary angioedema, a disease characterized by recurrent episodes of subcutaneous and submucosal edema. This deficiency can be inherited or acquired following the development of autoantibodies to C1 inhibitor. Deficiency of factor H due to a novel homozygous factor H gene mutation has been described in an 8-month-old child and was associated with thrombotic microangiopathy and ultimately renal failure (atypical hemolytic-uremic syndrome [aHUS]) (Licht, 2005). Table 47-5 lists complement deficiency assays in common use.

ASSESSMENT OF COMPLEMENT ACTIVITY IN DISEASE

Complement promotes inflammation or tissue damage during the immune response, and plays an important role in the pathogenesis of some diseases. In the latter situation, complement is often activated by an abnormal antibody (autoantibody), by an immune complex, or by foreign material. To track disease activity in these cases, it is frequently necessary to measure serum complement levels (Table 47-6), as with SLE, in which depressed serum C3 or C4 correlates with disease activity. In such instances, nephelometric techniques are frequently employed (see “Assays of Complement,” later).

It is important to recognize that serum complement measurements are only snapshots of a dynamic process involving variable rates of complement consumption and production. Many of the complement proteins behave as acute phase reactants, with their serum levels rising dramatically in some inflammatory states, while they may fall dramatically through catabolism in other inflammatory conditions such as autoimmune states. Depending on the rate of complement production and consumption, a normal serum complement level may be associated with tissue damage, just as a decreased serum complement level may be. For example, patients with biliary cirrhosis have an increased catabolic rate of C3, and it has been suggested that C3 may play a role in the development of this disease. Nevertheless, the level of C3 in the serum of patients with biliary cirrhosis

is almost always elevated. In this case, increased synthesis obscures the increased catabolism. Along these lines, it is useful to bear in mind that complement levels in different anatomic compartments may differ. For instance, serum complement levels in patients with seropositive rheumatoid arthritis may be normal or elevated, while joint fluid complement levels may be severely depressed (where tissue damage is greatest).

Several investigators have attempted to identify which complement activation pathway predominates in mediating tissue damage in one illness or another by establishing a **complement profile**. The simplest approach to this problem examines the levels of various complement components and assumes that decreased levels of a given component of one of the pathways of complement activation are more likely to occur when that

pathway is activated. So, if a patient has depressed levels of C3 and C4 and normal levels of factor B, the classical pathway is likely to be involved. If a patient has decreased levels of C3, factor B, and properdin, and normal levels of C4, alternative pathway activation is most likely. In this way, determining the levels of a limited number of components can provide a great deal of clinically useful information.

An important advance in this area is the use of ELISA to detect stable complexes formed in serum during complement activation. These assays are highly sensitive and can readily demonstrate which pathway of complement is activated in various disease states (Morgan, 1994a) (Table 47-7).

On activation, many complement proteins express new antigens (neo-antigens) that are not revealed on the native plasma protein. The neo-antigen present on the MAC, but not present on native terminal components, is perhaps the most interesting. Antibody to this neo-antigen exists and has been used to study serum neo-antigen levels by immunofluorescence and by ELISA (Falk, 1983; Sanders, 1985). The neo-antigen level is elevated in blood and spinal fluid in many patients with ongoing complement activation (Sanders, 1986), and the neo-antigen is present in tissues at sites of terminal complex deposition. For example, it is present in the glomeruli of patients with some forms of glomerulonephritis (Falk, 1983) and in lesional skin at sites of active SLE (Biesecker, 1982). Unlike C3 deposited in normal skin of patients with SLE and a positive lupus band test, the MAC neo-antigen is found only in lesions.

COMPLEMENT IN DISEASE STATES

RHEUMATOLOGIC DISEASES

Complement analysis in patients with autoimmune disease is useful for establishing the differential diagnosis and for following disease activity. A variety of autoimmune conditions are now linked to disorders of the complement systems, including the antiphospholipid syndrome, leukocytoclastic vasculitis, cryoglobulinemia (types I–III), and systemic forms of rheumatoid arthritis. Deficiency of an early complement component (C1, C4, or C2) is frequently associated with autoimmune disease (Wen, 2004), and the rheumatologic disease that has been evaluated most extensively in terms of the contribution of complement to disease activity is SLE (Agnello, 1986; Atkinson, 1986; Liu, 2004). The incidence of deficiency of complement components C1q, C4, and C2 is 90%, 75%, and 15%, respectively, in those with SLE (Pickering, 2000), and the incidence of SLE is increased in those with MBL deficiency (Kilpatrick, 2002). Large quantities of immune complexes, both circulating and tissue-bound, are formed in SLE. These immune complexes activate complement, and complement activation products contribute to the ongoing inflammation typical of SLE. It is postulated that removal of immune complexes from the circulation with the assistance of complement may reduce the formation of antibodies (autoantibodies) to these complexes. Extended exposure to circulating immune complexes, as well as to necrotic and apoptotic cell debris, due to impaired complement-related clearance mechanisms, especially in those with complement deficiencies, may be a factor in the loss of self-tolerance and the development of autoimmunity (reviewed in Markiewski, 2007). C3 and C4 levels are often reduced in SLE, and, in general, low levels are found in patients with active disease.

Some suggest that a low C4 level is the best indicator of ongoing active disease. However, some patients with active disease show normal C4 levels. Some believe that the level of circulating sC5b–9 or neo-antigen of the MAC might serve as a better indicator of active disease (Gawryl, 1988). As mentioned earlier, complement appears to play an essential role in the clearance of immune complexes from the circulation, particularly those that contain IgM or IgG complement-activating isotypes. C3b deposition on the immune complex resulting from complement activation allows interaction with cells that possess a C3b receptor (CR1). Upon binding to erythrocytes via CR1, immune complexes are prevented from diffusing from the plasma to tissues, where they could cause damage. Erythrocytes bearing immune complexes circulate to the liver, where immune complexes are removed by a process that does not shorten the life span of the red cell (Cornacoff, 1983; Birmingham, 1995). In diseases in which complement is activated and immunologically active products are formed in the circulation, the number of CR1s per red cell is decreased, possibly as the result of removal of CR1 from erythrocytes in the liver (Ross, 1985). In addition to those seen in SLE, erythrocytes from patients with chronic cold agglutinin disease, paroxysmal nocturnal hemoglobinuria (PNH), autoimmune hemolytic anemia, Sjögren's syndrome, and *Mycoplasma pneumoniae* are reported to have reduced erythrocyte CR1, suggesting that immune deposits have been removed from erythrocytes in these diseases as well (Ross, 1985; Atkinson, 1986).

Complement proteins also act as acute phase reactants, so that complement levels may not be depressed even in situations in which complement activation occurs. For instance, normal or elevated serum complement levels may be found in juvenile rheumatoid arthritis (JRA), palindromic arthritis, pseudogout, gout, Reiter syndrome, and gonococcal arthritis. On the other hand, depressed complement levels may be found in the joint fluid in other rheumatologic conditions such as rheumatoid arthritis (RA). Depressed total hemolytic complement activity (CH50; see later under *Assays of Complement*) and the presence of cleavage products of C3 and factor B are thought to represent intra-articular complement activation (in the synovial fluid) in patients with seronegative rheumatoid arthritis, SLE, pseudogout, gout, Reiter syndrome, and gonococcal arthritis. This is not true of fluids obtained from patients with degenerative arthritis.

HEREDITARY ANGIOEDEMA

Hereditary angioedema (HAE) is a potentially life-threatening condition marked by submucosal, subcutaneous, nonpruritic, and nonerythematous swelling. It usually resolves within 48–72 hours but may instead be fatal when it involves the laryngeal mucosa. The cause of HAE is a heterozygous deficiency of C1-Inh. Because C1-Inh is the regulator of various components of the clotting, complement, and kinin-generating pathways, the actual pathway involved in the genesis of episodes of HAE is difficult to pinpoint. Several forms of HAE have been identified, including type I, in which patients have a reduced (30% or less) level of functional or antigenic C1-Inh, and type II, in which C1-Inh has reduced or absent activity, although it is present at normal levels (Wen, 2004).

INFECTIOUS DISEASES

As mentioned earlier and as evidenced by clinical findings in patients with genetically controlled complement deficiencies, the complement system plays a crucial role in defense against microorganisms. Patients with gram-negative septicemia and pyogenic infection often have deficiency of C3, or components of the alternative pathway. It is known that patients with hepatitis B surface antigen (HBsAg)-positive infectious hepatitis have an early fall in serum C3, which later returns to normal. This may be associated with signs of immune complex disease such as arthralgia. In a similar fashion, complement appears to play an important role in many parasitic infections, including leishmaniasis, trypanosomiasis, giardiasis, and malaria. In those with recurrent infections by *N. gonorrhoeae* or *Neisseria meningitidis*, a deficiency of MAC or properdin may be suspected. A thorough discussion of the interactions between the complement system and parasites, bacteria, and viruses may be found in several excellent reviews (Frank, 1988; Fishelson, 1994; Moffitt, 1994; Kozel, 1996; Cooper 1998). However, it is important to recognize that serum complement levels in general are not a reliable index of disease activity in these infectious conditions.

The role of complement in the adult respiratory distress syndrome (ARDS), a common occurrence in patients with severe trauma or overwhelming sepsis, has been studied. Evidence of massive activation of complement has been found in these patients, suggesting that bacteria and

bacterial products activate complement (Hammerschmidt, 1980), with activation of the classical and alternative pathways (Langlois, 1988) and the formation of proinflammatory factors such as neutrophil-activating factor and C5a. Much of the pulmonary damage that occurs in ARDS may be due to neutrophil infiltration of the lung. Recent evidence suggests a role for complement receptors in the human immunodeficiency virus (HIV) infection of follicular dendritic cells (Doepper, 2002; Stoiber, 2005); a similar role for MAC has been suggested in prion disease (see “Neurologic Diseases,” later).

RENAL DISEASES

Complement appears to play a key role in the glomerular damage found in many of the glomerulonephritides (West, 1998). This is usually demonstrated by the deposition of C3 or other complement components within or near damaged glomerular basement membranes. Also, the MAC has been identified in damaged glomeruli in patients with SLE-related glomerulonephritis. Patients with serum sickness and glomerular damage due to circulating immune complexes show evidence of activation of the classical or alternative pathway, or both. Traditionally, it has been believed that immune complexes are deposited in glomeruli during their passage through the kidney. Once deposited, these complexes activate complement, typically leading to depressed serum complement levels. Evidence of complement activation and deposition is routinely identified by immunofluorescence microscopy in the glomeruli of those with IgA nephropathy, membranous glomerulonephritis, and poststreptococcal glomerulonephritis, among other glomerulonephritides. An alternative view is that antibodies to glomerular structures form immune complexes in situ on the glomerular basement membrane (GBM), which then activate complement, causing local damage (Daha, 1979).

Although antibodies to GBM structures are clearly of importance in Goodpasture syndrome, their overall role in glomerulonephritis is questionable. In some patients with a rare form of glomerulonephritis, membranoproliferative glomerulonephritis, type II, with very low C3 levels, the protein known as C3 nephritic factor (C3NeF or NFa) stabilizes the alternative pathway C3 convertase. C3NeF is an autoantibody directed against Bb that extends the half-life of the alternative pathway C3 convertase by more than 10 times (Daha, 1976, 1979), and may protect it from decay dissociation by factor H (Fearon, 1980). Although C3NeF is thought to be responsible for the very low C3 levels present in these patients, it is not thought to play a central role in the development of nephritis. This is supported by experimental evidence using factor H-deficient and factor I-deficient mouse models (Thurman, 2006; Holers, 2008).

Dysregulation of the alternative complement pathway plays a role in aHUS, an atypical form of hemolytic-uremic syndrome that occurs without the usual bloody diarrhea prodrome. Most patients with aHUS have mutations of the genes encoding alternative pathway proteins such as factor H, factor I, and C3. The ability to identify mutations of complement-associated genes has useful clinical management applications. For instance, those with factor H gene mutations are recognized to have especially early and frequent recurrence of aHUS after renal transplant, leading to the practice of simultaneously transplanting both the liver, where factor H is manufactured, and the kidney, to improve allograft longevity (Thurman, 2006; Holers, 2008).

OPHTHALMOLOGIC DISEASES

Age-related macular degeneration (AMD) is the major cause of irreversible vision loss in developed countries. The risk of developing AMD is now known to be closely associated with a polymorphism of factor H, and possibly associated with genes encoding factor B and C3. This condition usually affects older patients and is characterized by progressive loss of retinal cells, retinal atrophy, subretinal bleeding and neovascularization, and retinal lesions known as drusen. The linkage of AMD to complement dysregulation was first suggested by the finding of components of complement, specifically C3 and C5a, in drusen typical of the condition (Markiewski, 2007; Holers, 2008).

DERMATOLOGIC DISEASES

Complement is thought to play a part in ongoing tissue damage in a variety of dermatologic illnesses. These include bullous pemphigoid, pemphigoid gestationis, cicatricial pemphigoid, epidermolysis bullosa acquisita, dermatitis herpetiformis, and pemphigus vulgaris (Yancey, 1998). Serum complement levels are usually normal or elevated in these inflammatory states,

and the importance of complement in these conditions is suggested by immunofluorescence analysis of tissue biopsies and by studies of blister fluid. Gammon (1984) developed an in vitro model useful for the study of anti-basement membrane zone antibody-mediated skin disorders. These authors have shown conclusively that C5a is a key element in the pathogenesis of bullous pemphigoid and epidermolysis bullosa acquisita. C5a acts as the chemoattractant necessary for the influx of neutrophils into sites of subsequent tissue damage in these diseases.

HEMATOLOGIC DISEASES

In many types of autoimmune hemolytic anemia, complement plays an important role in the opsonization of erythrocytes, leading to their clearance by cells of the reticuloendothelial system. However, even in those cases in which complement is clearly involved, serum complement levels are usually normal. Complement is particularly important in the clearance of cells coated with IgM cold-reactive autoantibodies with anti-I specificity. These autoantibodies (cold agglutinins) are associated with lymphoproliferative disorders following infection, or they may occur as isolated findings, especially in the elderly. Cold agglutinins generally bind erythrocytes optimally at the subphysiologic temperatures found in some areas of the body such as the tip of the nose, fingers, and ears. They usually mediate cell lysis when circulating erythrocytes return to core body temperatures. Not all cold agglutinins are IgM antibodies. The syndrome of paroxysmal cold hemoglobinuria (PCH), for example, results from cold-reactive Donath-Landsteiner IgG antibodies, which bind to cells at temperatures below 37° C but mediate lysis upon warming. Although the antibody is different, the pathophysiologic effects are similar.

Other autoantibodies that activate complement bind more efficiently at warm temperatures. In general, these warm-reactive antibodies are of the IgG isotype. In some cases, these antibodies may be associated with lymphoproliferative malignancy and viral infection. Most IgG warm-reactive antibodies found in autoimmune hemolytic anemia have Rh specificity and are poor complement activators, as opposed to cold agglutinins and anti-A and anti-B blood group antibodies. However, some antibodies, such as Tja, activate complement well and cause lysis.

In PNH, patients experience recurrent episodes of intravascular hemolysis. Lysis of erythrocytes in these patients is believed to proceed via the alternative pathway (Rosse, 1998; Jarva, 1999), although serum complement levels are always normal, and the direct antiglobulin test is always negative. The defect in PNH is lack of glycosyl phosphatidylinositol-linked proteins on the surface of a patient's cells, resulting from mutations in the X-linked phosphatidylinositol glycan A (*PIGA*) gene. Among other proteins linked via this cell membrane anchor are DAF/CD55 and CD59, two molecules that control complement activation at the level of the C3 convertase, and C8 and C9, respectively (see earlier, under “Regulation of Complement Activation”). Alteration of these proteins caused by mutations of *PIGA* indicates that all cell lineages produced in the marrow, including erythrocytes, lack the ability to protect themselves from complement activation on their surfaces (Holers, 2008). Recently, the therapeutic mAb eculizumab (binds to C5 blocking C5 convertase) was approved for the treatment of this disease.

NEUROLOGIC DISEASES

The role of the complement system in diseases of the nervous system has become evident in recent years. This is somewhat surprising, in that the blood-brain barrier effectively blocks complement penetration into spinal fluid. Complement activation was demonstrated in diseases such as myasthenia gravis, multiple sclerosis, cerebral lupus, Guillain-Barré syndrome, and Alzheimer's disease (Morgan, 1994a, 1997b; Shin, 1998). Deposition of complement proteins was demonstrated in diseased tissue, and complement activation was shown in the cerebrospinal fluid of patients with most of these diseases. Presumably, inflammation causes a breakdown in the blood-brain barrier with local penetration of complement proteins. Moreover, some cells synthesize complement proteins. Evidence suggests that complement activation might be involved in myelin damage, thus leading to both central and peripheral nervous system illnesses. Complement was also shown to be involved in Alzheimer's disease and Pick disease. In Alzheimer's disease, a peptide derived from amyloid termed β -A4 binds C1q and activates complement in senile plaques of the diseased brain. The most abundant glial cell type, the astrocyte, was shown in vitro to synthesize all of the complement proteins under inflammatory conditions (Morgan, 1996). Furthermore, astrocytes and microglial cells express complement receptors in vitro (Morgan, 1997a). Therefore, despite the

blood-brain barrier, the brain has the ability to mount a potent complement-dependent inflammatory reaction as a defense mechanism. Complement components may play a facilitating role in the neuropathology of prion diseases. The neuronal loss associated with transmissible spongiform encephalitis may be related to MAC formation on neuronal surfaces and the presence of extracellular C3b and C1q in disease-associated prion protein deposits (Kovacs, 2004).

CARDIOVASCULAR DISEASES

Involvement of the complement system in myocardial ischemia/reperfusion (I/R) injury is well accepted (Lucchesi, 1997). The mechanism by which complement contributes to acute myocardial infarction in patients is still unclear. Nevertheless, deposition of components of the classical and alternative pathways has been demonstrated in the affected myocardium, along with C5b-9. Production of anaphylatoxins that accompany complement activation appears to be responsible for the local inflammatory reaction. The most dramatic demonstration of an effect of complement, especially the terminal complement components (C5b-9), comes from an animal model of coronary artery occlusion (Kilgore, 1998). Rabbits with genetically controlled C6 deficiency showed significantly reduced infarct size as compared with normal rabbits. In addition, neutrophil infiltration was significantly reduced in C6-deficient rabbits, suggesting the crucial role of terminal complement components in the generation of local inflammation.

The role of complement in I/R-related injury following restoration of blood flow after cardiac (or other organ) infarction is becoming better appreciated. Reestablishment of blood flow to ischemically damaged tissue leads to increased vascular permeability with attraction and activation of inflammatory cells to the injured site. Newly arrived inflammatory cells release mediators of inflammation (cytokines) that further damage ischemically injured tissue and contribute to activation of the complement system. The actual means of complement activation in I/R is not yet elucidated, but binding of surface proteins found on damaged endothelial cells to pre-formed circulating antibodies may play an important role (Markiewski, 2007). Complement also appears to play a role in the development of atherosclerotic lesions (Torzewski, 1997) through mechanisms that are not yet clear. However, deposition of the terminal complement components (C5b-9) has been demonstrated in intimal plaque lesions of atherosclerosis, and activation of the complement system is associated with prelesional stages and progression of atherosclerotic lesions (Niculescu, 1987; Seifert, 1989). In keeping with this observation, C6-deficient rabbits were shown to be less susceptible than control rabbits to cholesterol-induced atherosclerotic lesions (Schmiedt, 1998).

A mouse model of autoimmune myocarditis suggests a role for complement in the human form of that condition, because protection from cardiac tissue injury is noted in animals lacking the C3 ligand CR2 (Kallwellis-Opara, 2007).

BIOCOMPATIBILITY

Many of the biomaterials implanted in the body activate complement, particularly the alternative complement pathway (Mollnes, 1997). On contact with blood or tissue fluids, these materials may activate complement and produce local inflammation or tissue damage. Materials must be tested for their complement-activating activity before they are widely used.

ORGAN TRANSPLANTATION

The success of organ transplantation has created a major problem—a shortage of human organs to meet the demands of an ever-growing number of patients awaiting such a surgical procedure. Therefore, use of animal donors such as the pig is proposed by many in the field as a logical alternative to human organs. However, vascularized porcine organs are susceptible to an intense rejection reaction, termed hyperacute rejection, when implanted in nonhuman primates or humans (Dalmaso, 1992; Platt, 1998). This reaction is mediated by antibody binding to vascular endothelial cells and complement activation. Complement activation was shown to be crucial in tissue damage in hyperacute rejection of xenografts. Complement activation on xenogeneic endothelial cells leads to their activation (i.e., endothelial cells adopt a procoagulant phenotype), which results in intravascular and interstitial thrombosis and hemorrhage. Such an intense reaction is due to the inability of porcine cell-associated complement-regulatory molecules such as DAF, MCP, and CD59 to control human complement activation. Therefore, the success of this

Figure 47-3 Fluorescence-labeled antibody to complement fragment C4d stains peritubular capillaries in a transplant kidney biopsy. In the early posttransplant setting, this staining pattern is a marker of humoral rejection. (40 \times , fluorescein isothiocyanate.)

promising therapeutic intervention relies on proper control of complement activation. The role of complement in the rejection of human organs (allografts) is becoming better appreciated, and it is likely that complement activation contributes to some extent to acute and chronic rejection episodes (Baldwin, 1995). Identification of C4d in the peritubular capillaries of renal transplant biopsies by immunofluorescence microscopy is a useful adjunctive study in the recognition of humoral rejection (Fig. 47-3) (Onitsuka, 1999).

CLINICALLY USEFUL COMPLEMENT INHIBITORS

Many complement inhibitors have been produced, and still more are in development. To be clinically useful, a complement inhibitor should avoid production of the proinflammatory byproducts of complement activation, such as the anaphylatoxins C3a and C5a. Inappropriate activation or inadequate regulation of complement activation is involved in a variety of human diseases. Therefore, the development of agents that selectively block complement activation would be useful in limiting tissue damage. Development of clinically useful complement inhibitors has been slow, but progress is being made, as evidenced by the recently approved mAb preparation eculizumab, a humanized long-acting mAb directed against C5 and marketed for the treatment of patients with PNH; other mAbs are in clinical testing phases and in preclinical development. As recently reviewed by Ricklin (2007), current strategies used to therapeutically regulate complement may be classed into five major categories: (1) purified plasma protease inhibitors, primarily C1-Inh (currently approved for treatment of hereditary angioedema); (2) soluble complement regulators, such as sCR1, which act to prevent complement attack on host cells; (3) therapeutic antibodies such as eculizumab, intended to selectively block various stages of complement activation; (4) small peptides, nucleotides, and synthetic molecules such as compstatin, which are used to sterically hinder or induce conformational changes in the elements of the complement cascade; and (5) anaphylatoxin receptor inhibitors, intended to reduce the proinflammatory signaling initiated by complement components such as C5a. Because of the critical role of complement in host defense, especially in infection, potential complement inhibitors will have to avoid interfering with intact and properly regulated elements of the system. As mentioned earlier, C1-Inh is absent or reduced in the serum of those with hereditary angioedema and has been administered as a therapeutic concentrate during acute attacks. Because C1 inhibitor is often reduced in severe inflammatory states as well, concentrates of C1-Inh have been shown to have promising clinical utility in conditions such as septic shock, reperfusion injury, hyperacute transplant rejection, and PNH (Kirschfink, 2001; Davis, 2004).

ASSAYS OF COMPLEMENT

GENERAL PRINCIPLES

Methods that allow accurate determination of levels of each of the components of the classical, alternative, and MBL pathways, as well as several enzymes and regulators of the complement system, are available. However, many of these assays are not available in routine clinical laboratories and are restricted to research laboratories. We focus our attention here on techniques that do not require a laboratory skilled in complement research for their performance. The reader is referred to other publications for details relative to methods that require more specialized techniques (Whaley, 1985; Harrison, 1986; Dodds, 1997; Giclas, 1997; Würzner, 1997; Mollnes, 2007). Complement assays can be divided into two types: those that measure complement proteins as antigens in biological fluids, and those that measure the functional activity of a given component. Both types of techniques have advantages and disadvantages. Methods used for antigenic (immunochemical) analysis are generally simpler to perform. These antigenic assays are highly specific, require fewer specialized reagents, are cheaper, and are considerably less time-consuming. In these assays, serum or plasma can be used, and commonly available methods of freezer storage (−20° C) are sufficient. For these reasons, antigenic assays are easily adaptable to a clinical laboratory.

On the other hand, antigenic assays do not provide information about the activity of a component, because they may detect degradation products, as well as functionally active components. The presence in serum of small fragments of a protein with antigenic activity may confuse the results. Some antigenic assays use radial immunodiffusion. In these assays, a protein fragment may diffuse more rapidly than the parent molecule, which may result in falsely high levels. As an example, the most commonly employed antigenic assays for C3 measure its major degradation product, C3c, by radial immunodiffusion. For accurate measurements of C3c, the specimen should be thawed at 37° C for a number of days to allow complete conversion of C3 to C3c. In fact, this is not usually done, which can represent a source of error, although the error is small and is not usually of clinical consequence. In general, antigenic assays are not as sensitive as functional assays and may not detect low levels of a component present in certain body fluids. The sensitivity of antigenic assays depends to some degree on the strength of the antibody employed; with the usual assays, as little as 10 µg/mL of protein antigen can be measured.

Kits are available that use inhibition of binding of radiolabeled substrate to detect various complement peptides. Such kits are available for measurement of C3a, C4a, and C5a. The usefulness of these measurements is still debated. Assays designed to measure the functional activity of the control proteins, factors H and I, in human serum have also been reported but require specialized reagents that may not be commercially available (Gaither, 1979). ELISA assays have been developed for the measurement of split products of complement proteins or complexes formed following complement activation. These kits measure breakdown products of complement proteins as they are generated after complement activation using specific monoclonal antibodies. Complement activation via the classical pathway can be measured by following the levels of C4d in serum versus those of C4. Also, ELISA of C1r–C1s–C1Inh complexes provides a measure of complement activation via the classical pathway. Activation of the alternative pathway can be measured by ELISA by assessing levels of Bb, or C3bBbP, or C3bP complexes in the circulation (Mayes, 1984). Measurement of as little as 10–20 ng/mL of C3bP in serum has been reported. This assay may also be used to measure surface-bound activation complexes. Activation via either pathway can be monitored by measuring levels of iC3b, or sC5b-9, the soluble form of the membrane attack complex.

Recently, an ELISA test for the measurement of serum or plasma MBL complex activity was developed that eliminates interference by components of the classical pathway (Petersen, 2001; Kuipers, 2002). In addition, ELISA kits are available that measure the generation of anaphylatoxins in serum/plasma. Because C3a and C5a are rapidly converted to their inactive desArg fragments by carboxypeptidase-N in serum, these assays utilize monoclonal antibodies specific for C3a-desArg and C5a-desArg. Because of their high sensitivity, ELISA assays serve as an excellent tool by which to assess complement activation in biological fluids via the classical pathway or the alternative pathway. Seelen (2005) describes a simple approach using three ELISAs that is suitable for screening deficiencies of all three pathways and is commercially available (WIELISA, Wieslab, Lund, Sweden). Advantages of this approach include the coverage of all three pathways simultaneously, the ability to detect properdin deficiency in the alternative

TABLE 47-8 CH50 and AH50 Interpretation	
Test result	Interpretation
CH50 very low or 0 (AH50 normal)	Missing C1q, C1r, C1s, C2, or C4
AH50 very low or 0 (CH50 normal)	Missing properdin, or (very rarely) factor B or factor D
CH50 and AH50 very low or 0	Missing C3, C5, C6, C7, C8, or C9
Late components low (especially C3) CH50 and AH50 low	Missing factor H or factor I

pathway, and freedom from consideration of the availability of erythrocytes (Mollnes, 2007).

FUNCTIONAL EVALUATION OF THE CLASSICAL PATHWAY

Functional complement assays are sensitive and precise tools for providing information about the activity of a complement component. Some of these methods may be used to quantify activity at the molecular level, and others to express complement function in arbitrary units. Commercial reagents are available for titrating each component of classical or alternative pathways. Assays that measure the total hemolytic activity in a specimen (CH50) or the functional activity of isolated complement components in general use sheep erythrocytes as targets of complement-mediated lysis. Sheep erythrocytes are more sensitive to antibody- and complement-mediated lysis than erythrocytes from other species. The alternative pathway of complement activation (AH50) is easily measured using rabbit erythrocytes. These cells are particularly sensitive to antibody-independent lysis mediated by human serum. In addition, a functional hemolytic assay using chicken erythrocytes to assess functional MBL levels in serum has been developed, which the authors claim is useful for large-scale testing of patient samples (Petersen, 2001; Kuipers, 2002). A useful summary of the clinical significance of CH50 and AH50 testing is provided in Table 47-8.

The simplest functional assay of the classical pathway measures total hemolytic complement. Absence of any of the nine components, as occurs in homozygous genetically deficient patients, generally results in a total hemolytic complement titer (CH50) of zero. However, a normal value does not exclude the possibility of reduced levels of individual components in test subjects. When a patient's history and symptoms suggest a possible deficiency, hemolytic or antigenic titrations of individual components may be required. Often, a CH50 titer will be an adequate functional measure of complement activity. In the CH50 assay, commercially available antibodies added to sheep red blood cells react with antigen on red cell surfaces, forming immune complexes. Patient test serum is then added to the mixture as the source of classic pathway complement. Complement in the test serum will bind the immune complex previously formed on the sheep red cells, leading to activation of the classical complement pathway and to red cell lysis. By titrating the addition of patient test serum, it is possible to calculate the complement activity present in the patient sample, and to express that activity as the reciprocal of the dilution that causes lysis of 50% of red cells in the assay (the CH50). The complement titer is expressed in CH50 units (the reciprocal of the dilution of the complement source that lyses 50% of sensitized sheep erythrocytes).

Serial dilutions of the specimen are prepared and added to antibody-sensitized sheep erythrocytes. In this case, the 50% endpoint is determined by Von Krogh transformation of the data. This empirically derived formula converts the S-shaped dose-response curve into a linear function. Values of $Y/1-Y$ are calculated, in which Y is the fraction of red cells lysed in a test dilution. A graph is constructed in which the log of the relative volume of complement is plotted against the log of $Y/1-Y$ values. Usually, a straight line is obtained, and the titer is calculated by determining the relative volume of complement at which $Y/1-Y = 1.0$ (or 50% lysis). This value is divided into the reciprocal of original serum dilution (1:60 for human serum) to calculate the concentration of serum complement that lyses 50% of the cells. The complement titer represents the number of 50% hemolytic units present in 1.0 mL of undiluted serum (Mayer, 1961; Rapp, 1970). Clinical laboratories may use one of two commercially available

variations of this classic test to perform the CH50 assay. One is based on the lysis of liposomes, releasing a marker enzyme, and the other is an ELISA that detects the final C9 neo-antigen formed with complete activation of the classical pathway.

FUNCTIONAL EVALUATION OF THE ALTERNATIVE PATHWAY

In this assay, human serum (usually first diluted 1:5) is serially diluted and is added to rabbit erythrocytes that are not sensitized with specific antibody, in a buffer that contains magnesium ions and ethylene glycol tetraacetic acid, to chelate calcium ions (calcium ions are required for classical pathway activation, not for alternative pathway activation) (Pangburn, 1988). The alternative pathway titer is designated AH50 and represents the final dilution of human serum in the assay that lyses 50% of the rabbit erythrocytes. A graph similar to that described for total hemolytic complement titration is produced to determine the AH50. Human serum may at times possess “natural” antibody to a carbohydrate widely expressed on cells of species other than humans and nonhuman primates. A high concentration of serum mixed with rabbit erythrocytes may induce agglutination, which can be misleading in interpreting an AH50 titer (Tomlinson, 1997). Therefore, it may be useful to absorb the serum with washed, packed rabbit erythrocytes on ice for 15–30 minutes to remove a certain proportion of natural antibodies, hence reducing cell agglutination in the assay.

FUNCTIONAL ASSAY OF C1-INHIBITOR AND FACTOR H

Assays for the assessment of C1-Inh function have been developed that are useful in the diagnosis of HAE. One that is in common use is an ELISA-based assay that measures formation of a complex between biotinylated C1s and C1-Inh on an avidin-coated solid phase. A second test makes use of steric hindrance created by the binding of inhibitor to C1r, preventing the subsequent binding of antibody to C1r. During radial immunodiffusion of C1r, unbound and therefore active C1r quantities will increase as the amount of C1-Inh present decreases. Factor H functional assays are important for the diagnosis of aHUS, membranoproliferative glomerulonephritis, type II (dense deposit disease), and AMD. A method described by Sánchez-Corral (2004) uses unsensitized sheep red blood cells incubated in serum. With this method, normal serum will provide factor H-conferred protection from hemolysis, whereas factor H-deficient serum will not prevent complement-mediated red cell lysis.

COMPLEMENT LEVELS BY ANTIGENIC ASSAYS

For use in antigenic assays, the specimen (serum or plasma) is stored frozen (–20° C or lower). Bacterial contamination may cause protein denaturation or fragmentation, whereas freezing and thawing do not usually have a major adverse effect on antigenic levels. For certain complement assays, the specimen is diluted in saline to achieve the correct concentration range for accurate measurement.

Antigenic analyses of complement proteins make use of one of several immune precipitin techniques. Single radial immunodiffusion using the method of Fahey or Mancini is commonly used to calculate specific protein quantities. With both methods, antigen is added to wells in a gel that contains antibody, and rings of precipitation are formed. The Fahey method employs antibody that is not in excess. The diffusion time at which results are read is thus critical. Diffusion endpoints are not reached, and this can lead to inaccurate measurement of antigenic complement levels. The Mancini method uses excess antibody in the gel and is more sensitive and accurate. Most commercial firms preparing immunodiffusion plates use the Mancini method. Radial immunodiffusion kits are available for all components of the classical and alternative pathways. These kits consist of plates coated with a thin layer of 2% agarose-containing monospecific antibody. Protein standard serum (a stabilized pool of normal human serum) is supplied, usually in prediluted solutions. Each standard solution contains a specific amount of the particular protein being measured for use in construction of the reference curve.

Nephelometric methods are also used to measure complement component levels, which in some instances may be comparable with those

obtained with radial immunodiffusion (Bossuyt, 2002); they are commonly used in hospital laboratories to measure serum C3 and C4.

Ingvarsson (2007) recently described a proteomic approach that uses an antibody-based microarray platform employing recombinant human scFv antibodies, thus permitting protein expression profiling of serum complement-related proteomes. The microarray data correlated well with conventional clinical laboratory methods when plasma samples from both healthy and complement-deficient individuals were tested. Similarly, Janzi (2005) described a reverse array format in which serum samples are themselves spotted to a microarray slide in large sample numbers and are screened for the presence of a single serum protein, as proof of the principle that large numbers of serum samples may be simultaneously screened for clinically relevant proteins.

KININS AND THE KININ-GENERATING SYSTEM

The kinin-generating system is another inflammatory response pathway present in plasma that controls the generation of peptides important in the inflammatory response. Briefly, the most important biologically active peptide generated by the system appears to be bradykinin, a nonapeptide with potent activity in many biological systems. It is active in increasing vascular permeability, vasodilation, hypotension, induction of pain, contraction of many types of smooth muscle cells, and activation of the phospholipase A2 system, with activation of cellular arachidonic acid metabolism. Although in many respects it is similar to the complement system, the plasma kinin-generating system is simpler, because it is composed of only four plasma proteins. The major proteins of the kinin-generating system as currently understood are Hageman factor, clotting factor XI, prekallikrein, and high molecular weight kininogen.

On interacting with negatively charged surfaces, such as those supplied experimentally by glass or naturally by many biologically active materials such as lipid A of gram-negative bacterial endotoxin, Hageman factor is cleaved and activated. Proteolytic enzymes including kallikrein can cleave and activate Hageman factor as well. The cleaved Hageman factor (α HfA) has proteolytic activity and further activates and cleaves additional Hageman factor molecules to generate additional α HfA.

α HfA activates factor XI to factor XIa, resulting in activation of the intrinsic coagulation cascade. α HfA also cleaves the single-chain prekallikrein into a two-chain molecule, kallikrein, with the chains linked by disulfide bonds. Cleaved prekallikrein has proteolytic enzymatic activity located on the lower molecular weight chain. Activated kallikrein cleaves high molecular weight kininogen at several sites, thereby releasing bradykinin.

Bradykinin has a short half-life mainly caused by the activities of four membrane-bound and/or soluble zinc metallopeptidases: angiotensin 1-converting enzyme, aminopeptidase P, neutral endopeptidase 24.11 (neprilysin), and carboxypeptidases M and N (Moreau, 2005). These four act to convert bradykinin to inactive low molecular weight peptides lacking known biological activity.

Bradykinin has been postulated to play a role in a variety of diseases. Free bradykinin and lysyl-bradykinin have been found in the nasal fluid of patients with rhinitis. A pathogenic role for bradykinin has also been suggested in diseases ranging from asthma to hereditary or acquired angioedema. Bradykinin is an important mediator of the inflammatory response, and when administered locally, it produces the four cardinal signs of inflammation. Development of pharmacologic agents to block or ameliorate the effects of the kinin system has met with limited success but is ongoing (Dietrich, 2009).

CYTOKINES

Cytokines are soluble proteins acting at the picomolar to femtomolar range and released by many cell types to permit usually short-distance (autocrine and paracrine) communication between cells. The term cytokine encompasses lymphokines, interleukins, colony-stimulating factors (CSFs), interferons (IFNs), tumor necrosis factor (TNF), and chemokines. Although cytokines are produced by many cell populations (endothelial cells, fibroblasts, epithelial cells, and others), they are mainly the products of helper T cells (Th) and macrophages. These mediators are released to assist in upregulation or downregulation of the immune response and to orchestrate associated inflammatory and reparative activities, hematopoiesis, and immune cell proliferation and differentiation.

TABLE 47-9

Cytokines by Type and Function

Cytokine type	Cytokines	Actions
Adipokine (cytokine released from adipocytes)	IL-1 α , TNF- α , IL-6, leptin, adiponectin, others	Proinflammatory, proatherogenic, antiinflammatory
Angiogenic	VEGF, IL-1, IL-6, IL-8	Neovascularization, prometastatic
Anti-inflammatory	IL-10, IL-13, TGF- β , IL-22, IL-1Ra, IFN- α/β	Upregulate inflammatory genes, depress cytokine-mediated lethality, downregulate autoimmune disease
Chemokine	IL-8, MCP-1, MIP-1 α	Increase cell migration and activation
Colony stimulating	IL-3, IL-7, G-CSF, GM-CSF, M-CSF, erythropoietin	Hematopoiesis, proinflammatory, anti-inflammatory
gp130 signaling pathway	IL-6, IL-11, others	Growth factors, B cell activation, acute phase response
Lymphocyte growth	IL-2, IL-4, IL-7, IL-15	Clonal expansion, Th1/Th2/Th17 regulation
Mesenchymal tissue growth	FGF, TGF- β , others	Fibrosis, prometastatic
Nerve growth	NGFa, BDNF	Nerve and Schwann cell growth, B cell activation
Osteoclast-activating	RANKL	Bone resorption, immune stimulation
Proinflammatory	IL-1 α , IL-1 β , TNF- α , IL-12, IL-18, IL-23, MIF, IL-32, IL-33, CD40L	Upregulate inflammatory mediators and innate immune responses
Th1	IFN- γ , IL-12, IL-18	Upregulate Th1 response, clonal expansion of CTL
Th2	IL-4, IL-5, IL-18, IL-25, IL-33	Upregulate Th2 response, increase antibody production
Th17	IL-17, IL-23, IFN- γ	Upregulate Th17 response, autoimmune response
Type I IFN	IFN- α , IFN- β	Antiviral, upregulate MHC class I, antiangiogenic, antiinflammatory
Type II IFN	IFN- γ	Macrophage activation, upregulate MHC class II

BDNF, Brain-derived neurotrophic factor; *CSF*, colony-stimulating factor; *IFN*, interferon; *IL*, interleukin; *MCP-1*, monocyte chemotactic protein-1; *MHC*, major histocompatibility complex; *MIF*, macrophage migration inhibitory factor; *MIP-1 α* , macrophage inhibiting protein-1 α ; *NGF*, nerve growth factor; *RANKL*, receptor activator of NF κ B.

Secretion and binding of cytokines is the cellular equivalent of connecting to the Internet. The prevailing milieu of cytokines within the region of an organism creates a web of communication between cells. Cytokine signals are received at the cell surface not only as single messages but also in complex, subtle synergistic and antagonistic combinations that coordinate processes, including stimulation of hematopoiesis, orchestration of directed leukocyte migration (chemokinesis), activation of various inflammatory cells, stimulation of lymphocyte development and maturation, and processes related to the immune response. To respond to specific cytokine messages, cells display surface cytokine receptors, arrayed as so many antennae. Using these receptors, cells sample, process, and respond to combinations of soluble and substrate-bound cytokines in a manner dependent on surface receptor density and state of activation.

As mentioned, many cell types are capable of producing cytokines, but for the most part it is the T cell and the macrophage that are virtual cytokine factories; for this reason, many familiar cytokines are known as interleukins (ILs). The biological actions of a given cytokine, for instance, IL-1, may overlap with those of another cytokine such as TNF- α , as a form of built-in redundancy, and are often dependent on the circumstance in which the cytokine is secreted and the responding cell type. The same cytokine may have more than one effect or may function in regulating the immune response.

It is becoming more and more apparent that the family of cytokine proteins is extensive (now more than 100 known proteins), and classifying them conveniently requires examining them in more than one way. For instance, it might be convenient to think of the various cytokines as members of discrete functional classes, rather than solely as members of classes based on structural homology (Table 47-9). In this approach, there are two major classes of cytokine: the class that promotes cell-mediated immunity, and the class that promotes antibody-mediated immunity. The cytokines may be subdivided further according to their major activities, for example, proinflammatory, lymphocyte growth factor, anti-inflammatory, and CSF activities, among others.

Another means of classifying cytokines that may have clinical utility is to group them according to the structural homology of their receptors. To some degree, it is this receptor homology that accounts for cytokine functional pleiotropy and the redundancy mentioned earlier. Cytokine receptors may be divided into five major receptor types with subfamilies (Table 47-10): (1) the immunoglobulin superfamily receptor class shares structural homology with immunoglobulins and certain cell adhesion molecules; (2) the TNF receptor class members conserve a cysteine-rich common extracellular binding domain; (3) the G-protein-coupled seven transmembrane receptor class members contain seven transmembrane

α -helices; and (4 and 5) the type I and type II receptor class members lack intrinsic tyrosine kinase activity. Receptors of this last type communicate with the nucleus through the STAT (signal transducers and activation of transcription) family of cytoplasmic transcription proteins via binding and activating of members of the JAK (Janus kinase) family of proteins. These receptors also make use of the RAS-RAF-MAP kinase and PI3 pathways to initiate gene transcription.

As mentioned, cytokines may be produced and released by several different cell types, including lymphoid cells, stromal cells (such as fibroblasts, osteocytes, and endothelial cells), and epithelial cells. The extent of influence of these soluble proteins may possibly extend over the long range (systemically) when released into the circulation (endocrine effect), as with the pyrogen IL-1, or their action may be local only, producing an effect on the cell releasing them (autocrine effect) or its neighboring cells (paracrine). For instance, IL-2 released by T cells has an autocrine proliferative effect through the IL-2 receptor (CD25). In the thymus, cytokines such as IL-7 released from thymic epithelial cells affect thymocyte maturation in a paracrine fashion. A majority of cytokines bind to high-affinity receptors that transduce signals to the cell nucleus through systems such as JAK/STAT signaling pathways, mitogen-activated protein kinase, cyclic adenosine monophosphate, and PI3-kinase, among others. Because of the profound biological effects of these powerful proteins, attempts at mass-producing and therapeutically administering them are ongoing. Clinical laboratory detection and measurement of them therefore is becoming more common. Bioassays are sometimes the “gold standard” for detecting cytokine activity, but they are usually time-consuming and unmanageable in the hospital laboratory. ELISA kits are widely available for many of the cytokines described in the text. Molecular techniques (polymerase chain reaction, in situ hybridization) are employed almost routinely now in hospital laboratories to identify the presence of cytokines with great sensitivity, and to localize a cytokine more precisely to a particular cell type.

Ever increasing interest in manipulating cytokine activity to treat disease has led to exploitation of several approaches (Table 47-11), including cloning and producing recombinant forms of cytokines or their receptor antagonists; delivering cytokines by gene and antisense nucleotide insertion through viral and nonviral vectors (commonly adenovirus or retrovirus vectors, or nonviral DNA plasmid vectors); vaccinating patients against their own (autologous) cytokines (Cutler, 2005); raising cytokine-blocking monoclonal antibodies; and genetically fusing molecules of interest, such as an enzyme, ligand, peptide, or extracellular domain of a surface receptor, to the Fc portion of human IgG1 or albumin. This “fusion” approach has the advantage of conferring increased half-life and stability

TABLE 47-10

Selected Cytokines Grouped by Receptor Class

Receptor class	Structure and signaling pathway	Example receptors
Immunoglobulin superfamily	These receptors contain paired antiparallel β sheets forming the sandwich-like structure known as the Ig-fold seen in antibodies.	IL-1, IL-18, SCF (<i>c-kit</i>), M-CSF
Tumor necrosis factor	These receptors share a cysteine-rich common extracellular domain and activate the NF κ B pathway.	TNF- α , TNF- β , NGF, CD40, CD27, CD30, CD120
G-protein-coupled receptor (serpentine receptors)	These receptors have a 7-transmembrane helix that couples to G-protein, ultimately activating MAP kinase via the cAMP and phosphatidylinositol signaling pathways.	IL-8, CCR1, CXCR4, MCAF, NAP-2
Type I (hemopoietin receptors)	These are transmembrane protein receptors with paired high-affinity α and β chains; these receptors share a common extracellular motif (WSXWS); they signal the nucleus through the JAK/STAT, RAS-RAF-MAP kinase, and PI3 pathways.	IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-11, IL-12, IL-15, IL-21, GM-CSF, EPO, PRL, GH, G-CSF, LIF
Type II	These transmembrane protein receptors are similar to type I, but lack the WSXWS motif, while having conserved cysteine pairs in their extracellular domain; they signal the nucleus through the JAK/STAT, RAS-RAF-MAP kinase, and PI3 pathways.	IFN- α , IFN- γ , IFN- β , IL-10

cAMP, Cyclic adenosine monophosphate; CSF, colony-stimulating factor; IFN, interferon; IL, interleukin; JAK, Janus kinase; NF, nephritic factor; STAT, signal transducers and activation of transcription; TNF, tumor necrosis factor.

on the fusion product. In some instances, multiple ligands may be sequentially fused to a single gene to create a “trap” for the target by “trapping” or binding two target molecules on a single fusion protein, possibly as a result of the trap’s high binding affinities (Huang, 2009).

Unfortunately, many disease states are complex conditions driven by an intricate interplay of numerous cytokines, so that a single “magic cytokine bullet” for those conditions is unlikely to arise in the very near future. For conditions in which dysregulation of a single cytokine is largely at fault, the challenge is less daunting. Several cytokine-related therapeutic agents have entered routine medical practice in recent years (see Table 47-11).

CELL ADHESION MOLECULES

The glue that binds living tissues into complex multicellular organisms comprises in part the cell adhesion molecules (CAMs) described subsequently. These complex glycoproteins permit cell migration during embryogenesis and wound healing, and govern the leukocyte trafficking and homing critical to lymphopoiesis and the immune response. Adhesion molecules are conventionally divided into five groups based on structural homology: cadherins, mucins, integrins, selectins, and immunoglobulin superfamily molecules. Cadherins are expressed most often on epithelial cells and interact with each other in a calcium-dependent manner. Mucins are heavily glycosylated proteins that interact mainly with selectins. Immunoglobulin superfamily members have immunoglobulin-like domains and interact with integrins, selectins, and each other. Integrins and selectins are discussed. Because of their ubiquitous presence and their critical importance in intercellular activity, significant investigation of CAMs and their role in disease activity is under way. The goal is to identify and target CAM interaction sites for therapeutic modulation with specific monoclonal antibodies, as well as sense/antisense oligonucleotides or other small molecules designed to block gene transcription (Mousa, 2008).

INTEGRINS

The integrin family (Gonzalez-Amaro, 1999) of adhesion molecules provides a critical physical link between those things external to the cell (other cells and the extracellular matrix [ECM]) and those things within the cell (cytoskeleton, intracytosolic molecules, and nucleus). Each integrin family member is composed of a heterodimer of noncovalently linked α and β subunits (Table 47-12). The major integrins are divided into four subfamilies, differing in patterns of expression and ligand specificity. The α 1 integrins, also known as the very late activation antigens (VLAs), are created from the association of a β 2 chain subunit (CD29) with any of the α chain subunits (CD49a–CD49h). They are expressed on all cells requiring firm anchoring to the ECM, and on circulating leukocytes, platelets, and some tumor cells. The β 2 integrins, which tend to be expressed mainly by leukocytes and myeloid cells, result from association of the β 2 chain subunit (CD18) with any of several α subunits. When combined with the

α L (CD11a) subunit, the β 2 integrin LFA-1 (lymphocyte function-associated antigen, CD11a/CD18) is formed. LFA-1 plays a crucial role in leukocyte adhesion to vascular endothelium during transendothelial migration. The β 2 chain subunit, in association with the α M subunit (CD11b), forms Mac-1 (CD11b/CD18), an integrin expressed on myeloid cells and mononuclear phagocytes. The α integrin subunits are 120- to 180-kDa membrane proteins with short intracytoplasmic domains, a long extracellular fragment with seven homologous domains, and several metal ion-binding motifs (metal ion-dependent adhesion sites [MIDAS]) thought to function in converting an integrin from an inactive to an active conformation. Both α and β subunits bind to ligand, but the α subunit generally is thought to provide ligand specificity.

The intracytoplasmic tails of α and β integrin subunits associate with cytoskeletal components to transduce intracytoplasmic signals. In the process of signal transduction, integrins associate and interact with other cell membrane-associated proteins, cytoskeletal components, and noncytoskeletal cytoplasmic components. The integrin-associated protein (IAP or IAP 50) designated CD47, a member of the immunoglobulin superfamily, is one such membrane-associated protein that, mainly through association with β 3 integrins, may function as a signal transducer. Other membrane-associated proteins involved in integrin signaling include caveolin-1 and CD9, which are involved in cell membrane caveola formation and platelet aggregation, respectively. Cytosolic molecules, including integrin cytoplasmic domain-associated protein (ICAP-1), help orchestrate the complex activity of β 1-integrin-mediated cell migration.

Perhaps the best studied intracytoplasmic associations of integrin molecules are those with the cytoskeleton-associated proteins α -actinin, talin, filamin, vinculin, tensin, and paxillin. These cytoskeleton proteins, through their association with β 1, β 2, and β 3 integrin subunits, bridge integrin and cytoskeleton and direct cell migration, phagocytosis, stress fiber formation at focal contact sites, and intracellular signal transduction, and link separate cytoskeletal proteins.

The pattern of integrin distribution is wide, especially among those integrins (mostly β 1) involved in anchoring cells to components of the general ECM such as collagen and laminin. For those integrins mediating attachment to less widely distributed components, tissue distribution likewise is more restricted.

Monoclonal antibodies raised against specific integrin components (anti-integrins) are in clinical trials. β 1 integrin is the target of the recently approved humanized monoclonal antibody natalizumab, which is used in the treatment of Crohn’s disease and multiple sclerosis. Abciximab is an antithrombotic chimeric monoclonal antibody that is useful in preventing thrombosis and restenosis during some coronary artery procedures by blocking glycoprotein (GP)IIb/IIIa-dependent platelet aggregation. These novel therapies are not without serious risk, however, as several cases of therapy-related opportunistic infection and progressive multifocal leukoencephalopathy have been reported specifically with natalizumab (Stuve, 2007).

TABLE 47-11

Selected Engineered Therapeutic Agents

Class	Generic name	Agent/Action	Therapeutic indication
Cytokine	Aldesleukin (Proleukin)	Recombinant IL-2, binds and activates IL-2R	HIV
	IFN- β -1a (Avonex)	Recombinant IFN- β -1a, anti-inflammatory cytokine	Relapsing MS
	Sargramostim (Leukine)	Recombinant GM-CSF, modulates hematopoiesis	Leukemia, bone marrow stem cell transplant
Anticytokine Antibody	Adalimumab (Humira)	Recombinant humanized anti-TNF- α IgG1 mAb, binds and inhibits TNF- α	RA, CD, PA, AS
	Infliximab (Remicade)	Chimeric (75% human/25% mouse) IgG1 mAb binds TNF- α	RA, CD, AS
	Mepolizumab (Bosatria)	Recombinant humanized anti-IL-5 mAb	Allergic asthma
	Bevacizumab (Avastin)	Recombinant humanized anti-VEGF-A mAb, inhibits angiogenesis	Colorectal and non-small cell carcinoma
Small Molecule Antagonist	Thalidomide	VEGF and TNF mRNA inhibitor	ENL, MM, RCC
	AP12009	TGF- β 2-blocking antisense oligonucleotide	High-grade glioma
Cytokine Receptor Antagonist	Anakinra	Recombinant IL-1R α antagonist, competitively inhibits binding of IL-1 α to its receptor	RA
	Tocilizumab (Actemra)	Recombinant humanized IL-6R mAb, acts as an immunosuppressant	RA
	Daclizumab (Zenapax)	Recombinant humanized IL-2R α chain mAb, binds IL-2R α (CD25) on T cells to prevent allograft rejection	Renal transplant
	Oprelvekin (Neumega)	Recombinant IL-11, stimulates stem cell and megakaryocyte progenitor growth	Chemotherapy-related thrombocytopenia
	Trastuzumab (Herceptin)	Recombinant humanized mAb, binds Her2/neu receptor overexpressed on some carcinomas; inhibits angiogenesis	Breast carcinoma
Fusion Protein	Etanercept (Enbrel)	Soluble TNF- α RII fused to human IgG1 Fc fragment; neutralizes membrane-bound and soluble forms of TNF- α	RA, AS, JRA, PA
	NBI-3001	Recombinant IL-4- <i>Pseudomonas aeruginosa</i> exotoxin fusion protein	Malignant high-grade gliomas
	Alefacept (Amevive)	LFA-3 fused to Fc domain IgG1, binds CD2 to inhibit T cell activation	Plaque psoriasis
Anti-Cell Adhesion Molecule	Natalizumab	Recombinant humanized leukocyte α_4/β_1 integrin mAb, blocks attachment of leukocytes to CNS endothelial cells	MS
	Abciximab	Anti- α_{IIb}/β_3 , α_v/β_3 chimeric mAb Fab fragment, antithrombotic	Angioplasty procedures
	Efalizumab (Raptiva)	Recombinant humanized anti- α_L/β_2 mAb, binds CD11a to act as an immunosuppressant	Psoriasis

AS, Ankylosing spondylitis; CD, Crohn's disease; CSF, colony-stimulating factor; ENL, erythema nodosum leprosum; HIV, human immunodeficiency virus; IFN, interferon; IL, interleukin; JRA, juvenile rheumatoid arthritis; LFA, lymphocyte functional antigen; MM, multiple myeloma; MS, multiple sclerosis; PA, psoriatic arthritis; RA, rheumatoid arthritis; RCC, renal cell carcinoma, TNF, tumor necrosis factor.

SELECTINS

The selectin family (Gonzalez-Amaro, 1999) contains three homologous proteins. L-selectin (CD62L) is expressed by most leukocytes, especially lymphocytes, and is thought to play an important role in naive and memory lymphocyte homing or trafficking to lymph nodes through high endothelial venules (HEVs). L-selectin also tethers neutrophils to activated endothelial cells in regions of inflammation. Its ligands include Glycam (glycan-bearing cell adhesion molecule)-1, MadCAM (mucosal addressin cell adhesion molecule)-1, and CD34. P-selectin (CD62P) is stored in the α granules and Weibel-Palade bodies of platelets and endothelial cells, respectively, and is expressed on the cell surface after cell activation. Once on the cell surface, P-selectin binds neutrophils, lymphocytes, and monocytes via its ligands, Lewis-X-, and Lewis-A-family-type complex carbohydrate groups. E-selectin (CD62E) is found on the surface of activated endothelial cells only and recognizes ligands similar to those recognized by P-selectin. It plays a recognition role for homing effector and memory T cells as they localize to sites of inflammation. Selectins interact with carbohydrate moieties such as sialyl-Lewis X and sialyl-Lewis A, and possibly other ligands, including integrins and glycolipids. The full extent of physiologic selectin ligands has not been determined, but it is expected that the list will include molecules expressed on leukocytes and

endothelium because selectins are important for leukocyte-leukocyte and leukocyte-endothelium interactions.

The role of selectins is twofold: to mediate cell-cell interaction, and to contribute to cell activation by intracytoplasmic signaling. As with integrins, selectins are critical to the initial tethering and rolling of leukocytes along activated endothelium prior to extravasation. After binding a soluble form of the mucin-like glycoprotein GlyCAM-1 (a high endothelial venule product), L-selectin is able to mediate the activation of β_1 integrins and their adhesion to fibronectin. P- and E-selectin may also serve as signal-transducing receptor molecules because a rise in intracellular free Ca^{2+} within leukocytes adhering to endothelial cells is linked to these selectin molecules (Huang, 1993). The most frequently used quantitative assays for soluble plasma or serum selectins are sandwich immunoassays (Mousa, 2008).

LEUKOCYTE EXTRAVASATION

Expression of integrin molecules is dependent on cell activation and may be upregulated or downregulated in response to specific cues from the external environment, including local cytokine stimulation or immune interaction. Leukocyte integrin interaction with endothelial cells is critical to the evolution of inflammatory and immune responses. In addition,

TABLE 47-12

Major Integrins and Their Ligands

Integrin	Name	Ligands

homing of lymphoid cells to their sites of residence and intravascular spread of metastases involve similar endothelial interactions mediated through surface integrins and another set of cell adhesion molecules, the selectins and their ligands.

Extravasation of leukocytes occurs during cell homing, as with trafficking of $\gamma\delta$ T cells to Peyer's patches, and as part of the inflammatory response. Both processes involve similar steps and the use of different adhesion molecules. In inflammation, the process begins with local release of proinflammatory cytokines such as TNF, IL-1, and IFN- γ , which activate the local endothelium to increase surface expression of adhesion molecules, including members of the immunoglobulin superfamily, vascular cell adhesion molecule (VCAM)-1 and ICAM-1. In addition, endothelial cells release chemotactic agents, including IL-8, forming a surface-bound and soluble chemotactic gradient recognizable by trans-migrating inflammatory cells, which localize them to the inflammatory focus.

This process for white cells (Fig. 47-4) involves (1) tethering of the passing leukocyte to the endothelial surface mainly by endothelial selectins (E- and P-selectin) and their leukocyte ligand sialyl-Lewis X-modified glycoprotein; and (2) leukocyte rolling, in which, through rapid sequential surface expression of mainly leukocyte VLA-4 and $\alpha 4\beta 7$ integrin, the shear force provided by the bloodstream rolls leukocytes along the endothelial surface, thereby bringing these integrins into contact with their endothelial ligands, VCAM-1 and MAdCAM-1, respectively. In the case of neutrophils, rolling is mediated by selectins alone. As they roll, leukocyte cell adhesion molecules trigger biochemical events, leading to (3) leukocyte

Figure 47-4 Adhesion molecules on the surfaces of leukocytes and activated endothelial cells guide the movement of white blood cells from the bloodstream to foci of tissue inflammation. Direction is provided by a chemotactic gradient. ICAM, Intracellular adhesion molecule; IL, interleukin; TNF, tumor necrosis factor.

activation and conversion of its integrins to an activated state of increased avidity. This leads to increased leukocyte–endothelial cell adhesion, and eventually to (4) arrest of leukocyte rolling, and (5) leukocyte transmigration of the endothelium with the assistance of the homotypic adhesion molecule CD31 expressed on both white cells and the endothelium, while following a chemotactic gradient. It is still a matter of debate whether leukocytes pass directly through individual endothelial cells or merely pass between adjacent endothelial cells. Endothelial cell retraction early in the inflammatory response would seem to make movement between endothelial cells easier. Once through the endothelium, integrin-mediated cell migration through the extracellular matrix along a chemotactic gradient completes the leukocyte journey to a focus of inflammation.

Deficiency states for $\beta 2$ integrins (leukocyte adhesion deficiency type I) and congenital defects in the expression of selectins and their ligands demonstrate the indispensable role that these receptors play in producing the inflammatory response and in lymphocyte trafficking. In these patients, neutrophils are unable to exit the bloodstream and migrate to sites of

inflammation or infection, creating in effect a state of immune suppression with increased susceptibility to bacterial infection and a paradoxical peripheral neutrophilia (Bullard, 1996). The events surrounding septic shock, thrombosis, reperfusion injury, and metastases also require integrin and selectin activity. This knowledge has led to the therapeutic use of monoclonal antibodies, soluble adhesion molecule ligands, and other interventions, including antisense oligonucleotides, to overcome adhesion molecule–mediated disease (Buckley, 1996; Gonzalez-Amaro, 1998).

PERSPECTIVES

Complement, cytokines, and adhesion molecules all play a role in disease states. In recognition of this, therapies have been designed to directly trigger or block various cytokine, cell adhesion molecules, and complement components as part of the treatment of disease. Clinical laboratory detection and measurement of native proteins and the clinically administered therapeutic agent continues to become more commonplace.

KEY POINTS

- Major histocompatibility complex (MHC) class I molecules include HLA-A, HLA-B, and HLA-C; MHC class II molecules include HLA-DR, HLA-DQ, and HLA-DP; these are the classic “transplantation” antigens.
- MHC genes are closely linked and segregate en bloc to offspring.
- Characterization of human leukocyte antigen (HLA) alleles and molecules has been combined with clinical protocols to maximize donor and recipient compatibility, and to minimize the impact of the immune response on the transplanted organ. Advances in this area have contributed to the development of transplantation as a successful treatment modality for the replacement of diseased tissue.
- HLA matching usually includes evaluation of at least three loci: HLA-A, HLA-B, and HLA-DR. Individuals matched, at whatever resolution, for all three loci are termed 6/6 matches or 0 mismatches.

- Patients can be sensitized to specific foreign HLA molecules through transfusion, pregnancy, or prior transplantation. Assessment of compatibility between the recipient and the possible donor includes testing for this sensitization.
- Several methods are available for HLA typing, including serologic and cellular typing approaches and DNA-based typing. DNA-based typing has significant advantages over the other methods.

Survival depends on the ability of the immune system to recognize and respond to a multitude of foreign substances (antigens). Although this defense mechanism is basic to survival in a hostile world of microorganisms, this same defense system has a negative impact when tissue is transplanted from one individual to another, or when malfunctioning triggers autoaggressive reactions. The MHC genes encode proteins that are essential to immune recognition: the class I and class II molecules (Fig. 48-1).

Figure 48-1 Map of the major histocompatibility complex (MHC) gene on chromosome 6. HLA-DPB2 in the human leukocyte antigen (HLA) class II region is located closest to the centromere. HLA-F is the most telomeric. The region between HLA-DRA and HLA-B is not shown. (With permission from the Anthony Nolan Bone Marrow Trust, Available at: www.anthonynolan.org.uk/HIG.)

Figure 48-2 Model of the molecular interactions involved in antigen recognition.

In the human, class I molecules include HLA-A, HLA-B, and HLA-C, and class II molecules include HLA-DR, HLA-DQ, and HLA-DP. These molecules are the classical transplantation antigens. Other molecules encoded within the MHC are the class III molecules (see Chapter 49). These include the MHC-linked complement components (C2, C4, and Bf), 21-hydroxylase (CYP21), heat-shock protein (HSP)70, and tumor necrosis factor (TNF).

During an infection, the invading microorganism may infect or be engulfed by cells, and then may be degraded into peptide fragments. Inside the cell, MHC class I or class II molecules bind antigenic fragments derived from the microorganism. Once antigenic fragments have bound to the MHC molecules and have translocated to the cell surface, receptors on T lymphocytes interact with the complex of antigen fragment-MHC molecule, triggering humoral and cellular immune responses (Fig. 48-2).

T cell specific cell surface molecules, CD4 and CD8, act to strengthen this cellular interaction and to transmit activation signals. Other cell surface molecules act to increase the affinity of cellular interactions (e.g., CD2 and its ligand, CD58 [LFA-3], or CD11a/CD18 [LFA-1] and its ligand, CD54 [ICAM-1]) and to transmit costimulatory signals (e.g., CD28 and its ligands, CD80/CD86 [B7], or CD40 and its ligand, CD154). Polymorphism in genes that specify MHC class I and class II molecules affects the antigen-binding specificity of the molecules, resulting in differences in immune responses among members of the species. The same pattern of interactions between a cell bearing an MHC class I or class II antigen fragment complex and a T lymphocyte occurs not only in recognition of invading pathogens but also in recognition of foreign class I and class II molecules (alloantigens) and in recognition of self-antigens (autoantigens) (see Chapter 49).

Because donor MHC class I and class II molecules are recognized by the recipient's immune system as foreign antigens, it is beneficial to ensure that donor and recipient are histo- (i.e., tissue) compatible (i.e., HLA-matched). Class I and class II molecules have great allelic diversity within a population, so ensuring compatibility between donor and recipient is often a difficult task that requires collaboration among medical staff, clinical HLA-typing personnel, and donor tissue coordinators (e.g., large organ-sharing networks, registries or banks of hematopoietic progenitor cell donors).

The genetics, structure, function, nomenclature, and techniques of detection of human MHC gene products—HLA-A, -B, and -C (class I) and HLA-DR, -DQ, and -DP (class II)—are discussed in this chapter. Also discussed is the importance of HLA matching for transplantation. In addition to references listed at the end of the chapter, Table 48-1 presents helpful websites that provide both reference material and updates of clinical outcomes.

GENETICS OF THE MAJOR HISTOCOMPATIBILITY COMPLEX

BASIC GENETICS

Mendel's first law, the law of segregation, is based on the principle that hereditary traits are determined by factors that are distributed to progeny. In any one individual, these factors, or genes as they are now called, are present on chromosomes (see Chapter 68). Each gene may have multiple forms (i.e., alleles). Because humans are diploid, two genes are included per pair of homologous chromosomes. In meiosis, the chromosomes segregate randomly during formation of the gametes (ova or sperm) so that only one of each pair of chromosomes (i.e., a haploid number) is transmitted by any given gamete. The double, or diploid, number of chromosomes is restored when the male and female gamete fuse to form the zygote.

Thus, for a trait determined by one gene, there will always be four possible genetic combinations in the offspring, each with equal probability of occurrence. These laws of segregation and random assortment apply to genes of the MHC system. Following are definitions for genetic terms that will be used in this chapter (Crow, 1976; www.nhgri.nih.gov):

Gene: Unit factor of inheritance

Chromosome: Carrier of the unit factors of inheritance

Locus: Position of a gene on a chromosome

Allele: An alternative form of a gene at a single locus

Homozygous: Having identical alleles at a locus, one on each chromosome

Heterozygous: Having different alleles at a locus, one on each chromosome

Codominance: The state in which the allele at each locus expresses its characteristic effect equally in the heterozygote

Genotype: Genetic composition of an organism or individual

Phenotype: Observable characteristics produced by the genes

Polymorphic: Having two or more common distinct genotypes maintained in a population

Homologous chromosomes: The two members of a chromosome pair that have corresponding gene loci, one derived from each parent

Crossing over: Exchange of segments between homologous chromosomes; also termed recombination.

Allo-(antigen, graft): Refers to antigenic differences between individuals of a single species

Auto-(antigen, graft): Refers to tissue or antigens of the same individual (i.e., self)

COMPOSITION OF THE MHC

The major histocompatibility gene complex in humans is located on the short arm of chromosome 6 (i.e., 6p21). It spans 3600 kb (kilobases) and includes 224 identified gene loci, of which 128 are predicted to be expressed. Approximately 40% of the expressed genes are estimated to have an immune system function (Aguado, 1999). HLA genes of the MHC are located in six subregions: HLA-A, HLA-C, HLA-B, HLA-DR, HLA-DQ, and HLA-DP (see Fig. 48-1). Each subregion encodes a minimum of one cell surface glycoprotein. With only one exception, the HLA genes are highly polymorphic, that is, each HLA gene has multiple alleles in the human population. Indeed, the HLA genes are the most polymorphic loci known in man (Parham, 1995; Table 48-2; www.anthonynolan.org.uk/hig). Because HLA genes specify molecules that play an important role in the immune response, polymorphism is believed to be essential to survival of the species and to be maintained in the population by selection; the introduction of molecular typing

HLA, Human leukocyte antigen; WHO, World Health Organization.

[†]Each column of the table is independent. Numbers in parentheses indicate the broad serologic specificity. The serologic type may be listed without the broad specificity. For example, both A23(9) and A23 are correct designations.

[‡]HLA-A alleles specify HLA-A antigens. The antigen A1 is specified by either A*0101 or A*0102 or A*0103 alleles. A*0104N is a null or nonexpressed allele.

[§]HLA-DQA1 and HLA-DQB1 alleles specify HLA-DQ antigens. The antigen DQ5 (1) is specified by several different DQA1 and DQB1 combinations, including (1) DQA1*0101 and DQB1*0501 and (2) DQA1*0101 and DQB1*0502 alleles. In the past, serologic split designations were given to specificities that appeared to identify the antigen specified by a single HLA allele (e.g., A2 splits A203, A210; B7 split B703; B39 splits B3901 and B3902). It is now recognized that other alleles may also encode antigens that carry these serologic specificities, and the WHO Nomenclature Committee has recommended that these splits be discontinued.

techniques in the 1980s allowed determination of the variability of the MHC region. As of December 2010 (<http://hla.alleles.org/nomenclature/stats.html>), more than 4383 class I and more than 1291 class II alleles had been identified (Fig. 48-3; http://hla.alleles.org/nomenclature/nomenclature_2009.html). In this newly found genetic variation, the HLA-B locus presents the greatest variability with 1927 alleles, and the HLA-C locus has the least with 960 alleles. In contrast, for class II alleles, the most variable locus is the DRB1 with 924 alleles.

LOCALIZATION OF MHC GENES

The genes of the MHC were assigned to the short arm of chromosome 6 (6p) on the basis of cytogenetic studies of aberrant chromosomes (i.e., chromosomes that have undergone a translocation). The map order and

Figure 48-3 Numbers of class I and II alleles discovered from 1987–2009. The increase in the number of discovered alleles during this period has been made possible by the introduction of DNA typing methods; class I alleles include HLA-A, -B, and -Cw, and class II alleles include HLA-DRB1, -DQB1, -DQA1 and -DPB1. (Data from Anthony Nolan Research Institute. Available at: http://hla.alleles.org/nomenclature/nomenclature_2009.html.)

positioning of the MHC genes were determined by meiotic linkage analyses (i.e., studies of crossing over in families) and molecular biology techniques, including gene cloning, DNA sequencing, and pulsed field gel electrophoresis. The latter technique detects the presence of genes on single long fragments of DNA. The map order of genes within the MHC is HLA-A, -C, -B, -DR, -DQ, -DP, with HLA-A being distal to the centromere (see Fig. 48-1).

INHERITANCE

The MHC genes are closely linked, that is, they segregate en bloc to the offspring. The complex of linked genes that resides on one of the pair of homologous chromosomes and that segregates en bloc to the offspring is termed a haplotype. Each individual inherits two MHC haplotypes—one from each parent—and thus has two alleles for each of the genes. These alleles are codominantly expressed. The inheritance of the MHC genes follows the rules of segregation set down by Mendel. Within a family, each child inherits one MHC haplotype from the mother and one from the father. By convention, the paternal haplotypes are designated a and b, and the maternal haplotypes c and d. Thus, there are four possible MHC genotypes in the offspring: ac, ad, bc, and bd. Because the chance of inheriting a given haplotype is random, the probability of occurrence of any one of the four genotypes is one in four for each mating. In a family with five children, at least two of the children will be HLA-identical (assuming no crossing over). Although the MHC genes are closely linked, families have been reported in which a crossover has occurred. The frequency of crossing over between two linked genes was thought to be a measure of the distance separating the genes; however, molecular data have suggested the existence of recombination “hot” spots in the intervening DNA that can increase or decrease the likelihood of recombination during meiosis (Uematsu, 1988).

LINKAGE DISEQUILIBRIUM

The observation that alleles at different genetic loci occur in the population on the same haplotype significantly more frequently than would be expected on the basis of chance alone is called linkage disequilibrium. The expected frequency of two alleles (f_1 , f_2) is the product of the gene frequency of each allele in that population ($f_{\text{expected}} = f_1 \times f_2$). The observed frequency is determined from family studies within the same population. Linkage disequilibrium is a hallmark of the human MHC and extends from HLA-A through HLA-DQ. The best known example of linkage disequilibrium is the A1,Cw7,B8,DR17(3),DR52,DQ2 haplotype in Caucasians, which is observed approximately four times more frequently than expected. The significance of linkage disequilibrium as it applies to immune competence and disease is discussed in Chapter 49 under Extended Haplotypes.

Growth of NMDP Donor Registry

Figure 48-4 More than 7 million donors for hematopoietic stem cell and bone marrow transplantation were registered by the National Marrow Donor Program in 2008. (Data from the National Marrow Donor Program. Available at: http://www.marrow.org/PHYSICIAN/images/NMDP_donor_growth_a.gif.)

Growth of NMDP Cord Blood Registry

Figure 48-5 The number of umbilical cord units has increased in the last decade, primarily for the treatment of blood malignancies in pediatric patients; more than one HLA mismatch and more than one cord unit can be used in umbilical cord transplantation. (Data from the National Marrow Donor Program. Available at: http://www.marrow.org/PHYSICIAN/images/NMDP_donor_growth_a.gif.)

ETHNIC VARIATION

Accumulated data from the study of the world population groups (Dausset, 1973; Imanishi, 1992; Cadavid, 1997; Bugawan, 1999) demonstrate that the frequencies of HLA alleles differ significantly among ethnic population groups. MHC haplotypes and linkage disequilibrium of alleles also differ. These observations must be taken into account when unrelated allograft hematopoietic progenitor cell donor registries and banks such as the U.S. National Marrow Donor Program (NMDP) are established (Perkins, 1994). Both allele and haplotype frequencies dictate the number of volunteers required to find an HLA-matched unrelated donor for any patient. Some patients (e.g., those with rare or unusual types) cannot find closely matched unrelated donors from among the more than 7 million volunteers listed in all donor registries worldwide (Fig. 48-4). Currently, patients are more likely to find a match because the number of donors has increased, as has the use of umbilical cord blood units for transplantation (Fig. 48-5). It appears that cord blood transplantation may be more tolerant of HLA mismatches; this may be a result of reexposure to noninherited maternal antigens (NIMAs) found in the graft (Van Rood, 2009). Improvement in methods used for engraftment of progenitor cells from partially HLA-mismatched donors may allow transplantation in patients for whom close matches cannot be found (see Chapter 38).

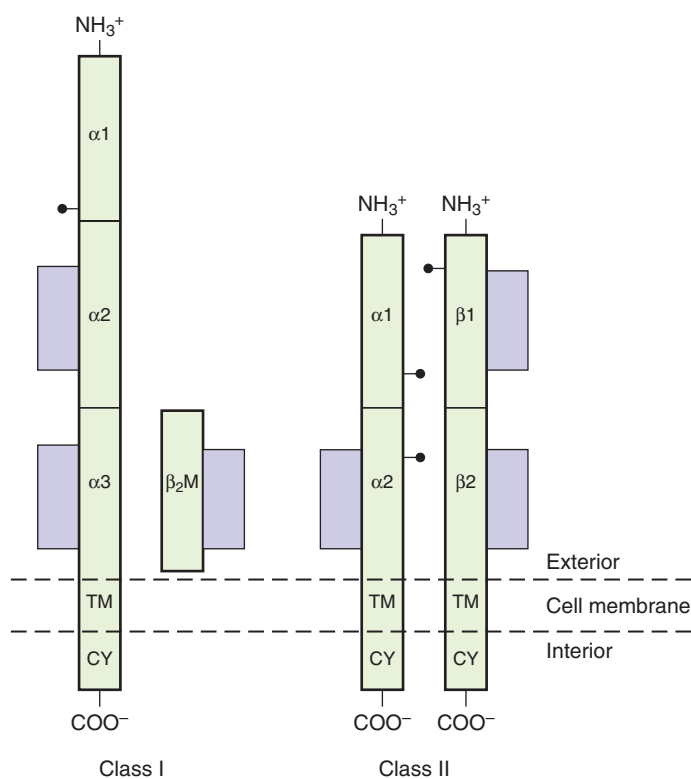

Figure 48-6 A schematic model of the structure of class I and class II molecules.

CLASS I MOLECULES—HLA-A, HLA-B, HLA-C SUBREGIONS

The HLA-A and -B molecules were the first MHC molecules to be described in humans (Dausset, 1981; van Rood, 1993). Because these molecules were defined by antibody responses to white blood cells (WBCs), they were called human leukocyte **antigens**. Leukocyte antibodies were observed in humans as early as the 1920s, but it was not until the 1950s that a systematic study began. In 1952, Dausset convincingly demonstrated the existence of leukocyte antibodies (leukoagglutinins). Because these leukoagglutinins did not react with leukocytes from the antibody producer but did react with a percentage of leukocytes from red cell group O unrelated individuals, he suggested that leukoagglutinins were alloantibodies. Shortly thereafter, Payne (1964) reported that sera from patients who had febrile nonhemolytic blood transfusion reactions frequently contained leukoagglutinins that demonstrated allospecificity. In 1958, Dausset described the first HLA alloantigen MAC (now HLA-A2 + HLA-28) and showed it to be genetically determined.

Originally, leukocyte specificities were thought to be the products of a single locus. A two-locus model, each locus with multiple alleles, was established through HLA studies in families by the identification of recombinational events that separated the two allelic series. These two allelic series were called the first, or LA (now HLA-A), and the second, or four, series (now HLA-B). These names were derived from descriptions of the LA 1, 2, 3 allelic series by Payne in 1967, and of the 4a, 4b allelic series by van Rood in 1969. A third locus was first proposed in 1970; however, it was not confirmed until 1975, when a family with a recombination between HLA-B and the new locus was identified. This third locus was designated HLA-C following the 1975 International Histocompatibility Workshop. Dausset (1981) was awarded the Nobel Prize for Medicine in 1980 for his original work on the human HLA system.

STRUCTURE OF CLASS I MOLECULES

The classical class I molecules, termed HLA-A, HLA-B, and HLA-C in the human, are heterodimers consisting of a transmembrane glycosylated polypeptide (heavy chain, 44 kDa) noncovalently associated with β 2-microglobulin (12 kDa) (Fig. 48-6) (Bjorkman, 1990). The heavy chain of the class I molecule spans the cell membrane and is oriented with its

amino-terminus on the outside of the cell. β 2-Microglobulin is associated with the extracellular region of the heavy chain and is necessary for cell surface expression. The extracellular region of the class I heavy chain is divided into three domains designated α 1, α 2, and α 3, each consisting of about 90 amino acid residues. The amino-terminal α 1 domain contains a glycosylation site at the asparagine residue in position 86. The transmembrane segment of approximately 24 amino acids is mostly hydrophobic, whereas the intracellular carboxy-terminal segment of the molecule consists mainly of hydrophilic residues with a cluster of basic residues adjacent to the cytoplasmic surface of the cell membrane.

Polymorphism of class I molecules (see Table 48-2 and Figure 48-3) (Bodmer, 1997, 1999) is defined by the use of (1) class I specific antibodies (alloantisera and monoclonal antibodies) that bind to the HLA molecules; (2) cytotoxic T lymphocytes (CTLs) that recognize and kill in response to stimulation by foreign or allogeneic class I molecules in vitro; (3) isoelectric focusing of isolated class I molecules; (4) polymerase chain reaction (PCR)-based DNA typing of class I alleles; and (5) nucleotide sequencing of class I alleles. Most of the class I polymorphism arises from amino acid sequence differences clustered in the α 1 and α 2 domains of the heavy chain. The α 3 domain is highly conserved among HLA class I molecules.

Fresh insights into the structure of the HLA molecule came when the three-dimensional structure of the class I molecule was defined using X-ray crystallography (Bjorkman, 1987). The structure of the extracellular portion is shown in Figure 48-7. The molecule consists of two pairs of structurally similar domains: α 1 has the same tertiary conformation as α 2, and α 3- and β 2-microglobulin have similar tertiary conformations. The α 3- and β 2-microglobulin domains are each composed of two antiparallel β -pleated sheets—one with four strands and one with three strands, connected by a disulfide bond. The α 3 and α 2 domains interact with one another through these β -pleated sheets, and their structure closely resembles that described for an immunoglobulin constant region domain. The α 1 and α 2 domains are paired to form an eight-strand β -pleated sheet. This sheet is topped by two α -helices forming a groove at the top of the molecule. This groove is the site for binding of antigenic peptide fragments by the class I molecule (Fig. 48-7). The sides and bottom of the groove are formed by side chains of the amino acids that constitute the helices and β -pleated sheets. Many of the amino acids that line this groove are polymorphic, creating allele-specific differences in antigen binding specificity among the different class I allelic products (Stern, 1994). Other residues in the helical regions of the groove interact with the T cell receptor during recognition of the class I antigenic fragment complex by a T lymphocyte (see Fig. 48-2).

ORGANIZATION OF CLASS I GENES

The HLA heavy chains are encoded within the MHC on chromosome 6 (see Fig. 48-1) (Shiina, 1999) and are highly polymorphic, whereas β 2-microglobulin is encoded on chromosome 15 and is not known to be polymorphic in humans. The typical class I gene is encoded by eight exons. The first exon encodes the 5' untranslated region and a hydrophobic leader peptide. Exons 2–4 encode the three extracellular domains; exon 5 encodes the transmembrane region. The sixth and seventh exons encode the cytoplasmic region, and the eighth exon encodes the 3' untranslated region, including the poly(A) addition site. Intervening sequences (termed introns) between the exons are transcribed into RNA but are removed during messenger RNA (mRNA) splicing.

REGULATION OF CLASS I GENE EXPRESSION

HLA class I molecules are expressed as transmembrane glycoproteins on the surface of many cell types. However, the level of surface expression can vary extensively (Singer, 1990). The resting level of class I molecules is highest on β 2-microglobulin lymphoid cells, and HLA-C expression is 10 times less than that of HLA-A or HLA-B (Le Bouteiller, 1994); this is a result of inefficient association and a mutated cis-regulatory element of transcriptional control found in region I of the HLA-C promoter (enhancer A) that reduces its expression (Neeffjes, 1988). Differential expression of HLA molecules appears to reflect the level and antigenic specificity of the allogeneic sensitization seen in patients awaiting kidney transplantation, because these patients are subjected to multiple random blood transfusions while on dialysis; more kidneys are rejected because of the presence of HLA-A or -B or both A and B specific antibody, and far fewer are rejected by only HLA-Cw specific antibodies; class I molecules are undetectable on the membranes of certain other cell types such as brain cells, muscle

Figure 48-7 Three-dimensional model of the extracellular portion of a class I molecule. (With permission from Bjorkman PJ, Saper MA, Samraoui B, et al. *Structure of the human class I histocompatibility antigen, HLA-A2*. *Nature* 1987;329:506.)

cells, and sperm cells. Sequence elements located upstream of class I genes bind regulatory factors that control the cell surface expression of class I molecules. During an immune response, the cell surface expression of class I genes can be upregulated by binding of cytokine (e.g., interferon- γ , and TNF) to upstream regulatory elements. Tumors and certain viruses (e.g., human immunodeficiency virus) can suppress class I expression (Brodsky, 1999).

FUNCTION OF CLASS I MOLECULES

The HLA-A, -B, and -C molecules play key roles in an immune response. First, in the adaptive immune response, class I molecules bind peptides derived from proteins degraded or synthesized in the cytosol and display them on the cell surface for perusal by the antigen receptors on T lymphocytes (see Chapter 45). Presentation of antigen by class I molecules allows T cells to detect and mount a cytotoxic response to foreign material (e.g., a virus, abnormal proteins from a malignant cell). In the cytosol, intracellular antigens (including self-proteins and viral or abnormal proteins) are broken down into peptide fragments (Rock, 1999). These peptide fragments are transported to the endoplasmic reticulum, where they bind to the groove at the top of newly synthesized class I molecules and then are carried to the cell surface (Hansen, 1997b; Pamer, 1998) (see Fig. 48-2). Four genes, located in the class II region of the MHC (see Figs. 48-1 and 48-8), are involved in this process. Two of these genes (*LMP2* and *LMP7*) encode components of the proteasome complex, a macromolecular structure that degrades proteins within the cytosol (Tanaka, 1997). The other two genes (*TAP1* and *TAP2*) encode components of peptide transporters that move peptides from the cytosol into the endoplasmic reticulum (Momburg, 1998). CD8⁺ CTLs recognize the processed peptide in conjunction with the class I molecule (Jorgensen, 1992). In the experimental system used to dissect this mechanism, CTLs were generated by in vitro

stimulation with virally infected autologous cells. Recognition and lysis of the target cell were specific for the priming virus strain. Recognition also was affected by allelic polymorphism of class I molecules because only virally infected target cells sharing the appropriate class I allelic product(s) with the responder were lysed (Zinkernagel, 1997a, 1997b). The latter requirement is termed **MHC restriction**. Zinkernagel and his collaborator Doherty were awarded the Nobel Prize for Medicine in 1996 in recognition of the importance of the concept of MHC restriction to immunology.

Second, surface expression of class I molecules has a protective function in the innate immune response by preventing target cell lysis effected by natural killer (NK) cells. Unlike CTLs, NK cells do not require activation through the recognition of peptide bound to the class I molecule but can lyse and destroy target cells lacking classical HLA class I molecule expression on the cell surface. Through this innate mechanism, NK cells play an important role in surveillance against viruses and tumor cells that down-regulate expression of the class I molecule to avoid recognition by CTLs (Lanier, 1998; Long, 1999).

There are two groups of NK receptors: (1) the C-type lectin receptor CD94/NKG2, whose genes reside on chromosome 12, and (2) the killer cell immunoglobulin-like receptors (KIRs) encoded by genes on chromosome 19. NK cell function appears to be regulated by a balance between positive signaling receptors that initiate and inhibitory receptors that suppress cell activation. Both groups of receptors recognize HLA class I ligands. For example, the KIR2D receptors differentiate between HLA-C ligands based on the presence of specific amino acid residues at codons 77 and 80 (i.e., asn77lys80 vs. ser77asn80). Another NK receptor, KIR3D, recognizes the HLA-Bw4/Bw6 polymorphism. A third NK receptor, CD94/NKG2, recognizes the HLA-E molecule complexed with the HLA leader peptide from some of the allelic products of HLA-A, -B, -C, and -G molecules (Brooks, 1999).

NK cells can specifically recognize and lyse allogeneic cells that do not express the specific class I molecules expressed by the effector cell (i.e., “missing self”) (Valiante, 1997). This could occur even in apparently HLA-matched transplant pairs where one member of the pair is homozygous and the other is heterozygous (e.g., donor: Bw4,Bw6; recipient: Bw6). Thus Bw4 specific NK cells from the donor might lyse cells without Bw4 from the recipient in a hematopoietic progenitor cell graft. This response may be unidirectional in some settings. In the example, the donor does not lack any HLA molecule present in the recipient; thus, the recipient NK cells will not detect any missing self. Because NK cells are relatively radioresistant and make up a subpopulation of about 10%–15% of peripheral blood lymphocytes, the NK response could be substantial; however, the extent of the role of NK activity in affecting transplant outcome is not known at present (Ruggeri, 1999).

OTHER CLASS I GENES

As many as 20 additional nonclassical or class Ib genes have been identified within the class I region of chromosome 6p by gene cloning (Aguado, 1999). Many of these are pseudogenes; however, several encode and express class I-like mRNA and/or molecules HLA-E, HLA-F, and HLA-G. These molecules may be key mediators of both adaptive and innate immune responses (O’Callaghan, 1998). Their genes are homologous to classical class I genes in structure, and the polypeptides encoded by these loci also associate with β 2-microglobulin. However, just as a high level of allelic polymorphism is a hallmark of the HLA-A, HLA-B, and HLA-C loci, a low level of polymorphism of the HLA-E, HLA-F, and HLA-G loci is a defining feature of these genes. In addition, by comparison with classical class I molecules, the cell surface expression of nonclassical class I molecules is low, and the distribution of these class Ib molecules on specific cell types varies.

HLA-G

HLA-G is expressed principally on extravillous cytotrophoblast cells at the fetal/maternal interface, where it is thought to play a role in maternofetal tolerance (Le Bouteiller, 1999). HLA-G, as a ligand for at least three NK and other cell inhibitory receptors, protects the invading placental tissue from the cytolytic action of NK cells. Although HLA-G has the capability to bind and present processed antigen (i.e., peptides) to T cells, the diversity of peptides bound by HLA-G appears to be less than the diversity of peptides bound by classical class I molecules. Regulation of expression of HLA-G also differs from that of classical class I genes, as the gene contains no interferon response signal; thus, it is not interferon-inducible. It has been hypothesized that the soluble forms may act as

specific immunosuppressors during pregnancy (Le Bouteiller, 1999). Recent evidence supports this hypothesis. HLA-G transcripts are present in great numbers in placental extravillous membranes in the first trimester, but at term, transcript numbers decline sharply, in keeping with the theory that HLA-G provides protection for the allogeneic embryo from maternal NK cell surveillance (Agrawal, 2003). This putative role raises the possibility that HLA-G may play a role in tolerance for transplanted tissues. Along these lines, it is interesting to note that liver–kidney transplant recipients with high concentrations of HLA-G in their sera had low numbers of acute rejection episodes and therefore may require less immunosuppressive therapy (Creput, 2003).

HLA-E

HLA-E may play a role in protecting a target cell from NK cell–mediated lysis. HLA-E molecules bind a set of almost identical hydrophobic peptides derived from the leader sequences of the classical class I and HLA-G heavy chains. HLA-E displays these bound peptides at the cell surface for recognition by NK cells, providing a check for the integrity of the antigen-presenting pathway (Lee, 1998a, 1998b; O’Callaghan, 1998). Skin grafting in a transgenic mouse model suggests that HLA-E may be recognized as a transplantation antigen (Pacasova, 1999). Recent studies suggest that host NK cells may be able to recognize HLA-E on allogeneic cells and possibly tolerate it, even when it is bound to donor peptides. With this finding comes the potential for exploiting this tolerance in pursuit of preventing NK cell–mediated graft rejection and graft-versus-host disease (GVHD) (Matsunami, 2002).

HLA-F

The role of HLA-F is unknown. Computer modeling predicts that certain amino acid residues of HLA-F could contribute to a putative peptide-binding groove, consistent with a role in antigen presentation by HLA-F (O’Callaghan, 1998). To date, HLA-F appears to be normally expressed only on the surfaces of extravillous trophoblasts that have invaded the maternal decidua, and has also been found on the surfaces of lymphoblastoid cell lines infected with Epstein-Barr virus (Ishitani, 2003).

CLASS II MOLECULES—HLA-DR, HLA-DQ, HLA-DP SUBREGIONS

The class II molecules in humans were first recognized by their ability to stimulate allogeneic T cells in the mixed leukocyte culture (MLC). During the 1975 International Histocompatibility Workshop, the MLC was used to define the HLA-D allelic series (Thorsby, 1975). Because MLCs required 7 days before results could be obtained, rapid serologic detection of HLA-D was sought. In 1975, it was determined that alloantisera contained antibodies reactive with molecules closely associated with the specificities previously identified as HLA-D by cellular techniques (Dausset, 1981). Following the 1977 International Histocompatibility Workshop, these serologic specificities were termed DR, for D-related specificities, because HLA-D and HLA-DR were observed to be associated but not identical to each other. Serologic testing coupled with genetic and immunochemical studies identified additional class II molecules: DR52, DR53, DR51, and DQ. Cellular techniques identified still another class II molecule in the late 1970s (Shaw, 1981). This molecule (now termed HLA-DP) was initially described as a secondary B cell antigen (SB) because it was usually weak or undetectable in a primary MLC and required secondary phase stimulation in culture for detection. Subsequently, the DNA coding sequences and locations of these genes within the MHC were further characterized using molecular biology techniques (Beck, 1999).

STRUCTURE OF CLASS II MOLECULES

The class II HLA-DR, -DQ, and -DP molecules are heterodimers consisting of two noncovalently associated transmembrane glycoproteins: an α chain (33–35 kDa) and a β chain (26–28 kDa) (see Fig. 47-3) (Gorga, 1992). Both polypeptide chains span the cell membrane and are oriented with their amino-termini on the outside of the cell. The extracellular regions of the α and β polypeptides are each divided into two domains, designated $\alpha 1$ and $\alpha 2$ and $\beta 1$ and $\beta 2$, and each domain consists of approximately 90 amino acid residues. The α chain has two carbohydrate moieties, one high-mannose and one complex-type glycan, at amino acids 78 and 118, respectively. β chains have one complex-type oligosaccharide at amino acid 19. The amino-terminal $\alpha 1$ and $\beta 1$ domains of α and β chains contain the polymorphic residues, while the membrane proximal $\alpha 2$ and $\beta 2$

domains are highly conserved and are homologous to immunoglobulin constant region domains. A region of approximately 12 amino acids in length connects the second extracellular domain to the hydrophobic transmembrane region (23 amino acids) and a small intracytoplasmic domain (8–15 amino acids).

Based on crystallography, the class II molecule is similar in structure to the class I molecule (Brown, 1993) (Fig. 48-7). In the class II molecule, the $\alpha 1$ and $\beta 1$ domains of the α and β chains form an eight-stranded β -pleated sheet topped by two α helices to form the antigen-binding groove at the top of the molecule. The $\alpha 2$ and $\beta 2$ domains each form two antiparallel β -pleated sheets that support the groove at the top. As with class I, many of the amino acids that line the antigenic peptide-binding groove are polymorphic, creating differences in peptide-binding specificities for the different class II allelic products.

Similar to the class I molecules, the class II molecules are highly polymorphic (see Table 48-2 and Figure 48-3) (Bodmer, 1997, 1999; Marsh, 2002). Class II polymorphism is defined by (1) class II specific antibodies (alloantisera and monoclonal antibodies), which bind to class II molecules; (2) alloproliferative T cells that recognize and proliferate in response to foreign class II molecules in vitro; (3) two-dimensional gel electrophoresis of isolated class II molecules; (4) hybridization of restriction endonuclease digests of DNA-encoding class II genes using locus-specific probes (a technique that detects restriction fragment length polymorphism); (5) PCR-based DNA typing of class II alleles; and (6) nucleotide sequencing of class II genes. Most of the class II polymorphism arises from amino acid sequence differences localized in the $\alpha 1$ and $\beta 1$ domains of the two polypeptide chains.

ORGANIZATION OF CLASS II GENES

In contrast to the class I molecules, both the α and β chains of class II molecules are encoded within a 1100-kb section of the MHC region (see Figs. 48-1 and 48-8) (Beck, 1999). The class II region includes three subregions—DR, DQ, and DP—each of which encodes at least one expressed A (encoding an α chain) and B (encoding a β chain) gene. Sequence comparisons suggest that both class I and class II genes arose through a successive series of gene duplications during the evolution of this gene complex. The original duplication in the class II region most likely gave rise to primordial A and B genes. More recent gene duplications generated the DR, DQ, and DP subregions containing multiple genes.

A typical A gene contains five exons encoding (1) the 5′ untranslated region and leader sequence; (2) $\alpha 1$ domain; (3) $\alpha 2$ domain; (4) connecting peptide, transmembrane region, cytoplasmic tail, and a portion of the 3′ untranslated region; and (5) the remainder of the 3′ untranslated region, including the poly(A) addition signal. A typical β -chain gene is similar to the α -chain gene but has an extra exon for the cytoplasmic tail.

DR Subregion

The DR subregion encodes one or two DR molecules, depending on the haplotype (Bodmer, 1997, 1999). The subregion contains a single expressed DRA gene that is similar in different haplotypes, differing only in a single conservative amino acid substitution found in the cytoplasmic domain.

The most centromeric DRB gene, *DRB1* (Fig. 48-8), encodes a highly polymorphic β chain that, when associated with the α chain, exhibits serologic specificities DR1–DR18. This molecule is the predominant class II molecule on the cell surface, accounting for well over half of total cell surface class II molecules. There are multiple nucleic acids, hence amino acid sequence differences among *DRB1* alleles.

The second expressed DRB gene, present only in some class II haplotypes, is located between the *DRB1* locus and the *DRA* locus (see Fig. 48-8). In cells expressing DR alleles, *DRB1**03, *11, *12, *13, and *14, the second DRB gene is termed *DRB3*. (HLA nomenclature is described subsequently.) The *DRB3* gene is polymorphic, although at present the number of identified alleles is approximately 10 times less than the number of *DRB1* alleles. The *DRB3* product combined with the *DRA* product forms the DR molecule, which carries DR52 serologic specificity. In cells expressing *DRB1**04, *07, and *09 alleles, the second DRB gene is termed *DRB4*. The *DRB4* product combined with the *DRA* product forms the molecule that carries the serologic specificity DR53. Last, in cells expressing *DRB1**15 and *16 alleles, the second DRB gene is termed *DRB5*. This *DRB5* product combined with the *DRA* product carries DR51 serologic specificity. Haplotypes expressing *DRB1**01, *08, or *10 alleles do not usually carry a second expressed DRB locus. There are exceptions to these associations. For example, a haplotype carrying *DRB1**15 without a *DRB5* locus has been described (Wade, 1993).

Figure 48-8 Map of the class II region of the human major histocompatibility complex (MHC). Gene products encoded by each subregion are listed. Not all genes are included.

Figure 48-9 Model of the cis and trans associations of DQ α and DQ β chains.

DQ Subregion

One set of A and B genes, *DQA1* and *DQB1*, encode the DQ heterodimer that carries DQ1–9 serologic specificities (see Table 48-2 and Fig. 48-8) (Bodmer, 1997, 1999). DQ molecules represent approximately 15%–20% of the total class II molecules expressed on the cell surface. Because both *DQA1* and *DQB1* loci are polymorphic, and because the protein products can associate in trans as well as in cis, heterozygotes may potentially express four different DQ molecules on their cell surfaces (Fig. 48-9). Other DQ-like A and B genes in the DQ subregion such as *DQA2* and *DQB2* are very similar to the *DQA1* and *DQB1* genes; however, no functional protein products are expressed.

DP Subregion

The DP subregion contains two sets of A and B genes (see Fig. 48-8). One set, *DPA1* and *DPB1*, encodes the DP protein product; the other set is made up of pseudogenes. Both *DPA1* and *DPB1* genes are highly polymorphic (Bodmer, 1997, 1999). The level of DP expression on the cell surface is very low.

LINKAGE DISEQUILIBRIUM OF GENES IN THE CLASS II REGION

Specific combinations of DRB1/DRB3, DRB1/DRB4, DRB1/DRB5, and DQA1/DQB1 alleles are common. The DQA1/DQB1 combinations found may be controlled in part by the ability of α and β chains to pair

(Kwok, 1993). In addition, certain DR and DQ alleles are inherited together more frequently than expected, resulting in linkage disequilibrium in a population. The frequency of these combinations differs strikingly among different ethnic population groups. For example, both the DRB1*1101, DQB1*0501 (DR11[5], DQ5[1]) and the DRB1*0901, DQB1*0303 (DR9, DQ9[3]) haplotypes frequently are found in populations of direct African heritage, whereas these DR–DQ combinations are rarely found in populations of Caucasoid heritage. Crossing over between the DP loci and the DR/DQ loci is common. Thus, minimal linkage disequilibrium is noted between the DR/DQ and DP alleles. Lists of common DRB1/DQA1/DQB1 haplotypes have been published (Begovich, 1992; Imanishi, 1992).

REGULATION OF CLASS II GENE EXPRESSION

Class II molecules, HLA-DR, -DQ and -DP, are constitutively expressed on antigen-presenting cells (APCs) of the immune system, including monocytes, macrophages, dendritic cells, B lymphocytes, and neoplastic cells. HLA class II expression is highest for HLA-DR, intermediate for HLA-DQ, and lowest for HLA-DP (Glimcher, 1992; Guardiola, 1993); as with class I, differential expression of HLA class II molecules is reflected in the antigenic specificity of allosensitization seen in patients awaiting kidney transplantation; more kidneys are rejected because of the presence of an HLA-DR or -DQ specific antibody, and fewer are rejected because of an HLA-DP specific antibody. DNA sequences found upstream of the coding sequences in class II genes are critical to expression. Binding of proteins to these regions regulates the expression of class II genes. Alterations in the ability of DNA-binding proteins to interact with the 5' regulatory DNA sequences eliminating the expression of class II genes lead to an immunodeficiency called the **bare lymphocyte syndrome** (Kovats, 1994; Mach, 1996). Class II genes are inducible by interferon (IFN)- γ in many cell types (Glimcher, 1992; Mach, 1996), and expression may be affected by other cytokines (Guardiola, 1993). Expression of class II molecules in APCs may be modulated, particularly in dendritic cells, following antigen deposition and inflammation. The level of antigenic peptide class II complex expression and the presence of a costimulatory signal on the mature APC may play an important role in transplantation and in autoimmune disease (Nepom, 1991; Banchereau, 1998) (see Chapter 49).

FUNCTION OF CLASS II MOLECULES

Class II molecules act as antigen receptors in the immune response (see Fig. 48-2), binding antigenic peptide fragments processed from exogenous antigens such as bacteria. The exogenous antigens enter the cell through the endocytic pathway and are degraded into peptide fragments in late endosomes, where they encounter and bind to the newly assembled class II molecules (Watts, 1997). Binding of processed protein peptide fragments to the class II molecule is facilitated by two proteins encoded within the class II region of the MHC: DM and DO (see Fig. 48-8). Peptide binding is affected by polymorphic residues located in the groove of the class II molecule. The complex of antigenic fragment bound to the class II molecule is transported to the cell surface for display to and recognition by circulating T cells.

Antigen receptors on CD4⁺ T lymphocytes interact with the class II-antigenic fragment complex, triggering activation of the cell (Jorgensen, 1992). In the experimental system used to dissect this mechanism, effector T lymphocytes were stimulated in vitro with autologous APCs previously incubated with antigen. As observed for class I, recognition of the antigenic

fragment by the effector T cell is influenced by MHC allelic polymorphism. The effector T cell is specific for the priming antigenic peptide in conjunction with the particular class II allelic product that originally presented the antigen (MHC restriction) (Rosenthal, 1973).

Each T cell activated by recognition of the complex of antigen fragment bound to class II molecule can perform one or several functions (Paul, 1994). The CD4⁺ T cell can help B lymphocytes differentiate to antibody-producing plasma cells, or it can help other T lymphocytes differentiate to either cytotoxic cells or cells with suppressor function. In addition, the T cell itself can function either as a cytotoxic cell, directly killing cells with the appropriate target (i.e., cells expressing class II MHC molecules complexed with the specific antigen), or as a cell with suppressor function, causing a dampening of the immune response. T cells also produce a number of biologically important molecules (such as IFN- γ) that augment the immune response and increase the expression of MHC molecules on target cells. In addition, T cells produce growth factors such as interleukin (IL)-2. These growth factors affect a wide range of cells from hematopoietic progenitor cells to mature lymphocytes.

OTHER CLASS II GENES

At least four other class II genes—*DOA*, *DOB*, *DMA*, and *DMB*—have been described that express protein products (see Fig. 48-8). The proteins encoded by the *DMA* and *DMB* genes form the DM heterodimer. The proteins encoded by the *DOA* and *DOB* genes form the DO heterodimer. These gene products are not detected on the cell surface, but rather are expressed inside the cell, localized to specialized intracellular compartments where newly synthesized class II (DR, DQ, DP) molecules bind their antigenic peptides. The DM molecule regulates peptide binding to HLA-DR, -DQ, and -DP, serving both chaperone-like and editor-like functions (Morris, 1994) that favor the presentation of stably bound peptides. The DO molecule negatively regulates the function of DM (van Ham, 1997).

CHARACTERISTICS OF ANTIGENIC FRAGMENTS BOUND BY MHC CLASS I AND CLASS II MOLECULES

The function of class I and class II molecules as antigen-binding receptors is similar; however, the peptides they bind have different characteristics (Cresswell, 1994; Engelhard, 1994). Peptides derived from proteins synthesized *de novo* in the cell (endogenous antigens such as viral antigens) associate with class I molecules in the endoplasmic reticulum. In contrast, peptides from soluble and particulate antigens taken up by the cell into the endocytic pathway (exogenous antigens) bind with class II molecules in an endosomal compartment. Both class I and class II molecules can alternatively bind self-peptides found in these compartments. Self-peptides result from the normal degradation of cellular proteins. Some of these self-peptides are fragments of histocompatibility molecules themselves. Usually, the self-peptides bound to MHC molecules do not trigger T lymphocytes, as they are molecules to which the immune system of the individual is tolerant. However, these self-peptides may trigger immune responses, initiating a self-destructive process leading to autoimmunity (Nepom, 1991) (see Chapters 51, 52, and 53).

Peptide binding to MHC molecules occurs only when the peptide fragment is of a suitable length and contains a particular amino acid sequence or motif that allows it to bind to one or more of the MHC molecules expressed in that individual. Examples of motifs for a peptide that binds to the HLA molecule encoded by A*0201 is leucine (or methionine or isoleucine) at residue 2 of the peptide, a hydrophilic amino acid at residue 3, and a valine (or leucine or isoleucine or alanine) at residue 9. The amino acids that make up the motif are referred to as **anchor** residues of the peptide. Different HLA molecules, either molecules encoded by different alleles at the same locus (HLA-A*0203, *0211, or *0301) or molecules encoded by different loci (B*4001 or DRB1*0406), bind peptides with different motifs. The amino acids forming the peptide motif bind to the MHC molecule in pockets found within the antigen-binding groove (Stern, 1994). The polymorphic amino acids of the MHC molecules line this groove and thus create differences in peptide-binding specificities for the different MHC molecules.

The peptides bound to class I molecules are 9–10 amino acids in length. Both the carboxy- and amino-terminal ends of the peptide are buried in

the class I-binding groove, forming a **closed** peptide–MHC complex. The peptides bound to class II molecules vary in length from 12 to 30 amino acids. While maintaining the requirement for specific motif residues nested in the central portion of the peptide, both the carboxy- and amino-terminal ends of the peptide extend outside the class II-binding groove, forming an **open** peptide–MHC complex (Stern, 1994).

RECOGNITION OF FOREIGN MHC MOLECULES

Allorecognition involves the recognition by a T lymphocyte of a foreign MHC molecule on a cell from a second (allogeneic) individual. Upon recognition, the interaction triggers a series of events, resulting in activation of the T cell and initiation of an immune response not unlike the recognition of pathogens. Based on data from models of vascularized organ transplantation, two pathways of allorecognition have been hypothesized (Sayegh, 1996). The direct pathway for allorecognition involves the stimulation of recipient T cells by the donor MHC–peptide complex (i.e., direct recognition of intact foreign MHC molecules). The second route of allorecognition, the indirect pathway, involves stimulation of recipient T cells by self-MHC molecules presenting peptide fragments from donor cells. Indirect presentation occurs when antigen-processing cells of the recipient ingest cellular material from the grafted tissue, degrade the material intracellularly, and display the allogeneic peptide(s) complexed with self-MHC molecules. Peptides derived from polymorphic regions of donor MHC molecules are the major candidates for stimulation of the indirect immune response (Suciu-Foca, 1998; Gould, 1999; Harris, 1999).

TANDEM REPEATS AND SINGLE NUCLEOTIDE POLYMORPHISMS IN THE MHC

More than 300 short tandem repeats (STRs) have been identified within the human MHC region (Foissac, 1997). Multiple single nucleotide polymorphisms (SNPs) are also present. A study by Abbal (1997) examined six STR loci within the MHC in a population of unrelated individuals and found strong linkage disequilibrium between specific HLA haplotypes and the STR markers. Because these markers cover a larger region of the MHC than the classical HLA markers now used, they may provide a more comprehensive approach to identifying MHC-identical individuals. These markers might, for example, be used to identify a recombinant MHC haplotype within a family (Carrington, 1996) or to enhance the probability that any unidentified histocompatibility genes in the MHC are matched. Molecular methods have been developed to identify both STRs and SNPs that are accurate and reproducible (Carrington, 1998).

MINOR HISTOCOMPATIBILITY MOLECULES

Minor histocompatibility antigens (mHags) are immunogenetic peptides that bind to MHC molecules and can be recognized by T cells to cause undesirable GVHD, but in the setting of leukemic recipients can produce the beneficial condition graft-versus-leukemia. Achieving the proper balance of acceptable GVHD and sufficient graft-versus-leukemia is problematic. In MHC-identical progenitor cell grafts, GVHD may be induced by mHag differences between the recipient and donor (Mutis, 1999). The mHags can be any polymorphic gene product encoded outside the MHC that differs between donor and recipient and that stimulates a T cell response (Goulmy, 1997; Simpson, 1998). Similar to other protein antigens, the polymorphic protein must be processed into antigenic fragments, and the polymorphic peptide fragment(s) must bind within the groove of MHC molecules. Because of the requirement for antigen presentation by MHC molecules, any polymorphic peptide must carry a motif suitable for MHC-specific binding. Thus, not all individuals can present and respond to all mHags even if there is a difference between donor and recipient. Most mHags are presented to CD8⁺ T cells by MHC class I molecules. T cell responses are initiated when the T cell receptor recognizes complexes formed by the polymorphic peptides of the mHags bound to the MHC molecules expressed on APCs.

The mHags were originally defined by skin graft rejection and by cytotoxic assays with T cell clones. These polymorphic peptides have restricted binding to class I MHC molecules, so biochemical definition of the minor histocompatibility antigenic peptide components was accomplished by elution, purification, and sequencing of the mHag peptide bound to a specific MHC molecule (den Haan, 1995). Recent studies have demonstrated the potential significance of mHags in clinical transplantation (Goulmy, 1997, 1996; Martin, 1997; Dupont, 1998). mHag-specific cytotoxic T lymphocytes have been demonstrated in patients with GVHD (Mutis, 1999). Recipient disparity for one mHag (HA-1) was associated with increased risk of acute GVHD after marrow transplantation using genotypically HLA-identical sibling donors, although this may not always be the case. Recently, HA-1 disparity has been shown to be associated with ongoing graft-versus-leukemia and suppression of progenitor leukemia cells in some patients (Kircher, 2004; Kloosterboer, 2004). The importance of matching for other mHags (HA-2, HA-3, HA-4, HA-5, H-Y) is less clear. DNA-based techniques to detect differences in mHags have been developed (Tseng, 1998; Wilke, 1998) and are being used in studies to measure the impact of these disparities on the outcome of transplantation.

HLA NOMENCLATURE

SEROLOGIC AND CELLULAR SPECIFICITIES

HLA terminology is designated by a World Health Organization (WHO) Committee for HLA Nomenclature (see Table 48-2) (Bodmer, 1997, 1999). Historically, serologic and cellular defined specificities localized on the HLA protein molecules were assigned according to the results of international workshops during which typing reagents were exchanged among participating laboratories (13th International Histocompatibility Workshop website; see Table 48-1). (The 14th HLA and Immunogenetics Workshop convened during November 2005 in Melbourne, Australia). Assignments included the name of the HLA molecule and a numeric designation based on the order in which the serologically defined specificity was defined. For example, HLA-A1 (or just A1) was the first HLA-A specificity to be assigned, and HLA-A80 was the most recent. Over time, older serologically defined specificities were "split," as the definition became more discriminating. The narrowest definition of the specificity is called the subtypic or private specificity. The broader, shared specificities are called supertypic specificities. For example, B44 and B45 are subtypic specificities of the supertypic specificity B12. Thus, a cell that is either B44⁺ or B45⁺ must also be positive for B12.

In serologic testing, some alloantisera bind to more than one HLA allelic product—a phenomenon termed cross-reactivity. This serologic cross-reactivity among allelic products of HLA-A and HLA-B loci has been extensively studied and has been used to cluster molecules within cross-reactive antigen groups (CREGs) (Rodey, 1987). Class I molecules within a CREG share one or more determinants that are not shared by molecules in another CREG. An antigenic determinant (epitope) shared among members of a CREG is called a public specificity. Some of the CREG reactivity can be explained by the sharing of amino acid sequences among the HLA molecules in a CREG (Terasaki, 1992). Inclusion of HLA specificities within a CREG is not standard, as different sets of antibodies produce unique reaction patterns, and two different investigators with different sets of reagents may identify slightly different CREG groups. However, the various CREG groupings overlap considerably (Ellison, 1994). To be able to appropriately name newly discovered HLA alleles, a more logical format for HLA nomenclature assignment was implemented in 2010. This change was defined by the Update to HLA Nomenclature, 2009. The WHO Nomenclature Committee for Factors of the HLA System met during the 15th International Histocompatibility and Immunogenetics Workshop in Buzios, Brazil, in September 2008, and introduced colons into the naming scheme. These colons will allow for the discovery of more than 100 alleles in a given group; the following examples of these changes were listed in the WHO 2008 workshop report, http://hla.alleles.org/pdf/nomenclature_2009.pdf:

A*01010101 becomes A*01:01:01:01.

A*02010102L becomes A*02:01:01:02L.

A*260101 becomes A*26:01:01.

A*3301 becomes A*33:01.

B*0808N becomes B*08:08N.

DRB1*01010101 becomes DRB1*01:01:01:01.

For *antigen groups* that have more than 100 alleles such as the A*02 and B*15 groups, it will be possible to encode these in a single series. Thus the

A*92 and B*95 alleles will now be renamed into the A*02 and B*15 allele series. For example,

A*9201 becomes A*02:101.

A*9202 becomes A*02:102.

A*9203 becomes A*02:103.

The HLA-Bw4 and -Bw6 specificities are broad, public epitopes that reside on the same molecule as the HLA-B locus subtypic specificities, but at a different site. Thus Bw4 and Bw6 are a diallelic system, and all B locus (and some A locus) molecules carry either Bw4 or Bw6 specificities. The region of the HLA molecule carrying the Bw4/Bw6 specificities has been identified in the $\alpha 1$ helix between amino acid residues 77 and 83 (Parham, 1991).

The WHO-designated serologic specificities localized to the class II molecules, HLA-DR and -DQ, have been assigned as described for the class I molecules (Bodmer, 1997, 1999) (see Table 48-2). Six HLA-DP types were originally defined by cellular techniques. Class II HLA-DP molecules are not adequately defined serologically.

Twenty-six HLA-D specificities were identified by MLC. All HLA-D specificities retain the "w" designation because these specificities are defined functionally by the measurement of stimulation of a responder cell. This stimulation is generated by differences in the DR molecules expressed on a stimulator cell and, to a lesser extent, by additional stimulation by the DQ and DP molecules.

DNA-BASED ALLELE DESIGNATIONS

Nucleotide sequencing has been used to identify the many different alleles encoding the HLA molecules. Currently, a single, serologically defined specificity may reside on two to more than 25 different allelic products (see Table 48-2). Each HLA allele is designated by the name of the gene locus followed by an asterisk and a four- to seven-digit number indicating the allele. For example, A*0201 is an allele of the HLA-A gene; B*1510 is an allele of the HLA-B gene; DPB1*0101 is an allele of the HLA-DPB1 gene; and DQA1*0601 is an allele of the HLA-DQA1 gene.

The first two numbers in the numeric designation of each allele are frequently based on the serologic type of the resultant molecule and/or the nucleotide sequence similarity to other alleles in the group. For example, the HLA-A molecule expressed by the A*0201 allele bears the A2 serologic specificity defining the HLA-A2 antigen. However, the HLA-B molecule expressed by the B*1510 allele does not bear the B15-associated serologic specificity, but rather the B71 serologic specificity defining the B71 antigen. It was designated B*1510 because of its predicted amino acid sequence similarity to B15 antigens. Cells expressing DRB1*0103 were serologically typed as DR-blank, DR1, or even DR13. Nucleotide sequencing identified an allele with a similar DNA structure to alleles bearing the DR1 serologic specificity (e.g., DRB1*0101 and *0102), and the name of this allele was based on that structural similarity. When a unique serologic specificity was later identified, the DR antigen determined by DRB1*0103 was given the DR103 serologic designation. The third and fourth numbers in the allele designation refer to the order in which the allele was described. For example, A*0201 was the first A2 allele to be sequenced, and A*0203 was the third.

Some alleles may differ in the DNA sequence of their coding regions, but their predicted amino acid sequence does not differ (often termed a silent or synonymous substitution). These combinations of alleles are identified by a five-digit designation. The first four numbers are shared, and the fifth digit is used to distinguish the unique nucleic acid sequences of the alleles (e.g., B*27051 and B*27052). In addition, two or more alleles may have a seven-digit name in which the first four digits are shared (e.g., DRB4*0103101 and DRB4*0103102). Digits five through seven indicate that the two alleles differ only outside the protein coding region. In the example listed here, the difference affects the RNA splice site of DRB4*0103102, resulting in loss of expression of the allele (Sutton, 1989). Finally, alleles that are not expressed as proteins at the cell surface may have an N added to their names (e.g., A*0215N, DRB4*0103102N) to indicate "null." Because each allele has a unique numeric designation, the N designation is not always written (i.e., A*0215 and A*0215N are the same allele).

New alleles are described in regular reports of the WHO HLA Nomenclature Committee (see Table 48-1; www.anthonynolan.com/hig/nomenc.html; Bodmer, 1999), and the nucleotide sequences of all alleles are deposited in a computerized databank (GenBank, EMBL, IMGT/HLA databases). Currently, for example, more than 349 HLA-A alleles have been assigned. New alleles are continually being identified and can be accessed through the website.

TECHNIQUES FOR IDENTIFYING HLA POLYMORPHISM

Histocompatibility testing or HLA typing or tissue typing is performed in a limited number of laboratories because it uses specialized procedures and reagents. Commercially available kits can be obtained for both DNA-based and serologic testing; however, interpretation of the test results requires considerable experience and knowledge. Histocompatibility laboratories usually are found in medical centers that have organ and/or hematopoietic progenitor cell transplantation programs. HLA testing techniques are discussed in general in this section. For detailed procedures, the reader should refer to the American Society for Histocompatibility and Immunogenetics (ASHI) Laboratory Manual, 4th edition (2001) (see Table 48-1 for the ASHI website). HLA testing laboratories are accredited through ASHI, the European Foundation for Immunogenetics, and other organizations.

DNA-BASED TYPING OF CLASS I AND CLASS II ALLELES

Although serologic and cellular typing of HLA antigens has been extremely useful, there are a number of technical drawbacks to these techniques. With the advent of rapid and reliable methods for the isolation and characterization of class I and II genes and the determination of nucleotide sequences of class I and II alleles, it has become possible to use DNA-based methods for HLA typing. DNA-based typing of HLA alleles is now a commonly used technique in HLA typing laboratories (Hurley, 1997a; Middleton, 1999).

In contrast to other forms of testing, DNA-based typing has five significant advantages as follows:

1. It is specific. The specificity of each DNA typing reagent (i.e., synthetic oligonucleotide primers and probes) is clearly defined and is based on a specific, known nucleotide sequence. Because the oligonucleotides used as DNA typing reagents are synthetic, reagents are not limited and there should be no lot-to-lot variation in specificity.
2. It is flexible. New reagents can be designed as new alleles are discovered and unique nucleotide sequences identified. Testing can be carried out at several levels of resolution, depending on the typing requirements and the time available for testing.
3. It is more robust than other techniques. DNA typing does not require viable lymphocytes and is not influenced by the health of the patient. Furthermore, DNA-based testing is highly reproducible when standard methods such as sequence specific oligonucleotide probe (SSOP) testing are used in conjunction with a standard test protocol (Ng, 1996; Hurley, 2000a).
4. It can be used for large-scale typing. The batching of samples facilitated by automated and computerized methods reduces cost and errors. DNA-based methods are particularly applicable for the HLA typing of large numbers of volunteers for donor registries.
5. It can discriminate by detecting the full extent of HLA diversity. HLA alleles can specify HLA proteins that are indistinguishable using serologic typing. For example, an individual carrying the DRB1*0401 allele would have the same serologic type (DR4) as an individual carrying the DRB1*0412 allele (DR4). Thus, DRB1*0401 and DRB1*0412 are splits of the broad specificity DR4. These splits are identified by DNA typing. Serologic reagents specific enough to define this split are not available. Currently, more than 30 subdivisions of DR4 have been defined. There are many other examples of splits defined using DNA typing that cannot be identified using serologic typing; some are listed in Table 48-2.

The problems with serologic typing are particularly acute when typing some population groups. For example, populations of direct African origin can express class I and class II antigens that are difficult to identify with currently available serologic reagents (Bozon, 1997; Yu, 1997; Mytilineos, 1998). DNA-based HLA typing has greatly improved the ability to define HLA types in these populations.

Preparation and Amplification of DNA

Any cell with a nucleus can be used as a source of DNA. Although red blood cells do not contain nuclei, other cells in the blood, such as lymphocytes, are a good source of DNA. Cell lines such as Epstein-Barr virus-transformed B lymphocytes are also a good source of DNA. Because transformed cells can be grown in culture in the laboratory, they provide

a replenishable supply of DNA and are used to provide reference DNA for quality control of typing procedures.

DNA is usually prepared from a small quantity (0.2–1 mL) of whole blood. Many different protocols can be used to isolate DNA from cells, and commercial kits are available for the preparation of DNA. The sensitivity of detection of HLA types is enhanced greatly by the amplification of DNA-encoding HLA genes using the PCR technique (Saiki, 1988). A pair of synthetic oligonucleotides (primers) should be complementary to sequences flanking a specific HLA gene and are utilized to generate millions of copies of that gene for use in the HLA typing reaction. Some typing reactions utilize primer sequences that are shared by all alleles at an HLA locus; other typing procedures utilize primer sets that are shared by only a subset of alleles at a locus. Annealing of the primers to sample DNA during the PCR reaction uses reaction conditions that guarantee that the primers will bind to perfectly matched sequences (target sequences) and not to sequences of other loci or other alleles that are not matched. By adjusting the temperature of the annealing component of the PCR reaction, the typing laboratory can control the specificity of the amplification.

Sequence-Specific Priming

One method of identification of HLA alleles uses sequence-specific primers (SSPs) in the PCR reaction (Olerup, 1992; Bunce, 1995). These primers anneal to denatured DNA containing the HLA alleles from which the primer sequences were derived. In the subsequent PCR reaction, only these selected alleles are amplified. DNA amplified by the primers is identified by gel electrophoresis or, if the DNA is labeled with a dye during amplification, by fluorescence. This procedure is useful in typing a small number of samples within a short time period. Commercial kits are available.

Sequence-Specific Oligonucleotide Hybridization

It has been possible to use hybridization of SSOPs to amplified DNA to identify alleles (Gao, 1991; Williams, 1997; Cao, 1999). The use of several different oligonucleotide probes to define a specific HLA allele or the use of sequence-specific priming coupled with hybridization with panels of probes is usually required. A set of oligonucleotides capable of identifying each allele is hybridized to denatured PCR-amplified DNA attached to a solid support. Hybridization conditions are adjusted so that the probes will anneal to denatured DNA containing the HLA alleles from which the oligonucleotide sequence was derived. The oligonucleotides are labeled with a tag for detection of hybridization. For example, the oligonucleotide might be coupled to an enzyme such as alkaline phosphatase. Following addition of a substrate, alkaline phosphatase cleaves the substrate to yield a colored compound or to produce light (chemiluminescence). After visualization, the pattern of hybridization can be read to determine the alleles present. Figure 48-10 illustrates the approach using an oligonucleotide probe for the DQB1 allele, DQB1*0302, to identify patients with insulin-dependent diabetes who carry this allele (Todd, 1987). The SSOP method is highly accurate, specific, and reliable (Ng, 1996; Hurley, 2000a). It is often used in situations where many samples are typed in large batches. Commercial kits using this method are available.

In a related procedure, called the reverse format, the oligonucleotide probes are bound to a solid support (Bugawan, 1994). DNA from the samples to be tested is amplified using primers labeled with, for example, biotin. The amplified DNA is then hybridized to the immobilized probes, which contain sequences found in the alleles present in the DNA. After visualization (using an avidin-linked detection system), the pattern of hybridization can be read to determine the alleles present. This procedure is useful for typing both small and large numbers of samples. Commercial kits utilizing this method are available.

Sequence-Specific Conformational Polymorphism or Heteroduplex Analysis

Another, although little used, method of identification of HLA alleles analyzes the mobility of amplified DNA, either denatured (sequence-specific conformational polymorphism [SSCP]) or as a renatured DNA duplex (heteroduplex analysis), following electrophoresis (Arguello, 1996). The mobility of the DNA is compared with the mobility of amplified DNA from known HLA alleles to define an HLA allele. This procedure is useful in typing a small number of samples, particularly in comparisons between individuals, for example, within a family.

1987;329:599.)

A final method of identification of HLA-A alleles involves direct determina-

specific fluorescent tags (Arguello, 1998).

TABLE 48-3

Therapeutic Drugs, Mechanisms of Action, and Monitoring Methods

Drug	Mechanisms of action	Monitoring methods*
Azathioprine	Purine antagonist; blocks cell proliferation	Routine labs, pharmacokinetic studies, pharmacodynamic studies
Glucocorticoids	Blocks cytokine gene transcription; inhibits T cell proliferation and T cell-dependent immunity	Routine labs, pharmacokinetic studies
Cyclosporine	Inhibits expression of nuclear regulatory proteins and T cell activation genes	Routine labs, pharmacokinetic studies, pharmacodynamic studies
FK506	Inhibits expression of nuclear regulatory proteins and T cell activation genes	Routine labs, pharmacokinetic studies
Mycophenolate mofetil	Inhibits purine biosynthesis, thereby suppressing T and B cell proliferation	Routine labs, pharmacokinetic studies, pharmacodynamic studies
Rapamycin	Inhibits DNA and protein synthesis, blocking T cell proliferation; inhibits antigen-driven B cell proliferation	Routine labs, pharmacokinetic studies, pharmacodynamic studies

Adapted from Massey D, King A, Riley R. Renal allograft dysfunction in kidney transplant. American Society for Clinical Pathology, Clinical Chemistry Check Sample 2003;43:19–38.

*Routine labs include serum creatinine, blood urea nitrogen (BUN), complete blood count (CBC), liver enzymes, etc. Pharmacokinetic studies include measurement of trough levels and calculation of area under the curve (AUC). Pharmacodynamic study refers to measuring the biological effects of the drug at its target site.

HLA Typing Sera Trays

HLA typing reagents are derived from the sera of alloimmunized individuals (multiparous women, transplant recipients, multitransfused patients, and planned immunization of humans). Multiwell plates of human alloantisera (i.e., HLA typing trays) are commercially available. Because of the antigenic complexity of HLA antigens, several antisera should be used to define each specificity. Most laboratories use trays from at least two different vendors or may use locally derived alloantisera. Because many alloantisera are not truly monospecific and many exhibit some cross-reactivity, the reactivity of each antiserum must be thoroughly tested and known to the individual interpreting the results. This requires stringent quality control of each new lot of typing trays with well-characterized reference cells. The titer and the specificity of antibody formed by a sensitized individual may not remain constant over time; therefore, supplies of antisera are limited. In an attempt to create a consistent and unlimited supply of reagents, some companies have produced monoclonal antibodies. These monoclonal reagents are not available for all HLA specificities.

Cross-Reactivity

HLA alloantisera may react with more than one HLA allelic product. This phenomenon can result from polyspecificity of the antisera and/or from cross-reactivity and is responsible for the complex reactivity patterns of some alloantisera. Polyspecific sera contain two or more HLA-specific antibodies that can be adsorbed to remove one antibody with little effect on the reactivity of the other(s). Cross-reactive antisera contain, most frequently, a single antibody that reacts with an antigenic determinant shared among several different HLA allelic products (i.e., CREG or broad determinants, as previously discussed) (Rodey, 1994). Cross-reactions occur most frequently among allelic products encoded by the same locus but can occur between allelic products encoded by different loci (e.g., A2 + B17).

CELLULAR DETECTION OF CLASS II MOLECULES

The response of one cell in tissue culture to the alloantigens on the surface of a second cell is called the mixed leukocyte culture or mixed lymphocyte reaction (Hartzman, 1971). The MLC is considered an *in vitro* measure of class II disparity between individuals that recognizes determinants found on class II molecules, which are known collectively as HLA-D. The T cell response is made unidirectional by preventing cells from one of the two individuals from replicating by treating those cells with radiation or mitomycin C prior to addition to the culture. The MLC represents a summation response of a responder cell to differences in the multiple determinants on HLA class II molecules (DR, DQ, and DP) encoded by the irradiated stimulator cell haplotypes. The response to DR molecules appears to predominate.

Use of the MLC in clinical laboratories to determine histocompatibility has declined because of limitations inherent in the technique. The MLC can be influenced by the health of the patient, the type of disease,

and the history of prior transfusion (Mickelson, 1996). For these reasons, the MLC assay has been replaced by more precise DNA-based typing methods. Currently, in some transplantation centers, the MLC is used to identify renal allograft recipients with specific hyporeactivity to donor HLA molecules following transplantation as a guideline for tapering of immunosuppression (Reinsmoen, 1993).

Limiting dilution analysis to define the frequency of donor cytotoxic or helper T lymphocytes has been used to predict the extent of allorecognition in hematopoietic progenitor cell transplantation (Madrigal, 1997). The correlations of these frequencies with subsequent events such as the extent of GVHD is still controversial.

TISSUE/ORGAN TRANSPLANTATION

Long-term survival of solid organ and hematopoietic progenitor cell grafts represents one of the most challenging goals in medical science. Renal transplantation is the therapy of choice for most patients with end-stage renal disease. Hematopoietic progenitor cell, heart, lung, liver, and pancreas transplantation is gaining wide acceptance as a therapeutic procedure with successful outcomes. The primary obstacle to solid organ and to hematopoietic progenitor cell transplantation is immunologically mediated rejection of the foreign tissue. Therefore, the success of allografting is dependent on the ability to deter the immune reaction, which may be accomplished by (1) histocompatibility matching between the donor and the recipient; (2) immunosuppressive therapy of the recipient (see Table 48-3 for a list of common immunosuppression drugs and laboratory approaches used to monitor them) (Suthanthiran, 1996); and (3) ultimately achieving specific unresponsiveness to donor alloantigen(s) (i.e., tolerance) (Remuzzi, 1995).

GENETIC BASIS OF TRANSPLANTATION

The genetic basis of transplantation was first determined in 1916 as a result of tumor transplantation experiments in mice and was subsequently extended to transplants of normal tissue (Snell, 1981). It was demonstrated that skin grafts within inbred strains that were homozygous at histocompatibility loci (i.e., syngeneic grafts) were successful, but grafts between two different inbred strains (allografts) were rejected. Furthermore, allografts from either parent inbred strain (two copies of the same MHC genes; homozygous) to first-generation (F1) hybrids (one copy of each of the two different sets of MHC genes from two homozygous parents) survived in all animals, whereas grafts from F1 hybrid offspring to either parent (one haplotype mismatch) did not survive. These observations established the laws of transplantation. In 1948, the factors or genes determining the fate of allografts were named histocompatibility or H genes. Also in 1948, the major histocompatibility locus in the mouse, H-2, was defined by Gorer (Snell, 1981). There are other histocompatibility or H antigens, which are termed mHags. Although called minor, mismatching for these antigens can have major effects (Goulmy, 1997; Dupont, 1998).

Because convincing evidence already existed in experimental animal models that molecules encoded by the MHC represent the major genetic

barrier to successful allografting, HLA typing was used in humans to determine and to optimize compatibility between graft donor and recipient. Initially, the influence of HLA antigens on graft survival was investigated by grafting of nonvascularized skin between family members. As in studies with inbred mice, skin grafts between HLA-identical siblings survived significantly longer than grafts between one-haplotype-matched siblings, parents, or unrelated donors. These observations were extended to renal transplantation during the late 1960s and early 1970s. The most recent data from the international Collaborative Transplant Study (CTS) in Heidelberg and from the United Network for Organ Sharing (UNOS) Registry in the United States (analyzed at University of California, Los Angeles) confirm the MHC as the major genetic barrier to transplantation for renal grafts (Cecka, 1999; Opelz, 1999) (Fig. 48-11); for current updates, see the websites listed in Table 48-1. The data for hematopoietic progenitor cell transplantation also reaffirm the role of the MHC in transplant outcome as measured by both patient survival and GVHD (Hansen, 1999) (Fig. 48-12).

HISTOCOMPATIBILITY MATCHING

HLA Matching

Although the level of HLA match is an important element in transplant outcome, histocompatibility matching means different things in different settings, and strategies for matching vary. Criteria differ with variables that include the type of graft (e.g., solid vascularized organ vs. hematopoietic progenitor cell), the disease (e.g., chronic myelogenous leukemia vs. aplastic anemia), the age of the patient, and the clinical protocol (e.g., marrow vs. umbilical cord blood; T cell depletion of marrow vs. non-T cell depletion) (see Chapter 38).

Matching usually includes evaluation of at least three loci: HLA-A, HLA-B, and HLA-DR. Individuals matched, at whatever resolution, for all three loci are termed 6/6 matches or 0 mismatches. Zero mismatches (a term used in solid organ transplantation) may also refer to donor/recipient pairs where the donor has no detectable HLA differences from the recipient, that is, where the donor is homozygous for the alleles at one or more of the loci (e.g., homozygous donor: A*0101; B*0801; DRB1*0301; heterozygous recipient: A*0101, A*0301; B*0801, B*0702; DRB1*0301, DRB1*1501). Individuals matched for four of six alleles or antigens are termed 4/6 matches. Apparent differences in the level of match can arise because of the typing method used to assign HLA types (e.g., serologic vs. DNA-based typing). The serologic and DNA nomenclatures, although they are related, can differ. The definition of a match can also vary depending on the typing resolution. A patient and a donor may appear to be matched at the serologic level (e.g., recipient: A2, A26; donor: A2, A26); however, the pair may be mismatched at the level of HLA alleles (e.g., recipient: A*0201, A*2601; donor: A*0205, A*6601).

Matching for classical HLA molecules at the allele level could optimize outcome for all grafts (both vascular organs and hematopoietic progenitor cells) (Petersdorf, 1998; Opelz, 1999). However, because of the extremely large number of HLA alleles, allelic-level matching is difficult. Therefore, the level of matching that ensures a good outcome for the largest number of patients of all ethnic populations must be considered.

Following hematopoietic progenitor cell transplantation, subtypic determinants or allelic differences initiate important cytotoxic T cell responses leading to graft rejection and GVHD. Indeed, studies have shown that high-resolution matching for class I and class II alleles of the donor and recipient can improve outcome after unrelated marrow

Figure 48-11 Five-year renal allograft (first transplant) survival of three categories of histocompatibility: human leukocyte antigen (HLA)-identical siblings; one-haplotype living-related; cadaver donor. Grafts from HLA-identical sibling donors (both HLA chromosomes matched) have the best outcomes. Numbers of transplants studied are indicated (regression, $p < 0.0001$). (With permission from Opelz G, Wujcik T, Dohler B, et al. HLA compatibility and organ transplant survival. *Rev Immunogenet* 1999;1:334.)

Figure 48-12 Probability of grades II-IV acute graft-versus-host disease (GVHD) in human leukocyte antigen (HLA)-identical sibling (HLA genotypic match) and haplo-identical related marrow donor transplants variably matched for HLA-A, -B, or DR/Dw (HLA mismatch: 3 loci, 2 loci, 1 locus, or 0 loci). Matching for HLA-A, -B, and -DR was defined by serology, and matching for HLA-Dw was defined by mixed leukocyte culture (MLC) or by typing for HLA-DRB1 alleles with sequence specific oligonucleotide probe (SSOP). All patients received unmodified marrow (without T cell depletion) following a conditioning regimen that included total body irradiation. Cyclosporine and methotrexate were given for GVHD prophylaxis. (With permission from Hansen JA, Yamamoto K, Petersdorf E, et al. The role of HLA matching in hematopoietic cell transplantation. *Rev Immunogenet* 1999;1:359. Copyright © 1999 Munksgaard International Publishers, Copenhagen, Denmark.)

transplantation. Recent data suggest that multiple mismatches are detrimental to outcome; however, the impact of neither single mismatches nor specific loci has yet been well defined (Petersdorf, 1998; Sasazuki, 1998; Hansen, 1999). With respect to single allele mismatches and their impact on transplantation, a report by Flomenberg (2004) describes a differential impact of HLA mismatches at specific loci between donor and recipients; this multivariate analysis of more than 1800 donor–recipient pairs showed that single allele mismatches at HLA-C adversely affected engraftment; mismatches at HLA-A, -B, -C, and -DR were significant in terms of grade III–IV acute GVHD incidence, and in that the highest effect on this disease was given by mismatches at HLA-A, whether this was acute or chronic GVHD; mismatches at HLA-A, -B, -C, and -DR showed significant effects on mortality, and again HLA-A mismatches demonstrated the largest impact on survival, perhaps because single allele mismatches at this locus appeared to induce resistant GVHD. Only a minority of patients awaiting transplantation will receive grafts from fully allele-matched donors (Hurley, 2000b). To enable all patients to benefit from life-saving transplantation, identifying allele mismatches that are well tolerated would allow the selection of mismatched donors to be prioritized according to the biological risk of specific HLA mismatches.

Optimal matching for solid organ grafts may differ from matching requirements for hematopoietic progenitor cell transplantation. Recent data suggest that both the HLA loci matched and the level of resolution of HLA testing contribute to renal graft outcome (Opelz, 1999). Currently, UNOS facilitates sharing of cadaveric kidneys based on subtypic specificities. Because subtypic matches are infrequently identified, it has been proposed that the HLA class I molecules should be matched for the broader CREG determinants. CREG may define immunodominant determinants recognized in the humoral immune response. Rodey (1994) showed that 80%–90% of the HLA alloantibodies formed by kidney recipients following transplantation are directed to CREG determinants. CREG determinants are shared among different class I HLA molecules and, in contrast to subtypic specificities, have a similar distribution among ethnic population groups. Rare subtypic specificities are included within the CREG. Because the number of CREGs is less than the number of subtypic specificities, the probability of a CREG-level match is greater than for a subtypic or allele-level HLA class I match. Therefore, allocation of organs based on CREG matching should result in a higher probability of matched grafts being distributed equitably to recipients of all ethnic populations. CREG matching for the allocation of kidneys has been characterized as immunologically flawed, and its observed positive effect in prolonging graft survival and reducing immunosuppressant requirements has been attributed entirely to the effect of HLA matching (Egfford, 2003). Others cite a positive role for CREG matching in reducing HLA sensitization among minority recipients of renal transplants (Crowe, 2003).

Other strategies focus on matching for biologically relevant fragments of MHC molecules (e.g., epitope matching) (Suciu-Foca, 1998; Harris, 1999). Until recently, direct recognition of alloantigens was thought to be the main pathway for graft rejection responses. However, studies suggest that the indirect response plays a significant role in graft rejection, at least of solid organ grafts (Sayegh, 1996). If the indirect pathway is activated, then the peptide epitopes generated by proteolytic breakdown of the HLA molecule and not the HLA molecule itself would be the immunogenic stimulus. Therefore, new innovative strategies can be designed for defining allowable mismatches based on recognition of the peptide fragments. For example, a strategy could consider whether the mismatched donor HLA molecules would be perceived as immunogenic in the recipient (i.e., whether the recipient HLA molecules would bind and present these epitopes). Theoretically, one could identify foreign HLA peptide sequences not presented by specific recipient HLA molecules and thus define allowable mismatches for given HLA molecules. The introduction of solid-based methods (Luminex, enzyme-linked immunosorbent assay [ELISA], and flow cytometry methods) for detecting antibodies to HLA molecules, in which eluted HLA molecules from cells are bound to polystyrene beads (or polystyrene microtiter plates), has allowed the more accurate identification of antibodies generated by patients awaiting transplantation. It is now possible to group HLA molecules based on the immunogenic epitope that is shared among them, thus allowing for better selection of donors for transplantation. The level of sensitization is more accurately interrogated by beads carrying a single HLA molecule, and absorption of alloantisera with these beads elucidates the epitope that the antibody is directed to and can be inferred by testing the unabsorbed and the absorbed serum with a panel of single-antigen beads; reduced panel reactivity in the absorbed serum defines the epitope specificity, and the HLA molecules that carry

the epitope can be determined by evaluating Tables 48-4 and 48-5. Marrari (2009) and El-Awar (2007) have reported several epitopes or Eplets shared by multiple HLA class I and II molecules; some laboratories are currently using these epitope tables to determine unacceptable antigens in donors based on the patient's immune reactivity assessed using single-antigen Luminex bead methods and the HLA-Matchmaker algorithm (Valentini et al., 2007), which predicts some of these epitopes.

The inherent complexity in interpretation of HLA typing results and in selection of a donor makes it critical to include an expert in histocompatibility testing. Experts in HLA typing will know the strengths and weaknesses of each method of typing, as well as the frequency of alleles and haplotypes in the population; this information is important in both the search for and the selection of a suitable donor.

HLA-Specific Antibody Detection in Recipient Serum

Patients can be sensitized to specific foreign HLA molecules through transfusion, pregnancy, or prior transplantations. Assessment of compatibility between the recipient and the possible donor includes testing for this sensitization. Recipient serum is tested prior to transplantation on a panel (lymphocytes or immobilized soluble HLA molecules) of known HLA profile to measure panel reactive antibody (PRA). At the time of transplantation, the recipient serum is tested with the prospective donor lymphocytes to identify specific reactivity to the potential donor in the donor-specific crossmatch. Although the techniques used to detect antibody binding may differ among laboratories, the purpose remains to obtain a profile of the immunologic risk factors of a recipient on the waiting list, which will aid the medical team in both pretransplantation and posttransplantation decisions. Binding of antibody in the current serum of the recipient to the T lymphocytes of the donor is a contraindication to renal transplantation.

Serum Screening (PRA)

Thorough characterization of the antibody profile in patients awaiting transplantation aids in interpretation of the pretransplantation donor-specific crossmatch. The goals of a PRA screen are as follows:

1. To identify the level of presensitization of the patient to HLA antigens. A patient with PRA in excess of 60% (i.e., serum from the patient reacts to specificities found in at least 60% of the panel) has a decreased likelihood of a negative donor-specific crossmatch and thus of receiving a transplant from an unrelated transplant.
2. To identify the HLA specificity of the antibodies to predict the HLA antigen(s) to be avoided when donors are selected.
3. To identify patients with irrelevant antibodies (e.g., immunoglobulin [Ig]M autoantibodies) so that appropriate techniques may be selected to avoid false-positive readings at the time of the donor-specific crossmatch.

Characterization of HLA-specific antibody present in the recipient serum requires testing on a selected panel of well-defined HLA specificities. Lymphocytes or soluble antigen from a sufficient number of individuals must be included in the screening panel to ensure that all but the rarest HLA-directed antibody will be detected. As far as possible, the screening panel should remain the same so that results are comparable over time. Renal transplantation recipients frequently form antibodies to CREGs rather than to subtypic specificities (Rodey, 1994, 1997), so the analyses of panel reactivity should consider identification of CREG, as well as of subtypic specificities. Identification of antibody specificities in patients awaiting transplantation aids in preselecting a potential donor for whom the recipient will have a negative final crossmatch. Computer programs assist in this selection (Claas, 1999; Duquesnoy, 1999).

The frequency of screening and the selection of assays used for the screening procedure are decisions based on the immunologic profile of the individual recipient. Decreased use of blood transfusions has negated the requirement for screening monthly serum samples on all patients (ASHI website; see Table 48-1). The presence of both HLA class I- and class II-specific antibodies is detected by serum testing on a panel of lymphocytes (e.g., by direct complement-dependent cytotoxicity or antiglobulin-augmented cytotoxicity assays) or on a panel of soluble HLA molecules immobilized on plates (i.e., ELISA) or on beads (i.e., flow cytometry). (The assays are described in detail in the ASHI manual [2001].) An advantage of the solid-phase soluble antigen assay is that it can be designed to detect only IgG, HLA class I-specific antibodies.

Human leukocyte antigen I epitopes: update to 103 total epitopes, including C locus. *Transplantation* 2007;84:532–40.

Serum samples from potential recipients should be stored at -70°C and protected from carbon dioxide and from evaporation. The stored characterized serum samples will be used in the donor-specific crossmatch to assess compatibility with a prospective donor.

Donor-Specific Crossmatch

The lymphocyte crossmatch tests for the presence of antibodies, if any, in the serum of the potential recipient that react with lymphocytes of the specific donor. In the crossmatch test, the lymphocyte is the target cell of choice because it expresses high levels of HLA molecules and is easy to isolate. This test is probably the most important contribution of the HLA tissue typing laboratory to clinical renal transplantation. The purpose of the crossmatch is to prevent hyperacute rejection and to detect antibodies

that identify immunologic risk factors in patients awaiting transplantation. The occurrence of hyperacute rejection is significantly correlated with a positive direct complement-dependent cytotoxicity (CDC) crossmatch between donor T lymphocytes and recipient serum at the time of transplantation. Reactivity of current valid serum of the recipient to the T lymphocytes of the donor is a contraindication to renal graft transplantation. Detection of donor-reactive antibodies in noncurrent recipient serum samples is not a contraindication but may represent risk for graft loss other than immediate hyperacute rejection (Cardella, 1982; Geddes, 1999). A donor-specific crossmatch also is used in some centers to predict hematopoietic progenitor cell graft failure (Hansen, 1997a).

Requirements and methods for the donor-specific crossmatch are stated in the standards of the American Society for Histocompatibility and

Immunogenetics (see Table 48-1) and in the ASHI procedure manual (2001). Acceptable techniques at present include the Amos-modified CDC, the extended incubation time CDC, the antiglobulin-augmented CDC, and flow cytometry.

Antibody Detection Techniques

Different laboratories may use different combinations of assays to detect antibody. The level of sensitization detected will vary with the assay. The antibody specificity detected will vary with the target cell.

Direct Complement-Dependent Cytotoxicity

Direct CDC includes all assays that use the addition of complement to detect the direct binding of antibody to lymphocytes. Fixation of complement by the antibody-antigen complexes on the cell surface results in cell death or cytotoxicity. CDC methods include the basic technique (no wash step before addition of complement), the Amos-modified technique (wash step added before addition of complement), and extended-time incubation techniques. The wash step removes serum, which may contain substances that hinder complement activation. The advantages of direct CDC techniques are that they are reproducible, and that correlation with the incidence of hyperacute rejection is excellent.

Indirect Crossmatch Techniques

Indirect techniques include the anti-globulin augmented lymphocytotoxicity assay technique also known as anti-human globulin cytotoxicity assay, and flow cytometry. Both use a reagent specific for human immunoglobulin to augment detection of HLA-directed antibody. Indirect techniques detect the presence of antibodies specific for CREGs that frequently go undetected in direct CDC assays. Advantages of the flow cytometry assay include discrimination of the subclass of the cell-bound immunoglobulin (IgG vs. IgM) and characterization of the target cell binding the alloantibody (T lymphocyte vs. B lymphocyte vs. monocyte).

Autoantibodies

The presence of circulating autoantibodies in the recipient is not known to be deleterious. Thus, an autocrossmatch should be performed, preferably when the patient is put on the transplantation waiting list. If autoantibodies are present, the sera used for donor crossmatching should have the autoreactivity removed. Autoantibodies are primarily IgM, and HLA-specific antibodies are primarily IgG (Barger, 1989). Either heat inactivation at $63 \pm 1^\circ \text{C}$ or reduction with the chemical agent dithioerythritol or dithiothreitol (DTT) of any potential IgM antibodies is used to differentiate between IgM and IgG antibodies in the serum samples. If the heat-inactivated or DTT-treated serum sample is negative even though the untreated sample is positive, most centers will proceed with transplantation. However, DTT or heat inactivation should be used with caution because not all HLA-specific antibodies are IgG, and because if they are not properly controlled, both procedures can remove IgG activity, as well as IgM.

B Cell Antibodies

A crossmatch using donor B lymphocytes (B cell crossmatch) may be performed in sensitized patients in some centers. A positive donor-specific B cell crossmatch is not a contraindication to transplantation. The clinical significance has not been resolved, but a positive test may be a risk factor, particularly in patients who have previously been transplanted. Antibodies detected in a B cell crossmatch can be (1) class II, HLA-DR, -DQ specific, (2) weak HLA-A, -B, -C specific antibodies (B cells have a higher density of class I molecules and are more sensitive to complement-dependent assays than are T cells), and/or (3) non-HLA-specific antibodies (e.g., autoantibodies). To interpret a positive B cell crossmatch, it may be necessary to adsorb recipient sera with platelets before performing the donor crossmatch. (Platelets express class I but not class II molecules.) The two most commonly used B cell crossmatch techniques are the CDC and flow cytometry assays.

Selection of Recipient Serum Samples for Donor Crossmatch

For patients with no detectable sensitization (i.e., 0% PRA), the most recent serum sample available can be used for the donor-specific crossmatch. If the patient has preexisting antibodies or has had a recent sensitizing event, a current serum sample (i.e., within 48 hours of transplantation) should be collected. For sensitized recipients, representative samples, including the most reactive or "peak" serum sample, are tested in most centers; a donor-positive noncurrent sample may be considered to be a risk factor, particularly in the patient who rejected a primary graft early in the posttransplantation period (Mahoney, 1996).

RENAL TRANSPLANTATION

Current practice is to select donors for recipients who are ABO compatible, T cell, donor specific, crossmatch negative with appropriate recipient sera and the best available HLA match. The original finding that kidney grafts transplanted between HLA-identical siblings survive significantly longer than grafts transplanted between HLA-mismatched siblings or parent-sibling combinations has been consistently confirmed. [Figure 48-11](#) shows a recent analysis of 5-year survival of renal allografts from the international CTS registry among three categories of donors: (1) HLA-identical sibling, 84% survival; (2) one-haplotype living-related, 73% survival; (3) all cadaver, 66% survival. The impact of matching for MHC in living-related transplantation is clearly observed by comparing categories 1 and 2. Similar results are observed in the UNOS database (Cecka, 1999).

Although outcome analyses of living-related grafts confirm the role of the MHC as the major genetic barrier to successful graft outcome, demonstration and acceptance of a positive influence of HLA matching in graft outcome for unrelated cadaveric transplantation have been more controversial. However, long-term survival data from collaborative, multicenter

studies are consistent in showing a highly significant effect of HLA matching on graft survival in cadaveric renal transplantation (Cecka, 1999; Opelz, 1999). Moreover, two recent single-center studies—one from Europe (Oslo) and one from North America (Toronto)—have reported significant improvement in graft survival as a function of HLA match (Geddes, 1999; Leivestad, 1999). A single center may require prioritization based on HLA match to transplant sufficient recipients with well-matched grafts to achieve statistical significance in outcome analysis. Although the numbers are smaller, a highly significant influence of HLA matching has been observed on the outcome of kidney grafts from living-unrelated donors (Opelz, 1999).

Zero mismatched (0 MM) grafts from cadaver donors survive significantly better than and approximately as well as grafts from HLA-identical siblings (see Fig. 48-11); thus, UNOS mandates the sharing of 0 MM kidneys. Graft survival in patients following first kidney transplantations decreases stepwise as the number of mismatches increases from 0 MM to 6 MM (Cecka, 1999; Opelz, 1999). However, to ensure equitable sharing of organs for all recipients, including those with rare HLA haplotypes, new algorithms for prioritizing recipients on the waiting list have been adopted by organ-sharing programs (Opelz, 1999). The most recent outcome data for both graft and patient survival can be accessed through the CTS website (www.ctstransplant.org).

Matching of the initial graft not only increases survival time for that graft, but it decreases the probability of recipient sensitization and facilitates retransplantation. Accumulation of highly sensitized patients on the waiting list is a significant problem in many centers, as patients wait for long periods of time and may present difficult clinical management problems (Sanfilippo, 1992).

NONRENAL ORGAN TRANSPLANTATION

Survival of heart, liver, lung, and pancreas grafts is good, with between 58% and 67% of first grafts surviving at 5 years. Donors usually are not matched for HLA type, and a pretransplant donor crossmatch is not routinely performed. Serum antibody screens are recommended to identify the state of sensitization as an immunologic risk factor for the recipient. If feasible, the graft recipients and cadaveric donors of nonrenal vascularized grafts should be typed for HLA to allow for retrospective analyses. Recent international CTS data show no effect of HLA matching on outcomes of liver transplantation; however, the CTS data do show a significant impact of matching for HLA-A, -B, and -DR on outcomes of first heart transplants (Opelz, 1999). The acceptable period for cold ischemia preservation may limit the extent of HLA matching possible for heart transplantation.

ALLOGENEIC HEMATOPOIETIC PROGENITOR CELL TRANSPLANTATION

Allogeneic hematopoietic progenitor cell transplantation is performed for hematologic malignancies and disorders, bone marrow failure, certain inherited metabolic disorders such as lipid storage diseases, and congenital immunodeficiency syndrome. From a histocompatibility standpoint, the best donor is either self (autogeneic transplant), if the malignancy is not one that involves the bone marrow or the disease is not genetic, or an identical twin (syngeneic transplant). Progenitor cells from an HLA-identical sibling donor are a frequent source. These donor cells usually will be genetically identical to cells of the patient across the entire MHC region. Use of a sibling donor also increases the probability that non-HLA genes that might affect transplantation success and that are not well defined (i.e., minor histocompatibility genes) will be matched (Goulmy, 1997). Haploidentical family members may also be chosen as donors (Aversa, 1998), although a greater risk of severe GVHD is associated with mismatched HLA donors. Based on data from the International Bone Marrow Transplant Registry (IBMTR) (see Table 48-1; www.ibmtr.org), more than 16,000 allogeneic bone marrow transplants were performed from 1996 to 1997; 75% used related donors.

Most patients (≈70%) do not have an HLA-matched sibling and may be considered for transplantation with cells from an HLA-matched, unrelated donor. To facilitate the search for a matched donor, national registries of unrelated donors have been developed around the world (Hansen, 1996). The NMDP in the United States is such a registry and contains more than 3.9 million HLA-typed donors, making it the largest unrelated donor registry in the world (Perkins, 1994; see Table 48-1; www.marrow.org).

Hematopoietic progenitor cell grafts are among the most difficult of all clinical procedures for several reasons (Hansen, 1997a; Madrigal, 1997). First, at the time of transplantation, the recipients are nearly totally immunodeficient, either because of inherited deficiency (severe combined immunodeficiency) or because of pretransplantation conditioning (cytotoxic chemotherapy and irradiation). Conditioning is required to eliminate malignant cells and to prevent the immune system of the recipient from rejecting the donor progenitor cells, which are infused several days after conditioning. The amount of cytotoxic pretreatment is great enough to eliminate circulating leukocytes, nearly eliminate platelets, and abrogate production of new erythrocytes. Thus, the recipient is profoundly susceptible to all types of infection and would certainly die if not rescued by extraordinary medical care and transfused progenitor cells.

The second risk is the potential for immunologic attack of the recipient by the transplanted allogeneic progenitor cells, resulting in GVHD. GVHD has several forms and can be fatal. In spite of associated difficulties, a number of transplant centers have achieved exceptional success. Recent reports from single institutions and the IBMTR suggest leukemia-free survival of 40%–60% at 5 years after unrelated hematopoietic progenitor cell transplantation of patients with chronic myelogenous leukemia in chronic phase (see Table 48-1; www.ibmtr.org) (Hansen, 1998). Survival for patients with severe aplastic anemia transplanted with cells from unrelated donors varies from 30%–50% at 5 years, depending on patient age (see Table 48-1, NMDP, at www.marrow.org and www.ibmtr.org); survival rates of nearly 90% have been reported at some centers (Deeg, 1998).

In addition to marrow as a source of hematopoietic progenitor cells, collection of hematopoietic progenitor cells from growth factor–mobilized peripheral blood (Anderlini, 1997) or umbilical cord blood progenitor cells (Cairo, 1997) increases the availability of unrelated donors. New approaches to immunosuppression, including less aggressive conditioning protocols (e.g., “minitransplants”) (Storb, 1999), may extend the availability of progenitor cell transplantation as a therapeutic procedure to patients presently excluded by age or by organ dysfunction. Hematopoietic progenitor cell transplantation can also be used to generate immune responses directed at malignant cells. Relapse of disease following transplantation is greater for patients receiving an HLA-matched graft, suggesting that some degree of mismatching may be beneficial in stimulating an immune response against tumor cells (Beatty, 1993). As problems surrounding this most difficult procedure are overcome, hematopoietic progenitor cell transplantation may become one of the most widely used methods for the treatment of a variety of diseases (see Chapter 38).

HLA Typing for Progenitor Cell Transplantation

Many factors, including histocompatibility, influence the outcome of hematopoietic progenitor cell transplantation (Madrigal, 1997). The pretransplantation workup includes HLA-A, -B, and -DR typing of all available members of the immediate family to identify a matched related donor and to establish inheritance of haplotypes. DNA-based typing for class II genes has become standard, and DNA-based typing for class I genes has been implemented in many centers. Typing of the extended family, allele-level (i.e., high-resolution) typing of specific HLA class I and class II loci, typing of other loci within the MHC (i.e., short tandem repeats or complement loci), or use of other tests (e.g., crossmatching, cytotoxic T cell precursor measurements) to measure compatibility may also be appropriate (Hurley, 1999).

The level of HLA typing resolution required differs for hematopoietic progenitor cells and renal transplantation. It is likely that higher-resolution HLA typing is required to match donor and recipient for progenitor cell transplantation than is required for renal transplantation because progenitor cell transplantation involves the transfer of an entire immune system to the patient. Current research is focused on defining the loci that must be considered in donor selection, the level of resolution that must be used for matching, and the additive effect of multiple mismatches. The level of matching required may vary for each disease or protocol. Evidence suggests that matching unrelated donor and recipient for HLA-A, -B, -DRB1 alleles is related to improved outcomes. The impact of matching at other HLA loci (e.g., HLA-C, HLA-DQ) is under evaluation. Single mismatches may be tolerated; however, multiple mismatches appear to have a negative impact on outcome (Petersdorf, 1995b, 1998; Hansen, 1997a; Madrigal, 1997; Sasazuki, 1998). Furthermore, the positive effect of histocompatibility matching on outcome must be balanced by the positive impact of transplantation early in the course of the disease. Data from the IBMTR and the NMDP show that survival following transplantation is reduced as the disease phase advances (data on websites listed in Table 48-1).

SUMMARY

The HLA class I and class II molecules encoded within the major histocompatibility complex have a significant role in the specificity and character of immune responses. Extensive polymorphism of these molecules provides the diversity needed to ensure survival in an environment of hostile and adaptive pathogens. Unfortunately, this ability of the immune

system to distinguish self from nonself extends to the recognition of foreign HLA molecules following tissue transplantation. Definition and characterization of HLA alleles and molecules have been combined with clinical protocols to maximize compatibility and to minimize the impact of the immune response on foreign tissue. These advances have contributed to the development of transplantation as a successful treatment modality for the replacement of diseased tissue.

SUMMARY, 962**SELECTED REFERENCES, 962****KEY POINTS**

- The major histocompatibility complex (MHC) genomic region contains several genes with immune-related functions.
- Recent identification of several genes within the MHC has increased the possibility of defining the genetic basis of immunity.
- The clustering of immune-related genes in the MHC region may not be coincidental and may be the result of evolutionary forces joining genes with similar functions.
- The MHC is associated with more diseases than any other region on the human genome.
- Nonrandom associations of fixed stretches of MHC DNA complicate the study of susceptibility genes but also provide the means for their identification.
- Methods are available for detecting associations or linkage between polymorphisms found with the MHC and disease.
- Although class I and class II encoded proteins are distinguished by structural and functional similarities shared by the members of each class, class III molecules can be defined only as non-I and non-II, because their genes and their products have no common features and are not recognized by T cells.
- Despite convincing genetic association studies showing the importance of the class III region in health and disease, neither the genes responsible for disease nor the underlying mechanism of pathology is known for many of the associated conditions.
- Almost half the genes within the MHC class III region play roles in the innate immune system, including members of the complement fixation cascade (C4, C2, Bf) and tumor necrosis factor family.
- Deficiency of the second component of the complement system has been reported only in Caucasians, and it is the most common complement protein deficiency state in that population.

- Complete C4 deficiency is extremely rare. The level of C4 in the serum of patients with C4 null alleles is extremely variable and cannot be used reliably to detect heterozygotes for complete deficiency because there is no correlation between the level of C4 and the number of expressed C4 genes.
- Extended haplotypes are highly characteristic of an ethnic subgroup and have lower frequencies or do not occur at all in other ethnic groups.
- It is critical to know the ethnic distribution of a disease-associated MHC allele to evaluate whether the allele in patients is increased compared with ethnically matched control populations and is in fact truly a marker for the ethnic distribution of the disease.
- A major problem with MHC gene associations is their incomplete penetrance, making ordinary formal segregation and linkage studies very difficult, if not impossible, to carry out.

Understanding the role of the MHC in immune responses and in the pathogenesis of disease requires defining polymorphisms in the class I and class II regions, as well as genes in the central region of the MHC, sometimes called the MHC class III region. The strong interest in the MHC genomic sequence originates from its established role in regulating inflammation and the innate and adaptive immune responses. Several genes in the MHC play important roles in cellular discrimination of self and nonself that require an essential knowledge of the effects of the MHC system in transplantation medicine and in susceptibility to autoimmunity. Variants of class I and class II genes were described in detail in the previous chapter. In this chapter, we discuss the non-human leukocyte antigen (HLA) region genes, disease associations, and methods for detecting the association of diseases with genetic markers.

OVERVIEW OF THE HUMAN MAJOR HISTOCOMPATIBILITY COMPLEX DNA SEQUENCE

Completion of the MHC deoxyribonucleic acid (DNA) sequence preceded completion of the total human genome sequence by almost 4 years (The MHC Sequencing Consortium, 1999). The rush to complete the entire MHC sequence followed the need to understand the biology and genetics of the mouse MHC (H-2) and HLA regions, which were initially provided by murine inbred experiments and serologic typing (reviewed in Klein, 1986). Although the MHC was discovered more than 50 years ago, its nature has been resolved only in the last two decades, with the advent of DNA cloning and discovery of the structure of class I and class II molecules (Bjorkman, 1987; Brown, 1993).

The MHC located in the short arm of chromosome 6 spans approximately 4Mb and contains more than 250 identified loci, by far the most gene-dense region of the human genome sequenced to date (reviewed in Shiina, 2009). It encodes the most polymorphic human proteins—the HLA class I and class II molecules, some of which have more than 1000 allelic variants identified so far (Marsh, 2009). More than 40% of the total expressed loci in the MHC are associated with immune-related functions. This clustering of immune-related genes in the MHC region may not be coincidental and may be the result of evolutionary forces joining genes with similar functions.

Traditionally, the MHC region has been classified into three regions from telomere to centromere: HLA class I, non-HLA class (MHC class III), and HLA class II. HLA class I and class II gene functions were reviewed in detail in the preceding chapter. We will concentrate on the MHC class III region and will later return to HLA class I and class II genes to discuss disease associations.

GENES IN THE CENTRAL OR CLASS III REGION

The human MHC class III, or central MHC region, located between the HLA class I and class II regions, is the most gene-dense region of the human genome. Specifically, the MHC class III region contains 55 protein-coding genes in ~900 kb sequence, with an average gene size of ~8.5 kb (Xie, 2003), compared with the entire human genome, which contains, on average, fewer than 11 genes per megabase and has an average gene size between 27 and 45 Mb (Lander, 2001; Heilig, 2003). Although HLA class I and class II encoded proteins are distinguished by structural and functional similarities shared by the members of each class, MHC class III molecules can be defined only as non-I and non-II, because their genes and their products have no common features and are not recognized by T cells. Figure 49-1 shows a genetic map of the MHC class III region.

Despite convincing genetic association studies showing the importance of the MHC class III region in health and disease, neither the genes responsible for disease nor the underlying mechanism of pathology is known for many of the associated conditions. One reason for this is the fact that the functions of nearly half the genes in the MHC class III region are not completely known. Recently, a high-throughput yeast two-hybrid system was used to look into the function of several intracellular proteins encoded within the MHC class III region (Lehner, 2004). This study

revealed that approximately one third of the analyzed proteins encoded within the MHC class III region may have a role in mRNA processing, which again suggests clustering of functionally related genes within this region of the human genome. Specifically, four of the proteins in the MHC class III region (LSM2, BAT1, DOM3Z, and SKIV2L) are orthologs of yeast proteins involved in mRNA processing, and another five proteins (BAT2, STK19, CLIC1, PBX2, and BAT5) interact with proteins previously implicated in RNA processing. Three proteins (STK19, PBX2, and RDBP) interact with proteins implicated in transcriptional regulation.

The region closer to HLA class II genes contains several genes of known function, including *TNXB* (Morel, 1989), which encodes tenascin X, a large extracellular matrix protein expressed in connective tissues, and *NEU1*, encoding neuraminidase 1, a lysosomal sialidase. Mutations of *TNXB* are a cause of the Ehlers-Danlos syndrome (Burch, 1997), and mutations of the *NEU1* gene are responsible for congenital sialidosis (Bonten, 1996).

Almost one half of genes within the MHC class III region play roles in the innate immune system, including members of the complement fixation cascade (*C4*, *C2*, *CFB*) and the tumor necrosis factor family (*TNF*, *LT α* , *LT β*), which will be discussed in greater detail later in this chapter. Other members of the immunoglobulin superfamily are also located within the MHC class III regions: *NCR3* (natural cytotoxicity triggering receptor 3) and the less characterized *LY6G* genes. The *NCR3* gene encodes the NKp30 protein responsible for triggering natural killer (NK) cells (Pende, 1999), and it is involved in the killing of cells infected with *Plasmodium falciparum* (Mavoungou, 2007) and cytomegalovirus (Arnon, 2005). Increased expression of *NCR3* and the adjacent *LST1* (leukocyte-specific transcript 1) gene has been found in the blood of rheumatoid arthritis patients (Mulcahy, 2006). Both genes are also significantly upregulated in response to lipopolysaccharide, interferon- γ , and bacterial infection, suggesting a role for these gene products in autoimmune-related inflammation and dendritic cell/NK cell-associated functions.

The *NFKBIL1* (NF- κ B-inhibitor-like) and *BTNL2* (Butyrophilin-like protein 2) genes are also located in the MHC class III region (Albertella, 1994; Stammers, 2000). Much interest has recently been focused on the *NFKBIL1* and *BTNL2* proteins after single mutations in their promoter regions were linked to rheumatoid arthritis (Okamoto, 2003) and sarcoidosis (Valentonyte, 2005), respectively. Other immune-related genes (e.g., *LY6* family members and *AIF1*) are likely to function as part of immune/inflammatory control (Utans, 1995; Autieri, 1996; Ribas, 1999; Mallya, 2002). Finally, the genes for the microsomal enzyme steroid P450 21-hydroxylase and three members of the major heat-shock protein 70 family are also contained in the MHC class III region and will be discussed later.

TUMOR NECROSIS FACTOR AND LYMPHOTOXIN α AND β GENES

Tumor necrosis factor (TNF) and lymphotoxin α (LT α) are potent immunomodulatory cytokines produced in response to inflammatory stimuli. The biological functions of these cytokines and the laboratory methods used to measure them in body fluids were reviewed in great detail in Chapter 47. TNF and LT α proteins are each encoded by separate genes (*TNF* and *LT α*) and share approximately 34% amino acid identity (Carroll, 1987). TNF and LT α are either maintained as cell surface molecules nor

Figure 49-1 Gene map of the class III region of the major histocompatibility complex. Shown in order but not to scale are 55 genes from centromere to telomere. Genes presenting “immune loci” are marked by green boxes.

released from cells. *LT α* is retained on the cell surface via a transmembrane region. Surface TNF results not from the presence of a transmembrane region, but rather from an association with lymphotoxin β (*LT β*) (Brown-ing, 1993). *LT β* encoded by *LTB* has 21% and 24% amino acid identity with *TNF* and *LT α* , respectively.

To date, several *TNF* promoter polymorphisms, located at -1030, -862, -857, -851, -574, -376, -308, -244, -238, and +70 nucleotides relative to the transcription start site, have been identified (Wilson, 1992; Brinkman, 1994; Higuchi, 1998; Uglialoro, 1998). Throughout the past decade, the *TNF* loci have been the center of intense attention concerning the relevance of its promoter polymorphisms to susceptibility to various autoimmune and infectious diseases. This work remains controversial both at the genetic level and, more importantly, with regard to functional relevance. As recently demonstrated for some of the *TNF* promoter polymorphisms, these gene variations may be ethnic-specific markers for other linked and unidentified factors that may have an impact on host immune response in the development of autoimmune diseases and susceptibility or resistance to infectious diseases in a given population (Delgado, 2002). Polymorphisms in the *TNF* promoter region have been correlated in large-scale population studies with cerebral malaria (McGuire, 1994; Knight, 1999), rheumatoid arthritis (Criswell, 2004), coronary heart disease (Nicaud, 2002), type 2 diabetes (Kubaszek, 2003), Alzheimer's disease (McCusker, 2001), ankylosing spondylitis (McGarry, 1999), mortality to septic shock (Mira, 1999), and mucocutaneous leishmaniasis (Cabrera, 1995). In relation to *LTA* polymorphisms, large-scale analysis has linked both promoter and coding polymorphisms within the *LTA* gene to myocardial infarction (Ozaki, 2002).

HEAT-SHOCK PROTEIN 70 GENES

Stress proteins, or heat-shock proteins, are expressed by cells in response to a variety of stress stimuli. This response has been observed in all species examined to date. The family of stress proteins, 70 kDa in size, has a highly conserved amino acid sequence identity as found from primitive eukaryotes to humans. Several studies have identified loci for heat-shock protein 70 (HSP70) on chromosomes 6, 14, and 21 (Hunt, 1985; Sargent, 1989). Three genes encoding members of the HSP70 family are located telomeric to the *C2* locus (*HSPA1L*, *HSPA1A*, and *HSPA1B*, formerly known as *HSP70-Hom*, *HSP70-1*, and *HSP70-2*, respectively).

Sequence analysis of *HSPA1A* and *HSPA1B* genes has shown that they are intronless genes that encode an identical protein product of 641 amino acids. *HSPA1L* is also an intronless gene that encodes a protein of 641 amino acids and has 90% sequence identity with *HSPA1A* (Milner, 1990). Because of the high degree of sequence similarity between coding regions of the various *HSP70* genes, DNA probes corresponding to coding regions tend to cross-hybridize. However, sufficient sequence differences have been observed between the 5' and 3' untranslated regions to design oligonucleotide primers and probes to allow specific amplification and hybridization of the three genes (Milner, 1992).

The *HSP70* gene cluster lately has drawn attention because of a recent study that linked both *HSPA1L* and *HLA-B*5701* loci to hypersensitivity to the antiretroviral drug abacavir (Martin, 2004). Other polymorphisms in the *HSP70* genes have been correlated to cytokine response in trauma (Schroder, 2003; Wu, 2004), uveitis in patients with sarcoidosis (Spagnolo, 2007), and risk of clozapine-induced agranulocytosis in Ashkenazi Jews (Corzo, 1995).

C2, C4, AND CFB GENES AND TYPING

The *C2*, *C4*, and factor B proteins encoded within the MHC class III demonstrate inherited structural variants that can be studied by using techniques that detect differences in net surface charge due to amino acid differences. Two methods are used to separate these proteins: (1) high-voltage agarose gel electrophoresis, which detects variations in mobility due to charge differences between proteins at a given pH, and (2) isoelectric focusing in thin-layer polyacrylamide gels, which shows differences in isoelectric points. Proteins can be visualized by immunofixation electrophoresis using insolubility of antigen-antibody complexes, or by detection of functional hemolytic activity with overlay gels, in which antibody-sensitized sheep erythrocytes are combined with complement-deficient serum (Alper, 1983).

At the protein level, *C2* shows minor polymorphism by isoelectric focusing. The alleles for *C2* are *C* (common), a less common *B* (basic) allele with three rare basic variants, and four rare *A* (acidic) variants (Jahn, 1990). The polymorphic site for the *C2*B* allele is carried by the *C2a* complement

fragment. The *C2* protein is genetically polymorphic in a wide variety of ethnic groups, although *C2*C* accounts for more than 90% of *C2* genes in most populations (Alper, 1976; Meo, 1977). In Caucasian and Asian populations, *C2*B* accounts for 5%–10% of *C2* genes. A nonexpressed allele (*C2*QO*) is found in 2% of the Caucasian European population (Truedsson, 1993a). For *C2* typing, proteins are separated by isoelectric focusing in polyacrylamide gels and are visualized by *C2*-induced hemolysis in overlay gels. Diluted normal human serum can replace *C2*-deficient serum as a reagent, because *C2* is the limiting factor in the classical complement pathway.

Two distinct but closely related loci for the *C4* protein (*C4A* and *C4B*), presumably the result of tandem gene duplication, encode for two forms of *C4*. The genetics of *C4* is extraordinarily complex, not only at the genetic level, but also at the protein level. It has been shown that the number of *C4* genes in humans varies from two to four, and in exceptional cases, six (Chung, 2002; Wu, 2007). Three quarters of *C4* genes carry endogenous retrovirus sequences that might confer intrinsic protection against exogenous retroviral infection (Schneider, 2001). Recent data suggest a negative correlation between the presence of endogenous retrovirus sequences and the level of *C4* proteins, as well as a direct relationship between the number of genes and *C4* protein levels (Yang, 2003).

At the protein level, *C4A* and *C4B* differ only by four amino acid residues in the α chain between positions 1101 and 1106. *C4B* is several times more hemolytically active than *C4A*, but *C4A* is more active at inhibiting the formation and dissolution of immune complexes than *C4B*. *C4A* variants usually carry Rodgers antigenic determinants (a Val-Asp-Leu-Leu epitope of the *C4A* chain), and *C4B* variants carry Chido determinants (an Ala-Asp-Leu-Arg epitope of the α chain of *C4B*). Extensive genetic polymorphism is detectable in *C4A* and *C4B* proteins among populations; more than 35 variants have been observed by agarose gel electrophoresis and DNA-based typing methods (Awdeh, 1980; Sim, 1986; Schneider, 1996; Hui, 2004). Among the *C4A* and *C4B* allotypes, the most common alleles are *C4A*3* and *C4B*1*. *C4A*4*, *C4A*2*, *C4B*2*, and *C4B*5* show a worldwide general distribution. *C4A*6* is also observed in many populations, with the exception of some Mongoloid groups. *C4B*3* is identified mainly in African and Caucasian groups.

C4 typing requires a combination of several techniques (Awdeh, 1980): (1) Immunofixation electrophoresis after treatment with neuraminidase. The patterns produced show three bands for each variant with some overlap occurring between certain variants. Additional treatment of the sample with carboxypeptidase reduces each variant to a single band. (2) Detection of *C4A* versus *C4B* by functional hemolytic assay. This method distinguishes *C4A* and *C4B* overlapping patterns because *C4B* variants have 5–10 times the hemolytic activity of *C4A* variants. (3) Rodgers (*C4A*) or Chido (*C4B*) serologic reactivity. The serum is incubated with human anti-Rodgers or human anti-Chido to test for inhibition of agglutination with appropriate positive erythrocytes. Alternatively, *C4* variants can be typed for Chido or Rodgers reactivity by immunoblotting. Null alleles of *C4* heterozygotes can be detected in two ways. Electrophoresis of *C4* null (*C4A QO* and *C4B QO*) samples demonstrates an absence of bands in homozygotes, but in heterozygotes requires quantification by visual inspection, crossed immunoelectrophoresis, or densitometric scanning of immunofixation patterns. An alternative method is to determine the presence and ratios of the *C4A* and *C4B* α chains after sodium dodecyl sulfate polyacrylamide gel electrophoresis of immunoprecipitates. More recently, DNA-based typing methods, including sequence-specific primer (SSP) amplification, restriction fragment length polymorphisms analysis, and direct DNA sequencing, have been used to complement inconclusive *C4A* and *C4B* protein allotyping (Schneider, 2003).

Factor B is synthesized by the *CFB* gene. Human factor B is highly polymorphic, with more than 20 variants identified to date, including several dysfunctional proteins, those present in low concentration, and null alleles. Factor B typing is normally performed by combining agarose electrophoresis and/or isoelectric focusing at the protein level with polymerase chain reaction (PCR) analysis at the DNA level (Geserick, 1998). By using these methods, it is possible to identify two very common alleles, *CFB*F* and *CFB*S*, two less common alleles, *CFB*F1* and *CFB*S1*, and a host of rare alleles. Variants are named for their decimal fraction migration in gel electrophoresis: *CFB F* to *CFB F1* for fast variants, and *CFB S* to *CFB S1* for slow variants. In European Caucasian populations, *CFB*F* has a frequency of 0.2, *CFB*S* of 0.77, *CFB*F1* of 0.01, and *CFB*S1* of 0.01; rare alleles account for only 0.002. *CFB*S* is most common in Caucasian, Mongoloid, and Australoid populations, and *CFB*F* is most common in Negroid populations. *CFB*F1* is observed in African groups, as well as in some Caucasian populations.

DISEASE ASSOCIATIONS WITH C2, C4, AND CFB GENES

Deficiency of the second component of the complement system has been reported in about 1 in 10,000 Caucasians, and is the most common complement protein deficiency state in that population (Silverstein, 1960; Klemperer, 1966). People with complete C2 deficiency are homozygous for null C2 alleles (*C2*Q0* for quantity zero). *C2*Q0* results from a 28-bp gene deletion that generates a frameshift and a stop codon 14 bp distal to the end of exon 6 (Johnson, 1992). Remarkably, *C2*Q0* has a gene frequency of approximately 0.01 among Caucasians. Rarely, C2 deficiency is the result of missense mutations resulting in impaired C2 secretions that have been termed C2 deficiency type II (Wetsel, 1996). Although C2 deficiency can lead to disease, most patients remain asymptomatic. Up to 25% of homozygotes for C2 deficiency have increased susceptibility to bacterial infection due to immunoglobulin deficiency (Densen, 1991; Alper, 2003). Between 20% and 40% of reported patients with C2 deficiency have a systemic lupus-like disease (Truedsson, 1993b; Sullivan, 1994). A polymorphism in the C2 gene has been correlated with reduced risk of age-related macular degeneration (Gold, 2006; Maller, 2006).

A high incidence of *C4 null* alleles is seen in the general population. *C4A*Q0* and *C4B*Q0* result from gene deletions, premature stop codons, and other mutations that cause transcription failure (Braun, 1990; Barba, 1993; Lokki, 1999). Thirty-five percent of individuals of all races do not express one *C4A* or *C4B* gene (i.e., carry *C4A*Q0* or *C4B*Q0*), 8%–10% carry two null alleles, and less than 1% do not express three alleles. Complete C4 deficiency (trans *C4A*Q0*, *C4B*Q0*) haplotypes are extremely rare (Hauptmann, 1986). The *C4A*Q0* allele, particularly in homozygous individuals or those with complete C4 deficiency, has been associated with systemic lupus erythematosus (Wilson, 1988; Huang, 1995). This susceptibility is probably related to defective handling of immune complexes (Fielder, 1983). Children homozygous for *C4B*Q0* have a 3.5-fold greater incidence of bacterial meningitis (Colten, 1992).

Increased frequency of the *C4B*Q0* allele has been found in patients with severe coronary artery disease who underwent bypass compared with healthy controls (Szalai, 2002).

Absence of homozygous factor B deficiency in humans has led to the notion that the condition might be lethal during embryonic development. Based on inheritance patterns and serum levels, some heterozygotes from *CFB*Q0* have been identified as having reduced protein products (Siemens, 1992). The *CFB F* variant has been associated with higher protein concentration but lower hemolytic activity than *CFB S* (Lokki, 1991). Mutations in the *CFB* gene have been associated with age-related macular degeneration (Gold, 2006; Maller, 2006) and hemolytic-uremic syndrome (Goicoechea de Jorge, 2007).

COMPLOTYPE

The four genes of the complement region occupy approximately 120 kb of genomic DNA (Carroll, 1984). The *C2* and *CFB* genes are located in very close proximity, separated by less than 2 kb, but *CFB* and *C4A* are separated by about 30 kb. *C4A* and *C4B* are about 10 kb apart. Alleles of the complement genes occur as a unit at the population level and show striking linkage disequilibrium in haplotypes determined by family studies. That is to say, they occur together as sets on the same chromosome more frequently than expected from the frequencies of their individual alleles and with no well-documented recombinations. For these reasons, haplotypes of the four complement loci have been called *complotypes*, as an abbreviation for “complement haplotypes” (Alper, 1983). Although their order from telomere to centromere is *C2*, *CFB*, *C4A*, *C4B* (see Fig. 49-1), for clarity in using variant alleles to designate complotypes, the positions of *CFB* and *C2* are transposed. Thus, *CFB*S*, *C2*C*, *C4A*Q0*, *C4B*1* is a complotype that in abbreviated form is *SC01*. More than a dozen complotypes in Caucasians have frequencies of about 0.01 or higher (Table 49-1). In most populations, the *SC31* complotype is most common. In people of African descent, *FC31* is common, as is *SC42* in East and Southeast Asians.

EXTENDED HAPLOTYPES

Based on the study of the distribution of complotypes in relation to *HLA-B* and *HLA-DR* specificities on normal Caucasian haplotypes determined in family studies, striking linkage disequilibrium involving the whole region became evident. One could easily recognize *HLA-B*, complotype, *DR* allele sets that showed statistically significant three-point linkage disequilibrium (Fig. 49-2) and that define what are regarded as extended haplotypes

TABLE 49-1

Common Complotypes in Normal Chromosomes of Caucasoid Populations*

†*C4B* locus is heteroduplicated.

(Awdeh, 1983). A shorthand nomenclature for extended haplotypes has been designed by enclosing *HLA-B*, complotype, and *HLA-DR* variants in brackets. Thus, the most common extended haplotype in Caucasians is [*HLA-B8*, *SC01*, *DR3*]. Extended haplotypes are highly characteristic of an ethnic subgroup and have lower frequencies or do not occur at all in other ethnic groups (Alper, 1982; Fraser, 1990).

Initial studies defined extended haplotypes as the genomic interval between *HLA-B* and *DR*. It then became evident that other uncharacterized MHC alleles in the interval were likely to be included. Despite the fact that *HLA-A* alleles have shown limited variation for extended haplotypes, only half such haplotypes show unique and significant *HLA-A* allele associations (Alper, 1982). The *HLA-Cw* locus was by far the last to be characterized. Based on genetic distance and previously incomplete typing data of *HLA-B/Cw* pairs, it was evident that conserved haplotypes would also include the *HLA-Cw* genetic region. Thus, different *HLA-Cw* alleles have been recently associated with different extended haplotypes (Table 49-2) (Clavijo, 1998). Furthermore, several *TNF* and *HSP* allele systems and microsatellites have been studied in relation to extended haplotypes (Table 49-3). More recently, models have been created to describe the variable sizes of stretches of conserved DNA in the MHC, using the known frequencies of four different types of small blocks (<0.2 Mb) of relatively conserved DNA sequence: *HLA-Cw/B*; *TNF*; complotype; and *HLA-DR/DR* (Yunis, 2003). Using HLA allele identification and *TNF* microsatellites, Yunis and colleagues have shown that some extended haplotypes extend to the *HLA-A* and *HLA-DPB1* loci, which form fixed genetic units of at least 3.2 Mb of DNA. Intermediate fragments of extended haplotypes also exist, which are, nevertheless, larger than any of the four small blocks. This complexity of genetic fixity at various levels should be taken into account in studies of genetic disease association, immune response control, and human diversity.

Extended haplotypes, which account for at least 30% of normal Caucasian haplotypes, have relatively fixed gross structure and DNA sequence and carry very similar, if not identical alleles, even when they are found in apparently unrelated individuals. The frequency of extended haplotypes is more likely to be underestimated than overestimated because haplotypes must be determined from family studies involving thousands of unrelated index cases. Recently, the MHC reference sequence (The MHC Sequencing Consortium, 1999) has been used as the starting point for numerous studies undertaken to ascertain multiple common and rarer extended haplotypes (Walsh, 2003; Stewart, 2004; Smith, 2006; Traherne, 2006). These studies will facilitate the identification of precise disease loci and may help us to better understand events such as recombination and polymorphism.

MHC DISEASE ASSOCIATIONS

The MHC is associated with more diseases than any other region on the human genome. We have reviewed concepts about complotypes and

Figure 49-2 The haplotype distribution of the complotypes (haplotypes of complement alleles) SC01 (*CFB**S, *C2**C, *C4A**QO, *C4B**1) and SC21 (*CFB**S, *C2**C, *C4A**A, *C4B**1) in relation to *HLA-B* alleles on the ordinate and *HLA-DR* alleles on the abscissa. Heights and widths representing HLA specificity are proportional to allele frequencies for the respective populations. Clustering represents linkage disequilibrium and flags the extended haplotypes [*HLA-B*16(38), SC21, DR4] in Ashkenazi Jews [*HLA-B*8, SC01, DR3] and in the English and, to a much lesser extent, among Jews. extended haplotypes to enhance our understanding of the relevance of a rather extensive literature on MHC disease associations. Most of the MHC disease associations reported to date are contained within extended haplotypes. It is probably because of this simple fact that so many MHC-allele-associated diseases have been reported, because it is not a single base pair but more than 3 million base pairs of conserved DNA that constitute the marker. For example, complement alleles such as *CFB**F1 and *C4B**3 have been linked to type 1 diabetes, because the extended haplotypes that carry them, [*HLA-B*18, F1C30, DR3] and [*HLA-B*62, SC01, DR3], are more common in these patients than in the general population. This association means that haplotypes comprising 3 million bases or more in length of

conserved genomic DNA carry susceptibility alleles for type 1 diabetes. It is also critical to know the ethnic distribution of an associated MHC allele to evaluate whether the allele in patients is increased compared with that in ethnically matched control populations, or is in fact truly a marker for the ethnic distribution of the disease. Furthermore, it is more difficult to map the genes responsible for disease in Caucasian Americans than in African Americans or Asian Americans because the level of genetic diversity is lower in Caucasians.

A remarkable number of diseases show an association with MHC genes. Most diseases associated with MHC are autoimmune and do not show clear-cut mendelian inheritance. Many problems confound attempts to understand the inheritance mechanisms by which these diseases occur, and analysis of MHC markers in patients and their families has clarified the picture only marginally. A major problem with MHC gene associations is their incomplete penetrance, making ordinary formal segregation and linkage studies very difficult, if not impossible, to carry out. This is seen most clearly in monozygotic twins, who presumably have identical genes. If one such twin has one of these diseases (e.g., type 1 diabetes), the other twin does not necessarily have the same disease. For type 1 diabetes, the concordance rate appears to be no higher than 50% (Rubinstein, 1977; Barnett, 1981). This suggests that penetrance of a disease in a completely susceptible host is incomplete. Although there is excellent reason to consider genes in the MHC as determinants of type 1 diabetes susceptibility, only 15% of MHC-identical siblings of diabetic patients have insulin-dependent diabetes. This difference between 50% and 15% provides evidence for the influence of genes at a second, non-MHC-linked locus (or loci), and suggests the influence of other factors, such as environmental factors, in determining susceptibility.

Incomplete penetrance makes assignment of a specific mode of inheritance difficult and makes the likelihood of finding families with more than one affected member within one or more generations low. Families are frequently used to determine modes of inheritance. Another complicating factor is the inability to determine whether we are studying a group of patients that are homogeneous in terms of genetic determination. About 5%–6% of random families with a type 1 diabetic proband will have a second affected child. Of these sibling pairs, approximately 60% will be MHC-identical, 35% will be haploidentical, and a few percent will share

Data from Clavijo O, Delgado J, Awdeh ZL, et al. HLA-Cw alleles associated with HLA extended haplotypes and C2 deficiency. *Tissue Antigens* 1998;52:282–5.

*The numbers or letters under each column refer to a particular allele variant of the complement, heat-shock protein (HSP), tumor necrosis factor (TNF) microsatellite, or TNF promoter polymorphisms that are associated with the human leukocyte antigen (HLA) specificities as noted. See text for explanation. In the case of TNF-308, 1 and 2 represent the -308/G and -308/A variants, respectively. The TNF-857/C allele is noted as 1, and the TNF-857/T allele as 2. The TNF-863/C TNF allele is noted as 1, and the -863/A as 2.

no MHC haplotypes. This pattern suggests recessive inheritance of an MHC-linked susceptibility gene for the disease. At the very least, however, family studies provide highly useful haplotype data and usually allow the assignment of homozygosity for an HLA marker in probands. They have also established that MHC association in most diseases of interest is based on linkage between a susceptibility gene and the MHC.

Yet another unknown is the number of different susceptibility alleles for a disease in any specific population. In this regard, extended haplotypes can be helpful because, if increased in patients, they probably represent a single susceptibility allele that could be anywhere in the region of fixity. However, some patients have only portions of these haplotypes, and this provides little information about the location of specific allele involvement. Furthermore, it appears likely that many MHC-associated diseases are polygenic. Because of this, we will first discuss diseases associated with mutations of a single MHC gene; this will be followed by a discussion of polygenic diseases.

MHC MONOGENIC DISEASE ASSOCIATIONS

Table 49-4 lists MHC monogenic disease associations and their genes. We will discuss the most common diseases. We have already reviewed two of these disorders earlier in the chapter: C2 and C4 protein deficiencies.

Hereditary Hemochromatosis and the HFE Gene

Hemochromatosis is an autosomal recessive disease and is the most common hereditary metabolic disease in Caucasians. Hemochromatosis consists of an inherited metabolic defect in iron metabolism, resulting in failure to control iron absorption in the setting of increasing iron stores, leading to tissue iron overload and eventually to organ damage (reviewed in Adams, 2000). The most common manifestations of hemochromatosis are cirrhosis of the liver, hepatocellular carcinoma, diabetes mellitus, and

cardiomyopathy. Discovery of the hereditary hemochromatosis (HH) gene in the MHC was based on the early finding of increased frequency of the *HLA-A3* allele in HH patients (Simon, 1976). After years of effort in the vicinity of the *HLA-A* locus, the *HFE* gene was found several megabase pairs away (Feder, 1996). *HFE* encodes a 343 amino acid protein that belongs to a group named MHC class I-related molecules because of their similarities to HLA class I molecules. The HFE protein interacts with the transferrin receptor and modulates enteric absorption of dietary iron (Waheed, 1999).

The *HFE* gene has two common missense mutations: the C282Y mutation, resulting in the substitution of a tyrosine for a cysteine, and the H63D mutation, resulting in the substitution of an aspartate for a histidine. Methods for diagnosis of hemochromatosis are discussed in detail in Chapter 70. The C282Y mutation, unlike the H63D mutation, interferes with protein interaction with β_2 -microglobulin, abolishing the cell surface expression of HFE (Feder, 1997; Waheed, 1997). A homozygous C282Y mutation is present in the majority of HH Caucasian patients. The C282Y mutation has a remarkably high allelic frequency in northern European populations (0.05%–0.1%) and is rare in non-Caucasian populations. Penetrance of the C282Y homozygous state is as low as 10% or even 1% (Beutler, 2002). For this reason, population screening for this mutation is not recommended. The H63D mutation is present at high frequency in control Caucasians (>0.1%) and was also found in non-Caucasian populations; however, its role in HH remains unclear.

Congenital Adrenal Hyperplasia Due to 21-Hydroxylase Deficiency

Immediately 3' to each *C4* locus are two loci for the adrenal steroid enzyme 21 hydroxylase (*CYP21A* and *CYP21B*) (Carroll, 1985; Higashi, 1986; White, 1986). The two genes are highly homologous, but three mutations cause premature termination of transcription of the *CYP21A* gene, rendering it a pseudogene (White, 1988). Congenital adrenal hyperplasia is clinically heterogeneous, with a severe salt-wasting form, a milder late-onset form manifested largely by masculinization in girls, and a mild cryptic form. The MHC linkage of this disorder was discovered before any MHC associations were detected, and before it was known that the *CYP21* loci were located within the MHC. Subsequently, studies found that 20% or more of European Caucasian patients with the salt-wasting form carried the rare extended haplotype [*HLA-A1, Cw6, B47, FC(91)0, DRB1*07, DRB4*0101, DQA1*0201, DQB1*0201*] (Fleischnick, 1983). It has been shown that this haplotype has a deletion of both *C4B* and *CYP21B*, thus explaining the severity of symptoms and the complete deficiency of the enzyme in homozygotes for this haplotype. Among patients with milder and cryptic disease, a different extended haplotype is common: [*HLA-B65, SC2(1,2), DRI*] (Sinnott, 1991). This haplotype is particularly common in southern Europe, and has a frequency of over 0.01% among Caucasians living in Boston. In all forms of 21-hydroxylase deficiency, the bulk of MHC haplotypes are not extended, and there is a great variety of

TABLE 49-5

complotypes, suggesting that many independent mutations have led to deletion or derangement of the *CYP21B* gene.

POLYGENIC DISEASES WITH MHC ASSOCIATIONS

Table 49-5 lists some polygenic diseases and their MHC gene associations. This list is not exhaustive, and we will discuss only a few of the diseases in greater detail.

Abacavir Hypersensitivity

Abacavir is a reverse transcriptase inhibitor used in combination with other antivirals in the treatment of human immunodeficiency virus (HIV) infection. A severe hypersensitivity reaction occurs in 5% of abacavir patients; is characterized by symptoms such as fever, rash, and acute respiratory symptoms; and can lead to potentially life-threatening hypotension if drug therapy is not discontinued (reviewed in Clay, 2002). Patients with the *HLA-B*5701* allele are at risk for an abacavir hypersensitivity reaction (Hetherington, 2002; Mallal, 2002). Recent studies have demonstrated the cost-effectiveness of *HLA-B*5701* screening to reduce the risk of hypersensitivity reaction to abacavir in the treatment of HIV infection (Hughes, 2004; Mallal, 2008). *HLA-B*5701* genotyping can be performed by a variety of PCR or sequencing methods, as discussed in Chapter 48.

Ankylosing Spondylitis

A strong association has been noted between *HLA-B*27* and ankylosing spondylitis (AS) in several populations (reviewed in Khan, 1992). About 90% of Caucasian patients with AS have *HLA-B*27*, as compared with 5% to 10% of healthy controls (Rubin, 1994). *HLA-B*27* shares sequence with proteins from enteric bacteria and peptides that both mimic and bind B27 and may constitute the molecular components of a mechanism for AS (Scofield, 1995). Another hypothesis suggests that “auto-display” occurring within or between B27 molecules provokes an autoimmune attack in AS (Luthra-Guptasarma, 2004). *HLA-B*27* genotyping is frequently performed by flow cytometry. However, *HLA-B*27* screening is of limited usefulness given its poor positive predictive value, because among *HLA-B*27*-positive individuals in the population at large, only 2% will develop AS (Gran, 1995).

Celiac Disease

Celiac disease (CD), also known as celiac sprue and gluten-sensitive enteropathy, is a disorder characterized by malabsorption resulting from inflammatory injury to the mucosa of the small intestine after ingestion of wheat gluten (reviewed in Green, 2007). Among Caucasians, two HLA-DQ alleles (*HLA-DQ2* and *DQ8*) are found in more than 99% of individuals with CD (Marsh, 1992; Goggins, 1994). Gliadin peptides, which were previously shown to exacerbate CD lesions in vitro and in vivo, have been found to bind to DQ2, lending further credence to the role of this *HLA-DQ* allele in the pathogenesis of CD (Kim, 2004). This finding suggests that HLA-DQ2 could present the gliadin peptide to T cells for autoimmune recognition. Another possible explanation for susceptibility to CD in HLA comes from recent studies showing the binding of atypical invariant chain fragments to HLA-DQ2 (Fallang, 2008; Wiesner, 2008). These studies suggest that HLA-DM-mediated exchange of invariant chain

variants and other HLA-DQ2 peptides might be reduced compared with other HLA-DQ molecules, which may provide a basis for the association of CD and *HLA-DQ2*. HLA genetic testing before serologic screening in patients with suspected CD eliminates up to 60% of the population to be screened, and increases the cost-effectiveness of serologic workups (Chang, 2009).

Narcolepsy

Narcolepsy, also known as cataplexy, is a sleep disorder characterized by attacks of disabling daytime drowsiness and low alertness. Most patients with narcolepsy carry the specific *HLA-DQB1*0602* allele (Matsuki, 1992; Mignot, 1997). Patients with narcolepsy have a marked reduction of hypocretin-producing neurons in the hypothalamus compared with normal controls (Matsuki, 1992; Blouin, 2005). Findings of recent studies are consistent with immunologically mediated destruction of hypocretin-containing cells in patients with narcolepsy (Mignot, 2001). HLA testing in patients with narcolepsy has an excellent negative predictive value and is useful in ruling out the disease in patients with unexplained sleepiness (Hong, 2006).

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is an inflammatory disease, primarily of the joints, with autoimmune features and a complex genetic component. The association between MHC markers and RA is well documented (Nepom, 1992; Ollier, 1992; Auger, 1998). For most of the populations studied, the primary associated marker is *HLA-DR4* (MacGregor, 1995). In Caucasians, for example, the most common RA-associated *DR4* alleles are *DRB1*0401* and *DRB1*0404*, and in Japanese, Israeli, and Chinese patients, it is *DRB1*0405*. Other *HLA-DR* specificities are also associated with RA: *DR1* has been reported in association with RA in Caucasian, Japanese, Spanish, Greek, and Israeli patients; *DR3* in Kuwaitis; *DR6* in Yakima American Indians; *DR9* in Chileans; and *DR10* in Spanish, Greek, and Israeli patients (reviewed in Zanelli, 2000).

To explain this broad spectrum of different *HLA-DR* associations with RA, it has been proposed that a shared DRB1 peptide epitope is involved in conferring RA susceptibility (Penzotti, 1996). The alleles associated with RA share a highly conserved sequence of amino acids in their third hypervariable region (amino acids 67–74). Individuals with RA frequently have autoantibodies to citrullinated peptides. Citrullination of self-antigens increases the affinity between these peptides and HLA-DR molecules carrying the shared peptide epitope (Hill, 2003; Lundberg, 2005). Thus, if a citrullinated arthritogenic peptide exists, it may bind preferentially to molecules with the RA DRB1 sequence. As yet, no such arthritogenic peptide has been identified. An alternative explanation may involve molecular mimicry between the shared RA DRB1 and antigenic sequences of a pathogen that can induce RA (Albani, 1992). Sequence homology has been found between the shared RA sequence and an HSP from *Escherichia coli* (Auger, 1998).

RA differs clinically from juvenile rheumatoid arthritis (JRA), and HLA associations with JRA are different as well. Furthermore, other *HLA-DR* associations vary among JRA clinical subsets (Stastny, 1993). For example, it has been reported that the frequency of haplotype *HLA-DRB1*0801, DQA1*0401, DQB1*0402* is increased in the whole pauciarticular group and in patients with the persistent pauciarticular form. The haplotype *HLA-DRB1*1301, DRB3*0101, DQA1*0103, DQB1*0603* was also associated with patients with persistent pauciarticular JRA (Fernandez-Vina, 1994). In keeping with the view that the polyarticular form of JRA is RA occurrence in the young, *DRB1*0401* shows a strong association.

Type 1 Diabetes

The most studied of all MHC-linked diseases is type 1 diabetes mellitus (Nepom, 1991; Thorsby, 1992; Winter, 1993; Lernmark, 1999). Type 1 diabetes is a disorder of glucose homeostasis that is characterized by susceptibility to ketoacidosis in the absence of insulin therapy. It is a genetically heterogeneous autoimmune disease affecting about 0.3% of Caucasian populations (Todd, 1990). Alleles of the HLA class II genes *DQ* and *DR* in the MHC region are major determinants of genetic predisposition to type 1 diabetes. Several alleles of these loci are associated with susceptibility to or protection from disease. Striking increases have been noted in the frequency of *HLA-DR3* and *HLA-DR4* among Caucasian patients (Thomson, 1984; Jenkins, 1991). Using molecular-based HLA typing analysis, the increase in *DR4* is found primarily in the subset of *DR4* in linkage disequilibrium with *DQB1*0302* (Kockum, 1993). Although the latter gene is now considered a major marker and perhaps a primary

determinant of type 1 diabetes susceptibility, it is present in only 70% of Caucasian patients. Even among those who carry it, variability in the relative risk for diabetes is observed: *DRB1*0401*, *DQB1*0302* and *DRB1*0402*, and *DQB1*0302* are highly associated with the disease, but *DRB1*0404*, *DQB1*0302* is less so.

In many Caucasian patient populations with type 1 diabetes, there is an excess of *DR3/DR4* heterozygotes over the number of *DR3* or *DR4* homozygotes predicted by the Hardy-Weinberg equilibrium (Kockum, 1999). In addition, the relative risks for some *DR-DQ* genotypes are not simply the sum or product of relative risks for the single haplotype. For example, risk for the *DRB1*03-DQB1*02/DRB1*0401-DQB1*0302* genotype is often found to be higher than for the individual *DRB1*03-DQB1*02* and *DRB1*0401-DQB1*0302* homozygous genotypes. It has been hypothesized that this synergy occurs through the formation of highly susceptible *trans*-encoded HLA-DQB1 and HLA-DQA1 heterodimers (Nepom, 1987; Khalil, 1992). The DR- α molecules are not polymorphic, and mixed DR α - β dimers would not result in novel HLA molecules. On the other hand, both the α and β chains of *DQ* are polymorphic, and a *DQ* α - β dimer composed of transcomplementing chains would be unique to a heterozygous individual and would not be expressed in either parent. In the mouse, such transcomplementation has been demonstrated structurally, and epitopes newly formed in the resulting hybrid molecules allow for an altered functional immune response different from that of either parent (Charron, 1984; Long, 1984).

The *DRB1*1501*, *DQB1*0602* haplotype is negatively associated with type 1 diabetes. Individuals heterozygous for *DRB1*1501*, *DQB1*0602* who also carry a susceptibility gene for type 1 diabetes on the other haplotype are nonetheless not at risk for the disease (dominant protection), as would be expected with a recessive disorder (Noble, 1996). A recently proposed model for type 1 diabetes, which assumes that *DQB1* is a direct determinant of susceptibility, suggests a hierarchy of affinities among different class II molecules that compete for binding to the same type 1 diabetes peptide (Nepom, 1990). Susceptibility occurs if a gene product (e.g., *DQB1*0302*) binds and presents the type 1 diabetes peptide. In the presence of a high-affinity competitor (*DRB1*1501*), this event does not occur. Another model proposes that codon 57 of the *DQB*-encoded chain plays a critical role in the pathogenesis of type 1 diabetes. The presence of a nonaspartic acid at position 57 of *DQB1* has been suggested as an important determinant of susceptibility to type 1 diabetes mediated by the *DQB1* genes (Lee, 2001; Siebold, 2004). The excess presence of valine or serine at this position in diabetic patients carrying the *HLA-DR3* or *DR4* haplotype supports this concept.

METHODS OF DETECTING ASSOCIATION OR LINKAGE OF DISEASE WITH GENETIC MARKERS

GENETIC POLYMORPHISM

Genetic polymorphism is defined as the occurrence of two or more alleles at one gene, each with appreciable frequency in the same population. The frequency has been arbitrarily defined to be higher than 1%. Two groups of genetic polymorphisms are known: balanced or stable, and transient. A balanced or stable polymorphism occurs when two or more alleles are maintained in a population by selection. The heterozygous advantage is the classic example of a balanced polymorphism. A transient polymorphism represents a phase of allelic changes driven by genetic drift or by selection. Polymorphism of a gene can be stable in one population and transient in another, depending on the effect of selection.

GENE AND PHENOTYPE FREQUENCIES

To determine genetic polymorphism, it is necessary to find a representative sample of the population, assess the individuals, count the genes, and estimate the number of genes contained in the entire population. For example, assuming that a population of 100 individuals has been studied for a particular genetic trait or allele at a given gene, we can define the phenotype frequency as the number of individuals carrying the trait or the genetic variant. To calculate the frequency (f) of a given allele, divide the number of times that allele occurs (x) by the total occurrences of all alleles of that gene in the population ($x+y+z+\dots$):

$$f(x) = x/(x + y + z + \dots) \quad (49-1)$$

It is possible to calculate the gene frequency (g) without knowing the mode of inheritance by using the formula:

$$g = 1 - \sqrt{f} \quad (49-2)$$

STRENGTH OF ASSOCIATION

Several methods have been devised for detecting the degree of association of genetic markers with hypothesized genes for disease susceptibility. One method is to compute the risk of disease among individuals carrying a specific allele of a polymorphic system. In this computation, the relative risk (RR), or odds ratio, calculates the risk of carrying a marker in a population of diseased individuals compared with a control population. This strength of association is the delta of Bergston and Thomson (Svejgaard, 1983), which is the same as the etiologic fraction (EF) (Miettinen, 1976). If, in a patient population, "a" individuals carry the specific character but "b" individuals do not, and in the control (normal) population, "c" individuals carry the character, we may write the information conveniently in the 2×2 table as follows:

	Character-Positive	Character-Negative
Patient	a	b
Control	c	d

The frequency of the character in this patient population (b_p) is:

$$b_p = \frac{a}{a + b} \quad (49-3)$$

The RR, or odds ratio, is defined as follows:

$$RR = \frac{a \times d}{b \times c} \quad (49-4)$$

Etiologic fraction is defined as follows:

$$EF = \frac{RR - 1}{RR} \times \frac{a}{a + b} = \frac{RR - 1}{RR} \times b_p \quad (49-5)$$

Similarly, in decreased risk, for which the RR is less than 1, the preventive factor (PF) can be used:

$$PF = \frac{(1 - RR) b_p}{RR (1 - b_p) + b_p} \quad (49-6)$$

EF and PF fraction can vary between 0 (no association) and 1.0 (maximal association). Apart from providing estimates of having a marker if one already has a disease, these calculations ignore the mode of genetic determination of the disease in question. This is particularly problematic for recessive or more complicated modes, in which both haplotypes are important for determining disease, but heterozygotes and homozygotes for a given marker are given the same weight, that is, both are positive for the marker.

ANALYSIS OF MODE OF INHERITANCE BASED ON SIBLING PAIRS

Analysis of mode of inheritance based on sibling pairs was introduced to help overcome the problems of incomplete penetrance of disease genes and variations in the age of onset (Penrose, 1935). This analysis is based on the assumption that if HLA and/or genes closely linked to HLA have no influence on the development of a disease, then the affected sibling pairs will share HLA haplotypes with a normal frequency: 25% will share both haplotypes, 50% will share one, and 25% will share no haplotypes. Thus, observed and expected distributions of haplotype sharing are compared. If susceptibility genes or their closely linked markers are rare and fully penetrant in a purely recessively determined disease, the distributions of two-, one-, and no-haplotype-sharing sibs would be 100, 0, and 0. For dominant determination, the ratios would be 33, 66, and 0. What is observed in diabetes, for example (Rubinstein, 1977), is 60, 35, and 5—closer to recessive than dominant predictions. Once the mode of inheritance has been established, disease gene frequency and penetrance can be determined (Thomson, 1977).

ANALYSIS OF MODE OF INHERITANCE BASED ON POPULATION STUDIES

Investigators (Thomson, 1977) have devised a method for analyzing population data for markers closely linked to susceptibility loci for diseases with

incomplete penetrance. In essence, this method predicts the proportions of homozygotes, heterozygotes, and noncarriers for the linked marker that are expected in cases of dominant or recessive inheritance. The greatest difference between the two modes of inheritance is observed in the proportions of individuals who are homozygous for the marker. Application of this method to *HLA-B27* and AS led, on statistical grounds, to rejection of a recessive mechanism. Thus, it was concluded that susceptibility to AS is inherited as a dominant trait.

The same method of analysis was applied to the distribution of *CFB*F1* among 1107 patients with type 1 diabetes mellitus (Raum, 1981). For dominant inheritance, 1.89 homozygotes were predicted, and for recessive inheritance, 6.2 homozygotes were predicted. Seven *CFB*F1* homozygotes were found—a result that is consistent only with recessive inheritance. Other modes of inheritance that could be rejected by these observations include simple dominant, epistatic (disease resulting from the presence of nonallelic genes), and overdominant (disease with greater penetrance when two specific alleles are present than when other combinations, including homozygosity for each specific allele, occur). Although a mixed model with different penetrance for homozygotes and heterozygotes could not be completely ruled out, other considerations make such a model unsatisfactory.

LOD SCORE METHOD

The logarithm of the odds (LOD) score is a statistical measure of linkage between a marker locus, such as in the MHC, and a disease susceptibility gene (Sutton, 1980). In the equation for calculating the LOD score, (1) the Z value is the ratio of the maximum likelihood of finding linkage ($P(F_1/\theta)$) to that of no linkage at a particular recombination value of θ , and (2) the $\theta(q)$ value, or recombination frequency, is a measure of the distance from a given locus corresponding to maximum Z value. The LOD score expresses the probability that alleles at two loci will segregate together, in terms of the ratio between the observed and the predicted recombination frequency if they assort independently. Various values of (q) from 0 to 0.5 are substituted into the following equation:

$$P(F_1/\theta) = 1/2 [\theta^n (1 - \theta)^{n-r} + \theta^{n-r} (1 - \theta)^r] \quad (49-7)$$

where n = the number of children in a given family and r = the number of recombinants. The probability of obtaining a pedigree for a given value of

θ (recombination frequency from 0 to 0.5), which is expressed as the ratio of $P(F_1/\theta)$ in a family at a given recombination fraction θ (from 0 to 0.5) to $P(F_1/0.5)$ in the same family assuming no recombination, can be expressed as the LOD score (Z). The LOD score is the sum of all z values where Z is

$$z = \log_{10} \frac{P(F_1/\theta)}{P(F_1/0.5)} \quad (49-8)$$

Values of Z greater than zero favor linkage, and those less than or equal to zero are against linkage. In general, a Z value greater than 3 (for some values of $\theta < 0.5$) means that the odds in favor of linkage are 1000 to 1 (p value = 0.05), as opposed to no linkage or independence. It is easier to calculate linkage for codominant traits (e.g., HLA) than for recessive traits. In studies that examine the linkage of HLA and disease, the parents may have recessive or dominant impenetrant susceptibility genes. Basic problems have been noted in using the LOD score method to detect linkage of partially penetrant genes, apart from impenetrant susceptible siblings. If susceptibility genes are common, as appears to be the case in type 1 diabetes, for example, apparent crossovers or nonidentical siblings could suggest additional susceptibility genes in a parent.

SUMMARY

The MHC comprises many alleles at many loci. The high resolution typing of class I and class II MHC genes and the identification of genes between and near them have increased the possibility of defining the genetic basis for immune responses and diseases of unknown origin, such as autoimmune diseases in man. The nonrandom association of markers with immune responses or associations with autoimmune diseases due to the presence of fixed stretches of MHC DNA and extended haplotypes and their fragments in the population complicate the study of susceptibility genes but also provide the means for their identification. Even though the human MHC is the most intensively investigated region of the genome, not all of the expressed genes within the MHC have been identified. It is probable that some unidentified MHC genes, rather than the one already identified, are susceptibility genes for some human MHC-associated diseases.

NOVEL APPROACHES TO TREATING IMMUNODEFICIENCY DISORDERS, 971

SUMMARY, 972

SELECTED REFERENCES, 972

KEY POINTS

- Primary immunodeficiencies are a group of single gene disorders.
- Because of the complexity of diagnosing a primary immunodeficiency, the cooperation of the clinician, the research scientist, and the clinical pathologist is required.
- A logical approach to the diagnosis of primary immunodeficiency disorders based on staged diagnostic testing is necessary because of the complex nature of the immune system.
- Preparation for specimen collection, handling, and delivery to a specialty laboratory is required for performing complex immunologic assays.
- As a result of technological advances, molecular genetic testing is increasingly employed in diagnosing primary immunodeficiency disorders and will be paramount in guiding future treatment.

Primary immunodeficiencies are a group of single-gene disorders that result in defects in the immune system. The manifestations can vary in terms of degree of severity, types of symptoms exhibited, or both. These conditions, when unrecognized and left untreated, can result in death from infection. A genetic defect may result in loss of a critical enzyme, may cause developmental arrest in one aspect of the immune system, may cause loss of a structural component, or may create a nonfunctional protein. Most of these disorders are X-linked, resulting in a disproportionate number of affected males—approximately 70% of patients with primary immunodeficiency disorders (Puck, 1997a). A majority of primary immunodeficiencies are detected before 20 years of age, but diagnosis can be delayed because recognition requires a high degree of clinical suspicion. More than 100 primary immunodeficiency disorders have been described; however, more than 90% of such patients are affected by fewer than 20 primary immunodeficiency disorders (Puck, 1997a). Whereas primary immunodeficiency disorders are due to single gene mutations, secondary immunodeficiencies may be due to malnutrition, viral infection, hematologic and other types of malignancy, chemotherapeutic treatment for malignancy, and immunosuppressive medication for treatment of a variety of disorders.

The natural physical barriers of the body are the first line of defense against invading microbes and include skin, mucus at exposed mucosal

surfaces, and ciliated cells of the respiratory, intestinal, and genital tracts. In addition to physical barriers, immunologic functions of the body exert continual surveillance through acquired and innate modes of action. The acquired immunologic response is specific, requiring previous antigen exposure for sensitization, and improves with each subsequent challenge from a given antigen. These responses are the result of a proliferation of antigen-specific B and T cells, which are stimulated after cellular receptors bind to antigens. B cells produce antigen-specific antibodies to eliminate extracellular antigens. T cells assist B cells to produce antigen-specific antibodies and also kill cells that are virally infected. Innate responses do not require prior antigen exposure and comprise phagocytic cells (macrophages, neutrophils, and monocytes), complement, cytokines, and acute phase reactants (Delves, 2000).

The immune system is an interlocking group of immune cells and immune functions, in which any defect may result in an immunodeficiency. The incidence of primary immunodeficiency diseases in the United States is estimated at about 1 in 200,000 liveborn infants, excluding selective immunoglobulin (Ig)A deficiency (Winkelstein, 2000). The most common immunodeficiency, selective IgA deficiency, has an incidence of 1 in every 1200 healthy blood donors, with IgA levels less than 0.05 mg/dL (Sandler, 1994). As a whole, the estimated incidence of diagnosed primary immunodeficiency disease is 1 in 10,000 (Immune Deficiency Foundation, 1992; Shearer, 1994; Smith, 1999). Data from Australia and Norway estimate the incidence of primary immunodeficiency at 2.1 per 100,000 (Baumgart, 1997) and 6.8 per 100,000, respectively (Ryser, 1988; Stray-Pedersen, 1997; Matamoros, 2000).

For unknown reasons, approximately half of reported immune defects involve defective antibody production due to low numbers of B cells or B cells with decreased production of antigen-specific antibody. Decreased antigen-specific antibody production most frequently manifests as recurrent pulmonary or sinus infection, as well as bacterial septicemia (Noroski, 1998). These infections are typically caused by encapsulated bacteria such as *Streptococcus pneumoniae* or *Haemophilus influenzae*. Defective T cell immunity is characteristically associated with opportunistic, viral, and fungal infections, such as *Candida albicans*, *Mycobacterium avium-intracellulare* (MAI), and *Pneumocystis (carinii) jiroveci* (Buckley, 2000). The type of infection a patient acquires may point toward the type of cellular immune defect that is present (Fig. 50-1). Primary immunodeficiency disorders are also associated with autoimmune diseases, as well as malignant neoplasms and especially lymphomas (Smith, 1999).

CLINICAL SIGNS AND SYMPTOMS OF IMMUNODEFICIENCY

Most frequently, increased susceptibility to recurrent infection is the first clinical indication of an immune defect. The type of recurrent infection provides insight into the immune defect and helps guide the clinician in evaluating the patient. Therefore, the most critical part of the medical evaluation is obtaining a complete medical history. Identifying children with immunodeficiency presents a significant challenge to pediatricians, because infections are a common occurrence in normal childhood but can be the principal manifestation of a primary immunodeficiency. Therefore, frequent and prolonged infections, coupled with failure to thrive, or opportunistic infections require a thorough immunologic workup (Puck,

1999). A confirmed report of an immunodeficiency disease occurring in a sibling or first-degree relative should also prompt careful clinical assessment and laboratory investigation, even without a history of severe or unusual infections. In one study of 70 patients with primary immunodeficiency disorders, approximately 18.6% had a family history of an immunodeficiency (Kobrynski, 2002).

Awareness of common clinical presentations can aid physicians in identifying individuals who are more likely to have a primary immune defect. Clinical signs and symptoms of primary immunodeficiency are presented in Figure 50-2. In addition to these warning signs, the physician should be alerted by elements in the history that are unusual, such as a history of autoimmune disease, significant lymphadenopathy, the need for an adult to have a myringotomy, severe herpes zoster or herpes zoster appearing in a young child, or intractable diarrhea or ulcerative colitis diagnosed in a child younger than 1 year old. These additional signs and symptoms should prompt evaluation for a possible immune defect.

It is not practical to investigate all immunologic systems in all patients, so the clinical picture and age of the patient will point the investigator to the portion of the immune system that is most likely to be affected. Taking a careful history and performing a thorough physical examination can narrow the possibilities to defects involving T cells, B cells, granulocytes, or the complement system. The roles of these host defenses and their correlation with different immunodeficiency disorders are presented in Figure 50-3.

It is also important to pay attention to the clinical circumstances and not to dwell exclusively on the number or severity of infectious episodes (Atkinson, 2000). For example, when an infectious process involves the same anatomic site repeatedly, the cause is more likely to be structural, not failure of one of the host defenses. Examples include chronic osteomyelitis in one location, recurrent episodes of pneumonia that affect only one lobe of the lung, and recurrent infection of a surgical wound. Additionally, some primary immunodeficiency disorders, such as chronic granulomatous disease, may present later in life than expected; however, it is still important to keep these disorders in the differential diagnosis (Lukela, 2005).

Figure 50-1 Infections associated with cellular immune defects.

EVALUATION OF THE IMMUNE SYSTEM

Based on the previous considerations, when an immune defect is suspected, evaluation of the immune system is best approached in stages, with basic screening tests performed first and more complex testing conducted as indicated. For example, if a patient presents with strong clinical symptoms suggestive of a B or T cell disorder but a normal lymphocyte count, further investigation by a lymphocyte enumeration panel is warranted. An overview of this staged approach is given in Figure 50-4, and a basic testing algorithm for immunodeficiencies is provided in Figure 50-5.

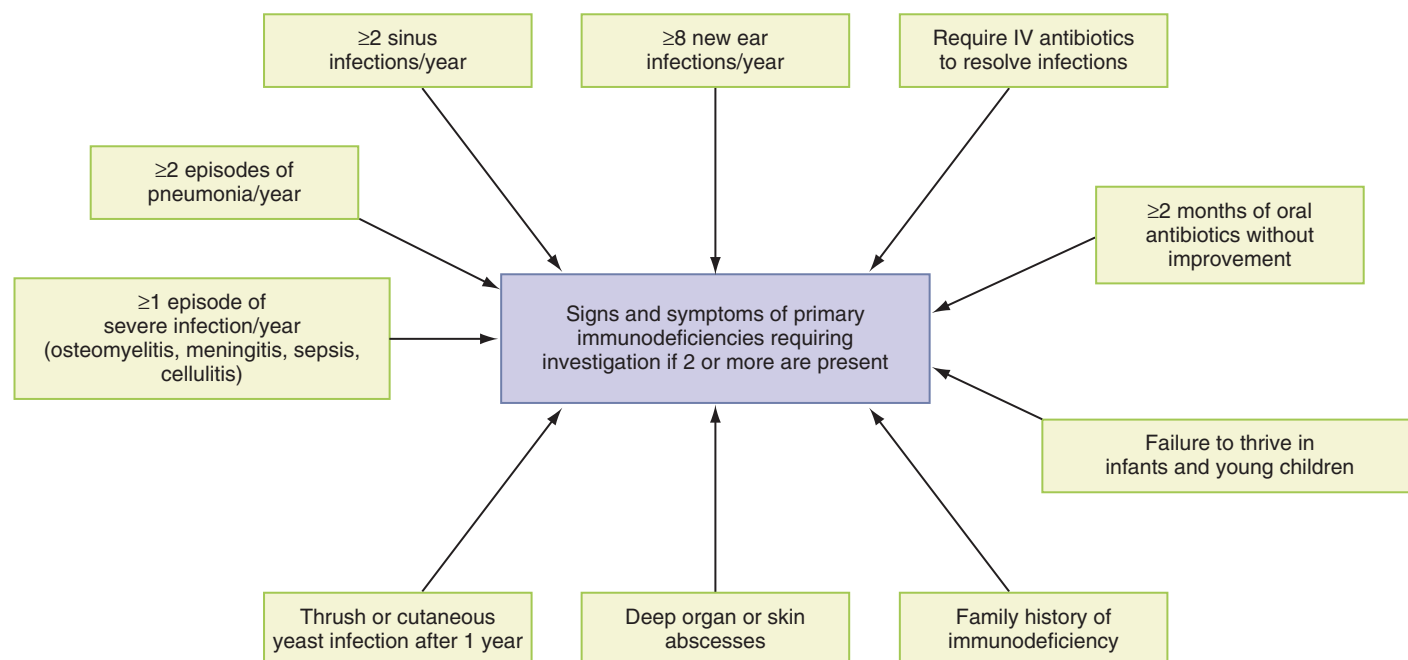

Figure 50-2 Clinical signs and symptoms of primary immunodeficiencies.

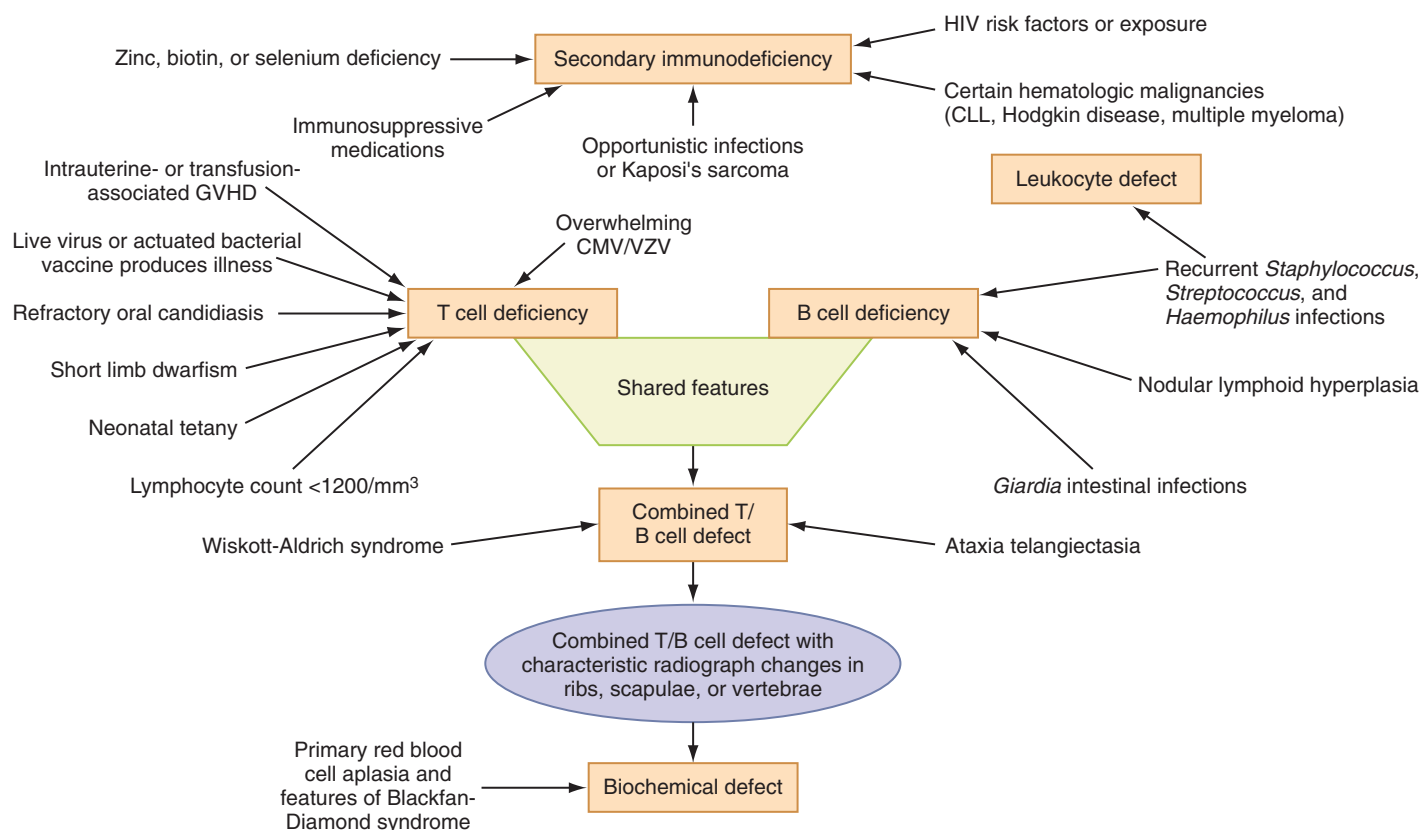

Figure 50-3 Patterns of immunodeficiency disorders. *CLL*, Chronic lymphoid leukemia; *CMV*, cytomegalovirus; *GVHD*, graft-versus-host disease; *HIV*, human immunodeficiency virus; *VZV*, varicella zoster virus.

Primary Investigation

- History and physical examination
- CBC/differential
- Radiographs
- Quantitative immunoglobulins (IgG, IgM, IgA)
- Review of previous culture results
- Pulmonary function testing

Secondary Investigation

- Titers for vaccines administered (tetanus, diphtheria, pneumococcus)
- IgG subclass analysis
- Lymphocyte enumeration panel (CD3, CD4, CD8, CD19, CD16, CD56)
- Complement levels (CH50, C3, C4)
- Skin testing
- Mononuclear cell proliferation studies
- NBT

Tertiary Investigation

- Enzyme studies (adenosine deaminase, purine nucleotide phosphorylase)
- NK cell cytotoxic studies
- Phagocyte studies
- Histology and immunohistochemistry analysis (or flow cytometry) of lymph nodes or lymphoid organs
- Cytokine production
- Advanced complement studies
- Molecular biology

FIRST-LEVEL INVESTIGATIONS

Clinical History, Physical Examination, and Initial Blood Count

A thorough clinical history provides the primary clues in diagnosing a primary immunodeficiency disorder. The typical history includes recurrent, persistent infections or infections caused by unusual microbes. The clinician will be guided by the types of infection the patient has acquired. Patients with immunoglobulin deficiencies typically report an increased number of bacterial infections. Repeated viral, fungal, or other opportunistic infections are associated with T cell immunodeficiencies. Patients with phagocytic defects usually report a history of infections with catalase-positive bacteria, such as *Staphylococcus* spp. Complement deficiencies are most frequently associated with *Streptococcus pneumoniae* or *Neisseria* spp. infections (see Fig. 50-1) (Lindegren, 2004).

The physical examination may reveal findings that are characteristic for particular primary immunodeficiency disorders. Patients with primary immunodeficiency diseases are pale and lethargic, and appear chronically ill. Infants and young children affected with primary immunodeficiency disorders may present with failure to thrive, so monitoring height and weight is important. Small or absent peripheral lymph nodes, tonsils, or adenoids are indicative of X-linked agammaglobulinemia (Lindegren, 2004). In addition to respiratory infection, the infant may experience rhinitis, conjunctivitis, or hematologic, gastrointestinal, and autoimmune disorders (Fleisher, 2003). In contrast, patients with chronic granulomatous disease (CGD) and common variable immunodeficiency present with normal or enlarged peripheral lymph nodes (Buckley, 2000). The genetic defect in Wiskott-Aldrich syndrome causes immunodeficiency and thrombocytopenia, resulting in the combination of increased bruisability, petechiae, and eczematous skin rashes (Zhu, 1997).

The first test performed to examine the immune system is the complete blood count. A white blood count and differential will provide information on the morphology and number of small lymphocytes (diameter <10 μ m). Normal parameters vary, based on the age of the patient, and therefore must be interpreted using age-appropriate normal ranges. At a minimum, regardless of age, one expects more than 1200 small lymphocytes per cubic millimeter. Because few (\approx 10%) of the lymphocytes are B lymphocytes, an

absolute lymphocyte deficiency primarily reflects T cell deficiency. Part of the first visit should include obtaining all previous medical records, including pathology reports or slides, and results of previous cultures and radiographs.

Immunoglobulins

Because antibody deficiency diseases are more common than other immune defects, first emphasis should be placed on investigation of immunoglobulins and their production (Stiehm, 1996). Approximately half of primary immunodeficiency disorders are related to inadequate antibody production or nonfunctional antibodies (Noroski, 1998). Quantitative immunoglobulin assays are readily available in all commercial and larger hospital laboratories and require only small volumes of serum to perform (see Chapters 19 and 46). Because immunoglobulin values increase with age, comparison with age-matched normal ranges is necessary for correct interpretation.

For the first few months of life, IgG is the major immunoglobulin found in infant serum and is maternal in origin. At approximately 3 months of age, dissipation of maternal IgG concentration, combined with a lag in production by the infant, creates a nadir in IgG levels. However, primarily IgM and secondarily IgA are synthesized by the infant; thus, the presence of these two immunoglobulins provides convincing evidence that X-linked agammaglobulinemia, characterized by pan-hypogammaglobulinemia, is not present. Therefore, IgA, IgM, and IgG should be quantified simultaneously.

Often, IgA is not present in significant amounts until 6 months of age; however, after 1 year of age, IgA levels that remain decreased indicate that this is a permanent defect (Plebani, 1986). IgA-deficient patients may be asymptomatic or may have mild symptoms such as increased respiratory or gastrointestinal infection; however, patients may experience severe or fatal anaphylactic reactions to plasma in blood products that contain IgA (Lindegren, 2004).

Hyper-IgM syndrome, an X-linked T cell inherited disorder, is characterized by normal to elevated levels of IgM with markedly low levels of IgA, IgG, and IgE (Levy 1997; Ramesh, 1998; Buckley, 2000). However, marked elevations of IgE are almost always part of the hyper-IgE syndrome (Buckley, 1978) and are common in immunodysregulation, polyendocrinopathy, enteropathy, immunodysregulation polyendocrinopathy enteropathy X-linked syndrome (IPEX), atypical complete DiGeorge syndrome, Wiskott-Aldrich syndrome (WAS), and Omenn syndrome (Ozcan, 2008). WAS characteristically shows marked elevation of serum IgA combined with low IgM concentrations (Ochs, 1998).

A simple way to assess functional antibody levels in children is to check for isohemagglutinins directed against ABO antigens that the patient lacks, because their presence will indicate active functional antibody production (Fleisher, 2003). Isohemagglutinins are naturally occurring antibodies that form at some point after 2–3 months of age; however, testing for these antibodies is not valid for children 4–6 months of age because of the persistence of maternal immunoglobulin. Additionally, because of relative immaturity, or perhaps inadequate exposure, children with normal immunity may have low concentrations of isohemagglutinins until 5–10 years of age (Cooling, 2008).

Radiologic Imaging

Radiographs, computed tomography (CT), and magnetic resonance imaging (MRI) studies can be helpful in assessing immunodeficiencies. Chronic interstitial pneumonia is common in infants, children, and adults with T cell deficiencies, and should be confirmed on chest radiograph. With time, many patients with primary B cell deficiency (agammaglobulinemia, common variable immunodeficiency) may develop chronic pulmonary fibrosis or bronchiectasis (Sweinberg, 1991; Cunningham-Rundles, 1999). Chest CT in a patient who has recurrent respiratory tract infection is the best means of investigating for

bronchiectasis; if these changes have developed, further investigation is clearly warranted.

In the past, lateral views of the neck were used to assess pharyngeal lymphoid tissue in children. However, radiographs are not recommended for evaluation of cervical lymphoid tissue because the information they provide is more easily obtained by alternative methods. Frontal views of the chest may reveal an absence of the thymic shadow in infants, but because the thymus can shrink easily because of stress, evaluation of thymic size by this method is not reliable. Bony abnormalities, however, can alert the radiologist to an immunologic problem presenting in childhood. A subset of patients with immunodeficiencies involving abnormalities of T cells, or both T and B cells, have short-limbed dwarfism. These patients show characteristic lesions, usually in the metaphyseal regions of the long bones. Patients with infant-onset adenosine deaminase deficiency show readily identifiable skeletal abnormalities of ribs and hips (Lindegren, 2004). Bony abnormalities may be present in patients with the hyper-IgE syndrome; these abnormalities include diffuse osteoporosis, fractures that occur with little trauma, craniosynostosis, and midline bony defects (Grimbacher, 1999).

Pulmonary Functions

Immunodeficiency, especially if it has persisted for some time, will often affect the pulmonary system and its function, as previously mentioned. Therefore complete lung volumes, with forced expiratory volumes, should be tested, even if the chest radiograph is normal. Patients with both T and B cell defects are subject to pulmonary infection, often resulting in bronchospasm, restrictive or obstructive disease, or combinations of these abnormalities. Those patients who are both IgA and IgG2 deficient have significantly abnormal pulmonary function tests, and a causal relationship may be seen between these deficiencies and deterioration of lung function (Bjorkander, 1985).

SECOND-LEVEL INVESTIGATIONS

Antibody Production

Investigation of specific antibody production may require only monitoring of immune response to vaccine antigens and is the most direct method by which to assess B cell function. This is a useful approach for patients with a history of recurrent bacterial infection and low-normal quantitative immunoglobulin concentrations. The definitive method used to assess decreased quantitative immunoglobulins consists of measurement of antigen-specific preimmunization levels and postimmunization antibody levels approximately 4 weeks later. If the child or adult has received the usual immunizations in the past, antibody titers for these vaccine antigens can be measured. The most useful vaccine responses to assess are those associated with tetanus, diphtheria, *Haemophilus*, and *Pneumococcus*; many commercial laboratories have developed sensitive tests such as enzyme-linked immunosorbent assays (ELISAs) that can be used to assess antibody production. Evaluation of immune responses to vaccine must include pre-immunization serum antibody concentrations and the patient's age, because these factors affect antibody response. The testing laboratory provides guidelines for appropriate antibody responses. In general, a fourfold increase in protein antigens and a twofold increase in polysaccharide antigens are expected.

Antibody responses to tetanus toxoid and diphtheria toxoid are useful in evaluating responses to T cell-dependent protein antigens. Assessment of B cell function requires evaluation of responses to carbohydrate antigens, which activate B cells directly. It is important to use carbohydrate antigens that are not conjugated to proteins, such as meningococcal and pneumococcal polysaccharide antigens (Balmer, 2003). Children younger than 2 years old will not respond to unconjugated carbohydrate antigens (Barrett, 1984), and no live virus vaccines should be administered to the child, or any family member, until immunodeficiency is ruled out (Go, 1996).

IgG Subclasses

IgG consists of four subclasses, IgG1 through IgG4, which are distinguished by both structural and biological differences (Normansell, 1987; Schur, 1987). Although individual roles for each of the IgG subclasses have not been established, antibodies to carbohydrate antigens are concentrated in the IgG2 subclass, and many bacterial cell wall antigens are composed of carbohydrates (Scott, 1988). Thus, absence of an IgG2 response could result in failure to develop protection against bacterial infection. This relationship is most convincing in the occasional patient with IgA

deficiency who also has a deficiency of IgG2 subclass and lacks an antibody response to vaccines for *Pneumococcus*. IgG subclass deficiency has also been implicated as the cause of recurrent infection in patients with normal or near normal IgG levels (Oxelius, 1979; Wedgwood, 1986; Shackelford, 1990; Gross, 1992; Popa, 1994).

The biological significance of IgG subclass deficiency is not always clear, and some individuals who completely lack genes for IgG2, IgA, and IgE are healthy (Lefranc, 1982; Migone, 1984). IgG1 is the first type of subclass response to carbohydrate antigens, and conversion to an IgG2 response occurs as the individual matures (Scott, 1988). No evidence indicates that those who are restricted to only IgG1 responses are at any disadvantage. To determine the biological significance of IgG subclass deficiency, testing of specific antibody production, usually by administering vaccines such as tetanus, diphtheria, *Haemophilus*, or a pneumococcal vaccine, is mandatory. Only patients with a clear antibody deficiency for multiple antigens would be considered to have a significant immune defect.

T Cell Immunity

Migration of stem cells from the bone marrow to the thymus results in development of T cells (Kruisbeek, 1999). During development of T cells in the thymus, many surface molecules are turned on and off in a regulated manner. These surface molecules are identified by their cluster of differentiation (CD). CD markers help distinguish the stage of maturation and the function of lymphocytes (Buckley, 2000). Despite regression of the thymus over time, T cell development persists throughout life (Jamieson, 1999). Unlike antibodies produced by B cells, which recognize antigens in their natural state, T cells recognize peptides along with MHC molecules after processing by antigen-presenting cells through CD3, the T cell receptor (Buckley, 2000).

Monoclonal antibodies are useful for detection of CD markers on lymphocytes and enable rapid enumeration of T cells and T cell subsets. This can be done by using small volumes of whole blood. The CD designation subdivides T cells (as a group, CD3⁺) into two major subsets: CD4⁺ and CD8⁺ T cells. CD4⁺ T cells are referred to as "helper" cells and are involved in initiation of immune reactions, cytokine secretion, and augmentation of B cell responses. CD8⁺ T cells also release cytokines and are associated with cytolytic (killer) functions. CD4⁺ and CD8⁺ markers on T cells serve as signaling molecules and work in conjunction with major histocompatibility complex (MHC) class I and II antigens to amplify and stabilize engagement of T cell receptors (TCRs) with antigens. CD4⁺ cells recognize antigens that are presented in the context of MHC class II antigens, and CD8⁺ cells recognize antigens presented in context with MHC class I antigens (Buckley, 2000). Immunodeficiency diseases resulting from defective generation of T cells may result in total loss or low numbers of CD3⁺ T cells, thereby creating similar effects on T cell subsets, CD4⁺ and CD8⁺ cells. For example, DiGeorge syndrome results in low numbers of CD3⁺ cells (Hong, 1998). MHC class II deficiency results in a low number of CD4⁺ cells (Klein, 1993), and an abnormality of Zap-70, a signaling molecule integral to the activity of the T cell receptor, leads to reduced numbers of CD8⁺ T cells (Elder, 1998). If an immune defect is suspected, a panel of T cell markers is examined by flow cytometry, and the percentage and absolute count of cells in each set are compared with age-appropriate normal ranges (Illloh, 2004).

T Cell Functional Assessment

A clinical history of opportunistic infections and a decreased absolute lymphocyte count in a complete blood count should prompt further investigation of a patient's T cell function (Fleisher, 2003). Mucocutaneous candidiasis, another indication of defective T cell function, is characterized by extension of infection from the mucous membranes onto contiguous skin and may involve the fingernails with granulomatous inflammation (Atkinson, 2000; Lilic, 2001). Delayed-type hypersensitivity (DTH) skin tests are commonly used as measures of T cell function because they measure the ability to recall, recognize and present antigen, mobilize T cells, and generate a specific inflammatory response. Despite a normal absolute lymphocyte count, DTH skin tests should be performed when a T cell defect is suspected. However, these tests are difficult to interpret in infants because they may not have had sufficient exposure to respond to antigens to mount an immunogenic response, and a reduced or absent response may be normal. Hypersensitivity skin testing should incorporate more than one antigen (Kniker, 1985). To ensure proper administration and appropriate interpretation of test results, personnel must be well trained (Fleisher, 2003).

Insight into the capability of T cells can be gained by performing functional assessments of in vitro proliferative responses to different

stimuli. Mitogens, antigens, and alloantigens are stimuli that cause proliferation of T cells. Mitogens are usually plant extracts that lack specificity and stimulate both CD4⁺ and CD8⁺ T lymphocytes. Alloantigens on unrelated donor cells also stimulate CD4⁺ and CD8⁺ cells in a relatively nonspecific way. Patients with significant T cell deficiency may still show proliferative responses to these stimulators, indicating the presence of T cells but not their ability to clear infectious agents from the host. Nonetheless, a proliferative response to specific antigens is a good indicator of the host's ability to resist infection (Lane, 1985). In the case of specific antigens, tetanus, diphtheria, and *Candida* are commonly used, although sufficient exposure to these antigens is required. Therefore, these are not reliable antigens for testing infants during the first year of life. A measure of specific T cell responses that is useful in infants consists of culturing peripheral blood mononuclear cells with mitogenic concentrations of anti-CD3 monoclonal antibody. This stimulator normally causes proliferation of all CD3⁺ T cells, and absence of proliferation demonstrates a severe T cell defect (Hong, 1996).

Polymorphonuclear Killing Assays

Testing neutrophil function requires careful planning because specimens may be transported over long distances to large reference laboratories for testing. Blood collected from a patient should be submitted to the investigating laboratory as soon as possible because neutrophils undergo apoptosis rapidly after collection. If the blood must be stored or transported, it should be collected in a preservative such as ethylenediaminetetraacetic acid (EDTA) or citrate in a polypropylene tube and maintained at room temperature (20°–25° C). This decreases metabolic activity and minimizes adhesion of cells to the wall of the tube. Even under optimal conditions, cells can be maintained only for approximately 24–36 hours (Kuijpers, 1999).

Neutropenia or neutrophil dysfunction results in recurrent bacterial or fungal infection in the skin, lymph nodes, liver, lungs, or bones. This most commonly occurs with myelosuppressive therapies used to treat malignant neoplasms. These disorders must be distinguished from CGD, in which phagocytosis is normal, but intracellular killing of infectious organisms is defective, resulting in abscess or granuloma formation in the liver, bones, and lungs (Lekstrom-Himes, 2000). CGD inheritance is most commonly X-linked or autosomal recessive owing to mutations involving chromosome locations 16p24, 7q11.23, and 1q25. These changes result in defects in one of the four subunits of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, the enzyme that catalyzes the formation of hydrogen peroxide. This error causes failure of the metabolic burst in granulocytes following phagocytic ingestion of bacteria (Meischl, 1998). As a result, molecular oxygen is not reduced to superoxide and other free radicals, such as hydroxyl radical and hydrogen peroxide, which are important components of the intracellular mechanism of bacterial death (Babior, 1978). Therefore, CGD is characterized by recurrent infection with catalase-producing organisms, such as *Staphylococcus aureus*, which are capable of destroying the hydrogen peroxide produced by granulocytes. Therefore, catalase-positive organisms survive intracellular ingestion, multiply, and cause a granulomatous tissue response that, when excessive, can obstruct the gastrointestinal and genitourinary tracts. Chronic infection with *Serratia* spp., *Klebsiella* spp., *Burkholderia cepacia*, and *Aspergillus* spp. is particularly problematic (Gallin, 1983, 1990). However, patients with CGD do not experience this problem with catalase-negative organisms.

The fundamental biological characteristic of CGD leukocytes is that they will phagocytose bacteria normally but will not kill them. This provides the basis for a bacterial killing assay for CGD. Historically, the nitroblue tetrazolium (NBT) slide test has been the laboratory assay used to screen for CGD and is performed by reference laboratories (Park, 1968). In this assay, the patient's neutrophils are incubated with NBT, a pale yellow dye that is then activated by phorbol-myristate acetate (PMA), a strong, receptor-independent activation stimulus. Functional neutrophils phagocytose, reduce, and precipitate the NBT dye, forming intracellular deposits of black formazan. These deposits are indicative of rapid activation of NADPH-oxidase enzyme, causing reduction of oxygen by NADPH to superoxide that is subsequently catalyzed to hydrogen peroxide by superoxide dismutase (SOD). A technician then microscopically scores neutrophils that contain intracellular black formazan deposits (Kuijpers, 1999). However, the NBT slide test has been replaced in many laboratories by a flow cytometry test that detects intracellular oxidation of dichlorofluorescein diacetate or dihydrorhodamine 123 (O'Gorman, 1995). These nonfluorescent dyes, once oxidized, will produce intracellular fluorescent products that are detected by flow cytometry. Flow cytometry is a more objective and reliable method of identifying intracellular products.

The hyper-IgE syndrome (HIES) is phenotypically similar to CGD, with a classic triad of pneumonia, recurrent cutaneous and pulmonary abscesses, and elevated IgE levels; however, defective polymorphonuclear leukocyte function is not a predominant finding (Buckley, 1978; Ozcan, 2008). In addition, this syndrome includes bone abnormalities, unusual facies, and cutaneous candidiasis. Demonstration of IgE levels greater than 2000 IU/mL and (even as high as 20,000–60,000 IU/mL) with the appropriate clinical manifestations points toward the diagnosis. HIES is actually two distinct entities—autosomal dominant and autosomal recessive—based on inheritance patterns and nonimmunologic features. Each entity is characterized by different genetic mutations. Autosomal dominant HIES (AD-HIES) has been related to dominant-negative mutations of the signal transducer and transcription activator 3 (STAT3), causing impaired signaling of cytokines interleukin (IL)-6 and IL-10. However, signaling for IL-12 and interferon (IFN)- α remains intact. Patients with STAT3 mutations fail to generate helper T cells that secrete IL-17, which is important in providing epithelial and mucosal immunity against fungal and bacterial organisms. It also plays an important role in producing neutrophil chemoattractants. Autosomal recessive HIES (AR-HIES) is a distinct disease entity separated from AD-HIES by four major criteria: (1) The inheritance pattern is distinctly different; (2) patients lack connective tissue abnormalities; (3) the incidence of central nervous system complications is higher, and these patients have a higher frequency of varicella-zoster; and (4) herpes simplex virus occurs at a younger age with more complications (Renner, 2004). Of note is a case report of a patient with AR-HIES and a homozygous tyrosine kinase 2 (TYK2) mutation that resulted in a premature termination codon and absence of TYK2 protein. TYK2 belongs to the Janus kinase family, which is important in multiple cytokine signaling pathways, including type 1 IFN, IL-6, IL-10, IL-12, and IL-23. The patient exhibited severe defects in response to these cytokines and had impaired Type 1 helper T cells (T_H1) and accelerated Type 2 helper T cells (T_H2) differentiation. To date, this mutation has not been identified in any other patients with AR-HIES, which suggests that other, as yet undiscovered genetic mutations can result in this syndrome (Fischer, 2007; Ozcan, 2008).

Complement Evaluation

A number of congenital defects of the complement system have been described, although this is not a frequent cause of primary immunodeficiency disorder. The defects are typically associated with absence of one of the complement molecules or a nonfunctional complement protein, thereby reducing the ability of complement to bind to the surface of invading microorganisms. Individual defects lead to distinct clinical syndromes such as hereditary angioedema or paroxysmal nocturnal hemoglobinuria, a propensity for recurrent bacterial infection, or autoimmune disease (Schneider, 1999). Many of the genetically based deficiencies of the classical activating pathway (C1, C2, C3, C4) and of the terminal components (C5, C6, C7, C8, and C9) can be detected by using antibody-sensitized sheep erythrocytes in a total hemolytic complement assay (CH50). This assay tests for the functional integrity of C1–C9. Many commercial laboratories perform this assay, but to get accurate results, freshly drawn serum or plasma that is then frozen must be used. Therefore, logistics must be carefully coordinated if specimens must be sent to a distant location. Deficiencies of alternative pathway component factors D, H, and I and properdin are uncommon but can be detected by a hemolytic assay using unsensitized rabbit erythrocytes as potent activators of the alternative pathway. If one of these assays is abnormal, identification of individual deficient components rests on specialized functional and immunochemical tests that are specific for each component (see Chapter 47).

THIRD-LEVEL INVESTIGATIONS

Enzyme Measurements for Metabolic Defects

Deficiencies of the enzymes adenosine deaminase and purine nucleoside phosphorylase are related to purine metabolism and result in immunodeficiency. Patients with adenosine deaminase deficiency have findings similar to those of severe combined immunodeficiency (SCID) syndrome, a collection of genetic disorders characterized by a severe defect in the function or development of B and T cells. In contrast to SCID, patients deficient in adenosine deaminase have chondro-osseous dysplasia, resulting in skeletal abnormalities, and more severe lymphopenia. Deficient adenosine deaminase is caused by mutation of the gene located on chromosome 20q13.2–q13.11, resulting in toxic accumulation of metabolites that inhibit cell replication and cause apoptosis of lymphocytic cell lines

(Buckley, 2000). Lack of adenosine deaminase initially causes loss of T cells (CD4⁺ T cells in particular) and subsequently B cells, leading to the common form of severe combined T and B cell deficiency (SCID) (Hirschhorn, 1995). As with many primary immune defects first recognized in the severe homozygous form, adenosine deaminase deficiency has been diagnosed as a heterozygous partial deficiency in adults with CD4 lymphopenia and significant T cell defects (Shovlin, 1994).

Purine nucleoside phosphorylase deficiency is characterized by recurrent infection, lymphopenia, neurologic abnormalities, and autoimmune disorders (Myers, 2004). This enzyme deficiency causes a decrease in T cells with minimal or no effect on B cells. Purine nucleoside phosphorylase enzymes are usually measured in erythrocyte lysates (Kizaki, 1977), but if blood products have been administered within the previous 3 months, the assay may be unreliable. More recently, capillary electrophoresis has been proposed as an alternative inexpensive assay that offers high separation flexibility in diagnosis of errors of metabolism and is capable of determining purine nucleoside phosphorylase or adenosine deaminase enzyme activity and the presence of toxic metabolites (Carlucci, 2003).

Natural Killer Cell Assays

Natural killer (NK) cells are a subset of lymphocytes that often function with T cells to eradicate intracellular organisms. Complete deficiency of NK cells is rare and is characterized by recurrent herpes infection (Fleisher, 2003). NK cells have the morphology of a large granular lymphocyte and express a unique group of cellular surface markers: CD16, CD56, and CD57 (Trinchieri, 1989). NK cells can be quantified easily by detecting these surface markers using flow cytometry. However, to assess the functional activity of NK cells, chromium release assays, which use chromium-51-loaded K-562 cell lines, have traditionally been performed (Biron, 1989). This older assay has limitations, in that it is more labor-intensive, incorporates radioactive materials, and cannot identify the cellular mechanisms for cell death of the target cells. These disadvantages have driven the development of newer, non-radioactivity-based methods, including fluorescent labeling techniques in combination with flow cytometry, to assess NK cell function. Another technique uses a colorimetric substrate to detect granzyme B, the serine protease found in the granules of cytotoxic T lymphocytes and NK cells, and plays a key role in granule-mediated apoptosis by cleaving cellular substrates (Hoppner, 2002; Ewen, 2003).

Additional Phagocyte Analyses

Genetic defects of the innate immune system are related to the formation or function of granules within neutrophils. Myeloperoxidase is the predominant enzyme detected in the primary granules of granulocytes and catalyzes the formation of hypochlorous acid (HOCL), which is capable of killing microorganisms (Kuijpers, 1999). However, its absence usually is not associated with clinical symptoms, with the notable exception of patients with diabetes mellitus, who experience increased susceptibility to disseminated candidiasis (Lanza, 1998). Myeloperoxidase deficiency, inherited as an autosomal recessive defect, is one of the most commonly inherited disorders of neutrophils, but its clinical significance is unknown (Lehrer, 1969; Klebanoff, 1999). Approximately half of affected patients have a deficiency of myeloperoxidase, and the remainder have normal concentrations, along with a structural defect in the enzyme (Nauseef, 1998).

Chédiak-Higashi syndrome and specific granule deficiency are congenital defects resulting in phagocyte granular disorders. Chédiak-Higashi syndrome is an autosomal recessive disorder in which all lysosome-containing cells have giant abnormal granules. In neutrophils, fusion of primary and secondary granules occurs, resulting in delay of fusion with phagosomes and recurrent bacterial infection. Patients with Chédiak-Higashi syndrome have a mild neutropenia, normal immunoglobulin levels, peripheral nerve defects, mild cutaneous and ocular albinism, mild platelet dysfunction, and periodontal disease (Introne, 1999).

Neutrophil-specific granule deficiency is a rare disorder characterized by recurrent bacterial infection of the skin and lungs. Patients lack secondary or specific granules of the neutrophils, which play an important role in acute inflammation and do not allow for proper migration of neutrophils. Morphologic examination of stained neutrophils shows characteristic abnormalities in specific granule deficiency (Ganz, 1988).

Patients with leukocyte adhesion deficiency (LAD) type 1 (a defect in the integrin CD18, the common β chain of LFA-1, Mac-1, and p150,95 molecules) (Anderson, 1987) are susceptible to all infections seen in CGD patients, along with otitis media and poor wound healing. Normally, because pathogens cause tissue damage and inflammation, adhesion molecules on vascular endothelium are upregulated and recognized by passing

neutrophils bearing the appropriate counterligands, ultimately leading to accumulation of neutrophils at sites of inflammation (see Chapter 47). Patients with LAD lack the adhesion molecules necessary for diapedesis, resulting in tissue neutropenia and therefore more infection (Arnaout, 1993). This abnormality starts after birth and is marked by delayed cord separation, chronic skin ulcers, periodontitis, impaired wound healing, and leukocytosis. Deficient leukocytes demonstrate defects of adherence and adhesion-dependent functions such as spreading, phagocytosis, and chemotactic orientation (Anderson, 1987).

LAD type 2 predominantly affects neutrophils and macrophages, with faulty expression of the selectin ligand sialyl-LewisX and failure to convert GDP mannose to fucose, resulting in a clinical syndrome similar to type 1. It is also responsible for expression of the rare Bombay blood group (LAD-2) on red blood cells (Etzioni, 1993).

Leukocyte mobility is usually evaluated by directed migration through membrane filters or under agarose (Nelson, 1975; Cates, 1981). Counting the number of cells at a particular endpoint or "stop filter" microscopically, or radioactive labeling, has the disadvantage of measuring only the fastest cells. This may give an inaccurate assessment of most of the patient's neutrophils. It is actually better to count the number of cells at different points along the filter (Kuijpers, 1999). Injections of epinephrine and steroids, which cause polymorphonuclear leukocytes to demarginate and leave the marrow reserves, are used to further assess polymorphonuclear leukocyte mobility. A disorder of actin important in polymorphonuclear leukocyte migration has been described (Southwick, 1988).

Adhesion proteins on the surface of neutrophils can be functionally tested with different immobilized ligands bound to a monolayer of endothelial cells attached to a glass slide, and can be measured after pretreatment with chemoattractants. Rolling, attachment, and migration of neutrophils can be monitored over time by a video camera. Phagocytosis can now be assessed by flow cytometry, in which the neutrophils are incubated with fluorescence-labeled microorganisms, the sample is washed to remove labeled undigested microorganisms, and the cells with ingested labeled microorganism are counted (Kuijpers, 1999). Much in the same fashion, flow cytometry may be used to assess killing of microbes by employing vital dyes that distinguish live from dead organisms after incubation with neutrophils (Martin, 1992). Degranulation may be assessed by measuring expression of granule membrane proteins on the neutrophil cell surface by means of flow cytometry (Kuijpers, 1999).

Cytokines and Cytokine Receptors

Immune responses are regulated by soluble mediators called cytokines that produce a multiplicity of immune events through interactions with appropriate cytokine receptors on tissue and inflammatory cells. Cytokines play an important role as messengers within the immune system and in conjunction with the rest of the body to regulate immune responses (Mire-Sluis, 1998). By studying immunodeficient patients and gene knockout mice, our understanding of the role cytokines play in our host defenses has expanded. Deficiencies in IL-12 and IFN- γ increase susceptibility to *Salmonella* and mycobacterial infections (de Jong, 1998). Impaired secretions or responses to IL-12 impair granuloma formation and therefore allow unregulated growth of mycobacterial organisms (Jouanguy, 1999). Recent studies show that the pathophysiology of many of these disorders may be the result of defective cytokine signaling, which causes dysfunction or arrested development of B, T, and NK cells (Kelly, 2003). Most notably, human X-linked SCID is associated with defects in the interleukin receptor gene (IL2RG), which codes for a common γ chain (γ c), a shared component of several cytokine receptors such as IL-4F, IL-7R, IL-9R, and IL-15R. Impaired production of γ c leads to cytokine dysfunction and lack of development of affected lymphoid cells (Malek, 1999). Additionally, the *JAK3* gene encodes for a tyrosine kinase used in signal transduction through γ c-containing cytokine receptors. Defects in this gene have been identified in patients with autosomal recessive SCID. IL-7 is a cytokine with a key role in T cell development, and a genetic defect in the α subunit of the IL-7 receptor has been identified in patients with a rare disorder of B⁺ SCID (Notarangelo, 2000).

Additional Cell Surface Markers

MHC Class I and II Molecules

Congenital mutations affecting MHC class I and class II expression have been described. Class II molecules are found primarily on the antigen-presenting cells, which initiate the acquired immune response. As one might predict, genetic defects of MHC class II (from mutations involving MHC class II gene transcriptional activation) result in a profound

immunodeficiency state (Klein, 1993) known as MHC class II deficiency, according to World Health Organization nomenclature. This is referred to as bare lymphocyte syndrome type II and is characterized by lack of expression of MHC II molecules on cellular surfaces. Thymic education and selection of immature T cells are compromised because of loss of antigen processing by MHC class II molecules. Quantities of B and T cells are normal in patients with bare lymphocyte syndrome; however, CD4⁺ counts are decreased as a result of loss of proper antigen processing. Patients thus are unable to respond to foreign antigens and present with recurrent bacterial, fungal, viral, and protozoal infections. They do not respond to skin testing (type IV DTH), have a decreased ability to respond to mixed lymphocyte reactions, and have pan-hypogammaglobulinemia (Nekrep, 2003). An interesting facet of this syndrome is that there is no genetic defect of the MHC class II genes. Instead, a defect occurs in one of the four genes that encode the four regulatory factors essential for surface expression of MHC class II antigens (Reith, 2001).

Elimination of foreign antigen can be accomplished by CD8⁺ T cell binding to MHC class I antigens expressed on nearly all nucleated cells. It is strange to note that immune defects resulting from MHC class I deficiency, a mutation involving either of the MHC class I cytoplasmic peptide transporters TAP-1 or TAP-2, produce an immune defect characterized by severe lung disease that becomes apparent in later childhood (Donato, 1995; de la Salle, 1999). This immunodeficiency was previously named type I bare lymphocyte syndrome, or human leukocyte antigen (HLA) class I deficiency, and is characterized by a decrease in CD8⁺ cells and NK cell activity (Yabe, 2002). Diagnosis of both defects involves examining expression of these MHC antigens on peripheral blood lymphoid cells by flow cytometry (Illoh, 2004).

Treatment by Targeting Cell Surface Receptors

Recent case reports describe therapies that target cell surface receptors to treat complications associated with primary immunodeficiency disorders. An example is anti-CD20 (rituximab), a monoclonal antibody directed against the CD20 antigen found on B lymphocytes and used to deplete peripheral benign and malignant B lymphocytes. Successful treatment using these monoclonal antibodies has been reported for IgM autoantibody (reactive at 37° C)-mediated autoimmune hemolytic anemia in a child with common variable immunodeficiency, and for lymphoproliferative disorder in a child with WAS caused by depleting peripheral B cells in patients (Sebire, 2003; Wakim, 2004).

Using Novel Immunogens to Assess Antibody Production

Another valuable tool to evaluate specific antibody responses is vaccination with neo-antigens such as the bacteriophage ΦX174 and keyhole limpet hemocyanin. These neo-antigens may also be used to evaluate patients receiving immunoglobulin replacement therapy, because monitoring antibody responses to standard vaccines while receiving passive infusion of pooled immunoglobulins is not possible. Primary and secondary responses may be monitored because the neo-antigens provoke a primary IgM response, and then, upon reexposure, cause a secondary IgG response (Curtis, 1970; Ochs, 1971). Using ΦX174 clearance patterns and isotypes, a patient's response can be measured, thereby further defining various degrees and subsets of B cell deficiency (Ochs, 1971). Currently, this evaluation is available only in some academic institutions using research protocols (Fleisher, 2004).

Molecular Genetics and Prenatal Diagnosis

A number of the genes involved in the primary immunodeficiency syndromes have now been identified, cloned, and sequenced (Conley, 1992; Puck, 1993; Derry, 1994; Ramesh, 1998; Vihinen, 1999; Fischer, 2007; Zhang, 2009). In many cases, mouse knockout models have been produced to further study the effects of genes on immune function. In the past, more traditional methods of screening for genetic mutations responsible for immunodeficiencies were used, such as dideoxy fingerprinting and single-strand conformational polymorphism (Sarkar, 1992; Sheffield, 1993; Puck, 1997b). More recent advances using fluorescence-based sequencing, which uses fluorescently labeled dideoxynucleotide terminators, allow for simple and sensitive identification of deoxyribonucleic acid (DNA) sequence variations in individuals. Automated multichannel capillary sequences serve as an automated method of rapidly detecting fluorescence-based sequences for multiple patients within hours, and make direct sequencing for genetic mutations responsible for immune deficiencies practical

(Niemela, 2000). Identification of mutated genes facilitates genetic counseling for prenatal diagnosis and aids in the detection of carrier status for defective genes. It also assists in the evaluation of previously undefined immune disorders. An excellent example of how these advanced techniques are enhancing our understanding of primary immunodeficiency disorders is exhibited by hyper-IgM syndrome. Previously, this was categorized as a single disorder, but genetic sequencing has revealed five distinct genetic defects affecting B or T cells with variable phenotypes (Durandy, 2004).

Analysis of immunodeficiencies with known genetic defects involves testing specific sites on DNA to detect specific mutations. Different methods such as polymerase chain reaction (PCR) may be used to detect the presence or absence of a particular gene, and immunoblotting or flow cytometry can be used to detect protein products and to confirm a diagnosis of primary immunodeficiency when the gene product is absent. High-resolution comparative genomic hybridization arrays detect microdeletions associated with complex immunodeficiency syndromes. For example, genomic hybridization arrays and targeted gene sequencing were performed on eight families with variant features of combined immunodeficiency characterized by recurrent sinopulmonary infection, cutaneous viral infection, and elevated serum IgE levels. The analysis revealed novel point mutations in the gene responsible for encoding the dedicator of cytokinesis 8 protein (DOCK8). Homozygous or compound heterozygous deletions in this gene lead to absence of DOCK8 protein in lymphocytes that regulate cytoskeletal rearrangements responsible for cell structure, adhesion, and migration, as well as other functions, resulting in this combined immunodeficiency (Zhang, 2009). An example of when it is important to determine the cause of an immunodeficiency is seen in SCID, a heterogeneous group of immunodeficiencies characterized by a number of different molecular defects. Distinguishing between various molecular defects in SCID has implications for treatment, antenatal diagnosis, and carrier testing. It is important to determine whether a patient has X-linked SCID because this may be treated using gene therapy. JAK3-deficient SCID is clinically indistinguishable from X-linked SCID, but gene therapy is not effective (Cavazzana-Calvo, 2000). Previously, testing to distinguish between these molecular defects took several weeks to complete because JAK3-deficient SCID is encoded by 23 exons. DNA analysis using single-stranded conformational polymorphism analysis and sequencing of all affected exons was required. More rapid screening methods can now be used to arrive at an expeditious diagnosis, with time-consuming genetic analysis being performed for subsequent confirmation. These protein-based assays employ flow cytometric analysis of γ c, immunoblotting for JAK3 and γ c, and detection of IL-2-induced tyrosine phosphorylation of JAK3 (Gilmour, 2001). However, with defects characterized by nonfunctional protein products, these assays are not useful. Table 50-1 lists the currently identified mutated genes and affected proteins associated with primary immunodeficiencies. Table 50-2 provides a summary of gene mutations with associated susceptibilities to pathogens.

With advances in technology, the ability to detect prenatally a wider range of immune defects is possible. If the specific mutation is known, or if the inheritance pattern is known to be X-linked, analysis of linked polymorphic markers or detection of specific mutations can be performed. Chorionic villous samples, amniocyte DNA prepared directly from fetal cells, or cultured and expanded cell lines can be analyzed (Durandy, 1985). In addition to prenatal testing, newborn blood screening (NBS), traditionally used to screen for genetically inherited metabolic disorders, is now used to screen for inherited immunodeficiencies. Several states have added TCR excision circles (TRECs) to the NBS by extracting DNA from the NBS cards to analyze episomal fragments of DNA formed during rearrangement of T cell receptors in the thymus. The δ Rec- ψ J α TREC is produced by 70% of all T cells that produce α/β T cell receptors. Therefore, PCR quantitation of this TREC provides a marker for naive T cells and identifies infants with profound T cell lymphopenia associated with primary immunodeficiencies such as SCID or DiGeorge syndrome (Routes, 2009).

Many of the primary immunodeficiencies are rare disorders that can be difficult to diagnose; in these cases, genetic mutation detection is the most reliable method. These specialized tests are not readily available, and physicians may have difficulty locating laboratories to perform the necessary genetic analyses. Mutation registries and databases are available to provide information about tests for clinical data, immune status, antibody response, cellular function, and enzyme assays. Additionally, some online registries contain information about laboratories that perform these assays that increases awareness of testing availability and the ability to obtain an exact and prompt diagnosis (Samarghitean, 2004).

TABLE 50-1

Gene Mutations, Affected Proteins, and Primary Immunodeficiencies

Disease	Natural mutant	Protein	Function
Agammaglobulinemia		Btk	Cell activation
APECED		AIRE	Negative selection of T cells
AT		ATM	DNA lesion sensing
Atypical complete DiGeorge syndrome		Base pair deletion on 22a11.2	Oligoclonal T cells
CGD		gp91phox, p22phox, p47phox, p67phox	NADPH oxidase
DC		Dyskerin	Telomere maintenance
FHLH		Munc 13-4	Exocytosis of lytic granules
FHLH		Syntaxin11	Cytotoxicity
Griscelli	Ashen	Rab27a	Exocytosis of lytic granules
HIES AD/AR		STAT3/TYK2	Defective cytokine signaling
HIGM		CD40L	Activation of Ig CSR
HIGM		AID	Ig CSR and SHM
IPEX	Scurfy	FOXP3	Treg function
LAD		β 2 integrin	Adhesion
NBS		Nibrin (NBS1)	DNA repair
Omenn syndrome		RAG, ARTEMIS, IL-7R, RMPR, IL-2R γ , ZAP70, ADA, DNA ligase IV mutations	Oligoclonal T cells and absence of B cells
	SCID	DNA-PKcs	VDJ (NHEJ)
SCID		Artemis	VDJ (NHEJ)
SCID		Cernunnos, XLF	VDJ (NHEJ)
SCID		γ c, JAK3	T (NK) cell development
SCN		HAX-1	Prevention of apoptosis
T cell deficiency		Orai-1, CRACMI	Ca channel
T cell deficiency (HLA II expression)		RFXAP, ANK, RFX5, CIITA	HLA class II transcription
Variant combined immunodeficiency		DOCK8	Cytoskeletal arrangements in lymphocytes
WAS		WASP	Cell cytoskeleton, migration
XLP		SAP	Coactivation (SLAM family), NKT
XLP2		XIAP	Control of apoptosis (NKT)
	lpr, gld	fas, fasL	Apoptosis
	Moth eaten	SHP-1	Phosphatase regulation

Data from Fisher A. Human primary immunodeficiency diseases. *Immunity* 2007;27:835–45.

AD, Autosomal dominant; ADA, adenosine deaminase deficiency; AID, activation-induced deaminase; APECED, autoimmune polyendocrinopathy candidiasis ectodermal dysplasia; AR, autosomal recessive; AT, ataxia telangiectasia; Btk, Bruton tyrosine kinase; CGD, chronic granulomatous disease; DC, dyskeratosis congenita; DNA, deoxyribonucleic acid; DNA PKcs, DNA-dependent protein kinase, catalytic subunit; DOCK8, dedicator of cytokinesis 8 protein; FHLH, familial hemophagocytic lymphohistiocytosis; gld, generalized lymphadenopathy disease; HIES, hyper-IgE syndrome; HIGM, hyper-IgM syndrome (Ig class switch recombination deficiency [CSR]); HLA, human leukocyte antigen; IPEX, immunoproliferative enteropathy X-linked syndrome; LAD, leukocyte adhesion deficiency; lpr, lymphoproliferation; NADPH, nicotinamide adenine dinucleotide phosphate; NBS, Nijmegen breakage syndrome; NHEJ, nonhomologous end-joining; NK, natural killer; SAP, SLAM-associated protein; SCID, severe combined immunodeficiency; SCN, severe congenital neutropenia; SHM, somatic hypermutations; Treg, regulatory T cells; VDJ, V(D)J recombination; WAS, Wiskott-Aldrich syndrome; WASP, Wiskott-Aldrich syndrome protein; XIAP, X-linked inhibitor of apoptosis; XLF, XRCC4-like factor; XLP, X-linked proliferative syndrome; XLP2, X-linked proliferative syndrome type 2.

NOVEL APPROACHES TO TREATING IMMUNODEFICIENCY DISORDERS

Genetic analysis of primary immunodeficiencies is important not only for diagnosis of the disorder but as a guide for therapy. Understanding the pathophysiology of each immunodeficiency disorder will aid clinicians in providing the missing component and ameliorating symptoms. For example, enzyme replacement therapy has been used in the past to treat enzyme-deficient forms of SCID, such as adenosine deaminase and purine nucleoside phosphorylase SCID; however, this requires prolonged treatment and results are variable, including decreased thymic output, lymphopenia, and increased viral infection (Gaspar, 2006). Direct genetic intervention may become a more suitable treatment as increasing numbers of successful case reports describe using autologous CD34⁺ hematopoietic stem cells transduced with a retroviral vector containing the normal gene. In children affected with Adenosine deaminase deficiency-deficient SCID and SCID-X1, direct genetic intervention is a safe and effective treatment, resulting in reinitiation of thymopoiesis, restoration of cellular immunity, and correction of the metabolic disorder, without enzyme replacement therapy (Gaspar, 2006; Aiuti, 2009).

TABLE 50-2

Gene Mutations and Susceptibility to Pathogens

CD40L, CD40	<i>Pneumocystis jiroveci</i> , <i>Toxoplasma</i> , <i>Cryptosporidium</i>
IL12p40, IL12R β , IFN γ R, STAT1	Mycobacteria
IRAK4	Encapsulated pathogens
SAP, XIAP	EBV
UNC93B, TLR-3	HSV encephalitis
Complement C5-C9	<i>Neisseria</i>
EVER 1,2, γ c, JAK-3	HPV-epidermodysplasia verruciformis

Data from Fisher A. Human primary immunodeficiency diseases. *Immunity* 2007;27:835–45.

EVER 1,2, Epidermodysplasia verruciformis 1, 2 genes; γ c, common cytokine γ chain; IFN γ R, receptor of the interferon γ receptor; IL12p40, p40 subunit of interleukin-12; IL12R β , β chain of the IL-12 receptor; IRAK4, interleukin-1 receptor-associated kinase 4; JAK-3, Janus-associated kinase; SAP, SLAM-associated protein; STAT1, signal transducer and activator of transcription 1; TLR-3, Toll-like receptor 3; UNC93B, polytopic endoplasmic reticulum CERI-resident membrane protein; XIAP, X-linked inhibitor of apoptosis.

Other future strategies may include using chemicals to modify protein glycosylation to prevent protein unfolding and degradation resulting in primary immunodeficiency disorders (Vogt, 2007). Although these strategies have been demonstrated only in in vitro models, if the medications can be introduced at nontoxic levels with appropriate bioavailability in humans, clinical application may be practical in the future. Other medications such as gentamicin and Ataluren (formerly known as PTC 124) prevent premature translation termination at a premature stop codon and may be employed to treat disorders such as muscular dystrophy and cystic fibrosis, characterized by nonsense mutations resulting in absence of a critical protein causing the disorder. Although these treatments are still experimental, the hope of treating primary immunodeficiencies effectively lies in defining the genetic mutation and utilizing mutation-related strategies for treatment (Fischer, 2007).

SUMMARY

Assessment of host defenses is an extraordinarily complex process entailing the cooperation of the clinician, the research scientist, and the clinical pathologist. A logical approach, based on appreciation of the multiple systems involved in host defense and various diagnostic options, can lead to identification of the underlying disorder. The impressive success of modern therapy, incorporating new antimicrobials, recombinant DNA technology, bone marrow transplantation, and gene therapy, allows more precise delineation and characterization of the immunologic deficiency state. This in turn improves recognition, and ultimately treatment, of these patients.

KEY POINTS

- Many types of autoantibodies to intracellular and nuclear antigens are present in the various systemic rheumatic diseases. Currently, it is considered important not only to detect the presence and quantity of intracellular and nuclear autoantibodies in the patient, but also to identify its immunologic specificity.
- Past studies have shown that distinct diagnostic profiles of autoantibodies are observed in many of the rheumatic diseases. Some diseases are characterized by the presence or absence of a specific antibody, or by differences in the quantitative level or titer of the autoantibody.
- Much progress has been made in improvement of sensitivity, specificity, and quality control of the many laboratory tests used for the detection of autoantibodies to intracellular and nuclear antigens.
- Immunofluorescence microscopy using human cellular extracts, such as HEp-2 cells, allows the sensitive detection of serum antibodies that react very specifically with various cellular proteins and nucleic acids.

- Widely used tests for screening of intracellular autoantibodies are immunofluorescence microscopy and the immunoenzyme tests. The secondary definitive tests for specific identification of autoantibodies to nuclear antigen are immunodiffusion, immunoprecipitation, particle agglutination, enzyme-linked immunosorbent assay, immunoblotting, and radioimmunoassay methods.
- Molecular biologists have used many of the autoantibodies as biological probes and have elucidated the biological functions of several of the autoantigens.

OVERVIEW AND CLASSIFICATION OF SYSTEMIC RHEUMATIC DISEASES

The rheumatic diseases are characterized by the presence of one or more autoantibodies that may be directed against components of the surface, cytoplasm, nuclear envelope, or nucleus of the cell. The last group, autoantibodies to nuclear antigens (ANAs), is a hallmark of the systemic rheumatic diseases (Tan, 1982a, 1989; Nakamura, 1985, 1986, 1992; von Mühlen, 1994). Many of the rheumatic diseases have a distinctive profile

of autoantibodies with diagnostic and prognostic implications. Moreover, the biochemical and biological functions of many of the antigens involved in deoxyribonucleic acid (DNA) replication, splicing of ribonucleic acid (RNA) precursor, and RNA processing have been elucidated (Tan, 1989). Classification of the various rheumatic diseases has been difficult because of the lack of firm etiologic bases for most of them. A comprehensive classification developed by Decker and the Glossary Subcommittee of the American College of Rheumatology (Decker, 1983) is still in use. Our abridged classification of the systemic rheumatic diseases and related disorders is shown in Table 51-1.

SYSTEMIC LUPUS ERYTHEMATOSUS AND RELATED LUPUS-LIKE DISORDERS

Systemic lupus erythematosus (SLE) is the prototype systemic rheumatic disease and has the following significant features (Nakamura, 1994a):

1. SLE is a non-organ-specific autoimmune disease in which tissue injury is mediated primarily by DNA-anti-DNA immune complexes.
2. It is a multisystem disease that affects persons of all ages and both sexes, although it is most prevalent in women during childbearing years.
3. The disease demonstrates a hyperactive immune system with multiple abnormalities.
4. Patients with SLE demonstrate a heterogeneous and polyclonal antibody response, with autoantibody formation reaction involving similar mechanisms to those seen in a typical immune response to foreign immunogens (Fatenejad, 1998).
5. The typical case of SLE has an average of three different circulating antibodies present simultaneously. The prevalence of antibodies varies over a wide range, and more than 110 different types of autoantibodies have been identified in SLE (Sherer, 2004).

ETIOLOGIC FACTORS IN SYSTEMIC LUPUS ERYTHEMATOSUS

The origin is still not known. Some of the important causative factors in SLE include (1) endocrine-metabolic, (2) environmental, and (3) genetic (Chan, 1989). The strongest risk factor for the development of SLE is female gender (Hochberg, 1990). The presence of antinuclear antibodies was detected in female laboratory workers with varying degrees of exposure to blood from patients with SLE. The presence of antinative DNA

antibodies was higher in laboratory workers than in an unexposed non-laboratory group of women ($p < 0.001$) (Zarbinski, 1992). These results help support the hypothesis that a transmissible agent that can cause auto-antibody formation may exist in the blood of patients with SLE.

Certain chemicals have been implicated in SLE (Hochberg, 1990). The syndrome of drug-induced lupus with hydralazine, procainamide, and isoniazid has been studied for clues to the pathogenesis of SLE. Various reports show the acetylation mechanism as a risk factor in SLE. Studies have demonstrated a greater concordance rate of SLE among monozygotic and dizygotic twins (Block, 1975). Concordance of SLE was present in 11 (58%) of 19 monozygotic twins. The end result of the interaction of multiple etiologic factors is polyclonal activation of B cells in SLE patients with production of a wide spectrum of antibodies (Nakamura, 1994a; Sherer, 2004).

WHAT ARE THE DIAGNOSTIC CRITERIA FOR SYSTEMIC LUPUS ERYTHEMATOSUS?

In 1971, the American College of Rheumatology (ACR; previously the American Rheumatism Association [ARA]) published preliminary criteria for the classification of SLE (Cohen, 1971). Patients were considered to have SLE if four of the criteria were met sequentially or simultaneously during any interval of observation. In 1982, the Subcommittee for SLE Criteria of the ARA published revised criteria that incorporated new immunologic knowledge and improved the disease classification of SLE (Tan, 1982b). The 1982 revised criteria for classification of SLE included 11 categories, adding (1) abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay, and (2) antibody to native DNA and/or Sm antigen. In contrast to the 1971 criteria, the 1982 criteria removed Raynaud's phenomenon and alopecia because of their lack of sensitivity and specificity.

When the 1982 ARA criteria for classification of SLE were compared with the 1971 criteria, definite improvement in sensitivity and specificity was evident. The 1982 criteria showed 96.7% sensitivity and 96% specificity when evaluated with known SLE and control patients (Tan, 1982). In 1997, an update of the criteria were published, in which the lupus erythematosus (LE) cell test was dropped and anticardiolipin antibodies were added (Table 51-2)—changes emphasized in the "Guidelines for Referral and Management of SLE in Adults" put forth by the ACR Ad Hoc Committee on SLE Guidelines (Gladman, 1999).

WHAT ARE "LUPUS-LIKE" SYNDROMES AND DISEASES?

Many diseases and syndromes may share certain clinical features with SLE but are not SLE and have differing etiologies and pathogeneses. Diseases that have been listed in this category include vasculitis, cryoglobulinemia, relapsing polychondritis, lymphoproliferative disease, rheumatic fever, glomerulonephritis, syphilis, lupoid hepatitis, drug-induced lupus, and occult malignancy (Panush, 1993). There is a very broad category of patients who demonstrate fewer than four of the 1982 ARA classification criteria for SLE (Lazaro, 1989; Lom-Orta, 1980; Schurr, 1993) but are considered to have "lupus-like" illnesses. These patients have been classified as follows: (1) undifferentiated rheumatic disease, (2) nonrheumatic disease, (3) overlap syndrome, and (4) incomplete, latent, or incipient lupus. If these patients are followed, some stay with mild symptoms and as such remain labeled as having **undifferentiated connective tissue disease (UCTD)**, a few may develop definite SLE, but many evolve into other diseases with a better prognosis. Actually, up to 75% of patients with UCTD never fulfill diagnostic criteria for specific systemic rheumatic diseases (Mosca, 2004). In our hands, 99 patients with anti-U1nRNP antibodies followed for 10 years, many diagnosed as having UCTD when entering the cohort, developed characteristic signs and symptoms of rheumatoid arthritis, Sjögren's syndrome, systemic lupus, or scleroderma (Fig. 51-1), according to their human leukocyte antigen (HLA) profile and antibody titers (unpublished results).

AUTOANTIBODY PROFILE IN SYSTEMIC LUPUS ERYTHEMATOSUS

Characteristic of SLE is the presence of a broad spectrum of autoantibodies, including antibody to native DNA (ds-DNA), chromatin, Sm antigen,

TABLE 51-2

1997: Update of the 1982 Revised Criteria for Classification of Systemic Lupus Erythematosus*

1. Malar rash
2. Discoid rash
3. Photosensitivity
4. Oral ulcers
5. Nonerosive arthritis
6. Serositis (pleuritis or pericarditis)
7. Renal disorder (persistent proteinuria, cellular casts)
8. Neurologic disorder
9. Hematologic disorder
 - a. Hemolytic anemia with reticulocytosis, OR
 - b. Leukopenia $<4000/\text{mm}^3$ on ≥ 2 occasions, OR
 - c. Lymphopenia $<1500/\text{mm}^3$ on ≥ 2 occasions, OR
 - d. Thrombocytopenia $<100,000/\text{mm}^3$ in the absence of offending drug
10. Immunologic disorder
 - a. Anti-DNA: antibody to native DNA in abnormal titer, OR
 - b. Anti-Sm: presence of antibody to Sm nuclear antigen, OR
 - c. Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (2) a positive test result for lupus anticoagulant using a standard method, or (3) a false-positive test result for syphilis known to be positive for at least 6 months and confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test
11. Positive antinuclear antibody
 - a. An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with "drug-induced lupus" syndrome

From Hochberg MC. Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus [letter]. *Arthritis Rheum* 1997;40:1725.

*The proposed classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a person shall be said to have SLE if any four or more of the 11 criteria are present, serially or simultaneously, during any interval of observation.

Figure 51-1 Classification criteria fulfilled by 99 patients with anti-U1nRNP antibodies over more than 10 years of observation. Many patients in this cohort were classified as having undifferentiated connective tissue disease (UCTD) in the first 2 years of clinical symptoms, and 43 individuals could be classified as having rheumatoid arthritis (RA). The number of RA-classified patients did not grow significantly toward the end of the study, but diagnoses of systemic lupus erythematosus (SLE) and scleroderma (Scl) were fulfilled ever more often ($p = 0.02$ and 0.0008 , respectively, chi-square for trend). Patients developing SLE had low titers of anti-U1nRNP antibodies and were HLA-DR2/3. Those developing Scl had high anti-U1nRNP titers and were HLA-DR4. SjS, Sjögren's syndrome. (From von Mühlén CA, Genth E, Mierau R, unpublished data.)

U1nRNP, SS-A/Ro, SS-B/La, C1q, and several other nonhistone protein or nonhistone protein-RNA complexes (Nakamura, 1994a; Sherer, 2004). Polyclonality of antibodies is seen in SLE and scleroderma, and is rarely seen in the other systemic rheumatic diseases. Anti-native DNA, anti-Sm, anti-C1q, anti-ribosomal RNP, and anti-proliferating cell nuclear antigen (PCNA) are generally specific for SLE. The prevalence of autoantibodies varies over a wide range. Antibodies to native DNA and chromatin are detectable in up to 90% of patients, and antibodies to PCNA and cyclin or Alu-RNA protein are seen in 3% or less (von Mühlén, 1995) (Table 51-3).

Antibodies to Native DNA or Double-Stranded DNA

Anti-double-stranded DNA (ds-DNA) antibodies are rather specific for SLE and are observed at a frequency of 75%–90% in SLE patients with active disease (Buskila, 1992; Rekvig, 2003). Many earlier reports described antibodies to ds-DNA in diseases other than SLE. However, current thinking is that the reactive antibodies to DNA in the other diseases were actually anti-single-stranded DNA antibodies. The ds-DNA antibody tests often used ds-DNA preparations contaminated with denatured or single-stranded DNA. One possible exception could appear in primary Sjögren's syndrome, a disease sometimes difficult to differentiate from SLE in older people. Antibody to DNA plays a definite role in the pathogenesis of SLE. In studies of SLE patients, antibody to DNA is followed by the appearance of circulating DNA antigen—a sequence of events that results in the formation of immune complexes. Such DNA-anti-DNA immune complexes, mostly containing complement-activating IgG3, have a special tropism for basement membranes and are readily deposited in the kidney glomeruli. This initiates kidney damage through inflammatory mechanisms that end with complement activation and cell lysis (Okamura, 1993). Earlier methods for detection of DNA antibodies included the insensitive precipitation method, complement fixation, and passive hemagglutination. Current methods used are radioimmunoassay, indirect immunofluorescence on *Critidia luciliae*, and enzyme-linked immunosorbent assay (ELISA) (Buskila, 1992; Kavanaugh, 2002). These can detect anti-DNA in 75%–90% of active untreated SLE patients. Transient increases in anti-DNA antibodies were described in rheumatoid arthritis (RA) patients treated with anti-TNF therapy (Allanore, 2004; Bobbio-Pallavicini, 2004). Occasional clinical lupus-like cases may occur in this situation (Swale, 2003; Eriksson, 2005).

Antibodies to Sm and Nuclear Ribonucleoprotein

Precipitating antibodies to Sm antigen have been considered highly specific markers for SLE (Tan, 1989). Antibodies to both Sm and nuclear ribonucleoproteins (nRNPs) are found in patients with SLE. The Sm and nRNP antigens were clearly associated because the nRNP could not be biochemically isolated from the Sm antigen. Lerner and Steitz (1979) used the tools of molecular biology to show that Sm and nRNP antigens were subcellular particles comprising small nuclear RNAs complexed with proteins. The particle bound by anti-nRNP is composed of an RNA component designated U1 (U for uridine-rich), complexed to at least seven proteins varying in molecular mass from 12–68 kDa (Tan, 1989), found at a frequency of 30%–40% in active SLE (Ter Borg, 1990).

The antigens of Sm consist of several proteins, conventionally called B1 (29 kDa), D (16 kDa), and E (13 kDa) (Tan, 1989). Purified anti-B1/B antibodies cross-react with the D protein and vice versa, but no cross-reaction is observed in smaller percentages of SLE sera. Thus, at least two epitopes on the B1/B protein are recognized by anti-Sm sera. Antigens reactive with anti-Sm and antinuclear RNA therefore are present in assemblies of interactive proteins and RNAs engaged in precursor nRNA splicing (Tan, 1989). No characteristic clinical features are apparent in SLE patients with anti-Sm antibodies (Barada, 1981), although some authors claim these autoantibodies to be associated with renal disease or with disorders of the central nervous system. Patients who have antibodies to only nRNP have a low frequency of antibodies to DNA and a low frequency of clinically apparent renal disease (Ter Borg, 1990). Anti-Sm and anti-nRNP antibodies may be detected by immunodiffusion, passive hemagglutination, or counterimmunoelectrophoresis. However, the previously mentioned methods do not accurately distinguish between antibodies against different small nuclear RNA-associated polypeptides. Reactivities with individual RNAs and polypeptides can be best demonstrated by RNA immunoprecipitation and immunoblotting techniques, respectively. Immunoblotting has been found to be more sensitive than conventional

TABLE 51-3
Antigens and Autoantibodies in Systemic Lupus Erythematosus

Antigen	Molecular structure	Autoantibody frequency*
Native DNA	Double-strand DNA	40%–90%
Denatured DNA	Single-strand DNA	70%
Histones	H1, H2A, H2B, H3, H4	50%–70%
Chromatin (nucleosome)	DNA–histones complex	50%–90%
Sm	Proteins 29 (B'), 28 (B), 16 (D), and 13(E) kDa, complexed with U1,U2, and U4-U6 snRNA's; spliceosome component	15%–30%
Nuclear RNP (U1nRNP)	Proteins 70, 33(A), and 22 (C) kDa, complexed with U1 snRNA; spliceosome component	30%–40%
SS-A/Ro	Proteins 60 and 52 kDa, complexed with Y1–Y5 RNA's	24%–60%
SS-B/La	Phosphoproteins 48 kDa, complexed with Y1 nascent RNA Pol transcripts	9%–35%
Ku	Proteins 86 and 66 kDa, DNA-binding proteins	1%–19%
hnRNP protein A1	Nuclear protein 34 kDa	31%–37%
PCNA	Protein 36 kDa; auxiliary protein of DNA polymerase	3%
Ribosomal RNP	Phosphoproteins 38, 16, and 15 kDa associated with ribosomes	10%–20%
Hsp-90	Heat-shock protein 90 kDa	5%–50%
Golgi complex	Golgins, giantin	Unknown
HMG-17	DNA-associated proteins, 9–17 kDa	34%–70%
β2-glycoprotein I	Anionic phospholipids, cardiolipin	25%

Data from Nakamura and Bylund (1994); Krapf and von Mühlen (1996); and Sherer (2004).
DNA, deoxyribonucleic acid; PCNA, proliferating cell nuclear antigen; RNA, ribonucleic acid; RNP, ribonucleoprotein.
*Frequencies are mostly related to patients with active disease.

methods for the detection of anti-Sm and anti-nRNP (Nakamura, 1994b). Currently, the most widely used laboratory tests for the detection of anti-Sm and anti-nRNP antibodies are immunodiffusion and ELISA. These tests can differentiate between Sm and nRNP antibodies but cannot define the specific antibody epitopes present in patients' sera. Antibody specificity and epitopes are best determined by Western and Northern blotting methods.

Antibodies to SS-A/Ro and SS-B/La

Patients with SLE can have antibodies to SS-A/Ro alone, or they may have both anti-SS-A/Ro and anti-SS-B/La. Having anti-SS-A/Ro alone is strongly associated with HLA-DR2 and with being young (<22 years of age at onset). The presence of both anti-SS-A/Ro and anti-SS-B/La in SLE is associated with HLA-DR3 and is seen in older patients (>50 years of age at disease onset) (Hochberg, 1985). A study of 55 patients with SLE showed that patients with anti-SS-A/Ro alone had much more serious renal disease (Hochberg, 1985). SLE patients with only anti-SS-A/Ro also had a higher incidence of concomitant anti-DNA antibodies than SLE patients who had both anti-SS-A/Ro and anti-SS-B/La antibodies (Chan, 1989). Anti-SS-A/Ro autoantibodies have been closely associated with the appearance of nephritis, vasculitis, lymphadenopathy, photosensitivity, and leukopenia in SLE patients. Anti-SS-B/La antibodies, similar to anti-SS-A/Ro antibodies, are noteworthy for their strong association with Sjögren's syndrome, occurring in more than two thirds of patients with this disorder. The SS-B/La antigen is a cellular protein bound to a small RNA species, forming a small RNP that may function in processing of RNA polymerase III transcripts (Chan, 1989).

Recently, attention has been called to the differentiation between antibodies to SSA (SSA-60 kDa) in opposition to anti-SSB (SSA-52 kDa) (Schulte-Pelkum, 2009). Different clinical associations have been noted for each system, with anti-SSA 60 associated with primary Sjögren's syndrome and SLE, and anti-SSA 52 with scleroderma and myositis. Masked reactivities in up to 20% of tested sera were reported when both antigens were present in commercial ELISAs, pointing to the fact that each autoantibody should be tested separately.

Clinical Subsets of Systemic Lupus Erythematosus Associated With Antibodies to SS-A/Ro

Elevated levels of SS-A/Ro antibodies are related to several clinical autoimmune disorders, including (1) subacute cutaneous lupus erythematosus, (2) neonatal lupus erythematosus syndrome with congenital heart block and cutaneous lesions, (3) homozygous C2 and C4 deficiency with

SLE-like disease, (4) primary Sjögren's syndrome vasculitis, rheumatoid factor positivity, and severe systemic symptoms, (5) ANA-negative SLE, and (6) SLE with interstitial pneumonitis (Bylund,1991). Precipitating antibodies to SS-A/Ro are seen in 65%–95% of patients with anti-SS-A/Ro associated subsets, and more than 90% of patients have anti-SS-A/Ro levels when detected by ELISA methods (Bylund,1991).

Anti-Ku and Anti-Ki Antibodies

The Ku antigen system consists of a pair of proteins called p70/p80 (Francoeur, 1986; Reeves, 1992). These proteins have a high affinity for DNA and are known to be DNA-binding proteins, interacting covalently with the ends of native DNA. With the use of both immunoprecipitation and immunoblot assays, the Ku autoantibody was found in 10% of SLE sera and was not detected in 100 scleroderma sera examined. In studies with an enzyme immunoassay, Reeves showed that 39% of patients with SLE, 55% of those with mixed connective tissue disease (MCTD), and 40% of scleroderma patients had low levels of antibody to Ku protein (Reeves, 1992). Anti-Ki antibody was first reported in Japan (Tojo, 1981) and was observed in approximately 10% of SLE patients. A relationship was observed between anti-Ki and the clinical features of arthritis, pericarditis, and pulmonary hypertension in SLE patients. The Ki antigen was purified from rabbit thymus and had a molecular weight of 32 kDa. Sakamoto (1989) developed an ELISA and observed anti-Ki antibodies in 21% (30/140) of SLE patients; 11 of 140 were positive for anti-Ki by double-immunodiffusion tests.

Antibodies to P Ribosomal Proteins

Ten percent to 20% of SLE sera show autoantibodies targeting three ribosomal phosphoproteins of 15, 18, and 38 kDa in Western blot assays. Association of anti-rRNPs with major central nervous system disorders in SLE, mainly psychotic symptoms, was reported in a retrospective study (Bonfa, 1987). No association was shown with cognitive impairment or depression in lupus patients. Significant differences in the prevalence of anti-rRNP are found among races. These antibodies occur at a higher frequency together with anti-Sm and anti-U1nRNP antibodies in SLE (Yalaoui, 2002). An etiopathogenic role for anti-rRNP in the central nervous symptoms of lupus patients is not conclusively established (Nakamura, 1997; Isshi, 1998). Observations in larger multicentric samples of SLE patients showed association of anti-rRNP antibodies with hemolytic anemia, leukopenia, alopecia, malar rash, proteinuria, and neurologic complications (Hoffman, 2004; Mahler, 2006). One recent study found correlation with disease activity (Haddouk, 2009). Anti-P ribosomal autoantibodies, because of their high specificity, are proposed to join other criteria for SLE diagnosis and classification.

Proliferating Cell Nuclear Antigen Multiprotein Complex

Antibodies to PCNA proteins are detected in 3% of patients with active SLE with no distinctive clinical associations (Miyachi, 1978; Kaneda, 2004). A possible association with central nervous system features, such as transverse myelitis, has been seen in our own patients (von Mühlen, unpublished results). The PCNA complex has been characterized as cell cycle related, and PCNA antibodies have served as useful probes in the study of agents regulating DNA replication, cell proliferation, and blast transformation.

Antiphospholipid Antibodies in Systemic Lupus Erythematosus

The lupus anticoagulant/antiphospholipid antibody syndrome is characterized by the presence of circulating antibodies to phospholipids and clinical features of arterial and venous thrombosis, thrombocytopenia, hemolytic anemia, miscarriage, and several systemic symptoms. Antiphospholipid antibodies have been found frequently in patients with SLE and other disorders such as infectious diseases (McNeil, 1991; Alarcon-Segovia, 1992). Antiphospholipid antibodies are found in up to 60% of patients with SLE. This is a very heterogeneous family of antibodies, functionally and immunochemically (McNeil, 1991). Cardiolipin (anionic phospholipid) has been widely used for the detection of antiphospholipid antibodies. A majority of anticardiolipin antibodies cross-react with zwitterionic phospholipids (McNeil, 1991). Antibodies to anionic phospholipids may be immunoglobulin (Ig)G or IgM, whereas antibodies to zwitterionic phospholipids are more frequently IgM.

Antibodies to phospholipids are identified in SLE patients in three ways (Alarcon-Segovia, 1992): (1) serologically false-positive test for syphilis (a positive Venereal Disease Research Laboratory test); (2) the lupus anticoagulant assay, which is a prolongation of the kaolin partial thromboplastin time that is not corrected by normal plasma; and (3) cardiolipin immunoassay with the use of cardiolipin or other negatively charged phospholipids as antigens and β_2 -glycoprotein I as cofactor. Patients with SLE will usually react with a negatively charged phosphate group present in cardiolipin, phosphatidic acid, phosphatidylserine, or phosphatidylinositol.

Harris (1987, 1990) convened international workshops to improve the precision and accuracy of antiphospholipid antibody immunoassays. Reference sera were prepared and standard IgG phospholipid units (GPL) and IgM phospholipid units (MPL) were defined. One GPL (MPL) unit is equivalent to 1 mg/mL of an affinity-purified standard IgG (IgM) sample. However, Lopez (1992) suggested that an IgA-specific assay for antiphospholipid antibody is important in assessing the antiphospholipid syndrome in patients with SLE. A higher prevalence of the IgA isotype seems to be found in black persons.

Newly developed assays for β_2 -glycoprotein I autoantibodies seem to bring specificity to the findings; it was described that β_2 -glycoprotein is the specific epitope for antiphospholipid autoantibodies (Obermoser, 2004). Furthermore, IgA antibodies targeting β_2 -glycoprotein I, or antibodies recognizing a complex of β_2 -GP I/oxLDL (oxidized low-density lipoprotein), seem to be pathogenic in atherosclerotic vascular disease (Staub, 2003; Matsuura, 2004; Ranzolin, 2004). Domain 4 of the molecule seems to be the target for proatherosclerotic anti- β_2 -GP I autoantibodies, and domain 1 seems to be involved in the antiphospholipid syndrome, as demonstrated by our group in deletion mutant studies (Iverson, 2006).

CHRONIC DISCOID LUPUS AND OTHER CUTANEOUS VARIANTS

A benign form of lupus may present as “discoïd” (coin- or disk-shaped) cutaneous lesions without symptoms of systemic disease. This disorder is called chronic discoid lupus erythematosus (CDLE) (Sontheimer, 1992; Wallace, 1992). The skin lesions of CDLE are as follows: (1) persistent localized erythema, (2) adherent scales, (3) follicular plugging, (4) telangiectasis, and (5) atrophy (Wallace, 1992). Subacute cutaneous lupus erythematosus (SCLE), a similar skin condition, consists of papulosquamous or nonscarring lesions with a major association with SS-A/Ro autoantibodies. Additional variants of CDLE, such as lupus panniculitis (also called lupus profundus) and urticarial lupus, have been described (Sontheimer, 1992).

Wallace (1992) has defined CDLE as the fulfillment of the description of CDLE or SCLE, or one of the variants of SLE, in which the 2008 ACR criteria for SLE are not met. Unfortunately, CDLE is a cutaneous

autoimmune disorder that lacks any unifying diagnostic serologic abnormality. It is a mild form of lupus erythematosus that uncommonly disseminates to SLE. Otherwise, considerable overlap is seen between CDLE and SLE, in that up to 15% of patients with SLE have cutaneous discoid lesions. About 6%–12% of patients with SLE had discoid lupus for a varying number of years before the onset of systemic disease (Wallace, 1992). Antinuclear antibodies are commonly found, with estimates of prevalence in discoid lupus ranging from 6%–50%. The sex ratio of discoid lupus (2 females/1 male) is much less biased toward females than that of the systemic form. Figure 51-2 depicts some clinical aspects of cutaneous disease in SLE.

DRUG-INDUCED LUPUS ERYTHEMATOSUS, ANTIHISTONE AND ANTICHRROMATIN ANTIBODIES

Characteristic of drug-induced lupus is the presence of histone autoantibodies. Histones are basic molecular proteins containing high molar ratios of positively charged amino acids, lysine, and arginine. Histones are found in eukaryotic cells closely associated with genomic DNA. The subunit of this histone–DNA complex is called a nucleosome, which has two molecules of each of the “core” histones (H2A, H2B, H3, and H4) and one molecule of H1, along with DNA about 200 base pairs in length (Rubin, 1985, 1987).

In studies of drug-induced lupus, the liver enzyme acetyltransferase appears to play an important role (Woosley, 1987). Acetyltransferase is an enzyme that can acetylate drugs such as hydralazine and procainamide, promoting detoxification and excretion of the drug. Patients with low levels of acetyltransferase were more prone to develop ANA and clinical symptoms than those who were treated with hydralazine, and had phenotypically high levels of acetyltransferase. Patients with high levels of enzyme who were rapid acetylators were not immune to the development of ANA. These patients, however, took a longer and larger cumulative dose of hydralazine before developing clinical disease. These findings related to acetyltransferase phenotypes have been confirmed in patients treated with procainamide (Rubin, 1988). Procainamide is the most common drug involved in drug-induced autoimmunity. Hydralazine, quinidine, and other drugs have also been implicated as causing drug-induced autoimmunity.

In drug-induced lupus, antibodies to single-stranded DNA and histones are present. In SLE, on the other hand, antibodies to double-stranded native DNA, Sm, and U1nRNP antigens are often present, in addition to antibodies to histones. Procainamide is used to treat patients with cardiac arrhythmias, and most patients eventually develop antihistone antibodies. However, only 10%–20% of procainamide-treated patients develop symptomatic autoimmune disease (Rubin, 1988). Patients with symptomatic disease develop a unique type of IgG antihistone antibody, which, rather than reacting with individual histones, shows specific reactivity with the histone H2A–H2B dimer complex (Rubin, 1988). Thus, the IgG anti-(H2A–H2B) is a useful diagnostic marker, with high sensitivity and specificity for symptomatic disease, in contrast to the benign form of procainamide-induced autoimmunity, with IgM antibodies to the individual histone. Fifty percent of all patients treated with procainamide developed ANAs after 1 year of treatment (Tan, 1989). Slow acetylators developed ANAs more rapidly than rapid acetylators (Woosley, 1987). All patients on prolonged procainamide treatment developed a positive ANA response, irrespective of acetylator phenotype.

Because antihistone antibodies are found in many other conditions, more specific antibodies such as antichromatin are replacing assays for antihistones. Synonym names for antichromatin antibodies are LE cell factor, antinucleosome, antideoxyribonucleoprotein, and anti-(H2A–H2B–DNA). They are found in 75% of all patients with SLE, in up to 100% of drug-induced lupus patients, and in 20%–50% of patients with autoimmune hepatitis type I (lupoid hepatitis). In SLE patients, antichromatin antibodies correlate better with kidney disease than anti-dsDNA (Burlingame, 2002; Cervera, 2003; Burlingame, 2004), although recent emphasis on strong association with active lupus nephritis is being pushed toward the presence of antibodies to the first component of the classical complement cascade: anti-C1q autoantibodies (Tsirogianni, 2009).

SJÖGREN'S SYNDROME

Sjögren's syndrome is a chronic inflammatory exocrinopathy, that is, an autoimmune disease marked by dryness of the eyes, mouth, and other

Figure 51-2 Typical cutaneous lesions in systemic lupus erythematosus (SLE). **A**, Scarring discoid lesions. **B**, Finger vasculitis. **C**, Vasculitis with ulcers. **D**, Subacute cutaneous geographic lesions. **E**, Typical malar rash. **F**, Lupus panniculitis.

mucous membranes (Schumacher, 1993; Ramos-Casals, 2005). The disease may evolve from exocrine glands to a systemic disorder, as well as to B cell lymphoproliferative transformation. It is much more frequently found in women than men, with an increasing prevalence throughout adult life. Often associated with Sjögren's syndrome is another rheumatic disease, such as RA, SLE, primary biliary cirrhosis, or systemic sclerosis (Table 51-4). Affected salivary or lacrimal glands are infiltrated with aggregates

of lymphocytes. Extraglandular manifestations include lymphadenopathy, cutaneous vasculitis, and interstitial pneumonitis, among others.

The disease has been classified into (1) primary Sjögren's syndrome, which is not associated with another connective tissue disease, and (2) secondary Sjögren's syndrome, in which RA or some other autoimmune disorder is present. Sjögren's syndrome is known to occur in a primary form, with the sicca complex (keratoconjunctivitis sicca and xerostomia) as

5. Primary biliary cirrhosis
6. Necrotizing systemic vasculitis
7. Autoimmune thyroiditis
8. Chronic active hepatitis
9. Mixed cryoglobulinemia
10. Hypergamaglobulinemic purpura

its hallmark feature. Autoantibodies in Sjögren's syndrome are normally restricted to SS-A/Ro and SS-B/La antigens (Tan, 1989), but we have seen patients with other specificities alone, such as anti-Golgi complex or anti-NuMA. Anti-SS-A/Ro and anti-SS-B/La are present in SLE, but in lower prevalences than in Sjögren's syndrome. Anti-SS-B/La is seen in 60% of Sjögren's syndrome patients and in 35% of SLE patients; anti-SS-A/Ro is seen in 40% and 15%, respectively (von Mühlén, 1995). The presence of anti-SS-A/Ro, when associated with anti-SS-B/La, is indicative of primary Sjögren's syndrome, at times coexisting with SLE. The presence of anti-SS-B antibodies is less than 1% in RA (Tan, 1988). A striking association has been seen between anti-SS-A/Ro and the presence of both systemic and cutaneous vasculitis (Bylund, 1991). The association of SS-A/Ro antibody with vasculitis has been observed in patients with UCTD. Determination of anti- α -fodrin autoantibodies, which are also found in RA sera, does not add much to the diagnosis of Sjögren's syndrome (Ruffatti, 2004; Zandbelt, 2004). Clinical and laboratory characteristics of the disease are shown in Figure 51-3.

TABLE 51-5
Autoantigens and Autoantibodies in Scleroderma

Autoantigen	Molecular structure	Autoantibody frequency
Scl-70	100-kDa native and 70-kDa degradation product; DNA topoisomerase I	70% in diffuse scleroderma; 20%–59% in all patients; 13% in CREST
Centromere	Proteins 17, 80, and 140 kDa, localized at inner and outer kinetochore plates	57%–82% in CREST; 8% in diffuse form
RNA Pol I	RNA Pol I complex of subunit proteins, 210–211 kDa	4%–20% in scleroderma; 13% in diffuse form
RNA Pol II	Transcripts mRNA	4%
RNA Pol III	Transcripts 5S rRNA, tRNA	23% in scleroderma; 45% in diffuse form; 6% in CREST
Fibrillarin	Protein 34 kDa, component of U3 RNP particle	6%–8%; 5% in diffuse form; 10% in CREST
U1nRNP	Spliceosome complex	2%–5% in all patients; 24% in PM/scleroderma overlap
PM-Scl	Complex of 11 proteins, 110–120 kDa	2%–5%; 24% in PM/scleroderma overlap
Ku	DNA-binding protein	1%–14% in scleroderma; 26%–55% in PM/scleroderma overlap
Th/To	Protein 40 kDa, complexes with 7S and 8S RNAs	4%–10% in scleroderma; 1%–11% in diffuse form; 8%–19% in CREST; up to 3% in PM/scleroderma overlap
NOR-90	Protein 90 kDa, human upstream binding factor, localized in nucleolus organizer region	Rare

CREST, Calcinosis cutis, Raynaud’s phenomenon, Esophageal dysmotility, Sclerodactyly, and Telangiectasia; DNA, deoxyribonucleic acid; PM, polymyositis; RNA, ribonucleic acid; tRNA, transfer ribonucleic acid.

SCLERODERMA

Systemic sclerosis (scleroderma) is a multisystem connective tissue disorder of unknown etiology in which vascular lesions and tissue fibrosis are prominent features. The cause of systemic sclerosis remains obscure. Patients with systemic sclerosis spontaneously produce autoantibodies against nuclear, nucleolar, and mitochondrial antigens (Reimer, 1990; Rothfield, 1992; Ho, 2003; Cepeda, 2004), which are of diagnostic and prognostic significance (Harris, 2003). A scleroderma patient usually has a restricted heterogeneity of autoantibody types. Table 51-5 lists the various types of autoantibodies described in scleroderma.

Patients with rapidly progressive and diffuse cutaneous involvement affecting the distal and often proximal extremities and trunk are at greater risk for early visceral involvement. Included in the classification of scleroderma is a large subset of patients who have a form of the CREST (Calcinosis cutis, Raynaud’s phenomenon, Esophageal dysmotility, Sclerodactyly, and Telangiectasia) syndrome. This subset of CREST patients may account for 20%–30% of all scleroderma patients (Fritzler, 1980). Patients with the CREST variant have limited cutaneous involvement confined to the distal extremities of fingers and face, and usually have a better prognosis and clinical course than those with diffuse cutaneous involvement (Fig. 51-4).

ANTIBODIES TO CENTROMERE ANTIGENS

The autoantibodies to centromere antigens were detected initially by immunofluorescence microscopy. The centromere antigen was localized to the region of the condensing metaphase chromosomes. In immunoblotting studies, the centromere antigens consist of three proteins: 16 kDa, 80 kDa, and 120 kDa. Autoantibodies to centromere proteins are present in 50%–80% of patients with the CREST subset. Twenty-five percent of those with idiopathic Raynaud’s phenomenon with other signs or symptoms of CREST have anticentromere antibodies (Rothfield, 1992). Anticentromere antibodies are most often associated with lower frequency of pulmonary fibrosis and mortality, although an increased risk for pulmonary hypertension has been described (Cepeda, 2004).

ANTIBODIES TO SCL-70 (DNA TOPOISOMERASE I)

A major autoantigen is Scl-70, which was initially detected as a 70-kDa protein. This was later recognized as a degradation product of a 95-kDa protein, DNA topoisomerase I (Tan, 1989). The antigen was localized in punctate distribution in the nucleoplasm and nucleolus. In early studies, autoantibodies to Scl-70 were detected in 20% of unselected scleroderma patients by immunodiffusion studies (Bernstein, 1982). In later studies, Scl-70 autoantibodies were found in 75% of patients with the diffuse,

severe form of scleroderma by immunodiffusion tests (Jarzabek-Chorzelska, 1986). This latter finding was probably caused by better preservation of topoisomerase I antigen in the tests, as well as by demonstration of higher prevalence of Scl-70 autoantibody in patients with the diffuse severe form of scleroderma (Nakamura, 1992). In summary, in many literature series, anti-Scl-70 autoantibodies are associated with diffuse and rapidly progressive cutaneous involvement, increased frequency of pulmonary fibrosis, and higher mortality.

ANTIBODIES TO RNA POLYMERASES

Three RNA polymerases catalyze the transcription of genes into RNA (von Mühlen, 1994). Autoantibodies targeting RNA polymerases tend to occur together in the same patients, appear to be specific for scleroderma, and are most often detected in individuals with diffuse scleroderma. Association with diffuse cutaneous disease, interstitial lung fibrosis, renal crisis, and higher mortality has been noted (Harris, 2003; Cepeda, 2004; Ioannidis, 2005). In one longitudinal cohort in the recent literature, investigators showed correlation of antibody titers with the scleroderma skin score (Nihtyanova, 2009).

AUTOANTIBODIES TO THE NUCLEOLAR ANTIGEN FIBRILLARIN (U3-snRNP)

The name fibrillarin comes from antigen localization in the dense fibrillar component of nucleoli. Antifibrillarin antibodies are seen most often in young men with scleroderma, minimal joint involvement, or pulmonary hypertension (von Mühlen, 1994; Harris, 2003).

ANTIBODIES TARGETING THE NUCLEOLAR ORGANIZING REGION

Nucleolar organizing region (NOR)-90 antibodies recognize the RNA polymerase I transcription factor hUBF (human upstream binding factor) in the fibrillar center of the nucleolus. NORs are regions where the nucleolus re-forms after mitosis, along with clusters of ribosomal RNA genes, and sites where Scl-70, U3-RNA/fibrillarin, NOR-90, and RNA polymerase I antigens can be detected (von Mühlen, 1994; Fritzler, 1995; Dagher, 2002).

RHEUMATOID ARTHRITIS

RA is a systemic autoimmune disorder characterized by chronic, symmetrical, and erosive arthritis of the peripheral joints. A large percentage of patients have elevated titers of serum rheumatoid factors. Nonarticular manifestations, such as subcutaneous nodules, vasculitis, interstitial

Figure 51-4 Systemic sclerosis (scleroderma): clinical and laboratory aspects. **A**, Intestinal malabsorption radiologic study showing diffuse dilation and hypoperistaltic waves. **B**, Centromere decoration in rat Indian Muntjac preparation. **C**, Centromeric pattern in indirect immunofluorescence assay on HEp-2 cells. **D**, Collagen deposition brings thickness to the lingual frenulum. **E**, Typical facial appearance in scleroderma: telangiectasias, lack of expression, thin lips and nose. **F**, Advanced sclerodactyly.

fibrosis, and anemia, may be associated. Sjögren's and Felty's syndromes commonly occur in RA. The primary cause of the disease is unknown. RA is associated with several autoantibodies, which can serve as diagnostic and prognostic markers (Aho, 1994; Viander, 1997; Firestein, 2003). These include the following:

1. Rheumatoid factor (RF)
2. Antifilaggrin antibodies (also known as anticitrullinated protein antibodies; Table 51-6):

- Antikeratin antibodies (AKAs)
- Antiperinuclear factor (APF)
- Antibodies to citrullinated peptides (often referred to as anti-cyclic citrullinated peptide [anti-CCP])
- Anti-Sa antibodies, targeting citrullinated vimentin

3. Anti-RA33

All of these may precede the onset of clinical RA (Klareskog, 2004) (Fig. 51-5).

TABLE 51-6				
Autoantibodies in Common Use in Rheumatoid Arthritis				
	IgM RF (1940)	APF IIF (1964)	Anti-CCP 1st gen. ELISA (1998)	Anti-CCP 2nd gen. ELISA (2002)
Sensitivity (%)	66–85	60 (30–97)	68	73
Specificity (%)	72	95 (73–99)	90–98	95–98

APF, Anti-perinuclear factor; CCP, cyclic citrullinated peptide; ELISA, enzyme-linked immunosorbent assay; RF, rheumatoid factor. See text for references.

RHEUMATOID FACTOR

This antibody is directed against the Fc portion of the IgG molecule. Studies of monoclonal and polyclonal RF have shown polyreactive RF with binding specificity for substances other than IgG, such as nuclear components (Schumacher, 1993). Polyreactive RF is usually of the IgM class with low affinity. RF is not specific for RA and often is seen in cases of chronic infection and other systemic inflammatory conditions. RF in rheumatic disease has considerable immunochemical heterogeneity. In addition to the common IgM RF, both IgA RF and IgG RF have been detected. IgA RF has been related to more severe disease with erosions. The group of RFs consists of some of the only autoantibodies clearly shown to be involved in disease pathogenesis (Smolen, 1998).

Figure 51-5 Rheumatoid arthritis (RA) with anti-perinuclear factor. **A**, Negative preparation for anti-perinuclear factor (APF) using oral mucosa cells as substrate in indirect immunofluorescence. **B**, Positive preparation for APF. Note the dense homogeneous granules around nuclei counterstained with ethidium bromide (orange color). **C**, Subcutaneous nodules in elbow region, common in seropositive RA. **D**, Episcleritis in RA. **E**, Proximal interphalangeal joint synovitis of the third finger in juvenile RA. **F**, Typical hand appearance in adult RA, with intrinsic muscle atrophy and cubital deviation of fingers.

TABLE 51-7

Autoantigens and Autoantibodies in Polymyositis and Dermatomyositis

Autoantigen	Molecular structure	Antibody frequency
Jo-1	Histidyl tRNA synthetase protein, 52 kDa	23%–36% in PM
PL-7	Threonyl tRNA synthetase protein, 80 kDa	4% in PM
PL-12	Alanyl tRNA synthetase protein, 110 kDa	3% in PM
Zo	Phenylalanyl-tRNA synthetase	<3% in PM
YRS	Tyrosyl-tRNA synthetase	<3% in PM
KS	Asparaginyl-tRNA synthetase	<3% in PM
Mi-2	Nuclear protein complex, proteins 53 and 61 kDa	15%–35% in PM; 5%–9% in DM
SRP	Protein 54 kDa complexed with 7 SL RNA	4%–5% in PM; does not occur in DM
PM-Scl	Complex of 11 proteins, 110–120 kDa	8%–12% in PM; 25% in PM/scleroderma overlap
U1nRNP	Spliceosome complex	4%–17% in PM/DM
SAE	Small ubiquitin-like modifier activating enzyme	4% in myositis patients, 8% in DM
p155(p140)	p155-TIF1- γ (involved in nuclear transcription and cellular differentiation)	21% of myositis patients, 75% in adult DM associated with cancer
56 kDa	56 kDa, RNP component	80% of myositis patients
EJ	Glycyl-tRNA synthetase	<3% in PM
OJ	Isoleucyl-tRNA synthetase	<3% in PM

Data from Tan (1988), Nakamura (1992), von Mühlen and Tan (1994), Targoff (2006), Betteridge (2009), and Gunawardena (2008). DM, Dermatomyositis; PM, polymyositis; RNP, ribonucleoprotein; SRP, signal recognition particle; tRNA, transfer RNA.

ANTI-KERATIN ANTIBODY

This antibody reacts against the stratum corneum of rat esophagus (Young, 1979). AKA is a fairly specific but not very sensitive marker for RA. The occurrence of positive reactions in RA sera is 36%–59% and 0%–3% in normal healthy individuals (Aho, 1994). Most antikeratin-positive sera are also reactive with antiperinuclear factor, suggesting that these antigens share some similarities. Actually, it was demonstrated that AKA reacts with water-soluble acidic-neutral isoforms of fillagrin in the epidermis and with molecular forms of (pro)fillagrin in the rat esophagus epithelium, instead of cytokeratin (Simon, 1993; Sebbag, 2004).

ANTIPERINUCLEAR FACTOR

This antibody is reactive with perinuclear keratohyalin granules of buccal mucosa cells (Nienhuis, 1964). The amino acid citrulline seems to be an essential component of epitopes recognized by these autoantibodies (Schellekens, 1998). This immunofluorescence test is sensitive but less specific than AKA in RA patients. APF-positive tests in RA patients have been reported to range from 49%–87% (Janssens, 1988; Aho, 1994) and account for up to 5% in other connective tissue diseases or in normal controls. Both AKA and APF have been described in early seronegative RA, bringing a clear improvement to diagnosis of the disease.

ANTI-CYCLIC CITRULLINATED PEPTIDE

Antibodies to citrullinated peptides detected by ELISA constitute early, specific markers for RA (Sebbag, 2004; van Venrooij, 2004; Vossenaar, 2004; Hoffman, 2005). The antigen used in most assays is citrullinated fillagrin. The unusual amino acid citrulline is generated by action of the enzyme peptidyl arginine deiminase, which generates a posttranslational modification on peptides containing arginine. A second-generation ELISA is claimed to reach 98% specificity for the diagnosis of RA, with 70% sensitivity, representing major improvements over the RF test (Lee, 2003; Sebbag, 2004). Furthermore, anti-CCP antibodies can be detected in 50% of patients with early RA, at a time when RF is negative, allowing for improved diagnosis and early specific treatment. Many series in the literature point to associations with erosive, more severe and progressive disease (Forslind, 2004; Kastbom, 2004; Sebbag, 2004; Alexiou, 2008).

Anti-CCP antibodies are rarely found in other clinical conditions, such as viral infections (mainly hepatitis C), Lyme disease, Graves' disease, SLE, and Sjögren's syndrome (both with associated erosive articular disease). Children with juvenile RA generally do not benefit from this laboratory test, as its sensitivity is only 0.2%–3%. Positive results are seen in the polyarticular, RF-positive subset among children who commonly evolve to the erosive, adult form of RA (Low, 2004).

On the other hand, anti-CCP autoantibodies may better discriminate between patients with RA and those with polyarticular manifestations

associated with hepatitis C virus infection (Bombardieri, 2004). Many authors now suggest that the anti-CCP test should greatly improve accuracy for RA disease classification, when added to the modified 1987 criteria of the American College of Rheumatology (Silveira, 2007).

ANTI-RA33

Hassfeld (1989) has reported an antinuclear antibody (anti-RA33) that may be specific for RA. From extracts of HeLa cells, an antigen of approximately 33 kDa was found to react with 36% of 95 sera from RA patients and with only 1 of 170 control patients. The antigen was termed RA33, and the autoantibody has no discernible relationship to other nuclear antibodies. Anti-RA33 was not related to antihistone. Immunoblot analyses with soluble extracts from HeLa cells showed an autoantibody targeting a 33-kDa antigen (anti-RA33) in 30% of Austrian RA patients and none in patients with ankylosing spondylitis or psoriatic arthritis (Aho, 1994). However, the prevalence of anti-RA33 in Finnish RA was found to be a low 6% (Aho, 1994). Anti-RA33 autoantibodies may also be found in MCTD, and in SLE (Steiner, 1996).

POLYMYOSITIS AND DERMATOMYOSITIS

Polymyositis (PM) is an inflammatory disease of striated muscle of unknown etiology. It is characterized by the presence of inflammatory infiltrates in the skeletal muscle, with associated muscle fiber necrosis and degeneration (Targoff, 1992). When the disease is accompanied by typical skin changes, it is called dermatomyositis (DM). PM is characterized serologically by the presence of a number of autoantibodies of various specifications directed against different transfer RNA (tRNA) synthetases (Targoff, 2002; von Mühlen, 1994) (Table 51-7). These autoantibodies define a subgroup of patients with PM, arthralgia, interstitial lung disease, and poorer prognosis than patients without the autoantibodies.

Antibodies to Jo-1 (histidyl tRNA synthetase) occur in 23%–36% of PM patients, most with interstitial lung disease (Targoff, 1992). Autoantibodies to threonyl and alanyl tRNA-synthetase occur at a lower prevalence in autoimmune myositis. In patients with a clinical syndrome showing overlapping features of PM and scleroderma, an antibody called anti-PM-Scl has been reported (Tan, 1988). The anti-PM-Scl antibody reacts with a complex of 11 polypeptides ranging from 110–120 kDa. Anti-PM-Scl shows staining of nucleolus and nucleoplasm in substrate cells by indirect immunofluorescence microscopy. Antibodies directed to Mi-2, a DNA-dependent, nucleosome-stimulated adenosine triphosphatase (ATPase) remodeling factor (Wang, 2001), are considered specific for dermatomyositis (von Mühlen, 1995). Attention is being called to the presence of antibodies to the 52-kDa component of SSA/Ro in a certain proportion of patients with PM/DM (Peene, 2002).

CONCEPT OF OVERLAP SYNDROMES

Overlap syndrome is a term used when patients exhibit symptoms of more than one disease (Pope, 2002). For example, patients who meet the diagnostic criteria for SLE and have typical manifestations suggestive of a second diagnosis, such as RA, have been described (Lazaro, 1989). It is uncertain whether overlap syndromes may represent the coexistence of two or more different diseases, or whether the syndrome is a distinct entity.

MIXED CONNECTIVE TISSUE DISEASE

The concept of MCTD was initially proposed by Sharp in 1972. The 20 patients described in the initial report had a combination of features usually associated with SLE, systemic sclerosis, and polymyositis. Characteristically, a high titer of autoantibody to a nRNP was found in all of the patients by hemagglutination (Sharp, 1972). The lack of renal and neurologic abnormalities and the excellent response of these patients to small doses of oral corticosteroids initially justified the classification as a separate group from SLE and systemic sclerosis. However, the concept of MCTD as a separate group has changed with time. Many think that MCTD represents an overlap of systemic sclerosis, SLE, and polymyositis (Nimelstein, 1980). A group of patients originally diagnosed as having MCTD was restudied 8 years later and showed a general evolution out of the overlap pattern to one of single disease; scleroderma was the most prevalent diagnosis (Nimelstein, 1980). There appears to be a large overlap that becomes apparent when the previously mentioned criteria are applied to a certain population of patients, and studies do not completely support the existence of MCTD as an individual clinical entity. Recently, it was shown that antibodies to a subunit of nRNP appearing in apoptotic blebs, named U1-70K, are a superior marker for early MCTD compared with autoantibodies to U1nRNP (Hof, 2005).

MOLECULAR BIOLOGY AND FUNCTIONS OF CERTAIN NUCLEAR AND INTRACELLULAR AUTOANTIGENS

Many of the intracellular autoantibodies, including ANAs, have been identified as diagnostic markers for rheumatic diseases such as SLE, scleroderma, Sjögren's syndrome, MCTD, drug-induced lupus, and polymyositis/dermatomyositis (Tan, 1989). Autoantibodies in human diseases have been used as tools to study various molecular biological functions and mechanisms. ANAs have been used to screen complementary expression libraries, with later identification of autoantigens. Biological functions that the autoantibodies have been demonstrated to inhibit are pre-mRNA splicing, DNA replication, DNA repair, transcription, transcription of rRNA, microtubule-based chromosome movement during mitosis, and aminoacylation of tRNAs (Tan, 1988, 1989; Casiano, 1996; Tan 1997).

PROFILES OF AUTOANTIBODIES IN VARIOUS SYSTEMIC RHEUMATIC DISEASES

It has been observed that distinct profiles of ANA are seen in different systemic rheumatic diseases, characteristics of which include the presence or absence of certain antibodies and differences in the mean titers of these antibodies (Nakamura, 1986; Tan, 1988; Bizzaro, 2004). Nonetheless, one should be aware of the low positive predictive value of the ANA test in settings with low prevalence of systemic rheumatic disease and in aging populations (Slater, 1996). The following features are noteworthy:

1. Multiple ANAs frequently seen in SLE, often with high levels of anti-dsDNA antibodies in active disease.
2. Distinctiveness of anti-Sm, anti-rRNP, anti-C1q, and anti-PCNA for SLE.
3. Restriction of ANA in drug-induced lupus to antihistone and/or antichromatin (antinucleosome) antibodies.
4. Antibodies to U1nRNP or nuclear antibodies to RNP present in several rheumatic diseases with different frequencies.
5. Restriction of ANA in MCTD to U1nRNP (by disease definition), or nuclear RNP antibodies.
6. Sjögren's syndrome sera characterized primarily by the presence of antibodies to SS-A/Ro and SS-B/La.

TABLE 51-8

Decision Chart for the Identification of Some Autoantibodies Using HEp-2 Cells and Their Disease Association

1. Nuclear pattern
Envelope (rim)
 - Punctate, mitotic figure negative → PBC
 - Continuous, mitotic figure negative → Chronic liver disease
 - Homogeneous, mitotic figure positive → SLE, drug-induced SLE
- Speckled*
 - Large → hnRNP in SLE
 - Coarse → Sm, RNP in SLE, MCTD
 - Fine → SS-A/Ro, SS-B/La in SLE, SS
 - Pleomorphic → PCNA in SLE
- Discrete*
 - Mitotic figure positive → Centromere in SCL
 - Mitotic figure negative → p95 (Sp100) in PBC
2. Nucleolar pattern
 - Homogeneous → PM-Scl in SCL
 - Clumpy → Fibrillarin in SCL
 - Speckled
 - Mitotic figure punctate* → RNA pol I, NOR-90 in SCL
 - Mitotic figure homogeneous* → Scl-70 in SCL
3. Cytoplasmic pattern
 - Dense fine speckles → Jo-1, PL-7, PL-12 in PM/DM
 - Homogeneous → rRNP in SLE and juvenile SLE
 - Fibrillar → Actin, myosin in MCTD, PBC, CAH
 - Segmental → α -Actinin, vinculin in MG, CD, UC
 - Reticular → Mitochondria in PBC
 - Polar → Golgi in SS, SLE, viral infections
 - Spindle apparatus → NuMA in SS, SLE; midbody, p330^d in cancer
 - Discrete speckles → GWB bodies, EEA1, CLIP 170

Modified from Krapf AR, von Mühlen CA, Krapf FE, Nakamura RM, Tan EM. Atlas of immunofluorescent autoantibodies. Munich: Urban & Schwarzenberg; 1996. CAH, Chronic autoimmune hepatitis; CD, Crohn's disease; DM, dermatomyositis; MCTD, mixed connective tissue disease; NuMA, nuclear mitotic-associated antigen; PBC, primary biliary cirrhosis; PCNA, proliferating cell nuclear antigen; PM, polymyositis; RNP, ribonucleoprotein; SCL, scleroderma; SLE, systemic lupus erythematosus; SS, Sjögren's syndrome; UC, ulcerative colitis.

7. Patients with scleroderma showing a profile consisting of antibodies to Scl-70, the centromere/kinetochore antigens, anti-RNA polymerases, and other nucleolar antigens such as fibrillarin and Th/To.
8. The frequent presence of RF and anticitrullinated proteins (AKA, APF, anti-CCP) in RA.
9. The presence of Jo-1, Mi-2, and PM-Scl autoantibodies in PM/DM.
10. Autoantibodies such as anticentromere, anti-CCP, and anti-dsDNA may antedate overt clinical disease by many years.

DECISION CHART FOR THE DIAGNOSTIC WORKUP OF AUTOIMMUNE DISEASES

Immunofluorescence microscopy using human cellular extracts, such as HEp-2 cells, allows for the sensitive detection of serum antibodies that react very specifically with various cellular proteins and nucleic acids. This technique is essential nowadays in immunology laboratories committed to the routine diagnosis of human autoimmune disease. With a positive immunofluorescence, one is able to associate the specific pattern with the presence of a distinct autoantibody in that particular patient's serum. Because distinct autoantibody patterns occur in distinct diseases, as discussed earlier, the laboratorian offers the clinician the real possibility of narrowing down the diagnostic chase. A decision chart developed with those issues in mind is presented in Table 51-8, as is the cytoplasmic pattern classification for use in the routine laboratory (Table 51-9). **Figures 51-6 through 51-8** depict some examples of immunofluorescence patterns as seen in our laboratories.

TABLE 51-9

Classification of Cytoplasmic Patterns in Indirect Immunofluorescence

Cytoplasmic patterns in IIF (cell substrate)	Representative antigens	Disease and clinical associations
1. Fibrous		
Stress fibers: linear cytoskeletal fibers, sometimes with small, discontinuous granular deposits (HEp-2, fibroblasts)	Actin Nonmuscle myosin	Both in chronic active hepatitis, liver cirrhosis, and myasthenia gravis; actin in autoimmune hepatitis, Crohn's disease, PBC, long-term hemodialysis, NHS, but rare in DCTD
Filamentous: filaments and fibrils spreading out from the nuclear rim (HEp-2, PtK2 epithelial cells)	Vimentin Keratin	Antivimentin often caused by cross-reaction with anti- α helix antibodies, detected in many types of infectious or inflammatory conditions, and in long-term hemodialysis; rare in DCTD; both seen in NHS; keratin is major system in ALD (69%), also common in DCTD and psoriasis
Segmental: just small segments of fibers (periodic dense bodies) are decorated (HEp-2, fibroblasts)	α -Actinin, vinculin tropomyosin	Myasthenia gravis, Crohn's disease, ulcerative colitis
2. Speckled		
Fine speckled: scattered small speckles, mostly with homogeneous or dense fine speckled background (HEp-2)	Many of the aminoacyl-tRNA-synthetases, mainly Jo-1	PM; "Jo-1 syndrome" (myositis and interstitial lung disease)
Dense fine speckled: cloudy, almost homogeneous throughout the cytoplasm (HEp-2)	rRNP, ribosomal phosphoproteins	Neuropsychiatric SLE
Granular pole: perinuclear, arrow-shaped, coarse granular, corresponding to the lamellar stacks of the Golgi complex (HEp-2)	Golgi apparatus	Rare in SLE, SjS, RA, MCTD, Wegener's granulomatosis, and other systemic rheumatic diseases; reported in idiopathic cerebellar ataxia, paraneoplastic cerebellar degeneration, and viral infections, including EBV and HIV
Coarse reticular: coarse diffuse reticular and granular (HEp-2)	Proteins in the inner mitochondrial membrane (mainly M2)	PBC; systemic sclerosis (43%); rare in other DCTD; centromere antibodies are frequently associated
Scattered small speckled: countable cytoplasmic speckles irregularly distributed (HEp-2)	Lysosomes/endosomes/ peroxisomes/proteasomes	Limited scleroderma, glioblastoma and other neurologic diseases, idiopathic pleural effusion
Fine reticular: fine diffuse reticular and granular (HEp-2)	Endoplasmic reticulum (?); other unknown proteins	CLD; detected in all types of (chronic) inflammatory conditions
ANCA, pANCA: irregular perinuclear staining; cANCA: dense, fine, or coarse speckles (peripheral blood granulocytes, HL-60 leukemia cell line)	pANCA targets myeloperoxidase, other enzymes; cANCA targets PR3 (proteinase 3)	First reported in systemic vasculitis with necrotizing glomerulonephritis and inflammatory pulmonary disease; Wegener's granulomatosis (cANCA) and other necrotizing vasculitis (pANCA); cathepsin-G is the main antigen in ulcerative colitis, Crohn's disease, and primary sclerosing cholangitis; autoimmune hepatitis; vasculitis in PTU therapy; recently reported in RA (32%); IgM ANCA in tuberculosis and malaria

Data from Humbel (1993), von Mühlen and Tan (1994), and Stinton (2004).

ALD, Alcoholic liver disease; ANCA, antineutrophil cytoplasmic antibody; cANCA, cytoplasmic antineutrophil cytoplasmic antibody; CLD, chronic liver disease; DCTD, diffuse connective tissue disease; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; Ig, immunoglobulin; IIF, indirect immunofluorescence test; MCTD, mixed connective tissue disease; NHS, normal human serum; pANCA, perinuclear antineutrophil cytoplasmic antibody; PBC, primary biliary cirrhosis; PM, polymyositis; PTU, propylthiouracil; RA, rheumatoid arthritis; RNP, ribonucleoprotein; SjS, Sjögren's syndrome; SLE, systemic lupus erythematosus; tRNA, transfer ribonucleic acid.

DIAGNOSTIC METHODS IN AUTOANTIBODY DETECTION

Commonly used methods for autoantibody detection are listed in Table 51-10. Widely used tests for screening of intracellular autoantibodies are immunofluorescence microscopy and the immunoenzyme tests with many distinct antigens altogether (Nakamura, 1994b; Sahto, 2009), sometimes called **anti-ENA**. Secondary definitive tests for specific identification of ANA include immunodiffusion, immunoprecipitation, particle agglutination, immunoenzyme, immunoblotting, and radioimmunoassay methods (Teodorescu, 1992). Research for the presence of ANAs by immunofluorescence in HEp-2 cells will be positive 98% of the time when SLE patients with active disease are screened. In other words, a negative test most often will rule out an SLE diagnosis.

Standardization of the indirect immunofluorescence (IF)-ANA has been difficult (Nakamura, 1992; Felkamp, 1996; Smolen, 1997). Many factors are involved in the performance of IF-ANA tests, including (1) substrate and fixative variations, (2) microscopic optics, (3) method and quantitation of results, (4) establishment of reference range, (5) interpretation of results, (6) reference sera, and (7) specificity and avidity of the ANA. The ANA Standardization Committee of the World Health Organization (WHO) recommends (1) that laboratories should report IF-ANA results at both 1:40 and 1:160 dilutions, and (2) that they should supply

information on percentages of normal individuals who are positive at these dilutions in their own experience (Tan, 1997).

Bylund and Nakamura (1991) have shown the importance of SS-A/Ro autoantibody determination in screening tests for autoantibodies to nuclear antigens. Detection of anti-SS-A/Ro requires implementation and adherence to several technical and quality assurance recommendations. With use of appropriate substrate cells containing the SS-A/Ro antigen, many of the so-called ANA-negative lupus erythematosus patients will have a positive result on the indirect immunofluorescence test. Immunoprecipitation and double-immunodiffusion analysis have been used to determine the specificity of several ANAs. Assay specificity in double immunodiffusion is generally dependent on the quality of other control sera used in the procedure, as well as on the nature of the antigen preparation. Immunodiffusion tests are not very sensitive, but positive tests have a high degree of specificity. Immunodiffusion commercial kits are available for the detection of antibodies to RNP, Sm, SS-A/Ro, SS-B/La, and Scl-70, as well as other less prevalent markers (Nakamura, 1994b).

An increasing number of enzyme immunoassays have been developed with the use of standard purified and recombinant antigens (Saitta, 1992). Many of these enzyme immunoassays have proved to be more sensitive than comparable immunodiffusion methods. Thus, because of the high sensitivity of enzyme immunoassays, one needs to determine carefully the reference range of normal patients and the proper cutoff values. Compared with immunodiffusion tests, ELISA tests showed much greater sensitivity

Figure 51-6 Indirect immunofluorescence with autoantibodies to nuclear and nucleolar antigens in HEp-2 cells (400 \times , fluorescein isothiocyanate [FITC] stain). In part **A**, autoantibodies to lamin proteins A, B, and C of the nuclear envelope give a homogeneous nuclear pattern in HEp-2 cells, associated with a continuous nucleoplasmic rim. No rim is seen when the antibodies are specifically directed to histones or double-stranded DNA (ds-DNA). Previous reports of a peripheral pattern elicited by anti-ds-DNA antibodies were probably due to fixation artifacts. The speckled nucleoplasmic pattern seen in part **B** is characteristic of autoantibodies directed to the so-called extractable nuclear antigens, like the anti-U1nRNP shown here. The nucleoli and metaphase cells are negative. Part **C** shows anti-ds-DNA autoantibodies, with homogeneous pattern in interphase as well as in metaphase cells. Part **D** is from a preparation with anticentromere autoantibodies, typically found in patients with the limited form of scleroderma (CREST syndrome), but also in primary biliary cirrhosis. Distinct speckles are seen in the interphase nuclei, one for each chromosome pair, which aggregate in the metaphase plates during cell division. Autoantibodies to NOR-90 and RNA-polymerase I elicit the same pattern in HEp-2 cells (**E**), with nucleolar speckles and dots along some spindles of metaphase cells. They can be differentiated by other assays, such as immunoblot or immunoprecipitation. Autoantibodies targeting fibrillarin (U3-nRNP) give clumpy staining of all nucleoli (**F**).

Figure 51-7 Indirect immunofluorescence of Hep-2 cells with autoantibodies to distinct cytoplasmic antigens (400 \times , fluorescein isothiocyanate [FITC] stain). In part **A**, the characteristic pattern of autoantibodies to the Golgi organelle is seen, with granules arranged in clusters at one pole of the cell and sparing the nuclei. Autoantibodies to nonmuscle myosin (**B**) decorate the stress fibers of the cytoskeleton (nuclei staining in blue with DAPI). These antibodies are found in patients with myasthenia gravis and chronic liver disease. Antimitochondrial autoantibodies display a coarse granular pattern involving the whole cytoplasm (**C**), mostly seen in primary biliary cirrhosis. Part **D** shows the dense granular, almost homogeneous, cytoplasmic pattern obtained with anti-rRNP antibodies. They target ribosomal phosphoproteins and are clinically associated with central nervous system manifestations in patients with systemic lupus erythematosus. As can be noticed in the picture, not uncommonly such antibodies also stain the nucleoli in a homogeneous pattern, although weakly. In part **E**, a homogeneous decoration of the cytoplasm was conferred by autoantibodies to PL-7 in polymyositis. Antikeratin antibodies (**F**) are seen as filamentary staining of cytoskeletal stress fibers and constitute the major specificity found in alcoholic liver disease (69%), also common in rheumatoid arthritis (36%–59%), psoriasis, and healthy individuals.

Figure 51-8 Some other distinct patterns in indirect immunofluorescence of HEp-2 cells (400 \times , fluorescein isothiocyanate [FITC] stain). In part **A**, cells at the end of metaphase show antigens condensing in the midbody, also called the intercellular bridge region. The spindle poles of dividing cells can be decorated, as in part **B**, with antibodies targeting the mitotic apparatus, such as NuMA (nuclear mitotic-associated protein). Proliferating cell nuclear antigen (PCNA) autoantibodies give a mosaic of nucleoplasmic patterns (**C**), ranging from homogeneous to distinct speckled, according to the phases of cellular division (details in the text). Part **D** shows the pattern obtained with anti-p80-coilin autoantibodies, where one can see from 1 to 8 nucleoplasmic dots. Part **E** shows one of the most common patterns seen in the routine laboratory—dense, fine, speckled nuclear in interphase as well as in mitotic cells. This is a nonspecific autoantibody found in systemic connective tissue disease, but also in interstitial cystitis, breast cancer, and allergic reactions. Nuclear and nucleolar stainings are seen with anti-Ku autoantibodies (**F**). Chromosomes in mitotic cells are negative (see clinical associations in text).

TABLE 51-10

Methods for Detection of Autoantibodies to Nuclear and Intracellular Antigens

Method	Antigen source	Sensitivity and use
Immunofluorescence microscopy	Tissue sections; cell lines	Sensitive assay; often used for screening
Double immunodiffusion (Ouchterlony)	Tissue and cell extracts	Requires precipitin reaction; high specificity but not very sensitive
Counterimmunoelectrophoresis	Tissue and cell extracts	Increased sensitivity and speed as compared with immunodiffusion procedure
Immunoblotting, Western blot	Cell extracts	Very sensitive; permits detection of antibodies against soluble and insoluble antigens
Dot blot, linear blot (line immunoassays)	Purified native or recombinant antigens	Qualitative assay; average sensitivity
ELISA	Purified native or recombinant antigens	Very sensitive, quantitative; high throughput; can determine antibody class; low cost
Microsphere multiplexed assay	Purified native or recombinant antigens	Very sensitive (compares with ELISA), semiquantitative, rapid, expensive proprietary technology

ELISA, Enzyme-linked immunosorbent assay.

but had lower specificity (Nakamura, 1992). Further, ELISA tests were frequently positive in low titers in sera of patients with rheumatic diseases other than SLE. For example, the presence of antibodies to Sm as assayed by immunodiffusion is considered to be highly specific for SLE. However, in ELISA tests, the Sm antibody was positive in 23% of 54 RA patients, 25% of 24 systemic sclerosis patients, 9% of 11 polymyositis patients, and 2% of 59 normal patients (Maddison, 1985). Increasing sensitivity and decreasing specificity might result in false-positive test results. Furthermore, clinical associations with distinct autoantibodies were determined mainly with the use of ID techniques.

New commercial ELISA kits developed for screening purposes claim to detect a variety of autoantibodies in a single assay, but having “total” fractions of cellular antigens in one ELISA well is not technically feasible nowadays. Those assays are not 100% sensitive for the screening of anti-nuclear antibodies, as they cannot detect certain autoantibodies such as antinucleolar specificities, PCNA or distinct NuMA types. Reported results using those kits, for the moment, should correctly specify to physicians which types of autoantibodies were tested, so as not to imply that a particular sample is “negative for all nuclear antibodies.” Each ELISA test kit in such a situation should be validated for which antibody specificities it can actually detect (von Mühlen, 2002).

More recently, multiplexed assays are being incorporated into the routine work of bigger laboratories. The so-called multiplexed fluorescent microsphere immunoassay uses spectral addresses, allowing for the simultaneous determination of several autoantibodies—all in just one incubation and with no wash steps. We recently demonstrated that results for a proprietary multiplexed assay compared favorably with results from established ELISAs (Martins, 2004): agreement, sensitivity, and specificity, respectively, for five nuclear antigens evaluated were as follows: SSA, 99.1%, 100.0%, and 98.8%; SSB, 98.6%, 88.9%, and 99.5%; Sm, 97.6%, 95.8%, and 97.9%; RNP, 97.2%, 92.7%, and 98.8%; and Scl-70, 93.6%, 50.0%, and 99.0%. The multiplexed microsphere-based immunoassay seems to be a sensitive and specific method for the detection and semi-quantitation of common antibodies in human sera. Clusters of clinically important autoantibodies, such as those in lupus or in systemic vasculitis, may be rapidly tested in a single batch. This is not to imply that the flow cytometry-based assay may be an alternative to screening autoantibodies with HEp-2 immunofluorescence, because there are clear limitations in identifying important autoantibodies in clinical samples by using current microsphere technology (Kroshinsky, 2009). One recent position paper of the American College of Rheumatology clarifies the state of the art in detecting autoantibodies and may be accessed at www.rheumatology.org/publications/position/ana_position_stunt.pdf.

VARIATIONS IN METHODS USED FOR DETECTION OF AUTOANTIBODIES TO NUCLEAR AND INTRACELLULAR ANTIGENS

Most probably, the best studies regarding different methods for detection of autoantibodies to intracellular antigens were reported by a European Consensus Study Group. The European Consensus Study Group for the Detection of Autoantibodies to Intracellular Antigens in Rheumatic

Figure 51-9 Immunoblotting analysis of common autoantibodies seen in rheumatic disease. In lane 1, the nitrocellulose strip was probed with a normal human serum (negative control), and no reactivity is seen as expected. The next three lanes show distinct bands obtained by mixing positive control sera containing known specificities. Lane 2 depicts reactivities to the ribonucleoproteins (RNPs) SSA (52 and 60 kDa), SSB (48 kDa), Sm (B/B', 28 kDa, and D, 14 kDa), and U1nRNP (the 70 kDa) and a faint band around 19 kDa, the C antigen. (The A protein, with 32 kDa and also characteristically recognized by U1nRNP antibodies, is not seen in this experiment.) Lane 3 shows the bands obtained by using the human prototype antisera to Jo-1 (52 kDa), Ku (two bands around the 70- and 80-kDa regions), and ribosomal RNP (15, 18, and 37 kDa). The small band above the 52-kDa antigen is not identified. Lane 4 displays the bands most commonly seen using sera from scleroderma patients (e.g., anti-DNA topoisomerase I [Scl-70, 95 kDa] and anticentromere antibodies [16 kDa, CENP-A, and 80 kDa, CENP-B]). On the left, positions in kilodaltons of the broad-range molecular weight standards can be seen. (Used with permission from von Mühlen CA, Tan EM. Autoantibody specificities in autoimmune rheumatic diseases. *Rev Bras Rheumatol* 1994;34:173.)

Diseases was formed in 1988 and conducted four annual workshops from 1989 to 1992 (van Venrooij, 1991; Charles, 1992). In 1988 and 1989, consensus workshops were conducted to define interlaboratory concordance in the detection of autoantibody specificities in rheumatic disease. Twenty-eight laboratories participated in the study and used various methods. The objectives of the consensus study initiated in 1989 were (1) to define the interlaboratory consensus in detecting autoantibodies and

specificities, (2) to test whether discrepancies were due to the method used, and (3) to make recommendations for improved quality of results with improved sensitivity and specificity.

ENZYME-LINKED IMMUNOSORBENT ASSAYS

In the 1988 and 1989 studies, many false-positive reactions were noted. False-positive reactions were caused by poor blocking reagents in the procedure; also, impure antigen preparations were used. In the 1990 and 1991 cooperative study, the laboratory using ELISAs performed very well, with few false-positive or extraneous negative results. ELISA assays also performed well in sorting out sera with multiple specificities.

The percentage of clinical laboratories using ELISA increased from 25%–47% over a 4-year period, from 1989–1992. Homburger (1998) reported a comparison between a commercial ELISA and IF-ANA on HEp-2 cells, concluding that both methods were substantially equivalent for detecting clinically relevant ANA in patients with systemic rheumatic disease. Reaching an opposite conclusion, Emlen and O'Neill (1997) tested six commercial ELISA kits and concluded for the existence of significant differences in the detection of ANA by immunofluorescence and ELISA. A group of international scientists joined by the WHO reported on the performance of many commercial ELISAs, showing that (1) no single manufacturer was clearly superior to others in terms of overall sensitivity, specificity, and precision of products, and (2) areas that needed improvement were noted in kits used for the detection of antibodies to dsDNA and to Sm antigens (Tan, 1999). Great care should be exercised when selecting ELISA reagents and commercial kits. A good source of quality

control data for the best commercial reagents is the periodic review of the College of American Pathologists in Immunology.

IMMUNOBLOTTING

This technique is very sensitive and is an important method for characterization of the specific nature of many autoantibodies. One important advantage is that a specific antibody can be identified with the use of crude cell extract antigen preparations (Fig. 51-9). The European Consensus Study observed the following with the immunoblotting test (Nakamura, 1994b):

1. The antigen preparation is very important in the immunoblotting procedure.
2. Detection of antibodies to nRNP, Sm, and Scl-70 was acceptable. This sensitive method is helpful in the detection of multiple specificities of antibodies in the same specimen.
3. The method requires careful controls to monitor molecular weight bands. For example, histone bands can be confused with a centromeric antigen (CENP-A, 19 kDa), and Scl-70 (topoisomerase I) can be confused with other 100-kDa bands.
4. Protein degradation can occur in the antigen cell extract used for immunoblotting, especially Scl-70 and centromere antigens.
5. The anti-Sm is distinguished by the presence of anti-D (the D antigen is a 16-kDa protein contained in all major nRNP particles).
6. Anti-SS-B/La is readily detected by immunoblotting. Anti-SS-A/Ro is poorly detected by immunoblotting and is insensitive because SS-A/Ro may not demonstrate the proper structure for recognition.

SUMMARY, 1002

SELECTED REFERENCES, 1002

KEY POINTS

- The etiology and pathogenesis of vasculitides remain obscure and poorly understood, and may vary between different forms of vasculitis.
- There is no widely accepted standard classification system for idiopathic vasculitides, although the American College of Rheumatology and the Chapel Hill Consensus are the most widely used systems.
- The diagnosis of idiopathic systemic necrotizing vasculitides requires a high degree of suspicion.
- There are no pathognomonic clinical laboratory tests for patients with systemic necrotizing vasculitides.
- Antineutrophil cytoplasmic antibody (ANCA) tests are most valuable when selectively ordered in clinical situations where some form of ANCA-associated vasculitis is a serious consideration; they should not be used as screening tests.
- Detection of ANCA, particularly the association of cytoplasmic antineutrophil cytoplasmic antibody (c-ANCA) with Wegener's granulomatosis, has become an important adjunct in the diagnosis of systemic necrotizing vasculitis.
- c-ANCA immunofluorescence pattern should be confirmed using proteinase 3 enzyme-linked immunosorbent assay (ELISA).

- The pattern of perinuclear antineutrophil cytoplasmic antibodies (p-ANCAs) on indirect immunofluorescence is diagnostically nonspecific, so p-ANCA-positive sera should be tested in ELISA for myeloperoxidase-specific ANCA.
- Tissue biopsy with histologic confirmation of vasculitis remains the most important laboratory test for diagnosis of systemic necrotizing vasculitis.

The clinical, laboratory, and pathologic expressions of systemic necrotizing vasculitis are protean. Clinicians face a patient who presents with a wide array of confusing and conflicting symptoms and/or signs. Diagnosis of a systemic necrotizing vasculitic syndrome requires thorough evaluation that correlates an individual patient's history and physical examination with laboratory, imaging, and pathologic data. Although vasculitis can occur anywhere in the body, distinctive patterns of disease have been defined, and their identification points to particular disorders with specific treatment and prognosis (Langford, 1995, 2003).

Systemic necrotizing vasculitis is characterized pathologically by inflammation causing vascular lesions. These lesions may include the proliferation of intimal cells inside vessel lumina and narrowing or even closing of that space, causing ischemia and possible infarction to anatomic

structures distal to the site of vascular injury. Also, the vessel wall may thin and weaken until an aneurysm forms or the vessel ruptures.

Idiopathic (primary) vasculitis occurs when vascular inflammatory damage is the principal clinicopathologic finding and no other underlying illness is present. Secondary vasculitis occurs when vasculitic lesions accompany underlying disorders such as infectious disease, connective tissue disease, and hypersensitivity reaction (Table 52-1). This chapter focuses on idiopathic vasculitis and those clinical laboratory tests useful for its diagnosis and management. Because methods of diagnosis and management in secondary vasculitides concentrate on the underlying disorders, they are discussed in appropriate chapters of this book. However, comments related to laboratory evaluation of end-organ damage in idiopathic vasculitis are relevant to secondary vasculitis.

CLASSIFICATION

No standard classification system for idiopathic vasculitides has been widely accepted. Historically, their classification has been based on various combinations of clinical and pathologic findings in an effort to provide standardization with regard to presentation, prognosis, and treatment (Jennette, 1997; 1998b). Working classifications have improved in recent years owing to efforts at standard nomenclature (Hunder, 1990; Jennette,

1994; Hoffman, 1998a; Langford, 2003). In the 1980s, the American College of Rheumatology began an effort to improve sensitivity and specificity in distinguishing individual types of primary vasculitis from others (Table 52-2). The classification scheme was not intended to provide diagnostic criteria for primary vasculitis, as diagnosis is defined primarily by clinical judgment. In 1993, this was further expanded upon by the Chapel Hill Consensus Conference (CHCC), which provided additional nomenclature (Jennette, 1994; Falk, 2004). Table 52-3 contains the names and definitions of vasculitides adopted by the CHCC. Both schemes rely largely on dividing different vasculitides by the caliber of the vessel involved, with the CHCC criteria including the ANCA as a biomarker that can be used to distinguish certain forms of small-vessel vasculitis.

PATHOGENESIS OF VASCULITIS

The etiology and pathogenesis of vasculitides remain obscure and poorly understood, and may vary between different forms of vasculitis (Langford, 2003). Most idiopathic vasculitides are attributed to immune-mediated vascular injury induced by any of several mechanisms, including (1) immune-complex deposits; (2) direct autoantibody binding to vessel wall structures (e.g., endothelium, basement membrane antigens) or to neutrophils when vasculitis is associated with ANCA; and (3) cell-mediated inflammation (Jennette, 1994a) (Table 52-4). The pathogenic effects of these different mechanisms all unite in a final common pathway of vascular injury that activates humoral and cellular mediators of inflammation.

TABLE 52-3

Names and Definitions of Vasculitides from the Chapel Hill Consensus

	Definition
Large-Vessel Vasculitis	
Giant cell (temporal) arteritis	Granulomatous arteritis of the aorta and its major branches, with a predilection for the extracranial branches of the carotid artery. Often involves the temporal artery. Usually occurs in patients older than 50 and is often associated with polymyalgia rheumatica.
Takayasu's arteritis	Granulomatous inflammation of the aorta and its major branches. Usually occurs in patients younger than 50.
Medium-Sized Vessel Vasculitis	
Polyarteritis nodosa (classic)	Necrotizing inflammation of medium-sized or small arteries without glomerulonephritis or vasculitis of the arterioles, capillaries, or venules.
Kawasaki disease	Arteritis involving the large, medium-sized, and small arteries, and associated with mucocutaneous lymph node syndrome. Coronary arteries are often involved. Aorta and veins may be involved. Usually occurs in children.
Small-Vessel Vasculitis	
Wegener's granulomatosis	Granulomatous inflammation involving the respiratory tract, and necrotizing vasculitis affecting small to medium-sized vessels (capillaries, venules, arterioles, and arteries). Necrotizing glomerulonephritis is common.
Churg-Strauss	Eosinophil-rich and granulomatous inflammation involving the respiratory tract, and necrotizing vasculitis affecting small to medium-sized vessels and associated with asthma and eosinophilia.
Microscopic polyangiitis	Necrotizing vasculitis, with few or no immune deposits, affecting small vessels (capillaries, venules, or arterioles).
Henoch-Schönlein purpura	Vasculitis with immunoglobulin (Ig)A-dominant immune deposits, affecting small vessels (capillaries, venules, or arterioles).
Essential cryoglobulinemic vasculitis	Vasculitis with cryoglobulin immune deposits, affecting small vessels (capillaries, venules, or arterioles). Typically involves skin, gut, and glomeruli, and is associated with arthralgias and arthritis.
Cutaneous leukocytoclastic vasculitis	Isolated cutaneous leukocytoclastic angiitis without systemic vasculitis or glomerulonephritis.

T cells release interferon- γ and can also recruit monocytes and macrophages to vessel walls. These cells express increased levels of interleukin (IL)-1, IL-2, IL-6, tumor necrosis factor (TNF)- α , and TNF- β (Grau, 1989; Arimura, 1993). These mediators initiate the infiltration of inflammatory cells, activation of complement and coagulation cascades, and upregulation of other inflammatory molecules and growth factors such as platelet-derived growth factor and vascular endothelial growth factor. Sustained inflammation ultimately leads to extensive intimal thickening and vessel occlusion (Conn, 1993; Niles, 1995; Sneller, 1997; Langford, 2003; Guillevin, 2007). Substantial evidence of direct ANCA involvement in vasculitis tissue damage exists. In Wegener's granulomatosis (WG), ANCAs primarily target proteinase 3 (PR3), and in other vasculitides such as microscopic polyangiitis (MPA) and Churg-Strauss syndrome (CSS), myeloperoxidase (MPO) is a major target. Both of these antigens are enzymes contained in the granules of neutrophils and monocytes (Guillevin, 2007). Neutrophils that have been primed with low-dose TNF will have increased expression of MPO and PR3 and can release lytic enzymes when incubated with sera containing ANCA antibodies to these antigens (Kallenberg, 2006). In vitro studies also demonstrate that ANCA can increase attachment of rolling neutrophils to the endothelial layer (Radford, 2001). Finally, an association between the Birmingham Vasculitis Activity Score and the extent of disease and the number of activated B cells has been described (Seo, 2004b).

PERSPECTIVE ON USE OF CLINICAL LABORATORY TESTS

When evaluating patients with complicated multisystem disease, the clinician's goal is accurate diagnosis to the level that defines proper treatment.

Because no pathognomonic clinical or laboratory features of vasculitis have been identified, the physician must use combinations of clinical, laboratory, imaging, and pathologic findings to recognize patterns of disease. This may allow specific diagnosis or classification of the patient's disease as one in a group of vasculitic disorders requiring similar treatment, even when no specific entity is identifiable.

Deciding that a patient has vasculitis strictly on the basis of clinical symptoms is fraught with risks because of the large number of differential diagnostic possibilities and the lack of pathognomonic findings. Consequently, histologic or angiographic confirmation of vasculitis should be obtained from tissue biopsy or angiography for definitive diagnosis prior to therapy (Mandell, 1994; Langford, 2003).

Clinical laboratory tests are of limited value in establishing a specific diagnosis of vasculitis (Mandell, 1994; Langford, 2003), although clinicians use these tests to assist in identifying patterns of organ involvement characteristic of vasculitis, evaluating the extent and severity of end-organ damage, distinguishing idiopathic vasculitis from alternative secondary forms, and establishing baseline values for management. The association of ANCA with certain idiopathic vasculitides is an important aid in diagnosis and management. ANCAs are discussed in detail subsequently.

When evaluating a patient whose differential diagnoses includes vasculitis, utilize the following principles regarding the use and interpretation of clinical laboratory tests.

ROUTINE TESTS

Patients whose history and physical examination findings suggest idiopathic vasculitis often have a confusing array of multisystem complaints that have been occurring for some time. First-order tests include the following: cultures for infectious agents (particularly if the patient has fever), complete blood cell count (CBC) with differential, markers of inflammation such as the erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP), urinalysis, blood chemistry panel, and tests for specific organ function, such as the liver.

SPECIAL TESTS

Special tests help to differentiate idiopathic vasculitis from alternatives in the working differential diagnosis. Relevant laboratory tests would include those used to identify the circulating autoantibodies listed in Table 52-5 along with immune complexes. Directed tissue biopsy for histologic confirmation of vasculitis and/or angiography are considered the definitive tests for idiopathic vasculitis.

TEST PATTERNS IN VASCULITIS

Certain patterns of clinical laboratory test results are useful.

CBC

- Finding leukopenia and/or thrombocytopenia in idiopathic vasculitides is rare and suggests alternative diagnoses such as systemic lupus erythematosus (SLE), neoplasm, bone marrow disorders, lymphomatoid granulomatosis, or hypersplenism (Mandell, 1994).

TABLE 52-5

Antibodies Associated With Vasculitis

Antibody	Disease association	Principal test method(s)
ANCA, usually c-ANCA	Wegener's granulomatosis	IIF, ELISA
ANCA, c-ANCA, or p-ANCA	Microscopic polyangiitis	IIF, ELISA
Anti-C1q antibodies	Hypocomplementemic urticarial vasculitis	C1q binding
Hepatitis B antibodies	Hepatitis B-associated PAN	ELISA
ANA	Systemic lupus erythematosus	IIF, ELISA
Mixed cryoglobulins	Cryoglobulinemic vasculitis	Cryoprecipitation, IEP, IF
SSA (Ro), SSB (La)	Sjögren's syndrome	IIF, ELISA, ID
Rheumatoid factor	Rheumatoid arthritis	LA, ELISA
Hepatitis C antibodies	Hepatitis C-associated PAN	EIA
Anti-DNA	Systemic lupus erythematosus	IIF, ELISA

ANA, Antinuclear antibody; ANCA, antineutrophil cytoplasmic autoantibodies; c-ANCA, cytoplasmic ANCA; DNA, deoxyribonucleic acid; EIA, enzyme immunoassay; ELISA, enzyme-linked immunosorbent assay; GBM, glomerular basement membrane; ID, immunodiffusion; IEP, immunoelectrophoresis; IF, immunofixation; IIF, indirect immunofluorescence; LA, latex agglutination; PAN, polyarteritis nodosa; p-ANCA, perinuclear ANCA.

- Anemia with hemoglobin less than 9 g/dL results from conditions other than anemia of chronic disease, such as hemolysis, occult bleeding, or renal disease (Mandell, 1994).
- Peripheral blood eosinophilia occurs in a wide variety of inflammatory disorders. About 15%–20% of patients with polyarteritis nodosa (PAN) or WG may have eosinophilia, but not at the high levels seen in CSS.
- Vasculitis with histologic features of PAN associated with pancytopenia can be seen in patients with hairy cell leukemia (Mandell, 1994). Classic hairy cells may be observed on a peripheral blood smear.

ESR/CRP

- Markers of inflammation such as ESR or CRP, although nonspecific, are typically elevated in idiopathic vasculitides. If the ESR (before antiinflammatory therapy initiation) is not elevated, the diagnosis is probably not giant cell arteritis or WG.

Urinalysis

- First morning urine, both before and after centrifugation, should be carefully examined for protein, hematuria, cells, and casts that accompany glomerulonephritis, which may occur in vasculitides. If renal amyloidosis is in the differential diagnosis, proteinuria is typically seen without cells.

Viral Disease

- When PAN is suspected, serologic tests for liver function, hepatitis B virus (HBV), hepatitis C virus (HCV), and cytomegalovirus should be obtained (Langford, 2003; Golden, 1994; Mandell, 1994). Similarly, serologic tests for HBV and HCV are appropriate when a patient has cryoglobulins, leukocytoclastic vasculitis on cutaneous biopsy, and/or renal disease.
- Numerous vasculitides, including large vessel vasculitis, hypersensitivity vasculitis, a PAN-like syndrome, and primary angiitis of the central nervous system (CNS), have been described in association with human immunodeficiency virus (HIV) (Chetty, 2001).

Connective Tissue Disease

- Testing for antinuclear antibodies (ANAs) and rheumatoid factor (RF) is useful only when connective tissue disease or arthritis is suspected.
- Patients with rheumatoid vasculitis have high-titer RF.

ANTINEUTROPHIL CYTOPLASMIC ANTIBODY

ANCA reacts with neutrophil cytoplasmic antigens (Tervaert, 1991; Jennette, 1993a), which were previously shielded (Seo, 2004b). Identification of ANCA has become an important adjunct in the diagnosis of systemic necrotizing vasculitis (Niles, 1993; Seo, 2004b), although it must be stressed that because ANCA-associated vasculitides are relatively rare, the likelihood of false-positive results is increased if not used in the appropriate clinical context. Use of ANCA and autoantigen titers in monitoring disease activity is controversial.

DETECTION METHODS

Several laboratory methods, including indirect immunofluorescence (IIF), ELISA, radioimmunoassay, Western blotting, dot blotting, flow cytometry, immunoprecipitation, and capture enzyme immunoassay techniques, have been used to detect ANCA (Wieslander, 1991; Roberts, 1992; Seo 2004b). IIF and ELISA are the most common test methods used for this purpose. IIF is the most sensitive widely used method for ANCA detection.

IIF is done using isolated normal human neutrophils as substrate. These neutrophils are cytocentrifuged against multiwell glass slides, fixed with 99% ethanol, and then incubated with dilutions of patients' sera. Neutrophils may also be attached to slides by adherence, smear, or drop techniques (Roberts, 1990, 1992). Slides are stained with a fluorescein-labeled polyspecific antihuman immunoglobulin (Ig) conjugate; polyspecific conjugate is recommended because IgM and IgA c-ANCAs occur (Roberts, 1992). Slides are read on a fluorescence microscope by an experienced laboratory technician. With the use of IIF, three patterns of neutrophil staining are observed: c-ANCA, p-ANCA, and atypical patterns (Seo, 2004b).

Figure 52-1 Antineutrophil cytoplasmic antibody cytoplasmic pattern (c-ANCA). Most ethanol-fixed neutrophils show finely granular, cytoplasmic fluorescence with central accentuation. There is no nuclear staining (×400).

c-ANCAs are characterized by finely granular staining of neutrophil cytoplasm with central accentuation between nuclear lobes; the nucleus itself does not stain (Fig. 52-1). Criteria useful for differentiating c-ANCA from nonspecific cytoplasmic staining due to other autoantibodies include the following: (1) lack of central accentuation; (2) less than 95% of neutrophils demonstrate cytoplasmic staining; (3) nonneutrophil specificity (e.g., lymphocytes on the slide should not stain when true ANCA is present); and (4) heterogeneous cytoplasmic granularity (Roberts, 1992; Savage, 1998).

p-ANCAs are characterized by staining of the perinuclear area (Fig. 52-2). The staining pattern that defines p-ANCA is caused by redistribution of target antigens from the neutrophil cytoplasm to the positively charged nuclear membrane when ethanol is used to prepare human neutrophils as substrate (Jennette, 1993a; Fig. 52-3). When formalin rather than alcohol is used to fix neutrophils, target antigen is immobilized and the immunofluorescent staining pattern is cytoplasmic (Jennette, 1993a). The use of formalin-fixed neutrophils to detect ANCA in routine diagnostic work remains controversial (Chowdhury, 1999). Nuclear staining mimicking ANAs may occur when this autoantibody is present in high titers (Niles, 1993). Distinguishing p-ANCA from atypical patterns is difficult (Seo, 2004b).

Atypical ANCA, which sometimes is referred to as X-ANCA, combines features of both c-ANCA and p-ANCA. Faint diffuse cytoplasmic staining typically occurs with strong linear perinuclear staining. This pattern is similar on methanol- or ethanol-fixed slides but can appear cytoplasmic or abolished altogether on formalin-fixed neutrophils (Beauvillain, 2008).

ANTIGENIC SPECIFICITY

The antigenic specificity of c-ANCA has been identified as a 29-kDa neutral serine protease, PR3, located within azurophilic granules of neutrophils and peroxidase-positive lysosomes of monocytes (Roberts, 1992; Niles, 1993; Seo 2004b). It has been implicated in the destruction of bacteria within phagosomes. PR3 is also found on the plasma membrane of resting neutrophils and monocytes in many patients (Seo, 2004b). It has been described as myeloperoxidase and is involved in differentiation of the HL60 promyelocytic cell line (Beauvillain, 2008). In the primary vasculitides, p-ANCA is usually produced by autoantibodies against MPO (Falk, 1988). MPO is also located within the primary granules of the neutrophil and acts to catalyze the formation of hypochlorite, a potent bactericidal agent (Beauvillain, 2008). Many p-ANCAs and atypical ANCAs are not directed at MPO or PR3, but rather are directed at other neutrophil cytoplasmic enzymes, including bactericidal agents, thereby increasing permeability protein, elastase, lactoferrin, lactoperoxidase, lysozyme, azurocidin, or cathepsin G (Jennette, 1993a; Niles, 1993; Hoffman, 1998b). ANCA patterns should be confirmed with more specific tests for PR3 and MPO, the antibodies most often associated with vasculitis (Savage, 2000; Langford, 2003; Seo, 2004b).

ELISAs for detecting autoantibodies to PR3 (PR3-ANCA) show good correlation with the presence of c-ANCA when experienced observers perform IIF (Roberts, 1992; Niles, 1993). An ELISA for detecting

Figure 52-2 Antineutrophil cytoplasmic antibody perinuclear pattern (p-ANCA). Most ethanol-fixed neutrophils show perinuclear and nuclear fluorescence without cytoplasmic staining (**A**, $\times 400$) that is cytoplasmic when formalin rather than alcohol is used to fix neutrophils (**B**, $\times 400$).

Figure 52-3 Atypical perinuclear antineutrophil cytoplasmic antibody pattern on ethanol-fixed neutrophils shows perinuclear fluorescence (**A**, $\times 500$) but no fluorescence when formalin rather than alcohol is used to fix neutrophils (**B**, $\times 500$).

PR3-ANCA must be carefully validated, with particular attention to using proven techniques for solid-phase antigen preparation, and to using background subtraction or a specific absorption step to control for nonspecific binding of immunoglobulin to the solid phase (Roberts, 1992; Niles, 1993; Wang, 1997). Efforts to standardize solid-phase ELISAs are ongoing in Europe (Hagen, 1996, 1998).

Licensed commercial ELISAs for both PR3 and MPO are available. Most use standard direct antigen coating of polystyrene microwell plates, so that antigen purity is of critical importance in defining analytic sensitivity and specificity (Roberts, 1992; Niles, 1993). Attempts to preserve native antigen conformation are important, in that ANCAs to PR3 are directed against conformational epitopes (Hoffman, 1998b). Loss of these epitopes through denaturation during antigen purification or coating onto the solid phase may partially explain detection of c-ANCA via IIF without a correlative PR3 titer. Capture ELISA utilizes monoclonal antibodies to capture the antigen on the ELISA plate, without obscuring the relevant epitopes. One study has suggested that this method has improved sensitivity for detecting PR3 compared with direct ELISA in WG (Csernok, 2004).

The correlation between p-ANCA and detection of myeloperoxidase on ELISA, however, is not good (Roberts, 1992). Several autoantibodies, including ANA, antineutrophil elastase, and granulocyte-specific ANA (GS-ANA), can produce a p-ANCA pattern on IIF. Therefore, sera that produce nuclear fluorescence on IIF require additional testing to confirm MPO. MPO-ELISA is recommended to confirm anti-MPO specificity because true ANA or GS-ANA and myeloperoxidase-specific ANCA (MPO-ANCA) are known to occur concurrently. IIF using HEP-2 cells (which are typically used for the detection of ANA) does not adequately make this distinction because ANA and MPO-ANCA can occur together, and GS-ANA may be negative on HEP-2 cells (Roberts, 1992; Specks, 1994).

ELISA has limitations; ultimately each laboratory must carefully verify a manufacturer's claims, so the clinician can receive information on performance characteristics. This proves especially important in confusing clinical situations in which there may be discrepancies between clinical presentation and laboratory results, and/or discordant results between IIF and ELISA tests.

In summary, it is recommended that a combination of IIF and ELISA be used to detect ANCA specific for PR3 MPO. By utilizing a combination of the two studies in the workup of suspected vasculitis, the specificity of both PR3 and MPO ELISA is near 99%. The sensitivity for newly diagnosed WG was 73%, and 67% for microscopic polyangiitis (Hagen, 1998). Disease-specific rates of ANCA positivity in the ANCA-associated vasculitides are described in the following sections.

DISEASE ASSOCIATIONS

Vasculitis

Both PR3-ANCA (c-ANCA) and MPO-ANCA (p-ANCA) are associated with WG, PAN, MPA, CSS, idiopathic pauci-immune necrotizing vasculitis and crescentic glomerulonephritis, and polyangiitis overlap syndromes (Niles, 1993; Langford, 2003; Seo, 2004b). PR3-ANCA is identified in about 70%–80% of patients with active WG, whereas MPO-ANCA is identified in less than 10% of such patients (Wiik, 2002; Seo, 2004b). Eighty to ninety percent of patients with active microscopic polyangiitis have PR3-ANCA (30%) or MPO-ANCA (60%) (Wiik, 2002). ANCA is found in about 30% of CSS patients, with an equal distribution of PR3 and MPO antibodies reported. In pauci-immune glomerulonephritis, ANCA is detected in 50%–80% of patients with active disease, typically MPO-ANCA (Langford, 2003; Seo, 2004b). Coexistence of ANCA and anti-glomerular basement membrane (anti-GBM) antibodies has been

reported (Bonsib, 1993; Niles, 1993), and this may represent a crossover syndrome between WG and Goodpasture's syndrome, an autoimmune pulmonary-renal syndrome.

Inflammatory Disease of Gastrointestinal and Hepatobiliary Tracts

A variety of serologic tests, including p-ANCA, are emerging that are relevant to the diagnosis and treatment of ulcerative colitis, Crohn's disease (Sandborn, 2004), and disorders of the hepatobiliary system (Jennette, 1993b). p-ANCAs have been reported in about 75%–80% of patients with active ulcerative colitis (UC) or primary sclerosing cholangitis (Klein, 1991; Lo, 1993; Ellerbroek, 1994), about 75% of patients with chronic autoimmune hepatitis, about 30% of patients with primary biliary cirrhosis (Kallenberg, 1992; Mulder, 1993), and about 20% of patients with Crohn's disease (Roberts, 1992; Jennette, 1993b). Target antigen specificities in inflammatory bowel disease have not been fully defined, although autoantibodies against lactoperoxidase, bactericidal permeability-increasing protein (Hoffman, 1998b), lactoferrin (Peen, 1993), or cathepsin G have been reported (Jennette, 1993b). Most adult patients with UC have detectable p-ANCA that is sensitive to deoxyribonuclease, which helps differentiate p-ANCA in inflammatory bowel disease from p-ANCA in other disorders such as autoimmune hepatitis and primary sclerosing cholangitis (Nakamura, 2003). A subgroup of patients with Crohn's disease with p-ANCA may have colon involvement that mimics the clinical presentation of ulcerative colitis.

Other Diseases

ANCAs have been reported in other diseases, including drug-induced lupus erythematosus, SLE, Felty's syndrome and rheumatoid arthritis, Sjögren's syndrome, polymyositis and dermatomyositis, juvenile rheumatoid arthritis, reactive arthritis, relapsing polychondritis, antiphospholipid antibody syndrome, myelodysplastic syndromes, HIV infection, chromomycosis, invasive amebiasis, subacute bacterial endocarditis, cystic fibrosis, and certain neoplasms (Peter, 1993; Jennette, 1993b; Hoffman, 1998b; Choi, 2000). In the connective tissue disorders, ANAs that mimic p-ANCA must be excluded. Many patients treated with hydralazine appear to develop MPO-ANCA (Roberts, 1992). Propylthiouracil-associated vasculitis has been associated with positive ANCA (Hoffman, 1998b; Langford, 2003).

TEST INTERPRETATION

Interpretation of ANCA tests must consider several factors (Hagen, 1998; Hoffman, 1998a; Vassilopoulos, 1999; Seo, 2004a):

- ANCA tests should not be used as screening tests in nonselected patient groups in which the prevalence of vasculitis is low (Langford, 1998a).
- ANCA tests are most valuable when selectively ordered in clinical situations in which some form of ANCA-associated vasculitis is a serious consideration.
- c-ANCA immunofluorescence pattern should be confirmed using PR3 ELISA (Savage, 1999; Langford, 2003; Seo, 2004b).
- Anti-PR3 reactivity is most often seen in active WG or PAN but may be seen in idiopathic crescentic glomerulonephritis or CSS.
- c-ANCA in WG is considered highly sensitive in signaling active systemic disease (Vassilopoulos, 1999).
- Predictive value of an increased c-ANCA titer as a harbinger of WG relapse is controversial, in that not all increases in c-ANCA titer are followed by worsening WG (Specks, 1994; Langford, 2003).
- Rise in ANCA titer is a risk factor for a flare but is insufficient to adjust immunosuppressant medications on this basis alone (Langford, 2003; Seo, 2004).
- p-ANCA pattern on IIF is diagnostically nonspecific.
- p-ANCA-positive sera should be tested in ELISA for MPO-ANCA (Savage, 1999; Seo, 2004b), although several other antigens may be target antigens for p-ANCA.
- MPO-ANCA is most often seen in PAN, idiopathic crescentic glomerulonephritis, or CSS; however, it may be seen in WG.
- Neither a diagnosis of systemic necrotizing vasculitis nor a decision to treat should be based solely on a positive ANCA test result.
- A negative ANCA should not be used to exclude disease.

Ultimately, interpretation of a test for ANCA depends on the experience of individual clinicians who treat vasculitis and the pattern

of disease manifested by the patient at hand (Jennette, 1998a; Langford, 2003; Seo, 2004b).

SYNOPSIS OF MAJOR IDIOPATHIC VASCULITIC SYNDROMES

POLYARTERITIS NODOSA

Epidemiology

PAN, similar to all idiopathic vasculitides, is an uncommon disease. Estimates of the prevalence of PAN have varied from 4.6 per 1,000,000 in England, to 9.0 per 1,000,000 in Olmstead County, Minnesota (Conn, 1993; Langford, 1995). PAN may occur in either gender and at any age but is more common in men (male/female ratio = 2:1) between 40 and 60 years old (Langford, 1995). No racial predilection has been observed (Conn, 1993). Older series of patients with PAN include patients who now would be thought to have microscopic polyangiitis (Langford, 2003). HBV may be an etiologic factor in some cases of PAN. For example, the prevalence of HBV infection in an Alaskan Eskimo population hyperendemic for HBV was 77 per 100,000 (Langford, 1995). With increased knowledge regarding the transmission of HBV, in addition to the development of a preventive vaccine, the frequency of PAN due to HBV has decreased from 30% in the 1970s to 7% (Trepo, 2001).

Clinical Features

The clinical manifestations of classic PAN are highly variable. Patients often present with such nonspecific symptoms as fever, weight loss, and malaise. Hypertension is common and can be an important diagnostic clue. Although PAN can occur in virtually any organ system, symptomatic involvement of skin, joints, peripheral nerves, gastrointestinal (GI) tract, and nonglomerular renal vessels dominates the clinical picture (Conn, 1993; Savage, 2000; Langford, 2001, 2003). Tests indicating abnormal liver function suggest the possibility of concurrent hepatitis B infection (Langford, 1995, 2003; Savage, 2000). Pulmonary involvement in classic PAN is rare and even controversial. Although some investigators think that pulmonary PAN occurs (Lie, 1989), others think that such patients had CSS or WG, in which pulmonary disease is common (Langford, 1995; Fauci, 1998). The course of PAN is characterized by remissions, relapses, and, if untreated, high mortality (Fauci, 1998). Five-year survival with treatment is estimated to be 80%, and less than 10% of patients relapse (Langford, 2003).

Clinical Laboratory Findings

Results of clinical laboratory tests, although diagnostically nonspecific, reflect the systemic inflammatory nature of PAN. Typically, one finds normochromic anemia, neutrophilic leukocytosis, hypoalbuminemia, hypergammaglobulinemia, and a markedly elevated ESR. Measurement of serum creatinine and blood urea nitrogen (BUN) together with urinalysis to check for proteinuria, hematuria, and abnormal sediment is important for evaluating renal function. The positive ANA or RF found in 10%–40% of these patients may be associated with decreased levels of complement components C3 and C4. Serologic tests for HBV, HCV, and HIV should be obtained in all patients with PAN (Conn, 1993; Langford, 1995, 2003); eosinophilia is seen only rarely, and when present in high levels, should lead to consideration of CSS (Fauci, 1998).

Diagnosis

PAN can be difficult to diagnose given its nonspecific presentation, potential for diverse and diffuse organ involvement, and low prevalence. However, once suspected, a diagnosis of PAN is based on angiography and/or the histologic demonstration of PAN on biopsy of tissue from symptomatic site(s), such as muscle, nerve, kidney, and testes. Pathologically, PAN is a focal but pan-mural necrotizing arteritis of small- and medium-sized muscular arteries, preferentially occurring at vessel branch points (Fig. 52-4). Necrotizing mixed cell inflammation with fibrinoid necrosis, either circumferential or segmental in the vessel wall, is the hallmark lesion of active PAN. Microaneurysm or aneurysmal dilatation is also characteristic of acute phase PAN. The inflammatory process heals with fibrosis that may lead to proliferative endarteritis. An admixture of active and/or healing lesions adjacent to normal segments of blood vessel is a characteristic feature of PAN (Langford, 1995).

Angiography may be especially valuable in identifying GI abnormalities, or when a potential biopsy site is unavailable. In particular, angiography should be considered before attempting a closed needle biopsy of

Figure 52-4 Polyarteritis nodosa. Skeletal muscle biopsy reveals circumferential pan-mural necrotizing arteritis of a small muscular artery with mixed cell inflammation, fibrinoid necrosis, and proliferative endarteritis. Eosinophils are a prominent component of the inflammation in this case, but there are no granulomas (hematoxylin and eosin [H&E], $\times 200$).

the liver or kidney in patients suspected to have PAN, because the predilection for aneurysms at these sites increases the risk of severe bleeding (Langford, 1995).

Treatment and Prognosis

Patients with PAN are treated with glucocorticoids. The goal of glucocorticoid therapy is control of the disease without significant complications from the drug itself. Cyclophosphamide may be used for patients with severe PAN (GI, cardiac, and CNS involvement), for those failing corticosteroids alone, and to spare steroid in patients having significant corticosteroid adverse effects (Langford, 1995; Jayne, 2000; Watts, 2000; Langford, 2003). The prognosis for PAN patients has greatly improved with the use of glucocorticoids, extending the 5-year survival rate from 13% to 50%–60%. A majority of deaths occur within the first year, but whether before or after 1 year of disease, mortality most often results from infection as a complication of treatment, or from sequelae of vessel obliteration such as myocardial infarction or stroke (Langford, 1995). PAN associated with hepatitis infection or HIV should be accompanied by antiviral or antiretroviral therapy, respectively (Langford, 2003).

CHURG-STRAUSS SYNDROME

Epidemiology

CSS is thought to be a rare clinical condition, and a prevalence of 3 per one million people has been estimated (Conn, 1993; Langford, 2003). CSS typically begins between ages 15 and 69 years, with 38 years as the median age for onset of vasculitis (Langford, 1995).

Clinical Features

CSS, also called allergic angitis and granulomatosis, is a systemic necrotizing vasculitis characterized by vascular and extravascular granulomatous inflammation, multiple organ involvement, and associations with allergic rhinitis, severe asthma, fever, and hypereosinophilia (Langford, 1995, 2003; Fauci, 1998). Clinical manifestations of CSS may resemble those of PAN in many respects but differ in that lung disease is typical and renal disease is uncommon, usually less severe in CSS than in PAN (Fauci, 1998).

The clinical course of CSS is often divided into three distinct phases, although in reality, these three phases are not always identifiable, or they may overlap (Langford, 1995, 2003): (1) a prodromal phase characterized by allergic respiratory disease; (2) an eosinophilic phase characterized by peripheral blood and tissue hypereosinophilia; and (3) a vasculitic phase. Cardiac involvement—either transmural eosinophilic carditis or coronary vasculitis—occurs in 25%–62% of CSS patients and is the major cause of death (Langford, 1995, 2003). Involvement with sites such as the heart, CNS, GI tract, and kidney is associated with a poor prognosis (Langford, 2003).

Clinical Laboratory Findings

A hallmark of CSS is striking peripheral blood eosinophilia, which may be seen at any phase of the disease. The peripheral blood eosinophil count reaches 1000 eosinophils per microliter in 80% or more of CSS patients (Conn, 1993); however, eosinophilia may not be found in all patients because of prior steroid treatments for asthma, or the wide and rapid fluctuation in the eosinophil count that can occur in this disorder. Normalization of the eosinophil count in response to steroid treatment is a feature of CSS, distinguishing it from the hypereosinophilic syndrome, in which eosinophilia may be steroid resistant. The degree of eosinophilia may correlate with the activity of vasculitic disease in some patients.

Other laboratory findings in CSS are nonspecific. Anemia, leukocytosis, and increased ESR frequently accompany the vasculitic phase. Serum IgE levels may be elevated. Serum RF may be identified, but the titer is usually low. Serum complement is reported as normal (Conn, 1993). Unlike PAN, no association between CSS and hepatitis B has been described (Langford, 1995).

Diagnosis

Historically, the diagnosis of CSS has been made solely on the basis of histologic demonstration of necrotizing eosinophilic vasculitis, eosinophilic tissue infiltration, and extravascular granuloma. In practice, however, few biopsy specimens contain all these findings. To increase the likelihood of identifying and diagnosing CSS, the emphasis can be shifted from these diagnostic indicators to include clinical features. One study has recommended the following criteria:

1. Asthma (Katzenstein, 2000).
2. Peripheral blood eosinophilia in excess of 1.5×10^3 cells/ μ L.
3. Systemic vasculitis involving two or more extrapulmonary organs (Conn, 1993).

Definitive diagnosis still requires demonstration of biopsy-proven vasculitis. Open-lung biopsy frequently does not confirm all histologic features of CSS and must be considered before the institution of therapy, if there is concern over possible infection. When clinical symptoms so indicate, useful biopsy specimens are most often obtained from muscle, sural nerve, prostate, and kidney. The differential diagnosis of CSS includes PAN, WG, and the hypereosinophilic syndrome (Langford, 1995, 2003).

Treatment and Prognosis

Corticosteroids are the basis for treatment of CSS. The utility of immunosuppressive therapy with azathioprine or cyclophosphamide is not well studied (Langford, 1995). Early diagnosis of CSS and corticosteroid treatment has led to a 5-year survival rate of 62%. Congestive heart failure and myocardial infarction cause 48% of all deaths in CSS. Cerebral hemorrhage, renal failure, GI perforation or hemorrhage, status asthmaticus, and respiratory failure also cause the demise of CSS patients. All of these features should lead to strong consideration of cytotoxic agent (cyclophosphamide) therapy in conjunction with corticosteroid (Langford, 1997). A short interval between the onset of asthma and the onset of vasculitis is considered an unfavorable prognostic sign.

MICROSCOPIC POLYANGIITIS

Epidemiology

MPA was recently distinguished from PAN, and little is known about its epidemiology.

Clinical Features

MPA occurs in a heterogeneous group of patients who, by definition, have a systemic necrotizing vasculitis of small vessels with few or no immune deposits (Langford, 2003). The sentinel features of MPA are glomerulonephritis, pulmonary hemorrhage, mononeuritis multiplex, and fever, similar to WG (Langford, 2003; Seo, 2004b). Presentation is often acute and severe. Neurologic disease (peripheral or central) manifests in 60%–70%, arthralgia/arthritis in 40%–60%, and cutaneous disease in 50%–65% of patients with MPA (Langford, 2003).

Clinical Laboratory Findings

Chest radiographs reveal a nodule, infiltrates, or alveolar hemorrhage in up to 70% of patients. Proteinuria and hematuria compatible with glomerulonephritis occur in 75%–90% of patients. Electromyography/nerve conduction velocity tests reveal evidence of peripheral neurologic disease in up to two thirds of patients. CNS imaging may show evidence of central neurologic disease in 10% of people with MPA (Langford, 2003).

Diagnosis

MPA is diagnosed when tissue biopsy reveals small to medium-sized vessel nongranulomatous necrotizing vasculitis. In the lung, capillaritis is seen in the face of alveolar hemorrhage and the absence of linear immunofluorescence that would be seen in Goodpasture's syndrome. Renal biopsy reveals focal segmental necrotizing glomerulonephritis with few to no immune complexes (Langford, 2003).

Treatment and Prognosis

Patients with life-threatening disease in the lungs, kidneys, or nerves should be treated with cyclophosphamide (2 mg/kg/day) and prednisone (1 mg/kg/day) in a manner similar to the treatment of WG (see later) (Langford, 2003). Less severe disease may be treated with corticosteroids alone. Five-year survival is estimated to be 74%, and relapses occur in one third of patients (Langford, 2003).

WEGENER'S GRANULOMATOSIS

Epidemiology

Detailed annual incidence and prevalence data for WG are not available, but WG is estimated to be less common than PAN. WG occurs in persons of any age, race, or sex, although it affects predominantly Caucasians and has a slight male predominance (Conn, 1993). The mean age at onset is 41 years (Langford, 1995). Males and females are equally affected (Langford, 2003).

Clinical Features

WG is a clinicopathologic syndrome of unknown etiology characterized pathologically by necrotizing granulomatous inflammation of upper and lower respiratory tracts, focal segmental glomerulonephritis, and necrotizing vasculitis predominantly involving medium-sized and small arteries. WG presents in the ear/nose/throat regions with sinusitis, nasal obstruction or ulceration, otitis media, or hearing loss (Fauci, 1998; Lie, 1989). Forty-five percent of WG patients have lung involvement at presentation, and 85% manifest lung disease at some time during the course of their disease. Common lung manifestations include pulmonary infiltrates, pulmonary nodules, hemoptysis, or pleuritis (Fauci, 1998). Although renal disease initially afflicts only about 18% of these patients, 80% demonstrate glomerulonephritis at some time in the course of WG (Fauci, 1998). Other common signs of systemic illness include skin rash, arthralgias, fever, eye manifestations, and weight loss (Fauci, 1998; Lie, 1989). Although patients with WG limited to the respiratory tract without renal involvement have been described (**limited WG**), more than 50% of patients with such limited disease at presentation eventually develop more generalized disease (Langford, 1995).

Clinical Laboratory Findings

Clinical laboratory findings typical of WG include moderate leukocytosis without striking eosinophilia, mild normochromic anemia, and thrombocytosis (Conn, 1993; Langford, 1995). Leukopenia is not seen in the untreated patient and, thus, helps distinguish WG from other disorders. The presence of c-ANCA supports the diagnosis. Circulating immune complexes, measurable by C1q binding, may be found together with normal complement levels and hypergammaglobulinemia; quantities of the IgA subclass are often elevated (Conn, 1993; Langford, 1995). Indicators of glomerular involvement include microscopic or gross hematuria, proteinuria, red blood cell casts, and/or elevated serum creatinine and BUN. More than 50% of these patients are RF-positive, but ANAs are usually absent (Langford, 1995; Fauci, 1998). Serologic tests for anti-GBM autoantibody are negative. Prior to treatment, 80% of these patients have an elevated ESR.

Diagnosis

Although clinical and laboratory findings may be suggestive, a diagnosis of WG should be made only when there is biopsy-proven, histologic confirmation, or when c-ANCA is established in the patient with sinusitis, pulmonary infiltrate or nodule, and glomerulonephritis (Langford, 1998b, 2003). Pulmonary tissue obtained via open-lung biopsy offers the best opportunity to make an accurate diagnosis (Langford, 1995). Transbronchial biopsy does not yield adequate tissue for diagnosis more than 90% of the time. Although head and neck tissue is more directly accessible, characteristic pathologic features are found in fewer than 23% of such biopsy specimens. Diagnostically useful tissue from the head and neck region is best obtained from, in decreasing order of frequency, paranasal

sinuses, nasal tissue, and the subglottic region. Glomerular changes in renal biopsy tissue, although suggestive of WG, are rarely diagnostic (Langford, 1995).

Although the morphologic spectrum of WG is broad, the hallmark pathologic lesion in WG is necrotizing granulomatous vasculitis. Affected vessels undergo fibrinoid necrosis with early infiltration by polymorphonuclear leukocytes followed by mononuclear cells. Pulmonary tissue may reveal any combination of necrosis, vasculitis, and granulomatous inflammation; microabscesses and scattered multinucleated giant cells in a highly inflammatory background may also occur (Yi, 2001) (Fig. 52-5). However, biopsy specimens often do not include all of these characteristic features.

Figure 52-5 Wegener's granulomatosis. Paranasal sinus tissue reveals a florid mixed inflammatory cell infiltrate in a granulation tissue-type background. Inflammatory cells include multinucleated giant cells and neutrophil microabscesses (A, hematoxylin and eosin [H&E], $\times 200$). Lung biopsy reveals nodular inflammation with necrosis (B, H&E, $\times 20$) and granulomatous vasculitis (C, H&E, $\times 200$).

The most common finding found on renal biopsy is segmental necrotizing glomerulonephritis, which is present to varying degrees in 80% of specimens. Renal vasculitis not related to glomeruli is unusual and is present in only 8% of biopsies.

Many disorders can mimic WG, including infectious or noninfectious granulomatous disease, CSS, Goodpasture's syndrome, idiopathic midline granuloma, lymphomatoid granulomatosis, and neoplasms of the upper airway or lungs (Fauci, 1998). Of these, infection is an important consideration because misdiagnosis can have fatal consequences when mistakenly treated with immunosuppressive therapy (Langford, 1995).

Treatment and Prognosis

A regimen of daily oral cyclophosphamide and corticosteroids is the therapy of choice for WG. Using this regimen, the National Institutes of Health reported that marked improvement or partial remission was achieved in 91% of patients, and complete remission in 75%. An overall mortality rate of 20% was noted, 13% of which could be completely or partially attributed to WG. Despite this marked improvement in survival and remission compared with 100% mortality in untreated patients, relapse and morbidity from both disease and treatment were noted. One half of the complete remissions were followed by one or more relapses, which occurred 3 months to 16 years after achieving remission (Langford, 1995; de Groot, 2001). Methotrexate is an alternative to cyclophosphamide in patients who do not have immediately life-threatening diseases (Langford, 1997). Also, methotrexate (20–25 mg/week) or azathioprine (2 mg/kg/day) can be given to maintain remission after 3–6 months of cyclophosphamide to induce remission. This therapy is given for an additional 1–2 years (Langford, 2003). Recently, rituximab, an anti-CD20 monoclonal antibody, has been utilized successfully in small case series of patients with disease limited to the eyes and ears, as well as in systemic disease affecting the lungs and kidneys (Sailler, 2008). Typically, rituximab is reserved for disease that is refractory to conventional treatments, and randomized controlled prospective trials of its use are under way.

During the first year of WG, the extent of renal disease is the factor most closely related to prognosis (Koldingsnes, 2002). Thereafter, lung involvement becomes the most important prognostic indicator, and glomerulonephritis does not appear to significantly affect prognosis.

LYMPHOMATOID GRANULOMATOSIS

Lymphomatoid granulomatosis (LG) is considered to be an unusual lymphoproliferative disorder that may evolve into malignant lymphoma in approximately 50% of patients. LG mainly affects the lungs, where it clinically mimics WG. Characteristic histologic findings include prominent blood vessel infiltration (“angiocentric”) and destruction mimicking vasculitis (Fig. 52-6), but cellular morphology is more suggestive of

lymphoma or lymphoproliferative disorder (Langford, 1995). No specific clinical laboratory tests are recommended.

HENOCH-SCHÖNLEIN PURPURA

Epidemiology

Henoch-Schönlein purpura (HSP) occurs primarily in children between the ages of 4 and 11 years (Conn, 1993) but also afflicts some adults. HSP presents most commonly in the spring and classically follows an upper respiratory infection (Conn, 1993; Langford, 2003). HSP has a 3:2 male predominance (Langford, 1995).

Clinical Features

HSP, sometimes referred to as anaphylactoid purpura, is a systemic small vessel vasculitis classified as a subgroup of hypersensitivity vasculitis. The etiology of HSP is not known. Typical clinical findings in HSP include nonthrombocytopenic palpable purpura, arthralgias, renal disease, and GI tract abnormalities (Langford, 1995; Langford, 2003). Seventy percent of HSP patients manifest GI signs and symptoms that include colicky abdominal pain associated with nausea and vomiting, blood or mucus in the stool, life-threatening GI hemorrhage, and intussusception (Langford, 1995). Associated renal disease is characterized by focal proliferative glomerulonephritis that has variable clinical expression from isolated hematuria with red blood cell casts, to acute renal failure, to rare chronic renal failure (Lie, 1989; Langford, 1995; Fauci, 1998).

Clinical Laboratory Findings

Clinical laboratory studies in HSP are nonspecific and are primarily useful in excluding other disorders and seeking evidence of renal involvement. Leukocytosis and elevated ESR may be seen. Tests of CBC with platelet count and of coagulation are important in the evaluation of cutaneous purpura; in HSP, purpura is not the result of thrombocytopenia. Stool guaiacs should be performed intermittently to look for evidence of occult blood loss. Serum complement levels are usually normal, although an association between HSP and congenital absence of complement component C2 has been reported (Conn, 1993). Urinalysis and serum creatinine measurements should be performed at the onset of illness and twice weekly until systemic signs have ceased (Langford, 1995). Skin biopsy of the purpura reveals leukocytoclastic vasculitis with IgA deposition (Langford, 2003) (Fig. 52-7).

Diagnosis

Difficulty in diagnosing HSP is rare, except when the involvement of other major sites precedes the appearance of palpable purpura. Unlike other systemic necrotizing vasculitides, diagnosis is clinical, with laboratory studies used to rule out other disorders. Renal biopsy, which demonstrates proliferative glomerulonephritis, typically is not necessary for diagnosis, although it is used to assess disease severity and to estimate prognosis. Disorders to be considered in the differential diagnosis of HSP include any that cause acute abdomen, nephritis, or purpura (Langford, 1995).

Treatment and Prognosis

Treatment of HSP is supportive, and no specific treatment of proven benefit is available for HSP nephritis. Although glucocorticoids may be useful for decreasing edema, joint pain, and abdominal discomfort, sustained glucocorticoid therapy is not helpful because it does not decrease the risk of recurrent disease or improve renal prognosis (Langford, 1995). Nonsalicylate pain relievers for analgesia may soothe joint and soft tissue discomfort. Therapy for adults is similar to that for children, although hypertension in adults must be carefully controlled (Langford, 1995).

Prognosis for this generally self-limited disease, lasting from 6 to 16 weeks, is good (Conn, 1993). The mortality rate is about 1%–3% (Langford, 1995), and renal disease is the major cause of death (Langford, 1995). Those who have an acute nephritic presentation, particularly with nephrotic syndrome, have the worst outcome, with less than 50% returning to normal renal function and urinalyses in 2 years. The percentage of glomeruli with crescents may also be a useful prognostic indicator; however, it is important to realize that the course of HSP can be extremely variable. Patients who have severe clinical or histologic abnormalities may recover fully, and those with mild changes can progress to renal insufficiency. The disease recurs in 25%–40% of patients and largely consists of skin manifestations. Deterioration or improvement may be most notable during the first 2–3 years after resolution of the acute episode, although

Figure 52-6 Lymphomatoid granulomatosis. Lung biopsy reveals admixtures of large atypical lymphoid cells and histiocytes with prominent blood vessel infiltration (**angiocentric**) and destruction mimicking vasculitis. The atypical lymphoid cells are malignant B cells. (Hematoxylin and eosin [H&E], $\times 400$.) (Case courtesy Dr. Robert W. Sharpe.)

Figure 52-7 Henoch-Schönlein purpura. Skin biopsy reveals leukocytoclastic vasculitis with fibrinoid necrosis of small blood vessels in the superficial dermis associated with abundant perivascular nuclear leukocytoclastic debris (**A**, Hematoxylin and eosin [H&E], $\times 400$). Direct immunofluorescence of the skin biopsy reveals granular vascular immunoglobulin (Ig)A immunofluorescence (**B**, $\times 200$) and corresponding vascular and perivascular fibrinogen immunofluorescence (**C**, $\times 500$).

significant changes in outcome have been seen later than that. Regular follow-up with measurements of blood pressure and urinalysis is extremely important for at least the first 5 years following an episode of HSP (Langford, 1995, 2003).

GIANT CELL (TEMPORAL) ARTERITIS

Epidemiology

Giant cell (GC) arteritis is a relatively common vasculitic disorder. Epidemiologic studies have shown increased incidence with age; one study that included biopsy-proven GC arteritis demonstrated an annual incidence rate of 23.3 per 100,000 persons older than 50 years (Conn, 1993). Nearly all cases of GC arteritis begin after age 50; women are involved twice as often as men (Langford, 2003).

Clinical Features

GC arteritis is a systemic disease characterized by granulomatous vascular inflammation involving medium-sized to large arteries. Although arteries in multiple sites can be affected, GC arteritis classically involves the temporal artery and/or other branches of the carotid artery (Fauci, 1998). Clinical manifestations include fever, headache, diplopia, and jaw claudication in patients older than 50 years of age. Ischemic optic neuritis can lead to sudden blindness, particularly in untreated patients (Fauci, 1998). GC arteritis is closely associated with polymyalgia rheumatica, which is characterized by stiffness and pain in the neck, shoulders, lower back, hips, and thighs that is worse in the morning and better with activity of the day

(Fauci, 1998; Langford, 2003). Findings on physician examination can include temporal artery tenderness, nodularity, and absent pulsations (Langford, 2003).

Clinical Laboratory Findings

Characteristic laboratory findings include an elevated ESR and a normochromic anemia. Serum alkaline phosphatase is commonly elevated. Hypergammaglobulinemia and increased levels of complement and immune complexes have been reported (Fauci, 1998).

Diagnosis

Diagnosis is based on identifying typical clinical manifestations and a high ESR in an elderly patient who may or may not also have symptoms of polymyalgia rheumatica (Fauci, 1998). Diagnosis is confirmed by biopsy of the temporal artery showing pan-mural mononuclear cell infiltration, which can be granulomatous with giant cells and typically reveals disruption of the internal elastic lamina (Langford, 2003) (Fig. 52-8).

Treatment and Prognosis

GC arteritis is treated with glucocorticoids, and the clinical response to this therapy is usually dramatic. Prognosis is good, in that most patients achieve and maintain complete remission after glucocorticoid therapy (Fauci, 1998). Unfortunately, recovery of eyesight following blindness secondary to GC arteritis is rare, even with rapid and high-dose corticosteroid therapy (Hayreh, 2002). Treatment is begun with 60 mg of prednisone daily, with taper starting in 2–4 weeks and patients often requiring 2 years of corticosteroid therapy (Langford, 2003).

Figure 52-8 Giant cell (temporal) arteritis. Temporal artery biopsy reveals perivascular mononuclear cell infiltration with prominent giant cells associated with disruption of the internal elastic lamina (hematoxylin and eosin [H&E], $\times 200$).

TAKAYASU'S ARTERITIS

Epidemiology

Similar to many of the idiopathic vasculitides, Takayasu's arteritis is uncommon, and the epidemiology of the disease is not accurately known. This disorder is most prevalent in adolescent and young females between the ages of 10 and 30 years; in fact, 80%–90% of cases occur in females. Although more common in Japan, this disease has no proven racial or geographic restrictions (Conn, 1993; Fauci, 1998).

Clinical Features

Takayasu's arteritis is a granulomatous vasculitis of medium-sized to large elastic arteries that causes vascular stenosis or occlusion or aneurysm; there is a strong predilection for the aortic arch and its large branches, including pulmonary arteries (Langford, 1995; Fauci, 1998; Johnston, 2002; Langford, 2003; Seo 2004a). This disorder is sometimes called the aortic arch syndrome or pulseless disease. Patients present with acute systemic symptoms, including fever, malaise, night sweats, and weight loss. Ischemia in organs receiving their blood supply through the affected vessel(s) causes organ-specific symptoms and signs (Smetana, 2002). In the chronic obliterative phase, arterial pulses are decreased or absent in involved arteries (Langford, 1995), most commonly in the subclavian artery (Fauci, 1998). Vascular bruits and hypertension are common (Langford, 1995). Other findings include aortic regurgitation, cardiomegaly secondary to aortic or pulmonary hypertension, and stroke (Fauci, 1998). Takayasu's arteritis may progress slowly, may stabilize, or may rapidly cause death (Fauci, 1998).

Clinical Laboratory Findings

Laboratory studies of Takayasu's arteritis define a systemic inflammatory disorder (Langford, 1995). The ESR is elevated in 75%–100% of patients with active disease and tends to return to normal over time. ESR is thought to be a reliable index of inflammatory activity and has been used as a tool to monitor the effectiveness of therapy. Resolution of the disease, both symptomatically and angiographically, has been found to correlate with decline of the ESR, although one surgical series observed that 44% of patients thought to be quiet clinically were not upon arterial biopsy (Langford, 2003).

Hematologic studies often show mild to moderate normochromic anemia and/or mild leukocytosis. RF and ANA are usually negative. Hypergammaglobulinemia, hyperfibrinogenemia, and hypoalbuminemia may occur (Conn, 1993). Circulating immune complexes may be present in up to 50% of these patients but do not appear to correlate with disease activity.

Diagnosis

Takayasu's arteritis is diagnosed by correlating data from history, physical examination, and angiography. The disease should be considered as a

diagnostic possibility in any young female who lacks or has a markedly decreased peripheral pulse rate, or who has blood pressure discrepancies and/or arterial bruits (Fauci, 1998). Characteristic angiographic findings help confirm the clinical diagnosis. Biopsy for tissue confirmation of diagnosis is seldom required or done (Fauci, 1998; Langford, 2003). The predilection of this syndrome for young females is an important feature that often separates it from other diagnostic considerations, particularly GC arteritis (Langford, 1995).

Treatment and Prognosis

In patients with active disease, corticosteroid therapy is the initial treatment of choice. If active disease persists despite corticosteroids, cyclophosphamide or methotrexate may be administered. Vasodilators, anticoagulants, and nonsteroidal antiinflammatory agents are used for symptomatic relief. Surgical intervention may be necessary for symptomatic vascular stenosis or occlusion (Langford, 1995; Hoffman, 2003).

The clinical course of Takayasu's arteritis is variable. Although spontaneous remissions occur, most patients require treatment. Prognosis appears to be related to the presence and severity of complications. Major complications include Takayasu's retinopathy, secondary hypertension, aortic valve insufficiency, and aortic/arterial aneurysm (Langford, 1995). Overall survival declines from 72%–97% at 5 years to 59% at 10 years, as the number and/or severity of these complications increases (Langford, 1995; Nordborg, 2003). Disease-related deaths usually occur from vascular complications, such as congestive heart failure, stroke, myocardial infarction, and aneurysm rupture (Langford, 1995).

PRIMARY ANGIITIS OF THE CENTRAL NERVOUS SYSTEM

Epidemiology

Primary angiitis of the central nervous system (PACNS) is a rare condition in which difficulty in making a definitive diagnosis hinders epidemiologic studies. PACNS is slightly more common in males than in females (4:3) and begins at a mean age of 43 years (Langford, 1995).

Clinical Features

Patients with PACNS present with headaches, focal neurologic deficits, altered mental status, paraparesis, quadriparesis, cranial neuropathies, seizures, and ataxia (Calabrese, 1997; Fauci, 1998). Initial symptoms are more generalized, and focal symptoms and signs generally develop later in the course of the disease (Langford, 1995). Fifteen percent of cases have spinal cord involvement (Calabrese, 1997). The course may be rapidly progressive or may wax and wane over a long time. Systemic symptoms are rare.

Clinical Laboratory Findings

Laboratory studies are not useful in making a diagnosis of PACNS, but they do play an important role in excluding other disease processes. The ESR is elevated in most, but not all, of these patients. Anemia has been seen in only 17% of them, and other hematologic parameters are usually normal. RF, ANA, and ANCA are typically absent. However, the cerebrospinal fluid (CSF) is usually abnormal with findings that include increased opening pressure, elevated protein, and lymphocytic pleocytosis. Because the CSF can also be completely normal, such testing does not always rule out the possibility of vasculitis (Langford, 1995).

Diagnosis

The diagnosis of PACNS remains one of exclusion. Proposed diagnostic criteria have included CNS dysfunction that is not explained by clinical, laboratory, or neurologic investigation; documentation by angiogram and/or biopsy of an arteritis within the CNS; and no evidence of a systemic vasculitis or other condition to which the angiographic or pathologic features could be secondary.

Given the difficulty with certainty regarding the last criterion and the poor discriminatory power of angiography regarding inflammatory versus noninflammatory vascular disease (Calabrese, 1997), CNS biopsies are underutilized. The role of brain biopsy in the diagnosis of PACNS remains controversial, although some advocate that such biopsy is essential to make a definitive diagnosis (Calabrese, 1997). Precluding the widespread application of brain biopsy has been not only its invasive nature but also the inconsistency of demonstrating histologic vasculitis, given the patchy nature of the process. Biopsy yield may be increased by obtaining samples of both parenchyma and leptomeningeal vessels. Given the difficulty in

obtaining diagnostic certainty for this disease, biopsy is equally as important to rule out other possible etiologies. Histologically, segmental mixed inflammation with necrosis involves predominantly small and medium-sized cranial arteries. Granulomatous inflammation may be present. Thrombosis is often noted, and extracranial arteries are rarely involved (Langford, 1995; Rhodes, 1995). Therefore, differential diagnoses must be carefully considered in all cases and used in deciding appropriate tests to support a diagnosis of PACNS and to exclude other processes. The combination of normal magnetic resonance imaging and CSF has strong negative predictive value and excludes consideration of PACNS in most clinical situations (Calabrese, 1997).

Treatment and Prognosis

Aggressive treatment is indicated for patients in whom other disorders are ruled out, the diagnosis of PACNS is supported, and progressive neurologic difficulties are evident (Calabrese, 1997). Combination therapy using corticosteroids and daily cyclophosphamide is advocated; however, the prognosis of PACNS is poor, with 60%–70% of patients dying from their disease within 1 year of diagnosis (Langford, 1995).

KAWASAKI DISEASE

Kawasaki disease, or mucocutaneous lymph node syndrome, is a form of vasculitis involving small and medium-sized arteries (Fig. 52-9). This disease typically occurs in children who present with cervical lymphadenitis and alterations in skin and mucous membranes. Kawasaki disease is usually self-limited, but arteritis causes coronary aneurysms in 25% of patients. Death occurs in up to 3% of patients, usually from coronary vasculitis. Anti-endothelial cell autoantibodies have been demonstrated in patients with Kawasaki disease (Fauci, 1998).

SUMMARY

The diagnosis of idiopathic systemic necrotizing vasculitides requires a high degree of suspicion and can be difficult because of the large number of differential diagnostic considerations. No pathognomonic clinical laboratory tests are available for patients with systemic necrotizing vasculitides,

Figure 52-9 Kawasaki disease. Lymph node biopsy reveals necrotizing vasculitis with fibrin thrombi and mixed inflammation including neutrophils (hematoxylin and eosin [H&E], $\times 200$). (Case courtesy Dr. Robert W. Sharpe.)

but such tests are useful for defining the extent and patterns of organ involvement. ANCA and their associations with systemic necrotizing vasculitis, particularly the association of c-ANCA with WG, have become an important serologic test used in the evaluation of these patients. However, clinicians and laboratorians using this test must thoroughly understand the operating characteristics, including limitations, of the test as performed in their laboratory. Tissue biopsy of symptomatic site(s) with histologic confirmation of necrotizing vasculitis remains the most important laboratory procedure for diagnosis of systemic necrotizing vasculitides.

SUMMARY, 1020

SELECTED REFERENCES, 1020

KEY POINTS

- The dominant clinical feature of organ-specific autoimmune disease is chronic inflammation, generally localized in a single organ specific for each individual disease.
- The etiology of virtually all organ-specific autoimmune diseases remains elusive.
- Direct immunofluorescence is essential for resolving the microscopic differential diagnosis of acantholytic and subepidermal bullous disorders.

- The presence of circulating autoantibodies at significant titers is often useful in establishing the etiology of autoimmune liver disorders.
- Antimitochondrial antibodies (AMAs) are the most specific and sensitive diagnostic markers for primary biliary cirrhosis (PBC). As a general guideline, an AMA titer greater than or equal to 1:160 is highly predictive of PBC.
- The prevalence of gluten-sensitive enteropathy/celiac sprue in the U.S. population is considered much greater than previous estimates.

Continued

[†]Deceased

- In gluten-sensitive enteropathy/celiac sprue, immunoglobulin A antiendomysial autoantibodies detect tissue transglutaminase (tTG), the primary autoantigen in gluten-sensitive enteropathy (GSE). Enzyme-linked immunosorbent assays are now available for the detection of anti-tTG. Their identification is considered diagnostically sensitive and specific for GSE alone or GSE associated with dermatitis herpetiformis.
- For specificity reasons, the use of assays to detect deoxyribonuclease-sensitive perinuclear antineutrophil cytoplasmic antibodies and antibodies to *Saccharomyces cerevisiae* should be limited to patients with colitis and should not be applied to the general population.
- Technical advances in enzyme-linked immunosorbent assays have made this technology available in most clinical laboratories, so that many assays for organ-specific autoantibodies (e.g., thyroid, kidney, pancreatic islet cells, peripheral and central nervous system) are more widely available when indirect immunofluorescence microscopy is not feasible.

DEFINITION OF AUTOIMMUNITY VS. AUTOIMMUNE DISEASE

Normally, each individual can distinguish **self** from **nonself** and can respond to invading foreign molecules without producing adverse reactions against self or host antigens (Nakamura, 2002). However, there are many pathways and alterations of self-recognition control mechanisms that can initiate an autoimmune response. **Autoimmunity** has been broadly defined as the failure of an organism to recognize its own healthy tissue as self. This autoimmune response includes any immune response to the host's own tissue, whether humoral (e.g., circulating autoantibodies) or cellular (e.g., delayed hypersensitivity). Autoimmunity can also be defined by the presence of autoantibodies and/or T cells that react against self antigens. Autoimmunity thus can explain "normal" regulatory physiologic mechanisms such as aging, physiologic clearance of dead cells and their components, and response to microbial infections. However, autoimmunity can also induce immunologic injury to the host and is the primary cause of diseases such as autoimmune thyroiditis and systemic lupus erythematosus (SLE). The term **autoimmune disease** is usually assigned to those conditions in which an autoimmune mechanism or injury has contributed to the pathogenesis of the disease.

CLASSIFICATION OF AUTOIMMUNE DISEASES

Human autoimmune diseases can be classified in several ways. They can be divided into the following categories:

1. Organ-specific autoimmune diseases, which include thyroid, adrenals, stomach and pancreas, etc.
2. Non-organ specific or systemic autoimmune diseases, such as SLE and rheumatoid arthritis.

This chapter will discuss various organ-specific autoimmune diseases in which the immune response is primarily against antigens localized to particular organs. Examples of organ-specific autoimmune diseases include insulin-dependent diabetes mellitus (IDDM), Hashimoto's thyroiditis, pernicious anemia with chronic atrophic gastritis, primary adrenal gland atrophy (Addison's disease), pemphigoid skin disorders, Grave's disease, and so forth.

LABORATORY TESTS FOR EVALUATING AUTOIMMUNE DISEASES

The patient history and the results of common clinical laboratory tests will help the physician select additional tests. Test selection is critical in determining the positive predictive value of autoantibody tests.

A direct approach in the diagnosis and evaluation of autoimmune disease is tissue biopsy of the affected organ for histologic and immunohistochemical and immunofluorescent study examinations. This is most often used in autoimmune diseases that involve the kidney or skin. One can evaluate the tissue injury and determine the immunopathologic mechanism of injury, for example, by immunofluorescent localization of immunoglobulin and complement components in the basement membrane of the skin, glomerular basement membrane, or blood vessels.

TABLE 53-1

Methods for Autoantibody Detection

Methods	Use
Immunofluorescence	Sensitive assay for screening
Enzyme immunoassay	Sensitive assay for screening
Chemiluminescence	Sensitive assay for screening
Double immunodiffusion	Requires precipitin reaction, high specificity but low sensitivity
Counterimmunoelectrophoresis	Increased sensitivity and speed compared with immunodiffusion
Particle agglutination	More sensitive than immunodiffusion
Immunoblotting	Very sensitive, allows detection of antibodies to soluble and insoluble antigens

Antibody reactions may be (1) primary—the antigen and the antibody react by combining with each other (i.e., immunoenzymatic or immunofluorescence assays); (2) secondary—the antigen and the antibody initiate a secondary reaction, such as precipitation, agglutination, or complement fixation; and (3) tertiary—the antigen–antibody reaction initiates a biochemical reaction, such as IgE- and antigen-mediated histamine release from mast cells seen with skin lesions.

Primary, secondary, and tertiary antibody reactions vary in their relative sensitivities. The agar gel diffusion test may be considered a precipitin test with a sensitivity of 1. The electroimmunodiffusion (ED) method may increase the sensitivity 10 times, and an enzyme immunoassay or radioimmunoassay (RIA) may increase the sensitivity 10,000 times compared with the immunodiffusion assay. With the new, rapid, ultrasensitive nonisotopic immunoassays, analytes can be detected in pico(10^{-12})mole and subatto(10^{-18})mole concentrations.

The words zepto(10^{-21})mole and yocto(10^{-24})mole have been introduced into the vocabulary of clinical laboratorians for describing small numbers of molecules. Beginning with a mole consisting of roughly 6.022×10^{23} molecules, a zeptomole would correspond to about 600 molecules, and a yoctomole to only 0.6 or roughly 1 molecule.

The most commonly ordered clinical laboratory tests for autoimmune diseases involve detection of circulating antibodies. Immunofluorescent, enzyme-labeled, chemiluminescence antibody tests and RIA methods use primary antigen–antibody binding reactions. These primary direct antibody–antigen binding tests have high sensitivity and are preferred for use in the detection of circulating and tissue-bound antibodies and antigens (Table 53-1).

Tests that involve secondary antigen–antibody preparations such as complement fixation, agglutination, and precipitation in agar gel are not as sensitive as immunofluorescent enzyme tests, RIA, or chemiluminescence tests, but such secondary tests have higher specificity and may be more suitable for the identification of certain autoantibodies.

Cell-mediated studies may be useful laboratory tests in special circumstances. In summary, each clinical laboratory should also state on the report the immunologic method used as a screening tool to rule out the presence of a specific autoantibody.

INTERPRETATION OF SERUM AUTOANTIBODY LEVELS IN AUTOIMMUNE DISEASES

Test results must be interpreted in the context of the patient's medical history and clinical disease state and with a clear understanding of the technical limitations of the test systems employed.

In general, the level of autoantibody is high in patients with autoimmune disorders and low in apparently healthy patients. A very high titer of autoantibody is significant, although a low or absent titer of autoantibody does not rule out the possibility of an autoimmune disorder. For example, at the height of severe thyroiditis, the gland may act as an immunoabsorbent and may remove circulating antibody. In addition, thyroglobulin may be released into the circulation during the acute stage and may neutralize circulating autoantibody. Therefore, the level or titer of a given antibody must be interpreted in relation to the stage or treatment of a particular disease. In contrast, serum antibody levels in

pemphigus correlate with the severity and course of the disease. Also, in idiopathic inflammatory bowel disease, the higher titers of antibodies to common microbial antigens correlate with the severity of the disease, such as Crohn's disease (Dubinsky, 2008).

The incidence of certain autoantibodies increases with age. In patients older than 60 years, 50% demonstrated low titers of one or more autoantibodies. Antinuclear, anti-parietal cell, and antithyroid antibodies are age or sex dependent, with an increasing incidence in women and older people (Hooper, 1972; Whittingham, 1972; Hawkins, 1979). On the other hand, the incidence of smooth muscle antibody and rheumatoid factor does not correlate with age or sex and was similar in men and women. A study in Australia tested a normal population for the presence of 13 autoantibodies. Of 1830 individuals tested, 22% displayed one or more autoantibodies. Several of these antibodies appeared to be persistent, lasting 6 years or longer. The parietal cell antibody persisted in 75.3% of individuals. Antinuclear, thyroid microsomal, and smooth muscle antibodies also were persistent.

RECENT ADVANCES IN DIAGNOSTIC TECHNOLOGIES FOR THE EVALUATION OF AUTOIMMUNE DISEASES

Within the last several years, advances in proteomic, microarray technology have allowed the simultaneous measurement of a number of autoantibodies within the same biological sample, called **multiplexing**. These multiplexing technologies, which use different addressable microbeads or non-bar-coded particles, have opened up new horizons in the diagnosis of autoimmune diseases. The new methods of multiplexing with arrays will allow testing of individual autoantibody profiles. The various autoantibody profiles will (1) improve understanding of the pathophysiology of specific diseases; (2) allow early diagnosis and prognostic information with predictive values of autoantibodies; and (3) allow more efficient implementation of specific therapies for treatment and prevention of autoimmune diseases (Tozzoli, 2008).

Several proteomic platforms have emerged that are capable of analyzing a large panel of known analytes (Balboni, 2006). At present, the main analytes that can be systematically studied in autoimmunity and autoimmune diseases include autoantibodies, cytokines, chemokines, components of signaling pathways, and cell surface receptors.

Much progress has been made on the multiplex antinuclear antibody (ANA) test profiles. Strong concordance has been noted between the multiplex ANA and conventional methods of assay for ANA (Xu, 2007).

One problem is that multiplex assays with limited numbers of autoantigens can miss some clinically important autoantibodies, which has led to a loss of confidence in them as screening tests for ANA by many physicians. This deficiency was addressed by the American College of Rheumatology (2009) with the position statement Methodology of Testing for Antinuclear Antibodies in which they recommend:

- IFA should remain the gold standard for ANA testing.
- Laboratories using bead-based multiplex or other solid phase assays for ANAs must provide data on that assay compared with IFA.
- In-house assays for ANA and other autoantibodies should be standardized according to national/international standards.
- When reporting results of ANA testing, the method of detection should be specified.

Simultaneously, considerable advances have been made in **biomedical informatics**, which will help in analysis of various multiarrays and autoantibody profiles (Baboni, 2006).

AUTOANTIBODIES AS PREDICTORS OF DISEASES

Several studies in the past have shown that autoimmune diseases are preceded by a long preclinical phase, and that many autoantibodies can be detected in the serum of asymptomatic patients years before the clinical manifestation becomes evident. Examples are IDDM and autoimmune thyroiditis. Therefore, tests for specific autoantibodies could be used for screening of high-risk populations to identify individuals predisposed to the development of diseases at an early stage. Identification may allow implementation of early treatment and preventive measures (Bizzaro, 2007; Rose, 2007).

Autoimmune diseases have a gender bias and represent the fifth leading cause of death by disease among females of reproductive age (Zandman-Goddard, 2007). Clinical studies indicate that the gender bias in autoimmunity may be influenced by sex hormones, as found in SLE.

Autoimmune disorders can be categorized broadly into systemic and organ-directed diseases (Nakamura, 2002). In this chapter, we discuss most of the organ-directed autoimmune diseases listed in Table 53-2.

The dominant clinical feature of these autoimmune disorders is chronic inflammation, generally localized in a single organ specific for each individual disease. Within this group of autoimmune disorders, familial clustering of diseases occurs with remarkable frequency. The relevant autoantibodies may or may not be species-specific, but they do exhibit specificity for an antigen present in the diseased organ or tissue.

Included in this chapter are some diseases with autoantibodies and inflammatory lesions restricted to one or a few organ(s) that combine clinicopathologic features of both organ-specific and systemic autoimmune diseases. Autoimmune liver disorders, such as PBC or autoimmune hepatitis, are examples of diseases in this group. Except for autoantibodies to thyroid receptors, the pathogenesis of autoantibodies in organ-specific diseases remains largely unproven.

DETECTION METHODS

Direct immunofluorescence microscopy (DIFM) is the laboratory method used to detect immune deposits in a patient's tissue. Indirect immunofluorescence microscopy (IIFM), briefly described in the following section, is the method most commonly used to detect circulating autoantibodies to specific target organs or tissues. Clinical laboratories are using enzyme-linked immunosorbent assays (ELISAs) more frequently because technical aspects of this method have improved.

Indirect Immunofluorescence Microscopy

This test procedure for IIFM is essentially the same as DIFM, except for the substrate used to bind target autoantibodies. The general procedure follows:

1. Prepare screening dilution of patient sera, or serial dilutions, and appropriate controls in phosphate-buffered saline (PBS).
2. Use a moisture chamber to incubate for 20–30 minutes diluted sera and controls layered over cryostat tissue sections of the substrate on multiwell glass slides. Do not allow the slides to dry.
3. Remove slides from the moisture chamber. Briefly but carefully wash each entire slide two to three times using PBS at room temperature. Then wash slides in PBS for 15 minutes, changing the wash once during this period.
4. Remove one slide at a time from the PBS wash, blot each slide dry, and place each in a moisture chamber. Dispense diluted fluorescein-labeled conjugate over each well. Incubate slides at room temperature for 20 minutes. Do not allow slides to dry.
5. Wash slides for 10 minutes in PBS that contains Evan's blue counterstain.
6. Mount coverslips.
7. View slides under a fluorescence microscope.
8. Store slides in the dark at 4° C.

SKIN

Detection of autoantibodies is highly useful in the workup for cutaneous bullous disease. In patients with autoimmune skin diseases, autoantibodies include those to basement membrane zone (BMZ), epidermal intercellular spaces (ICSs), or dermal blood vessels, as summarized in Table 53-3. Several excellent technical reviews detail the use of immunofluorescence for examination of skin (Crosby, 1993; Flotte, 1995).

PEMPHIGUS

Pemphigus refers to a group of disorders that are characterized clinically by blisters and histologically by acantholysis. Three major subtypes of pemphigus are known: Pemphigus vulgaris, pemphigus foliaceus, and paraneoplastic pemphigus (Beutner, 1973; Ding, 1999; Nousari, 1999a). Each of these subtypes is characterized by autoantibodies to desmosomal adhesion molecules. Both IIFM to detect circulating autoantibodies and the more informative DIFM to identify tissue-bound autoantibodies are used for initial evaluations to maximize diagnostic sensitivity.

Antidesmoglein reactivity was detected in all patients with pemphigus and in none of the controls. Patients with a more benign form of

TABLE 53-2

Organ-Specific Autoimmune Diseases

Organ disease	Autoantibody	Detection method(s)
Thyroid Gland		
Autoimmune thyroiditis	Thyroid peroxidase Thyroglobulin	ELISA; IIFM using unfixed monkey thyroid IIFM using methanol-fixed monkey thyroid; passive hemagglutination; latex agglutination
Graves' disease	TSH receptor	Radioreceptor binding assay; cAMP bioassay
Adrenal Gland		
Addison's disease	Adrenocortical	IIFM on unfixed monkey or human adrenal cortex
Parathyroid Gland		
Hypoparathyroidism	Parathyroid endothelial proteins	IIFM on unfixed bovine parathyroid gland
Pancreas		
Type 1A diabetes mellitus	Islet cells Insulin-associated Antiglutamic acid decarboxylase	IIFM on unfixed human pancreas, blood group O Radioimmunoprecipitation ELISA, RIA, immunoblotting
Muscle		
Dermatomyositis/polymyositis	PM-1, Jo-1	ELISA, immunodiffusion
Gastrointestinal Tract		
Atrophic gastritis	Gastric parietal cell	IIFM—mouse stomach/kidney
Pernicious anemia	Intrinsic factor Salivary duct cells Gastric parietal cell	Radioactive vitamin B ₁₂ binding assay IIFM—unfixed human salivary gland IIFM—human, monkey, mouse, or rat gastric mucosa substrate
Ulcerative colitis	Colon; lipopolysaccharide DNase sensitive, p-ANCA associated	IIFM—human or rat colon; hemagglutination IIFM—ethanol-fixed neutrophils
Crohn's disease	ASCA IgA, ASCA IgG, OmpC, CB1r1	ELISA
Celiac disease	Tissue transglutaminase IgA endomysial Deaminated gliadin peptides	ELISA IIFM—monkey esophagus ELISA
Liver		
Autoimmune hepatitis	Smooth muscle Liver-kidney microsomal ANA	IIFM—mouse stomach/kidney IIFM—mouse stomach/kidney; ELISA HEp-2 cells
Primary biliary cirrhosis	Mitochondrial (M2)	IIFM—mouse stomach/kidney; ELISA
Primary sclerosing cholangitis	p-ANCA	IIFM—ethanol-fixed neutrophils
Neurologic		
Myasthenia gravis	AChR	Immunoprecipitation of iodine-125 α -bungarotoxin-conjugated AChR (human skeletal muscle); ELISA
Demyelinating diseases (e.g., multiple sclerosis)	Myelin; tubulin; myelin basic protein; myelin-associated glycoprotein	IIFM—mammalian spinal cord; ELISA; immunoblotting
Kidneys		
Anti-GBM disease	Glomerular and lung basement membrane	ELISA
Skin		
Pemphigus vulgaris	Intracellular space (ICS) Desmogleins Dsg 1, Dsg 3, BP 180	DIFM on skin biopsy IIFM on monkey or guinea pig esophagus ELISA
Pemphigus foliaceus	Dsg 1	
Paraneoplastic pemphigus	ICS and BMZ envoplakin, periplakin	DIFM on skin biopsy Immunoblotting
IgA pemphigus	IgA ICS	DIFM on human skin biopsy; IIFM on monkey esophagus
Bullous pemphigoid	BMZ (hemidesmosomal) proteins	
Mucous membrane pemphigoid		DIFM on skin biopsy IIFM on monkey esophagus DIFM—oral or ocular mucosa
Dermatitis herpetiformis	Tissue transglutaminase Antigliadin Anti-deaminated gliadin peptide IgA endomysial	ELISA IIFM on monkey esophagus
Linear IgA dermatosis	IgA BMZ	DIFM on human skin biopsy; IIFM on monkey esophagus

AChR, Acetylcholine receptor; *ANA*, antinuclear antibody; *ASCA*, antibodies to *Saccharomyces cerevisiae*; *BMZ*, basement membrane zone; *cAMP*, cyclic adenosine monophosphate; *DIFM*, direct immunofluorescence microscopy; *DNase*, deoxyribonuclease; *ELISA*, enzyme-linked immunosorbent assay; *GBM*, glomerular basement membrane; *Ig*, immunoglobulin; *IIFM*, indirect immunofluorescence microscopy; *p-ANCA*, perinuclear antineutrophil cytoplasmic antibody; *RIA*, radioimmunoassay; *TSH*, thyroid-stimulating hormone.

TABLE 53-3

Autoimmune Skin Diseases

Immunologic Findings Essential for Diagnosis**Epidermal Interstitial Spaces**

Pemphigus

Paraneoplastic pemphigus

Basement Membrane Zone

Dermatitis herpetiformis

Immunologic Findings Useful for Diagnosis**Cutaneous Manifestations in Systemic Rheumatic Diseases**

Dermatomyositis/polymyositis

Lupus erythematosus

Mixed connective tissue disease

Relapsing polychondritis

Sjögren's syndrome

Systemic sclerosis

Vasculitis

Figure 53-1 Direct immunofluorescence microscopy of skin lesions in pemphigus shows linear/granular C3 deposition on the cell surfaces (intercellular spaces) of mainly basal keratinocytes without basement membrane zone immunofluorescence (x400).

pemphigus had anti-Dsγ 1 antibodies, while patients with more severe deeper cutaneous lesions or mucosal involvement had both Dsγ 1 and Dsγ 3 reactivity, or Dsγ 3 exclusively.

The BP 180–based assay was positive for 66.6% of patients with bullous pemphigoid and for none of those with mucous membrane pemphigoid (D'Agosto, 2004).

Pemphigus Vulgaris

Pemphigus vulgaris is a rare disorder that occurs in all racial and ethnic groups, although the incidence is slightly increased in the Jewish population. The disease affects both sexes and most commonly occurs in individuals between 40 and 60 years old (Becker, 1993). Desmoglein 3 is the major antigen in pemphigus vulgaris (Naparstek, 1993; Lin, 1998). ELISAs to detect anti-desmoglein-3 are available.

Direct Immunofluorescence Microscopy

DIFM of perilesional skin shows linear/granular IgG and C3 ICS immunofluorescence without BMZ staining (Fig. 53-1). This pattern is often described as “chicken wire” and preferentially stains the lower one half of the epidermis. IgG, especially IgG4, is present in nearly 100% of patients, whereas C3 is present in 50%–100% of patients, usually in acantholytic areas (Becker, 1993; Flotte, 1995; Lin, 1998). In 30%–50% of patients, IgA or IgM immunoreactants are seen (Izuno, 1986). C3 immunofluorescence only, without IgG, is described in drug-induced pemphigus and in impetigo (Nousari, 1997).

Indirect Immunofluorescence Microscopy

IIFM should detect circulating IgG autoantibodies to the surfaces of squamous epithelial cells in 100% of patients with active disease (Nousari, 1997). Monkey esophagus is considered the best tissue substrate (Fig. 53-2).

The presence of pemphigus vulgaris autoantibodies is abnormal at any titer. The titer generally correlates with disease activity, and increasing titers may be predictive of relapse (Becker, 1993; Crosby, 1993). Exceptions to this correlation do occur, however, so serial testing of IgG titers to monitor these patients must be carefully correlated with clinical findings. Patients who have only oral mucosal lesions may not have detectable circulating pemphigus vulgaris autoantibodies. In these patients, diagnosis is made using DIFM (Izuno, 1986).

Low titers of ICS-like autoantibodies may be infrequently detected in diverse conditions such as skin burns, penicillin or other drug allergy, toxic epidermal necrolysis, SLE, myasthenia gravis, pemphigoid, and lichen planus. Rarely, they are seen in healthy individuals (<1%) (Becker, 1993; Mutasim, 1993b; Nousari, 1997).

Figure 53-2 Indirect immunofluorescence microscopy in pemphigus shows linear immunoglobulin (Ig)G immunofluorescence on the cell surfaces of epithelial cells (intercellular spaces) using mouse esophagus as tissue substrate (x250).

Pemphigus Foliaceus

Subsets of pemphigus foliaceus include idiopathic pemphigus foliaceus, endemic pemphigus foliaceus (fogo selvagem), drug-induced pemphigus foliaceus, and pemphigus erythematosus. Desmoglein 1 is the major antigen in pemphigus foliaceus (Naparstek, 1993; Lin, 1998). ELISAs to detect anti-desmoglein-1 are available.

Direct Immunofluorescence Microscopy

For all forms of pemphigus foliaceus except pemphigus erythematosus, the DIFM pattern is similar to pemphigus vulgaris. In some cases, staining predominates in the superficial epidermis at the level of the stratum granulosum. In pemphigus erythematosus, linear IgG staining of epidermal ICS is combined with granular immunoreactants along the BMZ.

Indirect Immunofluorescence Microscopy

IIFM should detect circulating IgG ICS autoantibodies in virtually 100% of pemphigus foliaceus patients with active disease (Nousari, 1997). About 90% of these pemphigus foliaceus patients have detectable autoantibodies when monkey esophagus is used for indirect studies. Guinea pig esophagus

is somewhat more sensitive in that it detects the remaining 10% of patients and the indirect titers tend to run higher than those obtained when monkey esophagus is used (Jiao, 1997).

Paraneoplastic Pemphigus

Paraneoplastic pemphigus, an uncommon disorder characterized by painful blisters or erosions of mucous membranes and skin, is a condition of patients with neoplasms. These blisters or erosions usually erupt in the mouth, but other mucosal sites have been reported. Malignant neoplasms that have been associated with paraneoplastic pemphigus include malignant lymphoma, chronic lymphocytic leukemia, thymoma, bronchogenic squamous cell carcinoma, and sarcoma. Rarely, paraneoplastic pemphigus is associated with benign neoplasms (Camisa, 1993; Mutasim, 1993c; Flotte, 1995; Kiyokawa, 1999).

The following criteria to define paraneoplastic pemphigus have been proposed by Mutasim (1993c), Flotte (1995), and Kiyokawa (1999).

- Painful mucosal erosions and a polymorphous skin eruption, with papular lesions progressing to blisters and erosive lesions affecting trunk, extremities, and palms and soles, associated with an occult or clinically known neoplasm.
- Suprabasilar acantholysis, keratinocyte necrosis, and vacuolar interface changes on light microscopic tissue sections
- IgG ICS combined with linear/granular complement and IgG along the BMZ
- Circulating ICS autoantibodies that bind to rodent bladder urothelium and monkey/guinea pig esophagus
- Immunoprecipitation of a complex of four keratinocytic proteins bound by the autoantibodies; this is mainly a research tool but may provide helpful clinical information in difficult cases

Paraneoplastic pemphigus associated with malignant neoplasms signals an extremely poor prognosis. Although clinical improvement or remission of mucocutaneous lesions after tumor resection has been reported, treatment for malignancy-associated paraneoplastic pemphigus is supportive. Paraneoplastic pemphigus associated with a benign neoplasm remitted after tumor resection (Mutasim, 1993c).

Direct Immunofluorescence Microscopy

DIFM of perilesional skin and/or mucosa from patients with paraneoplastic pemphigus detects IgG ICS immunoreactant with or without complement components. Granular or, less commonly, linear BMZ deposits of complement components (C3, C1q) are present, in addition to IgG ICS immunofluorescence (Mutasim, 1993c).

Indirect Immunofluorescence Microscopy

IIFM using monkey esophagus and rodent bladder urothelium demonstrates IgG immunoreactant both in ICS and along the BMZ. Binding to rodent (rat or mouse) bladder epithelium is an important differential finding that distinguishes paraneoplastic pemphigus from other types of pemphigus (Liu, 1993; Mutasim, 1993c).

IgA Pemphigus (Intercellular IgA Dermatitis)

Direct Immunofluorescence Microscopy

Intercellular IgA dermatitis is a rare intraepidermal vesiculobullous disorder. Direct studies show linear ICS immunofluorescence for IgA that is suprabasilar and particularly accentuated in the upper epidermis.

Indirect Immunofluorescence Microscopy

IIFM detects circulating IgA anti-ICS autoantibodies (Teraki, 1991; Flotte, 1995).

PEMPHIGOID

Bullous Pemphigoid

Bullous pemphigoid is a subepidermal bullous disease of unknown cause that can occur in patients of any age but mainly affects adults older than 60 years (Fig. 53-3, A). This disorder typically involves flexor surfaces of the arms, legs, groin, axilla, and lower abdomen. The oral mucous membranes may be affected, but such lesions are rarely the presenting or predominant sign—a point that differentiates pemphigoid from pemphigus vulgaris.

The major antigens in bullous pemphigoid are two keratinocytic hemidesmosomal proteins, an intracellular 230-kDa protein (bullous pemphigoid antigen 1), and a transmembrane 180-kDa protein (bullous pemphigoid antigen 2) (Nousari, 1997; Lin, 1998).

Figure 53-3 Skin biopsy of pemphigoid reveals a subepidermal split, nonnecrotic epidermis and variable inflammation, often with prominent eosinophils (A, Hematoxylin and eosin [H&E], $\times 100$). Direct immunofluorescence microscopy reveals intense linear C3 deposition along the basement membrane zone (B, $\times 400$).

Direct Immunofluorescence Microscopy

DIFM of unblistered, perilesional skin from the edge of a fresh blister is diagnostically sensitive and typically demonstrates linear BMZ immunofluorescence in nearly 100% of patients (Fig. 53-3, B). C3 and IgG or C3 alone is the predominant immunoreactant. Also, IgA and/or IgM may be present in up to 25% of patients, usually in weaker intensity and in combination with IgG (Izuno, 1986; Crosby, 1993; Korman, 1993).

A linear epidermal BMZ pattern can be identified in several disparate clinical disorders, including benign mucous membrane pemphigoid, epidermolysis bullosa acquisita, gestational pemphigoid (herpes gestationis), and bullous lupus erythematosus.

To help separate these disorders, salt-split direct skin biopsies are useful (Domloge-Hultsch, 1991). In bullous pemphigoid and gestational pemphigoid, linear IgG is localized to the epidermal side, or roof, of the split. Linear C3 immunofluorescence, however, may be seen along epidermal and dermal locations. In epidermolysis bullosa acquisita and bullous lupus erythematosus, immunoreactants are seen along the dermal side of the split (Nousari, 1997). Clinical correlation then becomes important in resolving diagnostic alternatives.

Indirect Immunofluorescence Microscopy

Bullous pemphigoid is serologically characterized by the presence of circulating autoantibodies to the BMZ, in the skin or the oral mucosa. IIFM detects circulating IgG anti-BMZ autoantibodies in about 50% of patients with pemphigoid, but sensitivity increases to 70%–80% if normal human salt-split skin is used as substrate (Izuno, 1986; Domloge-Hultsch, 1991; Nousari, 1997). In bullous pemphigoid, autoantibodies bind only to the roof of salt-split skin in 80% of patients. In epidermolysis bullosa acquisita and bullous lupus erythematosus, autoantibodies bind to the dermal base, or floor, of the split in 50% of patients (Domloge-Hultsch, 1991; Crosby, 1993; Korman, 1993).

Benign Mucous Membrane Pemphigoid

Benign mucous membrane pemphigoid, or cicatricial pemphigoid, consistently affects oral and ocular mucosa. Other mucosal sites of these lesions can be the nasopharynx, larynx, genitalia, rectum, and esophagus (Mutasim, 1993a). Scarring follows the healing of lesions, and blindness is the most feared complication.

Direct Immunofluorescence Microscopy

The DIFM pattern is similar to that seen in bullous pemphigoid. Sensitivity is 90% but increases if additional biopsies are taken. Chronic localized scarring pemphigoid, also known as cicatricial pemphigoid of Brunsting-Perry, is a variant of benign mucous membrane pemphigoid that is localized to the head and neck region (Sarret, 1991). In this variant, DIFM demonstrates IgG only along the BMZ without IgA or IgM; circulating anti-BMZ autoantibodies are also rare (Izuno, 1986).

Indirect Immunofluorescence Microscopy

IIFM detects circulating IgG autoantibodies in less than 33% of benign mucous membrane pemphigoid patients when oral mucosal substrate is used, but in only 5%–15% of patients using standard substrates (Sarret, 1991; Crosby, 1993; Nousari, 1997). Salt-split human skin studies may reveal deposits of IgA, IgG, or both in about 80% of these patients (Sarret, 1991).

No correlation has been noted between the presence and titer of autoantibodies and disease activity.

Gestational Pemphigoid

Infrequently, the subepidermal bullous disease gestational pemphigoid (herpes gestationis) develops during or soon after pregnancy (Izuno, 1986). Lesions typically are pruritic and are located predominantly on the abdomen and/or extremities.

Direct Immunofluorescence Microscopy

With DIFM, one typically finds linear C3 BMZ deposits. Associated IgG deposits are detected in 30%–40% of cases, but IgA and IgM are rare (Izuno, 1986).

Indirect Immunofluorescence Microscopy

Linear C3 deposits only may be visualized along the BMZ, but often autoantibody titers are too low to be seen using standard IIFM substrates. Complement may be detected, however, if complement immunofixation using normal human salt-split skin is used as substrate (Izuno, 1986; Nousari, 1997).

EPIDERMOLYSIS BULLOSA ACQUISITA AND BULLOUS LUPUS ERYTHEMATOSUS

Epidermolysis bullosa acquisita and bullous lupus erythematosus are acquired subepidermal blistering diseases characterized by the presence of autoantibodies to type VII collagen in BMZ protein (Gammon, 1993). Epidermolysis bullosa acquisita can occur at any age but most commonly presents in adults who are 40–50 years old. Neither an ethnic nor a sex predilection has been noted. All such patients are afflicted with a combination of blisters, erosions, scars, milia, and dyspigmentation of skin, most often located on trauma-susceptible extensor skin surfaces such as knees, elbows, and dorsa of hands and feet (Gammon, 1993). Bullous lupus erythematosus occurs in patients with lupus erythematosus.

Direct Immunofluorescence Microscopy

When DIFM is used, patients with epidermolysis bullosa acquisita and bullous lupus erythematosus have linear BMZ immunoreactants that most commonly consist of IgG and C3. When direct salt-split skin biopsy tissue is used, linear immunoreactants are localized at the dermal, or floor, aspect of the induced blister.

Indirect Immunofluorescence Microscopy

Only about 40% of epidermolysis bullosa acquisita patients have demonstrable autoantibodies when human skin without salt treatment is used as substrate. When indirect salt-split skin technique is used, circulating autoantibodies can be identified in about 50%–85% of patients (Fine, 1994; Nousari, 1997).

Figure 53-4 Skin biopsy of dermatitis herpetiformis reveals a subepidermal split, nonnecrotic epidermis and neutrophilic microabscesses in the tips of dermal papillae (**A**, Hematoxylin and eosin [H&E], $\times 200$). Direct immunofluorescence microscopy reveals granular immunoglobulin (IgA) immunofluorescence in the tips of dermal papillae and, to a lesser extent, along the basement membrane region (**B**, $\times 400$).

DERMATITIS HERPETIFORMIS

Dermatitis herpetiformis is a severely pruritic subepidermal bullous disease associated with gluten-sensitive enteropathy (Fig. 53-4, **A**). Dermatitis herpetiformis is also associated with human leukocyte antigen (HLA)-B8, DR3 histocompatibility types (Crosby, 1993).

Direct Immunofluorescence Microscopy

The direct biopsy should focus on perilesional skin because a lesional skin biopsy may be negative. DIFM detects granular IgA in the tips of dermal papillae in approximately 80%–100% of dermatitis herpetiformis patients (Flotte, 1995) (Fig. 53-4, **B**). Concomitant IgA deposits may be seen along the BMZ. C3 deposits are often found with IgA, but IgG and/or IgM are detected infrequently (Izuno, 1986).

Indirect Immunofluorescence Microscopy

Patients with dermatitis herpetiformis do not have detectable anti-BMZ autoantibodies. However, antiendomysial IgA autoantibodies are detected in 80% of dermatitis herpetiformis patients. These autoantibodies are identified by their characteristic immunofluorescence pattern in the sub-epithelial muscularis mucosa of monkey esophagus (Peters, 1989).

LINEAR IgA DERMATOSIS

Linear IgA dermatosis is an uncommon acquired subepidermal blistering disorder that is now considered a distinct clinical entity, rather than a variant of dermatitis herpetiformis, as was once thought (Izuno, 1986; Crosby, 1993). Many cases are thought to be idiopathic but drug-induced, and systemic disorder-related forms are described (Kuehle, 1994; Nousari, 1995, 1999; Bouldin, 2000). Chronic bullous dermatosis of childhood is similar to linear IgA dermatosis, both clinically and immunopathologically (Elenitsas, 1995).

Figure 53-5 Skin biopsy of lupus erythematosus reveals epidermal atrophy, vacuolar alteration of basal keratinocytes, marked thickening of the basement membrane zone, perivascular and interstitial mainly lymphocytic inflammation, and melanin incontinence (**A**, Hematoxylin and eosin [H&E], $\times 500$). Direct immunofluorescence microscopy reveals continuous granular C3 (**B**, $\times 500$) and C1q (**C**, $\times 200$) immunofluorescence along the basement membrane zone.

Direct Immunofluorescence Microscopy

In nearly 100% of cases, DIFM demonstrates intense linear IgA deposits along the BMZ but none in dermal papillae (Izuno, 1986). Although occasional cases may show concomitant weak C3 BMZ staining, immunoreactants other than IgA are not usually present.

Indirect Immunofluorescence Microscopy

Circulating IgA anti-BMZ autoantibodies can be detected with IIFM in about 10%–30% of cases (Crosby, 1993; Flotte, 1995).

LUPUS ERYTHEMATOSUS

Lupus erythematosus (Fig. 53-5, **A**) is a disorder characterized serologically by the presence of multiple autoantibodies, including antinuclear antibodies, anti-native DNA, antihistones, and anti-Sm.

Direct Immunofluorescence Microscopy

With DIFM, one sees characteristic coarse, granular, continuous deposits of immunoglobulins and complement along the epidermal BMZ in 50%–95% of SLE patients (Izuno, 1986). BMZ deposits of the complement membrane attack complex C5b–9 in lesional skin may be a marker for SLE (Helm, 1993).

Whereas these patients commonly have deposits of IgG, IgM, and complement component (C3 and/or C1q) (Fig. 53-5, **B** and **C**), immunoglobulins of all classes may be identified (Izuno, 1986). When nonlesional skin concurrently contains immunoglobulins IgG, IgA, and/or IgM in the typical pattern, the diagnosis is more likely than not SLE (Izuno, 1986).

Although characteristic, this reaction pattern can be seen in other disorders, such as mixed connective tissue disease, dermatomyositis, graft-versus-host reaction, drug eruptions, and vasculitis (Izuno, 1986). Therefore, it is mandatory to correlate direct results with both the clinical presentation and the results of light microscopic study of a skin biopsy. This information is then interpreted in the context of an individual's direct findings to categorize the clinical type of lupus erythematosus. Many publications cite the utility of DIFM for the purpose of diagnosing SLE from biopsied skin, with or without lesions, and from sun-exposed or sun-protected sites. In patients diagnosed with SLE, normal sun-exposed skin proves positive about 70% of the time, whereas normal sun-protected skin is positive in about 40% of patients (Izuno, 1986). However, the potential for predicting disease activity or renal involvement in this way remains controversial (Izuno, 1986). Perhaps the most practical clinical application of laboratory testing comes in the differential diagnosis of SLE from discoid lupus erythematosus. Up to 95% of individuals with discoid lupus erythematosus have coarse, granular, continuous BMZ deposits similar to those of SLE (Izuno, 1986). However, positive DIFM findings in discoid lupus erythematosus are confined to lesional skin, whereas skin with or without lesions can give positive DIFM findings in SLE (Izuno, 1986).

Subacute cutaneous lupus erythematosus is characterized clinically by arthritis, mild systemic manifestations, and anti-SS-A/Ro autoantibodies. DIFM of skin biopsies from these patients detects BMZ immunoglobulin and/or complement deposits in only 50% of lesional skin biopsies and 30% of uninvolved skin biopsies (Izuno, 1986). IIFM is positive in 50%–70% of patients with subacute cutaneous lupus erythematosus.

Other major systemic autoimmune diseases do not offer diagnostically specific findings by DIFM or IIFM. Although some patients have granular IgM deposits along the BMZ, this immunopathologic finding is considered to be a completely nonspecific marker that may be detected not only in autoimmune disease but also in a large number of inflammatory dermatitides, or in sun-exposed skin of clinically normal individuals (Izuno, 1986).

VASCULITIS

Vasculitis (see Chapter 52) in the skin has a number of synonyms, including leukocytoclastic vasculitis, allergic vasculitis, and hypersensitivity angiitis/vasculitis. Histologically, small blood vessels of the dermis show endothelial cell swelling, neutrophilic exocytosis, nuclear debris (**leukocytoclasia**), and necrosis in conjunction with extravasated red blood cells.

Direct Immunofluorescence Microscopy

Biopsy of such a lesion within 24 hours of onset may display vascular deposits of IgM, C3, fibrinogen, and sometimes IgG. A negative result does not exclude vasculitis. Biopsy of a lesion older than 24 hours may not be helpful, in that nonspecific fibrinogen staining may be the only finding. Histologic confirmation of the diagnosis is therefore essential. Henoch-Schönlein purpura is diagnosed when granular IgA, with or without C3, vascular immunofluorescence is seen in the appropriate clinical setting.

LIVER

AUTOANTIBODIES

Antinuclear Autoantibodies

ANAs are most commonly detected by IIFM, although ELISAs for identification of specific autoantibodies are becoming popular in clinical laboratories. ANAs are a very heterogeneous group, and almost all subtypes that occur in rheumatologic disorders are found in persons with autoimmune hepatitis. Homogeneous or speckled ANA patterns on HEp-2 cells are more commonly identified in patients with autoimmune hepatitis. Also reported in liver disease are specific autoantibodies to double-stranded DNA (Manns, 1992). ANAs in titers greater than 1:80 are detected in about 80% of patients with autoimmune hepatitis (Nakamura, 1991). However, ANAs may also be found in about 60% of patients with PBC, 50% of patients with alcohol-related liver disease, 40% of patients with

Modified from Manns MP. Autoimmune diseases of the liver. Clin Lab Med 1992;12:25–40.

ACA, Anti-carbonic anhydrase; AiC, autoimmune cholangitis; AMA, antimitochondrial antibodies; ANA, antinuclear antibodies; HCV, hepatitis C virus; LKM, liver–kidney microsomal antibodies; p-ANCA, perinuclear antineutrophil cytoplasmic antibodies; PBC, primary biliary cirrhosis; PSC, primary sclerosing cholangitis; SLA, antibodies against soluble liver antigens; SMA, smooth muscle antibodies.

viral hepatitis type B, and 25% of patients with autoimmune hepatitis who also have anti-liver–kidney microsomal autoantibodies (LKMs) (Nakamura, 1991). Anticentromere autoantibodies can be identified in 10%–15% of PBC patients.

Antimitochondrial Autoantibodies

Nine separate mitochondrial antigens have been identified that react with AMAs. AMAs directed at M2 and M9 antigens are considered the most important diagnostic markers of PBC (Bylund, 1992).

AMAs detected using IIFM on a substrate of rodent stomach/kidney tissue block show a typical pattern of fluorescence that reflects homogeneous cytoplasmic staining of kidney tubules and stomach parietal cell regions; distal tubules are also positive. This distal tubular staining is an important point in differentiating the reactivity of AMAs from that of LKMs, which do not stain distal renal tubules.

The M2 autoantigen is a heterogeneous mix containing several components of the mitochondrial 2-oxo-acid dehydrogenase complex. The dominant M2 autoantigen in patients with PBC is the 70-kDa E2 subunit of pyruvate dehydrogenase (Manns, 1992). The second most common mitochondrial autoantigen is the 50-kDa E2 subunit of branched-chain oxo-keto-acid-dehydrogenase (Manns, 1992). A group of serum autoantibodies called naturally occurring mitochondrial autoantibodies (NOMAs) have been found in persons having close contact with PBC patients and even in laboratory technicians processing PBC sera (Bylund, 1992). NOMAs are rarely produced in PBC patients but are observed in sera from patients with Epstein-Barr virus infection, cytomegalovirus infection, and other infectious disorders. NOMAs are directed at epitopes on the M2 and M9 antigens in PBC, but not to the same antigens as AMAs (Bylund, 1992). Although the significance of NOMAs is uncertain, their presence in persons associated with PBC patients has raised questions about possible contagious agents in the serum of these patients (Bylund, 1992).

Smooth Muscle Autoantibodies

Smooth muscle autoantibodies (SMAs) are found in approximately 50% of patients with classic autoimmune hepatitis and often occur with ANAs (Nakamura, 1991). When accompanying liver disease, SMAs are directed against F-actin, which is part of the liver cell cytoskeleton in close association with the liver cell plasma membrane (Nakamura, 1991). The SMA titer is typically greater than or equal to 1:80 in serum from a patient with autoimmune hepatitis. However, low titers of SMA can be detected in patients with other diseases, and in apparently healthy individuals (Nakamura, 1991).

IIFM on a tissue substrate of rodent stomach is commonly used to detect SMA, which stains the muscularis propria of stomach in a uniform and consistent pattern. Specific staining of muscularis mucosae and walls of blood vessels is characteristic. If a rodent stomach/kidney tissue block is used as substrate, faint staining may be noted in glomerular mesangial zones owing to the presence of F-actin in this region. If HEp-2 cells are used instead of other substrates, IIFM reveals “cable-like” cytoplasmic staining when SMA is present.

Liver–Kidney Microsomal Autoantibodies

LKMs stain the microsomes of hepatocytes and proximal renal tubules when detected using a rodent stomach/kidney tissue block as the substrate

for IIFM. The distal renal tubules are characteristically negative for immunofluorescence. The simultaneous occurrence of AMA and LKM, although possible, is extremely unlikely.

ELISAs that detect LKM are becoming available for use in clinical laboratories. The presence of LKM can also be confirmed by using Western blotting, although this assay is not generally available outside of research laboratories.

Using the Western blotting procedure, LKMs have been grouped into three subtypes on the basis of their target antigens (Manns, 1992). A 50-kDa component of cytochrome P450 IID6 has been identified as the major antigen for LKM-1 (Manns, 1992). LKM-2, directed at cytochrome P450 IIC9, was found in patients taking ticrynafen (Manns, 1992), a drug that is no longer on the American market. LKM-3 has been identified in sera from patients with chronic viral hepatitis type D (Manns, 1992).

Other Liver Autoantibodies

The remaining groups of hepatic autoantibodies include anticytoskeleton, anticytosol, antiliver membrane, antinuclear lamins, liver-specific, and asialoglycoprotein receptor autoantibodies. All of these have been identified in patients with autoimmune liver disease, but their use as diagnostic markers is not currently widespread (Nakamura, 1991).

LIVER DISEASES

Table 53-4 lists typical serologic profiles in autoimmune hepatitis, PBC, and primary sclerosing cholangitis. These are typically chronic disorders defined by elevated concentrations of serum transaminases for at least 6 months.

Common clinical differential diagnoses include alcohol-related liver disease, drug-induced liver injury, viral hepatitis, and fatty liver of diabetes mellitus or obesity. Less common differential diagnoses include idiopathic hemochromatosis, Wilson's disease, α 1-antitrypsin deficiency, and hepatic involvement in systemic diseases.

Autoimmune Hepatitis

Autoimmune hepatitis classically occurs in females around 35 years of age, who present with high concentrations of serum aminotransferases, hypergammaglobulinemia, amenorrhea, arthralgias, and circulating autoantibodies such as ANA, SMA, and LKM. By definition, these patients have no serologic evidence of viral hepatitis, Wilson's disease, or other diseases in the differential diagnosis. Histologically, liver biopsy typically shows chronic hepatitis with interface activity (Fig. 53-6, A). The patient's response to corticosteroids is dramatic, and failure to respond sheds doubt on the diagnosis of autoimmune hepatitis.

Autoimmune hepatitis is a heterogeneous group of disorders of uncertain etiology. There are no pathognomonic features. The International Autoimmune Hepatitis Group (IAHG) has integrated clinical and laboratory features at patient presentation into a scoring system for definite or probable diagnosis of autoimmune hepatitis. Table 53-5 lists clinical laboratory parameters used as criteria to diagnose autoimmune hepatitis; other criteria and scoring interpretations can be found in the reference section (Johnson, 1993; Manns, 1998). The absence of ANA, SMA, or LKM does not exclude this diagnosis.

Figure 53-6 Liver biopsy in untreated autoimmune hepatitis shows prominent portal and lobular inflammation with interface activity and often numerous plasma cells at the leading edge of inflammation (**A**, Hematoxylin and eosin [H&E], $\times 500$). Indirect immunofluorescence microscopy (IIFM) in this instance reveals combined smooth muscle antibodies and antinuclear antibodies using mouse stomach/kidney as substrate (**B**, $\times 200$). The antinuclear antibody (ANA) pattern in liver disease is often homogeneous (**C**, $\times 400$). IIFM of liver-kidney microsomal autoantibodies using mouse stomach/kidney as substrate. There is finely granular cytoplasmic immunofluorescence of proximal renal tubules, not distal tubules (**D**, $\times 200$).

Although autoimmune hepatitis subtypes based on autoantibody patterns are presented in the medical literature, the clinical utility of such subtyping is uncertain, and the IAHG did not recommend subdivision of autoimmune hepatitis on the basis of autoantibody profiles. From a clinical perspective, autoimmune hepatitis can be viewed as a chronic liver disease characterized by the presence of a variety of autoantibodies. Most experts seem to agree that autoimmune hepatitis types 1 and 2 are the major forms of this disease, whereas additional subtypes are still at issue. Because the various subtypes are widely quoted, subclassification of autoimmune hepatitis according to its serologic profile is briefly discussed here.

ANAs characterize classical, type 1, autoimmune-type hepatitis. SMAs also are frequently detected (Fig. 53-6, *B* and *C*). Although AMAs are specific and sensitive diagnostic markers for PBC, as described later, AMAs can also be detected in about 15% of patients with both clinical and histologic features of autoimmune hepatitis, including clinical improvement in response to immunosuppressive therapy. Such patients are regarded as having a syndrome with features that “overlap” both autoimmune hepatitis and PBC. The AMA titer in this autoimmune hepatitis subgroup is rarely greater than 1:40 (Bylund, 1992). Additionally, the antigen specificity of these AMAs is similar to that seen in classical PBC (Manns, 1992). Liver disease in which LKMs are detected (Fig. 53-6, *D*), so-called type 2 autoimmune hepatitis, has been subdivided into two subgroups: types 2a and 2b. Usually, patients with this variant are negative for ANA and SMA. However, thyroid microsomal, thyroglobulin, and parietal cell autoantibodies are frequently detected. Type 2 autoimmune hepatitis is characterized by low IgA levels, and hypergammaglobulinemia is less prominent than in type 1 (Manns, 1992). Type 2a occurs in young females, who have high titers of LKM-1, negative serology for hepatitis C virus, and active but steroid-responsive disease.

The type 2b variant occurs in older patients, and less of a female preponderance has been seen. These patients have low titers of LKM-1, manifest milder liver disease, and often are serologically positive

for hepatitis C virus. Their disease tends to be less responsive to immunosuppression than the 2a type.

A third subgroup of autoimmune hepatitis, separated from other subgroups on the basis of identifying serum anti-soluble-liver autoantibody (SLA), has been proposed by some investigators (Manns, 1992). Although this may become an important autoantibody to identify because it has been reported as the only serologic marker in about 25% of patients with autoimmune hepatitis, reliable tests to detect SLA are technically difficult and, as yet, are not routinely available in clinical laboratories (Manns, 1992).

It may be that high titers of SMA directed against F-actin characterize a fourth subgroup of autoimmune hepatitis that is frequently observed in young children (Manns, 1992).

Primary Biliary Cirrhosis

PBC is a chronic, progressive, cholestatic disorder typically occurring in young or middle-aged females. Patients may be asymptomatic or may have symptoms of cholestasis (itch). Laboratory studies demonstrate an elevation in alkaline phosphatase with or without hyperbilirubinemia, as well as increased IgM and AMA. Associated extrahepatic immunologic phenomena such as Raynaud's phenomenon, sicca complex, rheumatoid arthritis, thyroiditis, scleroderma, or celiac disease may occur (Bylund, 1992; Manns, 1992). Histologically, the liver shows various stages of nonsuppurative destructive cholangitis (Fig. 53-7, *A*).

AMAs are the most specific and sensitive diagnostic markers for PBC (Fig. 53-7, *B* and *C*). As a general guideline, an AMA titer greater than or equal to 1:160 is highly predictive of PBC, although about 10% of PBC patients have AMA titers of 1:16 or less (Bylund, 1992). About 95% of patients with typical features of PBC have been shown to have anti-M2 and/or anti-M9 AMA, whereas the remaining 5% of patients are AMA negative.

The cause of PBC is unknown, and several pathogenetic mechanisms are proposed regarding the immune-related bile duct injury characteristic

TABLE 53-5

Laboratory Parameters and Score for Autoimmune Hepatitis Diagnosis

Clinical laboratory parameters	Score
Biochemistry	
Ratio of increased alkaline phosphatase to aminotransferase	
>3.0	−2
<3.0	+2
Total serum globulin, γ-globulin, or IgG (× upper normal limit)	
>2.0	+3
1.5–2.0	+2
1.0–1.5	+1
<1.0	0
Autoantibodies (IIFM)	
Adults	
ANA, SMA, LKM	
>1:80	+3
1:80	+2
1:40	+1
<1:40	0
Children	
ANA, LKM	
>1:20	+3
1:10 or 1:20	+2
<1:10	0
SMA	
>1:20	+3
1:20	+2
<1:20	0
AMA	
Detected	−2
Not detected	0
Adults and Children (if ANA, SMA, LKM not detected)	
Other Liver Autoantibodies (SLA, ASGP-R, LC-1)	
Detected	+2
Not detected	0
Viral Markers	
Acute HAV or HBV	−3
HCV by ELISA and/or RIBA	−2
HCV RNA by PCR	−3
Other active viral infection	−3
Seronegative for known viruses	+3
Genetic Factors	
HLA B8-DR3 or DR4 allotype	+1

Adapted from Johnson PJ, McFarlane IG. Convenors on behalf of the panel. Meeting report: international autoimmune hepatitis group. *Hepatology* 1993;18:998–1008.

AMA, Antimitochondrial antibody; ANA, antinuclear antibody; ASGP-R, asialoglycoprotein receptor; ELISA, enzyme-linked immunosorbent assay; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HLA, human leukocyte antigen; IIFM, indirect immunofluorescence microscopy; LC-1, liver cytosolic-type 1; LKM, liver–kidney microsomal autoantibodies; PCR, polymerase chain reaction; RIBA, recombinant immunoblot assay; SLA, soluble-liver autoantibody; SMA, smooth muscle autoantibody.

of this disorder (Gershwin, 2000). Although this disease is classically associated with serum AMA, T cell–mediated immune injury to intrahepatic interlobular bile ducts dominates tissue lesions (Batts, 1991; Manns, 1991, 1988; Poupon, 1996). The discovery of retroviral antibody in PBC patients has been ascribed to either an autoimmune response or immune reactivity to viral proteins that share antigenic determinants with retroviruses (Mason, 1998).

The diagnosis of AMA-negative PBC derives from the clinical presentation, liver biopsy findings, and cholangiogram to exclude primary sclerosing cholangitis.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis typically occurs in males with a history of inflammatory bowel disease and/or diarrhea. In 50% of these patients, ulcerative colitis is the inflammatory bowel disease linked with primary sclerosing cholangitis. A diagnosis of primary sclerosing cholangitis is typically based on cholangiography, which reveals a characteristic beading pattern of bile ducts due to multifocal strictures at those sites (Fig. 53-8, A). The hallmark histologic lesion is fibrous cholangitis of large and/or small bile ducts, although in practice, a wide spectrum of chronic inflammatory lesions is seen on liver biopsy (Fig. 53-8, B).

Routine biochemical studies demonstrate an elevation in alkaline phosphatase and an increase in aminotransferases with or without hyperbilirubinemia. Although ANAs may be present, AMAs are not.

Furthermore, a high prevalence of atypical perinuclear antineutrophil cytoplasmic antibodies (p-ANCA) detected with IIFM on ethanol- and formalin-fixed neutrophil displays has been reported (Manns, 1992; Lo, 1994; Gur, 1995; Bansil, 1996).

Autoimmune Cholangitis/Cholangiopathy

Autoimmune cholangitis/cholangiopathy is a chronic cholestatic liver disease that does not appear to be a variant of primary sclerosing cholangitis (Goodman, 1995; Tsui, 1997). The clinical presentation and histologic appearance of the liver resemble PBC, but serologic findings mimic autoimmune hepatitis type 1. AMAs are not detected. Additionally, an autoantibody to carbonic anhydrase has been detected in some autoimmune cholangitis patients (Gordon, 1995).

Although the connection between autoimmune cholangitis and PBC is not resolved, autoimmune cholangitis may be the same as AMA-negative PBC. Generally, autoimmune cholangitis patients respond to immunosuppression.

THYROID GLAND

THYROID DISEASES

Autoimmune thyroid diseases include Graves' disease and Hashimoto's thyroiditis (Burek, 1995).

Graves' Disease

The patient who has Graves' disease presents with symptoms of hyperthyroidism and diffuse goiter. The peak incidence is in the third to fourth decades of life, and the female/male ratio is 4–8:1; 60%–70% of these patients additionally manifest ocular disturbances (Patrick, 1993). Laboratory data show an increase in levels of triiodothyronine (T_3) and thyroxine (T_4) and in the uptake of T_3 . Therapy is directed at reducing the thyroid's ability to respond to stimulation by autoantibodies. This can be achieved by subtotal thyroidectomy, by administration of radioactive iodine, or by use of antithyroid drugs such as propylthiouracil or methimazole (Patrick, 1993).

Hashimoto's Thyroiditis

Hashimoto's thyroiditis, the most common form of thyroiditis, is functionally characterized by a slow progression to hypothyroidism. In patients with hypothyroidism, T_3 and T_4 levels and T_3 uptake are low, and amounts of thyroid-stimulating hormone (TSH) increase abnormally (Patrick, 1993). The incidence of Hashimoto's thyroiditis peaks during the third to fifth decades, with a female/male ratio of 10:1. Autoantibodies directed against thyroglobulin (anti-Tg) and thyroid peroxidase (anti-TPO) antigens are clinically the most important for diagnosis (Patrick, 1993), but up to 20% of the adult female population with no clinical disease has detectable anti-Tg and/or anti-TPO, raising questions about their pathogenic significance (Patrick, 1993). Thyroid hormone replacement is reserved for patients with proven hypothyroidism.

Similarities between Graves' disease and Hashimoto's thyroiditis have been noted (Utiger, 1991). Both are associated with HLA-B8 and have a fundamentally similar pathogenesis, and it is believed that Graves' disease may progress to Hashimoto's thyroiditis (Utiger, 1991; Patrick, 1993).

AUTOANTIBODIES

Three major autoantibodies, including anti-TPO, anti-Tg, and autoantibody to thyroid stimulating hormone receptor (anti-TSHR), are important in autoimmune thyroid disease (Naparstek, 1993). Although anti-TPO and anti-Tg are considered markers of autoimmune thyroid disease, their

Figure 53-7 Liver biopsy in primary biliary cirrhosis shows variable portal inflammation with nonsuppurative lymphocytic cholangitis and, in this example, a florid duct lesion with granulomatous inflammation centered on an interlobular bile duct (**A**, Hematoxylin and eosin [H&E], $\times 200$). Indirect immunofluorescence microscopy (IIFM) reveals diffuse immunofluorescence of renal tubules, including distal tubules (**B**, $\times 200$), that has a homogeneous cytoplasmic appearance at higher power (**C**, $\times 500$).

Figure 53-8 Cholangiogram in primary sclerosing cholangitis reveals the characteristic beading pattern of bile ducts due to multifocal strictures at those sites (**A**). Liver biopsy reveals prominent periduct fibrosis in the characteristic "onion-skin" pattern (**B**, Hematoxylin and eosin [H&E], $\times 500$).

etiologic role has not been proved. They may occur as well in other organ-directed autoimmune diseases. Anti-TSHR, however, clearly plays a causal role in autoimmune thyroid disease (Naparstek, 1993).

Antithyroid Peroxidase Autoantibodies

Anti-TPO is directed to a 105-kDa antigen that is contained within the microsomal fraction of thyroid epithelial cell cytoplasm (Burek, 1995). ELISA is becoming a common and available method for detecting anti-TPO.

Figure 53-9 Indirect immunofluorescence microscopy of thyroid microsomal autoantibodies using unfixed monkey thyroid tissue sections as substrate (**A**, $\times 400$) and of thyroglobulin autoantibodies using methanol-fixed cryostat tissue sections of monkey thyroid gland (**B**, $\times 200$).

Historically, IIFM has been a popular and sensitive method for detecting anti-TPO (antimicrosomal antibodies). The IIFM test uses unfixed and air-dried human or monkey cryostat tissue sections as substrate. Positive sera stain the cytoplasm of thyroid follicular epithelial cells but do not stain their nuclei (Fig. 53-9, *A*). Anti-TPO must be differentiated from AMA when coarse granular cytoplasmic staining is noted; testing sera on mouse stomach/kidney tissue block can do this.

Anti-TPO can be detected in sera from patients with Graves' disease or Hashimoto's thyroiditis; its presence and titer correlate strongly

with active clinical disease (Burek, 1995). Some controversy has arisen among investigators about whether determination of anti-TPO alone is sufficient to reliably detect autoimmune thyroid disease (Nordyke, 1993; Kaplan, 1999). The pathogenic role of anti-TPO remains unclear (Naparstek, 1993).

Antithyroglobulin Autoantibodies

Anti-Tg is targeted against thyroglobulin, which is the storage form of thyroid hormones within thyroid gland follicles (Burek, 1995). Several methods are available for measuring anti-Tg, including quantitative passive hemagglutination, IIFM, and ELISA.

Quantitative passive hemagglutination with chromic chloride hemagglutination or tanned red blood cells is the most widely used and sensitive method for detecting anti-Tg (Burek, 1995). Anti-Tg detected by hemagglutination is identified in titers greater than 1:1000 in about 80% of patients with Hashimoto's thyroiditis (Burek, 1995). Patients with Graves' disease (60%) or thyroid carcinoma (30%) or other autoimmune disorders such as pernicious anemia or Sjögren's syndrome, and 3%–18% of apparently normal individuals may also have anti-Tg, but their hemagglutination titers are usually (>90%) less than 1:1000 (Burek, 1995).

To locate anti-Tg, IIFM is done using methanol-fixed cryostat tissue sections of monkey thyroid gland (Fig. 53-9, B). Fixation is required to prevent loss of thyroglobulin during washing steps. Three patterns of immunofluorescence are described when anti-Tg is present (Burek, 1995): (1) floccular pattern, (2) dull colloid spaces but bright peripheral fluorescence, and (3) diffuse, bright, uniformly staining colloid in a "ground-glass" pattern attributed to the anti-Tg reaction with CA2 (Burek, 1995). CA2, or so-called second colloid antigen, is detected as the only serologic marker of autoimmune thyroiditis in the 5%–8% of patients who are positive by IIFM but negative for anti-Tg and anti-TPO using other methods (Bigazzi, 1992).

Anti-Thyroid-Stimulating Hormone Receptor Autoantibodies

Anti-TSHR autoantibodies consist of two groups of autoantibodies that can stimulate or block TSHRs, causing, respectively, hyperthyroidism or hypothyroidism. Anti-TSHR autoantibodies that bind to these receptors and stimulate thyroid hormone production are referred to as thyroid-stimulating immunoglobulins (TSIs), whereas anti-TSHR autoantibodies that bind to receptors and block the binding and function of TSH are referred to as thyroid-binding inhibitory immunoglobulins (TBIs) (Mooij, 1993; Brunt, 1995). TSIs probably cause the hyperthyroidism in Graves' disease (Wilkin, 1990; Bigazzi, 1992; Brunt, 1995). Their prevalence varies from 55%–95%, depending on the method of detection (Bigazzi, 1992; Brunt, 1995). TSIs, which are usually of the IgG class, stimulate production of thyroid hormones by activating the adenylate cyclase system after binding to TSHRs (Patrick, 1993).

Detection of anti-TSHR is complex and is not part of routine clinical testing. The test may be useful for confirming Graves' disease in hyperthyroid patients with equivocal results in routine laboratory studies (Bigazzi, 1992). Additionally, one of the anti-TSHR assays may be used to monitor patients' hormone replacement therapy or to diagnose neonatal thyrotoxicosis (Bigazzi, 1992).

Two main classes of assays for anti-TSHRs are available, namely, bioassays and binding assays; their methodologic aspects are reviewed elsewhere (Gupta, 1988; Bigazzi, 1992; Patrick, 1993). Newer assays of a patient's serum based on stimulation of cyclic adenosine monophosphate (cAMP) in rat thyroid cells, maintained in tissue culture, may prove to be an improvement over the technically difficult bioassays (Burek, 1995).

TSIs are measured in bioassays that determine increased TSHR-mediated activity by measuring the release of cAMP or by measuring the uptake of iodide by thyroid cells maintained in culture (Brunt, 1995). TBIs are measured by determining binding inhibition of radiolabeled TSH to its receptor, or by using cAMP bioassays (Brunt, 1995).

KIDNEY

GLOMERULONEPHRITIS

Glomerulonephritis is a major cause of primary renal disease. Immune-mediated mechanisms are thought to have an important role in the pathogenesis of glomerulonephritis, although experimental confirmation of such putative autoimmune mechanisms is still lacking.

DIFM has an important role in the study and diagnosis of glomerulonephritis (Fig. 53-10). The patterns of immune reactants can be divided

Figure 53-10 Direct immunofluorescence microscopy reveals global and linear glomerular basement membrane immunofluorescence in anti-glomerular basement membrane disease (x400).

TABLE 53-6
Major Glomerular Diseases With Direct Immunofluorescent Findings

Immunofluorescent pattern and disease	Immune reactant(s)
Granular, Mesangial, and GBM Deposits	
Acute poststreptococcal glomerulonephritis	Scattered C3 ± IgG, IgM
Diffuse proliferative lupus nephritis	IgG, IgA, IgM, C3
Membranoproliferative glomerulonephritis (MPGN, type I)	C3, IgG, IgM
Idiopathic immune complex crescentic glomerulonephritis	IgG, C3 ± IgM
Dense deposit disease (MPGN, type II)	C3 (globular) ± IgM
Chronic infections (e.g., bacterial endocarditis)	IgG, IgM, C3
Granular, Mesangial Predominant	
Lupus nephritis	
Mesangial	IgG, C3; usually IgM and IgA
Focal proliferative	IgG, C3, IgA; focal capillary loop deposits
Henoch-Schönlein purpura	IgA predominant; IgG, IgM, C3
IgA nephropathy	IgA predominant; often IgG, IgM, C3
Granular, GBM Predominant	
Membranous lupus nephritis	IgG, C3, IgA, IgM
Mixed cryoglobulinemia	IgM, IgG, C3; intravascular masses
Linear GBM	
Anti-GBM nephritis	IgG, C3; IgA and IgM infrequent
Light chain nephropathy	Usually κ light chain, may be in TBM, blood vessels, interstitium

Modified from McCluskey RT, Collins AB, Niles JL. Kidney. In: Colvin RB, Bhan AK, McCluskey RT, editors. Diagnostic immunopathology. 2nd ed. New York: Raven Press; 1995, p. 109.

GBM, Glomerular basement membrane; Ig, immunoglobulin; MPGN, membranoproliferative glomerulonephritis; TBM, tubular basement membrane.

broadly into those that cause granular or linear deposits within glomeruli or other kidney structures examined with DIFM. Granular deposits have been attributed to immune complexes that settle out of circulating blood or form in situ (McCluskey, 1995). DIFM patterns of immune deposits associated with major glomerular diseases are summarized in Table 53-6. Thorough reviews of these disorders are available in several texts (Heptinstall, 1992; McCluskey, 1995). However, for this discussion,

only anti-glomerular basement membrane (anti-GBM) autoantibodies are presented in some additional detail.

ANTI-GLOMERULAR BASEMENT MEMBRANE DISEASE

Patients with anti-GBM disease vary in clinical presentation in that about 50% have renal-limited disease, and the other 50% have both renal and pulmonary symptoms. This latter presentation is often called Goodpasture's syndrome. Rarely, patients with anti-GBM disease may have pulmonary limited disease (Wilson, 1987).

Diagnosis of anti-GBM disease requires detection of anti-GBM autoantibodies to the NC1 domain of type IV collagen (McCluskey, 1995), the so-called Goodpasture's antigen. Methods for detecting circulating anti-GBM have included IIFM, ELISA, and RIA (Wilson, 1987; McCluskey, 1995); some investigators have additionally developed a sensitive Western blot test (McCluskey, 1995). Because IIFM is difficult to standardize and requires experience to perform, methods for detection have focused instead on validation of quantitative RIA or ELISA. Currently, a licensed commercial ELISA kit is available for the measurement of anti-GBM. This assay determines patient values from a standard curve and reports negative, borderline, or positive ranges. Most patients with active anti-GBM disease appear to have values greater than 100 units. Although borderline values can be seen in both active and quiescent anti-GBM disease, we have also seen such values in patients with renal disorders that are not anti-GBM disease.

The coexistence of antineutrophil cytoplasmic antibodies (ANCA) has been documented in some patients with rapidly progressive glomerulonephritis (McCluskey, 1995). The coexistence of these two autoantibodies has varied from 0–40% of patients with rapidly progressive glomerulonephritis, accompanied by some evidence that the presence of ANCA in patients with anti-GBM disease affords a better renal prognosis (McCluskey, 1995).

ADRENAL GLAND

ADDISON'S DISEASE

Nontuberculous chronic adrenocortical insufficiency, or Addison's disease, has an estimated prevalence of 3–6 cases per 100,000 people (Muir, 1993). Among such patients, 65%–70% have circulating autoantibodies to adrenal cortex cells, demonstrable using IIFM on frozen sections of human adrenal cortex (Muir, 1993; Patrick, 1993; Burek, 1995). 21-Hydroxylase and 17 α -hydroxylase are two autoantigens that have been identified as reactive with adrenocortical autoantibodies (Song, 1994; Devendra, 2004). Adrenocortical autoantibodies are not found in Addison's disease caused by tuberculosis or other exogenous agents (Patrick, 1993). About 45% of asymptomatic individuals with serum adrenocortical autoantibodies develop impaired adrenocortical function within 2.5 years after the autoantibody is identified (Muir, 1991).

Addison's disease associated with autoantibodies is most commonly diagnosed in persons between the ages of 20 and 50 years and is two to three times more frequent in females when diagnosed after the age of 30 (Muir, 1993; Patrick, 1993).

Laboratory tests show metabolic acidosis, hyperkalemia, hyponatremia, and low levels of serum chloride and bicarbonate. Plasma cortisol levels are also low and adrenocorticotrophic hormone levels are elevated (Van Arsdel, 1993). Consequently, therapy consists of replacing glucocorticoids and mineralocorticoids (Patrick, 1993).

Addison's disease associated with autoantibodies can occur by itself but is more commonly accompanied by other autoimmune disorders as part of an autoimmune polyglandular syndrome (Muir, 1993). These companion diseases may include autoimmune thyroiditis, pernicious anemia, or insulin-dependent diabetes mellitus (Patrick, 1993).

In addition to adrenocortical autoantibodies, other adrenal autoantibodies have been detected in patients with Addison's disease, including steroid cell autoantibodies and autoantibodies that bind adrenocorticotrophic hormone receptors (Muir, 1993).

PANCREAS

DIABETES MELLITUS

Diabetes mellitus (see Chapter 16) is the diagnostic term applied to a group of metabolic disorders that share hyperglycemia as their common link

Figure 53-11 Indirect immunofluorescence microscopy of islet cell autoantibodies using human blood group O pancreas as substrate ($\times 400$).

(Eisenbarth, 1995). That it is a serious diagnosis is documented by the fact that acute and chronic multiorgan diabetic complications account for about 15% of total U.S. health care expenditures. However, significant progress has been made in the care of diabetic patients, with the knowledge that aggressive blood glucose control reduces the risk for development of and progression to vascular complications.

Clinical Subtypes

The major clinical subgroups of diabetes mellitus are type 1A for immune-mediated diabetes, type 1B for non-immune-mediated diabetes with severe insulin deficiency, and a subgroup of adult type 2 diabetes with anti-islet autoantibodies that is termed latent autoimmune diabetes mellitus (American Diabetes Association, 1997; Devendra, 2004). Type 2 diabetes mellitus was formerly termed non-insulin-dependent diabetes and most commonly occurs in obese individuals older than 30 years.

Major types of circulating autoantibody in type 1A diabetes mellitus include the following: islet cell autoantibodies (ICAs); glutamic acid decarboxylase autoantibodies (anti-GAD); insulin autoantibodies (IAAs); and insulinoma-associated-2 and -2 β autoantibodies (Lan, 1996; Schmidli, 1998; Devendra, 2004).

Islet Cell Autoantibodies

IIFM is the classical method used for detection of ICAs (Atkinson, 1993b). Frozen sections of human pancreas are used as the tissue substrate to detect specific, finely granular, cytoplasmic fluorescence in all cells of pancreatic islets (Fig. 53-11). Human blood group O is recommended as substrate to reduce nonspecific background interference due to ABO isohemagglutinins. Using IIFM, ICAs are detectable in about 80% of patients with newly diagnosed type 1A diabetes, 3%–4% of nondiabetic relatives of patients with type 1A diabetes, and only 0.5% of clinically normal subjects (Atkinson, 1994). ICAs include autoantibodies specifically reactive with anti-GAD, as well as non-GAD-reactive ICAs (Kaufman, 1992; Atkinson, 1993b).

ICA should be titrated in Juvenile Diabetes Foundation (JDF) units in reference to an 80-unit standard serum from the Immunology of Diabetes Workshop; titers greater than 20 JDF units seem to have prognostic significance (Maclaren, 1992). Commercial ICA assays using primate substrate are available.

Insulin Autoantibodies

IAAs are identified in about 50% of patients with type 1A diabetes at the time of diagnosis and before insulin therapy begins (Atkinson, 1994). IAAs are usually measured using a technically demanding competitive radio-immunoprecipitation assay. This assay cannot distinguish between IAAs occurring spontaneously and those that occur as a result of insulin therapy. Therefore, IAAs need to be measured before insulin is administered.

Glutamic Acid Decarboxylase Autoantibodies

Anti-GADs are detected in most newly diagnosed type 1A diabetes patients and in about 80% of prediabetic, first-degree relatives of patients (Hagopian, 1993; Schatz, 1995). The two GAD autoantigens, classified by molecular mass, are designated GAD65 and GAD67 (Atkinson, 1993a). Anti-GADs are directed primarily at the GAD65 isoform, which is found

Figure 53-12 Indirect immunofluorescence microscopy of gastric antiparietal cell autoantibodies using mouse stomach/kidney as substrate ($\times 400$).

mainly in pancreatic islets and in the central nervous system (CNS), where it functions as an enzyme responsible for formation of the inhibiting neurotransmitter γ -aminobutyric acid (Maclaren, 1988; Barneier, 1992; Kaufman, 1992; Luhder, 1994). The GAD67 form predominates in peripheral nerves (Atkinson, 1993; Falorni, 1994).

GAD autoantibodies are also associated with the rare stiff-man syndrome (Eisenbarth, 1995). A high percentage of these patients have type 1A diabetes.

Interpretation and Clinical Utility of Autoantibodies in Type 1A Diabetes

ICA, anti-GAD, IAA, and IA-2 autoantibodies are used currently as predictive markers for diabetes. ICA is a specific marker associated with an elevated risk of developing type 1A diabetes, but ICAs do not persist. Anti-GAD is usually detected before the diagnosis of diabetes and usually declines in titer after the onset of clinical diabetes (Schatz, 1994). Initial screening for autoantibodies associated with type 1A diabetes has been limited to ICA and IAA (Devendra, 2004).

Identification of islet autoantibodies can be used to confirm autoimmunity in patients with acute diabetes, which differentiates type 1A from type 1B diabetes. The use of these markers to identify individuals at risk for type 1A is being evaluated to determine the need for metabolic studies that would assess subclinical glucose intolerance and call for immunotherapy in the preclinical phase of diabetes (Maclaren, 1992). Measurement of anti-GAD using ELISA may eventually improve the feasibility of widespread screening for this autoantibody.

In addition to the autoantibodies discussed previously, patients with diabetes may have anti-TPO, antiparietal cell, and antiadrenocortical autoantibodies, so diabetes patients should be screened for these autoantibodies at least once (Maclaren, 1992).

GASTROINTESTINAL TRACT

PERNICIOUS ANEMIA

Pernicious anemia is an organ-specific autoimmune disease accompanied by cobalamin deficiency, megaloblastic anemia, neuropathy, and autoimmune gastritis with anti-intrinsic factor (anti-IF) (Gueant, 1997).

Pernicious anemia is characterized by histamine-fast achlorhydria, hypergastrinemia, and vitamin B₁₂ deficiency (Brown, 1995). The insidious onset of neurologic symptoms and the development of megaloblastic anemia are typical features of the clinical course (Patrick, 1993). Morphologically, biopsy of the stomach body mucosa contains evidence of chronic atrophic gastritis.

Pernicious anemia is associated with circulating antiparietal cell (APC) autoantibodies in 90% of patients and with anti-IF in 60%–75% of patients, although anti-IF may be more specific for pernicious anemia (Brown, 1995; Burek, 1995). APCs are detected by IIFM performed on mouse stomach/kidney tissue blocks. This combined tissue block allows identification of specific parietal cell staining when there is no concomitant staining of renal tubules as would be seen in the presence of AMAs (Fig. 53-12).

The epitope domain of type 1 antibodies was found to be an amino acid sequence of 251–256 in the human IF (Gueant, 1997).

Anti-IF is most commonly detected by RIA. Of the two known types of anti-IF, type 1 anti-IF, or blocking autoantibody, prevents the binding of IF to vitamin B₁₂, and type 2, or binding autoantibody, reacts with free or complexed vitamin B₁₂ to inhibit the action of IF (Patrick, 1993; Karen, 1994). Type 1 anti-IF is considered more diagnostically sensitive and specific for pernicious anemia (Karen, 1994). However, identification of APCs or anti-IF is not required for diagnosis of pernicious anemia. Pernicious anemia can occur in association with other autoimmune diseases, such as autoimmune thyroiditis or Addison's disease, and may be a part of autoimmune polyglandular syndrome 1 or autoimmune polyglandular syndrome 2 (Patrick, 1993).

CELIAC DISEASE (GLUTEN-SENSITIVE ENTEROPATHY)

Celiac disease is a lifelong inflammatory autoimmune disease of the gastrointestinal tract that affects genetically susceptible persons. Several other autoimmune diseases may be associated with celiac disease, such as type 1 diabetes mellitus and autoimmune thyroiditis (Shaoul, 2007). The common immunogenetic basis for this association is the fact that the diseases share common HLA and non-HLA genes.

More recently, deaminated gliadin peptides have been employed as targets for celiac disease-specific antibodies. Assay with the use of deaminated gliadin peptides measures a new species of antibodies, which differs from conventional gliadin antibodies (Mothes, 2007). The deaminated gliadin peptide antibody test showed a sensitivity of 90% and a specificity of 98% in celiac disease (Kaukinen, 2007). The deaminated gliadin peptide antibody test showed six of the nine cases with small-bowel mucosal damage persisting on a gluten-free diet, whereas tTG detected only two cases and the endomysial antibody test detected none (Kaukinen, 2007). The deaminated gliadin peptide antibody test has been recommended for workup of celiac cases, along with the tTG test. In a prospective study, almost all of the tTG-positive sera drawn from children who later developed celiac disease were also positive for gliadin peptide antibodies (Ankelo, 2007).

Susceptibility to celiac disease is genetically determined by possession of specific HLA-DQ alleles acting in concert with one or more non-HLA-linked genes (Bevan, 1999). Determination of HLA-DqZ and HLA-DQ8 is useful in the exclusion of celiac disease. Also, individual genetic testing will help to assess the risk of celiac disease among families in a high-risk population compared with the normal population (Karell, 2003; Liu, 2006).

Gluten-sensitive enteropathy (GSE), or celiac disease sprue, is a small-bowel disease characterized by malabsorption of gastrointestinal fat. Until recently, GSE was considered a rare disease in the United States, but now the prevalence is considered much greater than was previously estimated—about 1% of the U.S. population (Ferguson, 1997; NIH Consensus, 2004; Rostom, 2004). Patients may have nongastrointestinal manifestations that dominate the clinical presentation, such as anemia, neurologic symptoms, and autoimmune disease (Green, 2003). Hypersensitivity to gluten, or gluten derivatives, is the cause of GSE (Brown, 1995). Small-bowel biopsy from a patient with GSE is variably abnormal, but characteristic changes include villous atrophy, crypt elongation, intraepithelial lymphocytes, and crypt mitoses.

Patients with GSE manifest several humoral immune alterations. Serum IgA levels are usually elevated in GSE patients, except in those with an IgA deficiency, which does occur in GSE patients more commonly than in normal individuals (Brown, 1995). Patients with GSE may have circulating IgA antiendomysial, antireticulin, and/or antigliadin autoantibodies. IgA antiendomysial autoantibodies are detectable by IIFM using monkey esophagus as tissue substrate (Fig. 53-13). IgA antiendomysial autoantibodies detect tTG, the primary autoantigen in GSE (Dieterich, 1997). ELISA is now available for the detection of anti-tissue transglutaminase (anti-tTG). Their identification is considered diagnostically sensitive and specific for GSE alone or GSE associated with dermatitis herpetiformis (GSE-DH) (Táal, 1997). The titer of IgA antiendomysial autoantibody may be measured to monitor a patient's compliance with a gluten-free diet (Karen, 1994).

Antireticulin autoantibodies are detected by IIFM on a mouse stomach/kidney combined tissue block. These autoantibodies are detectable in adults (40%), in children with GSE (60%) and in adults with GSE-DH (20%). However, antireticulin autoantibodies are diagnostically nonspecific and generally are no longer considered useful in the diagnosis of GSE, being present also in patients with Crohn's disease, myasthenia gravis, Sjögren's syndrome, and other connective tissue disorders.

Figure 53-13 Indirect immunofluorescence microscopy of immunoglobulin (Ig) A endomysial autoantibodies using monkey esophagus as substrate ($\times 400$).

Antigliadin autoantibodies are detected by ELISA in almost all patients with GSE or GSE-DH (Brown, 1995). The target antigen, gliadin, is purified from gluten and is used in a solid-phase ELISA to detect these autoantibodies. Similar to IgA endomysial autoantibodies, antigliadin autoantibodies can be used to monitor a patient's adherence to a gluten-free diet. Antigliadin antibodies are less specific than anti-tTG and anti-endomysial antibodies.

A patient suspected of having GSE should be tested while on a normal, gluten-containing diet. In suspected patients without chronic liver disease, the presence of anti-tTG and/or IgA antiendomysial antibodies in the appropriate clinical setting is supportive of GSE. However, most clinicians consider histologic confirmation on small-bowel biopsy to be necessary to establish the diagnosis. Negative serology does not exclude a diagnosis of GSE, and IgA deficiency should be considered in patients with a suggestive clinical presentation. If IgA deficiency is identified, an IgG-tTG or IgG antiendomysial antibody test should be performed (NIH Consensus, 2004).

Compliance with a gluten-restricted diet can be monitored by anti-tTG, IgA antiendomysial, or deaminated gliadin peptide assay.

IDIOPATHIC INFLAMMATORY BOWEL DISEASE

Inflammatory bowel disease (IBD) is the term used to describe diseases that cause inflammation of the intestine. Crohn's disease (CD) and ulcerative colitis (UC) are the two major IBDs.

In CD, inflammation often occurs in the distal ileum but may affect any part of the digestive tract. In CD, inflammation is typically transmural with lymphoid aggregates and often forms granulomas. In UC, inflammation is mucosally based, with chronic active inflammation with ulcers involving the colon, especially the rectum.

Sensitive p-ANCA Associated With Ulcerative Colitis

p-ANCA, antineutrophilic cytoplasmic antibody, and a number of other (auto)antibodies have been described in patients with CD or UC (Nakamura, 2003; Vermeire, 2008). The antibody markers reflect a loss of tolerance toward bacterial and fungal antigens. These markers include p-ANCA, antibodies to *Saccharomyces cerevisiae* (ASCA), antipancreatic antibody, Omp C antibody, CBir1 antibody, I-2 antibody, and others (Nakamura, 2003; Bossugt, 2006; Vermeire, 2008).

Most adult patients with UC (60%–80%) exhibit a positive test for p-ANCA. p-ANCA has been observed in 83% of children with UC. Billing (1995) provided evidence that the p-ANCA associated with UC is nuclear in location and differs from other types of p-ANCA.

It appears that the p-ANCA-associated antigen seen with IBD is located in the nuclei and most likely is a complex conformational epitope associated with histone (H-1), HMG-1, HMG-2 (high mobility group nuclear protein), and a nuclear envelope protein that is a 50-kDa nuclear envelope protein (Nakamura, 2003).

This p-ANCA pattern seen in IBD is the result of nuclear antigens that are sensitive to DNase digestion of substrate cells. In approximately 70% of cases of UC, convergence of the patterns and antigen occurs, and in 30% of cases, convergence to a homogenous cytoplasmic staining pattern is seen. The p-ANCA pattern is noted in 60%–80% of UC patients and in 10%–30% of CD patients.

IBD-associated ANCA was first reported by Faber and Elling (1967), who described “leukocyte specific anti-nuclear antibodies” in patients with CD and UC. It is now clear that the granulocyte-specific antibodies in IBD are in fact p-ANCA. The p-ANCA antibodies in IBD differ from antibodies observed in vascular diseases that are reactive with myeloperoxidase (see Chapter 52). Studies have shown that p-ANCA production takes place in the colonic mucosa.

p-ANCA is detected in 10%–30% of patients with CD. In CD, the expression of p-ANCA identifies a subgroup of CD characterized as “ulcerative colitis (UC)-like” phenotype, in which patients have clinical features of UC.

CD patients who are p-ANCA positive do not respond as well as the majority of CD patients to anti-tumor necrosis factor (TNF) monoclonal antibody therapy. On the other hand, 65% of CD patients respond well to anti-TNF monoclonal antibody therapy.

High levels of p-ANCA in CD patients were associated with later age of onset and UC-like inflammatory response, as well as a relatively decreased incidence of fibrostenosis and penetrating disease.

The p-ANCA pattern has been reported in 92% of patients with well-defined type 1 autoimmune hepatitis and in up to 70% of primary sclerosing cholangitis patients. The p-ANCA associated with UC-reactive antigen was associated with epitopes within the nuclei. Also, UC p-ANCA demonstrated as a dominant feature loss of antigen recognition after DNase-1 enzyme digestion of neutrophils.

In contrast, a majority of type 1 autoimmune hepatitis and primary sclerosing cholangitis patients showed a p-ANCA pattern—recognizing cytoplasmic constituent. Thus, UC-associated p-ANCA with nuclear epitopes is highly specific for IBD (Vidrich, 1995).

Anti-ASCAs have been found to be significantly more prevalent in patients with CD as compared with UC patients or healthy controls. These antibodies include both IgA and IgG classes directed against mannose sequences in the cell wall mannan of *Saccharomyces cerevisiae*. The presence of IgG or IgA ASCA has been shown to have a high specificity for CD. However, a subgroup of CD patients do not have ASCA antibodies. IgG and IgA ASCAs have been demonstrated in 60%–70% of patients with CD, 10%–15% of patients with UC, and 0–5% of control patients (Vasilias, 2000; Bossugt, 2006).

Antibodies against exocrine pancreas have been described in CD patients with a prevalence of 30% (Joossens, 2006). The antigen has not been elucidated, and the antibodies are detected by IIFM.

NERVOUS SYSTEM

MYASTHENIA GRAVIS

Myasthenia gravis (MG) is a neuromuscular disorder characterized by use-associated muscular weakness, fatigue, and the presence of antiacetylcholine receptor (anti-AChR) autoantibodies. AChRs, located in postsynaptic membranes of skeletal muscle fibers, bind acetylcholine (ACh) from nerve endings, which causes a muscle contraction when enough ACh has been released (Naparstek, 1993; Rose, 1995). Anti-AChR autoantibodies interfere with this neuromuscular function, resulting in muscle weakness and fatigue.

Anti-AChR autoantibodies are detected in about 90% of MG patients (Rose, 1995). Radiolabeled α -bungarotoxin (α -BTx) is used in competitive RIAs to measure different forms of anti-AChR (Barna, 1995). α -BTx is a protein from snake venom that essentially irreversibly binds AChR, but it binds to ACh receptors at a site different from binding sites for anti-AChR (Rose, 1995). AChRs are obtained from extracts of denervated human skeletal muscle, such as from diabetic amputations, or from tissue cell culture. For testing, AChRs are labeled with α -BTx, then are incubated with patients' serum to allow any anti-AChR autoantibodies present to bind to AChRs at sites near the α -BTx binding site. After incubation, the radiolabeled complexes are precipitated by polyvalent antihuman immunoglobulin, and after correction for nonspecific binding, the washed precipitate is counted for radioactivity. The degree of radioactivity in the precipitate is directly proportional to the amount of anti-AChR in the patient's serum.

Modifications of this binding assay can be used to identify anti-AChR blocking and modulating autoantibodies. In a blocking assay, patients' sera containing anti-AChR are allowed to incubate with AChRs before α -BTx is added. The basis for this technique is the premise that anti-AChR capable of blocking α -BTx binding also blocks ACh binding to AChRs (Rose, 1995). The amount of radioactivity in the precipitate therefore is inversely proportional to the amount of anti-AChR in patients' sera.

Modulating anti-AChR autoantibodies are thought to accelerate AChR degradation, but their measurement in the clinical laboratory is technically difficult and is not widely performed.

Some MG cases have antibodies against skeletal muscle antigens, in addition to antibodies to AChR. A major epitope is the Ca^{++} release channel of the sarcoplasmic reticulum, called the ryanidine receptor (RyR) (Skeie, 2008). These RyR antibodies are found mainly in MG patients with thymoma and correlate with severe MG symptoms. Also, antititin antibodies are a sensitive marker of thymoma-associated MG (Yamamoto, 2001). Titin is the major autoantigen recognized by antistriated muscle antibodies. Non-AChR muscle autoantibodies are present in many MG serum samples, mainly from patients with thymoma or late-onset MG (Mygland, 2000; Romi, 2000).

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is a relatively common demyelinating disease involving the white matter of the brain and spinal cord. It occurs more frequently in females than in males (2:1 ratio) and is usually evident during young adulthood, with a wide variety of possible clinical manifestations. About 50% of patients undergo alternating periods of active disease and remission, whereas the remainder follow a chronic progressive course (Steinman, 1993; McFarland, 1995). The diagnosis of multiple sclerosis derives from clinical findings and exclusion of all other disorders.

MS is a T cell-mediated autoimmune demyelinating disease that may be initiated by a virus infection (Kurtzke, 1993; Miller, 1997). However, the exact cause of MS is unknown, and autoimmune mechanisms are important in the pathogenesis of this disease (McFarland, 1995). No characteristic circulating autoantibodies have been noted in MS.

Laboratory examination of cerebrospinal fluid (CSF) provides important information that supports a diagnosis of MS in an appropriate clinical setting (Barna, 1995). Synthesis of IgG increases abnormally within the CNS of MS patients, so that measurement of the IgG index and the IgG synthetic rate provides useful, but not specific, test results (Valenzuela, 1995; Zweiman, 1991; Karen, 1994; McFarland, 1995). Evaluation of CSF for oligoclonal bands is also useful in the appropriate clinical setting, because they are identified in more than 90% of MS patients; however, their presence is not diagnostically specific, in that they can be detected in patients with such diverse disorders as neurosyphilis, CNS vasculitis, Lyme disease, subacute sclerosing panencephalitis, Creutzfeldt-Jakob disease, stroke, Guillain-Barré syndrome, and neoplasms (Karen, 1994). Serum protein electrophoresis must also be performed to ensure that CSF oligoclonal bands are not the result of serum leakage into the CSF. CSF oligoclonal bands are usually measured by high-resolution agarose electrophoresis of concentrated CSF (Karen, 1994).

NEUROPATHIES

Autoimmune disorders of the peripheral nervous system consist of a heterogeneous group of diseases that result from an aberrant immune response (Quattrini, 2003). Serum antibodies against ganglioside (GMI) and/or GD1b are frequently detected in autoimmune neuropathies, such as multifocal motor neuropathy, IgM paraproteinemic neuropathy, and Guillain-Barré syndrome. Some of them bind to GMI or ED1b monospecifically, but others can cross-react with both antigens (Kusunoki, 1993). These autoantibodies may interact with endothelial cell-bound antigens, which can affect the permeability of the blood-brain or nerve barrier to permit entry of autoantibodies into the nervous system (Yu, 1990).

The autoantibodies that bind to or block ganglionic AChRs identify a group of patients with autoimmune neuropathy (Vernino, 2000).

Considerable evidence indicates that many of the neuropathies of the peripheral nervous system have an immune-mediated pathogenic mechanism with development of various autoantibodies (Ho, 1998; Naparstek, 1993).

Autoantibodies to neural antigens have been demonstrated in both motor and sensory neuropathies. Patients with motor neuropathies show evidence of high IgM anti-GMI antibody levels (Carney, 2002).

TABLE 53-7

Antibodies in Common Paraneoplastic Neurologic Syndromes and Associated Tumors

Antibody	Clinical syndrome	Associated tumors and conditions
Anti-Yo	Cerebellar degeneration	Ovary, breast
Anti-Hu (ANNA-1)	Brain and cerebellar dysfunction	SCLC, neuroblastoma
Anti-Ri (ANNA-2)	Opsoclonus-myoclonus	Breast, ovary, SCLC
Antiamphiphysin	Stiff-man syndrome	Breast, ovary, SCLC
	Encephalitis-neuropathy	Diabetes mellitus
Anti-VGCC	Lambert-Eaton	SCLC
	myasthenia syndrome	

SCLC, Small cell lung cancer; VGCC, voltage-gated calcium channels (anti-body).

High titers of antisulfatide antibodies are also present in motor and sensory neuropathies, but are more frequently associated with demyelinating neuropathies. Neuropathies with evidence of demyelination often demonstrate antibodies to myelin-associated glycoprotein and sulfoglucuronyl paragloboside.

These autoantibodies may be detected by ELISA, IIFM, or immunohistochemistry. The importance of identifying such autoantibodies will undoubtedly increase as/if clinical studies correlate their presence with a particular disease or a therapeutic benefit. However, to date, these autoantibodies are not disease-specific and can occur even after trauma to the nervous system. Autoantibodies to primary neural components include those to neuronal proteins or to neuronal gangliosides (Zeballos, 1992; Darnell, 2003).

PARANEOPLASTIC NEUROLOGIC SYNDROMES

Paraneoplastic neurologic syndromes (PNSs) are diseases that occur as remote effects of tumors.

The most common types of tumors involved in PNS are small cell lung cancer (SCLC), thymoma, neuroblastoma, ovarian, breast, testicular, and Hodgkin lymphoma.

One of the reasons for PNS is that the tumor and the nervous system share antigens, so that the autoimmune response generated against the tumor initiates the neurologic problem (Anderson, 2008).

In Table 53-7 are listed various autoantibodies in the PNS.

Neurologic paraneoplastic syndromes may be the presenting feature of an occult tumor (Dalmau-Posner, 1999; Posner, 2000). For example, Lambert-Eaton syndrome is strongly associated with SCLC and P/Q-type voltage-gated calcium channel antibodies. Paraneoplastic sensory neuropathy is associated with SCLC or gynecologic tumors and with ANNA-1 anti-Hu antibodies.

The diagnostic value of a positive antineuronal antibody in patients with PNS is high, because the existence of an underlying malignancy can be seen in more than 90% of seropositive patients (Nakamura, 2002).

STIFF-MAN SYNDROME

Stiff-man syndrome is a rare disorder of the CNS of progressive fluctuating muscle rigidity with painful spasms. It is associated with IDDM and with epilepsy. (Solimena, 1998) reported evidence that impairment of neuronal pathways that operate through γ -aminobutyric acid is involved in the pathogenesis of stiff-man syndrome. Patients have antibodies to anti-GAD, which is the enzyme responsible for the synthesis of γ -aminobutyric acid.

In 1956, Moersch and Woltman, who coined the term **stiff-man syndrome**, described the syndrome as a neurologic clinical entity at the Mayo Clinic. Symptoms begin from age 30–50 and show evidence of anti-GAD in 60% of patients.

OTHER ORGANS

HEART

In idiopathic dilated cardiomyopathy (IDCM), evidence suggests that autoimmune reactions against certain myocyte antigens may play a pivotal role in the initiation and/or progression of IDCM (Jahns, 2008). These

autoantibodies are probably “pathogenic” and can contribute in causing cardiac dysfunction and heart failure. Warraich (2006) presented evidence that human cardiac myosin autoantibodies can impair cardiac myocyte contractility. Other publications show evidence that autoantibodies could promote myocardial damage by inducing inflammation or interference with surface receptors on cardiomyocytes (Shmilovich, 2007). Also, organ-specific cardiac antibodies were seen more frequently in patients with dilated cardiomyopathy than in those with other cardiac diseases (Caforio, 1990).

Myocardial Autoantibodies

Autoantibodies to the myocardium have been reported as a part of several conditions that damage cardiac striated muscle, including myocardial infarction, post cardiac surgery, and cardiomyopathy; their identification may help differentiate immune-mediated cardiomyopathy from other causes of myocarditis (Naparstek, 1993; Burek, 1995). IIFM on frozen sections of monkey heart is used to detect myocardial autoantibodies. Specific myocardial staining can also be determined by excluding reactivity on noncardiac skeletal muscle. Unfortunately, AMA and/or heterophile autoantibodies can cause fluorescent staining that may be confused with that caused by myocardial autoantibodies.

MUSCLE

Skeletal Muscle Autoantibodies

Skeletal muscle autoantibodies have limited clinical applicability. Low titers (<1:30) may be seen in apparently healthy individuals, whereas some patients with myopathic disorders may have titers up to 1:60. Although high titers (>1:60) of skeletal muscle autoantibodies have been found in patients with MG, anti-AChR assays have greater clinical utility in diagnosing or monitoring MG.

About 50% of patients with thymoma have paraneoplastic MG. These patients with thymoma-associated MG produce autoantibodies to a variety of neuromuscular antigens, such as AChR, titin, skeletal muscle calcium release channel (RyR) and voltage-gated potassium channels (Mygland, 2000).

Skeletal muscle autoantibodies are detected by IIFM on frozen sections of monkey thigh skeletal muscle (Fig. 53-14).

Figure 53-14 Indirect immunofluorescence microscopy of skeletal muscle autoantibodies on frozen sections of monkey thigh skeletal muscle (×400).

SUMMARY

Autoantibodies have an important role in the study of patients with organ-specific autoimmune disease. Detection of these autoantibodies may be important in the diagnosis of some organ-specific autoimmune diseases, such as Graves' disease, but more often they are supportive rather than essential for diagnosis. Similarly, although some of these autoantibodies are directly involved in pathogenesis of a disease (e.g., pemphigus), their presence is often a marker of underlying immunologic injury attributable to another disease mechanism, as is the case in type 1A diabetes mellitus. Newer techniques in molecular biology have disclosed, and will continue to disclose, the specific nature of many antigens targeted by these autoantibodies. It is hoped that this work will elucidate underlying disease mechanisms, allowing improved diagnostic tests and perhaps new directions in therapy. Technical advances in ELISA have made this technology available in most clinical laboratories, so that many assays for organ-specific autoantibodies are more widely available when IIFM is not feasible.

KEY POINTS

- The prevalence of allergic disease has increased markedly in recent years throughout the world, especially in developed countries.
- IgE is the most important trigger molecule for allergic inflammation.
- Laboratory tests that establish a high likelihood of allergic disease have assumed increased importance. Test results support referrals to allergy specialists and enable primary care physicians to decide whether or not to manage patients within their own practices.
- New drug treatments for allergic diseases such as therapeutic monoclonal anti-IgE antibodies require demonstration of an elevated IgE level or the presence of IgE antibodies in serum prior to use.
- Clinical investigations of the natural history of allergic diseases in children have shown a reproducible sequence of sensitization to allergens that makes it increasingly important to establish the diagnosis of allergy at an early age to minimize exposure to allergen triggers and possibly ameliorate progression to serious diseases such as asthma.
- Tests for IgE and IgE antibodies are ordered principally for diagnosis.
- Measurement of serum total IgE in children and adults is of limited value in the diagnosis of allergic disease. The highest serum IgE levels typically occur in patients with hypersensitivity to several allergens and combinations of asthma, atopic dermatitis, and rhinitis. An elevated level carries a high predictive value for allergic disease, but a normal level does not exclude allergic disease.
- Measurement of IgE antibodies is useful and can be recommended in the following clinical situations:
 - Evaluation of children with early clinical signs of allergy, including eczema, gastrointestinal signs, or wheezing
 - Evaluation of children and adults suspected of having allergic respiratory disease to establish the diagnosis and to define the specificity of allergen sensitization to pollens, dust mites, fungal antigens, and foods
 - Confirmation of sensitization to food allergens and help in determining the presence of food allergy in children and adults with signs of immediate hypersensitivity on food ingestion
 - Evaluation of sensitivity to insect venom allergens, particularly as an aid in defining venom specificity in those cases in which skin tests are equivocal

- Confirmation of the diagnosis of drug hypersensitivity in patients with anaphylactic sensitivity
- Confirmation of the presence of IgE antibodies to occupational allergens, for example, natural rubber latex
- Testing for IgE antibodies is not routinely recommended for evaluating the effects of immunotherapy, or for excluding the diagnosis of anaphylactic sensitivity to insect venoms in treated patients. Tests for IgE antibodies are indicated only in patients who have had a thorough medical history and physical examination.

OVERVIEW

The prevalence of allergic disease has increased markedly in the United States and throughout the developed world (Bach, 2002). Estimates of the cumulative prevalence of allergic diseases in the United States range as high as 30% (Sly, 1999; Downs, 2001). According to recent data, up to 50 million persons in the United States are affected by allergies each year, including more than 31 million who suffer from asthma, of whom more than 9 million are children (Weiss, 2001). Seasonal allergies are estimated to have increased by more than 30% since 1985, childhood peanut allergies doubled in prevalence between 1997 and 2002, and asthma has increased from 35 cases per 1000 in 1982 to 56 cases per 1000 in 1994. Similar to many large categories of disease, estimates of the total yearly cost of allergic diseases run to the tens of billions of dollars. Simply stated, allergic diseases are a major public health concern.

Recent attempts to explain the increased prevalence of allergic diseases have focused on both genetic and environmental causes. Although it is clear that a host of genetic polymorphisms contribute to the development of allergic diseases (see later), genetic influences fail to account for the rapid changes in disease prevalence noted previously. Current theories emphasize the role of environmental influences in the changing prevalence of allergic disease. Several investigators have suggested that diminished exposure to microorganisms during early childhood in developed countries leads to aberrant development of the adaptive immune system and predisposes to both allergic disease and certain autoimmune diseases (Smits, 2005). This theory, called the Hygiene Hypothesis, postulates that early exposure to certain bacteria and parasites promotes development of mature dendritic cells and regulatory T cells, whereas diminished exposure leads to high levels of Th1 and Th2 effector T cells that participate in the

pathogenesis of immune-mediated disease (see later). The proposed mechanism for the beneficial effect of exposure to bacteria, parasites, and even pets includes enhanced release of antiinflammatory cytokines interleukin (IL)-10 and transforming growth factor- β by dendritic cells, which induce antigen-specific regulatory T cells. This effect is postulated to be mediated by interactions between bacterial products (e.g., bacterial endotoxin, Toll-like receptors [TLR2 and TLR4]) and cells of the innate immune system, including dendritic cells, monocytes, and macrophages. Large-scale longitudinal studies are under way at several centers to investigate the epidemiology of allergic disease development and to validate aspects of the hygiene hypothesis.

At the clinical level, it has been well documented that the signs and symptoms of allergic diseases can be difficult to distinguish from those of other disorders (Host, 2003). Clinical manifestations may be relatively mild and self-limited, as in seasonal allergic rhinitis, or severe with marked morbidity, as in asthma. Laboratory tests are useful in the evaluation of patients with allergic disease, but knowledge of the basic mechanisms of immediate hypersensitivity and awareness of the empirical relationships between test results and their diagnostic predictive values are needed to optimize testing. This chapter addresses these subjects, beginning with a review of the biological mechanisms of immediate hypersensitivity and the "allergic phenotype," and proceeding to a detailed discussion of laboratory tests applied to the diagnostic evaluation of children and adults with allergic disease. Consideration is given to the chemical nature of common allergens. The distinction between sensitization and allergy is emphasized. Emphasis is also placed on identifying the minimum numbers of tests needed to achieve high positive and negative predictive values for allergic disease in different clinical situations. Clinical applications are identified in which laboratory testing is not cost-effective or may lead to erroneous clinical conclusions. Finally, new directions in the laboratory evaluation of allergic diseases are discussed, including testing for antibodies by microarray methods and testing for antibodies to purified native proteins and recombinant allergen components.

PATHOGENESIS OF ALLERGIC DISEASE

MECHANISMS OF IMMEDIATE HYPERSENSITIVITY

Immunoglobulin E is the most important trigger molecule for allergic inflammation. In the late 1960s, investigators working independently in two laboratories described a new class of human immunoglobulin that was responsible for the skin-sensitizing activity of serum from patients with allergic diseases (Ishizaka, 1966; Bennich, 1969). This immunoglobulin, originally called IgND, was later named IgE (Ishizaka, 1967). In the years that followed, investigators have focused on discovering the basic biological mechanisms of immediate hypersensitivity, including mechanisms that control IgE production by immunocompetent B lymphocytes, and that promote the recruitment of inflammatory cells and the release of vasoactive mediators from IgE-sensitized effector cells at sites of allergic inflammation. Recent studies have focused on investigating genetic determinants of the allergic (atopic) phenotype and on identifying the genes responsible for regulating IgE production.

THE ALLERGIC (ATOPIC) PHENOTYPE: GENETIC INFLUENCES AND CANDIDATE GENES

It is well known that the likelihood of developing allergic disease is strongly influenced by family history (Sibbald, 1980; Taylor, 1981). Genetically predisposed individuals are often called atopic, a synonym for the clinical allergic phenotype. The results of genetic epidemiologic studies suggest that serum levels of IgE are influenced by several genes, and clinical studies have shown that the levels of IgE protein in serum are several times greater for high IgE phenotypes (Martinez, 1994). At the structural level, a number of candidate genes have been identified that may act to determine the allergic phenotype, but the results are controversial and vary according to the populations studied (Ono, 2000; Sadeghnejad, 2009). Population-wide linkage analysis studies have identified the chromosomal locations of several candidate genes, and positional cloning studies support the relationship of putative allergy genes to known genes for molecules involved in regulating the immune response, including the human leukocyte antigens HLA-DRB1 and DQB1 (chromosome 6p21), the α -chain of the high

TABLE 54-1

Genes and the Allergic Phenotype

Chromosome	Genetic locus	Phenotype
6p21-23	HLA D region (HLA-DRB1 and DQB1)	Responder or nonresponder to common allergens
11q13	Fc ϵ receptor β -chain	Enhanced responsiveness to aeroallergens; high total serum immunoglobulin (Ig)E
5q31	Cytokines interleukin (IL)-3, IL-4, IL-5, IL-9, and IL-13; β -adrenergic receptor	High total serum IgE; enhanced airway responsiveness
16	IL-4 receptor	High total serum IgE
20p13	ADAM33 gene	Enhanced airway responsiveness, airway remodeling

HLA, Human leukocyte antigen.

Note: More than 120 candidate genes have been described to be associated with allergic disease. This table lists a selected sample of genes found in multiple studies.

affinity IgE Fc receptor (chromosome 11q), several cytokines including IL-4 and IL-13 and cytokine receptors (chromosome 5q31), the IL-4 receptor α -gene, and tyrosine kinases and nuclear transcription factors (Table 54-1) (Ono, 2000; Pykalainen, 2005).

Among the various candidate genes, some of the strongest evidence for a role in allergic disease is seen for genes of the major histocompatibility complex. Class II HLA alleles on chromosome 6p determine responsiveness to the common aeroallergens Derp p and Derp f peptides from dust mites (*Dermatophagoides pterynissinus* and *Dermatophagoides farinae*) and are found in linkage with other loci associated with bronchial hyperresponsiveness in asthmatic individuals (Hizawa, 1998; Lara-Marquez, 1999). A similar linkage has been proposed for an atopy gene that is closely linked to the IgE Fc receptor α -chain locus on chromosome 11q. This putative atopy gene has been described in several studies, including a study of African American families with asthma and enhanced responsiveness to *D. farinae* and grass pollen allergens (Sandford, 1995). Studies of the regulation of IgE synthesis have shown that the cytokines IL-4 and IL-13 induce IgE synthesis by B lymphocytes and promote the differentiation of helper/inducer T cells of the Th2 phenotype (see later). The cytokine gene cluster that includes IL-4 is found on chromosome 5q in linkage with a locus that influences IgE responses to several aeroallergens (Ober, 1998). Other loci that may play a role in the allergic phenotype include the gene encoding the IL-4 receptor α -chain (chromosome 16). This gene has been found to contain mutations that influence signal transduction by the transcription factor signal transducer and activator of transcription 6 (STAT6) (see later), which in turn promotes transcription of ϵ -immunoglobulin heavy chains (Hershey, 1997; Pykalainen, 2005).

A host of other genes have been implicated in genome-wide linkage studies of asthma, including genes associated with transmembrane proteins involved in cell migration, cell adhesion, and transmembrane signaling (Sadeghnejad, 2009). These genes influence asthma susceptibility and severity, and may play a role in airway remodeling.

REGULATION OF IgE SYNTHESIS: MOLECULAR AND CELLULAR INTERACTIONS

As noted previously, class II genes of the HLA D region strongly influence individual responses to exogenous antigens (Pieters, 2000; Wang, 2002). Gene products of the highly polymorphic HLA D region; DR, DQ, and DP molecules expressed on the plasma membranes of antigen-presenting dendritic cells; and B cells bind antigen for processing and presentation to immunocompetent T cells, thus initiating the immune response (Wang, 2002). The cellular and humoral immune responses that follow are determined by a complex interplay of cellular interactions involving both cell-to-cell contacts and secretion of stimulatory (and inhibitory) cytokines. Production of mature IgE antibodies by B lymphocytes exemplifies these mechanisms (Fig. 54-1). Initially, all B lymphocytes produce IgM

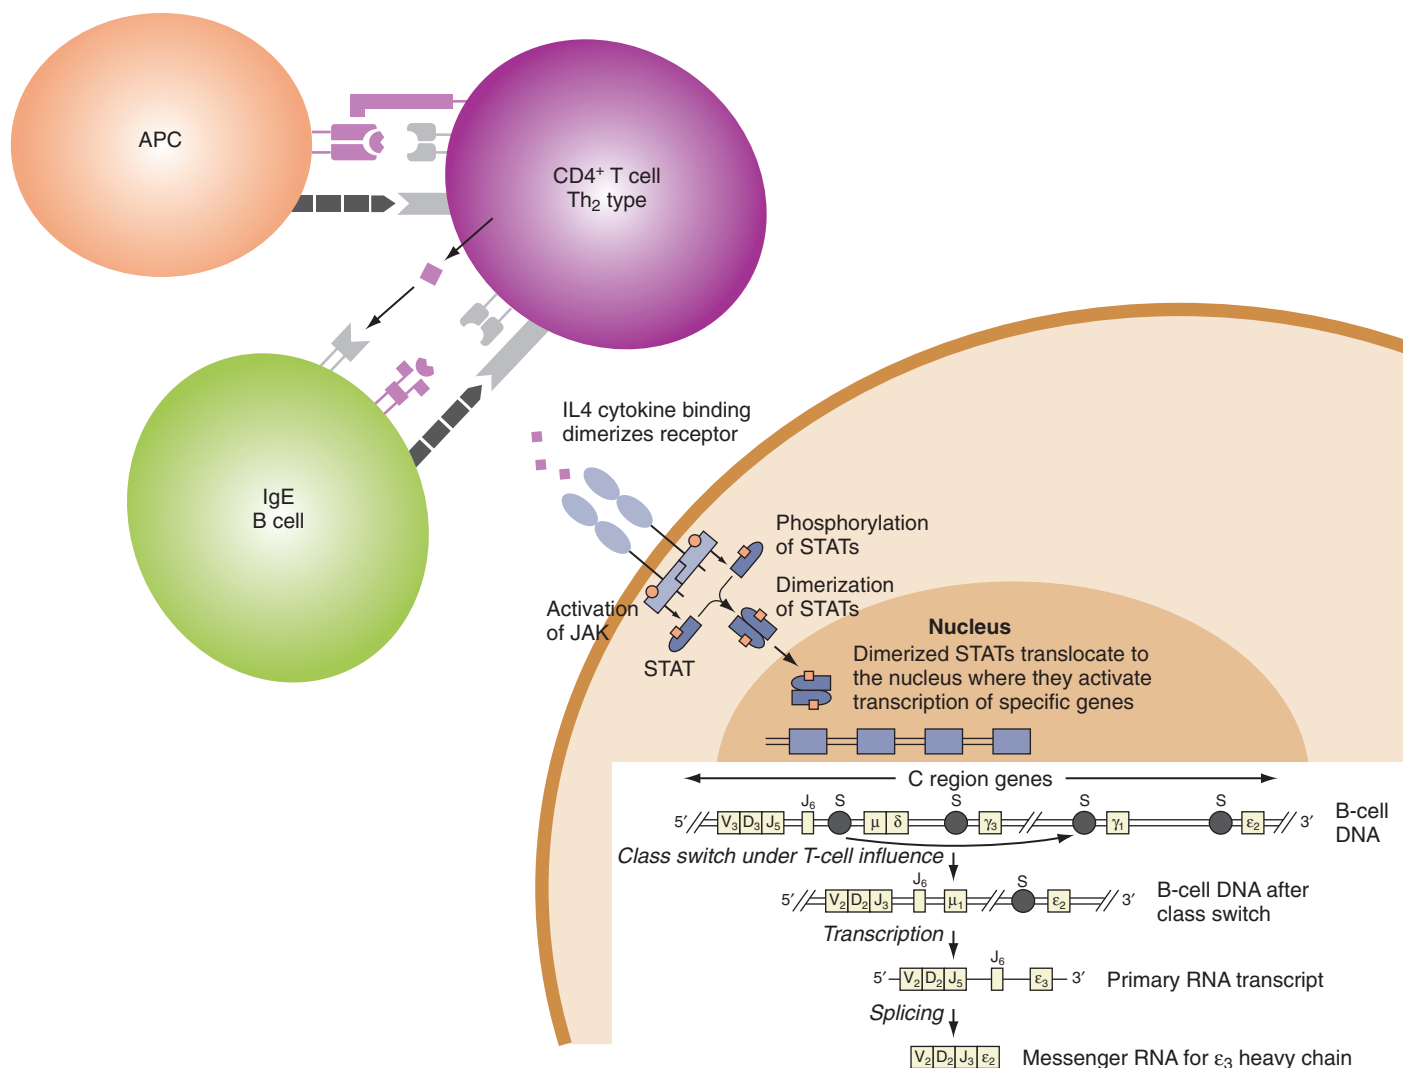

Figure 54-1 Cellular and molecular interactions regulating immunoglobulin (Ig)E synthesis.

antibodies. Antigen specificity is determined by rearrangement of V, D, and J exons that encode portions of the Ig variable region to create a variable region motif (VDJ) that encodes the antigen binding (Fab) portion of a mature Ig heavy chain. The rearranged VDJ motif is upstream from exons that encode the constant regions of the various Ig heavy chains, including the α -, γ -, and ϵ -exons. Production of mature transcripts for complete Ig molecules that bear these heavy chains requires additional rearrangements at the heavy chain (IgH) locus. These rearrangements result in a change in expression of heavy chain constant region domains from μ to another isotype (e.g., γ). This process is referred to as deletional switch recombination, because exons encoding domains of the μ -chain are excised by endonucleases in an irreversible process (Coico, 2003; Vercelli, 2009).

Synthesis of mature IgE molecules occurs in a series of steps that begin with expression of germline (sterile) transcripts of the ϵ heavy chain. Germline transcription must occur before deletional switch recombination can be completed. At the molecular level, this process involves interaction with a promoter exon upstream from the four exons that encode domains of the ϵ heavy chain (see later) (see Fig. 54-1). The ϵ -promoter contains binding sites for several transcription factors, including STAT6 and nuclear factor kappa B (NF- κ B), which drive transcription by activating the promoter. Mutations at binding sites for these transcription factors block isotype switching to IgE. Because germline transcripts are “sterile” and do not encode a functional heavy chain, further metabolism of the germline transcript by endonucleases is required to create a functional heavy chain molecule. Endonucleases excise $C\mu$ and ligate the now adjacent VDJ and $C\epsilon$ sequences. The process of deletional switch recombination involves rearrangement of double-stranded DNA at specific sites called S regions by enzymatically catalyzed breakage, cleavage, and recombination of DNA to create the functional heavy chain.

At the cellular level, IgE synthesis is initiated by cell-to-cell interactions and is driven by soluble cytokine mediators (Oettgen, 2001; Vercelli, 2009). Cytokines produced by T helper/inducer cells of the Th2 phenotype are required for the production of IgE heavy chain transcripts (Vercelli, 2009). This process is described by a two-signal model. The first signal for synthesis of IgE is provided by the cytokines IL-4 and IL-13. Th2 cells produce several cytokines that act as growth factors for B lymphocytes, including IL-4 and IL-13, which have been shown to induce production of germline ϵ -transcripts in human B lymphocytes (Vercelli, 1989; Defrance, 1994). These cytokines exert their effects by interacting with multimeric cell surface receptors. The receptors for IL-4 and IL-13 share a common, ligand-binding α -chain and a common transmembrane β -chain that participates in signal transduction (Palmer-Crocker, 1996). Binding of IL-4 and IL-13 to their receptors induces a series of phosphorylation reactions, which result in DNA transcription driven by phosphorylated transcription factors. Tyrosine kinases of the Janus family (JAK1, 2, and 3) are associated with intracellular domains of the IL-4 and IL-13 receptors and catalyze phosphorylation of the receptors, thus enabling them to bind intracellular transcription factors. The transcription factors, including STAT6 and NF- κ B, in turn are phosphorylated, dimerize, and translocate to the nucleus, where they bind to the ϵ -promoter and induce expression of germline ϵ -transcripts (Oettgen, 2001; Vercelli, 2009).

Coincident with the interaction of antigen-presenting cells and T lymphocytes described earlier, which takes place through the T cell antigen receptor (TCR) and leads to production of IL-4 and IL-13, a second signal provided by cell-to-cell interaction is required to promote switch recombination from μ to ϵ heavy chain expression by B lymphocytes (Vercelli, 2009). This signal is provided by the interaction of CD40 and CD40 ligand (CD154). Engagement of the TCR results in upregulation of CD40 ligand on the T cell surface. CD40 ligand interacts with CD40 on the surface of

TABLE 54-2

Physicochemical Properties of Immunoglobulin E (IgE)

B lymphocytes to catalyze activation of NF- κ B, which, in turn, facilitates activation of the ϵ -promoter through STAT6 and other activation-induced proteins (Oettgen, 2001; Vercelli, 2009). CD40 is a member of the tumor necrosis factor receptor superfamily, and engagement of CD40 by CD40 ligand antagonizes apoptosis of B cells. The importance of CD40 ligand (CD154) to the process of class switching is illustrated by some patients with X-linked hyper-IgM syndrome who are deficient in CD40 ligand and are unable to produce IgG, IgA, or IgE antibodies (Korthauer, 1993).

IMMUNOGLOBULIN E: STRUCTURAL AND FUNCTIONAL CHARACTERISTICS

The first demonstration that human IgE antibodies possess reaginic (skin sensitizing) activity and are different structurally from other immunoglobulins was put forth by the Ishizakas (Ishizaka, 1966). These investigators raised rabbit antisera to a reagin-rich immunoglobulin fraction isolated from the serum of an atopic patient. After absorption with purified immunoglobulins of all known isotypes (IgG, IgA, IgM, and IgD), the antiserum still reacted with γ_1 -globulin present in the serum of allergic patients. After immunoprecipitation with this antiserum, the skin-sensitizing activity of serum from different atopic patients was abolished. Conclusive evidence of the immunochemical uniqueness and reaginic activity of IgE was obtained somewhat later, when it was discovered that human myeloma proteins reacted with the previously mentioned antiserum (Bennich, 1969). Experiments performed with isolated immunoglobulin fragments (Fab and Fab $_2$ fragments) prepared by enzymatic digestion of IgE myeloma proteins demonstrated conclusively that skin-sensitizing activity required an intact Fc ϵ -region, and that the antigenic determinants unique to IgE molecules were contained on the Fc ϵ -fragment (Bennich, 1969). The physicochemical properties and immunologic functions of different regions of the IgE molecule, as determined by experiments performed with purified human IgE myeloma proteins and immunoglobulin fragments prepared by enzymatic digestion, are summarized in Table 54-2 (reviewed in CLSI, 2009). Human IgE protein makes up only approximately 0.0005% of serum immunoglobulin and is catabolized at a rate of greater than 70% per day (the half-life of IgE in blood is 1 to 5 days). Individual IgE molecules have a functional valency of 2, as shown schematically in Figure 54-2.

Human IgE antibodies sensitize effector cells in the skin to release histamine—a phenomenon referred to as passive cutaneous anaphylaxis. The skin-sensitizing activity of IgE is heat-labile and requires an intact Fc fragment. Heating at 56°C for 2 hours irreversibly modifies the C ϵ 3 and C ϵ 4 domains of the IgE molecule and abolishes skin-sensitizing activity (Ishizaka, 1967). Binding to effector cells is also abolished by reduction and alkylation of inter- ϵ -chain disulfide bonds. Aggregated human IgE does not fix complement by the classical pathway, and no significant placental transfer of human IgE occurs.

CELLS AND MEDIATORS OF IMMEDIATE HYPERSENSITIVITY REACTIONS

Mast cells are the principal effector cells of immediate hypersensitivity reactions, although other cell types, including eosinophils, basophils,

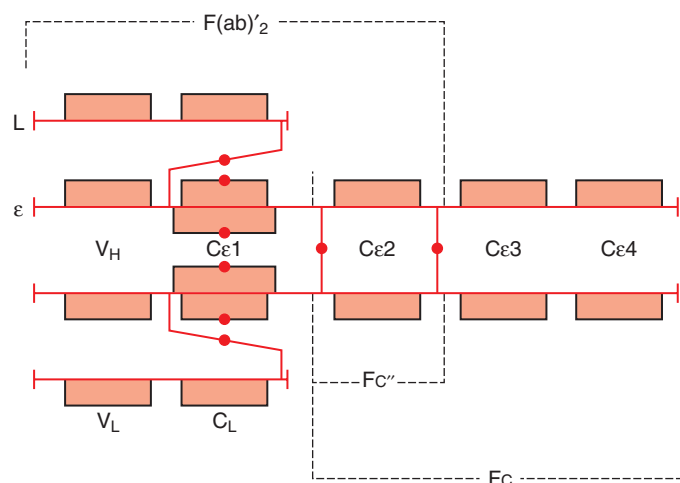

Figure 54-2 Immunoglobulin (Ig)E structure.

neutrophils, and lymphocytes, are involved in promoting and sustaining allergic inflammation (Church, 2003, reviewed in Barnes, 2009). Mast cells and basophils were once thought to be closely related cell types because both stain metachromatically with basic dyes and contain histamine in pre-formed granules. More recent evidence suggests that basophils are derived from granulocyte precursors, whereas mast cells are derived from mononuclear cell precursors and bear receptors for stem cell factor (Galli, 1990). Basophils develop in the bone marrow and enter the circulation as mature cells. Mast cells originate in the bone marrow as CD34+, protein tyrosine kinase Kit (CD117)+ progenitors and home to the tissues by binding to integrin and vascular cell adhesion molecule 1. Once located in the tissues, mast cell progenitors under the influence of the Kit ligand, stem cell factor, develop into mature cells. Two types of mast cells can be identified: Mast cells that predominate at mucosal surfaces require stem cell factor and T cell cytokines for development (IL-3, -4, -5, and -9); mast cells that develop in submucosal connective tissues require only stem cell factor and develop without cytokines from T cells.

Mast cells and basophils both contain histamine in pre-formed granules, but mast cells typically contain up to 10 times more histamine per cell than basophils. Two phenotypically distinct populations of mast cells have been identified and are termed MCt and MCtc, based on their content of tryptase (MCt) and tryptase and chymase (MCtc), respectively. MCt cells are found at mucosal surfaces at sites of allergic inflammation, often in proximity to T lymphocytes, whereas MCtc cells are more numerous in submucosal sites and in connective tissues and are not associated with allergic inflammation or T lymphocytic infiltration (Irani, 1986; Barnes, 2009). Mast cells are most numerous in the following tissues: lung (alveolar walls and bronchial epithelium and subepithelium), small intestine (epithelium and subepithelium), nasal mucosa, and skin. In all these locations, MCt cells predominate over MCtc cells.

Mast cells are the source of several important inflammatory mediators contained in pre-formed granules and are synthesized and released in response to signals associated with allergic inflammation (see later). The principal pre-formed mediators in mast cell granules are histamine, tryptase, chondroitin sulfates (proteoglycans), and tumor necrosis factor (TNF)- α . Newly generated inflammatory mediators include cyclooxygenase (prostaglandin) and lipoxygenase (leukotriene) products of arachidonic acid metabolism. In addition to these newly formed eicosanoid mediators, which are released within minutes of an allergic trigger, other cytokines and chemokine mediators are synthesized and released within hours of initiation of inflammation.

The primary mechanism of release of pre-formed mediators from mast cells involves transmembrane signaling mediated by cell surface (homocytotropic) IgE antibodies bound to high-affinity receptors for IgE (Fc ϵ RI) located diffusely on the plasma membranes of effector cells. Binding of IgE antibodies to Fc ϵ RI is reversible but of very high affinity ($K_a = 10^{10} \text{ M}^{-1}$) (Wank, 1983). Although IgE antibodies in blood have a half-life of less than 5 days, the half-life of IgE antibodies bound to Fc ϵ RI on mast cells is estimated to be more than 10 days. The number of receptors per cell ranges from 40,000 to 500,000. Higher numbers of receptors are found on cells cultured in the presence of IgE, possibly reflecting upregulation of Fc ϵ RI expression by IgE. Fc ϵ RI is a multimetric receptor, composed of α -, β -, and γ -subunits as follows: α 1, β 1, and γ 2. IgE

Figure 54-3 Metabolism of arachidonic acid. COX, Cyclooxygenase; FLAP, 5-lipoxygenase-activating protein; 5-LO, 5-lipoxygenase; LT, leukotriene; PG, prostaglandin; TX, thromboxane.

antibodies are bound by the α -subunit; the β - and γ -subunits contain intracytoplasmic regions that function in transmembrane signaling (Ravetch, 1991; Metcalfe, 2009). Fc ϵ RI molecules are mobile within the plasma membranes of sensitized cells, as indicated by capping studies performed with fluorescein-conjugated anti-IgE antibodies. This mobility over short distances is believed to be important for the release of mediators from mast cells. Extensive studies with mast cells sensitized in vitro with IgE myeloma proteins or with intact allergen-specific IgE antibodies have shown that cross-linking (or bridging) of occupied IgE receptors by multivalent antigens or by intact anti-IgE antibodies or their F(ab')₂ fragments triggers release of histamine and other pre-formed mediators and initiates the synthesis and release of prostaglandin and leukotriene mediators. Univalent allergens, including haptens and Fab fragments of anti-IgE antibodies, do not promote mediator release.

The process of mediator release from sensitized mast cells is exquisitely sensitive and is dependent upon release of Ca^{++} from intracellular stores in the endoplasmic reticulum and influx of extracellular Ca^{++} . Aggregation of as few as 1000 molecules of IgE per cell can result in release of histamine and other mediators. Transmembrane signaling mediated by Fc ϵ RI aggregation is a complex process that is dependent upon phosphorylation of receptor subunit proteins by enzymes of the Src family. These phosphorylation steps in turn lead to phosphorylation of membrane phospholipids, including inositol triphosphate, which binds to receptors on membranes of the endoplasmic reticulum, resulting in release of stored Ca^{++} . Degranulation with release of pre-formed mediators is accomplished by a process of exocytosis. Receptor aggregation by allergen also leads to methylation of membrane phospholipids, followed by activation of adenylate cyclase, a transient increase in intracellular cyclic adenosine monophosphate (cAMP), and influx of extracellular Ca^{++} ions, which promotes fusion of granule and cell membranes during exocytosis. Increased intracellular Ca^{++} also activates cytosolic phospholipase A₂, which promotes synthesis of arachidonic acid derived from membrane lipids. Free arachidonic acid is metabolized in mast cells to prostaglandin (PG)D₂ by enzymes of the cyclooxygenase (COX) pathway (COX-2, PG synthase, and isomerase), and to the cysteinyl leukotrienes LTB₄, LTC₄, LTD₄, and LTE₄ by enzymes of the 5-lipoxygenase pathway (Church, 2003; Metcalfe, 2009) (Fig. 54-3).

Histamine is the best known mediator of allergic inflammation. Injected intradermally, histamine produces a characteristic wheal and flare reaction that results from simultaneous vasoconstriction of postcapillary venules and neurogenic erythema (Petersen, 1997). Histamine in mast cells is contained in pre-formed granules with approximately 3–8 pg of histamine per cell. After release from mast cells, histamine interacts with specific G-protein-coupled receptors termed H1–H4 (Wess, 1997; Gether, 2000; Church, 2003). Engagement of the H1 histamine receptor leads to activation of phospholipase C with subsequent protein kinase C activation and Ca^{++} mobilization that causes the cellular responses associated with allergic inflammation. The effects of histamine are mediated by different receptors in different tissues. H1 receptors in the airway promote contraction of bronchial smooth muscle and mucous production, and H2 receptors in the stomach promote acid secretion. H3 and H4 receptors are found on histaminergic nerves and bone marrow cells, respectively. Histamine is degraded by two enzymatic pathways, with the major metabolite, N-methyl imidazole acetic acid (MIAA) resulting from sequential methylation and deamination of histamine by the enzymes histamine N-methyl transferase

and monoamine oxidase. Most secreted histamine is excreted in the urine as MIAA, with small amounts appearing un-degraded.

The most abundant proteins in mast cell granules are neutral proteases, including trypsin and chymase. As noted previously, mast cells are characterized by their content of these two proteases. MCt cells predominate at epithelial surfaces in mucosa of the gut and airway, and MCtc cells are found in submucosal connective tissues of the skin and gut. Human mast cell trypsin is a tetramer comprising 29–40 kDa subunits with a molecular mass of approximately 134kDa (Schwartz, 1981). Two cDNA subunits of trypsin termed α and β have been cloned from human mast cells and bear approximately 90% sequence homology with one another (Miller, 1990). Most trypsin in human serum occurs in the form of α - and β -monomers and is believed to be released constitutively from mast cells. β -Trypsin is stored in secretory granules as a noncovalent complex with the proteoglycan heparin and is released upon cellular activation associated with allergic inflammation. Consequently, trypsin in serum provides an estimate of mast cell mass, and β -trypsin is a marker of mast cell activation and release of mediators resulting from allergic inflammation, including anaphylaxis (Schwartz, 1987). The half-life of trypsin in circulation is approximately 90 minutes (Schwartz, 1989). In addition to exhibiting enzymatic activity, trypsin promotes growth of fibroblasts and smooth muscle cells, activates mast cells, and promotes release of the chemoattractant IL-8 from epithelial cells (Cairns, 1996).

Newly synthesized prostaglandins and leukotrienes are important pro-inflammatory allergic mediators. The principal prostaglandin mediator of mast cells is PGD₂ (see Fig. 54-3), which is much more potent than histamine on a molar basis but is released in smaller quantities than histamine by activated mast cells (Church, 2003). PGD₂ and its metabolite, 9 α ,11 β PGF₂, promote constriction of airway smooth muscle, peripheral vasodilation, and inhibition of platelet aggregation. IgE-mediated mast cell activation also results in synthesis and release of the cysteinyl leukotrienes LTC₄, LTD₄, and LTE₄ (see Fig. 54-3). These molecules are extremely potent bronchoconstrictors, up to 1000 times more potent than histamine, and they promote increased vascular permeability and mucous production. In the early allergy literature, the leukotrienes were referred to as slow-reacting substance of anaphylaxis (SRS-A). Their role in the asthmatic response is demonstrated by clinical trials that show effective elimination of much of the early asthmatic response to allergen by administration of leukotriene antagonists (Findlay, 1992).

Allergic inflammation often proceeds in two stages: an immediate response to allergen contact that occurs within minutes, followed by a late reaction that occurs up to 24 hours following allergen exposure. This biphasic response occurs commonly in asthma. Both stages of the allergic response depend on the presence and engagement of cell-bound IgE antibodies. The initial response reflects the effects of histamine, prostaglandin, and leukotriene mediators. The late response is caused by the recruitment of inflammatory cells, including eosinophils and neutrophils, at sites of allergic inflammation, followed by release of mediators from these activated cells. This late response is facilitated by the release of cytokines and chemoattractants from activated mast cells that promote the infiltration and degranulation of inflammatory leukocytes.

LABORATORY TESTING IN THE EVALUATION OF ALLERGIC DISEASES

THE RATIONALE FOR TESTING

Laboratory tests for allergic diseases have been available for longer than 30 years (Wide, 1967). Immunoassays for total IgE protein (IgE) and allergen-specific IgE antibodies (IgE antibodies) in serum have been the mainstays. During most of this time, there has been only modest interest in performing a full repertoire of IgE antibody tests onsite in hospital clinical laboratories, and many institutions have elected to send specimens to referral laboratories for testing. More recently, the use of laboratory tests in the evaluation of patients with allergic diseases has been driven by changes in the logistics of health care delivery, including the nearly universal adoption of managed care health plans. Other important developments favoring the use of laboratory tests in patients with allergic disease include the introduction of new therapeutic drugs for the treatment of allergic diseases, significant improvements in the analytic methods used for measuring IgE antibodies, better characterization of several classes of allergens, and improved knowledge of the natural history of development of allergic diseases, especially in children. Before the era of managed care, it was often possible for patients with symptoms and signs of allergy to be

TABLE 54-3

Protein Allergen Families

Protein family	Sensitivity to heat and proteases	Examples of plant food allergen sources	Clinical expression
PR-10 proteins (Bet v 1 homologues)	Sensitive*	Betulaceae: hazelnut* Rosaceae: e.g., apple, cherry, peach Apiaceae: e.g., carrot, celery,* fennel, parsley Fabaceae: e.g., peanut,* soybean,* mungbean	Oral allergy syndrome (OAS)
nsLTPs (nonspecific lipid transfer proteins)	Stable	Betulaceae: hazelnut Rosaceae: e.g., apple, cherry, peach Other: maize, peanut, barley, grape, cabbage	Systemic reactions common
Profilins (Bet v 2 homologues)	Sensitive	Profilins are widely distributed in plants. Typically: citrus fruits, melon, banana, tomato	Mainly OAS
Storage proteins (2S albumins, 7S/11S globulins)	Stable	Kennels/nuts/seeds: e.g., peanut/soybean, tree nuts, seeds, cereals	Systemic reactions common
CCDs (cross-reactive carbohydrate determinants)	Stable	CCDs are widely distributed in plant food. CCD allergenicity has been proposed for celery, tomato, and zucchini.	†

PR-120 proteins, Pathogenesis-related family 10 proteins from plants.

*Bet v 1 homologues in hazelnut, celery, peanut, and soybean have been found to be partially heat stable, and systemic reactions may occur.

†Immunoglobulin (Ig)E antibodies to profilins and CCDs in general are considered to have less clinical relevance than those to other allergen components.

seen by an allergy specialist without prior medical evaluation. This is no longer the case for most patients, who are evaluated initially by primary care physicians. In this paradigm, laboratory tests that establish a high likelihood of allergic disease assume increased importance, in that the results may justify referrals to allergy specialists and may enable primary care physicians to decide whether or not to manage patients within their own practices. New treatments for allergic diseases such as therapeutic monoclonal anti-IgE antibodies require demonstration of an elevated IgE level or the presence of allergen-specific IgE antibodies in serum as justification for their use (Soler, 2001; Lanier, 2003). Significant improvements have also been made to the analytic methods used for measuring IgE antibodies. As detailed later, the current generation of test methods bears little resemblance to the original tests introduced shortly after the discovery of IgE. Finally, and perhaps most important, clinical investigations of the natural history of allergic diseases in children have shown a reproducible sequence of sensitization to allergens that makes it increasingly important to establish the diagnosis of allergy at an early age to ameliorate progression to serious diseases such as asthma (Wahn, 2000).

In the field of clinical allergy, tests for IgE and IgE antibodies are ordered principally for diagnosis. In addition, test results may have prognostic significance for persistent allergy and may serve as a guide to specific therapies such as allergen avoidance or immunotherapy. The results of clinical studies are less clear about the role of laboratory data in evaluating the response to immunotherapy and in monitoring the course of disease. Ultimately, the medical usefulness of diagnostic test results is determined empirically by whether or not it is difficult to establish an accurate diagnosis on clinical grounds, and by studies of clinical outcomes that may justify trials of drug therapy without a specific etiologic diagnosis (so-called empirical therapy) (Gendo, 2004). Nevertheless, in many clinical situations, definitive management of allergic diseases requires that the offending allergens be identified unequivocally. For example, it is necessary to define allergen specificity in cases of anaphylactic sensitivity to foods, drugs, and insect venom allergens, in patients in whom allergen immunotherapy is indicated as treatment, and in patients who must practice rigorous allergen avoidance, as in occupational allergies or sensitivity to natural rubber latex.

ALLERGEN MOLECULES: STRUCTURE AND CROSS-REACTIVITY

Recent studies of common allergens have focused attention on the molecular basis of allergenicity and on the chemical properties of many important allergens (Kazemi-Shirazi, 2000; Shakib, 2008). Allergen proteins often have structural features that facilitate their recognition and binding by cells of the innate immune system and, in some cases, directly promote the synthesis of IgE antibodies by the adaptive immune system (Shakib, 2008). An example is Der p 1 antigen of the dust mite, *Dermatophagoides pteronyssinus*. *D. pteronyssinus* sensitivity is important in the pathogenesis of allergic asthma (see later), and Der p 1 has several properties that enhance its

allergenicity. Der p 1 is a cysteine protease that acts in the airway to degrade protective surfactant molecules and α_1 -antitrypsin, which normally offer a barrier to inhaled allergens. In addition, Der p 1 directly promotes mast cell degranulation and increased secretion of IL-4, and may act to inhibit the development of Treg cells that dampen the Th2-driven response to Der p 1 antigen exposure. Many other allergens also have intrinsic enzymatic activity or structural features that promote their allergenicity. Such intrinsic molecular features include patterns of glycosylation. An example is the storage glycoprotein Ara h 1 from peanut, which binds to cell surface receptors on dendritic cells and may promote synthesis of IL-4 and IL-13 by Th2 cells.

Knowledge of the chemical structure of allergens has been greatly facilitated in recent years by the study of recombinant allergen molecules (Kazemi-Shirazi, 2000). Recombinant protein technology has also fostered the development of a new generation of diagnostic reagents for measurement of IgE antibodies (see later) and has enhanced understanding of cross-reactivity between different classes of allergens. Studies of pollen and food allergens have focused on several classes of protein molecules, including pathogenesis-related family 10 proteins from plants (PR-10 proteins); nonspecific lipid transfer proteins from foods (LTPs); profilin proteins from foods; 2S albumin, 7S globulin, and 11S globulin storage proteins from foods; and cross-reactive carbohydrate determinants (CCDs) from glycoproteins in pollens and plants. The properties of these protein families are summarized in Table 54-3. Cross-reactive proteins from the PR-10 and profilin families are referred to as panallergens, reflecting the fact that these proteins are widely conserved in different plant species. Sensitization to panallergen proteins accounts for the presence in some allergic sera of IgE antibodies that are widely cross-reactive between seemingly unrelated allergens of common pollens and foods.

IN VIVO TEST TECHNIQUES: SKIN TESTS AND END-ORGAN CHALLENGE TESTS

It is not possible to discuss the use of laboratory tests in the diagnosis and management of allergic diseases without mentioning in vivo tests of immediate hypersensitivity, particularly the skin test and end-organ challenge tests. In vivo tests are regarded by many allergy specialists in the United States as the standards of diagnostic accuracy and reliability. The ability to reproduce a specific allergic reaction by in vivo challenge is considered the most sensitive technique for demonstrating the presence of immediate hypersensitivity and for defining its allergen specificity.

Skins tests are performed by skin prick and intradermal injection methods (Demoly, 1998). The response to intradermal injection of an allergen extract is graded by measuring the diameter of the wheal and erythema reaction immediately following the injection. A 1+ reaction corresponds to a 5–10-mm wheal. A response of this magnitude is usually considered as evidence of specific sensitivity to an allergen. Highly sensitive individuals may develop wheal diameters greater than 15mm with pseudopods. Skin tests performed by the prick method are used by most

TABLE 54-4

Serum Immunoglobulin E (IgE) Reference Ranges in Children and Adults

Age	Mean (kU/L)	+1 SD (kU/L)
6 weeks	0.6	2.3
3 months	1.0	4.1
6 months	1.8	7.3
9 months	2.6	10
12 months	3.2	13
2 years	5.7	23
3 years	8.0	32
4 years	10	40
5 years	12	48
6 years	14	56
7 years	16	63
8 years	18	71
9 years	20	78
10 years	22	85
*Adults	13.2	41

SD, Standard deviation.

*In adults, the mean +2 SD cutoff is 127 kU/L. See text for explanation.

practicing allergists and make use of more concentrated allergen extracts—up to 1000-fold greater concentrations than are used for intradermal testing. Mean wheal diameters in millimeters are recorded as an indication of the degree of sensitivity. A more quantitative estimate of sensitivity to a given allergen can be obtained by the technique of end-point titration. Serial, tenfold dilutions of a standardized allergen extract are used, beginning with the most dilute solution. The endpoint of sensitivity is defined as the greatest dilution that produces a 1+ reaction.

End-organ challenge tests are useful in clinical management and for investigative purposes. Adaptations of challenge techniques include the bronchial provocation test in the diagnosis of asthma; the rhinoconjunctival challenge test in the diagnosis of allergic rhinitis; the double-blind, placebo-controlled food elimination and challenge test in the diagnosis of food allergy; and the sting challenge in the diagnosis of anaphylactic sensitivity to insect venom. The application of challenge tests in routine clinical situations is limited by the requirement for well-standardized allergen extracts of defined potency, and by the limited number of allergens that can be tested in an individual on a single occasion. As an example, food elimination and challenge procedures often require periods of abstinence of several days between introductions of suspected foods. Although generally regarded as the most reliable test for food allergy, the double-blind, placebo-controlled food challenge test is performed by relatively few practicing allergists at a limited number of tertiary care centers.

MEASUREMENT OF IgE: ANALYTIC METHODS AND REFERENCE RANGES

A variety of immunochemical methods have been used to measure IgE, including competitive displacement immunoassays, immunometric (sandwich) assays with radiolabeled and enzyme-labeled second-stage antibodies, and enhanced sensitivity nephelometry (Homburger, 1998; Hamilton, 2009). Nonisotopic immunometric assays are the most widely used methods. A popular commercial immunometric method uses monoclonal anti-IgE antibody bound to a high-capacity cellulose solid phase to capture IgE in a test sample, after which bound IgE is detected with a second enzyme-labeled, monoclonal antibody that generates a fluorescent product. The amount of product is proportional to the amount of IgE captured in the first stage of the assay. Currently available commercial immunoassays for IgE are capable of detecting less than 1 kU/L of IgE and are routinely calibrated to measure concentrations in the range of 2–5000 kU/L (1 kU equals approximately 2.4 micrograms of IgE). Assay calibrators used in commercial products are well standardized between manufacturers and are traceable to an international standard (World Health Organization [WHO] preparation 75/502 for human IgE). Results of interlaboratory proficiency surveys indicate that measurement of IgE is highly reproducible, with interlaboratory coefficients of variation <10% for survey samples with IgE concentrations in the normal range.

A number of studies have examined the serum concentrations of IgE in healthy, nonallergic children and adults. Synthesis of IgE occurs in the human fetus as early as the 11th week of gestation, but cord serum typically contains less than 1 kU/L of IgE (Homburger, 1998). Serum concentrations of IgE in children increase slowly with age and reach adult levels at approximately 10 years of age (Table 54-4). In both children and adults, studies of healthy subjects have yielded frequency histograms of IgE measurements that are strongly positively skewed, with upper 95th percentile confidence intervals that are seemingly very high compared with mean levels of IgE. The distribution of IgE concentrations in allergic subjects overlaps the skewed distribution of results in healthy controls. Many laboratories report reference ranges that are based on logarithmic transformations of skewed distributions, and the upper limits of “normal” are often portrayed as +1 standard deviation (SD) of an age-related, geometric distribution (see Table 54-4). This convention is confusing to many clinicians who are not aware of the skewed histogram of serum IgE concentrations in healthy nonallergic subjects.

MEASUREMENT OF IgE: CLINICAL APPLICATIONS

The measurement of IgE protein in serum has been thoroughly evaluated for its clinical usefulness as a screening test in the diagnosis of various allergic diseases, for its predictive value as an indicator of the likelihood of development of allergic disease in asymptomatic infants and children, and as a prognostic indicator in adults with certain types of chronic allergic

disease. Measurement of IgE may also be useful in the evaluation of patients suspected of having immunodeficiency diseases, parasitic diseases, or the rare hyper-IgE syndrome.

The hyper-IgE syndrome was first described in 1972 by Buckley and colleagues, who reported two patients with greatly elevated serum IgE levels, diffuse dermatitis, recurrent furunculosis, and pneumonia with pneumatoceles secondary to *Staphylococcus aureus* infection. Subsequent reports of patients with this disorder have defined the clinical syndrome: elevations of serum IgE concentration are extreme (2000–50,000 kU/L), and patients have blood and tissue eosinophilia and strongly positive immediate wheal and flare reactions to inhalant allergens, pollens, foods, and bacterial and fungal antigens. Despite these findings, asthma is not common in patients with the hyper-IgE syndrome (Buckley, 1978).

The synthesis of IgE, as reflected by serum levels, has been studied in patients with a variety of primary immunodeficiency diseases. Increased IgE levels have been described in some patients with partial deficiencies of cellular immunity. Immunodeficiency diseases in which there is complete absence of synthesis of immunoglobulins G, A, and M, such as severe combined immunodeficiency disease, characteristically show diminished IgE synthesis and markedly decreased serum IgE levels. Serum IgE levels are variable in patients with IgA deficiency; ataxia telangiectasia patients typically have diminished levels, but patients with isolated IgA deficiency may have normal or modestly increased levels. Allergic disease is not common in patients with immunodeficiency diseases, with the exception of those individuals with selective IgA deficiency, who have elevated levels of serum IgE.

Parasitic infiltration of the gastrointestinal tract or parenchymatous organs stimulates IgE synthesis markedly, and studies in laboratory animals suggest that specific IgE antibodies are important in the host defense against parasites such as *Nippostrongylus brasiliensis* and *Schistosoma mansoni*. Serum IgE concentrations greater than 1000kU/L are regularly found in children in areas of endemic infestation with parasites. Other parasitic diseases known to be associated with increased serum IgE levels include visceral larva migrans (*Toxocara canis*), intestinal capillariasis (*Capillaria philippinensis*), schistosomiasis, ancylostomiasis, and echinococcosis. In patients with intestinal parasitic disease, serum levels of IgE have been noted to decrease considerably following successful treatment with anti-parasitic drugs.

In reviewing the usefulness of the serum IgE level as a diagnostic test for allergic disease, it is appropriate to discuss its use in children and adults separately. Elevated IgE levels in serum at birth or during infancy often antedate the development of clinical allergy (Kjellman, 1984). Serum IgE levels above the 95th percentile limit for age were described in 75% of children with a biparental family history of allergic disease; among healthy children with IgE levels more than 1SD above the mean for a given age, the incidence of development of allergic disease during the following 18 months was increased more than tenfold compared with a group with lower IgE levels. Although predictive of future development of allergic

disease, these data provide relatively little information upon which to base specific clinical decisions.

Measurement of IgE in children is of limited value in the diagnosis of allergic disease. The principal value of IgE measurements in infants appears to be in alerting the physician to the likely possibility of an allergic disease. Serum IgE levels greater than +1 SD in such cases support the diagnosis of an allergic disease, but a normal IgE level does not exclude the diagnosis of allergic disease during infancy or later in life. The results of other diagnostic tests, including tests for IgE antibodies, are more specific (see later). In those clinical situations in which the presenting signs of allergic disease are unequivocal, for example, eczema and rhinitis in a child with an atopic family history, the serum IgE level provides little additional information. The situation is similar in older children and adults. Measurement of IgE in serum has limited diagnostic sensitivity for allergic disease. In general, children with hypersensitivity to several different allergens and multiple allergic diseases have elevated serum IgE levels, and those with hypersensitivity to fewer allergens and limited end-organ involvement often have normal levels. Diagnostic sensitivity is greatest in patients with clinical sensitivity to a number of different allergens. In atopic children, the presence of cutaneous disease and gastrointestinal manifestations increase the likelihood that the serum IgE level will be elevated. Children with allergic diseases that involve several organs tend to have elevations in serum IgE of greater magnitude than those with more limited disease. The diagnostic specificity of an elevated IgE level for allergic disease is excellent.

Measurement of serum IgE is also of modest diagnostic usefulness in most adults suspected of having an allergic disease. Results of clinical studies of adult respiratory allergy indicate that approximately 50% of adults with allergic asthma and fewer than 5% of adults with so-called intrinsic (nonallergic) asthma have elevated serum IgE levels. Asthmatic adults with hypersensitivity to a limited number of allergens usually have normal levels. The highest IgE levels in adults typically occur in those patients with hypersensitivity to several allergens and combinations of asthma, atopic dermatitis, and rhinitis. Just as in children, the limited diagnostic sensitivity of the serum IgE level limits the clinical usefulness of IgE measurements in those situations in which the diagnosis of allergic disease is most uncertain (Klink, 1990). This is not to say, however, that serum IgE should not be measured in such cases, as an elevated concentration carries a high positive predictive value for allergic disease.

Allergic bronchopulmonary aspergillosis is associated with a marked elevation in the serum level of IgE. This disease typically occurs in patients with allergic asthma, generally of long duration. Levels of IgE in serum are elevated during times of acute pulmonary infiltration, but IgE levels may fluctuate considerably during the course of the disease. A normal IgE level in a patient with active lung disease virtually excludes this diagnosis.

MEASUREMENT OF IgE ANTIBODIES: ANALYTIC METHODS AND REPORTING OF RESULTS

Two methods are commonly used to test for IgE antibodies: allergen skin testing by prick or intradermal methods (see previous discussion) and in vitro testing by immunometric assay. A third method involves measuring the release of inflammatory mediators or the expression of activation antigens on the surface of blood basophils exposed to allergens in vitro. Methods that involve blood cells are based on quantitation of histamine or LTC₄ released from basophil leukocytes (leukocyte histamine release methods) or on flow cytometric detection of activation antigens (CD63 or CD203c) on the surface of basophils following exposure to allergen (de Weck, 1993; Nolte, 1993). These methods are commercially available but have not been widely adopted by clinical laboratories in the United States. Cellular assays require that blood samples be tested within 24 hours, and cells from up to 15% of individuals do not release histamine in vitro. Assays that rely on detection of activation markers do not require release of a mediator, but may be subject to false-positive results from IL-3 priming required before exposure to allergen. The results of early clinical studies of commercial cell-based assays indicate relatively poor sensitivity compared with skin tests for several allergens, including foods and insect venoms (Maly, 1997).

Immunometric assays for IgE antibodies were introduced in the late 1960s (Wide, 1967). Original (first-generation) methods utilized immunosorbents prepared by coupling allergens covalently to cyanogen bromide-activated Sephadex, paper disks, or microcrystalline cellulose particles as

capture reagents for IgE antibodies. After incubating with serum, the solid phase was washed with buffer, and radiolabeled, affinity-purified, polyclonal anti-IgE antibody was added as a detection protein. These methods were semiquantitative, with results determined by comparison to an arbitrary dose-response reference curve that measured binding of IgE antibodies in calibrator solutions to a birch pollen immunosorbent. Results were reported in classes from 0 (negative) to 5+ (strongly positive). The original commercial method was referred to by the term radioallergosorbent test (RAST). First-generation tests for IgE antibodies had a number of limitations: The immunosorbents had limited capacity to bind IgE antibodies, which resulted in relatively poor analytic sensitivity; long incubation periods were required; and immunosorbents were susceptible to interference from competing IgG antibodies. In addition, the allergens used to prepare these early immunosorbents were poorly characterized and varied considerably from lot to lot and from manufacturer to manufacturer. These methods are no longer available commercially, and the term RAST should not be used to refer to current methods.

The development of improved (second- and third-generation) commercial methods for IgE antibodies in the 1990s was marked by the ability to measure IgE antibodies quantitatively. This notable advancement was achieved by creating high-capacity allergen immunosorbents that had greatly increased antibody-binding capacity compared with earlier solid-phase reagents (Ewan, 1990). Calibration was based on WHO Reference Preparation 75/502. A different approach to quantification involved binding allergens to biotin, which enabled the use of a common avidin-coupled bead to capture fluid-phase allergen-IgE complexes (Iwamoto, 1990). Food and Drug Administration (FDA)-approved commercial assays based on both types of reagent are currently available. Second-generation and third-generation (automated) methods offer a number of improvements, including enhanced analytic sensitivity with detection of IgE antibodies at concentrations as low as 0.10 kU/L, improved calibration with the ability to measure allergen-specific IgE quantitatively, resistance to interference by IgG antibodies, improved consistency of allergen immunosorbents from lot to lot, and rapid incubation times with results available within 6 hours.

Significant improvements have also been reported in the reagent allergens used to measure IgE antibodies, with better characterization of native allergens and preparation of a number of recombinant proteins from clinically important complex allergens. Recombinant proteins have been described for major allergens of dust mite, cat, and dog; *Alternaria tenuis*; pollen aeroallergens from trees, grasses, and weeds; numerous foods including peanut, tree nuts, wheat, milk, egg, and stone fruits; and natural rubber latex. Some recombinant proteins (e.g., Hev b 5 from *Hevea brasiliensis* 5 [natural rubber latex]) are now used in commercial allergen test reagents and contribute to increased diagnostic sensitivity (Bernstein, 2003). Although much improved over earlier assays, and despite having been approved by the FDA as quantitative methods, the previously mentioned new-generation assays from different manufacturers cannot be assumed to yield equivalent test results in all cases. Assays from different commercial manufacturers may differ in their allergen immunosorbents, and some differences in quantitation of IgE antibodies have been reported (Diagnostic allergy [SE-C] survey, College of American Pathologists, 2006). Clinicians and laboratorians must use caution in comparing test results obtained through different commercial test methods (Hamilton, 2004).

Tests for IgE antibodies have also been adapted to detect several different IgE antibodies simultaneously (so-called multiallergen tests), and a new commercial test of moderate Clinical Laboratory Improvement Act complexity has recently been introduced for point-of-care testing. By coupling several allergens to the same immunosorbent, it is possible to test a single aliquot of serum for the presence of several different antibodies without loss of analytic sensitivity (Ownby, 1984). Multiallergen tests yield qualitative results and enable simultaneous testing for IgE antibodies that occur commonly in atopic children and adults. The diagnostic sensitivity of multiallergen tests exceeds that of other single screening tests for allergy, including measurement of IgE (Ownby, 1984). In addition, multiallergen reagents can be used effectively to test sera for antibodies to several allergens of a common class (e.g. grass pollens or foods), with the use of algorithms in which testing for individual specificities is indicated only if the screening test is positive. The point-of-care test already mentioned uses a disposable cassette and whole blood to measure individual IgE antibodies simultaneously with a panel of common inhalant allergens. Although less sensitive analytically than complex immunometric methods, this test shows promise for use in primary care situations for rapid detection of IgE antibodies to common aeroallergens.

MEASUREMENT OF IgE ANTIBODIES: CLINICAL APPLICATIONS

Current recommendations for clinical use of the IgE antibody test are based on the results of clinical studies in which the sensitivity and predictive values of results of IgE antibody testing were compared with those of other diagnostic tests, including skin tests and challenge tests. Testing for IgE antibodies has certain advantages compared with skin testing. It poses no risk to the patient, and the results are not influenced by concomitant treatment with antihistamines or adrenergic bronchodilators. In addition, IgE antibody testing may be preferable to skin testing in certain groups of patients, such as infants, patients with dermatographism, and patients with widespread dermatitis. Disadvantages have also been noted. Serologic testing is expensive if large numbers of individual tests are ordered indiscriminately, and the results are not available immediately. Recently, the multiallergen IgE antibody test performed with immunosorbents that have more than one allergen coupled to their surface has been shown to be a sensitive and cost-effective screening test for inhalant allergy.

It is difficult to define the absolute diagnostic sensitivity and specificity of IgE antibody results, because there is no universally accepted reference method (gold standard) for defining sensitivity to a given allergen. However, in most clinical studies, the results of IgE antibody tests have been compared with the results of *in vivo* diagnostic tests and allergic disease histories. It is clear from such studies that diagnostic sensitivity varies considerably, depending on the elapsed time between exposure to an allergen and testing, the class of allergen tested, the age of the patient, and the affected target organs. For the purposes of this chapter, it is useful to consider the following clinical applications separately: childhood allergic diseases including food allergy, adult allergic diseases, insect venom sensitivity, and drug and occupational allergies.

Children who are genetically predisposed to develop allergic diseases (atopic children) often develop symptoms and signs of disease in a predictable sequence as they progress throughout childhood. This concept has been called the **allergy march**. In genetically predisposed infants, eczema (atopic dermatitis) is often the first manifestation of allergic disease. Atopic infants and children younger than 3 years of age may also have gastrointestinal symptoms (colic, diarrhea, vomiting, and abdominal pain) or may suffer from chronic otitis. Children younger than 3 years may already suffer from recurrent wheezing. As the atopic child matures, cutaneous and gastrointestinal symptoms often give way to worsening respiratory symptoms with development of allergic rhinitis and asthma. The entire sequence of the allergy march is shown schematically in Figure 54-4.

Regardless of age, the presenting symptoms of allergic disease in children are not specific for immediate hypersensitivity and are easily mistaken for other etiologies. Increasingly, physicians have recognized that empirical therapy for suspected allergic diseases in children is not acceptable because it often results in unnecessary or inappropriate treatment with antihistamines, inhaled or systemic corticosteroids and leukotriene antagonists, and antibiotics. Empirical therapy allows the allergy march to proceed unchecked by missing the opportunity to lessen exposure to offending allergens. Although the results of clinical investigations are not

yet conclusive, evidence suggests that avoidance of offending allergens and optimum pharmacotherapy may lessen the risk of sensitization to additional allergens and may interrupt the progression to serious allergic respiratory diseases later in childhood (Wahn, 1998; Platts-Mills, 2003).

In a recent consensus document, the European Academy of Allergy and Clinical Immunology made the following recommendation (Host, 2003): Generally, all individuals with severe, persisting, or recurrent possible "allergic symptoms" and individuals with need for continuous prophylactic treatment should be tested for specific allergy, irrespective of the age of the child. Included in this description are children with cutaneous disease, gastrointestinal symptoms (colic, diarrhea, vomiting, or failure to thrive), recurrent wheezing, otitis, rhinitis, or asthma. Laboratory tests for IgE antibodies and skin tests were considered essentially interchangeable for the purpose of evaluating such children (Host, 2003).

The selection of appropriate allergens for testing is determined by clinical signs and symptoms and by the age of the child. The most frequent offending allergens in infants and children younger than 3 years of age are foods, notably protein allergens in cow's milk, egg white, wheat and soy, and dust mites (Nickel, 1997; Sampson, 2001). Immediate hypersensitivity to food allergens in infancy is commonly associated with eczema, gastrointestinal symptoms, chronic otitis, and wheezing. Less commonly, severely atopic children younger than 3 years may already have demonstrable IgE antibodies to house dust mites (*D. farinae* and *D. pteronyssinus*). These inhalant allergens are a common cause of asthma in older children. Except for the rare occurrence of a child with anaphylaxis whose symptoms are strongly associated with the ingestion of a particular food (e.g., peanut), it is seldom necessary to test for additional IgE antibodies to foods if the results of tests for common food allergens are negative. In addition, allergic respiratory disease caused by common seasonal inhalant allergens such as pollens is uncommon before age 3, and routine testing for IgE antibodies to these allergens is not recommended. In the age group younger than 3 years, the presumptive diagnosis of an allergic disease can be established with tests for IgE antibodies to common foods and dust mite allergens.

Positive test results for IgE antibodies to these allergens have dual significance: They establish a strong likelihood of immediate hypersensitivity disease, and they indicate an increased risk of sensitization to additional allergens later in childhood (Nickel, 1997; Wahn, 2009). For these reasons, the identification of IgE antibodies to common food allergens in symptomatic infants and children younger than 3 years is important for making proper treatment choices, and for deciding whether to seek referral to an allergy specialist. In children younger than 3 years, it is often more convenient to test sera for the presence of IgE antibodies than to perform skin prick tests. Levels of IgE antibodies that predict clinically significant, immediate hypersensitivity with high positive predictive values differ somewhat for different foods, and the clinical significance of low levels of IgE antibodies to common foods is limited (Sampson, 1997, 2001). Nevertheless, it is clear from the relationships shown in Figure 54-5 that the higher the level of IgE antibodies, the greater is the likelihood of clinically significant sensitivity to each food allergen. The receiver operating characteristic curves depicted in Figure 54-5 indicate cutoff concentrations for several common food allergens that have high predictive value for positive responses on subsequent food challenge testing. As illustrated by the graphs, a distinct advantage is associated with reporting results in quantitative units compared with the previous convention of class scores.

Allergic diseases in children older than 3 years typically manifest with respiratory signs and symptoms such as rhinitis, wheezing, and persistent cough (see Fig. 54-4). It is useful to think of the entire respiratory tract as a single allergic target organ. Allergic rhinitis and asthma often accompany one another. Most asthmatic children also suffer from rhinitis, and children with rhinitis often have asthma that may be clinically apparent or subclinical (Sly, 1999). With the development of disease affecting the respiratory tract, tests for IgE antibodies to inhalant allergens become much more important for clinical decision making (Host, 2003). Because a vast number of different inhalant allergens are available for testing, it is important to be selective in the initial testing of children with respiratory signs and symptoms, to avoid unnecessary testing. Data from clinical investigations support complementary approaches, such as the simultaneous use of small panels of individual inhalant allergens and of the multiallergen IgE antibody test for several antibodies.

The allergens chosen for testing in children with respiratory diseases depend on the age of the child and the scope of clinical manifestations (Table 54-5). After age 3 or 4, it is common for atopic children to develop IgE antibodies to indoor aeroallergens, including house dust mites, animal epithelia (cat and dog), cockroach, and moulds. The last antibody specificities to develop in children involve common outdoor aeroallergens,

Figure 54-4 Relationship of age and clinical manifestations of allergic disease in children.

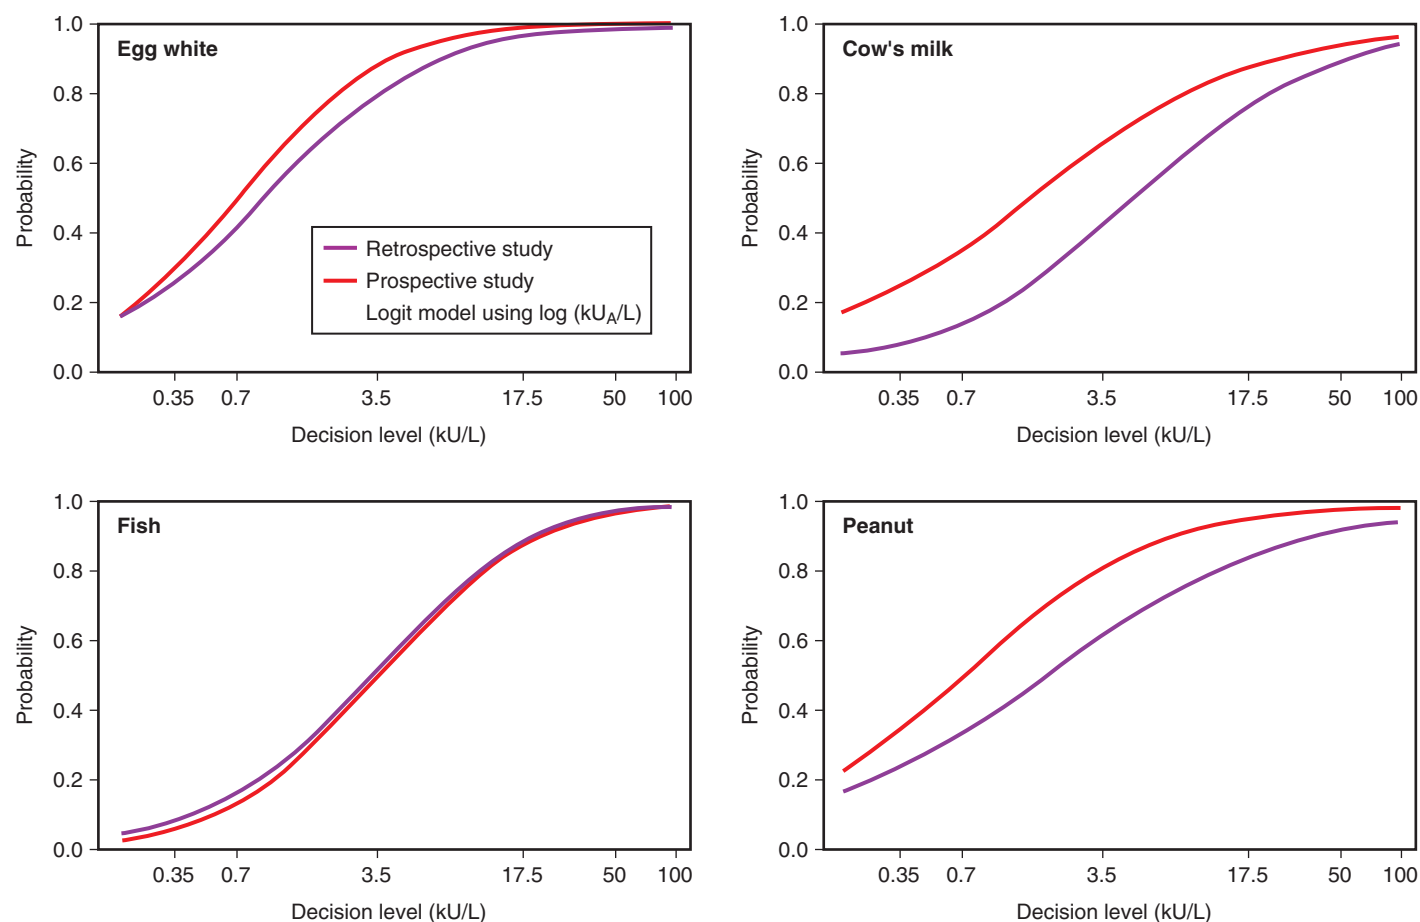

Figure 54-5 Probability of reacting to food allergens at increasing levels of immunoglobulin (IgE) antibodies. (With permission from Sampson HA. Utility of food-specific IgE concentrations in predicting symptomatic food allergy. *J Allergy Clin Immunol* 2001;107:891–6.)

TABLE 54-5

Selected Immunoglobulin (IgE) Antibody Tests for Evaluating Children With Clinical Signs of Allergy

Age, years	Signs of disease	Allergens
Younger than 3	Eczema with or without wheezing and otitis	Common foods: Egg white, milk, wheat, soy; house dust mites (<i>Dermatophagoides farinae</i> and <i>Dermatophagoides pteronyssinus</i>)
Older than 3 or 4	Rhinitis, wheezing, asthma	Common perennial inhalants: house dust mites, cat or dog, cockroach, <i>Alternaria tenuis</i>
Older than 3 or 4	Rhinitis, wheezing, asthma with seasonal exacerbations	Common perennial inhalants, as above, plus pollen inhalants (tree, grass, or weed pollens)

including pollen inhalants of trees, grasses, and weeds. No agreement has been reached on the minimum number of inhalant allergens that should be tested when evaluating children with respiratory symptoms, but consensus does indicate that testing should include house dust mites, cat or dog epithelium, a ubiquitous mould species (e.g., *A. tenuis*), and appropriate pollen allergens (Host, 2003). Testing for IgE antibodies to pollen allergens is indicated in older children, especially when symptoms are seasonal and tests can be performed at the time that symptoms are manifest. It is well known that levels of IgE antibodies to seasonal inhalants vary with the seasons, and there is little utility in performing tests for IgE antibodies to pollen inhalants when the allergens are not present in the environment, because false-negative results may be obtained. The multiallergen IgE antibody test is an efficient way to screen for the presence of IgE antibodies to pollen allergens. A positive result indicates the presence

of IgE antibodies to at least one of the allergens on the immunosorbent but is not specific for a particular allergen. As such, a positive result is useful in identifying patients who might benefit from further testing with individual allergen reagents.

Longitudinal cohort studies of children with allergic respiratory disease point to the importance of IgE antibodies and exposure to allergens in predicting the severity of disease in children with wheezing. The likelihood of wheezing increases directly with the summed concentrations of IgE antibodies to dust mite and cat allergens. In addition, high concentrations of IgE antibodies to dust mite and animal epithelia in children with wheezing predispose to greater morbidity and increase the likelihood of hospital treatment in children with concomitant acute respiratory infection (Custovic, 2005).

In adults with allergic rhinitis or allergic asthma, tests for IgE antibodies are reliable for identifying sensitivity to all classes of allergen. The most common sensitivities are to common aeroallergens, including house dust mites, cockroach, animal epithelia, mould spores, pollen allergens, and organic dust allergens (Hamilton, 2004). Testing is indicated in cases in which the results are likely to influence the choice of treatment modality (Gendo, 2004). In adults suspected of having allergic rhinitis, IgE antibody tests are most useful in making the diagnosis when the pretest probability of disease is relatively low (less than 30%). Such patients typically do not have clinical findings that strongly suggest an allergic etiology. In this situation, positive test results greatly increase the posttest probability of disease for most common aeroallergens, including animal epithelia, moulds, and pollens. Among patients with a strong clinical history (prominent nasal symptoms and allergen triggers), testing is less likely to be useful and empirical treatment is often indicated. The results of several studies indicate that skin tests and second- and third-generation IgE antibody tests have essentially equivalent diagnostic utility in adults with allergic rhinitis, and either test modality can be used to identify allergens for inclusion in immunotherapy regimens (Gendo, 2004). The use of allergen immunotherapy in adults with asthma is more controversial, with only some studies showing clear efficacy. The decision to test for IgE antibodies in adults

with asthma must be made on a case-by-case basis, with testing more likely to be useful in patients with clear-cut allergen triggers or occupational exposure to unique allergens.

New drug treatments for allergic diseases have become available in recent years. In particular, the treatment of severe persistent allergic asthma has been influenced by the introduction of anti-IgE pharmacotherapy (Busse, 2001; Soler, 2001; Lanier, 2003). Therapeutic anti-IgE is a recombinant humanized mouse monoclonal antibody to IgE that binds to the ϵ heavy chain of IgE, inhibits binding of IgE antibodies to Fc ϵ receptors on mast cells, and decreases antigen-induced mediator release from mast cells and basophils. Treatment with anti-IgE pharmacotherapy also decreases expression of Fc ϵ receptors on mast cells and decreases circulating IL-13. By interfering with binding of IgE antibodies to effector cells, anti-IgE antibody effectively blocks the release of inflammatory mediators that results from exposure to allergen. Results of clinical studies of anti-IgE pharmacotherapy for asthma have shown reduced rates of disease exacerbation and reduced requirements for corticosteroid drugs in treated patients (Soler, 2001; Lanier, 2003). Anti-IgE pharmacotherapy has also shown some efficacy in patients with food allergy, atopic dermatitis, or severe allergic rhinitis. For a physician to treat an asthma patient with anti-IgE, it must be documented that the patient has IgE antibodies to perennial aeroallergens and an elevated baseline level of serum IgE (30–700 kU/L). The dose of anti-IgE is determined by the serum IgE concentration and by body weight.

As noted earlier, the availability of quantitative assays for IgE antibodies has extended the usefulness of testing for several clinical applications (Yunginger, 2000). One such area is the evaluation of hypersensitivity to food allergens. Measurement of IgE antibodies is indicated to evaluate patients with food-induced symptoms that affect several end organs, including the skin, gastrointestinal tract, and airways, and even systemic reactivity. The gold standard for determining hypersensitivity to a food allergen is the double-blind, placebo-controlled food challenge. Recent data indicate that levels of IgE antibodies can be used to predict responses to food challenge for several common foods (see Fig. 54-5). These results define the levels of IgE antibodies above which a challenge is likely to be positive and therefore is not indicated. Similar attempts to define cutoffs for IgE antibody levels that predict reactivity to inhalant aeroallergens have failed to define levels that can be used across different practice situations (Soderstrom, 2003).

IgE antibody testing is also useful in the diagnosis of suspected sensitivity to Hymenoptera venom(s). Individuals sensitive to the venoms of honey bees, yellow jackets, hornets, or wasps may manifest signs of anaphylaxis following a sting; urticaria, angioedema, bronchospasm, or cardiovascular collapse may ensue. The reported death rate from sting-induced systemic reactions is at least 40 cases annually, but this figure probably underestimates the true incidence. The natural history of untreated venom sensitivity is not completely known. In many patients with documented venom sensitivity, it is possible to elicit a clinical history of progressively more severe reactions to successive sting episodes. On the other hand, venom sensitivity with anaphylaxis can occur in individuals with no prior history of allergic reactions, and venom sensitivity apparently ameliorates spontaneously in many individuals. The decision to treat a patient with venom immunotherapy is based on clinical assessment of the risk of anaphylaxis to possible future stings. The most reliable indicator of venom sensitivity is the response to a deliberate sting challenge, but this test is not widely performed and is rarely required in previously untreated patients to establish the diagnosis of venom sensitivity. Venom skin tests and IgE antibody tests are useful to confirm the clinical impression of venom sensitivity and to define its specificity. Comparative studies indicate that skin testing is a more sensitive diagnostic modality, with only approximately 80% of skin test-positive patients having elevated venom-specific IgE antibodies (Golden, 2003). Venom IgE antibody tests are useful primarily to confirm the results of skin tests, to define the allergen specificity of venom hypersensitivity, and in selected patients to identify venom sensitivity when a positive clinical history is not confirmed by venom skin testing (Golden, 2003).

With the exception of the sting challenge, no in vitro or in vivo test reliably predicts the clinical response to an insect sting in a treated patient following venom immunotherapy. Although levels of IgG antibodies in serum increase markedly with venom immunotherapy, no cutoff level has been defined that can be used to identify those patients who are no longer at risk. Semiquantitative estimates of IgG antibodies are not useful clinically, and levels of IgE antibodies following treatment bear no consistent relationship to clinical status. The decision to discontinue venom immunotherapy is based on clinical studies that show high protection rates after approximately 3 years of treatment (Yunginger, 1998).

Measurements of IgE antibodies have also been applied to the diagnosis of drug allergy. Although many drugs and their metabolites are capable of eliciting synthesis of antibodies, clinical data and the results of IgE antibody measurements are available for relatively few drugs, including penicillins and their metabolites and insulin. Penicillin and its isomer, penicillenic acid, combine with serum proteins through amide linkages to create allergenic moieties: penicilloyl-protein and penicillenic acid-protein are so-called major and minor antigenic determinants, respectively (Fig. 54-6). Measurable levels of IgM and IgG antibodies specific for the penicilloyl determinant occur commonly in penicillin-treated patients; although high titers of these antibodies persist in plasma for relatively short periods, lower titers can often be detected years after treatment (Shepherd, 1991). The diagnosis of hypersensitivity to penicillin has relied on skin testing with penicillin, penicilloyl-polylysine, and a minor antigen mixture. Positive skin test results occur infrequently, especially when testing is done remotely following treatment with penicillin. Less than 30% of patients with probable history of immediate hypersensitivity to penicillin have positive skin tests, and immediate hypersensitivity reactions to penicillin therapy are rare in patients with negative skin tests.

Using the results of skin tests as a diagnostic reference, clinical studies have reported finding measurable IgE antibodies to the penicilloyl determinant in 65% to 85% of patients with positive skin tests (Fontaine, 2007). Anti-penicilloyl antibodies are undetectable in control subjects. On the basis of these data, it is reasonable to recommend in vitro testing for penicilloyl-IgE antibodies only in patients with a history of recent hypersensitivity reactions. The absence of specific antibodies to penicilloyl-polylysine does not exclude the possibility of clinically significant IgE antibodies to other penicillin metabolites (Weiss, 1988; Fontaine, 2007). Genetically engineered recombinant drugs such as therapeutic monoclonal antibodies may also cause allergic reactions, including anaphylaxis (Chung, 2008). An example is the chimeric mouse-human monoclonal antibody against epidermal growth factor receptor used to treat patients with colon carcinoma and squamous cell carcinoma of the head and neck. Approximately one third of patients treated with the therapeutic antibody Cetuximab have signs of immediate hypersensitivity mediated by IgE antibodies to the oligosaccharide galactose- α -1,3-galactose present on the Fab portion of the antibody molecule. Diagnostic tests for this antibody can be anticipated for future clinical use.

Allergic diseases, particularly asthma, may be caused by a wide variety of allergens encountered in the workplace. Asthma may result from both allergic and nonallergic mechanisms. The list of causative agents associated with allergic occupational asthma is long and includes the following: animal proteins, enzymes, plant proteins, legumes, anhydrides, metallic salts, dyes, isocyanates, and wood dusts. Testing for IgE antibodies is available for several of these allergens. Recently, attention has been focused on natural rubber latex as an allergen in the health care workplace and in certain patients, for example, patients with spina bifida who have undergone several surgical procedures. Natural rubber latex is a complex allergen that contains several protein allergens. Testing for IgE antibodies to latex is useful for identifying sensitized individuals. Approximately 90% of skin test-positive patients have measurable IgE antibodies to latex allergens (Hamilton, 2003).

In concluding this section on testing for IgE antibodies with currently available tests, it is appropriate to summarize some of the major points made earlier. Measurement of IgE antibodies is useful and can be recommended in the following clinical situations: (1) to evaluate children with early clinical signs of allergic disease, including children with eczema, gastrointestinal symptoms, wheezing, and rhinitis; (2) to evaluate children and adults suspected of having allergic respiratory disease to establish the diagnosis of an allergic origin and to define the specificity of allergen sensitivity to pollens, dusts, fungal antigens, and foods; (3) to confirm sensitization to food allergens in patients with signs of clinical food allergy; (4) to identify allergens for use in immunotherapy regimens in patients with severe allergic rhinitis; (5) to evaluate the specificity of sensitization to insect venom allergens, particularly as an aid in defining venom specificity in those cases in which skin tests are equivocal; (6) to confirm the diagnosis of penicillin hypersensitivity in patients with recent clinical exposure; and (7) to confirm the presence of IgE antibodies to certain occupational allergens, for example, natural rubber latex. Testing for IgE antibodies is not routinely recommended for evaluating the effects of immunotherapy in treated patients, or for excluding the diagnosis of anaphylactic sensitivity to insect venoms in treated patients. Tests for IgE antibodies are indicated only in patients who have had a thorough medical history and physical examination.

Figure 54-6 Allergens derived from penicillin.

FUTURE DIRECTIONS: COMPONENT-RESOLVED DIAGNOSTICS AND TESTING BY MICROARRAY METHODS

It is important in clinical allergy practice for clinicians to identify sensitization to an allergen and to differentiate novel sensitization from cross-reactivity. As noted in Table 54-3, many allergens from seemingly unrelated sources (e.g., tree pollens, weed pollens, foods) share components from protein and glycoprotein families (e.g., profilins, PR-10 panallergens, CCDs) with high degrees of structural similarity. Other allergenic proteins are unique to a particular source (e.g. storage proteins from many food sources). Recombinant technology has made it possible to synthesize large quantities of individual allergen proteins; these proteins are now being used in clinical investigations and (some are available) as diagnostic reagents for the detection of IgE antibodies (Valenta, 1999). A panel of recombinant protein components from a single source can be used to determine the serologic phenotype of response to a complex allergen (e.g., peanut, natural rubber latex) and will reveal whether reactivity to the complex allergen is caused by sensitization to one or more unique allergen components, or is attributable to cross-reactivity arising from sensitization to a panallergen. This distinction can be important, as the likelihood of severe or persistent allergy often increases with sensitization to unique allergen components (e.g., Ara h 2 in peanut, ovomucoid in egg white), and knowledge of cross-reactivity may help to determine the optimum allergens for use in an immunotherapy regimen.

Testing with component allergens may prove to be very helpful in distinguishing between sensitization and clinical allergy. Recent data from epidemiologic studies indicate that rates of sensitization to some allergens may greatly exceed incidences of clinical allergy. For example, approximately 10% of U.S. children have demonstrable IgE antibodies to peanut, but less than 2% display immediate hypersensitivity to peanut ingestion (Visness, 2009). The evolving clinical science of testing for IgE antibodies

to component allergen proteins is referred to as component-resolved diagnostics. As more data become available from clinical studies of IgE antibodies to components, it is likely that additional recombinant reagents will be approved by the FDA for use in clinical practice.

Recombinant protein allergens have been used in combination with microarray technology to test for the presence of multiple IgE antibodies simultaneously. Up to 103 recombinant and purified allergen components from 47 allergens have been used in a single microarray panel. Results of microarray tests are consistent with established immunometric methods for IgE antibodies to aeroallergen and food component allergens (Jahn-Schmid, 2003). The results of a microarray analysis can be used to construct a serologic phenotype that displays reactivity to unique and cross-reactive allergen components. It is anticipated that microarray testing will be most cost-effective in the initial evaluation of suspected allergy to identify patterns of sensitization.

TESTS FOR MEDIATORS OF IMMEDIATE HYPERSENSITIVITY REACTIONS

As noted earlier, a number of mediators of immediate hypersensitivity reactions, including histamine, tryptase, the cysteinyl leukotrienes, and prostaglandin D₂, have been identified. Each of these mediators promotes inflammation in human allergic disease or in animal models of allergy and anaphylaxis. These mediators induce many of the characteristic biological effects of allergic reactions. Despite these findings, measurements of mediators in body fluids are of limited usefulness clinically in the differential diagnosis of allergic diseases. Measurements of histamine in plasma or urine can be of value in patients with anaphylaxis when tests are performed immediately following an anaphylactic episode (Friedman, 1989), but care is needed to obtain a suitable specimen. Hemolysis can lead to falsely elevated histamine levels in the blood and in histamine-rich foods, and

bacterial colonization can lead to falsely elevated levels in urine. A more useful test in this clinical setting is measurement of tryptase in blood (Schwartz, 1987, 1989). Tryptase in serum consists primarily of α - and β -monomers of tryptase released constitutively from mast cells. Following anaphylaxis, mature β -tryptase (tetramers) is released from sensitized mast

cells, and the level of tryptase increases rapidly (30 minutes to 1 hour) and remains elevated for up to 12 hours. By comparison, histamine is cleared rapidly from blood with a half-life of minutes. The leukotrienes are active locally and are present in minute concentrations in body fluids. Leukotrienes in blood are rarely measured for the diagnosis of allergic disease.

KEY POINTS

- Viruses cause more human infections than any other group of microorganisms and produce diseases that range from trivial upper respiratory infections to universally lethal rabies.
- Virus isolation in cell culture and viral antigen identification have been the traditional tests available in community hospital laboratories to diagnose genital and mucocutaneous, respiratory, gastrointestinal, central nervous system, and disseminated viral infections. However, several sensitive and specific molecular methods for detection of viral DNA and RNA are now available for routine diagnosis.
- Accurate and prompt viral diagnosis is fundamental for optimal patient management, for reasonable use of antiviral drugs, for reduction of unnecessary laboratory testing and inappropriate antimicrobial therapy, for application of infection control procedures, and for public health control of community outbreaks.
- Many common viruses grow in vitro in cell culture using primary, diploid, or heteroploid cell lines; viral growth produces distinct cytopathic changes in the cell culture monolayer or can be detected by staining the cell monolayer for viral antigen using fluorescein-labeled specific antibodies. Some fastidious viruses propagate only in newborn mice or embryonated egg tissue; some viruses have never been successfully grown in any culture system.
- The shell vial culture method uses a cell monolayer in a dram vial filled with culture medium; the specimen is inoculated by centrifugation onto the cell surface. After a shortened incubation (1–3 days), the monolayer is stained with fluorescein-labeled viral-specific antibodies. This method can be used for early identification of herpes simplex virus (HSV), cytomegalovirus (CMV), varicella zoster virus (VZV), respiratory viruses, and enteroviruses.
- Hybrid culture systems grow two cell lines together on the same shell vial coverslip. The cell mixture supports the growth of an expanded number of viruses and simplifies culture recovery of the common respiratory viruses (influenza, parainfluenza, respiratory syncytial virus [RSV], and adenovirus), enteroviruses, and HSV, CMV, or VZV from a single shell vial.
- Direct visualization of viral particles by electron microscopy (EM) can reveal unique morphologic features of several agents of viral gastroenteritis such as rotavirus, enteric adenovirus, norovirus, astrovirus, and calicivirus, none of which replicates in standard cell culture lines. EM has been largely supplanted by other methods in the clinical laboratory.
- Viral serology has two major applications: diagnosis of recent infection and determination of immunity. Demonstration of immunoglobulin (Ig)M-specific antibody during acute illness or a significant rise in IgG antibody between acute and convalescent sera defines acute infection. Serology may be helpful if culture, antigen assays, or nucleic acid–based testing is not available or feasible. Persistent specific IgG is a marker of immune status for measles, mumps, VZV, and hepatitis A and B viruses. Enzyme immunoassay methods are sensitive and are widely used for defining immunity.
- Nucleic acid hybridization and nucleic acid amplification tests detect virus by recognizing specific segments of the DNA or RNA viral genome; neither virus viability nor propagation is involved. In situ hybridization is a direct probe technique for detection of human papillomavirus (HPV), CMV, HSV, and parvovirus B19 in tissue; specificity is high, but sensitivity is suboptimal.

Continued

- Nucleic acid–based testing such as polymerase chain reaction (PCR), strand displacement amplification, and nucleic acid sequence–based amplification have raised the sensitivity of molecular diagnosis beyond culture or antigen detection methods. In addition to improved sensitivity, specimen transport is simpler because viable infectious virions are not needed. Combining several viral nucleic acid tests in a single multiplex or array assay has greatly expanded the clinical utility of molecular testing for viral infections. These assays generate a reliable answer within 24 hours.
- Real-time PCR transcription allows for the accurate quantization of viral load in a variety of specimen types. Quantitative analysis permits prognosis and monitoring of response to therapy for viral pathogens such as human immunodeficiency virus (HIV), hepatitis C virus, hepatitis B virus, CMV, Epstein-Barr virus, and BK virus.
- Detection of mutations associated with antiviral resistance is now available for HIV; resistance mutations may also have clinical significance for herpes viruses (CMV, HSV, and VZV) and influenza.

OVERVIEW

Viruses are responsible for an amazing spectrum of human illnesses that ranges from the annoying common cold to fatal immunodeficiency caused by HIV and some cancers. Virology has evolved rapidly from early characterization of viral morphology by EM to the development of techniques for virus replication in cell culture to sequencing of entire viral genomes and production of sophisticated nucleic acid–based diagnostic tests.

Established cell culture procedures for virus isolation are now being augmented or supplanted in clinical diagnostic laboratories by new, highly sensitive, and specific molecular techniques that can consistently detect as few as 10 virions per milliliter of specimen. Molecular tests have been developed to identify many common viruses and can also be used to quantify viral load to gauge response to therapy. Both community hospitals and large medical centers now offer a broad range of molecular tests for common respiratory, skin, central nervous system, gastrointestinal, and disseminated viral infections.

Accurate and timely viral diagnosis is fundamental to optimize patient management, to appropriately use antiviral drugs, to reduce unnecessary tests and superfluous antibiotics, and to implement hospital precautions to limit nosocomial spread (Aitken, 2001; Dellit, 2007). Early and precise identification and sequencing of viral pathogens clearly benefit the general population through focused public health initiatives, as was recently demonstrated by identification of the coronavirus associated with severe acute respiratory syndrome (SARS) and the 2009 H1N1 influenza A virus pandemic. Prompt antigenic and genomic characterization of this novel influenza A strain permitted the rapid development of accurate diagnostic tests and an effective vaccine (Shinde, 2009; Trifonov, 2009).

Several excellent references provide detailed information about taxonomy and pathogenicity of human viruses (Knipe, 2007; Murray, 2008). This chapter reviews common viral syndromes that generate the majority of testing conducted in a typical hospital laboratory. Organization and staffing, equipment and supplies, and specimen collection and test selection are discussed, along with isolation and identification methods. Most hospitals have a case mix of common viral infections in healthy and immunocompromised children and adults to support a virology service. Table 55-1 summarizes test volumes and recovery rates for a Chicago-based hospital system, with adult and pediatric primary care and high-risk obstetrics, neonatology, hematology-oncology, transplantation, and HIV services. Viruses were detected by culture and antigenic detection methods in 2004. By 2008, these methods had been largely replaced by nucleic acid–based assays. Recovery rates reflect the increased sensitivity of nucleic acid–based assays. Increased volumes seen for 2009 reflect a large influx of inpatient and outpatient samples from the 2009 H1N1 influenza outbreak. Hospitals with different medical specialty profiles recover the same viruses, but with variations in relative isolation percentages.

Average detection time for most viruses is between 1 and 2 days (the same time scale as routine bacterial cultures); this reflects the combined use of rapid antigen assays, shell vial cultures with short incubation schedules, and nucleic acid amplification–based tests. Overall recovery rates for viruses in clinical samples are surprisingly high (16%–23%)—several times greater than for routine bacterial blood or stool culture, mycobacterial culture, or ova and parasite examination (Epsy, 2006; Leland, 2007). Many

*2004: conventional virology testing methods; 2008: molecular testing methods; 2009: molecular testing methods; includes 2009 H1N1 influenza epidemic.

†Average recovery of respiratory viruses from respiratory specimens was 47%.

Figure 55-1 Seasonal variations in viral detection.

common viruses exhibit seasonal variations (Fig. 55-1). Influenza, RSV, and parainfluenza viruses 1 and 2 circulate every winter. Adenovirus, parainfluenza virus 3, CMV, and HSV infections occur year-round. Enterovirus disease clusters in late summer and early autumn. These temporal patterns have a direct impact on laboratory staffing needs and put the greatest demand on pediatric hospitals.

Four principal viral diagnostic laboratory methods are used: culture, antigen detection, nucleic acid detection, and serology. Each method has clear advantages and limitations (Fig. 55-2). Culture and antigen detection

Viral Nucleic Acid – Target Amplification

Viral Nucleic Acid – Signal Amplification

Figure 55-2 Laboratory methods for diagnosis of viral infection. CMV, Cytomegalovirus; DFA, direct fluorescent antibody; EBV-VCA, Epstein Barr virus-viral capsid antigen; HAV, hepatitis A virus; HBc, hepatitis B core antigen; HBsAg, hepatitis B surface antigen; HCV, hepatitis C virus; HEp-2, heteroploid cell line derived from laryngeal carcinoma; HIV, human immunodeficiency virus; Ig, immunoglobulin; PCR, polymerase chain reaction; RMK, Rhesus monkey kidney; VZV, varicella zoster virus.

requires viable virus or relatively intact viral fragments; specimens must be collected during active viral replication. Nucleic acid-based methods have the highest sensitivity and allow greater latitude in specimen collection and transport. The throughput time for most nucleic acid-based testing is 1 day or less and definitely outpaces timelines for standard culture. Nucleic acid-based tests are invaluable for identifying viruses that propagate slowly or not at all in cell culture. Viral nucleic acid fragments may persist into the recovery phase of illness, long after viable virions have been eliminated by the immune response; this limits their use as test of cure. Quantitative real-time PCR has become the standard of care in assessing viral loads and monitoring response to therapy for viruses such as HIV, CMV, HCV, HBV, and BKV. As the mechanisms of antiviral drug resistance are being defined, mutation detection is becoming the method of choice for appropriately targeting antiviral therapy.

Traditional serologic diagnosis requires paired sera from the acute and convalescent stages of infection to demonstrate a significant rise in specific viral antibody titer. Detection of virus-specific IgM antibody can diagnose acute illness from a single serum obtained during the acute or early convalescent period for some viral infections. Virus-specific IgG antibody tests are typically helpful to document immune status for selected viruses.

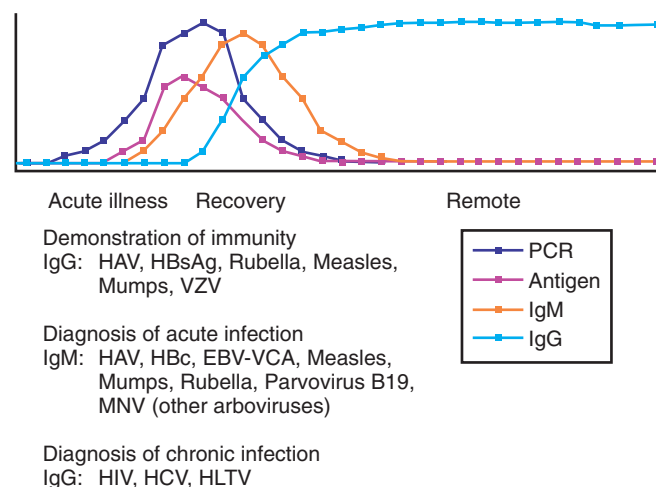

Viral Culture

Direct Antigen/Nucleic Acid Detection

Serological Detection of Virus Specific Antibodies

All necessary materials and reagents for virus isolation, antigen assays, and serologic procedures are available from commercial suppliers. The number of viruses that can be detected or quantified by nucleic acid-based tests continues to grow, and several assays are already commercially available. Laboratory-developed procedures require considerable technical expertise, and all molecular methods demand stringent quality control to guarantee accuracy and to minimize contamination. Despite these additional responsibilities, molecular approaches have enhanced overall sensitivity and quantitative accuracy, relative to conventional procedures. One should expect to see more molecular assays become standard of practice in clinical virology laboratories as available technologies continue to improve.

VIRAL CULTURE

Virus propagation in tissue culture was developed more than 60 years ago and remains a versatile, cost-effective, and comprehensive diagnostic approach. Many clinically significant viruses replicate in vitro, and virus recovery correlates well with acute disease. However, culture is labor-intensive, involves technical proficiency, requires at least 1-day turnaround for positive results, and frequently is less sensitive than nucleic acid-based detection methods (Leland, 2007).

Tissue culture cells are divided into three categories: primary cell cultures, diploid cell lines, and heteroploid cell lines, including genetically manipulated heteroploid cell lines that have been engineered for enhanced growth and detection of certain clinically significant viruses. Primary cell cultures are prepared directly from the parent organ (e.g., monkey or rabbit kidney) by mincing and trypsinization, and the mixture is transferred to tubes or shell vials, where the cells attach and form a confluent monolayer on the glass surface. Overlay medium with buffered isotonic inorganic salts, glucose, amino acids, vitamins, and cofactors at a physiologic pH sustains cell viability. Eagle minimum essential medium in Earl or Hanks balanced salt solution is a versatile nutrient system and is usually supplemented with a low concentration of protein-rich/immunoglobulin-poor fetal bovine serum to maintain a healthy monolayer but not promote ongoing cell proliferation. The most popular and versatile cell lines with a normal diploid karyotype are human diploid fibroblasts (HDFs) derived from lung or newborn foreskin. Cells are propagated in serum-rich growth medium and can be serially subcultured 20–50 times; examples include MRC-5, WI-38, and foreskin fibroblasts. Heteroploid cell lines are derived from malignant tumors and can be passaged indefinitely; they are aneuploid and divide rapidly. Heteroploid lines include HEp-2 (laryngeal carcinoma), HeLa (cervical carcinoma), and A549 (human alveolar adenocarcinoma). Heteroploid cell lines include genetically manipulated cells that have been engineered for enhanced detection of clinically significant viruses. Examples of genetically manipulated cells are ELVIS cells, which are stably transformed baby hamster cells containing an HSV-specific promoter sequence and the *Escherichia coli lacZ* gene (Stabell, 1993), and a buffalo green monkey kidney cell line (BGMK-hDAF) engineered to over-express CD55, a receptor that some enteroviruses require for infection. Detailed additional information about cell lines, media formulations, propagation, and maintenance techniques is provided in other sources (Clarke, 2010).

Diploid and heteroploid cell lines should be tested periodically for *Mycoplasma* contamination and continued sensitivity to viral infection. Suppliers of purchased cells should perform these quality control measures and provide documentation. Cocultured cells are a mixture of two cell types that together support growth of a wide range of viruses. R-Mix contains A549 and mink lung cells with added trypsin and will recover the respiratory agents: influenza, parainfluenza, RSV, and adenovirus. Super E-Mix contains genetically engineered BGMK-hDAF and A549 cells to maximize recovery of enteroviruses. Viruses differ somewhat in their ability to replicate in culture, so critical specimens should be inoculated to a variety of cell lines to maximize recovery. A more extensive discussion of cell culture can be found elsewhere (Landry, 2000; Hodinka, 2010).

Each laboratory should select sufficient lines to cover the usual viral pathogens in its patient population and can vary the number and type to meet seasonal demands (Chapin, 2007; Leland, 2007). Primary cultures must be checked for contamination with endogenous virus. Viral replication in tube monolayers can be detected by inspecting the cell sheet with an inverted phase-contrast microscope for cytopathic changes associated with virus proliferation. Tube monolayers are versatile: A single cell line may support growth of several viruses, each producing distinctive cytopathic effect (CPE) or other measurable identifying features (hemagglutination, hemadsorption, interference). CPE may develop in 1–3 days (HSV) or may not be recognized for 5–20 days (RSV, VZV, CMV); therefore, cultures may need extended incubation for 2 weeks or longer (Clarke, 2010).

With the shell vial technique, the cell sheet rests on a round coverslip, monolayer side up, in a shell vial. The specimen is inoculated into the vial, which then is centrifuged to enhance viral attachment to the cell surface. After 1–3 days of incubation, the monolayer is tested for specific viral antigen, usually with a fluorescent antibody stain (Clarke, 2010). Shell vials are ideal for identification of a single virus (HSV) or a limited number of viruses (RSV and influenza), and for faster detection of slow-growing agents such as CMV and VZV. HSV vesicular genital lesions are excellent candidates for shell vial culture; sensitivity is almost 100% compared with traditional tube culture, and turnaround for negative specimens is decreased from 1 week to 1–2 days. Shell vials are comparable or superior to tube methods for recovery of CMV from urine, but backup tube culture is recommended to maximize CMV recovery from peripheral blood, body fluids, and tissue biopsies. Molecular methods will eventually replace cell culture as the “gold standard” for detection of most clinically significant viruses in clinical virology laboratories. This transformation is well under way, but the versatility of cell culture is still a valuable asset of this established technology.

SPECIMEN COLLECTION

Success with any diagnostic test begins with proper specimen collection and transportation. The laboratory must have realistic guidelines for optimal specimen handling and a specimen rejection policy, and then must communicate this information to the clinical staff and patient care sites (Table 55-2). Specimens for culture and antigen assays should be obtained early in acute illness, when virus shedding is highest; these testing methods are, at best, unreliable during convalescence. Nucleic acid amplification is more sensitive and has optimal value early in the course of disease.

Viral transport medium (VTM) contains a buffered salt solution, protein and saccharide nutrients, pH indicator, and antibiotics to inhibit bacterial and fungal contaminants, and is designed to stabilize virions and the patient's infected cells. Swab specimens, nasopharyngeal aspirates, and tissue biopsies should be placed in VTM for culture and antigen detection. Tissue should be frozen for molecular assays. Body fluids, lavages, blood, and bone marrow samples do not need VTM (Forman, 2007). Multipurpose transport media such as M4, Flextrans, Universal Transport, and others have been made for viral, chlamydial, and mycoplasmal culture. Most VTM formulations can stabilize viruses for 48 hours or less (Johnson, 1990). All specimens except blood samples should be transported and stored until setup at 4° C. Room temperature transport of specimens may be unavoidable in some circumstances, but physicians should appreciate the negative impact on recovery. Blood samples for virus isolation should be held at room temperature at all times and processed for culture on the day of collection. Viral cultures are best set up on the day specimens arrive in the laboratory, preferably within 36 hours of collection; at least one culture inoculation session should be scheduled during weekend shifts.

Equipment and Supplies

Most virology equipment is relatively inexpensive and is already in use in the microbiology and immunology laboratory sections. A class II biosafety laminar flow cabinet must be used for culture setup and whenever cultures are manipulated, to protect the technologist from infectious aerosol and to reduce tissue culture contamination. A centrifuge with covered carriers to accommodate shell vials should be available. Incubators to maintain uninoculated cells and to incubate inoculated cultures are needed, preferably with an internal outlet for hook-up of a roller drum. Also needed are an inverted phase-contrast microscope to identify CPE in cell culture monolayers, and an epifluorescence microscope for direct and indirect immunofluorescence assay (IFA) procedures; freezer space at –20° C (–70° C, if available) is also desirable for specimen and reagent storage. Liquid nitrogen for cell storage is expensive and is not essential for laboratories that purchase cell lines.

All essential supplies and reagents used to identify the common viruses are commercially available. Cell cultures are nourished by a balanced salt solution (Hanks or Earle) with added buffers, serum, and a nutrient mixture such as Eagle minimum essential medium (MEM). Eagle MEM is a precisely defined formulation of amino acids, sugars, vitamins, cofactors, and other metabolic requirements for the cell monolayer. Fetal bovine or calf serum (FBS) is a popular nutritional and hormonal supplement added to MEM; 5%–10% FBS is used for cell culture growth medium, and 2% for maintenance medium. Trypsin (0.25% solution), phosphate-buffered saline (PBS), glutamine and sodium bicarbonate solutions, VTM, and antibiotic mixtures for specimen decontamination should be stocked in the laboratory as needed.

Laboratories undertaking viral diagnostic services for the first time should consider beginning with straightforward testing such as HSV culture. Influenza, RSV, and rotavirus assays and cultures for other respiratory viruses can be added during the winter months. CMV identification is a priority for a hospital with immunocompromised patients. Enterovirus isolation could be offered initially for the summer and autumn. VZV, adenovirus, and parainfluenza virus cultures and antigen assays would be reasonable year-round additions as staff time and expertise increase. The laboratory should be familiar with specimen collection and transport requirements of public health laboratories and reference laboratories that provide supplementary culture, serology, antigen assay, and nucleic acid assays, so that send-out specimens are processed efficiently.

VIRAL ANTIGEN DETECTION

Rapid identification by direct methods is especially useful when specific antiviral therapy is available (for HSV, VZV, CMV, and influenza), and when nosocomial control is a factor (influenza, RSV, rotavirus, norovirus, and VZV). Viral antigen is detected with comparable sensitivity

TABLE 55-2

Specimen Collection for Common Viral Syndromes

Syndrome	Common viruses	Preferred specimen and transport conditions	Specimen quality validation	Most useful tests
Bronchiolitis/bronchitis	RSV, PIV, hMPV adenovirus, influenza A and B	NP swab, NP aspirate/wash; BAL; transport on ice for culture	Ciliated columnar cells or alveolar macrophages for NP aspirates and BAL	Nucleic acid amplification; EIA or DFA (in season); culture
Influenza	Influenza A and B			
Pneumonia	RSV, hMPV, PIV, influenza A, adenovirus			
Conjunctivitis	HSV, adenoviruses, enteroviruses, VZV	Conjunctival scrapings/swab in VTM; transport on ice for culture	Conjunctival Epithelial cells	Nucleic acid amplification; DFA; culture
Vesicular rash	HSV, VZV	Vesicular fluid/cells in VTM or slide smear for DFA; transport on ice for culture	Squamous Epithelial cells	Nucleic acid amplification; DFA; culture
Meningitis	Enteroviruses, HSV, VZV, EBV, West Nile virus and other arboviruses	CSF; transport on ice for culture	Abnormal CSF protein and cell counts	Nucleic acid amplification; culture (enteroviruses); IgM serology
Encephalitis	HSV, VZV, West Nile virus and other arboviruses, rabies	CSF, fresh brain tissue; transport on ice for culture	Abnormal CSF, protein and cell counts	Nucleic acid amplification; IgM serology
Enteritis	Rotavirus, norovirus, enteric adenoviruses	Fresh stool; transport promptly	Swab must be covered with stool	Rotavirus and adenovirus: EIA Norovirus: RNA amplification
Disseminated viral infection	CMV, EBV, HSV, VZV, adenovirus	Blood, tissue biopsy, BAL, CSF; transport immediately		Nucleic acid amplification; viral load for CMV, EBV; culture for CMV, HSV, VZV, adenovirus
	HIV	Blood		Serology; viral load; ARV resistance testing
Prenatal/neonatal viral infection	HSV1 and -2, CMV, enterovirus, parvovirus B19, rubella	CSF, vesicular fluid, tissue biopsy, amniotic fluid, urine; transport immediately		Nucleic acid amplification; culture; IgM serology

ARV, Antiretroviral therapy; BAL, bronchoalveolar lavage; CMV, cytomegalovirus; CSF, cerebrospinal fluid; DFA, direct fluorescent antibody; EBV, Epstein-Barr virus; EIA, enzyme immunoassay; HIV, human immunodeficiency virus; HSV, herpes simplex virus; hMPV, human metapneumovirus; IgM, immunoglobulin M; NP, nasopharyngeal; PCR, polymerase chain reaction; PIV, parainfluenza virus; RSV, respiratory syncytial virus; VTM, viral transport medium; VZV, varicella zoster virus.

and specificity by both direct fluorescent antibody (DFA) and enzyme immunoassay (EIA) methods. DFA has the advantage of microscopic visualization of the specimen's cell content so sample adequacy can be easily verified (Clarke, 2010), but DFA procedures are labor-intensive and may be unfeasible during seasonal respiratory viral outbreaks with high specimen demand. EIA methods require less subjective interpretive judgment than DFA, but assessment of sample quality is lost. DFA is best performed with an epifluorescence microscope, and positive and negative controls must be run routinely. Many EIA procedures are engineered for individual specimen testing with positive and negative control verification incorporated into a single-use cassette. Automated EIA procedures for batch testing combine washing, spectrophotometry, and data processing into a self-contained system; positive and negative controls are standard with each run, and the reading for the patient sample is interpreted using an established cutoff value. Sensitivity is highly dependent on adequate specimen collection, as illustrated by the variable sensitivity seen with these assays in the recent outbreak of 2009 influenza A (H1N1) (Ginocchio, 2009).

MOLECULAR DETECTION

Nucleic acid hybridization and amplification-based tests detect virus by targeting specific regions of the viral RNA or DNA genome. In situ hybridization (ISH) is a direct probe technique that can be used in anatomic pathology to detect a variety of viral pathogens. ISH is a useful method for the localization of specific viral nucleic acids inside individual cells with preservation of cellular morphology. ISH is particularly useful for diagnosis of EBV-related neoplasms (Fanaian, 2009). PCR can also be used for the diagnosis of viral infection in formalin-fixed, paraffin-embedded (FFPE) tissue biopsies, and is particularly useful for confirming the diagnosis of herpes viruses when histologic features are "nondiagnostic" (Böer, 2006).

Nucleic acid amplification technologies have raised the sensitivity of viral diagnosis beyond that of antigen assays or culture. Commonly employed target amplification technologies include PCR, real-time PCR, strand displacement amplification (SDA), nucleic acid sequence-based amplification (NASBA), and transcription-mediated amplification (TMA).

Signal amplification technologies include hybrid capture, branched DNA (bDNA), invader chemistry, and gold nanoparticle probe technology. The clinical utility of PCR was greatly expanded with the introduction of real-time PCR, in which amplification and detection take place simultaneously in a closed tube or plate; crossing threshold (cycle number in which amplicon is detectable) is proportionate to viral copy, permitting accurate quantitation. Quantitative real-time PCR is now standard for monitoring HIV, HCV, HBV, CMV, and BKV viral loads. It is recommended to base clinical management on viral load assessment from a single laboratory to reduce the variability that is still inherent between laboratories and technologies (Hayden, 2008). Automation of nucleic acid-based testing, including extraction methods and incorporation of internal controls, has increased the precision of quantitative methods, reduced the risk of amplicon contamination, reduced the rate of false-positive or false-negative errors, and accelerated throughput.

Food and Drug Administration (FDA)-cleared commercial kits are still limited and include assays for HIV, HCV, HBV, HPV, CMV, enterovirus, and a variety of respiratory viruses. The Association for Molecular Pathology (AMP) website maintains a table of FDA-cleared assays, as well as available controls and proficiency panels (www.amp.org). The College of American Pathologists also provides proficiency testing (www.cap.org). Most nucleic acid-based viral assays are currently laboratory developed and utilize in-house designed primers and probes or commercially available analyte-specific reagents (ASRs). Strict adherence to specimen collection, storage, and processing requirements, proper handling and storage of extracted nucleic acid, particularly RNA, and routine monitoring for amplicon contamination are all essential for maximizing detection and reducing error. Analytic and clinical validation and verification are the responsibilities of the individual laboratories.

Equipment required to perform nucleic acid-based testing is becoming more accessible for community hospital laboratories. Most molecular virology methods currently require specialized facilities (separation of areas for reagents, specimen processing and amplification steps, and appropriate air handling) and highly skilled technologists. Many viruses contain RNA genomes, and sample processing requires a certain level of paranoia for accurate and sensitive diagnosis. However, this paradigm is rapidly changing; platforms have recently become available or are in development

to support near point-of-care (POC) sample-to-report testing processes (e.g., enterovirus and influenza testing). Increasing availability of automation has greatly influenced the precision and ease of use of nucleic acid-based testing, particularly for quantitative analyses (e.g., HIV, HCV, HBV viral loads, HPV detection systems). Still many nucleic acid-based virology assays remain highly complex laboratory-developed methods requiring an appropriate level of oversight and monitoring. Extraction methods range from column-based manual methods to fully automated extraction and PCR setup. Automated extractors are available for small-volume to high-throughput laboratories. Additional equipment might include PCR workstations, temperature blocks, thermal cyclers (real-time and conventional), sequencers, centrifuges, micropipettors, gel electrophoresis systems, hybridization platforms, spectrophotometers, and storage areas of adequate capacity (4° C, -20° C, -70° C).

VIRAL SEROLOGY

Serologic diagnosis of viral infection has its attractions because serum specimens are easy to obtain, transport, and store. Viral serology has two major clinical applications: diagnosis of recent infection and determination of immunity (Hodinka, 1999). Evidence of current/recent infection requires demonstration of virus-specific IgM during the acute stage of illness, or demonstration of a significant rise in virus-specific IgG titer between acute and convalescent sera. Specific IgM is usually found in blood within the first week of primary infection and typically becomes undetectable within 1–3 months; in general, EIA methods are more sensitive, so detectable IgM may persist for approximately twice as long as immunofluorescent assays. The specificity and sensitivity of IgM assays are improved by removal of rheumatoid factor, by removal of IgG to eliminate competition with IgM for viral antigen, and by selective IgM or IgG capture methods. Virus-specific IgG is normally produced 1–2 weeks after primary infection, peaks at 4–8 weeks, and then declines but usually remains detectable indefinitely at low titer. The secondary immune response following viral reinfection or reactivation produces a different serologic profile: IgM may reappear transiently and in low titer, and IgG rapidly increases in titer. These are only general response patterns; intensity, specificity, timing, and class of antibody are influenced by the infecting virus, site of infection, and immune status of the host. In congenital infection, maternal IgG antibodies passively transfer across the placenta into the fetal circulation, but any IgM, IgA, or IgE detected in fetal, cord, or newborn blood represents antibody produced by the fetus or neonate following primary perinatal infection.

Serology is particularly helpful when specimen quality or transportation conditions are suboptimal for culture or direct antigen testing. If viral disease was not suspected at initial evaluation, then serology may be the only diagnostic tool available once the opportunity for culture, antigen assay, or nucleic acid amplification has passed. Serology is a logical diagnostic choice for viruses that require complex isolation procedures (EBV, human herpesvirus 6) or animal inoculation (arboviruses, some coxsackie A viruses), are a biohazardous risk (HIV, arboviruses, hemorrhagic fever viruses), or have no readily available nucleic acid amplification protocols. For some infections, serology is fast and relatively inexpensive; measles, mumps, and rubella infections can be diagnosed by culture, but IgM-specific antibody is detectable within 3 days of onset of illness and is more reliable. Virus may no longer be present when clinical symptoms develop; West Nile virus (WNV) and other arboviruses are often cleared from spinal fluid at the onset of clinical encephalitis, making serology a more useful diagnostic approach. Infections with a prolonged prodrome often have detectable antibody when the patient first develops symptoms (e.g., EBV and CMV mononucleosis). Specific situations for serologic diagnosis are listed in Figure 55-2.

CLINICAL VIRAL INFECTIOUS SYNDROMES

Our approach to laboratory diagnosis separates viral infections into specific clinical syndromes; this encourages the physician to associate a reasonable but limited group of viruses with the patient's presenting illness. The requisition form or order screen should be designed to require specific patient demographic data and a working clinical diagnosis, so that the laboratory can streamline testing and focus on rapid, high-yield, efficient testing. In this chapter, the following viral diseases and syndromes are discussed:

- Herpetic mucocutaneous infections
- Pediatric and adult respiratory syndromes

- Infectious mononucleosis
- Congenital and neonatal infections
- Viral central nervous system infections
- Viral exanthems and cutaneous infections
- Viral enteric infections
- Viral hepatitis
- Viral infections in the immunocompromised host
- Acquired immunodeficiency syndrome
- Virus-associated neoplasia

HERPETIC MUCOCUTANEOUS INFECTIONS

HSV and varicella zoster virus (VZV) are alpha herpesviruses, are commonplace worldwide, and characteristically produce infections in the skin and squamous mucous membrane surfaces of the body. Neither is usually life threatening; however, the effectiveness of acyclovir therapy has produced demand for prompt laboratory diagnosis, particularly for HSV (Schiffer, 2010).

HSV is ubiquitous and infects all racial groups worldwide. The two strains of HSV (serotype 1 and serotype 2) share many genomic and biological features, and both preferentially infect squamous epithelium; however, each has a unique antigenic profile and a somewhat distinctive epidemiology. HSV1 is transmitted via saliva to infect oropharyngeal and labiofacial surfaces. Lesions may develop on the exposed skin of athletes (herpes gladiatorum) or the hands of medical personnel (herpetic whitlow) after direct salivary contact. Initial HSV1 infection usually occurs in early childhood; primary infection is typically mild or asymptomatic, although a substantial minority of patients develops fever with painful gingivostomatitis. HSV1 is also responsible for an increasing number of genital herpetic ulcers (Ribes, 2001); melt curve analysis of genital herpes infections detected at a large metropolitan health care system in 2010 showed that approximately one third were serotype 1.

HSV1 directly infects ectodermal cells; viral replication depletes the host cells, so squamous cells lose their cytoplasmic integrity, leak fluid, and separate from one another to create a vesicle. Surface bacteria convert the vesicle to a pustule, which then ulcerates. Cutaneous herpes lesions heal without scarring as the epidermal cells regenerate. The immediate immune response involves natural killer cells, cytotoxic T lymphocytes, and production of neutralizing antibody. Despite cellular and humoral factors, HSV1 is able to migrate through sensory nerve fibers to the trigeminal ganglion and persists indefinitely in a dormant state in the neuronal nucleus (Schiffer, 2010). HSV episodically reactivates and travels back down neurosensory axons to the mouth and lips, where it again initiates replication in squamous cells. Most recurrent herpes infections are asymptomatic or produce transient vesicles with only cosmetic significance. With severe impairment of cell-mediated immunity (in acquired immunodeficiency syndrome [AIDS] and transplant patients), reactivation infection may be severe or even fatal. Encephalitis is another rare but devastating HSV1 infection. These complications are discussed in later sections of this chapter.

HSV2 infection is found principally in genital squamous surfaces and is transmitted through intimate sexual contact. At least 40 million Americans have been infected, with estimates of 1 million new cases annually. HSV2 recovery in children is most unusual and raises concerns about sexual abuse; however, beginning with adolescence, seroprevalence rises steadily through middle age and is proportional to the number of sexual partners (Fleming, 1997). In the United States, HSV2 seroprevalence in persons 13 years or older had progressively increased to a rate of 22%; however, a recent survey has shown a modest decrease to 17% (Xu, 2006). HSV2 produces the same pattern of primary and recurrent mucocutaneous lesions seen with oral HSV1. Latency is established in sacral neural ganglia, but reactivation rates are at least twice as high as with HSV1, and transient meningitis may occur. Primary and recurrent HSV2 lesions also heal completely in people with normal cellular immune function. The principal concern is exposure of infants during vaginal delivery; neonatal herpes is discussed later in this chapter.

Specimen Collection and Handling Guidelines

HSV is probably the easiest and fastest human virus to propagate in cell culture. Antigen assays are also relatively straightforward procedures. Nucleic acid amplification tests are now widely available and have superior sensitivity. Specimen collection is simple, and HSV is sufficiently durable and present in sufficient numbers that stat transport and laboratory handling are not essential. Swab specimens in VTM with antibiotics can tolerate a room temperature (22° C) transportation delay of 12 hours with only

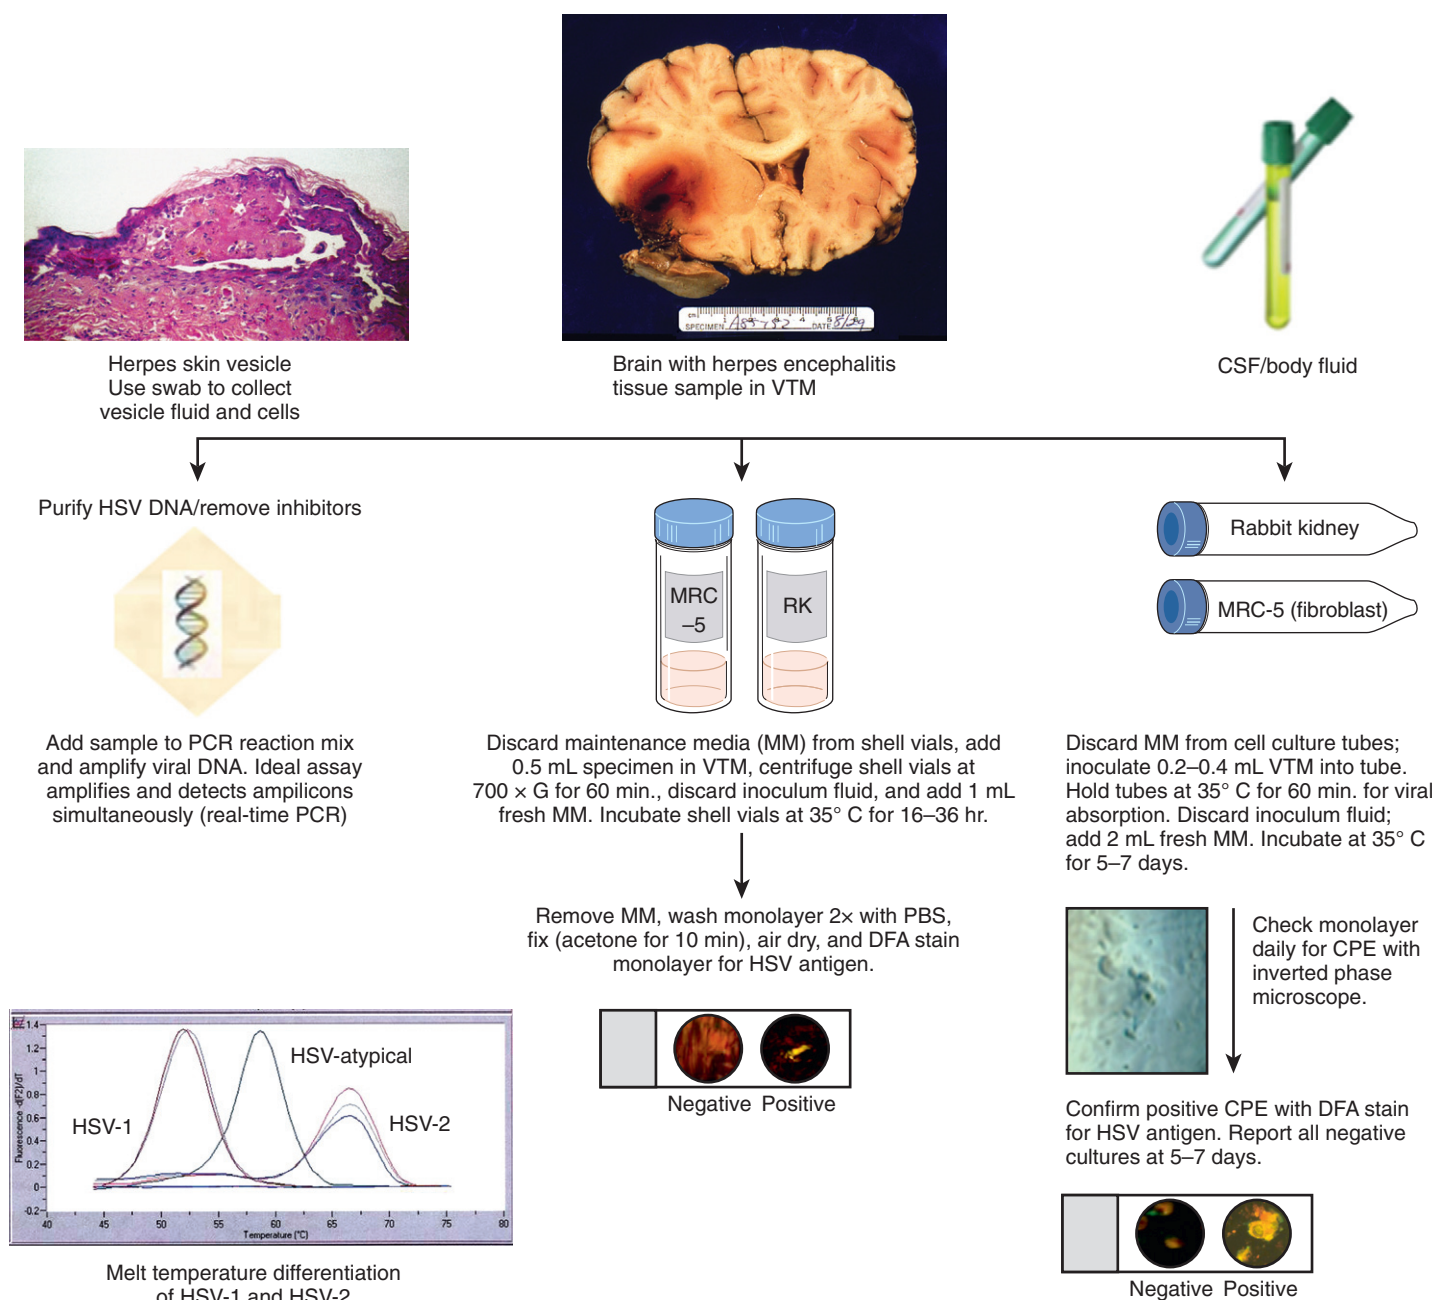

Figure 55-3 Traditional tube and shell vial cultures for herpes simplex virus (HSV) and HSV DNA amplification.

modest viral loss. Specimens should be inoculated to cell culture on the day of receipt, but overnight refrigeration is acceptable.

Cell Culture Isolation of Herpes Simplex Virus

HSV grows exceptionally well in a variety of cell lines; human fibroblasts (WI-38, MRC-5, foreskin), rabbit kidney (RK), mink lung, HeLa, rhabdomyosarcoma (RD), Vero, and HEp-2 cell lines work well; however, primary monkey kidney (PMK) is not reliable. Two tissue culture tubes (e.g., one RK and one MRC-5) are usually inoculated; the procedure is summarized in [Figure 55-3](#). HSV replicates rapidly with CPE usually apparent after 1 or 2 days of incubation. Genital cultures that fail to show HSV CPE after 5 days of incubation can be reported as negative. Incubation of cultures from central nervous system (CNS), corneal, oral, and other nongenital sites should be extended for 2 weeks, so other viruses (VZV, CMV, adenoviruses, enteroviruses, etc.) may be recovered. Individual HSV-infected cells become swollen and rounded, and this damage spreads rapidly across the monolayer. This CPE is characteristic of but not unique for HSV; changes caused by other viruses, toxins, or trichomonads may be confused with HSV, so confirmation with a DFA stain is needed. Reaction of infected cells with monoclonal HSV antibodies can distinguish HSV1 from HSV2 (Lipson, 1991). With the use of shell vial

centrifugation-enhanced culture, HSV can be identified in the monolayer by DFA staining after only 1 day of incubation (Clarke, 2010).

The ELVIS HSV shell vial culture system uses genetically altered cells that develop blue nuclear color after 1 day or less of HSV replication; it is a simple and very sensitive method for HSV culture (Patel, 1999).

Nucleic Acid–Based Detection of Herpes Simplex Virus

Real-time PCR followed by melt curve analysis is commonly used for the detection and typing of HSV. A wide variety of specimen types can be accommodated with molecular methods, including swab specimens in VTM or universal transport media, cerebrospinal fluid (CSF), bronchoalveolar lavage (BAL), frozen tissue specimens, and FFPE tissue. PCR-quality DNA can be extracted by a variety of commercially available methods (manual or automated). Specimen DNA is combined with PCR reagents, which minimally include an appropriate buffer system containing Mg^{++} and K^{+} salts, deoxynucleotide triphosphates, target-specific primers, fluorescently labeled probes, and a DNA polymerase. The samples are placed in a real-time thermal cycler for temperature cycling and fluorescence monitoring, resulting in multiple rounds of DNA replication of

specific regions of the viral genome with increasing levels of fluorescence. Costs are comparable with culture-based detection and typing methods; because of increases in sensitivity and rapid turnaround, nucleic acid amplification is quickly replacing conventional methods as standard of care.

Direct Detection of Herpes Simplex Virus

A direct smear from a herpetic skin vesicle can be stained with Giemsa reagent (Tzanck smear) to demonstrate viral multinucleated syncytial epithelial giant cells and intranuclear inclusions; however, these findings are not specific for HSV infection; identical changes are seen in VZV (chickenpox and shingles). Only 67% of herpetic lesions at the vesicle stage have a positive Giemsa Tzanck smear; sensitivity drops to only 30% for ulcerated skin lesions. Immunostaining of direct smears with fluorescein- or immunoperoxidase-labeled HSV antibodies eliminates confusion with VZV, and viral antigen can be identified in cells that do not yet have nuclear inclusions. However, when compared with culture, DFA staining has at best a 20%–30% false-negative error (Moseley, 1981; Lafferty, 1987). All negative direct specimen test results must be considered as possible false-negatives that should be validated by parallel culture. On the other hand, PCR diagnosis of mucocutaneous genital herpes infection is 20%–30% more sensitive than culture and has a more rapid turnaround time than culture (Espy, 2000). PCR is superior for identification of asymptomatic mucocutaneous viral shedding—eight times more sensitive than culture (Cone, 1994).

Serologic Diagnosis

Broad antigenic homology has been noted between HSV1 and HSV2, so accurate serologic testing requires antigens that are serotype-specific. EIA and Western blot methods that use unique HSV1 and HSV2 glycoprotein G (gG) envelope antigens do not detect cross-reacting antibodies (Ashley, 1988; Morrow, 2003). HSV2-specific antibody testing of pregnant women and their husbands helps predict neonatal transmission risk (Ashley, 1999; Cherpes, 2003). Positive HSV2 antibody in a patient with genital vesicles or ulcers is highly likely to represent true genital herpes (Jerome, 2007). IgM serology for HSV1 or HSV2, including gG IgM antibody, is not specific or sensitive and should not be used for diagnosis of primary infection.

VIRAL RESPIRATORY TRACT INFECTIONS

Every year, several million combined outpatient visits and hospitalizations in the United States are related to respiratory tract infections, most of which are viral in origin. All age groups are affected, and infections range from minor colds to serious laryngotracheobronchitis (croup), bronchiolitis, and pneumonia. Colds and pharyngitis have usually been managed with clinical judgment and no laboratory testing. Hospital laboratories have traditionally used a combination of antigen assay and culture to identify influenza viruses, parainfluenza viruses, RSV, and adenovirus among pediatric and adult patients. However, commercial multiplex nucleic acid panels in a single vial simultaneously test for influenza A and B, several influenza A hemagglutinin (H) antigens, parainfluenzas, RSV, adenoviruses, coronaviruses, metapneumoviruses, rhinoviruses, and enteroviruses. Most current assays are designed for batch testing with a throughput time of 4 to 8 hours (Li, 2007; Mahoney, 2007; Pabbaraju, 2008). Overall sensitivity compared with antigen assay and culture is excellent, with as many as 40% more viral infections identified, particularly when multiplex assay includes metapneumovirus, coronaviruses, and rhinovirus/enterovirus (Mahoney, 2007). The cost of an expanded amplified nucleic acid respiratory virus panel is competitive with the combined labor and reagent expenses charged for antigen testing, followed by virus culture of specimens with negative antigen results. During high-prevalence respiratory outbreaks, multiplex viral nucleic acid tests are the least costly diagnostic strategy for hospitalized children (Mahoney, 2009).

The obvious immediate advantage of these expanded test profiles for the individual patient is the far greater likelihood of prompt recovery of the viral pathogen for evidence-based use of antiviral drugs and for rapid implementation of appropriate infection control measures (Arnold, 2008). These assays should also help delineate the clinical effects of coinfection with multiple viral pathogens (Brunstein, 2008). With the addition of picornavirus/rhinovirus, coronavirus, and metapneumovirus pathogens, public health laboratories have used multiplex amplified molecular tests to successfully characterize additional viral respiratory infection outbreaks (Marshall, 2007; Wong, 2009).

Molecular techniques have been successfully applied in the rapid evaluation of recent novel viral respiratory disease outbreaks. An example is the

initial emergence of worldwide SARS in 2003; the causative agent was sequenced and was promptly characterized as a novel coronavirus, and accurate diagnostic testing quickly became available (Ksiazek, 2003). In the spring of 2009, a novel H1N1 influenza A virus, first detected in Mexico, rapidly evolved into a global pandemic. Within a matter of weeks, the strain had been sequenced and accurate diagnostic reagents had been developed; within 6 months, a vaccine was mass-produced and distributed (Greenberg, 2009; Perez-Padilla, 2009; Sullivan, 2010). The wider implementation of molecular methods has also demonstrated that clinical respiratory tract symptoms can be caused by a more diverse range of viral agents than was previously presumed. Metapneumovirus has been defined as having epidemiologic and clinical properties similar to those of RSV (Kahn, 2006). Acute upper respiratory tract colds are caused by rhinoviruses and coronaviruses; more than 100 of these agents circulate almost continuously in the pediatric and adult communities. Healthy hosts get many colds over a lifetime, with up to 25% of total sick days severe enough to miss work or school. Rhinoviruses have been the only viral pathogen recovered by multiplex amplified nucleic acid testing in babies with typical bronchiolitis and acute exacerbations of asthma. Both coronaviruses and rhinoviruses have caused clinically severe lower respiratory illness in compromised hosts (Piotrowska, 2009; Talbot, 2009; Kuypers, 2010).

Influenza

Influenza A and B viruses cause predictable annual cold weather outbreaks of acute febrile upper and lower respiratory tract illness with characteristic accompanying systemic features (Fig. 55-4). Influenza A is usually more common than B and produces more serious disease. Influenza antigens change through point mutations in the genome (antigenic drift, influenza A and B) and through recombination of human and animal viral RNA segments (antigenic shift, influenza A), so antibodies from prior infections may not be protective in subsequent outbreaks (Sullivan, 2010; Treanor, 2010). Influenza is easily spread from person to person in aerosol droplets; the virus attaches to and replicates rapidly in the ciliated columnar epithelial cells of the pharynx and tracheobronchial tree. After incubation of 1 to 2 days, disease usually begins abruptly with the onset of fever and chills; viral respiratory epithelial necrosis causes sore throat and cough, but associated systemic myalgias, headache, and generalized weakness are typically more severe than respiratory symptoms. Uncomplicated influenza usually resolves after 4–5 days. However, during every influenza outbreak, a small number of patients develop severe acute primary pneumonia with viral necrosis extending into the alveolar lining cells. These patients are at risk for developing bacterial lower respiratory infection following acute influenza, because the bronchi are temporarily covered by metaplastic epithelium and have not yet reacquired normal ciliated mucosa; individuals with chronic lung and cardiac disease are most vulnerable and account for a majority of the deaths recorded each year for influenza epidemics (Yeldandi, 1994; Soto-Abraham, 2009).

Influenza outbreaks in a local community have a characteristic epidemiologic curve (Treanor, 2010); numbers of infected individuals rise rapidly, peak, and then decline rapidly over about a 6–8 week period. A second peak of influenza-related bacterial pneumonia then follows. Every year, approximately 100,000 hospitalizations and 20,000 deaths in the United States are linked to influenza, and most fatalities are caused by bacterial bronchopneumonia, usually affecting patients with preexisting chronic obstructive lung disease or congestive heart failure. Myocarditis, meningoencephalitis, Reye syndrome, and Guillain-Barré syndrome are relatively rare complications.

Influenza is diagnosed best during the first 2–3 days of illness, when viral shedding is maximal. Infected cells from the upper respiratory tract are the easiest to collect for testing. Nasopharyngeal aspirate (NPA) and pharyngeal swab specimens provide sufficient material for simultaneous testing for several viral agents, including influenza viruses. Proper specimen collection is critical. A video demonstrating collection of both specimen types is available at <http://www.thepathologycenter.org/Education.asp>. Nucleic acid testing by RT-PCR has been shown as the most sensitive method for diagnosis, and has surpassed culture methods in both accuracy and turnaround time (Erdman, 2003; Templeton, 2004). Culture is the next most sensitive diagnostic test; nasopharyngeal secretions/NPA samples are ideal; nasopharyngeal swabs and throat swabs may be satisfactory but often provide suboptimal samples. Shell vial culture with 1–2 days' incubation has excellent sensitivity (Dunn, 2004) and may still provide a diagnosis within a time frame to affect management of the index patient or prophylaxis of contacts. Hybrid mink lung and A549 shell vial monolayers are versatile and can recover influenza A and B, parainfluenzas, adenovirus, and RSV (Figs. 55-5 and 55-6). Culture with traditional cell

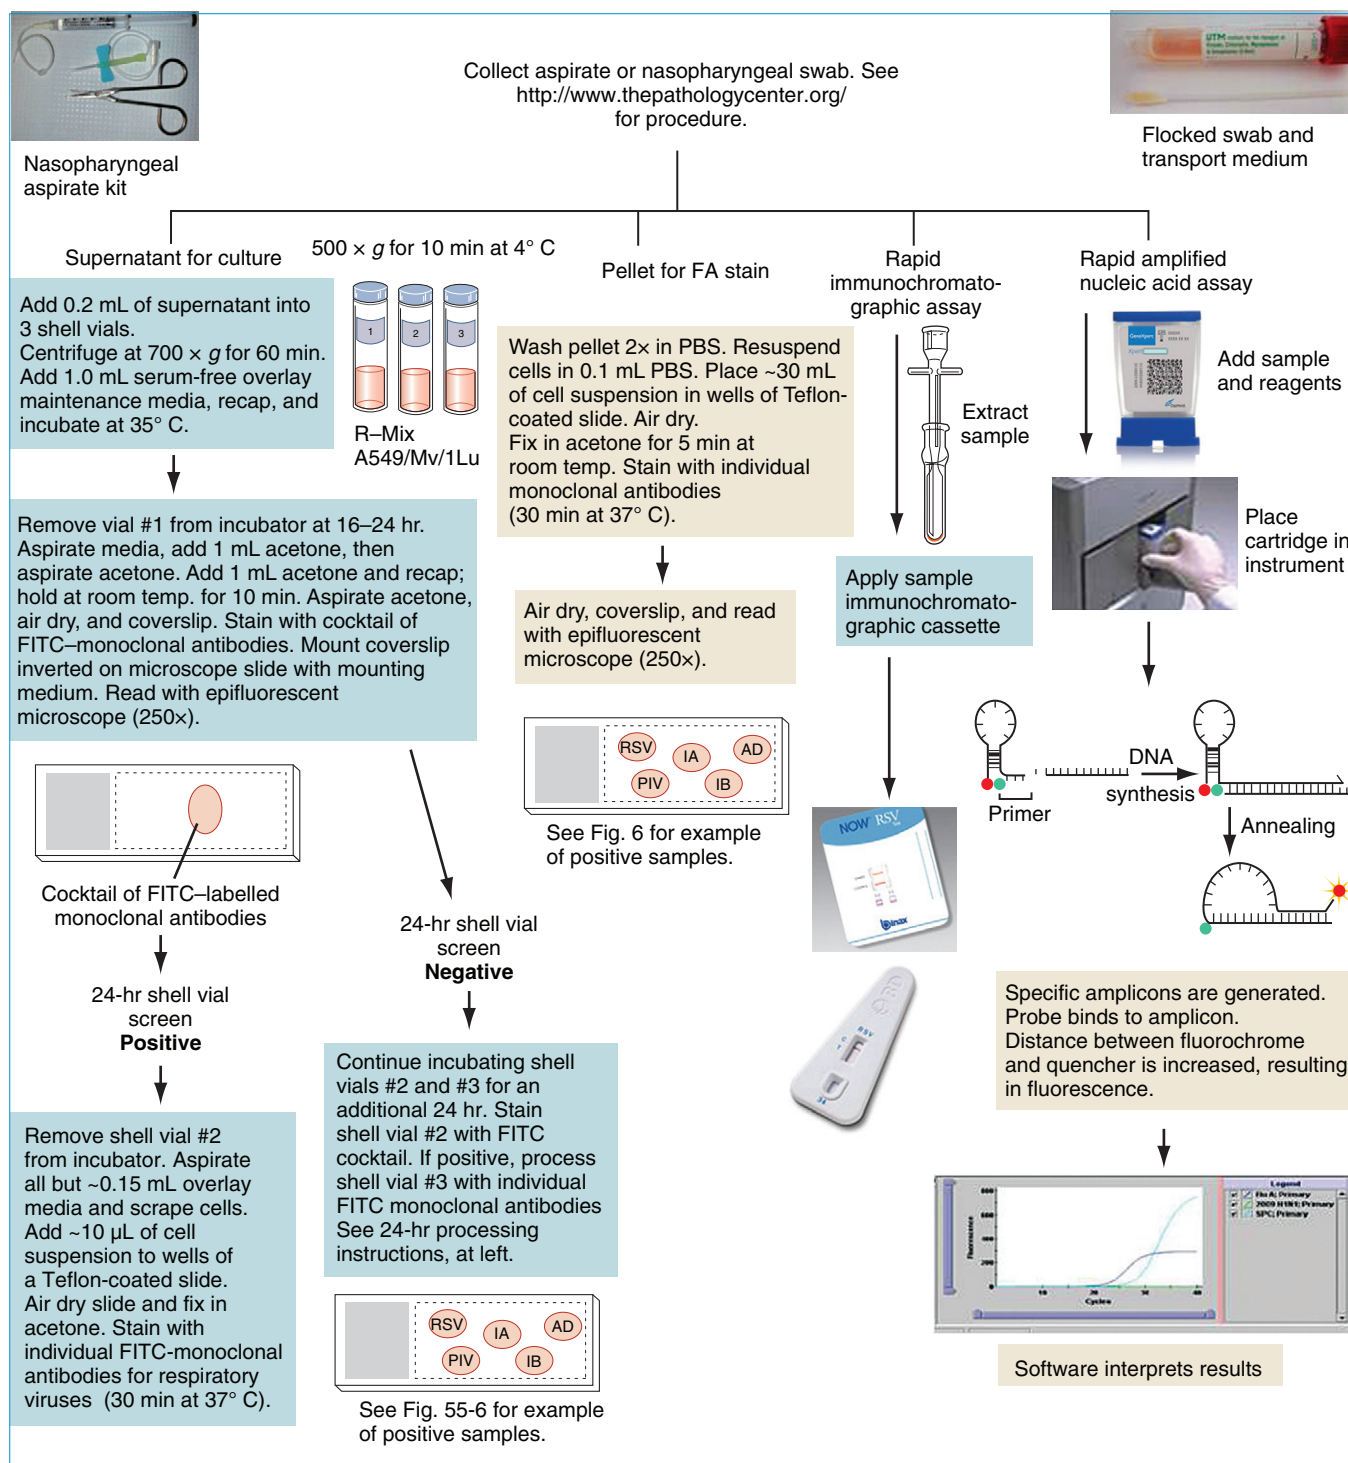

Figure 55-4 Laboratory diagnoses of respiratory viral infections with direct antigen assays (enzyme immunoassay [EIA] and direct fluorescent antibody [DFA]), shell vial culture, and nucleic acid assays.

monolayers and red cell hemadsorption attachment to influenza-infected cells expressing surface hemagglutinin antigen may not yield a positive result for 2–7 days, and currently is rarely used in hospital laboratories.

DFA stain can demonstrate virus-infected columnar epithelial cells in NPA samples, which provide the preferred specimen (see Fig. 55-6). Compared with cell culture, DFA sensitivity ranges from 77%–93% for detection of influenza A, and from 70%–80% for influenza B (higher in pediatric patients). Specificity is greater than 95%; however, good results are heavily influenced by the experience of the microscopist and by specimen quality. Throat and nasopharyngeal swabs generally lack sufficient columnar cells for DFA staining. Commercial immunochromatographic EIA methods are rapid and easy to perform but have only fair sensitivity for influenza antigen detection in NPA specimens during outbreaks. Specificity of any

antigen testing during nonseasonal times of the year is poor, so laboratories should restrict ordering to high-prevalence months. Sensitivity with nasopharyngeal swabs is considerably lower, particularly for antigen assays and culture. Nasopharyngeal swab specimens collected during the 2009 H1N1 influenza outbreak were tested by DFA and two rapid EIA methods, along with a commercial RT-PCR multiplex test and an R-mix shell vial culture. DFA sensitivity was poor (46%), and EIA methods showed only 10%–40% sensitivity; all antigen assays had 6% false-positive results (Ginocchio, 2009). It is not surprising that RT-PCR was clearly superior to all other methods; however, antigen assays performed more poorly than anticipated. Comparison of an antigen assay with RT-PCR in a similar H1N1 influenza outbreak in the Chicago area also showed low sensitivity (50.5%) and a 39% false-positive rate (Sabatini, unpublished data).

Figure 55-5 Seasonal variation in respiratory viral infections. Chicago area and southeast Wisconsin—January 2008 to April 2009.

Bronchiolitis and RSV

RSV is the most important cause of serious lower respiratory viral disease in infants and young children (Hall, 2001, 2010). Like influenza, RSV is transmitted by droplet aerosol, and outbreaks recur every winter. Currently, no vaccine for RSV is available; natural immunity to RSV is incomplete and of short duration, so multiple infections occur throughout life. RSV, similar to influenza, infects ciliated columnar epithelial cells from the nasopharynx to the distal bronchioles. Small babies experience the most serious infections because their narrow terminal airways become occluded by necrotic epithelial cells; bronchiolar obstruction leads to air trapping and hypoxia, which may be severe enough to require hospitalization. Acute symptoms usually resolve in a few days; administration of oxygen and other supportive measures are often the only medical interventions needed. Most critical RSV infections occur in premature infants, in children with underlying cardiopulmonary disease or immunodeficiencies, and in transplant recipients. Adults who are immunocompromised and the elderly may also have severe lower airway RSV disease (Falsey, 2005). Treatment with ribavirin or with the monoclonal antibody palivizumab is available but generally is prescribed only for severe cases (Empey, 2010).

RSV is a particularly fragile and labile virus that may not remain viable if specimen transport is delayed. It replicates slowly in cell culture, and recovery times range from 3–10 days (Tristram, 2003; Tang, 2008). Hep-2 and A549 cell lines are ideal for RSV replication; characteristic cytopathic changes are seen with fusion of adjacent infected cells into a large multinucleate syncytium (see Fig. 55-6). Shell vial culture improves RSV recovery somewhat and shortens isolation time to 1–2 days (Dunn, 2004). Use of shell vial monolayers with a hybrid mix of A549 and mink lung cells detects RSV, as well as influenza A and B, parainfluenzas, and adenoviruses (see Figs. 55-4 and 55-6). Detection of RSV antigen in respiratory secretions by DFA staining (see Fig. 55-6) or by EIA is as sensitive as or superior to culture, and availability of results is clinically relevant; therefore, rapid tests have remained popular and practical methods for RSV diagnosis in children (Ohm-Smith, 2004; Tang, 2008). EIA is easy and rapid to perform; DFA requires more time and interpretive expertise, but it can be expanded

to assay multiple viruses, and confirmation of specimen quality is simple. Similar to rapid antigen assays for influenza, RSV antigen tests should be performed only during wintertime outbreaks; off-season testing has poor specificity, with false-positive results outnumbering true-positive results. RT-PCR has been shown to have superior sensitivity over all other methods, and transport conditions are not as restricted because viability is not required (Falsey, 2002; Perkins, 2005); RSV nucleic amplification is the ideal method for off-season specimens. With the advent of multiplex testing, other viruses, such as metapneumovirus, coronaviruses, bocavirus, parainfluenzas, and even rhinoviruses, have been shown to produce respiratory disease that clinically mimics RSV (Kahn, 2006; Falsey, 2010).

Croup

Croup is most commonly caused by parainfluenza viruses (PIVs) (Henrickson, 2003). PIV1, PIV2, and PIV4 are more common during cold weather; PIV3 causes disease year-round (see Fig. 55-5). PIVs (particularly PIV3) are the second most frequent cause of viral lower respiratory tract infection in young children. Viral epithelial necrosis and mucosal edema in the larynx, trachea, and large bronchi narrow the airway, producing hoarseness, barking cough, and the stridorous obstructed breathing pattern characteristic of croup. Immunity is transient, and repeat infections are common; however, in older children and adults, symptoms are less severe and are centered in the upper respiratory tract, possibly resembling rhinovirus colds. Antigen assay methods are limited to DFA staining of virus-infected nasopharyngeal cells (see Fig. 55-6), which shows 70%–85% compared with culture; all DFA-negative specimens should be cultured to maximize recovery (Costello, 1993). Multiplex viral nucleic acid tests, which include the parainfluenzas, are superior to both antigen assays and culture for clinical diagnosis (Mahoney, 2008, 2009).

Metapneumovirus

Human metapneumovirus (hMPV) is a recently recognized RNA myxovirus, genus Metapneumovirus (Falsey, 2010). Similar to RSV, hMPV causes a range of cold weather respiratory infections, including upper

airway disease, lower airway bronchitis and bronchiolitis, influenza-like syndrome, and pneumonia. hMPV bronchiolitis tends to be less harsh than RSV, but coinfection with RSV and hMPV can be more severe than infection with either one alone (Konig, 2004). hMPV ranks as the second or third most common cause of serious lower airway pediatric disease; the elderly and the immunocompromised also can experience severe respiratory tract infection (Bouscambert, 2005; Kahn, 2006; Dare, 2007; Lüsebrink, 2010).

Recovery in LLC-MK2 cells or Vero cells may take up to 7 days (Deffrasnes, 2005). Culture of NPA and bronchial lavage specimens using a shell vial culture format and anti-hMPV monoclonal antibody DFA staining can shorten recovery (Ebihara, 2005; Landry, 2005). However, nucleic acid testing is considered the “gold standard,” and inclusion of hMPV in commercial multiplex RT-PCR assays has demonstrated that hMPV is a consistently recovered pathogen in a community hospital practice (see Fig. 55-5). During the early spring of 2010, as 2009 H1N1 abated, hMPV supplanted influenza in the Chicago area, accounting for up to 42% of viral respiratory infections. Wider availability of nucleic acid assays will better define the spectrum of hMPV disease and the true incidence of infection.

Other Viral Respiratory Tract Infections

Adenovirus has a consistent year-round epidemiology profile, and most clinical isolates are seen in patients with respiratory tract and conjunctival infections (see Fig. 55-5); most adenovirus respiratory disease is mild and self-limiting. However, outbreaks of severe respiratory infection have been reported in military personnel and in other populations living in crowded conditions. Outbreaks of a virulent adenovirus serotype 14 and a

recombinant adenovirus with properties of serotypes 11 and 14 have recently been reported in otherwise healthy adults and children (Lewis, 2009; Tate, 2009; Yang, 2009). Serious adenoviral pneumonia can also develop in the immunocompromised; stem cell and solid organ transplant recipients are the most common patient groups involved, and disease is identified by standard culture and molecular methods (Rhee, 2010). Adenovirus can be demonstrated by DFA staining of nasopharyngeal aspirate cells (see Fig. 55-6). Adenovirus also grows well in R-Mix hybrid mink lung/A549 shell vial monolayers (see Fig. 55-6).

In 2003, an outbreak of highly contagious acute hemorrhagic pneumonia originated in China and was spread by international travelers within Asia and beyond; the responsible organism was identified as a coronavirus variant (CoV), the clinical disease was named severe acute respiratory syndrome, and the outbreak had a mortality rate of almost 10% (Peiris, 2003). With detailed molecular characterization of CoV, accurate diagnostic testing was developed within a matter of months. Strict infection control measures were implemented for all recognized cases to limit transmission. Nucleic acid amplification for CoV-SARS is available through public health laboratories. However, even though these diagnostic methods are available, only very rare cases of SARS have been reported since the 2003 epidemic, and these were connected to research facilities. The explanation for the dramatic disappearance of CoV-SARS is not clear, but public health facilities continue surveillance for a possible recurrence.

With the advent of multiplex nucleic acid tests, the significant impact of rhinoviruses, human coronaviruses, and human bocaviruses and the possibility of WU and KI polyomaviruses in both upper and lower respiratory tracts are better appreciated. Expanded availability of broad testing panels has highlighted the importance of these respiratory viral agents,

with small children having the most frequent and most serious lower respiratory tract infections (Choi, 2006; Louie, 2009; Tregoning, 2010; Zorc, 2010).

Specimen Collection

The respiratory myxoviruses and adenovirus can infect ciliated columnar epithelial cells from the nasopharynx to the alveoli, so when lower airway disease (croup, bronchiolitis, pneumonia, or influenza) is suspected, the upper respiratory mucosa is still the easier and more accessible site to sample for culture, antigen assay, or nucleic acid assays. The upper respiratory tract is the most common site of infection for rhinovirus and coronavirus. Specimens should be collected during the first few days of illness, when viral replication is greatest. A throat swab placed in VTM with antibiotics may be accepted for influenza culture, but yield is 10%–20% less; expectorated sputum is also adequate for culture, particularly in adults who are coughing productively. Nasopharyngeal swab specimens vary considerably in quality but are adequate for nucleic acid assays; culture and a limited panel of viruses for direct antigen detection can also be performed on NP swabs. Collect swab specimens using sterile Dacron, rayon, or flocked swabs with plastic shafts; do not use cotton or calcium alginate. Nasopharyngeal specimens obtained with flocked swabs collect a larger volume of sample with more numerous epithelial cells, and consistently provide better samples than are provided by fiber swabs (Daley, 2006; Walsh, 2008).

NPA is straightforward and simple: a catheter attached to a syringe is inserted through the nares to the nasopharynx; 1–3 mL of saline is instilled, then saline and mucosal cells and secretions are immediately reaspirated directly back into the syringe. A video demonstrating collection of swab and aspirate samples can be reviewed at <http://www.thepathologycenter.org/Education.asp>. All specimens should be transported on ice promptly to minimize RSV loss. Specimen quality can be verified before performing culture or antigen assay. NPA with at least two ciliated columnar epithelial cells per 250× field yields a fourfold greater recovery of respiratory viral pathogens (Costello, 1993). Nasal swabs are never acceptable for testing by any method.

Virus Antigen Assays

Figure 55-4 outlines a strategy for specimen collection and testing by culture, antigen assay, and nucleic acid methods for respiratory virus diagnosis. Reproducible and accurate viral antigen detection by DFA requires interpretive expertise; therefore, if possible, both viral culture and antigen assay should be done to maximize recovery. Hospitals with a large pediatric service routinely test respiratory specimens for a panel of viruses (RSV, hMPV, influenza A and B, PIVs, and adenovirus) during winter months if budgets permit. Adults should be tested for influenza virus; RSV and possibly hMPV should also be considered for elderly patients. The NPA sample is used for EIA testing, and then is washed in PBS and centrifuged with the supernatant used for virus culture. If DFA stains for viral antigens are ordered, the cell button is resuspended in PBS, and drops of fluid/cells are spread on Teflon and poly-L-lysine-coated slides. Air-dried smears are fixed with 100% acetone and are stained for viral antigen(s) using specific fluorescein conjugated antibodies with Evans blue counterstain. NPA cyto-spin preparations increase cell recovery (Landry, 2000). Cell recovery is superior from flocked swab collections. Note the number of ciliated columnar epithelial cells and the degree of nonspecific staining caused by residual background mucus or neutrophils. Figure 55-6 shows that NPA DFA stains positive for influenza A, parainfluenza 3, RSV, and adenovirus. Fluorescein-conjugated antisera are tested for specificity with a panel of known positive tissue culture control cells; reagent lots should show consistent cellular stain distribution and intensity. Overall, DFA methods have excellent specificity and sensitivity.

Several EIAs are commercially available for RSV and influenza A and B. The specificity and sensitivity of these products are comparable with those of DFA staining (Ohm-Smith, 2004; Weinberg, 2005). NPA can easily be checked for the presence of ciliated columnar epithelial cells by scanning a wet mount slide prepared by mixing one drop of specimen with one drop of saline at 250× to verify that sufficient nasopharyngeal columnar cells are present. Swab specimens from the throat or nasopharynx contain too little cellular material for cytologic prescreening.

Virus Isolation

The same specimen requirements and restrictions used for antigen assays also apply to virus culture. Respiratory cultures in nonimmunocompromised adults and children can be modified throughout the calendar year to accommodate predictable seasonal epidemics of influenza, RSV, metapneumovirus, and PIV (see Fig. 55-5). At a minimum, virology

laboratories should attempt to isolate RSV and influenza during the winter; if staffing permits, PIV, metapneumovirus, and adenovirus can be included for pediatric patients (Hodinka, 2010). Culture improves overall diagnostic yield beyond antigen assays by approximately 10%–20% for all agents except RSV, which is fastidious and may not remain viable in transport. Culture setup can be expanded to recover viruses that are not included in the antigen assay panel.

Nasopharyngeal swabs for influenza culture only should be placed in VTM with antibiotics at collection and transported promptly, preferably on ice. Sputum that contains lower respiratory tract cells and/or acute inflammation is also acceptable for influenza culture and should be placed in VTM with antibiotics. VTM vial specimens should be vortexed vigorously; culture inoculation should not be delayed past 24 hours; inoculation on the day of collection is obviously preferable. For prompt recovery, the supernatant is inoculated into duplicate shell vials (i.e., two trypsinized Madin-Darby canine kidney [MDCK], two Rhesus monkey kidney [RMK], or two hybrid R-Mix), which are refed after centrifugation with FBS-free MEM (bovine serum may contain antibodies to influenza virus). After 1–2 days' incubation at 35° C, shell vial monolayers are DFA-stained for influenza antigen.

Figure 55-4 outlines a shell vial culture procedure for NPA, using a "hybrid" cell monolayer (R-Mix) that contains both A549 and mink lung (MvL) cells, which together support growth of RSV, influenza A and B, adenovirus, metapneumovirus, and the parainfluenzas. Compared with traditional cell lines, this hybrid cell mix has overall recovery rates of 96%–100%, with shortened turnaround time and overall reduced cost of materials and labor (Schindler, 1999).

Laboratories that culture for only RSV should consider using shell vials in place of traditional tubes to reduce recovery time. HEp-2 or A549 cells in Eagle MEM supplemented with 2%–5% fetal bovine serum support RSV replication. Cell culture tube monolayers should be checked daily for CPE for 10 days. Figure 55-6 shows typical RSV multinucleated cellular syncytium CPE, a pattern that is influenced by cation content and freshness of the maintenance medium (Shahrabadi, 1988; Tristram, 2003). Adenovirus also replicates in HEp-2 and A549 cell lines and produces a grapelike rounding and swelling of monolayer cells, usually by 5–7 days; shell vial cultures shorten adenovirus detection to 3 days (see Fig. 55-6).

A number of serologic methods may be used to detect specific antiviral antibodies, but none is practical for rapid diagnosis and clinical management. Serologic diagnosis is most useful for public health epidemiology studies.

Molecular Detection Methods

Multiplexed nucleic acid and array based assays are consistently more sensitive than culture and, as this technology matures, will become the testing of choice for detection of common respiratory viral pathogens (Nolte, 2007; Mahony, 2008). Several commercial assays are available; some detect single agents, and some contain a minimum of influenza A and B and RSV; others detect a broad panel of respiratory viruses. Technology is rapidly evolving for POC rapid testing. A respiratory virus panel has recently been approved for moderate complexity laboratories and incorporates viral RNA extraction, RT-PCR amplification, and multiplexed detection in a fully automated system that requires only a single pipetting step. The clinical importance of subtyping influenza A virus varies seasonally, depending on the dominant circulating strains and their responses to antiviral therapies (<http://www.cdc.gov/h1n1flu/diagnosis/>). Simultaneous amplification of a panel of viral agents can provide sensitive and accurate results, typically within 24 hours. The currently available assays have all been approved for use with nasopharyngeal swabs in viral transport media. Clinical laboratories should consider incorporating these versatile molecular assays when possible into their service menu (see Fig. 55-4).

INFECTIOUS MONONUCLEOSIS AND RELATED INFECTIONS

Infectious mononucleosis is a common systemic lymphoproliferative disease usually caused by primary EBV infection. EBV is part of the Herpesviridae family and, similar to HSV, eventually infects the vast majority of the population worldwide. EBV is spread by saliva; primary infection in early childhood is usually asymptomatic, but if delayed until the teen or young adult years, it often leads to classic infectious mononucleosis. Approximately 150,000 mononucleosis cases are reported annually in the United States (Cohen, 2000; Johannsen, 2010).

EA, Early antigen; EBNA, Epstein-Barr nuclear antigen; IgM, immunoglobulin M; VCA, viral capsid antigen.

*Atypical serologic profiles may require further testing (VCA-IgG avidity testing, Western blot, or polymerase chain reaction) for evaluation.

[†]Positive results are lower in younger patients.

EBV first infects the pharynx; sore throat, fever, and tonsillitis typically mark the onset of infectious mononucleosis. EBV is strikingly lymphotropic; it attaches to the C3d receptor (CD21) on the surface of B lymphocytes in the oropharynx and initiates a polyclonal proliferation of immortalized B lymphoblasts, which generates a polyclonal array of nonspecific IgM antibodies (detected in heterophile antibody assays for infectious mononucleosis). The cell-mediated immune system responds with natural killer cells and CD8⁺ cytotoxic T lymphocytes to eradicate infected B cells. EBV-infected B lymphocytes accumulate in lymph nodes throughout the body, and defensive cytotoxic T lymphocytes infiltrate nodal interfollicular areas, spleen, and liver and circulate as atypical lymphocytes in the peripheral blood (Strickler, 1993; Luzuriaga, 2010). As the patient's cell-mediated factors bring EBV replication under control, infectious mononucleosis symptoms diminish, and lymphadenopathy, splenomegaly, and hepatitis subside.

Similar to other herpesviruses, EBV infection persists in a dormant asymptomatic state. A small percentage of the immortalized B lymphocytes evade eradication and remain latently infected, serving as a lifelong reservoir for reactivation. The EBV genome circularizes and persists as an episome in the lymphocyte nucleus; Epstein-Barr–encoded RNA (EBER) and the Epstein-Barr nuclear antigen (EBNA) and latent membrane protein antigens maintain the EBV genome in a dormant state, working in concert with CD8⁺ cells. Asymptomatic EBV reactivation is common, and up to 20% of healthy adults sporadically shed infectious virus in the saliva. With impaired cell-mediated immunity (AIDS, organ transplantation, X-linked lymphoproliferative disease), EBV cannot be held in check; overt diseases such as oral hairy leukoplakia and B cell lymphoproliferative disease and lymphoma may develop. EBV DNA and EBER are identified by nucleic acid tests in the spinal fluid of patients with primary CNS lymphoma, and by nucleic acid amplification assay and in situ hybridization in transplant recipients who develop B cell lymphoproliferative disease during immunosuppressive therapy. EBV is also linked to nasopharyngeal carcinoma in Asians and to African Burkitt's lymphoma; EBV apparently functions as an initiator; then proliferative factors such as coinfection or immune dysregulation lead to malignancy (Johannsen, 2010).

Diagnosis of Infectious Mononucleosis

Cytotoxic T lymphocytes and apoptotic lymphocytes circulate in the bloodstream during infectious mononucleosis (Fisher, 1996); lymphocytosis (>50%) along with atypical lymphocytosis (>10% total lymphocytes) is relatively insensitive for diagnosing EBV mononucleosis, but the combined findings have a specificity of at least 95%. EBV can be cultivated in lymphoblastoid cell lines, but positivity does not differentiate primary infection from reactivation. Serologic testing is the principal laboratory method for infectious mononucleosis diagnosis (Johannsen, 2010). The polyclonal B lymphocyte proliferation of acute EBV infection generates a variety of transitory but generally harmless autoantibodies such as IgM anti-i (cold agglutinin), rheumatoid factor, and antinuclear antibody. Perhaps the most unusual immunoglobulins produced in infectious mononucleosis are the Paul-Bunnell heterophile antibodies. These IgM class antibodies have affinity for sheep, horse, and bovine erythrocytes, and are not directed against any EBV antigens. They are apparently random antibodies produced during EBV-induced B lymphocyte polyclonal proliferation; they emerge during the first week of infectious mononucleosis, decline during convalescence, and are usually undetectable by 3–6 months. Various heterophile antibodies can also develop during serum sickness and

occasionally in other viral infections; however, heterophile antibody with strong affinity for beef erythrocyte antigens unchanged by adsorption with guinea pig kidney antigen (the differential absorption test) is specific for acute EBV infectious mononucleosis.

Several commercial rapid assays directly mix patient serum on a slide with a suspension of guinea pig kidney antigen; this is followed by addition of preserved equine or bovine erythrocyte antigen bound to latex particles; agglutination occurs almost immediately if the serum contains infectious mononucleosis heterophile antibody. Rapid agglutination tests and solid-phase modifications are approximately 80%–90% sensitive, have a false-positive rate of less than 2% and a positive predictive value of 95% or greater, and are excellent POC assays (Rogers, 1999; Hess, 2004). Their chief limitation is sensitivity: Heterophile antibody is present in more than 90% of teens and adults but in only 40% or less of young children with EBV infectious mononucleosis.

As EBV evolves from primary infection into latency, various EBV antigens are sequentially expressed, and the specific antibodies generated can be used as markers of the stage of infection. The structural nucleocapsid protein viral capsid antigen (VCA) is produced during acute lytic infection; VCA IgM is a specific and sensitive indicator of acute primary EBV infection and subsides with recovery; VCA IgG can usually be detected with onset of symptoms and then persists for life. The early antigens (EAs) (DNA polymerase and thymidine kinase) are produced during acute infection and active EBV replication; antibody to EA-D is present in recent infection, but EA-R antibody is a persistent late marker. As acute mononucleosis subsides, a small percentage of Epstein-Barr–immortalized B lymphocytes escape immune destruction and latently retain episomal EBV DNA; EBNA is responsible for duplication and survival of this episome. Therefore, EBNA IgG typically develops after acute EBV infection has resolved.

The serologic patterns encountered in the various stages of EBV infection are summarized in Table 55-3. IFA serologic assays use lymphoblastoid cell lines, and EBV production is arrested at specific stages for expression of specific antigens; IFA methods are sensitive and specific but have some interpretive subjectivity and require technical expertise. EIA methods using purified or recombinant VCA show better than 95% sensitivity and almost 100% specificity, and have the advantage of objective interpretation and automated processing (Chan, 1998; Tranchard-Bunel, 1999; Hess, 2004). Most primary care physicians rely upon demonstration of atypical lymphocytes in peripheral blood, rapid heterophile screens, and IgM and IgG VCA for diagnosis of infectious mononucleosis. Quantitative tube heterophile reference methods, IgG-EBNA, and IgG-EA are procedurally more complex and have less practical applicability in outpatient practice.

Heterophile-Negative Infectious Mononucleosis

Of the many patients who present with typical clinical features of infectious mononucleosis in the United States, 70% or more have a positive heterophile test, identifying EBV as the cause. Of the 30% who lack heterophile antibody, up to half are IgM-VCA positive, which also verifies acute EBV infection. In approximately 15% of patients with a febrile lymphoproliferative mononucleosis syndrome, primary infection with *Toxoplasma gondii*, CMV, human herpesvirus 6 (HHV6), or HIV is demonstrated; in the remaining 5%–10%, no etiology is established.

Toxoplasmosis is discussed in Chapter 62; accurate diagnosis is most critical in pregnancy, in immunocompromised hosts, and in chorioretinitis

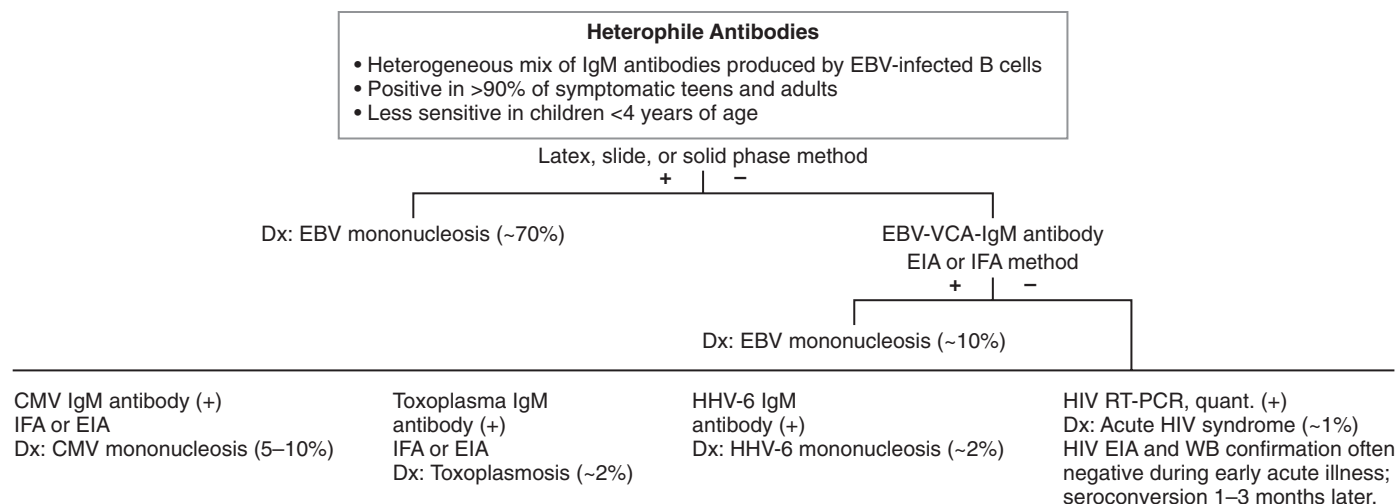

Figure 55-7 Serologic evaluation of patients with clinical symptoms of acute infectious mononucleosis and atypical lymphocytosis. No diagnosis is established in 5%–10% of cases. CMV, Cytomegalovirus; Dx, diagnosis; EBV, Epstein-Barr virus; EIA, enzyme immunoassay; IFA, immunofluorescent assay.

(Remington, 2004). Primary CMV infection acquired in childhood is usually asymptomatic, whereas teens and adults may have a systemic febrile lymphoproliferative illness that clinically overlaps with EBV infectious mononucleosis (Wreghitt, 2003; Crough, 2009). Isolation of CMV from saliva or urine is not helpful because asymptomatic reactivation and shedding is such a common event. Recovery of CMV from circulating leukocytes is valid and sensitive but is expensive and time-consuming compared with serodiagnosis. CMV IgM IFA serology is complicated by the fact that CMV-infected substrate cells express receptors for immunoglobulin Fc; the anticomplement IFA method (ACIF) is procedurally more complex but reduces this false-positive error. IgM-specific EIAs and enzyme-linked fluorescence assays have overall accuracy that is comparable with the ACIF-IFA IgM assay and have less interpretive subjective variation; pretreatment of serum to remove IgG and rheumatoid factor improves sensitivity (Hodinka, 2007).

HHV6 is another ubiquitous lymphotropic virus with affinity for T cells. HHV6 causes roseola infantum (exanthem subitum), a common febrile exanthem in young children (Braun, 1997; Prober, 2005; Zerr, 2005). Most primary infections occur in young children; when first exposure is delayed until adulthood, infection is often symptomatic and clinically similar to mononucleosis (Braun, 1997). Both IFA- and EIA-specific IgM assays can diagnose acute infection; virus can also be identified in saliva and plasma with PCR. However, confirmatory testing is not practical for routine primary care practice (Steeper, 1990; Chiu, 1998; Zerr, 2005).

Infection with HIV1 can also produce an acute illness that clinically mimics EBV mononucleosis (Kassutto, 2004). One third or more of patients develop fever, lymphadenopathy, atypical lymphocytosis, and occasionally mild hepatocellular damage or meningoencephalitis. As many as 2% of EBV-negative mononucleosis cases may be caused by HIV acute retroviral syndrome. Standard anti-HIV EIA may fail to detect specific antibody if blood is collected during this early phase of infection, but quantification of plasma HIV by RT-PCR is typically high (10^5 copies/mL). EIA, Western blot, and IFA serologic tests all become positive for HIV antibodies within 1–3 months, as features of acute infection resolve (Schupbach, 2003). **Figure 55-7** shows an algorithmic approach to the serologic evaluation of a patient with symptoms of acute mononucleosis. Despite extensive laboratory testing for these acknowledged causes of mononucleosis, no etiologic agent is identified in at least 10% of cases.

CHRONIC FATIGUE SYNDROME

Both the medical press and the lay press have discussed at length a clinical entity characterized by persistent disabling fatigue accompanied by fever, pharyngitis, tender lymphadenopathy, arthralgias, and myalgias (Holmes, 1988; Natleson, 2001). Although the clinical features of this syndrome suggest an infectious cause, none has yet been clearly identified. Initial reports implied that EBV, as chronically persistent primary or reactivated infection, was responsible because many patients had high titers to EBV VCA and EA. However, serologic tests were neither standardized nor reproducible, and EBV culture and ISH performed on saliva and circulating leukocytes showed no difference between chronic fatigue patients and

normal controls. Some studies have suggested a role for CMV, enteroviruses, *T. gondii*, HHV6 and HHV7, and human T cell leukemia virus, but other reports have failed to verify a causative role (Reeves, 2000; Colby, 2006). Immunologic and serologic testing is not helpful for diagnosis or prognosis. Chronic fatigue syndrome remains defined by clinical signs and symptoms, rather than by laboratory test results (Lloyd, 1998; Gantz, 2001). A recent study has suggested a link between the retrovirus xenotropic murine leukemia virus and chronic fatigue syndrome (Lombardi, 2009); although this remains unproven, the preliminary association has prompted several blood banks to exclude donors with a clinical history of chronic fatigue syndrome.

CONGENITAL AND PERINATAL VIRAL INFECTIONS

The pregnant uterus is a sterile secluded environment that shelters the fetus from external microbial injury. Maternal vaginal bacteria that ascend through a flawed cervical barrier cause many infections in pregnancy, but maternal infection also can spread hematogenously to the fetus across the placenta, or can directly involve the baby at the time of vaginal delivery. These perinatal infections are collectively named TORCH infections, for toxoplasma (see Chapter 62), rubella, cytomegalovirus, HSV, and other organisms such as HIV, parvovirus B19, enterovirus, and *Treponema pallidum* (see Chapter 59). Infection with these agents may be silent or may cause only minor symptoms in the mother; however, the immature fetal immune system does not generate an effective cellular or humoral response, so fetal tissue necrosis may be severe or even fatal.

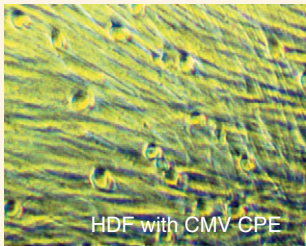

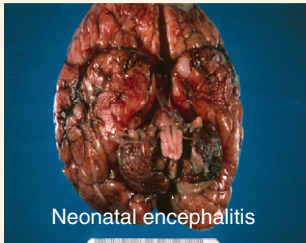

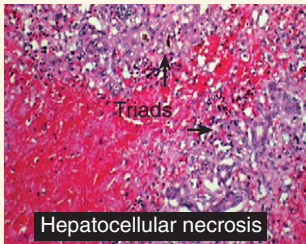

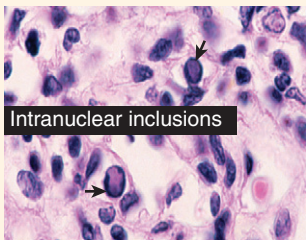

Diagnosis of perinatal infection centers on two issues: identification of acute maternal infection (particularly primary infection) and verification of involvement of the fetus or newborn. Maternal infection is best established by recovery of the suspected organism, but for many infectious agents this is impractical, and serologic demonstration of specific IgM antibody, although imperfect, is the first-line diagnostic test. Maternal infection crosses the placenta in 30%–60% of cases. Ultrasound may detect fetal organ damage (microcalcifications, microcephaly, hydrocephalus, organomegaly, hydrops, etc.), but recovery of the organism by culture, demonstration of its antigen or genome in fetal blood or tissues, or detection of specific antibody is required to prove specific fetal infection. Test selection for diagnosis of common perinatal and congenital infection is summarized in Table 55-4. Routine screening of all pregnant women for syphilis, for immunity to rubella, and also for HIV serostatus is standard of care; however, routine prenatal testing for toxoplasma, HSV, and CMV antibodies is not advised. IgM serologic methods in particular may show interlaboratory and intralaboratory variation, with false-negative and false-positive errors; IgG assays do not differentiate primary from recurrent or latent maternal infection and cannot predict fetal involvement. Testing should be reserved for mothers with suspected infection.

Cytomegalovirus

CMV, the most common intrauterine infection, affects 1% of liveborn babies in the United States. About 90% of these infants are asymptomatic

TABLE 55-4

Laboratory Testing for Congenital and Perinatal Infections

Pathogen	Maternal serology	Culture, antigen assays, nucleic acid amplification	Fetal or newborn serology
Cytomegalovirus  HDF cell monolayer with CMV cytopathic changes	IgM EIA IgG avidity	CMV culture, mother: blood CMV culture, newborn: urine, saliva, blood, tissues (first 2 weeks of life) CMV nuclear inclusions: tissues CMV PCR, in utero: amniotic fluid, umbilical cord blood CMV PCR, newborn: blood, urine (first 2 weeks), tissues	IgM EIA
Herpes simplex virus  Neonatal encephalitis	IgM EIA for HSV1 and HSV2 (gG)	HSV PCR or culture: newborn conjunctiva, oral mucosa, skin, CSF HSV nuclear inclusions: newborn tissues, skin lesions	IgM EIA or IFA
Enterovirus  Hepatocellular necrosis		Enterovirus RT-PCR, newborn: CSF, blood, tissues, throat Enterovirus culture, newborn: blood, CSF, tissues, stool, throat Request enterovirus typing from Public Health Laboratory	
Parvovirus B19  Intranuclear inclusions	IgM EIA or IFA	PB19 PCR: maternal blood Ground glass viral nuclear inclusions: newborn erythroblasts PB19 ISH, newborn: erythroblasts PB19 PCR: placenta, fetal tissues, blood	IgM EIA
Hepatitis B virus	HBsAg, HBeAg, anti-HBsAg	HBV PCR quantitative viral load: newborn blood	
Human immunodeficiency virus	HIV EIA and Western blot HIV RNA quantification	HIV DNA PCR, newborn HIV RNA RT-PCR after 3 months of age	Monitor HIV EIA for possible seroreversion (6–18 months)
Rubella	IgM EIA or IFA	Rubella culture, newborn: urine Rubella RT-PCR: amniotic fluid, placenta, fetal or newborn tissue	IgM EIA or IFA

HBc, Hepatitis B core antigen; HBsAg, hepatitis B surface antigen; CMV, cytomegalovirus; CSF, cerebrospinal fluid; EIA, enzyme immunoassay; gG, glycoprotein G; HDF, human diploid fibroblast; HIV, human immunodeficiency virus; HSV, herpes simplex virus; IFA, indirect immunofluorescence assay; IgG and IgM, immunoglobulin G and M; ISH, in situ hybridization; PB19, parvovirus B19; PCR, polymerase chain reaction; RT-PCR, reverse transcriptase PCR.

at birth; isolation of CMV from urine or saliva or detection of IgM CMV may be the only marker of congenital infection. The symptomatic 10% may present with jaundice, hepatosplenomegaly, pancytopenia, and compensatory cutaneous hematopoiesis (Abdel-Latif, 2010); approximately 10% of these babies will die, and the remainder will suffer permanent neurologic sequelae. Primary CMV infection in the mother is often viremic, with risk of vertical hematogenous transplacental fetal infection and prenatal tissue injury (Stagno, 1982; Revello, 2002; Cheeran, 2009).

Reactivation of CMV infection in the mother can cross the placenta, but maternal IgG CMV antibody traverses the placenta and is somewhat protective; these infants are usually asymptomatic at birth, but 5%–15% have sensorineural hearing loss or neurodevelopmental difficulties (Istas, 1995). Maternal reinfection with a new CMV strain has a greater risk of causing symptomatic congenital infection (Boppana, 2001).

IgM-specific assays have shifted from complement fixation, IFA, and anticomplement IFA methods to EIA methods, which use refined

recombinant CMV antigens and IgM capture to improve specificity and sensitivity. IgM may persist for longer than 3 months in at least one third of adult women, obscuring the interpretive value of a positive result during pregnancy. CMV IgG avidity testing may be useful in dating recent versus remote infection, similar to assessment of toxoplasma serology in pregnancy; identification of both IgM and low-avidity IgG in a pregnant woman correlates with primary CMV infection with a high risk of intra-uterine transmission (Revello, 2002; Remington, 2004; Munro, 2005). Automated IgG avidity serologic testing appears accurate and has potential diagnostic applications (Lagrou, 2009).

Identification of CMV viremia in a nonimmunocompromised pregnant woman through shell vial culture of peripheral blood leukocytes or detection of CMV pp65 antigenemia or detection of CMV DNA by PCR in blood provides conclusive evidence of active maternal infection. However, risk of fetal involvement is estimated at about 40%, and no test performed on the mother can predict fetal infection accurately.

The most reliable prenatal tests to verify fetal infection are viral culture and PCR detection of CMV in amniotic fluid, which have a combined sensitivity of 75%–92% (Revello, 2002). Virus in amniotic fluid indicates overflow shedding from the in utero infected child, and a positive result has 100% specificity for infection. High CMV viral load in amniotic fluid has also been proposed as an indicator of severity of fetal tissue damage. However, false negative error can occur if there is less than a 7-week interval between the onset of maternal infection and the collection of amniotic fluid for testing. Detection of CMV-IgM in fetal cord blood is less sensitive (55%–60%) because of delayed fetal immune response following exposure; cordocentesis CMV DNA PCR has a sensitivity of 84%. IgM CMV in cord blood collected at delivery is also diagnostic, but can be false-negative in up to 30% of cases (Fowler, 1992). Identification of CMV by culture or PCR from newborn urine, saliva, CSF, or blood is very sensitive. PCR detection of CMV DNA in newborn tissue or blood has very high sensitivity—almost 100%; however, use of dried blood samples collected from neonates has variable sensitivity, and its practical applications have not yet been verified (Soetens, 2008; Boppana, 2010). Specimens for any testing must be collected during the first 2 weeks after birth to avoid confusion with postnatally acquired infection (Nelson, 1995; Revello, 2002). Monitoring viral load has no defined predictive value. Typical CMV nuclear inclusions in urine cytology preparations are specific but very insensitive; even autopsy material may have few remaining diagnostic cells if tissue necrosis is advanced. Placenta specimens may show nuclear inclusions or may yield recoverable virus by culture; infection that occurred several weeks before delivery may show only nonspecific avascular sclerotic chorionic villi.

Rubella

Rubella (German measles) is highly communicable and produces mild fever and a transient rash in children and adults. All infections are viremic, and transplacental spread during the first trimester produces devastating teratogenic cardiac, ocular, and brain malformations (Schluter, 1998). Rubella is no longer endemic in the United States because of widespread vaccination; genome analysis demonstrates that most recent rubella cases are imported from Latin America. Routine prenatal screening for maternal rubella IgG as proof of immunity is standard practice. Only four cases of congenital infection have been identified since 2001, three of which occurred in immigrant mothers (MMWR, 2005). When acute rubella is suspected in a pregnant woman, the most straightforward diagnostic method is assay of maternal serum for rubella IgM by EIA or IFA. Culture of rubella is technically complex and is not routinely available. RT-PCR for rubella virus RNA performed on amniotic fluid is almost 100% sensitive and specific and can also be performed on placenta and autopsy tissues (Revello, 1997; Mace, 2004). Multiplex assays that can detect genomic material from rubella and from several other agents of perinatal infection have been developed (McIver, 2005). The congenitally infected newborn is IgM positive and excretes rubella in urine for months to years.

Herpes Simplex Virus

Despite the high prevalence of HSV in adults, neonatal disease is uncommon, occurring at a rate of 5 to 60 cases per 100,000 live births in the United States. Acquisition of maternal genital HSV1 or HSV2 infection during pregnancy has devastating implications for the newborn. Primary disease rather than recurrence puts the baby at great risk for two reasons: The total number of mucocutaneous genital lesions is often higher with first involvement, and although maternal serum contains IgM, little or no IgG is present for transplacental passive protection of the baby (Corey, 2009).

Most babies have a vertex presentation during labor, so the scalp and the face are the first to encounter HSV in the maternal tract; viral exposure on the chest wall and buttocks occurs in breech delivery. Vesicles develop where skin and mucous membranes are directly inoculated with virus. Because the newborn immune response is still immature, a baby's chief resource for modifying infection is maternal IgG-HSV; when this passive protection is lacking, viral replication and visceral dissemination can proceed unchecked. Conjunctival and oral mucosa and skin lesions are usually rich in virus; if dissemination occurs, any visceral organ can be infected.

Obstetric management is complicated by several issues. Routine HSV culture of all mothers without vesicles or infants at the time of delivery has a 0.2% yield and is not recommended (Prober, 1988). Prenatal HSV surveillance cultures of women with known recurrent genital herpes fail to predict which mothers will shed virus at the time of delivery (Arvin, 1986). Studies of women who experienced their first recognized episode of genital herpes during pregnancy demonstrated that half had true primary genital herpes, and these pregnancies had a high rate of complications, such as herpetic amnionitis, preterm labor, and severe neonatal infection. Almost half of mothers who acquired their primary infection shortly before labor had severely affected babies (Brown, 1997). Mothers with recurrent genital herpes had a much lower rate of neonatal infection, with involvement confined to mucocutaneous sites and showing no visceral dissemination (Brown, 1991).

It is accepted practice that women in labor who have genital lesions suspicious for herpes are managed with cesarean section to prevent possible exposure of the baby. Women with a history of recurrent genital herpes can deliver vaginally if active lesions are not present at labor, but careful clinical monitoring of their newborns (including HSV culture/PCR of conjunctiva, oral mucosa, and any suspicious cutaneous lesions) is warranted. Neonatal herpes infection may be silent for up to several days before disease becomes apparent. Despite antiviral therapy, disseminated infection can be fatal; infants with infection confined to the CNS who survive are always severely retarded.

Laboratory diagnosis of HSV infection was discussed earlier in this chapter. Type-specific HSV serology is now available and can identify seronegative women with seropositive partners, highlighting their risk for acquiring infection during pregnancy (Ashley, 1999; Cherpes, 2003). Tzanck smears and rapid antigen assays may be positive for vesicle lesions but cannot replace culture (which yields a positive result in 24 hours when shell vials are used). Identification of HSV DNA by PCR in neonatal spinal fluid or mucocutaneous lesions has greater sensitivity than culture and is particularly valuable for detecting virus in CSF in babies with known CNS involvement (Kimberlin, 1996, 2004).

Human Immunodeficiency Virus, Parvovirus, Enterovirus, Hepatitis B Virus, and Varicella Infections

HIV can spread hematogenously to the fetus, with placental trophoblast and Hofbauer macrophages acting as a cellular reservoir. However, approximately 75% of perinatal infections are acquired at delivery, when the baby is exposed to maternal blood. Perinatal risk of HIV acquisition can be as high as 45%, particularly when maternal HIV1 viral load is high. Transmission rates are reduced to less than 2% by scheduled cesarean section delivery in mothers with high HIV viral load, and by administration of highly active antiviral drugs to the mother during pregnancy and labor, and also to the newborn (Watts, 2002; Anderson, 2009; Tubiana, 2010). HIV is also transmissible postpartum in leukocytes in breast milk; this should absolutely be avoided.

Diagnosis of maternal HIV infection is straightforward (positive EIA for HIV antibody with Western blot confirmation). Routine screening in the first trimester is strongly recommended; seropositive mothers can then be assessed with quantitative HIV RNA levels, and antiviral therapy given. For mothers in labor whose serologic status is unknown, intrapartum testing should be performed on a stat basis using a rapid HIV antibody method (Griffith, 2007), so that seropositive mothers can have intravenous antiviral prophylaxis initiated immediately to reduce the risk of perinatal infection of the baby. Maternal IgG crosses the placenta and persists in infant blood for up to 18 months, so standard EIA HIV serologic tests cannot be used to diagnose neonatal infection. Variations of both EIA and Western blot tests for detection of IgM and IgA HIV antibodies can identify an infected baby, because neither IgA nor IgM is passively transferred to the fetus; however, sensitivity is age dependent, and testing is not reliable in the first 3 months after birth.

Traditional HIV p24 antigen assays have been considered suboptimal in sensitivity for diagnosis during the immediate postnatal period (Sison, 1992). However, an ultrasensitive p24 assay performed on dried blood spots has shown 96%–98% sensitivity when performed on 6-week-old babies (Patton, 2008). If infection was acquired transplacentally during gestation, then newborn blood is positive for HIV DNA that has been transcribed and integrated into the infant's peripheral blood lymphocytes. PCR for HIV proviral DNA has a diagnostic sensitivity greater than 95% at 1 month of age (Rogers, 1989; Bremer, 1996). PCR for identification of HIV1 DNA in dried blood spots also has excellent sensitivity, and has valuable applications for testing infants in remote areas (Luo, 2005), as do DNA-PCR assays with simple rapid POC extraction methods (Jangam, 2009). HIV RNA RT-PCR is positive at birth if the baby was infected in utero, and will become positive within several weeks in infants who were infected during delivery. Real-time RT-PCR is also used for quantitative monitoring to assess the baby's response to antiretroviral therapy.

Parvovirus B19 (PB19) causes the benign, self-limited childhood exanthem erythema infectiosum (fifth disease) (Heegaard, 2002; Young, 2004), and major epidemics develop every few years. Approximately 50% of young women are seronegative, and infection in pregnancy can have serious consequences for the developing baby. PB19 targets erythroid progenitor cells, and virolytic cytotoxicity produces fetal anemia with risk for hydrops and intrauterine demise (Tolfvenstam, 2001). Maternal transmission during primary infection has an estimated risk of fetal infection of 25%; fetal death estimates vary from 2%–38% (Alder, 1993). A recent retrospective study of intrauterine fetal demise and miscarriage that included a major PB19 epidemic episode showed that PB19 DNA was found in 4.9% of fetal deaths, and intrauterine fatalities were six times more prevalent during epidemic intervals (Ripinen, 2008). Infected erythroblasts have characteristic ground-glass nuclear inclusions by hematoxylin and eosin (H&E) stain. Parvovirus can be cultivated only in human bone marrow containing erythrocytic precursor cells—an impractical method for diagnosis. Acute infection is characterized serologically by detecting specific IgM in maternal or fetal blood, or by ISH or PCR detection of viral DNA in amniotic fluid or cord blood (Bruu, 1995; Zerbini, 1996).

Enterovirus infection is very common, with 10 million or more cases reported each year in the United States. Many enteroviral infections are viremic; maternal infection just prior to delivery spreads virus transplacentally to the fetus, and the baby is born with disseminated virus but with no passively acquired maternal protective IgG antibody to modify infection. Nosocomial outbreaks with nursery personnel as the source of virus have also been reported. Echovirus 11 is particularly virulent, causing hepatocellular necrosis and meningoencephalitis that are often fatal. Coxsackie B viruses can produce neonatal myocardial injury (Bryant, 2004). Quantitative assay of coxsackievirus B3 in blood during a local outbreak showed highest viral load levels in neonates, which also correlated with disease severity (Yen, 2007). Perinatal infection with other enteroviruses usually is benign. The amount of virus in clinical specimens is generally low, and direct hybridization assays have poor sensitivity. However, RT-PCR and NASBA nucleic acid amplification assays detect a common sequence present in all enteroviruses and have excellent sensitivity, superior to standard culture, yielding positive results within 1 working day (Landry, 2003; Romero, 2007). Enteroviruses grow well in standard tube cultures (PMK, HDF, and RD cell lines); shell vial culture methods can shorten detection time to 2 days, and use of both BGMK and A549 cell lines in a single shell vial monolayer improves sensitivity (Romero, 2007). Suitable specimens for viral culture include neonatal blood, CSF, throat, and rectal swab samples, or tissues from fatal cases. Typing of specific enterovirus isolates is beyond the scope of hospital laboratories and can usually be done through regional or national public health laboratories.

Maternal infection with hepatitis B virus is often transmitted vertically; the baby may be infected transplacentally or, more probably, during delivery with exposure to maternal blood. Screening for hepatitis B surface antigen (HbsAg) is a standard component of prenatal care. Transmission rates are as high as 80% if the infected mother is positive for core antigen and approximately 30% if the mother is core antigen negative. If the maternal HBV screen is positive, then immediately after birth the neonate is given HBV immune globulin, along with the first dose of the HBV surface antigen vaccination series (Poland, 2004).

Varicella zoster virus infection acquired early in pregnancy is often teratogenic and causes limb hypoplasia and dermatome pattern skin scarring, as well as severe CNS disease (Whitley, 2005). This constellation of fetal complications from in utero exposure has also been reported with HSV2 (Johansson, 2004). Maternal chickenpox with viremia just prior to delivery can cause severe mucocutaneous chickenpox in the newborn.

VIRAL MENINGITIS AND ENCEPHALITIS

Several thousand viral infections of the CNS occur each year in the United States, with considerable variation in morbidity and mortality. Accurate and prompt laboratory diagnosis aids patient management and is important for public health interventions to control arboviral arthropod vectors and investigate waterborne sources. Viral proliferation in the meningeal layers covering the brain induces acute inflammation with fever, headache, nuchal rigidity, and CSF pleocytosis. In encephalitis, virus replicates within the brain parenchyma; inflammation and tissue necrosis may be diffuse or may produce a space-occupying lesion with mass effect. Many viruses are associated with meningitis or encephalitis, but overlap injury with involvement of both anatomic sites (meningoencephalitis) is common, particularly with arbovirus infection (Fig. 55-8).

Viral encephalitis is not infrequent in the United States, with an estimated annual incidence of 7.3 cases per 100,000 individuals (Khetsuriani, 2002). Some neurotropic viruses are fastidious and require molecular methods for accurate diagnosis. Arboviruses (arthropod borne) and HSV cause most cases of acute encephalitis in the United States. Mosquitoes are vectors for hundreds of neurotropic viruses worldwide, but only five arboviruses are encountered regularly in the United States: WNV, the Eastern and Western equines, St Louis, and California-LaCrosse encephalitis viruses. HSV encephalitis usually occurs as a reactivation of latent HSV1 that tracks (via the olfactory or trigeminal cranial nerves) into the cerebral cortex, producing a large necrotic mass. About 700 cases of herpes encephalitis are reported each year in the United States; the pattern is sporadic and nonseasonal. Progression is rapid and mortality is high, but early diagnosis with appropriate antiviral treatment reduces both mortality and the level of permanent disability (Mitchell, 1997; Steiner, 2007).

Arboviruses are a heterogeneous group, and mosquito transmission is their common denominator; the most frequent in North America are members of the flavivirus, togavirus, and bunyavirus families. Before the WNV outbreak, total annual U.S. arboviral cases varied between 100 and 2000; disease peaked during warm weather when mosquito populations were greatest. Severity and mortality are highest with the Eastern equine virus, the least frequent of the group (Kuno, 2005). The WNV outbreak originated in 1999 in New York; the virus then traveled in infected birds from the East Coast across America and involved all states by 2004. WNV has since become endemic (Snapinn, 2007). The estimated total number of cumulative human WNV infections is currently about 1 million; approximately 200,000 patients have become clinically ill with disease ranging from simple fever to meningitis, encephalitis, and flaccid poliomyelitic paralysis; both long-term encephalitic and paralytic disabilities have been reported, along with many fatalities (Nash, 2001; Petersen, 2004; Hayes, 2005). Mosquito bites are the typical route of acquisition, but blood transfusion and organ transplantation also accounted for several cases (Iwamoto, 2003; Pealer, 2003; Kleinman, 2005). Blood donations are now screened for WNV by nucleic acid tests during summer months, effectively interrupting this mechanism of spread (Busch, 2005).

By the time of onset of CNS disease, WNV and many other arboviruses often cannot be detected by culture or PCR in blood or spinal fluid; therefore, diagnosis primarily hinges on EIA for specific IgM antibody in CSF and serum, or demonstration of rising specific IgG. Nucleic acid amplification for WNV plays an important role in screening blood donors but is of limited clinical use and may be helpful only when WNV-infected patients seek medical attention very soon after onset of symptoms (Prince, 2008; Reznicek, 2010b). Interpretation of a positive IgM serologic test for WNV must be made with caution because elevated titers may persist for prolonged periods following acute infection, and because cross-reaction with other flaviviruses (yellow fever and dengue) may occur (Reznicek, 2010b). State health departments and reference laboratories offer a range of tests for common regional arboviruses, but hundreds of arboviruses are endemic outside the United States in Asia, Africa, Latin America, and parts of Eastern Europe. Testing for arbovirus infection in travelers is available through public health laboratories; the referring laboratory must provide a detailed travel history and clinical information, along with blood, CSF, or tissue specimens submitted for culture, nucleic acid detection, or serologic diagnosis (see Fig. 55-8). Current information about global arbovirus activity and risk to tourists is available at www.cdc.gov/travel.

More than 70 enteroviruses, some of which produce encephalitis (coxsackie virus and echovirus) have been identified. Paralytic polio caused by poliovirus necrosis of spinal cord or brainstem motor neurons has been eliminated in most of the world, with residual disease in Africa and Asia, which may soon be eradicated by vaccination efforts. Rabies virus travels

- CSF for cell count, glucose, protein
- Nucleic acid tests for HSV VZV, and enteroviruses
- Cell culture: Inoculation of super E-mix (engineered BGMK and A549 cells), HDF, PMK, Hep-2, RD, etc.
- Additional CSF/tissue: Freeze at -20° C
- Acute phases serum: Freeze 1-2 mL at -20° C
- Refer CSF and acute phase serum to public health or reference laboratory for seasonal West Nile virus/ arbovirus IgM antibody testing.
- Collect convalescent serum, if required.

Aseptic meningitis

- Enteroviruses
- WNV, other regional arboviruses
- Travel-associated arboviruses
- HIV
- HSV-2
- EBV
- VZV, mumps, adenovirus
- LCM
- Influenza A&B

Meningoencephalitis / encephalitis

- WNV, other regional arboviruses
- Travel-associated arboviruses
- HSV
- Enteroviruses (paraechoviruses)
- EBV
- VZV, measles, RSV, hMPV, influenza, adenovirus
- Rabies

Immunocompromised patient

- CMV, HSV, VZV
- HIV
- EBV
- JC virus
- Enteroviruses (paraechoviruses)
- HHV6

Consult with public health/reference laboratory for volume of CSF needed for all nucleic acid tests and serology ordered.

Brain biopsy: 0.5 cm³ tissue biopsy usually sufficient for imprints, surgical pathology, comprehensive microbiology, and nucleic acid tests.

Figure 55-8 Workup of cerebrospinal fluid (CSF) and brain biopsy for viral pathogens. *BGMK*, Buffalo green monkey cells; *CMV*, cytomegalovirus; *CSF*, cerebrospinal fluid; *EBV*, Epstein-Barr virus; *HDF*, human diploid fibroblasts; *HHV6*, human herpesvirus 6; *HIV*, human immunodeficiency virus; *hMPV*, human metapneumovirus; *HSV*, herpes simplex virus; *Ig*, immunoglobulin; *PMK*, primary monkey kidney; *RD*, rhabdomyosarcoma cells; *RSV*, respiratory syncytial virus; *VZV*, varicella zoster virus; *WNV*, West Nile virus.

via nerve fibers directly to the CNS and produces necrotizing brain damage; bat rather than canine strains account for most disease in the United States; a recent outbreak was traced to transplanted organs from a donor who had died with undiagnosed rabies (Smith, 2003; MMWR, 2004). Measles, mumps, EBV mononucleosis, and chickenpox rarely are complicated by acute encephalitis (Cherry, 1998). HHV6 can produce focal cerebral injury (Isaacson, 2005). HIV replication in CNS glial cells can cause progressive dementia in advanced AIDS (Atwood, 1993). Opportunistic necrotizing brain infection with HSV, CMV, and VZV, as well as JC polyomavirus destruction of oligodendroglia, may also develop in the immunocompromised host (discussed later).

Enteroviruses cause 75% of viral meningitis in the United States, usually a relatively benign and transient disease. Enteroviruses spread easily from person to person via fecal-oral means, and distinct seasonality is seen, with annual summer-fall outbreaks (see Fig. 55-1); most clinically recognized infections are seen in children and young adults. Chronic severe meningoencephalitis can develop in patients with hypogammaglobulinemia; any enteroviral CNS infection with an encephalitis component is more virulent and may leave permanent sequelae (McKinney, 1987). Acute HIV infection occasionally produces acute meningeal inflammation (Schupbach, 2003). About 1% of primary HSV2 genital herpes infections are accompanied by transient meningitis; HSV2 is the major cause of Mollaret's benign recurrent lymphocytic meningitis. Mumps, measles, metapneumovirus, and adenovirus infections rarely produce acute meningitis (Reznicek, 2010b).

Laboratory Diagnosis

Initial evaluation of CSF should include cell count and glucose and total protein quantitation. Pleocytosis is usually mild (50–1000 cells/mm³)

TABLE 55-5

Yield From CSF Specimens Tested for Enteroviruses, VZV, HSV, and CMV by Nucleic Acid Assays

Virus	Yield
Enteroviruses	11.3% (36/318)
Herpes simplex virus (HSV)	4.1% (56/1360)
Varicella zoster virus (VZV)	10.6% (13/123)
Cytomegalovirus (CMV)	2.1% (3/144)

Personal data, L. Sabatini, Multiple hospitals, Chicago area and southeast Wisconsin, 2008–2009.

compared with bacterial infection. Mononuclear cells usually predominate, but neutrophils can dominate early, particularly following infection with WNV. Protein may be somewhat elevated (rarely >200 mg/dL), and glucose levels are normal to slightly decreased (Tunkel, 2008; Reznicek, 2010a, 2010b). Comprehensive laboratory evaluation of viral CNS disease is currently beyond the scope of most hospital laboratories. A streamlined plan for stepwise testing based on the clinical scenario can coordinate in-house testing with efficient use of reference laboratory and public health laboratory services (see Fig. 55-8). For immunocompetent patients, initial testing of spinal fluid/brain biopsy tissue using nucleic acid amplification for enteroviruses HSV, VZV, and possibly CMV plus virus culture can be paired with serum and CSF assays for IgM antibodies to the prevalent regional seasonal arboviruses (Reznicek, 2010a). Table 55-5 illustrates yields of molecular detection for enterovirus, HSV, VZV, and CMV in a large metropolitan area laboratory. VZV may be overlooked as a cause of

TABLE 55-6

Laboratory Diagnosis of Common Viral Exanthems and Mucocutaneous Lesions*

Exanthem or skin lesion	Virus	Culture/antigen and nucleic acid assays	Serology
Chickenpox/shingles	Varicella zoster	Tzanck smear DFA smear Culture (shell vial most sensitive) PCR	IgM-EIA (chickenpox) IgG-EIA for immunity following chickenpox Commercial VZV-IgG tests may not be reliable for documenting immunity post vaccination
Enteroviral rash (hand, foot, and mouth disease)	Enteroviruses	Culture, RT-PCR	
Measles	Measles	Culture [†]	IgM-EIA or IFA [†]
Rubella	Rubella	Culture [†]	IgM-EIA [†]
Erythema infectiosum	Parvovirus B19		IgM-EIA or IFA [†]
Exanthem subitum	HHV6	Coculture in lymphoblasts [†]	IgM-EIA [†]
Anogenital condyloma	Papillomaviruses	Hybrid capture and Invader assays	
Evaluation of ASCUS cervical cytology			
HSV	HSV1 and HSV2	PCR Culture DFA smear or Tzanck smear	HSVgG1 and gG2G glycoprotein specific antibody; IgM, not specific

ASCUS, Atypical squamous cells of undetermined significance; DFA, direct fluorescent antibody; EIA, enzyme immunoassay; gG, glycoprotein G; HSV, herpes simplex virus; HHV, human herpes virus; IFA, indirect fluorescent antibody; IgM, immunoglobulin M; RT-PCR, reverse transcriptase polymerase chain reaction; VZV, varicella zoster virus.

*If smallpox is considered in a patient with vesicular lesions, contact local health authorities for specific instructions.

[†]Test available at reference and research laboratories.

meningoencephalitis, particularly if skin lesions are not appreciated (Hayes, 2005; Kupila, 2006; Frazen-Röhl, 2007). If clinically indicated, CSF reserved at -20°C and paired acute and convalescent sera can be referred for more extensive arbovirus testing in public health laboratories, and for culture and additional nucleic acid amplification for less common causes of viral meningitis or encephalitis. The 1999 WNV outbreak was quickly identified because of cooperative and coordinated efforts between hospital and government laboratories (MMWR, 1999). Despite extensive evaluation, an infectious cause for encephalitis often is not identified (Glaser, 2003).

Immunocompromised patients may develop CNS disease with the same viruses that afflict the healthy host; in addition, several opportunistic viral infections may produce CNS involvement. JC polyomavirus, CMV, VZV, and HSV can cause CNS disease; CNS B lymphocyte lymphoma is almost always related to EBV infection; PCR for EBV in CSF in patients with AIDS is diagnostic of CNS lymphoma.

The most practical approach to diagnosis of viral encephalitis is nucleic acid testing performed on CSF. RT-PCR identification of enterovirus and PCR for HSV, VZV, EBV, CMV, and HHV6 are more sensitive than virus recovery by cell culture from CSF or brain tissue. Several multiplexed and microarray-based assays have been developed (DeBiasi, 2004; Koralnik, 2005; Epsy, 2006; Wolffs, 2009) and are available through reference laboratories. Preliminary screening of CSF for elevated protein and pleocytosis is advisable because herpesviruses are rarely, if ever, identified when protein and cell counts are normal (Hanson, 2007). Brain biopsy is still performed on occasion, usually when tumor or nonviral infection is a clinical consideration. A 0.5-cm³ biopsy is sufficient for surgical pathology examination, imprint smears for direct examination, nucleic acid amplification, and comprehensive culture for all infectious organisms. HSV isolation in cell culture was discussed previously; recovery of other viruses should also be attempted, so the specimen should be inoculated to all cell lines that the laboratory carries. Imprints stained with DFA reagents can demonstrate HSV-infected cells. Some arboviruses and enteroviruses require animal inoculation for replication; if needed, tissue should be frozen at -20°C and the specimen forwarded to a public health or reference laboratory.

Enteroviruses are the most common agents of acute aseptic meningitis; nucleic acid tests are the gold standard for enterovirus identification in CSF, with yields of 128%–142% compared with cell culture recovery (Landry, 2003; Romero, 2007). Nucleic acid tests designed to detect enteroviruses do not detect parechoviruses and require separate primers and probes (Baumgarte, 2008; Nix, 2008).

Several tissue lines (PMK, HDF, HEp-2, RD, buffalo green monkey Super E-Mix [genetically engineered cell line BGIMK-hDAF]) support the growth of many enteroviruses and of HSV, VZV, measles, mumps, and adenovirus; E-mix hybrid shell vial culture is also an excellent choice for

culture of enteroviruses and related agents (Huang, 2002). From 0.1–0.2 mL of CSF should be inoculated directly into each tube or shell vial without delay. Enterovirus-specific typing is available in public health laboratories.

VIRAL EXANTHEMS AND COMMON CUTANEOUS INFECTIONS

Several viruses primarily target the skin. Some infect the squamous epidermis through direct inoculation (oral and genital herpes, warts caused by human papillomavirus or molluscum poxvirus). Exanthems are caused by viruses that spread hematogenously to skin and mucous membranes (VZV, measles, rubella, enteroviruses, parvovirus, HHV6) (Cherry, 1993). Many of these benign childhood exanthems are diagnosed clinically with no laboratory testing needed, and several are now preventable with pediatric vaccination requirements. When laboratory confirmation of acute infection is needed for unusual cases, or to apply infection control precautions in hospitalized patients, or to guide appropriate antiviral treatment, serology is often easier and more accurate than culture or antigen assay. With the exception of varicella, specific nucleic acid assays generally are not needed for diagnosis. Laboratory diagnostic procedures are summarized in Table 55-6.

VZV causes both varicella (chickenpox) and zoster (shingles). In chickenpox, VZV is spread through infected respiratory aerosol droplets, multiplies in the nasopharynx, and then enters the bloodstream and travels to the skin (Arvin, 1996). Replication in the squamous epithelium produces pruritic vesicles that rapidly progress to ulcers, which eventually crust over and heal without scarring—similar to HSV skin lesions. In healthy children, systemic symptoms are mild and sequelae are uncommon; however, serious bacterial superinfection, cerebellar ataxia, and encephalitis can occur. Along with the clinical resolution of chickenpox skin lesions, varicella virions travel via nerve fibers to regional sensory neural ganglions, where latent infection is established and maintained by memory CD4 and CD8 T lymphocytes (Arvin, 2005). When cell-mediated immunity is impaired by aging or immunosuppressive drugs or HIV infection, then active VZV replication begins again in neurons, and spreads from trigeminal or dorsal root ganglia back down nerve fibers to the skin, producing painful cutaneous vesicles with a classic dermatome distribution. Postherpetic persistent neuralgia is a frequent debilitating complication of zoster eruptions. CNS or disseminated visceral involvement from reactivated VZV develops only in the immunodeficient, but may be fatal. Varicella vaccine given in childhood produces high titers of specific IgG; because of waning humoral immunity and breakthrough mild atypical varicella cases (Vazquez, 2005), a second dose is needed to guarantee continued protection (Chaves, 2007). Varicella vaccine formulation administered to

geriatric patients markedly reduces the burden of zoster and its complications in the elderly (Oxman, 2005). Any vesicular rash in children or adults that raises the possibility of smallpox should be immediately reported to local public health officials.

Vesicle fluid is rich with virus and is the ideal specimen for culture or for DFA staining. VZV replicates in HDF cell lines. Traditional tube culture is slow and insensitive; shell vial culture has better yield (up to 75%) and allows more rapid detection (Brinker, 1993). Collection of skin vesicle specimens is identical to that used for HSV vesicles (see Fig. 55-3). Culture setup is also similar to herpes culture; however, tubes are held for 2 weeks and shell vial monolayers are stained at 3 and 5 days with VZV DFA reagent. VZV CPE develops in HDF as small patches of rounded, swollen, refractile cells. Because the behavior of VZV in tissue culture may be somewhat fastidious, DFA staining of vesicle cells for viral antigen is a rapid and practical diagnostic test and can differentiate VZV from HSV (Schrim, 1989). Nucleic acid assays have also been developed; they are more sensitive than culture and serve as the only practical approach for diagnosis when skin lesions have progressed to ulcers (Weidmann, 2003; Leung, 2010). IgM antibody is usually detectable by the time chickenpox vesicles first erupt and is a useful confirmatory test; serology is not helpful for evaluation of zoster lesions.

Of approximately 70 enterovirus serotypes, several produce vesicular or maculopapular eruptions (coxsackie B1 and A9, and echoviruses 2, 4, 9, 11, 19, and 33), usually during summer months. Hand-foot-mouth disease (coxsackie A16) in young children presents with vesicles on the tongue and palmar and plantar skin (Goksugur, 2010). Adult family members of infected children occasionally also develop symptomatic disease. Laboratory diagnosis is limited to enterovirus recovery from skin lesion specimens by cell culture and RT-PCR nucleic acid amplification assay; vesicles from the soles and palms should be completely unroofed and the exposed squamous cells vigorously swabbed. Cell culture identification of enterovirus was described earlier. DFA stains and serology are impractical and have low sensitivity and specificity for diagnosis of enteroviral exanthems.

Measles is highly contagious and presents with both mucocutaneous and respiratory features (fever, conjunctivitis, coryza, oral ulcerating lesions, cough, and generalized maculopapular erythematous rash). Vaccination has dramatically curtailed measles, and at present, 90% of confirmed cases in the United States are imported and then are disseminated in undervaccinated groups (MMWR, 2009). Despite international eradication efforts, measles still persists in impoverished countries; morbidity and mortality are high because of accompanying pneumonia and impaired nutrition. Measles virus in the nasopharynx can be identified by culture or nucleic acid amplification, but acute infection is most easily diagnosed serologically by detecting measles-specific IgM antibody. Immunity following natural infection presumably is lifelong, verified by the presence of specific IgG; however, immunity following vaccination may fade during the late teen years, with a second dose needed for sustained coverage. Breakthrough infection occurring in the setting of waning antibody may be atypical and difficult to diagnosis.

Parvovirus B19 (PB19) causes erythema infectiosum (fifth disease), a common childhood febrile illness with a distinctive maculopapular rash that gives the face a "slapped cheek" appearance (Young, 2004). PB19 infection in adults often produces arthralgias. Parvovirus infects erythroid precursor cells in the bone marrow and may provoke aplastic crisis in patients with hemoglobinopathy or HIV infection. Primary infection during pregnancy can cause fetal red cell aplasia with hydrops fetalis. Laboratory diagnosis was discussed earlier in this chapter.

Rubella virus produces German measles, a mild febrile illness with a transient maculopapular rash, and is the third infectious exanthem of childhood (Gershon, 2010). Infection in children is inconsequential, although adult-onset rubella may be associated with arthralgias. The only serious complication of rubella is transplacental spread to the first trimester developing baby, with risk of virus-induced tissue necrosis and congenital malformation. Widespread use of rubella vaccine has largely eliminated disease in developed countries. Laboratory confirmation of acute infection is most easily accomplished by detection of virus-specific IgM, rather than by attempting virus isolation. Verification of immune status is established with specific IgG antibody testing.

HHV6, a lymphotropic herpesvirus that infects lymphocytes, is the cause of exanthem subitum (roseola infantum, the sixth clinically distinctive exanthem). Roseola is a common early childhood illness characterized by high fever and development of a fleeting maculopapular rash as fever abruptly subsides (Prober, 2005; Zerr, 2005). Primary HHV6 infection in older children and adults produces a systemic, febrile lymphoproliferative illness resembling acute mononucleosis (discussed earlier); it may cause

pneumonitis in immunosuppressed patients (Cone, 1993). Laboratory diagnosis was reviewed earlier; however, the distinctive clinical presentation of roseola makes laboratory confirmation unnecessary.

Human papillomaviruses are ubiquitous and are found in all societies; hundreds of HPV serotypes have been defined by unique DNA sequences, and various HPV types target different skin or mucosal sites in the body. Most HPV warty cutaneous infections of the hands and feet are transient and of no medical consequence. Sexual encounters easily transmit HPV types that are associated with anogenital disease; quadrivalent vaccine is now in use for immunization of children against HPV types 11, 6, 16, and 18. Low-risk nononcogenic HPV types (6, 11, and others) can cause low-grade squamous intraepithelial proliferative lesions that usually resolve with no medical intervention. Infection with high-risk oncogenic HPV types (16, 18, and others) carries a much greater likelihood of persistent viral infection in the squamous epithelium of the cervix, vagina, vulva, or perineum; these oncogenic HPV viral infections can produce high-grade dysplastic intraepithelial lesions that over time may progress to invasive squamous carcinoma. The histopathologic and cytopathologic characteristics of HPV lesions are well described in standard pathology texts. However, HPV detection has been enhanced by the use of nucleic acid assays; the hybrid capture signal amplification method is most widely used and can identify several high-risk HPV and low-risk HPV types in liquid-based cervical cytology specimens (Burd, 2003). Nucleic acid-based methods for HPV identification have also been developed (Soderlund-Strand, 2005; Carozzi, 2007; Ifter, 2009). Novel linear array and line probe and HPV typing methods have been described (Castle, 2008; Ifter, 2009). Studies are under way to validate testing methods for males (Giovannelli, 2007). HPV can infect oropharyngeal and respiratory tract mucosa and is associated with carcinoma and papillomatosis (Glikman, 2005; D'Souza, 2007). Performance of HPV molecular assays for nongenital sites has not been established.

Although HPV genital infection is common, high-risk HPV infections that progress to high-grade intraepithelial lesions and on to invasive carcinoma are not, and the time line for progression to carcinoma spans many years. The sensitivity of HPV testing combined with cervical cytology is considered the gold standard for diagnosis of high-grade intraepithelial neoplasia (Mayrand, 2007). Recommendations for prudent use of HPV testing in connection with routine cervical cytology with the goal of preventing cervical carcinoma have been issued by a multidisciplinary panel of cytopathologists and gynecologists (Solomon, 2009); these utilization guidelines outline clinical scenarios in which HPV testing should and should not be ordered. Low-risk HPV testing is not helpful in routine screening or in the evaluation of abnormal cervical cytology findings. Testing for high-risk oncogenic HPV types is most useful in women over the age of 30 who have cervical cytology with atypical squamous cells of undetermined significance (approximately 1 million cervical smears per year in the United States), and in postmenopausal women with low-grade squamous intraepithelial lesions. The use of high-risk HPV testing outside of these recommendations is not prohibited and may be considered when there are extenuating clinical circumstances. The guidelines are intended to optimize the value of HPV testing in preventing invasive cervical cancer, and to avoid wasteful overtesting and unnecessary ancillary cervical biopsy procedures (Cox, 2009).

VIRAL GASTROENTERITIS

Viral gastroenteritis causes major morbidity and mortality worldwide, most significantly in young children in developing nations; in the United States, viral enteritis is rarely fatal but causes at least 3 million episodes annually and approximately 200,000 pediatric hospitalizations (Parashar, 1998). The viruses responsible constitute a diverse group, and all are ubiquitous. Severe debilitating diarrhea with rotavirus, enteric adenovirus, calicivirus, astrovirus, and coronavirus is largely confined to infants and young children. All treatment is supportive (Thielman, 2004).

Rotaviruses cause most cases of watery diarrhea in infants and young children in the United States (Musher, 2004); symptomatic infection occasionally develops in elderly adults in nursing homes. Transmission is fecal-oral; epidemics occur during cold weather in temperate climates and year-round in tropical regions. Rotavirus is highly infectious, with infection rates as high as 50% for children and up to 30% for adults following family exposure; some children and most adults will be asymptomatic (Musher, 2004). Dehydration with electrolyte imbalance is the most serious complication. Enteric isolation precautions must be followed to prevent nosocomial or day care spread. A safe and effective multivalent vaccine is currently available and has great potential for helping to

modulate outbreaks with this important gastrointestinal pathogen (Dennehy, 2008; Wang, 2010).

Adenovirus serotypes 40 and 41 are associated with gastroenteritis and account for 10%–20% of pediatric cases. Adenovirus enteritis is clinically similar to rotavirus disease but has no seasonality. Coronavirus and astrovirus have caused nosocomial and day care center outbreaks (Papaventsis, 2008; Principi, 2010), mild gastroenteritis in adults, and diarrhea in HIV patients (Grohmann, 1993).

Noroviruses (NoVs) cause epidemic acute gastroenteritis, characterized by nausea and vomiting that may be more intense than the accompanying diarrhea. NoVs are nonenveloped and can survive for days on inanimate surfaces, as well as in contaminated water, shellfish, and prepared foods; they have been identified in several community and national epidemics and cruise ship and day care outbreaks. They have been notoriously difficult to eradicate from the environment. NoVs have proved to be genetically diverse, with three out of five genogroups (GI, GII, and GIV) infecting humans. These genogroups are further divided into at least 25 genotypes (Glass, 2009). NoV infection is common in all age groups and is seen in a wide variety of settings, including but not restricted to nursing homes, hospital wards, day care centers, cruise ships, restaurants, and catered events. NoVs account for 12% of severe gastroenteritis cases among children <5 years of age and at least 12% of mild and moderate diarrhea cases among persons of all ages, making NoV the most common cause of diarrhea in adults and the second most common cause in children (Patel, 2008; Glass, 2009). High infection rates with NoV are due to its low infectious dose and its stability in food and on environmental surfaces. The great antigenic diversity of norovirus strains results in incomplete immunity, and multiple infections are common (Glass, 2009).

Laboratory Diagnosis

Gastroenteritis viruses grow poorly or not at all in standard cell lines. Historically, diagnosis had been based on the distinctive morphology of each virus when stool samples are negatively stained with phosphotungstic acid and examined by EM, but this service is time intensive to perform and requires special expertise, so it is not available in most laboratories (Goldsmith, 2009). Rapid detection of rotavirus antigen in stool is easily and accurately accomplished with commercially available latex agglutination and immunoassays. All methods have excellent specificity, and EIA is slightly more sensitive (Thomas, 1994; Dennehy, 1999). Rapid diagnosis is useful for patient cohorting and infection control measures to contain nosocomial spread. An accurate and sensitive commercial EIA for enteric adenovirus antigen detection is available. The clinical efficacy of nucleic acid–based multiplex testing for viral gastroenteritis is also being explored (Svraka, 2009). The scope of NoV-associated gastroenteritis was grossly underestimated until the recent availability of sensitive molecular diagnostic methods (e.g., RT-PCR, which is now considered the reference method). These assays are also available through referral laboratories.

VIRAL INFECTION IN IMMUNOCOMPROMISED HOST

The immune response to viral infection occurs as a complex interaction of humoral and cellular factors. The cell-mediated immune system responds to acute infection with natural killer large granular lymphocytes that circulate through blood and tissues, identify host cells with viral (“nonself”) antigens, and then destroy them by proteolytic lysis. Viral antigens are processed by macrophages, and the refined epitopes are presented to B and T lymphocytes. CD4⁺ cells produce cytokines that promote clonal expansion of sensitized cytotoxic CD8⁺ cells, which then eliminate host cells harboring foreign viral antigen (Kumar, 2010). Any impairment of normal interactions among macrophages, CD4⁺, CD8⁺, and natural killer cells reduces the ability of the host to control viral disease. Cell-mediated immunity is also critical in suppressing viruses that have the ability to persist in a latent form (such as HSV, CMV, EBV, etc.). In healthy individuals, episodic reactivation infections with these viruses are asymptomatic or produce limited disease confined to a discrete anatomic area (e.g., genital or oral herpes). With impaired cellular immune function, recurrent infections may be locally aggressive or may disseminate and produce severe multiorgan damage.

The number of immunocompromised patients continues to increase in societies with modern medical interventions. Use of corticosteroids, chemotherapy and radiation, and immunosuppressive drugs to prevent transplant rejection, as well as HIV-induced obliteration of CD4⁺ lymphocytes, damages cellular immune regulation and increases vulnerability to viral

infections (Copelan, 2006; Fishman, 2007). Primary viral infections that occur in an immunocompromised patient (such as EBV mononucleosis, influenza, and chickenpox) are clinically more severe. HPV anogenital condylomas show accelerated progression to squamous dysplasia and carcinoma. Many of the most serious viral diseases in the immunodeficient host are caused by reactivation of endogenous dormant organisms (CMV, HSV, VZV, EBV, etc.), which then progress to systemic fatal infection.

Reactivation of latent EBV infection is linked to the development of B cell CNS lymphoma in AIDS patients. Solid organ and allogeneic bone marrow/stem cell transplant recipients require intense immunosuppressive therapy to prevent graft rejection; as cell-mediated immune function diminishes, the host may be unable to contain dormant EBV organisms. In up to 20% of patients, unchecked EBV proliferation can lead to post-transplant lymphoproliferative disorder (PTLD). Initially, EBV-induced polymorphic plasmacytic and B lymphocyte expansion occur, with eventual emergence of a monoclonal B lymphoid population and overt B cell lymphoma (Gulley, 2010). Periodic monitoring of EBV viral load in peripheral blood is helpful in identifying patients with rising EBV levels at risk for PTLD; modification and titration of immunosuppressive agents can be considered in overall management of graft survival and EBV-induced complications. Comparison of EBV quantitation results among several laboratories has shown significant variation in viral load results, so as with all other viral load assays, clinical management should be based on testing confined to a single laboratory until methods are better standardized (Hayden, 2008).

The most common opportunistic viral infections in HIV and transplant patients are caused by CMV (Sia, 2000; Fishman, 2007). Graft survival is threatened by direct viral injury to the organ, by toxicity from antiviral drugs, or by unavoidable reduction of immunosuppressive therapy to help contain viral infection. CMV viremia is a sensitive marker of active viral replication and helps predict potential graft endangerment and risk of pneumonitis, colitis, or other organ injury. CMV may originate in the transplant itself or may result from reactivation of endogenous latent virus in the recipient; recipients who have no demonstrable CMV antibody (CMV-naïve) are at high risk of developing CMV disease if the donor is CMV positive; primary CMV disease after transplant is the most severe, with greater risk of organ loss. Surveillance for CMV proliferation after transplantation is very helpful for appropriate institution of antiviral prophylaxis to modulate the intensity of CMV disease. Adult AIDS patients with CD4 cell counts below 100/mm³ are at great risk for reactivation of latent CMV. Retinitis is a frequent complication in advanced HIV disease with high viral load and low CD4 levels; CMV pneumonia and gastrointestinal and CNS involvement are also common, and widely disseminated multiorgan disease at autopsy is not unusual (Drew, 1992). CMV systemic disease may also develop from primary infection in pediatric HIV patients.

Serology is very useful for screening blood donors to limit transfusion of CMV-positive blood products to newborns and naïve immunocompromised patients, and for assessing donor and recipient serostatus. EIA screens for CMV-IgG are most sensitive, have objective endpoints, and avoid the interpretive problems of complement binding in IFA procedures. However, serology has little or no practical value for diagnosing CMV infection in transplant recipients or HIV patients. IgM production may be impaired in marrow/stem cell and solid organ recipients, and IgG seroconversion requires acute and convalescent specimens.

Typical cytomegalic inclusions are specific for identifying CMV infection in biopsy samples and BAL, but H&E staining is relatively insensitive. Sensitivity improves somewhat with immunoperoxidase or in situ hybridization methods, but isolation of virus has greater diagnostic accuracy. CMV replicates almost exclusively in HDF cell lines; growth is slow, with incubation times of 7 days or longer before CPE develops. The infected fibroblast initially retains its fusiform shape as the nucleus becomes swollen and refractile; then the entire cell becomes rounded and distorted, and virus spreads into adjacent fibroblasts, producing an enlarging patch of damaged cells (see Table 55-4).

CMV recovery is shortened to only 1–2 days with shell vial culture (Gleaves, 1987). HDF monolayers are inoculated by centrifugation with peripheral blood leukocytes (harvested by density gradient separation), BAL fluid, or homogenized tissue; after 16–40 hours' incubation, the monolayer is stained with fluorescein-conjugated antibody to CMV early antigen. Infected fibroblasts show homogeneous fluorescence of the entire nucleus. CMV burden is usually high in infected end-stage HIV patients, and culture has excellent diagnostic sensitivity with tissue and BAL specimens (95%–100%). Shell vial culture of peripheral blood leukocytes has turnaround advantages, but sensitivity is only 75% compared with tube monolayer inoculation, so backup tube culture is recommended. Recovery

of CMV in standard tube and shell vial cultures is optimized when specimens are inoculated immediately to fresh cell monolayers; yield is reduced when inoculation is delayed (Brumback, 1997). Another advantage of shell vial culture is that results are semiquantitative (Buller, 1992); a standard inoculum of the patient's cells (peripheral leukocytes or BAL cells) along with a count of fluorescent CMV-positive nuclei in the shell vial monolayer generates a figure that has clinical value for estimating severity of infection, for monitoring response to therapy, and for predicting prognosis. CMV is the most common cause of viremia in compromised patients; however, VZV, HSV, adenovirus, and occasionally enterovirus may be recovered. HDF and A549 traditional tube cultures held for 14 days will recover these agents as well as CMV (Stanberry, 1994). When immunosuppression is severe, AIDS patients and transplant recipients are at risk for other viral infections with specific organ or site involvement. Central nervous system infections were described earlier. Adenovirus, HSV, and VZV may present with pneumonitis; herpetic infection (HSV and VZV) may develop initially in esophageal and mucocutaneous sites and then may disseminate. For this reason, mucosal, cutaneous, or tissue biopsy specimens should be inoculated to a comprehensive series of cell lines to maximize recovery. Amplified nucleic acid testing for HSV viremia has shown positive results in immunocompromised adults with solid organ transplants, malignancies, immunodeficiencies, HIV-AIDS, and autoimmune disorders; in addition to skin lesions, presentations include hepatitis, fever, abdominal pain, and CNS alterations (Berrington, 2009).

Even with improvement in recovery of CMV by shell vial culture, this approach is too insensitive for preemptive surveillance for CMV infection in the setting of iatrogenic immunosuppression of transplant recipients. CMV antigen can be identified in peripheral blood neutrophils by IFA or immunoperoxidase staining (Hodinka, 2007); commercially available CMV pp65 antigenemia assays are rapid, sensitive, and specific; the principal practical limitation of this method is host neutropenia. CMV viral load by PCR also provides sensitive quantitative assessment of CMV in peripheral blood (Sia, 2000; Razonable, 2002). Quantitative PCR methods can identify patients with escalating CMV levels before overt disease develops, so that antiviral therapy can be intensified and immunosuppression to prevent graft rejection can be continued. Biopsy of specific sites with suspected acute CMV disease, such as colonic mucosa, may be necessary to establish a diagnosis (Fishman, 2007). Antiviral susceptibility testing methods using plaque reduction assay or genotypic assay of mutations associated with resistance may be indicated in patients who do not respond to therapy (Sia, 2000; Razonable, 2002).

BK virus (BKV), a polyomavirus similar to the JC virus responsible for progressive multifocal leukoencephalopathy, reactivates during immunosuppression; it produces serious nephropathy in approximately 2% of renal transplant recipients, with progressive loss of graft function and even transplant failure. Identification of tubular epithelial cells with nuclear inclusions (decoy cells) in voided urine in BKV nephropathy has served as a screening test for many years. BKV viral load assessment in plasma and urine provides a noninvasive means of detecting and monitoring active infection (Fishman, 2002; Hirsch, 2002).

Parvovirus B19 is an uncommon but serious cause of refractory anemia and pancytopenia in solid organ and hematopoietic stem cell transplants and in HIV patients. Lung, liver, myocardial, and CNS disease can also develop, as can serious infection in allograft tissue. Diagnosis may be difficult, even with invasive procedures such as bone marrow biopsy. Serologic diagnosis has limitations in immunocompromised patients, who may be incapable of producing specific antibody. PCR detection and quantitation of parvovirus DNA in peripheral blood are both sensitive and specific for establishing the diagnosis (Eid, 2006).

Screening of donors for hepatitis B and C viruses and for HIV has dramatically reduced the transmission of these agents to organ recipients. However, the surprising dissemination of WNV and lymphocytic choriomeningitis virus via organ donation (Iwamoto, 2003; Fischer, 2006) has highlighted the ongoing vigilance that is needed to evaluate suspected infection in this highly vulnerable class of patients, for whom accurate diagnosis may be confounded and complicated by serious comorbidities. As molecular methods for detection and quantitation of other opportunistic viruses become generally available, better management of infection and graft survival will follow.

VIRAL HEPATITIS

Many viruses are hepatotoxic. Yellow fever virus (Monath, 2003) causes massive hepatocellular necrosis. All of the human herpesviruses can produce mild liver disease with system infection, but fulminant hepatic

necrosis is unusual. Serious herpesvirus infections of the hepatic allograft can occur after liver transplant. Adenovirus, HSV, VZV, CMV, and echoviruses occasionally produce aggressive hepatitis in the immunocompromised (Fishman, 2007; Riediger, 2009). However, hepatitis A, B, C, D, and E virus infections characteristically lead to lytic hepatocyte injury and account for most clinical cases of infectious hepatitis.

Hepatitis A virus (HAV) and hepatitis E virus (HEV) are nonenveloped agents with fecal-oral transmission; inadequate sewage treatment and crowded living conditions are linked to waterborne outbreaks, and HAV has been spread in contaminated foods. Acute hepatitis A incidence in the United States declined by 92% between 1995 and 2007 (to 1.0 case per 100,000) (Daniels, 2009). HAV is a picornavirus, distinct from but related to the enteroviruses. Children in day care and crowded institutions and their caregivers are at increased risk for HAV hepatitis (Cuthbert, 2001; Emerson, 2004). Acute disease in children is mild and often asymptomatic; adults occasionally develop severe infection, but fulminant hepatitis and death are unusual; IgM antibody is the most practical marker of acute infection (Mor, 2009) (http://www.cdc.gov/ncphi/diss/nndss/casedef/case_definitions.htm). Recovery is complete with no chronic infectious state. HAV vaccines are now available and are very effective (Nothdurft, 2008; Dentinger, 2009).

HEV is related to caliciviruses; outbreaks occur in developing countries and in refugee camps with suboptimal food and water sanitation, resulting in acute, mostly self-limiting, disease (predominantly genotypes 1 and 2). In industrialized nations, in addition to travel-associated disease, HEV is now an emerging disease and is considered an autochthonous, possibly zoonotic, disease (predominantly genotype 3). Teens and young adults are most commonly affected; mortality is rare, except in pregnant women, in whom death rates may reach 25% (Aggarwal, 2009). HEV does not progress to chronic infection, except in immunocompromised individuals (Kamar, 2008). IgG antibody develops promptly and persists at low titers indefinitely; specific IgM is a reliable test of acute infection (Herremans, 2007).

HBV is easily transmitted through blood and is classically acquired through transfusions, needle sharing, or occupational injury with contaminated sharp objects. Infection may be acquired transplacentally during pregnancy, and sexual contact and household exposure to virus in body fluids are important routes of spread. Acute infection is frequently symptomatic, with much of the liver damage inflicted by CD8⁺ cytotoxic T lymphocytes; 1% develop fulminant fatal massive hepatocellular necrosis. Diagnosis of acute infection is based on the presence of IgM antibody to hepatitis B core antigen (anti-HBc) or the presence of hepatitis B surface antigen (HBsAg) (http://www.cdc.gov/ncphi/diss/nndss/casedef/case_definitions.htm). HBV can also persist as a chronic infection. Up to 90% of infants born with HBV vertically acquired in utero become chronic carriers, compared with 25%–30% of infected older children and less than 5% of adults (Lok, 2009). Even with apparently resolved infection, HBV DNA persists despite host production of antibodies to core and e antigens. Diagnosis of chronic HBV infection is based on the absence of anti-HBc IgM and the presence of HBsAg, hepatitis e antigen, (HBeAg) or HBV DNA (http://www.cdc.gov/ncphi/diss/nndss/casedef/case_definitions.htm). T lymphocyte damage of hepatocytes is ongoing in chronic HBV infection. Unrelenting inflammation progresses to cirrhotic scarring in at least 2% of chronic infections (Lok, 2002; Ganem, 2004); HBV-induced cirrhosis is a risk factor for hepatocellular carcinoma. HBV infection and sequelae are largely preventable; with the implementation of vaccination programs, the incidence of new infections in the United States has decreased significantly (Wilkins, 2010). Acute hepatitis B incidence in the United States declined by 82% between 1990 and 2007 (to 1.5 cases per 100,000) (Daniels, 2009). Response to antiviral therapy in chronically infected patients can be monitored by quantitation of HBV (Ghany, 2009; Sorrell, 2009).

HBV coinfection or superinfection with hepatitis D virus (HDV) is associated with a severe course of hepatitis that frequently leads to rapid progressive fibrosis, hepatic decompensation, and the development of hepatocellular carcinoma. HDV is a defective RNA viroid that requires HBV surface antigen for full expression, replication, and transmission. HDV may be transmitted from person to person in household situations in endemic areas (Middle East, South America, Central Africa, Mediterranean countries). HDV is rare in the United States; intravenous drug abuse is the principal risk factor. Anti-HDV IgG and IgM testing is available when HDV coinfection is suspected in HBsAg-positive individuals (Wedemeyr, 2010).

HCV is estimated to infect 3.2 million Americans and is the leading cause of non-A non-B hepatitis; since the advent of serologic testing and nucleic acid amplification, transfusion-associated HCV has dropped dramatically (Cuthbert, 1994; Lauer, 2001; National Institutes of Health,

2002; Stramer, 2004). Following a peak in 1992 in the United States, the incidence of acute hepatitis C declined; however, since 2003 rates have plateaued, with the most common risk factor being injection drug use. HCV is transmitted primarily through percutaneous exposure, but no source is identified in many cases (Daniels, 2009). Transmission of HCV during pregnancy or through sexual and household contact is much less efficient than transmission of HBV and HIV. Fulminant and fatal acute hepatitis is rare; however, HCV clearance by cytotoxic T lymphocytes is inadequate in most patients. About 80% of infections become chronic, leading to hepatic fibrosis and hepatocellular regeneration that may progress further to cirrhosis (20%) and hepatocellular carcinoma (1%–4% per year in cirrhotic patients). Coinfection with HIV or HBV, as well as alcohol use, accelerates the natural course; superinfection with HAV can provoke fulminant hepatitis. Treatment with pegylated γ -interferon and ribavirin produces sustained remission in chronic HCV disease and may significantly modify or prevent serious long-term sequelae (McHutchison, 1998). However, response rates are lower for genotype 1, which represents 75% of infections in the United States (Zein, 2000).

Third-generation screening HCV antibody chemiluminescence and enzyme immunoassays (CIA and EIA) use an expanded number of refined viral antigens. Sensitivity is very good; false negatives may occur in the context of severe immunosuppression or early in acute infection. Specificity of the current EIAs for anti-HCV is better than 99% (Ghany, 2009). Because of the high rate of chronic HCV disease and favorable outcomes with antiviral therapy, an algorithm for efficient testing that begins with a CIA or EIA HCV antibody screen has been recommended by the Centers for Disease Control and Prevention (CDC). A screening HCV antibody result with a high signal-to-cutoff ratio has a high probability of being a true positive with chronic infection; quantitative HCV PCR is then appropriate to verify viremia and begin antiviral treatment. A low signal-to-cutoff HCV antibody screen result has a high likelihood of being a false positive, so confirmation is needed; specificity of available nucleic acid amplification assays is in the range of 98%–99% (Ghany, 2009). POC HCV antibody tests have recently become available. These easy to use HCV rapid antibody tests may prove to be an important tool for rapid HCV antibody detection. However, confirmation with a quantitative nucleic acid amplification assay is still recommended. Genotyping is useful in clinical management for predicting the likelihood of response and the optimal duration of therapy (Valsamakis, 2007; Ghany, 2009).

Hepatitis GB virus-C (GBV-C), a flavivirus related to HCV, has been identified in posttransfusion hepatitis. However, GBV-C does not appear to be hepatotropic, does not replicate efficiently in hepatocytes, and does not cause acute or chronic hepatitis (Baggio-Zappia, 2009). It is interesting to note that coinfection with GBV-C and HIV appeared to induce host antiviral activity against HIV and prolong survival (Xiang, 2001). In spite of a decade of follow-up studies, the question of whether GBV-C is associated with better prognosis in HIV-coinfected patients remains unresolved.

None of the hepatitis viruses replicates in standard culture cell lines. Detection of specific IgM and IgG antibodies and specific viral antigens designates the stage of infection with each virus; viral load assessment is used to monitor response to treatment of chronic infection. Table 55-7 summarizes virologic and serologic markers with viral hepatitis.

ACQUIRED IMMUNODEFICIENCY SYNDROME

HIV1 is a retrovirus in the Lentiviridae family that now has worldwide distribution. HIV infects and destroys CD3/4⁺ T lymphocytes and eventually leads to debilitating opportunistic infections and malignancies (Stein, 1992; Schupbach, 2003). HIV is also neurotropic and can cause acute meningitis and slow destructive encephalopathy (Atwood, 1993). The HIV2 strain present in West Africa is somewhat less pathogenic, with reduced risk of transmission and progression to AIDS.

Half of individuals acutely infected with HIV experience mononucleosis-like symptoms before entering an asymptomatic latent stage. During acute infection, circulating HIV viral load is high, but antibody may not yet be detectable. Median time for CD3/4⁺ cell destruction sufficient to develop

full features of AIDS is 10–11 years; 5%–10% of individuals develop AIDS in 3 years, and 5%–10% of individuals maintain stable CD3/4 blood levels and remain asymptomatic indefinitely (Munoz, 1995). Children vertically infected at birth often show accelerated progression if untreated.

Both the diagnosis and ongoing management of HIV infection rely heavily on laboratory testing (Table 55-8). Several commercial EIA screening tests for HIV antibody are made with an array of recombinant and purified HIV antigens; third-generation kits have overall excellent specificity and sensitivity and may detect HIV antibody as early as 2–4 weeks post infection. Fourth-generation EIA tests that combine screening for HIV antibody with detection of HIV p24 antigen have even greater sensitivity in recognizing early infection. CDC recommendations include routine screening for HIV antibody in all health care settings for all patients aged 13–64 years (Branson, 2006). Blood banks in industrialized countries always test donor blood for HIV RNA to identify donors in the false-negative window (Candotti, 2003; Schupbach, 2003; Stramer, 2004). U.S. blood banks also test for HIV2 antibody, which is standard screening in Africa and Europe. A positive EIA HIV antibody screen should be repeated and then confirmed with an additional test, such as immunofluorescence assay or Western blot assay (Carlson, 1987). Western blot is less sensitive than EIA, but a classic positive band pattern provides convincing serologic evidence of HIV infection (MMWR, 1991). When acute retroviral syndrome is a possibility, a plasma HIV RNA test should be used in conjunction with an HIV antibody test to diagnose newly acquired HIV infection (Kassutto, 2004; Branson, 2006). HIV2 infection should be suspected in persons of West African origin who have clinical conditions suggestive of HIV infection but with atypical serologic test results (Aberg, 2009).

HIV is propagated in tissue culture by cocultivating infected patient lymphocytes or tissues with normal donor lymphocytes that have been stimulated with phytohemagglutinin, interleukin-2, and interferon. Culture is complex, expensive, and dangerous and should be attempted only in research laboratories. HIV culture has been supplanted by nucleic acid testing for routine management; real time RT-PCR, NASBA, TMA, and bDNA methods are commercially available. Antiretroviral treatment has dramatically improved survival and quality of life for HIV patients (Freedberg, 2001; Aberg, 2004). Quantitative HIV RNA assays to measure viral load in plasma have revolutionized monitoring of antiretroviral therapy; treatment-related reductions in HIV RNA of more than 0.5–1.0 log copies/mL correlate with slower clinical progression.

HIV-infected patients typically have a genotypic resistance test performed at baseline, regardless of whether antiretroviral therapy will be initiated immediately (Aberg, 2009). Genotypic methods typically involve sequence analysis of the HIV reverse transcriptase and protease genes to identify mutations that are linked to drug resistance and have the greatest clinical utility. As use of agents with other HIV targets increases, testing will no doubt broaden.

Phenotypic testing is complex and involves amplification of protease and reverse-transcriptase genes from virus recovered from the patient's blood, followed by insertion of these genes into a test virus and then in vitro susceptibility testing of this hybrid laboratory-constructed virus against specific antiviral drugs. A virtual phenotype can be approximated from the genotypic mutation data to ascertain the likelihood of in vitro phenotypic actual susceptibility, with the two methods often showing excellent correlation (Shafer, 2002; Clavel, 2004). Tropism testing is recommended prior to initiation of a CCR5-antagonist antiretroviral drug, and HLA-B*5701 typing should be performed prior to treatment with abacavir to reduce the risk of a hypersensitivity reaction (Aberg, 2009).

In utero or perinatal transmission from HIV-infected mothers can be dramatically reduced with treatment and strict avoidance of breast feeding. The transmission rate has been reported to be <1% in women who achieve undetectable viral loads with treatment (Aberg, 2009). Early identification of HIV1 infection in exposed infants is important to allow early intervention with antiretroviral therapy and adjunctive care (Havens, 2009). Maternal antibody can remain detectable in the infant up to 18 months of age. Diagnosis of active HIV infection in the infant is primarily made by means of PCR-based assays for HIV DNA or RNA. Virologic testing should be

performed at 14–21 days, 1–2 months, and 4–6 months of age. Infected infants should also undergo HIV resistance testing (Aberg, 2009). (See earlier section on Congenital and Perinatal Infections.)

VIRUS-ASSOCIATED NEOPLASIA

Although the topic is beyond the discussion in this chapter, it is worth noting that viral infections are associated with 15%–20% of human cancers worldwide (Martin, 2009; Fernandez, 2010). The association of viruses

with tumorigenesis has been appreciated since the early 20th century (Rous, 1911). Tumorigenic viruses are found in diverse virus families and employ diverse mechanisms to contribute to neoplasia (Table 55-9). Oncogenic viruses tend to cause persistent infection, and viral proteins frequently disrupt normal cellular processes, such as apoptosis and cell cycle checkpoint activation. However, viral infections generally are not considered to be sufficient for carcinogenesis; additional factors, including host immunity and cell mutations, are certainly involved in the neoplastic process.

KEY POINTS

- *Chlamydia trachomatis* is the most common bacterial cause of sexually transmitted disease in the United States.
- The most sensitive method for detecting *C. trachomatis* is nucleic acid amplification.
- *Chlamydophila pneumoniae* (formerly *Chlamydia pneumoniae*) is responsible for at least 10% of community-acquired pneumonias. Infection is most often diagnosed serologically.
- Treatable rickettsial infections, including life-threatening Rocky Mountain spotted fever, boutonneuse fever, epidemic typhus, murine typhus, scrub typhus, human monocytotropic ehrlichiosis, and human granulocytotropic anaplasmosis, are seldom diagnosed serologically during the acute stage of illness owing to absence of an early antibody response.
- Immunohistochemistry and molecular diagnostics are effective in diagnosing rickettsioses and ehrlichioses, respectively, but are not generally available.
- Q fever endocarditis is a chronic infection that usually is diagnosed by detecting a high titer ($\geq 1:800$ by immunofluorescent antibody assay) of antibodies against *Coxiella burnetii* phase I antigen.

- The clinicoepidemiologic diagnosis of cat scratch disease can be confirmed serologically by antibodies to *Bartonella henselae* or by polymerase chain reaction testing of lymph node aspirates.
- Pneumonia due to *Mycoplasma pneumoniae* is often diagnosed on the basis of clinical manifestations alone. Definitive diagnosis requires detection of specific immunoglobulin (Ig)M, a fourfold change in IgG antibody titer between acute and convalescent serum specimens, or detection of nucleic acid in sputum or other respiratory specimens by nucleic acid amplification.

Human infections caused by chlamydias, rickettsiae, and mycoplasmas are discussed separately because the responsible pathogens differ from most other bacteria in several ways: The organisms are smaller, the structure of their cell walls is different, and chlamydias and many rickettsiae are obligately intracellular parasites.

CHLAMYDIAL INFECTIONS

The chlamydias have a tropism for columnar epithelial cells. They have a cell wall similar to that of gram-negative bacteria; they contain both deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), have prokaryotic

TABLE 56-1

Features Useful for Differentiating Species of *Chlamydia* and *Chlamydophila* Pathogenic for Humans

Parameter	SPECIES		
	<i>Chlamydia trachomatis</i>	<i>Chlamydophila psittaci</i>	<i>Chlamydophila pneumoniae</i>
Sulfa susceptibility	Susceptible	Resistant	Resistant
Glycogen staining of inclusion	Positive	Negative	Negative
Elementary body shape	Round	Round	Pear-shaped or round

ribosomes, and synthesize their own proteins, nucleic acids, and lipids; they divide by binary fission; and they are susceptible to particular antibiotics. Unlike most bacteria, the chlamydias are “energy parasites”; they lack cytochromes and so cannot synthesize high-energy adenosine triphosphate (ATP) metabolites. For this reason, they are obligate intracellular bacteria and cannot replicate outside cells.

The chlamydias are classified in the order Chlamydiales, family Chlamydiaceae, the only family that contains human pathogens (Everett, 1999). Two genera and three species are pathogenic for humans: *Chlamydia trachomatis*, *Chlamydophila* (formerly *Chlamydia*) *psittaci*, and *Chlamydophila* (formerly *Chlamydia*) *pneumoniae*. Features useful for differentiating the three species are shown in Table 56-1. These genera also contain six other species that have not been associated with infection in humans. There are two biovars of *C. trachomatis*: lymphogranuloma venereum (Biovar LGV) and trachoma (Biovar trachoma), which preferentially infect humans. Biovar LGV contains four serovars (L1, L2, L2a, and L3), and 15 serovars are included in Biovar trachoma: A, B, Ba, and C are associated with trachoma, whereas D–K, Da, Ia, and Ja are associated with genital infections. Mouse and hamster isolates that previously made up the third biovar of *C. trachomatis* have been reclassified as a new species, *Chlamydia muridarum* (Everett, 1999).

STRUCTURE

Two morphologically distinct forms of chlamydia are recognized. The elementary body is a dense, spherical form, 0.2–0.4 μm in diameter, that contains prokaryotic ribosomal RNA and has a rigid cell wall caused by extensive disulfide cross-linking of cell wall proteins. It is the infectious form of the organism, capable of limited extracellular survival. The reticulate body, 0.6–1.0 μm in diameter, is the intracellular, metabolically active form, incapable of surviving outside cells. The closed circular DNA of both forms is compactly organized in a central nucleoid and has a genome of 1.0–1.2 million nucleotide base pairs.

Two components of the outer membrane of the chlamydial outer membrane complex have diagnostic importance. The most prominent is the major outer membrane protein (MOMP), a transmembrane protein with serovar-, species-, genus-, and family-reactive epitopes defined by monoclonal antibodies. Infection with chlamydias induces MOMP-specific antibodies, but their role in protective immunity is unclear. The chlamydial outer membrane complex also contains a lipopolysaccharide (LPS) antigen, which is the major antigen detected in genus-specific serologic tests for chlamydial infection. Monoclonal antibodies and monospecific polyvalent antisera to the LPS or MOMP are used in direct fluorescent antibody (DFA) tests and enzyme immunoassays (EIAs) to detect chlamydial antigen in clinical specimens.

REPLICATION

Chlamydias replicate in the cytoplasm of infected host cells. The developmental cycle begins with attachment of the elementary body to a microvillus on a susceptible columnar cell via heparin bridges. The elementary body travels down the microvillus and localizes in indentations of the host cell plasma membrane. There, the chlamydia enters the host cell in an endosome, where *C. psittaci*, *C. pneumoniae*, and *C. trachomatis* remain during their intracellular development. Endosomes containing elementary bodies of *C. psittaci* do not become acidified or fuse with cellular lysosomes; those containing *C. trachomatis* elementary bodies fuse with one another and perhaps with lysosomes. Within 6–8 hours after the elementary body

enters the host cell, changes in its cell wall result in a transition to the reticulate body and subsequent initiation of DNA, RNA, and protein synthesis and its division by binary fission. Host cell mitochondria migrate to and are positioned against the enlarging endosome, allowing the reticulate body to utilize host cell ATP. Reticulate bodies begin to reorganize 18–24 hours after infection, and, presumably when nutrients are depleted, they mature into elementary bodies, which are released from the host cell. Cells infected with *C. psittaci* usually are severely damaged, and the organisms are released by cell lysis within 48 hours. In contrast, the inclusion of *C. trachomatis* appears to be extruded by fusion of the inclusion membrane with the plasma membrane 72–96 hours after infection, leaving a lesion in the surviving host cell membrane.

CHLAMYDIA TRACHOMATIS

C. trachomatis is the most common cause of sexually transmitted disease in the United States, and in trachoma-endemic regions of the Middle East, sub-Saharan Africa, and Asia, it is the primary infectious cause of blindness. The disorder is endemic in more than 50 countries, and estimates indicate that more than 3 million people are affected, with over a third having progressed to blindness (Burton, 2009).

Epidemiology, Pathology, and Clinical Manifestations

Humans are the only known natural host for all strains of *C. trachomatis*. The clinical manifestations and organ specificity of human infections with *C. trachomatis* are determined by both the mechanism of transmission and the properties of the infecting strain. Epidemiologically, *C. trachomatis* infections are divided into three categories: classic trachoma, sexually transmitted infections of adults, and perinatal ocular and respiratory tract infections.

Classic trachoma is an important cause of blindness in areas where public sanitation is inadequate and personal hygiene poor (Solomon, 2004). The disease is due to repeated infections of the conjunctiva, resulting in a pathologic sequence over time of follicular conjunctivitis, subepithelial scarring, contraction of the scar resulting in turning inward of the eyelid (entropion), rubbing of the eyelashes on the cornea (trichiasis) with subsequent corneal injury, and corneal scarring with opacification and reduced vision. Typically, acute infection is transmitted among children via fingers, fomites, and probably flies, and most children become chronically infected within a few years of birth. Conjunctival scarring usually becomes evident by the second or third decade of life, and blindness can occur anywhere from 10–40 years after the first infection (Dean, 2008). It is interesting to note that a recent study using molecular methods on infected patients in a trachoma-endemic location demonstrated that other species of the Chlamydiaceae, *C. psittaci* and *C. pneumoniae*, may also be involved in the pathogenesis of trachoma (Dean, 2008).

C. trachomatis-induced sexually transmitted infections of adults include LGV and urethritis/cervicitis and associated complications. LGV is endemic in Asia, Africa, and South America. In the United States, approximately 500 cases are reported each year; the disease affects males more frequently than females and is most common in persons of low socioeconomic status living in the southeastern states, in men who have sex with men, and in persons who have visited LGV-endemic countries outside the United States. LGV is transmitted sexually, although transmission by fomites and by aerosols produced during laboratory accidents has caused pneumonitis, pleural effusions, and mediastinal or hilar lymphadenopathy (Jones, 2000). Reservoirs of infection probably are persons with asymptomatic or ignored symptomatic urethral, cervical, or anorectal infection.

LGV is the only infection caused by *C. trachomatis* that produces multisystem involvement and constitutional manifestations. During the primary phase, a small, painless vesicle or a nonindurated papule or ulcer develops, often on the external genitalia, 3 days to 3 weeks after exposure, and heals quickly without scarring. If transmission is rectal, an acute proctitis is often the first manifestation. An outbreak of LGV proctitis in men who have sex with men was first noticed in Europe at the beginning of this decade and is due to infection with a unique LGV variant (labeled “L2b”) (Spaargaren, 2005). Genomic similarity to isolates obtained from patients in the early 1980s in the United States suggests a silent ongoing epidemic in this population caused by this unique variant (Spaargaren, 2005). The secondary stage, characterized by suppurative regional lymphadenopathy, fever, chills, anorexia, headache, myalgias, and arthralgias, begins 2–6 weeks after exposure. The primary ulcer or papule often resolves before

the secondary stage, but an acute proctitis may persist. Histologic examination of affected lymph nodes shows granulomas surrounding stellate abscesses. Involved lymph nodes become matted and eventually suppurate, producing draining fistulas that heal with scarring over several months. Fibrosis and resultant abnormal lymphatic drainage are responsible for the urethral or rectal strictures or induration and lymphedema of the genitalia that develop during the third stage.

Non-LGV *C. trachomatis* infection is the most frequent sexually transmitted disease reported to the Centers for Disease Control and Prevention (CDC). From 1990–2009, the rate increased from 160.2 to 409.2 cases per 100,000 population (Centers for Disease Control and Prevention, 2009). The clinical spectrum of sexually transmitted infections due to non-LGV strains of *C. trachomatis* is similar to disease caused by *Neisseria gonorrhoeae* (see Chapter 57). In men, *C. trachomatis* is responsible for 30%–50% of cases of nongonococcal urethritis, but as many as 85%–90% of men who harbor *C. trachomatis* in the urethra are asymptomatic (Peipert, 2003). Rarely, urethritis caused by *C. trachomatis* progresses to epididymitis. Among men who have sex with men, non-LGV strains of *C. trachomatis* have been associated with proctitis. Genital infection with *C. trachomatis* is diagnosed more often in women than in men, with a rate of 583.5/100,000 reported for women in the United States in 2008, compared with a rate of 211.1 for men—a rate difference that is thought, at least in part, to be reflective of the greater number of women who undergo testing (Centers for Disease Control and Prevention, 2008a). Infection of the endocervix with *C. trachomatis* is often asymptomatic, but at least one third of women have signs of infection on physical examination. The most common sign is mucopurulent cervicitis, which can spread to the urethra and urinary bladder, resulting in the acute urethral syndrome of abacteriuric pyuria, or to the endometrium and fallopian tubes, producing endometritis or salpingitis. Untreated infections of the upper reproductive tract may progress to pelvic inflammatory disease or may cause scarring and dysfunction of the oviduct transport system, which could result in infertility, ectopic pregnancy, or chronic pelvic pain. Intraperitoneal spread of the infection may cause acute peritonitis, perihepatitis (Fitz-Hugh–Curtis syndrome), periappendicitis, or perisplenitis. A portion (1%–5%) of patients with urogenital infection with *C. trachomatis* will develop a reactive arthritis that is usually self-limited but may develop a chronic relapsing course (Rihl, 2006; Carter, 2009). Chlamydial infection in pregnancy has been associated with preterm labor, premature rupture of membranes, low birth-weight, neonatal death, and postpartum endometritis. A small percentage of adults with chlamydial genital infections develop inclusion conjunctivitis from autoinoculation.

In developed countries, where sexually transmitted infection with *C. trachomatis* is epidemic, the organism may be transmitted from infected mother to infant during passage through the birth canal. Data from studies in North America indicate that 60%–70% of infants exposed to *C. trachomatis* during vaginal delivery become infected with the organism, whereas infection after cesarean section is uncommon (Jones, 2000). Among 15–24-year-old women seen in prenatal clinics in participating states in 2009, the CDC reported a *C. trachomatis* positivity rate of 7.7% overall, with a range of 3.6%–20.4%, depending on the state (Centers for Disease Control and Prevention, 2009). *C. trachomatis* is recovered from the conjunctiva of infected infants after 1–2 weeks and from the nasopharynx soon thereafter. The rate of isolation from the conjunctiva falls by 5–6 weeks, but *C. trachomatis* can be recovered from the nasopharynx, conjunctiva, rectum, and vagina (usually without producing symptoms) for several months.

Inclusion conjunctivitis, the most common manifestation of infection with *C. trachomatis* in infants, develops in nearly 80% of infants whose conjunctival culture or cytologic examination demonstrates the organism (Jones, 2000), and among those with conjunctivitis, approximately 50% will have a nasopharyngeal infection. A mucopurulent discharge appears 2–25 days after birth, and the conjunctiva becomes inflamed and edematous. Severity ranges from a mild infection with scant discharge to copious mucopurulent discharge with severe swelling and pseudomembrane formation.

Approximately 20%–30% of infants who acquire infection with *C. trachomatis* at birth develop interstitial pneumonitis. The illness begins at between 2 weeks and 3 months of age (peak, 3–6 weeks) with nasal congestion, followed by a distinctive staccato cough with tachypnea and rales but no fever. Hyperinflation with interstitial or alveolar infiltrates on chest radiograph and peripheral eosinophilia are frequently seen. About one half of patients have or have had conjunctivitis. Symptoms last several weeks, but inspiratory rales and chest roentgenographic changes may persist for months.

CHLAMYDOPHILA (FORMERLY CHLAMYDIA PSITTACI)

Pneumonia associated with exposure to birds was described in Switzerland in 1879. The disease was rare in the United States and Europe until the late 1920s, when pet tropical birds became fashionable. The pathogen was isolated by Bedson from human and avian tissue in 1930 during an investigation of an outbreak at the London Zoo.

Epidemiology

Infection caused by *Chlamydophila* (formerly *Chlamydia*) *psittaci* (also called psittacosis, parrot fever, or ornithosis) occurs worldwide. *C. psittaci* has seven genotypes (A–F, E/B), all of which are infective for humans. Psittacine birds are considered the major reservoir, but most species of birds can be infected with the organism. Infected birds may be obviously ill and may die of the disease, but frequently they have mild signs such as anorexia, diarrhea, lethargy, and ruffled feathers. Human illness is sporadic and has been associated with exposure to parrots, canaries, pigeons, sparrows, ducks, cockatiels, fowl (especially turkeys), and occasionally mammals. Owners of pet birds account for about half of the 40–60 cases reported in the United States each year. Pet shop employees, pigeon fanciers, zoo workers, veterinarians, and others who work with birds are at increased risk of infection. Outbreaks have occurred among poultry processing plant workers, principally among workers who killed the birds and plucked their feathers and those who eviscerated carcasses, with a mortality of about 1%, even with appropriate therapy (Centers for Disease Control, 1990; Petrovay, 2008). Before the discovery of antibiotics, the mortality rate for human infection was 15%–20%. Over the past two decades, the prevalence of psittacosis in the United States has declined dramatically as a result of adding tetracycline to poultry feed, requiring medication of commercially imported psittacine birds before entering the country and domestic breeding of parakeets.

C. psittaci is present in the blood, tissues, excreta, and feathers of infected birds and may be shed for months after acute infection. Transmission to humans occurs via inhalation of infectious aerosols derived from feces, fecal dust, and secretions of *C. psittaci*-infected birds, but may result from handling contaminated plumage or tissues, from bird bites, or from mouth-to-beak contact. Contact with birds does not have to be close or prolonged. Person-to-person spread of *C. psittaci* is rare.

Pathogenesis and Pathology

C. psittaci enters the body via the respiratory tract and is transported to the macrophages of the liver and spleen, where the organisms replicate. They then enter the blood and travel to the lungs, the primary target of infection, and other organs. Histologic examination of lung tissue shows lymphocytes in the alveolar and interstitial spaces and mucous plugging of the bronchioles. Small hemorrhages and macrophages with intracytoplasmic inclusions may be seen. The hilar lymph nodes, liver, and spleen may be enlarged and may contain foci of necrosis; in fatal cases, the myocardium, pericardium, meninges, brain, and adrenals may be involved.

Clinical Manifestations

After an incubation period of 1–2 weeks, psittacosis may begin abruptly with chills and fever, or it may begin more gradually with increasing fever and malaise. Persistent dry, hacking cough, occasionally productive of blood-streaked mucoid sputum, is prominent. The heart rate is often slow relative to body temperature, and a diffuse, severe headache is usual. Malaise, anorexia, painful myalgias, and arthralgias are common, and a macular rash (Horder spots) resembling the rose spots of typhoid fever may occur. Decreased mentation may develop at the end of the first week of illness, and some may have gastrointestinal complaints. *C. psittaci* is a rare cause of destructive endocarditis; most affected persons have a history of rheumatic heart disease or congenital valvular abnormalities (Jones, 1982).

CHLAMYDOPHILA (FORMERLY CHLAMYDIA PNEUMONIAE)

In 1986, a unique chlamydial organism, initially considered to be a strain of *C. psittaci*, was associated with acute respiratory tract disease in humans. The organism was named TWAR for the laboratory identifying letters of the first two isolates: TW-183, isolated in 1965 from the eye of a control child in a trachoma vaccine trial in Taiwan, and AR-39, recovered the same year from the throat of a student with pharyngitis at the University of

Washington. Soon after its recognition, data from DNA homology and electron microscopic studies showed that this unique organism was a separate species, designated as *Chlamydia pneumoniae*, which has been reclassified as *Chlamydophila pneumoniae* (Campbell, 1987; Chi, 1987; Cox, 1988; Everett, 1999).

Epidemiology

The epidemiology of infection with *C. pneumoniae* is based on data from retrospective studies of sera collected during respiratory tract illnesses. About 50% of adults have antibodies to *C. pneumoniae*. Antibody prevalence rates are low in children, increase sharply in teenagers, continue to increase until middle age, and remain high into old age; rates are 10%–25% higher for males. Data from retrospective and prospective serologic studies indicate that disease caused by *C. pneumoniae* is endemic in the United States and epidemic in Scandinavia and Finland, but does not occur with any consistent seasonal periodicity (Grayston, 1989, 1990). *C. pneumoniae* appears to be a primary human pathogen, transmitted from person to person without an avian or animal reservoir. The mechanism and place of transmission, incubation period, and infectiousness of the organism have not yet been determined.

Pathogenesis

The pathogenesis of infection with *C. pneumoniae* is unknown. Because the illness is generally mild and self-limited, autopsy studies are unavailable.

Clinical Manifestations

It is estimated that *C. pneumoniae* is responsible for at least 10% of community-acquired pneumonias (Grayston, 1990). The pneumonia usually is mild with a single subsegmental infiltrate, but it may be severe, especially in elderly persons and in those with chronic disease. It often begins with pharyngitis and hoarseness, followed by persistent cough. Although pneumonia is the most common syndrome associated with *C. pneumoniae* infection, serologic studies during epidemics among military trainees have shown that only about 10% of infections with *C. pneumoniae* result in pneumonia, suggesting that infection is frequently mild or asymptomatic and unrecognized. Other manifestations of *C. pneumoniae* infection are bronchitis, pharyngitis, fever of undetermined origin, otitis, influenza-like illness, myocarditis, endocarditis, and possibly atherosclerosis, although the latter is controversial (Campbell, 1998; Maraha, 2004).

LABORATORY DIAGNOSIS

Chlamydia trachomatis

Specimens for detection of *C. trachomatis* are determined by the type of disease suspected (Table 56-2). Screening women at risk for genital *C. trachomatis* infection (described earlier) has been shown to decrease the rate of pelvic inflammatory disease, thus preventing subsequent reproductive sequelae (Nelson, 2001). The transport system selected must be approved for the test method used. Specific collection techniques are discussed in Chapter 63. Most infections involve mucous membranes; specimens should be collected directly from the involved surface and must

contain an adequate sample of infected epithelial cells. Purulent discharge is not an appropriate specimen and should be removed before a sample is collected with a swab or brush. Of the types of swabs available, Dacron- or rayon-tipped swabs are preferred. Swabs with wooden shafts should be avoided because wood is toxic to the organism. Calcium alginate swabs may be toxic to the chlamydias or to the cells that support their growth. Cotton-tipped swabs are acceptable but are occasionally toxic to the chlamydias. Collection of urine for nucleic acid amplification testing should follow the recommendations of the manufacturer.

Cell Culture

Cell culture is the reference method for diagnosis of chlamydial infections and should be performed when the diagnosis is disputed and in cases of suspected sexual assault or abuse. Cell lines most commonly used are McCoy or buffalo green monkey cells. Both have equivalent sensitivity, but the latter cells are easier to maintain and are more resistant to cytotoxic substances; they have been associated with more inclusions and larger inclusions (Krech, 1989). Adding cycloheximide (0.5–1.5 $\mu\text{L/mL}$) to the growth medium enhances sensitivity. Cell monolayers are grown on glass coverslips in shell vials or 24-well plates, or on the surface of polystyrene 96-well or 48-well culture dishes. To enhance recovery of *C. trachomatis*, specimens are sonicated or agitated on a vortex mixer before inoculation to release elementary bodies from host cells, and inoculated shell vials or culture dishes are centrifuged. After incubation for 48–72 hours, monolayers are fixed and stained with fluorescein-conjugated monoclonal antibodies. If a 96-well culture system is used, passing specimens that are negative for *C. trachomatis* at 48 hours may enhance detection; however, passaging does not significantly increase detection in shell vials or 24-well plates. Although traditionally the “gold standard” for detection of *C. trachomatis*, it is now recognized that because of the fastidious nature of the organism, sensitivity of cell culture is only in the 50%–75% range, although with the use of monoclonal antibodies in the staining phase, specificity should be 100% (Solomon, 2004; Carder, 2006).

Nonculture Direct Detection Methods

Direct Fluorescent Antibody Tests. The DFA test allows direct visualization of *C. trachomatis* elementary bodies in smears of clinical specimens. Total processing time is 30–60 minutes. It is the only test that permits direct assessment of specimen adequacy. Specimens with columnar or metaplastic squamous cells are acceptable, whereas those with few columnar cells, excessive amounts of mucus, or predominance of squamous cells are not. However, interpretation of the smear is subjective, and operator fatigue can be a problem in high-volume situations. Monoclonal antibodies are available from several manufacturers. Antibodies directed against the species-specific MOMP of *C. trachomatis* appear to be more specific and produce more intense fluorescence than those directed against the chlamydial LPS (Cles, 1988). Occasionally, even the species-specific antibodies stain bacteria other than *C. trachomatis*, perhaps because of nonspecific immunoglobulin binding or cross-reactivity. Staining organisms other than *C. trachomatis* is especially frequent with rectal specimens; therefore for this site, culture is preferred, although some DFA reagents are approved for evaluation of rectal samples. Monoclonal antibody cross-reactivity between Chlamydiaceae and *Bartonella* has also been reported.

The sensitivity of the DFA test has varied from 50% to almost 100% compared with culture as the standard, and specificity is $\geq 95\%$. Sensitivity depends on the prevalence of infection in the population being evaluated and the number of elementary bodies required for a positive result (Barnes, 1989) and, in general, is greater with lower cutoff values for elementary bodies and in populations with high prevalence of disease.

Enzyme Immunoassays. EIAs detect chlamydial LPS with monoclonal or polyclonal antibodies labeled with an enzyme that converts a colorless substrate into a colored product. Both solid-phase systems, which use plastic or beads coated with the antibody, and membrane systems are commercially available. Total processing time ranges from 15–30 minutes for membrane systems to 3–4 hours for solid-phase systems. Advantages of EIA include the objective interpretation of results and ease of use for batching large numbers of specimens.

As with DFA, the sensitivities of EIAs vary (from about 70%–100%) compared with culture as the standard and tend to be higher in populations with a high prevalence of disease, such as persons attending a sexually transmitted disease clinic (Barnes, 1989; Mills, 1992; Clarke, 1993; Ehret, 1993; Kluytmans, 1993; Warren, 1993). The specificity of EIA is 95% or higher. Causes of false-positive results include the presence of a bacterial urinary tract infection (Demaio, 1991) or contamination of the

TABLE 56-2

Specimens for Detection of *Chlamydia trachomatis**

Disease	Specimen
Mucopurulent cervicitis	Endocervical swab, urine
Acute urethral syndrome (women)	Urethral swab, urine
Acute endometritis	Endometrial aspirate
Acute salpingitis	Fallopian tube biopsy
Nongonococcal urethritis (men)	Urethral swab, urine
Inclusion conjunctivitis	Conjunctival scrapings/swab
Trachoma	Conjunctival scrapings/swab
Lymphogranuloma venereum	Lymph node aspirate, biopsy of ulcerated lesion, serum
Pneumonitis (infants)	Serum, tracheobronchial aspirate, nasopharyngeal swab

*Urine is acceptable for some enzyme-linked immunoassays and for the commercial nucleic acid amplification tests.

specimen with cervical mucus or vaginal secretions. The latter problem can be reduced by improving the specimen collection technique (removing cervical mucus and obtaining a true endocervical sample) and by using blocking antibodies (Mills, 1992). Point-of-care (POC) rapid tests using an immunoassay format exist for possible use in situations where an immediate result would be very helpful. One such test, the Biostar Chlamydia OIA (optical immunoassay) was evaluated by the CDC in an inner city clinic environment, where it demonstrated a sensitivity of 78.6% and a specificity of 97.2% when compared with nucleic acid amplification (Banda, 2009). The test allowed immediate treatment of a significant portion (65.9%) of evaluated patients who otherwise would not have been treated.

Nucleic Acid Hybridization Tests. A commercially available acridinium-ester-labeled DNA probe complementary to *C. trachomatis* ribosomal RNA allows direct detection of *C. trachomatis* in urogenital and conjunctival specimens. The test requires a water bath and a luminometer. Total processing time is 2–3 hours. The sensitivity of the probe test compared with culture as the reference method varies for both endocervical samples and urethral swab specimens in men (76%–97%) (Iwen, 1991; Kluytmans, 1991, 1994; Blanding, 1993; Clarke, 1993; Warren, 1993; Centers for Disease Control, 2002b). The specificity of the probe test is 97% or greater, and it can be improved with a probe competition assay (Woods, 1996).

Nucleic Acid Amplification. Several nucleic acid amplification tests for direct detection of *C. trachomatis* in endocervical swab specimens, male urethral swab specimens, and male and female urine samples are commercially available. Total time to a result is 2–5 hours, depending on the test used and the number of samples being processed. The ability of these tests to accommodate high-volume batch testing has facilitated the increase in the national screening rate for *C. trachomatis* infection in women aged 16–25 in the United States from 25.3% in 2000 to 41.6% in 2007 (Centers for Disease Control and Prevention, 2009). Three major assay methods are currently being utilized in the United States and in Europe to detect *C. trachomatis* in cervical swabs and urine from women and in urethral swabs and urine from men. Two of these methods, the polymerase chain reaction (PCR) (Roche Diagnostics Corp., Indianapolis, and Abbott Laboratories, Abbott Park, Ill.) and the strand displacement assay (SDA) (Becton Dickinson Diagnostic Systems, Sparks, Md.) utilize a DNA target, and the third, transcription-mediated amplification (TMA) (Gen-Probe Inc., San Diego) utilizes an RNA target. Data from several studies comparing nucleic acid amplification and cell culture indicate that the amplification tests are highly specific and more sensitive than culture (Goessens, 1997; Carroll, 1998; Ferrero, 1998; Mahony, 1998; Puolakkainen, 1998; Toye, 1998; Wylie, 1998; Vincelette, 1999; van der Pol, 2001; Koumans, 2003; Boyadzhyan, 2004; Gaydos, 2004). TMA has demonstrated higher sensitivity than the other methods, possibly owing to the higher RNA target levels relative to DNA target levels and the lower susceptibility to inhibitors seen in urine samples, possibly due to a target capture portion of the assay that precedes amplification (Schacter, 2005; Chernesky, 2006; Lowe, 2006; Levett, 2008).

In 2006, an interesting set of events occurred in Sweden that demonstrated the importance of target selection in nucleic acid amplification, in that a new variant of *C. trachomatis* that contained a 377 base pair deletion in the target utilized in the PCR was discovered. The appearance of this variant resulted in a high proportion of infected patients escaping detection (an estimated 8000 cases) by two systems that utilized the PCR method: the Abbott m2000 and the Roche Cobas Amplicor/TaqMan 48 (Herrmann, 2008; Möller, 2008). TMA and SDA methods detected the variant, as amplification targets were different. The new variant spread rapidly in Sweden, and by 2007 accounted for up to 65% of cases in which these two platforms were being used (Herrmann, 2008b). Studies demonstrated that the new variant had no other biological advantage to aid in its rapid spread relative to other strains, other than its ability to escape detection by the testing systems in use at the time (Unemo, 2010). Affected manufacturers have implemented new assays that detect dual targets, such that the variant is detected (Møller, 2010).

Verification of Nonculture Tests

The CDC has recommended that positive nonculture test (DFA, EIA, probe, nucleic acid amplification) results should be verified with a supplemental test if a false-positive result is likely to have adverse medical, social, or psychological consequences (Centers for Disease Control, 1993, 2002b). In low-prevalence populations, verification should probably be routine, but

it might be selective in high-prevalence populations. Culture confirmation is optimal in theory but requires a second specimen collected during the first visit or during a return visit, and in the case in which the initial screening test was a nucleic acid amplification test, culture is less sensitive and may not confirm a true positive. Several confirmation strategies for nucleic acid amplification tests have been suggested. Confirmation of a positive test may be done by performing a second amplification test, using the same assay or a different assay that targets a different nucleic acid sequence. Similarly, the original specimen may be used, or a second specimen may be obtained. Each strategy poses issues that must be addressed by a testing facility if it is determined that a result is to be confirmed. For example, if a different assay is to be used on the original specimen, it must be confirmed that the second assay can utilize a specimen collected using the collection kit of the first, and that no inhibition of amplification will occur (Scragg, 2006). Whether the original specimen or a new specimen is used, attention must be paid to differing sensitivities of different assays, as a less sensitive assay should not be used to confirm a result obtained with a more sensitive assay (Schacter, 2005). The practice of confirming positive results of nucleic acid amplification tests is not without controversy, and some experts do not agree with the recommendation of the CDC to do so (Schachter, 2006).

Serologic Tests

Serologic tests have little value for diagnosis of chlamydial genital infections for two reasons. First, antibodies to *C. trachomatis* persist after the infection resolves, so a positive serologic test does not necessarily correlate with active disease. Second, many serologic tests are not specific for *C. trachomatis* because they detect genus-specific antibodies. Exceptions include diagnosis of LGV and *C. trachomatis* pneumonitis in infants. Because LGV has a long latent period and clinical diagnosis often is delayed, antibodies are generally present when the acute phase serum is collected, and a fourfold rise in titer between acute and convalescent phase serum samples often cannot be documented. Thus, a single or stable complement fixation titer of 1:64 or greater supports a presumptive diagnosis of LGV. For diagnosis of *C. trachomatis* pneumonitis in infants, detection of IgM antibodies by microimmunofluorescence (MIF) may be useful. A single IgM titer of >1:32 when tested by MIF supports a diagnosis of chlamydial pneumonia. IgG is not useful in neonates because of circulating maternal antibody.

Chlamydophila psittaci

The CDC has established case definitions for *C. psittaci* infections, which are described as laboratory confirmed if (1) *C. psittaci* is cultured from respiratory material, or (2) antibody titers against *C. psittaci* increase fourfold or greater when tested by complement fixation or MIF at least 2 weeks apart, or (3) a single IgM titer of >1:16 when tested by MIF is present after the onset of symptoms (Centers for Disease Control and Prevention, 1998). *C. psittaci* can be grown in cell culture, but this is recommended only for specially equipped laboratories with experienced personnel, because the organism is especially virulent and has been associated with laboratory-acquired infection. Infection with *C. psittaci* is usually diagnosed serologically. Antibodies usually are detected by the end of the second week of illness, but early antibiotic therapy can delay their appearance for several weeks.

Chlamydophila pneumoniae

Diagnosis of *C. pneumoniae* infection is based predominantly on serologic tests (Grayston, 1990; Kumar, 2007). The MIF test with the TWAR antigen is specific for *C. pneumoniae* and is the only serologic test considered acceptable for use in diagnosis by the CDC and the Infectious Disease Society of America (IDSA) (Kumar, 2007). IgM antibodies appear about 2–3 weeks after the onset of primary illness, usually decline over the next 2–6 months to a level that cannot be detected, and may not reappear with reinfection. IgG antibodies are detected 6–8 weeks after onset of the primary illness, persist for life, and may rise 1–2 weeks following reinfection. Serologic test results consistent with acute infection include a fourfold or greater rise in IgG titer between acute and convalescent phase serum samples, or an IgM titer of 1:16 or greater. The use of single IgG titers is discouraged. Despite prevalent use of the MIF test, it has been shown to be insensitive, especially in children, and cross-reactions with *Mycoplasma*, *Bartonella*, and *Yersinia* species may occur. *C. pneumoniae* can be isolated in cell culture, but it is more difficult to grow than *C. trachomatis* (Roblin, 1992). Many “in-house” nucleic acid amplification assays for *C. pneumoniae* have been published, but very few have been validated clinically (Kumar, 2007).

TREATMENT

Tetracyclines have been the treatment of choice for infection with chlamydia. For genital infections due to *C. trachomatis*, recommended regimens include azithromycin (1g orally, 1 dose) or doxycycline (100mg orally twice a day for 7 days); other effective agents include erythromycin, ofloxacin, or levofloxacin (Centers for Disease Control, 2006). LGV requires the same daily dosage of doxycycline or erythromycin as genital infections, but for a period of 3 weeks. Ocular infections with *C. trachomatis* require systemic treatment with doxycycline or azithromycin for adults, and erythromycin for newborns; topical therapy suppresses symptoms but does not eradicate the organism. Macrolides (azithromycin and erythromycin) are acceptable alternative agents for doxycycline in infections caused by *C. pneumoniae*. For *C. psittaci*, the treatment of choice is tetracycline hydrochloride or doxycycline for 3 weeks. Erythromycin is an alternative but may be less effective in more severe cases.

RICKETTSIAL INFECTIONS

Rickettsia is a concept that developed historically as the molecular and physical nature of viruses was defined (Weiss, 1988). In contrast with human viral agents, which also require eukaryotic host cells for their intracellular replication, rickettsiae have a gram-negative bacterial cell wall, and their growth is inhibited by particular antibiotics. Rickettsiae are further differentiated from other obligately intracellular bacteria by their ecology and frequent transmission by arthropod vectors. The traditional taxonomic scheme of rickettsiae based on such phenotypic characteristics as intracellular growth and arthropod vector transmission has undergone substantial modification in light of contemporary gene sequence analyses. Genera that contain rickettsiae pathogenic for humans are *Rickettsia*, *Orientia*, *Ehrlichia*, *Anaplasma*, *Neorickettsia*, *Coxiella*, and *Bartonella* (Dumler, 2001; Yu, 2003). Despite their historical association with rickettsiology and arthropod transmission, *Bartonella* organisms are cultivable in cell-free medium and do not belong in the order Rickettsiales (Brenner, 1993), which includes the genera *Rickettsia*, *Orientia*, *Ehrlichia*, *Anaplasma*, and *Neorickettsia*, which are more closely related to one another than to *Coxiella*. Grouped by genus, the following diseases are presented in this chapter: *Rickettsia*—Rocky Mountain spotted fever, boutonneuse fever, African tick bite fever, rickettsialpox, and murine typhus; *Orientia*—scrub typhus; *Ehrlichia*—human monocytotropic ehrlichiosis caused by *Ehrlichia chaffeensis* and human infection with *Ehrlichia ewingii*; *Anaplasma*—human granulocytotropic anaplasmosis; *Coxiella*—Q fever; and *Bartonella*—cat scratch disease, bacillary angiomatosis and peliosis, trench fever, and South American bartonellosis. The diseases of each genus comprise cohesive clinical and pathologic groupings, and overall the rickettsial diseases pose a similar set of diagnostic challenges, with similar technical approaches to their solution.

INFECTIONS CAUSED BY ORGANISMS OF THE GENUS RICKETTSIA

Structure and Function

Spotted fever, transitional, and typhus group rickettsiae are genetically closely related bacteria that have a thin ($0.3\text{--}0.5 \times 1\text{--}2 \mu\text{m}$) bacillary morphology and a gram-negative cell wall containing LPS with antigenic components that distinguish the spotted fever and typhus groups. All *Rickettsia* species reside free in the cytosol of the host cell and divide by binary fission. *Rickettsia* attach to the host cell via a protein adhesin, enter by induced phagocytosis, and escape from the phagosome (Li, 1998; Uchiyama, 1999; Martinez, 2004; Martinez, 2005). These functions can occur within minutes and are associated with phospholipase activity of rickettsial origin (Silverman, 1992; Whitworth, 2005). Spotted fever group rickettsiae are propelled within cells and during release from the cell by stimulating polymerization of host cell F-actin at one pole (Heinzen, 1993; Kleba, 2010). *Rickettsia* that manifest this activity (e.g., *Rickettsia rickettsii*) escape earlier from host cells and spread more quickly to other cells than those lacking this activity (e.g., *Rickettsia prowazekii*), which divide intracellularly to massive numbers before the host cell bursts and the organisms are released. According to the molecular phylogeny, *Rickettsia* species that are pathogenic for humans have evolved into three genogroups (Table 56-3) (Roux, 1995, 1997; Stothard, 1995). The typhus group includes *R. prowazekii* and *Rickettsia typhi*. The core spotted fever group contains *R. rickettsii*, *Rickettsia conorii*, *Rickettsia japonica*, *Rickettsia africae*, *Rickettsia parkeri*, *Rickettsia honei*, *Rickettsia sibirica*, *Rickettsia aeschlimannii*, and *Rickettsia slovaca*.

A newly recognized transitional group contains *Rickettsia akari*, *Rickettsia australis*, and *Rickettsia felis*. *R. akari* and *R. australis* were traditionally considered to be relatively distant members of the spotted fever group, with which they share LPS antigens.

Rocky Mountain Spotted Fever

The most severe of all the rickettsioses, Rocky Mountain spotted fever, has a substantial case fatality rate, 5%, even among previously healthy, immunocompetent children and young adults (Dalton, 1995a; Paddock, 1999). *R. rickettsii* normally resides in nature in ticks: *Dermacentor variabilis*, the American dog tick, in the eastern two thirds of the United States and California; *Dermacentor andersoni*, the Rocky Mountain wood tick, in the western United States; *Rhipicephalus sanguineus*, the brown dog tick, in Mexico, Brazil, and Arizona; and *Amblyomma cajennense* and *A. aureolatum* in South America. These ticks maintain *R. rickettsii* as they moult from stage to stage (larva, nymph, and adult) and transovarially from generation to generation. Fewer than 1 per 1000 ticks carries virulent *R. rickettsii*, which is pathogenic for ticks (Niebylski, 1999). New lines of ticks become infected by feeding on rickettsemic rodents, replenishing the population of organisms transovarially maintained in ticks (Gage, 1990).

Infections occur when and where humans encounter *R. rickettsii*-infected ticks (Helmick, 1984). Although Rocky Mountain spotted fever has been documented in recent years in nearly every state except Hawaii, Alaska, and Vermont, the highest incidence is in the south Atlantic states from Maryland to Georgia and the south central states of Oklahoma, Missouri, Arkansas, and Tennessee. Most cases occur in late spring and summer, but particularly in the southern latitudes, a few cases may occur even in winter. The highest incidence is seen in children, adults of retirement age, and others exposed to ticks during outdoor activities. Fatality/case ratios are higher for persons older than 30 years. Fulminant Rocky Mountain spotted fever (death by the fifth day of illness) occurs in association with moderate hemolysis, for example, in African American males with glucose-6-phosphate dehydrogenase (G6PD) deficiency (Walker, 1983).

Rickettsiae are injected via the infected tick's salivary gland secretions into the patient's dermis after 6–10 hours of tick feeding and spread hematogenously throughout the body. The vascular endothelium is the target of intracellular infection, with some invasion into adjacent vascular smooth muscle cells. Infected endothelium is injured by reactive oxygen species-induced damage to cell membranes (Silverman, 1992, 1997). Damage to the endothelium results in increased vascular permeability, edema, hypovolemia, and hypotension. Life-threatening consequences of vascular injury in the central nervous system (CNS) and lung are rickettsial meningoencephalitis and noncardiogenic pulmonary edema. Early in the course, lesions show endothelial rickettsiae without thrombi or a cellular response. Late in the course, the characteristic lymphohistiocytic perivascular infiltrate appears as interstitial pneumonia, interstitial myocarditis, perivascular glial nodules of the brain, and similar vascular lesions in the dermis, gastrointestinal tract, liver, skeletal muscles, and kidneys. Severe injury may be accompanied by focal hemorrhages but seldom by microinfarcts, except in the white matter of the brain.

Clinical illness usually begins with fever, headache, and myalgia 2–14 days after a tick bite (Kaplowitz, 1981). Nausea, vomiting, abdominal pain and tenderness, and diarrhea occur more frequently in the first 3 days of illness. The rash, which usually appears between days 3 and 5, typically begins as macules around the wrists and ankles and later on the arms, legs, and trunk. The lesions become maculopapular, and in half of cases, a central petechia appears in many of the maculopapules. Characteristic involvement of the palms and soles occurs in half of cases as a late manifestation. Renal failure is a feature of severe illness. CNS involvement is ominous; seizures and coma occur in 8%–10% of cases overall, often preceding a fatal outcome. Thrombocytopenia occurs in half of cases, but disseminated intravascular coagulation is rare (Elghetany, 1999).

African Tick Bite Fever, Boutonneuse Fever, and Other Spotted Fevers

R. conorii has been isolated in southern Europe; northern, eastern, and southern Africa; Israel; Turkey; India; Pakistan; Russia; Georgia; and the Ukraine. The ecology of *R. conorii* and the epidemiology of boutonneuse fever are closely tied to ticks, especially *R. sanguineus*, which maintain the rickettsiae transovarially and transmit the infection to humans while feeding (Walker, 1991). Imported cases are diagnosed in travelers returning to the United States and northern Europe from the Mediterranean basin. The fatality rate among hospitalized patients is 1.4%–5.6%,

TABLE 56-3

Rickettsia, *Orientia*, *Ehrlichia*, *Anaplasma*, *Neorickettsia*, *Coxiella*, and *Bartonella* Infections

Etiologic agent	Disease	Geographic distribution	Transmission
Spotted Fevers			
<i>R. rickettsii</i>	Rocky Mountain spotted fever	North, Central, and South America	Tick bite
<i>R. conorii</i>	Boutonneuse fever	Southern Europe, Africa, Russia, Georgia, Middle East, Indian subcontinent	Tick bite
<i>R. africae</i>	African tick bite fever	Southern and eastern Africa, Caribbean	Tick bite
<i>R. parkeri</i>	Maculatum disease	North and South America	Tick bite
<i>R. sibirica</i>	North Asian tick typhus and lymphangitis-associated rickettsioses	Russia, China, Mongolia, Pakistan, Europe, Africa	Tick bite
<i>R. japonica</i>	Japanese spotted fever	Japan, Korea, Thailand	Tick bite
<i>R. honei</i>	Flinders Island spotted fever	Australia, southeastern Asia	Tick bite
<i>R. slovaca</i>	Tick-borne lymphadenopathy	Europe	Tick bite
Typhus Fevers			
<i>R. prowazekii</i>	Epidemic typhus	Potentially worldwide; in recent decades in Africa, South America, Central America, Mexico, Asia	Feces of human body louse
<i>R. prowazekii</i>	Brill-Zinsser disease	Worldwide; wherever persons with past epidemic typhus now reside	Recrudescence of latent infection
<i>R. prowazekii</i>	Flying squirrel typhus	United States	Presumably feces of flea or louse of flying squirrel
<i>R. typhi</i>	Murine typhus	Worldwide in tropics and subtropics	Flea feces
Transitional Group Rickettsial Fevers			
<i>R. akari</i>	Rickettsialpox	United States, Ukraine, Croatia, Korea, Turkey, Mexico	Mite bite
<i>R. australis</i>	Queensland tick typhus	Eastern Australia	Tick bite
<i>R. felis</i>	Flea-borne spotted fever	Worldwide	Presumably flea bite or feces
Scrub Typhus			
<i>Orientia tsutsugamushi</i>	Scrub typhus	Southeastern Asia, Japan, China, Sri Lanka, India, Asiatic Russia, Indonesia, Indian Ocean and Western Pacific Islands, Northern Australia	Chigger bite
Ehrlichioses			
<i>E. chaffeensis</i>	Human monocytotropic ehrlichiosis	United States, Africa, Asia	Tick bite
<i>E. ewingii</i>	Ehrlichiosis ewingii	United States, Africa	Tick bite
<i>Anaplasma phagocytophilum</i>	Human granulocytotropic anaplasmosis	United States, Eurasia	Tick bite
<i>Neorickettsia sennetsu</i>	Sennetsu rickettsiosis	Asia	Apparently ingestion of fish parasitized with trematodes carrying neorickettsia
Coxiellosis			
<i>C. burnetii</i>	Q fever	Worldwide	Inhalation of aerosols from infected animals, possibly ingestion of animal products
Bartonelloses			
<i>B. bacilliformis</i>	Oroya fever, verruga peruana	Western South America	Sandfly bite
<i>B. henselae</i>	Cat scratch disease, bacillary angiomatosis and peliosis, endocarditis	Worldwide	Kitten scratch or bite
<i>B. clarridgeiae</i>	Cat scratch-like disease	Probably worldwide	Presumed cat scratch or bite
<i>B. quintana</i>	Trench fever, endocarditis	Worldwide	Feces of <i>Pediculus</i> louse

particularly in patients with underlying conditions such as diabetes and alcoholism (de Sousa, 2008). A milder disease caused by *R. africae* occurs with high frequency in travelers returning from southern Africa (McQuiston, 2004). The clinical illness resembles that recently associated in the Americas with *R. parkeri*, which is essentially conspecific with *R. africae* (Paddock, 2004, 2008). Tick bite eschars are often multiple, regional lymphadenopathy is observed frequently, and rash is typically sparse, sometimes vesicular, and often absent. *R. sibirica* has been isolated in Russia, China, Mongolia, and Pakistan, and a distinct strain *mongoliti-moniae* isolated in Asia, Europe, and Africa has been associated in half of cases with lymphangitis extending from the eschar. *R. japonica* has been documented in Japan, and infection with *R. japonica* occurs also in Korea and Thailand. Human infections with *R. australis* occur only in Australia,

and infection with *R. honei* has been documented in Australia and Thailand. After an average incubation period of 7 days, these illnesses begin with fever, headache, and myalgias. Frequently, an eschar can be discovered by careful examination of the skin at this time. The pathology of these spotted fevers is well described in the tache noire or eschar at the site of tick bite inoculation of rickettsiae (Walker, 1988a). Endothelial infection and injury by *R. conorii* in the eschar result in dermal and epidermal necrosis and perivascular edema.

Host defenses that effect killing of intracellular rickettsiae include nitric oxide, reactive oxygen species, and tryptophan limitation induced by cytokines secreted by T lymphocytes and macrophages, which infiltrate around the infected dermal blood vessels and target cell apoptosis triggered by cytotoxic CD8⁺ T lymphocytes (Herrero-Herrero, 1987; Walker,

2001; Valbuena, 2002). Activation of endothelial cells by cytokines, including γ -interferon and tumor necrosis factor- α , results in intracellular rickettsicidal activity, and ultimate clearance is mediated by cytotoxic T lymphocytes. Disseminated endothelial infection results in maculopapular rash, meningoencephalitis, and vascular lesions in the lungs, kidneys, gastrointestinal tract, and heart (Walker, 1985). Multifocal hepatocellular necrosis and granuloma-like lesions correlate with moderately increased concentrations of hepatic transaminases (Walker, 1986).

Rickettsialpox

R. akari is maintained in nature by transovarial transmission in the gamasid mite, *Liponyssoides sanguineus*, an ectoparasite of the domestic mouse, *Mus musculus*. *R. akari* has been detected only in the United States, Croatia, the Ukraine, Turkey, Mexico, and Korea, perhaps more an indication of the paucity of rickettsial investigations than the actual distribution of this rickettsial species.

A papule develops during the approximately 10-day incubation period at the site of mite bite and progresses to become a 1–2.5 cm eschar. Illness begins with chills, fever, malaise, severe headache, and myalgia. Rash, which appears 2–6 days later, is initially maculopapular, later papular, and in classic cases, pustular and/or vesicular. Some patients also suffer nausea, vomiting, pharyngitis, photophobia, splenomegaly, and nuchal rigidity.

Histopathologic examination of the eschar reveals coagulative necrosis of the epidermis, underlying vascular injury, and a perivascular lymphohistiocytic infiltrate in which macrophages appear to be the main target cell of infection (Brettman, 1981; Kass, 1994; Walker, 1999b). Regional lymphadenopathy and cutaneous rash presumably reflect lymphogenous and hematogenous spread, respectively.

Flea-borne Spotted Fever

A widely dispersed organism, *R. felis* is maintained transovarially in cat fleas (*Ctenocephalides felis*) with apparent involvement of opossums in a zoonotic cycle. Human infections have been documented in North America, Europe, Africa, and Asia (Schriefer, 1994a; Zavala-Velazquez, 2000; Raoult, 2001; Parola, 2003).

Murine Typhus and Louse-borne Typhus

Endemic flea-borne *R. typhi* infection, murine typhus, is presently the most important typhus group infection in the United States and causes extensive morbidity throughout the warm regions of the world (Azad, 1990). Historically, epidemic louse-borne *R. prowazekii* infections have had a major impact on the outcome of military campaigns, as well as scouring general populations disrupted by war, famine, and natural disasters (Zinsser, 1935; Patterson, 1993). *R. prowazekii* continues to cause disease in some poverty-stricken areas of the world and reappears in situations such as the civil war in Burundi, the extreme poverty of indigenous populations of the Andes, and other unsettled social and economic conditions. Recrudescence of latent *R. prowazekii* infections can occur years after the primary infection in immigrants from typhus-afflicted areas. Endemic transmission of *R. prowazekii* from a natural infectious cycle of flying squirrels and their ectoparasites occurs in the United States (McDade, 1980; Reynolds, 2003).

Murine typhus occurs particularly in tropical and subtropical coastal areas, where *Rattus rattus*, *Rattus norvegicus*, and the Oriental rat flea abound (Azad, 1990). The fleas imbibe rickettsiae in the blood of infected rats and maintain the infection for their normal life span. Transovarian transmission occurs only at low levels; thus, horizontal transmission to other rats is a key factor in maintenance of *R. typhi* in nature. Other mammal-arthropod cycles maintain the rickettsiae and result in transmission of infection to humans (e.g., the cat flea, *C. felis*, and the opossum in Texas and California) (Schriefer, 1994b).

Humans are thought to become infected by intradermal inoculation of infected flea feces into skin excoriated by scratching. However, inhalation of a rickettsial aerosol from dried infected flea feces or inoculation by flea bite may account for transmission in some cases. After an incubation period of 1–2 weeks, illness begins with fever accompanied in some cases by severe headache, chills, myalgia, and nausea. A macular or maculopapular rash, most prominent on the trunk, is visualized on day 5 or 6 in 80% of patients with fair skin and in 20% with darkly pigmented skin. A small proportion of patients have cough and pulmonary infiltrates. Severely ill patients may also suffer coma, seizures, and other neurologic signs. Approximately 10% of hospitalized patients require admission to the intensive care unit, and 1%–2% of murine typhus patients die (Dumler, 1991).

Pathologic lesions of murine typhus include endothelial swelling and perivascular lymphohistiocytic infiltrates involving the blood vessels in the dermis, CNS, lungs, heart, gastrointestinal tract, and kidneys (Walker,

1989). The most serious consequences include meningoencephalomyelitis and diffuse alveolar injury.

Rickettsiae as Agents of Bioterrorism

R. prowazekii and *R. rickettsii* are select agents, possession of which is restricted by law to registered scientists in approved institutions where rigorous security and safety regulations are applied to the laboratories. These organisms exist in nature, can be recovered and propagated, and are infectious via a stable aerosol, with infectivity of as little as a single bacterium.

Case fatality rates of 15%–25% in previously healthy persons would occur without prompt diagnosis and treatment. The potential for genetically engineered resistance to the effective antibiotics, tetracycline and chloramphenicol, would render these cases of typhus and Rocky Mountain spotted fever untreatable (Walker, 2003). Although the case fatality rates would be lower, bioterrorist-dispersed *R. typhi* or *R. conorii* could create terror and overwhelm the medical and public health systems.

Laboratory Diagnosis

Unlike most infectious diseases for which precise diagnosis is sought during the acute phase of illness, when critical therapeutic decisions are made, rickettsial diseases are usually diagnosed acutely purely on the basis of clinicoepidemiologic suspicion, and are treated empirically on a presumptive basis (Kaplowitz, 1981). Serologic diagnosis, which is often mistakenly sought early in the course of illness, provides the majority of laboratory-confirmed diagnoses by demonstration of a fourfold or greater rise in titer only during convalescence. Even with the most sensitive serologic methods, less than 20% of patients have detectable specific antibodies to rickettsiae when presenting to the physician for medical attention. Other approaches to diagnosis at the time of presentation include immunohistologic demonstration of rickettsiae in cutaneous lesions, immunocytologic identification of rickettsiae in circulating detached endothelial cells, detection of rickettsial DNA in blood and tissue specimens by PCR (Schriefer, 1994a; Sexton, 1994; Williams, 1994; Furuya, 1995), and cultivation of rickettsiae from blood or tissue specimens; however, these tests are not available in most clinical laboratories.

Rickettsiae were originally demonstrated in tissues of patients with Rocky Mountain spotted fever and epidemic louse-borne typhus by Wollbach using Giemsa stain during and shortly after World War I. This method, essentially a lost art, requires careful attention to details of fixation and staining of rickettsiae, and is not performed successfully in this manner in contemporary histology laboratories. A modified Brown-Hopps method stains a small fraction of organisms, which appear as thin bacilli within endothelial cells. A more sensitive and specific approach to visualization of rickettsiae in tissue section is immunohistology—immunofluorescence or immunoenzyme staining—using antibodies specific for the spotted fever or typhus group (Kaplowitz, 1983; Walker, 1989, 1997b, 1999b; Dumler, 1990). Staining of skin biopsies from patients with Rocky Mountain spotted fever by immunohistochemistry has a sensitivity of 70% and a specificity of 100%. Patients with boutonneuse fever, African tick bite fever, murine typhus, and rickettsialpox have also been diagnosed by immunohistologic detection of rickettsiae in rash and eschar lesions. A monoclonal antibody to a spotted fever group-specific epitope on the cell wall LPS demonstrates *R. rickettsii*, *R. parkeri*, *R. conorii*, *R. akari*, *R. japonica*, *R. australis*, *R. africae*, *R. honei*, and *R. sibirica* in formalin-fixed, paraffin-embedded tissues; a typhus group LPS-specific monoclonal antibody is similarly useful for detecting *R. typhi* and *R. prowazekii* (Walker, 1997b). Currently, reagents for diagnostic immunohistology of rickettsioses are not commercially available, but it is feasible that kits could be developed for rickettsial group-specific diagnosis using antibodies produced in research laboratories.

A unique diagnostic approach is the immunocytologic demonstration of *R. conorii* in detached, circulating endothelial cells captured from patient blood samples by immunomagnetic beads coated with a monoclonal antibody to a surface antigen of human endothelial cells (Drancourt, 1992; La Scola, 1996a). In boutonneuse fever patients, this method has a sensitivity of 58% for examination of a single blood sample and may be used in patients before the onset of rash, which must be present for selection of the site of skin biopsy for immunohistologic diagnosis.

PCR has been applied successfully to the diagnostic detection of *R. rickettsii*, *R. conorii*, *R. japonica*, *R. africae*, *R. parkeri*, *R. felis*, *R. akari*, *R. sibirica*, *R. slovaca*, *R. aeschlimannii*, *R. typhi*, and *R. prowazekii* from clinical samples, including biopsy of eschar or rash, peripheral blood, buffy coat, plasma, necropsy tissue, and arthropod vectors removed from patients. Target genes include the 17-kDa lipoprotein gene, *gltA*, *rrs*,

groEL, *ompA*, and *ompB*. This approach may fail to detect rickettsial nucleic acids early in the course or after development of immunity or effective antimicrobial treatment (Tzianabos, 1989; Schriefer, 1994a; Sexton, 1994; Furuya, 1995; Roux, 1999; Leitner, 2002; Walker, 2003; Fournier, 2004; Ndip, 2004; Stenos, 2005; Kidd, 2008; Nascimento, 2009; Prakash, 2009).

Isolation of rickettsiae is achieved frequently in antibiotic-free, centrifugation-enhanced shell vial cell culture in reference and research laboratories with biosafety level 3 containment and specialized expertise.

The “gold standard” serologic test for rickettsioses is the indirect immunofluorescent antibody (IFA) assay (Kaplan, 1986). The indirect immunoperoxidase antibody test yields similar results. For spotted fever and typhus-group rickettsial infections in the United States, IFA titers of 1:64 or greater are considered to be diagnostic in a compatible clinicoepidemiologic situation. In countries with a high prevalence of persons with antibodies to these rickettsiae, due hypothetically to stimulation by non-pathogenic rickettsiae or subclinical or undiagnosed infection, higher titers are required to establish the diagnosis. In any event, a fourfold rise in IFA antibody titer to a titer of at least 1:64, but usually 1:256 or higher, is diagnostic. The sensitivity of the IFA for Rocky Mountain spotted fever is 94%–100%, and the specificity is 100%. With a cutoff titer for IgG of 1:128 and for IgM of 1:32, the indirect immunoperoxidase test yields similar results and has the advantage of requiring only a light microscope instead of an ultraviolet microscope.

Commercially available serologic tests include indirect immunofluorescence, latex agglutination, and standard solid-phase enzyme immunoassay (Kelly, 1995). Latex agglutination and solid-phase enzyme immunoassays provide diagnostically useful information and require less expensive equipment to perform, but generally are not considered as reliable as the IFA. The greatly increased reliance of reference laboratories on EIAs has occurred in parallel with anomalous changes in public health reports of Rocky Mountain spotted fever. It has been suggested that a substantial portion of the tick-exposed population has standing titers of antibodies stimulated by spotted fever group rickettsiae of low pathogenicity (Graf, 2008; Walker, 2008). The Weil-Felix tests, which measure agglutination of *Proteus vulgaris* strains OX-19 and OX-2 (Kaplan, 1986), are insensitive and nonspecific and should not be used, except in developing countries in which no other method can be performed. Serology is seldom useful in assisting therapeutic decisions because antibodies appear later in the course.

Treatment

Spotted fever and typhus group rickettsioses are treated effectively with doxycycline, tetracycline, or chloramphenicol (Raoult, 1991). Fluoroquinolones, azithromycin, and clarithromycin are active against some rickettsiae *in vitro*. Ciprofloxacin, ofloxacin, and perfloracin have been used successfully to treat boutonneuse fever, and azithromycin and clarithromycin have been used to treat mild boutonneuse fever in children, but these agents have not been evaluated and are not recommended for treatment of Rocky Mountain spotted fever.

SCRUB TYPHUS CAUSED BY *ORIENTIA TSUTSUGAMUSHI*

The gram-negative cell wall of *Orientia* (formerly *Rickettsia*) *tsutsugamushi* differs from that of spotted fever and typhus group rickettsiae; it has an ultrastructurally thicker outer leaflet and a thinner inner leaflet of the outer envelope and different major proteins, and it lacks LPS (Tamura, 1995). Scrub typhus rickettsiae grow in the cytoplasm of the host cell and are released via a process involving pinching off of a host cell membrane-bound rickettsia. *O. tsutsugamushi* is transovarially maintained in mites of the genus *Leptotrombidium* (Traub, 1978). Infected ova hatch into larvae—the only stage that feeds on an animal host. Rats become infected after rickettsia-containing larvae (chiggers) feed on the rats' tissue fluids, but feeding mite larvae that acquire rickettsiae do not pass the infection to their offspring. Thus, humans and rats are only accidental, nonessential, dead-end hosts of scrub typhus rickettsiae. Scrub typhus occurs in countries within the geographic area formed by Japan, Russia, and Korea in the North, Australia and Indonesia in the South, Pakistan in the West, and the Philippines and Micronesia in the East. Infection is acquired in areas of dense vegetation where abundant rat populations harbor large populations of chiggers.

O. tsutsugamushi infects endothelial cells more extensively than macrophages (Moron, 2001). The basic pathologic lesion is vascular injury with perivascular lymphohistiocytic inflammation, which is present in

the cutaneous chigger inoculation sites and organs to which rickettsiae have disseminated—the brain, lung, heart, gastrointestinal tract, and kidney.

After incubation for 6–21 days, illness begins with fever, headache, and, in some patients, myalgia, cough, and gastrointestinal symptoms (Watt, 2006). An eschar develops in half of Westerners, usually before the onset of fever, but less often in indigenous patients. Likewise, a macular or maculopapular rash occurs in half of Westerners with primary infection 2–9 days after the onset of illness. Severely ill patients may develop hypotension, pneumonitis, meningoencephalitis, acute renal failure, and hemorrhagic phenomena. Unless treated with appropriate antimicrobial medications, 7% of cases are fatal. Greater severity is associated with greater bacterial loads (Sonthayanon, 2009). Scrub typhus may occur in trekkers and other travelers exposed to chiggers in endemic areas. For the diagnosis of scrub typhus in an endemic region, the cutoff titer should be determined for the particular population; for one region, a titer of 1:400 or greater by IFA is 96% specific and 48% sensitive, and a fourfold rise in titer is the preferred serologic criterion for diagnosis (Blacksell, 2007). Indirect immunoperoxidase is a similar method that does not require a fluorescent microscope. *Proteus mirabilis* strain OX-K agglutination is more readily available but insensitive. Serologic assays using a recombinant 56-kDa antigen representing the major immunodominant surface protein, including a dipstick test, a rapid lateral flow assay, and an IgM capture enzyme immunoassay, yield excellent results. (Ching, 2001; Coleman, 2002; Jang, 2003; Jiang, 2003).

PCR has been applied to the diagnosis of scrub typhus for more than a decade (Murai, 1992; Furuya, 1993; Kawamori, 1993; Sugita, 1993) and has been demonstrated to be effective in practice, including on eschar specimens (Manosroi, 2003; Saisongkorh, 2004; Kim, 2006; Paris 2008, 2009). Real-time PCR offers the opportunity for a highly sensitive, specific diagnosis with prompt turnaround time (Jiang, 2004).

Treatment with a tetracycline drug such as doxycycline or with chloramphenicol is effective, except among some cases in northern Thailand, where rifamycin and azithromycin are alternatives (Strickman, 1995; Watt, 1996, 2000; Kim, 2004; Liu, 2006).

INFECTIONS CAUSED BY ORGANISMS OF THE GENERA *EHRlichia* AND *ANAPLASMA*

Structure and Function

The family Anaplasmataceae consists of four genera—*Ehrlichia*, *Anaplasma*, *Neorickettsia*, and *Wolbachia*. Ehrlichiae and anaplasmas are small (0.5 μ m), tick-borne, obligately intracellular, gram-negative coccobacilli that reside in a cytoplasmic vacuole of white blood cells (Yu, 2003). This intravacuolar microcolony of bacteria stained by the Wright-Giemsa method resembles a mulberry and thus is called a morula (Latin for “mulberry”). *Neorickettsia*, similar small obligately intracellular bacteria, reside in trematode parasites in aquatic snails, insects, bats, and fish, and are transmitted by ingestion of a parasitized host (e.g., *Neorickettsia helminthoeca* in trematode-parasitized salmon eaten by dogs in the Pacific Northwest). *Wolbachia* reside in arthropods and filarial worms (e.g., *Onchocerca volvulus*), in which they play a role in the pathogenesis of the human illness.

Long known and studied as agents of veterinary disease, *Ehrlichia* and *Anaplasma* have recently emerged as human pathogens. The reasons for this are primarily their recent discovery in humans, their rapid characterization with contemporary molecular tools, and increasing populations and geographic distributions of particular ticks that depend on deer as a host. The well-documented human pathogens in the United States are *E. chaffeensis*, *E. ewingii*, and *Anaplasma phagocytophilum*. *Neorickettsia sennetsu* is the agent of a disease in Asia resembling infectious mononucleosis.

Human Monocytotropic Ehrlichiosis

E. chaffeensis is transmitted by ticks, primarily *Amblyomma americanum*, the Lone Star tick, but also *D. variabilis* and *Ixodes pacificus* (Anderson, 1992a; Ewing, 1995; Kramer, 1999). Cases are predominantly rural and seasonal (68% occur from May to July) (Fishbein, 1994; Olano, 2003a). Deer serve as a documented reservoir, and infected dogs and coyotes are potential reservoir hosts. Ticks become infected when feeding as larvae or nymphs, carry the ehrlichiae as they moult from stage to stage, and transmit the infection during a subsequent blood meal. Human monocytotropic ehrlichiosis has been reported in 47 states; most cases have occurred within the range of *A. americanum* in the third of the United States south of a line from New Jersey to Kansas. The number of reported cases is

particularly high in Oklahoma, Missouri, Arkansas, Tennessee, North Carolina, and Maryland.

Since the first case of human ehrlichiosis was reported in the United States in 1987, prospective studies have documented an incidence of laboratory-confirmed *E. chaffeensis* infection that exceeds that of Rocky Mountain spotted fever and is two orders of magnitude greater than suggested by passive reporting (Olano 2003b; Demma, 2005). Human ehrlichiosis may represent the most serious tick-transmitted infection in the United States. Fatalities have occurred in approximately 3% of cases—a rate that would be much higher without effective antibiotic treatment in many patients (Fichtenbaum, 1993; Fishbein, 1994). The severity is reflected in the admission of 41%–62% of patients to a hospital (Fishbein, 1994; Olano, 2003a, 2003b). Although severe cases often affect older persons, children are also susceptible to the illness (Schultze, 1997). The median duration of illness in a large CDC series, including treated cases, was 23 days. Signs and symptoms depict a systemic disease that has no clinically diagnostic features: fever (97%), headache (81%), myalgia (68%), anorexia (66%), nausea (48%), vomiting (37%), rash (6% at onset, 25% during the first week, and 36% overall), regional lymphadenopathy (29%), cough (26%), pharyngitis (26%), diarrhea (25%), abdominal pain or tenderness (22%), photophobia (27%), and confusion (20%) (Fishbein, 1994; Olano, 2003b). Severe complications include adult respiratory distress syndrome, disseminated intravascular coagulation, and renal insufficiency. Clinical laboratory findings include leukopenia (60%), thrombocytopenia (68%), and elevated hepatic transaminases (86%). CNS involvement manifested by seizures and coma has been documented by cerebrospinal fluid (CSF) pleocytosis, increased protein concentration and *E. chaffeensis* in CSF, and the presence of cerebral lesions at autopsy (Dunn, 1992; Ratnasamy, 1996; Walker, 1997a). Severity is age dependent (Olano, 2003a). In immunocompromised patients, including those with the acquired immunodeficiency syndrome (AIDS), human monocytotropic ehrlichiosis can be an overwhelming infection with massive growth of ehrlichiae and a fatal outcome (Paddock, 1993; Walker, 1997a). Mild infections have also been documented.

After entry via tick bite, *E. chaffeensis* spreads by lymphatic and/or hematogenous routes. Ehrlichial morulae have been identified in monocytes and macrophages in the bone marrow, peripheral blood (rarely), hepatic sinusoids, spleen, lymph nodes, meninges, kidney, gastrointestinal tract, and epicardium (Dumler, 1993a; Walker, 1997a; Sehdev, 2003). Bone marrow examination frequently reveals granulomas, myeloid hyperplasia, and megakaryocytosis. Other reported lesions include perivascular lymphohistiocytic infiltrates in the kidney, meninges, brain, and heart; interstitial mononuclear pneumonitis; foci of apoptosis-like cell death in the liver, lymph node, and spleen; diffuse reticuloendothelial hyperplasia; erythrophagocytosis; and cholestasis.

Human Infection with *Ehrlichia ewingii*

Recognized first as a canine pathogen in 1971, *E. ewingii* also infects white-tailed deer and is transmitted by *A. americanum* ticks (Ewing, 1971; Anziani, 1990). It shares antigens with *E. chaffeensis* but infects mainly neutrophils. A high proportion of infected patients are immunocompromised, suggesting that immunocompetent patients may be relatively resistant to the illness (Buller, 1999; Paddock, 2001).

Human Granulocytotropic Anaplasmosis

Thousands of cases of human granulocytic anaplasmosis have been documented, with most cases reported in the upper midwestern (Wisconsin and Minnesota) and northeastern states (New York, Connecticut, Rhode Island, and New Jersey) of the United States, but with confirmed autochthonous infections southward along the eastern seaboard and in California and Europe (Bakken, 1994; Aguero-Rosenfeld, 1996; Petrovec, 1997; Horowitz, 1998). Infection is transmitted by *Ixodes scapularis*, *I. pacificus*, and *Ixodes ricinus* ticks. The white-footed mouse (*Peromyscus leucopus*) and other small mammals are likely reservoir hosts in the United States, as are red deer, sheep, goats, and cattle in Europe (Hodzic, 1998). The pathology is poorly defined, with the observation of morula-containing neutrophils in peripheral blood and various organs, infiltrates of reticuloendothelial organs with foamy macrophages, multiorgan perivascular lymphohistiocytic infiltrates, and focal hepatocellular apoptosis (Walker, 1997a). Fatality may be associated with secondary opportunistic fungal and viral infections (Hardalo, 1995).

Human granulocytotropic anaplasmosis varies from asymptomatic to severe, with many diagnosed patients requiring hospitalization (Bakken, 1994). Infection is fatal in less than 1% of cases. The illness begins with chills, fever, headache, and myalgia. Thrombocytopenia occurs in most cases and leukopenia in nearly half. Hepatocellular injury is manifested as

elevated hepatic enzymes, and severely ill patients may have septic shock-like illness with multiorgan involvement.

Laboratory Diagnosis

Isolation of ehrlichiae and anaplasmae from human blood in antibiotic-free cell culture has been accomplished more often for *A. phagocytophilum* (in HL-60 cells) than for *E. chaffeensis* (in DH-82 cells), and only once for *E. canis* (in an asymptomatic person), and has yet to be reported for *E. ewingii* (Dawson, 1991; Edelman, 1996; Goodman, 1996; Perez, 1996; Childs, 1999). Amplification of ehrlichial DNA by PCR using species-specific primers is an efficient diagnostic tool for all the human ehrlichioses (Anderson, 1992b; Chen, 1994; Everett, 1994; Buller, 1999; Comer, 1999). For human monocytotropic ehrlichiosis, the sensitivity of PCR is reported as 79%–100%, and for granulocytotropic anaplasmosis caused by *A. phagocytophilum*, 48%–86% (Anderson, 1992b; Everett, 1994). Lateness in the course, a lower level of ehrlichemia, and tetracycline treatment reduce the sensitivity of detection of ehrlichiae by PCR. Target genes that have been validated clinically include 16S rRNA (*rrs*), 120-kDa protein, *groES*, *dsb*, *nadA*, and *VLPT* for *E. chaffeensis*, *rrs* and *dsb* for *E. ewingii*, and *rrs*, *ank-1*, *msp2*, and *ftsZ* for *A. phagocytophilum* (Dumler, 2004; Doyle, 2005). Although it is in many cases a laborious task, identification of morulae in peripheral blood neutrophils provides a diagnosis of human anaplasmosis or ehrlichiosis and can be performed in any clinical laboratory. It is a more sensitive approach for *A. phagocytophilum* infection (30%–80%) than for *E. chaffeensis* (7%–17% in immunocompetent patients and a very high proportion of immunocompromised patients [Hamilton, 2004]). It is important to avoid false-positive interpretation caused by toxic granulations, Döhle bodies, superimposed platelets, apoptotic bodies, or contaminant particles. Immunohistochemical identification of *E. chaffeensis* can be performed in tissue specimens (Dumler, 1993a; Yu, 1993).

Serologic diagnosis is the usual approach to the diagnosis of human ehrlichiosis, using cell culture-propagated *E. chaffeensis* and *A. phagocytophilum* antigens in IFA assays (Nicholson, 1997; Childs, 1999; Walls, 1999; Olano, 2003b). This method is very sensitive for the demonstration of seroconversion to a titer of 1:64 or greater 2–4 weeks after disease onset. The expected serologic result on acute serum is absence of detected antibodies. Thus, treatment should be initiated empirically on the basis of clinical and epidemiologic factors and should not be withheld pending laboratory confirmation. Opinion as to a diagnostic single serum titer for *E. chaffeensis* ranges from 1:64–1:256. Cross-reactivity of *A. phagocytophilum* and *E. chaffeensis* is observed in approximately 20% of patients with human monocytotropic ehrlichiosis and human granulocytic anaplasmosis. Thus, particularly in geographic regions where these infections overlap and, indeed, if there is a possibility of travel-associated exposure, it is essential to determine antibody titers against both organisms. A fourfold difference in titer determines the infecting agent. Cases with twofold or less difference are classified as ehrlichiosis of indeterminate etiology.

Distinguishing *E. chaffeensis* from *E. ewingii* serologically is more problematic because the latter has yet to be cultivated. Western immunoblotting is a useful research tool at present for distinguishing infection with *E. chaffeensis* with its distinctive 120-kDa protein and 28-kDa protein family from infection with *A. phagocytophilum* with its major 42–49-kDa protein patterns (Asanovich, 1997; Chen, 1997a, 1997b; Zhi, 1997). Serologic assays using these and other recombinant proteins show promise for future development (Yu, 1999; Knowles, 2003).

Treatment

Doxycycline is the drug of choice for the treatment of these human ehrlichioses (Bakken, 1994; Fishbein, 1994). The use of chloramphenicol is not recommended as it has been associated with a fatal outcome. Cell culture studies show *E. chaffeensis* and *A. phagocytophilum* to be resistant to it and the commonly prescribed β -lactams, macrolides, aminoglycosides, and sulfonamide drugs (Brouqui, 1992; Klein, 1997; Branger, 2004). *A. phagocytophilum* is susceptible to rifampin and rifabutin in cell culture, and rifampin has been used to treat a limited number of pregnant women and children successfully (Krause, 2003).

INFECTIONS CAUSED BY *COXIELLA BURNETII*

Structure and Function

C. burnetii is distant phylogenetically from other pathogenic rickettsiae and is the only one classified in the γ -Proteobacteria. These gram-negative bacteria vary morphologically from rods to cocci, and by electron

microscopic examination, two distinct forms can be seen: large cells (0.5–1.2 μm) and small dense cells (0.5 μm), which have been proposed to represent a developmental cycle that includes a spore-like form.

Much emphasis has been placed on a laboratory phenomenon associated with cultivation of *C. burnetii* by prolonged passage in cell culture or eggs, namely, loss of the organisms' ability to synthesize the entire LPS. This change from synthesis of the full to a truncated LPS, analogous to the conversion from smooth to rough phenotype by Enterobacteriaceae, has been designated phase variation from phase I to phase II. Phase I is found in nature and in infected persons and animals; phase II occurs in the laboratory and is the result of deletions of genes without selective advantage under conditions of passage outside of its hosts (Hoover, 2002).

C. burnetii enters its target cell, the macrophage, by phagocytosis after interaction with $\alpha\text{v}\beta 3$ integrin and is highly adapted (e.g., synthesis of superoxide dismutase and acid phosphatase) to the acidic conditions in the phagolysosome, where replication by binary fission occurs.

Q Fever

The name Q fever was derived from its unknown etiology when the clinicoepidemiologic syndrome was first described as query fever. The ecology of *C. burnetii* includes silent infections in animals: many species of ticks, ungulates (particularly sheep, cattle, and goats), other mammals (including cats and wild rabbits), fish, birds, and marsupials (Marrie, 1988, 1997). Humans usually are infected by inhalation, especially of aerosols that originate in infected birth products of domestic livestock and pets, and possibly also by ingestion of unpasteurized contaminated milk (Fishbein, 1992; Raoult, 2005). Many human infections occur as an occupational disease among abattoir workers, farmers, and veterinarians (McQuiston, 2006). However, urban nonoccupational cases are by no means rare in some populations in which they have been evaluated, such as among immunocompromised patients in France (Brouqui, 1993).

A majority of human infections are asymptomatic (Marrie, 1990). Acute illness is often a self-limited, undifferentiated febrile illness, pneumonia, hepatitis, or meningoencephalitis (Drancourt, 1991; Tissot Dupont, 1992; Bernit, 2002). Individual patients with myalgias, anorexia, and headache are unlikely to be investigated diagnostically for Q fever, even though this syndrome is the most likely clinical presentation of this infection and accounts for a substantial proportion of patients with these symptoms in some populations. Manifestations of Q fever pneumonia vary: Cough may be nonproductive or absent, and the pneumonia may be severe and progress rapidly or may be detected as multiple rounded or segmental radiographic infiltrates without pulmonary symptoms. Q fever hepatitis may have a clinical presentation similar to acute viral hepatitis or the pathologic presentation of granulomatous hepatitis.

Chronic Q fever is considered synonymous with *C. burnetii* endocarditis but occurs less frequently as infection of an aneurysm or vascular prosthesis or osteomyelitis (Marrie, 1990; Brouqui, 1993). Chronic Q fever endocarditis usually involves previously damaged aortic or mitral valves as an afebrile illness that may manifest with heart failure, hepatosplenomegaly, changing cardiac murmurs, and weight loss. Disease associated with circulating immune complexes includes vasculitis-based purpuric rash or glomerulonephritis.

The pathology of acute Q fever includes mixed interstitial-alveolar-bronchiolar pneumonia with mononuclear inflammatory cells and granulomatous inflammation of the liver and bone marrow (Walker, 1988b). Q fever granulomas often contain a clear central vacuole and a surrounding ring of fibrin, as well as epithelioid macrophages. These doughnut granulomas are neither pathognomonic lesions nor the only form of granuloma that occurs in the liver and bone marrow of Q fever patients. Involved cardiac valves in Q fever endocarditis have a small vegetation and show mixed subacute and chronic inflammation with many foamy macrophages having the cytoplasm filled with *C. burnetii* (Lepidi, 2003).

Laboratory Diagnosis

The laboratory diagnosis of Q fever is most often accomplished by demonstration of antibodies to *C. burnetii* (Fournier, 1996, 1998). Serologic methods employ both phase I and phase II antigens and often evaluate class-specific antibody production. Enzyme immunoassay and indirect IFA tests are highly specific and are more sensitive than complement fixation. In acute Q fever, antibodies to phase II antigens appear earliest after infection, and antibodies to phase I may be detected as early as 2 weeks after the onset of illness. In general, acute Q fever is associated with high titers to phase II antigens and lower titers to phase I antigens. By IFA, an anti-phase II IgG titer of 1:200 or greater and an anti-phase II IgM titer of 1:50 or greater have a sensitivity of 58% and a specificity of 92% in acute

Q fever. In chronic Q fever, antibodies to phase I are present at a higher titer (e.g., IgG-IFA anti-phase I titer of 1:800 or greater), and antibodies to phase II are generally equal to or lower than the phase I titer. An IgA response to phase I antigens is often observed in patients with chronic Q fever. A titer of 1:128 or greater against phase I antigen by the complement fixation test is also considered diagnostic of chronic Q fever, although some patients have lower titers. Because of cross-reactivity of *B. henselae* and *Bartonella quintana* with *C. burnetii*, a serologic diagnosis of *Bartonella* endocarditis should not be made until anti-*C. burnetii* titers have been determined (La Scola, 1996b). In Q fever endocarditis, the anti-*C. burnetii* titer is substantially higher than the anti-*Bartonella* titer. An IFA containing both *C. burnetii* and *B. henselae* effectively distinguishes the infecting bacterium (Rolain, 2003b).

PCR assays have been developed against diverse target genes, and during the first 2 weeks of acute Q fever, real-time PCR of serum is more sensitive (24%) than IFA serology (14%) (Fournier, 2003). It is likely that PCR of blood or buffy coat would detect a greater proportion of cases with *Coxiella* than serum.

Other methods for the diagnosis of chronic Q fever endocarditis include immunohistologic staining (sensitivity 32%), electron microscopy, culture (sensitivity 64%), and PCR (sensitivity 75%) detection of *C. burnetii* in a cardiac valve (Lepidi 2003). *C. burnetii* can be recovered from the blood or infected cardiac valves by in vitro cultivation using a centrifugation-enhanced shell vial (human embryonic lung) cell culture system. This method can identify the presence of coxiellae within 7 days but should be attempted only within cell culture facilities approved for biohazard containment level 3.

Treatment

Doxycycline is effective in shortening the course of acute Q fever when administered during the first 3 days after the onset of illness (Levy, 1991). Ciprofloxacin or a combination of ciprofloxacin and rifampin is alternative medication for patients who cannot be treated with tetracycline. Treatment of chronic *C. burnetii* endocarditis requires prolonged administration of doxycycline and a quinolone, which often does not eradicate the infection (Marrie, 2002). Successful treatment is indicated by a slow fall in anti-phase I IgG titer to below 1:200, when discontinuation of treatment can be considered. Cardiac valve replacement is often performed for hemodynamic reasons.

INFECTIONS CAUSED BY ORGANISMS OF THE GENUS *BARTONELLA*

Structure and Function

The genus *Bartonella* has been removed from the order Rickettsiales (Brenner, 1993; Birtles, 1996). The human pathogens, *B. quintana* (the etiologic agent of trench fever, a major louse-borne disease in World Wars I and II and among homeless persons), *B. henselae* (the etiologic agent of cat scratch disease), *Bartonella elizabethae* and *Bartonella vinsonii* (associated with infective endocarditis), and *Bartonella bacilliformis* (a sandfly-transmitted bacterium that causes febrile acute hemolytic anemia and chronic verruga peruana cutaneous lesions in South America), have been cultivated in blood-enriched media in the presence of 5% carbon dioxide (CO_2) (Walker, 2006). These facultative intracellular gram-negative bacilli do not produce acid from carbohydrates and usually reside within erythrocytes in their natural mammalian hosts. Among numerous described species of *Bartonella*, *Bartonella clarridgeiae* is a suspected second agent of cat scratch disease (Kordick, 1997).

Cat Scratch Disease, Bacillary Angiomatosis, and Bacillary Peliosis

B. henselae is transmitted to humans by the scratch or bite of infected kittens, which are bacteremic for many months while appearing healthy (Tappero, 1993; Chomel, 1995; Bergmans, 1997; Heller, 1997). Bacteria are transmitted from cat to cat by the cat flea (Chomel, 1996; Higgins, 1996). The nature of the disease is largely host determined. Among immunocompetent hosts, 80% are younger than age 21 years and present with a cutaneous papule or pustule at the inoculation site and self-limited regional lymphadenopathy. Less than 2% of patients suffer complications such as hematogenously disseminated involvement of the liver, spleen, lung, bone, CNS, retina, conjunctiva, or skin (Liston, 1996; Wade, 2000; Verdon, 2002). The histopathology of cat scratch disease lesions consists of granulomas surrounding stellate microabscesses. Among severely

immunocompromised patients, *B. henselae* infection is manifested by fever and bacteremia, or by cutaneous or visceral angioproliferative lesions. The latter are characterized by lobular vascular proliferations of plump endothelial cells with clusters of small capillaries surrounding ectatic capillaries, separated by edematous, mucinous, or fibrotic stroma containing clusters of neutrophils, neutrophil debris, and granular microcolonies of bartonellae. In the skin, these lesions are designated bacillary angiomatosis; in the liver and spleen, hepatic and splenic peliosis. Dissemination to other sites may occur also. The angioproliferative lesions of *B. henselae* and *B. quintana* in immunocompromised patients are indistinguishable, and they are similar to the verruga peruana of *B. bacilliformis* (Koehler, 1997). *B. henselae*, *B. quintana*, *B. vinsonii* subsp. *berkhoffii* and subsp. *arupensis*, *B. alsatica*, *B. koehlerii*, and *B. elizabethae* have been documented as agents of infective endocarditis (Drancourt, 1995; Roux 2000; Avidor, 2004; Fenollar, 2005; Raoult, 2006; Jeanclaude, 2009).

Trench Fever and Bacillary Angiomatosis

B. quintana causes prolonged bacteremia in convalescent humans, the apparent reservoir. Infections were recognized to be transmitted from person to louse (*Pediculus humanus corporis*) to another person in front-line trenches during World War I (Bruce, 1921). Among French homeless persons, 14% are bacteremic, of whom 80% are afebrile (Brouqui, 1999).

Louse feces laden with *B. quintana* are scratched into the skin, and approximately 8 days later, an illness of variable severity begins. Manifestations include fever, generally lasting less than a week, headache, myalgias, pretibial pain, and an evanescent macular rash. Relapses often occur at 4- or 5-day intervals. Bacteremia persists for weeks, months, or longer, serving as a source of infecting lice, even when the person feels relatively healthy. Cases occur at present in alcoholic and homeless populations in American and European cities (Spach, 1995; Foucault, 2002).

Oroya Fever and Verruga Peruana

South American bartonellosis, manifested as an acute illness called Oroya fever, or as chronic cutaneous lesions called verruga peruana, is transmitted by the bite of a *Lutzomyia* sandfly. Asymptomatic long-term human carriers are the reservoirs of *B. bacilliformis*. After an incubation period of approximately 3 weeks, Oroya fever begins insidiously with anorexia, headache, malaise, and low-grade fever, or abruptly with chills, high fever, headache, and mental status changes. Bartonellae invade the red blood cells and cause erythrocytic changes that result in erythrophagocytosis and anemia. Verruga peruana, characterized by red to purple nontender nodules that appear in crops over 1-2 months and persist for months to years, follows Oroya fever or occurs without prior symptoms (Arias-Stella, 1986; Walker, 2006).

Laboratory Diagnosis

Lysis release of intraerythrocytic bacteria followed by centrifugation and incubation at 35° C in a humid CO₂ atmosphere on chocolate or Columbia blood agar for longer than a month has been used to recover *B. henselae* and *B. quintana* from patients (Tierno, 1995). These *Bartonella* organisms are gram-negative bacilli, 0.2-0.5 µm in diameter and 1-3 µm long. *B. henselae* are oxidase, catalase, and urease negative and do not utilize carbohydrates. Identification is accomplished by twitching motility in wet mounts, immunofluorescent staining, analysis of fatty acid composition, DNA sequencing, or hybridization (Scott, 1996). PCR detects *B. henselae* DNA in 31% of lymph node biopsies and in 55% of lymph node aspirates (Bergmans, 1996). *B. bacilliformis* may be cultivated from blood by inoculation of Columbia blood agar supplemented with 5% defibrinated blood or other blood- or hemin-supplemented media with detection of colonies after an average of 18 days.

Formerly, the diagnosis of cat scratch disease required a combination of clinical, epidemiologic, and pathologic criteria. Histopathologic studies, including Warthin-Starry stain and immunohistochemistry, have been used to support the diagnosis of bacillary angiomatosis and cat scratch disease. Oroya fever may be diagnosed by visualization of intraerythrocytic bartonellae, appearing as cocci or bacilli, occasionally with curved or ring forms, in peripheral blood carefully stained by the Giemsa method to avoid misinterpretation of artifacts. Diagnosis of *B. henselae* and *B. quintana* infections is usually accomplished by serologic demonstration of antibodies by indirect immunofluorescence or enzyme immunoassay (Dalton, 1995b). Serologic diagnosis of *Bartonella* endocarditis should include measurement of antibody titers against *C. burnetii*, which may stimulate cross-reacting antibody titers against *Bartonella* (Maurin, 1997; Rolain, 2003a). Titers against *C. burnetii* phase I are much higher than the anti-*Bartonella* titers

in chronic Q fever endocarditis, and Western immunoblotting after cross-absorption yields a definitive diagnosis if necessary (Houpikian, 2003). Real-time PCR can also be used to establish the diagnosis of *Bartonella* endocarditis (Zeaiter, 2003).

Treatment

Cat scratch disease usually is self-limited, but the lymphadenopathy resolves more rapidly after azithromycin (Bass, 1999). Drugs of choice for the treatment of bacillary angiomatosis include doxycycline, erythromycin, and azithromycin (Rolain, 2004). *Bartonella* endocarditis has a more favorable outcome when treated with an aminoglycoside (Raoult, 2003). Relapses may occur, requiring retreatment or even long-term maintenance therapy. Ciprofloxacin is currently preferred for treatment of Oroya fever. The difficulty of treating an intraerythrocytic bacterium such as *B. quintana* in humans is evident in the lack of bactericidal activity of doxycycline, fluoroquinolones, and β-lactams, and an inability to achieve bactericidal intraerythrocytic levels of gentamicin, the most active antimicrobial agent (Rolain, 2000). Chronic *B. quintana* bacteremia is cleared by gentamicin for 14 days, followed by doxycycline for 28 days (Foucault, 2003). Verruga peruana is treated with oral rifampin.

MYCOPLASMA INFECTIONS

Mycoplasmas were proved to cause human disease in 1962, when one mycoplasma (subsequently named *Mycoplasma pneumoniae*) was recognized as the etiologic agent of primary atypical pneumonia (Chanock, 1962). Mycoplasmas are the smallest free-living organisms. They are pleomorphic, ranging from spherical cells 0.2 µm in diameter to filaments 0.1 µm wide by 1-2 µm long. Most are facultative anaerobes that replicate by binary fission. Mycoplasmas are unique among bacteria because they have no cell wall. They are unable to synthesize cell wall precursors, and they require cholesterol and related sterols for membrane synthesis. Mycoplasmas also lack the enzymatic pathways for purine and pyrimidine synthesis and, for this reason, require complex media (such as beef heart infusion broth supplemented with horse serum, yeast extract, and nucleic acids) for growth in vitro. The potential pathogens, *M. pneumoniae* and the genital mycoplasmas (*Mycoplasma hominis*, *Mycoplasma genitalium*, *Ureaplasma urealyticum*, and *Ureaplasma parvum*), are discussed. Other mycoplasmas are part of the normal human flora, primarily of the respiratory and genitourinary tracts.

MYCOPLASMA PNEUMONIAE

Epidemiology

Mycoplasma pneumoniae is found worldwide. Epidemics occur among confined populations such as children in schools, families, and military recruits, typically at 3-5-year intervals, and predominantly in late summer and fall. In nonepidemic years, infections occur year-round and in general spread slowly, possibly owing to the slow generation time of the bacterium (6 hours) and its low transmission rate, which apparently requires close contact with an ill person (Waite, 2004). During epidemics, however, infection may spread rapidly, and the occurrence of point-source outbreaks in which close and prolonged exposure is not recognized suggests that *M. pneumoniae* may be transmitted via aerosols. Rates of infection with *M. pneumoniae* are greatest in school-aged children and young adults, and pneumonia occurs most frequently in persons aged 5-20 years, especially in those between the ages of 15 and 19 years. Infection with *M. pneumoniae* is common before the age of 5 years but typically is asymptomatic or produces a mild illness with coryza and wheezing but no fever or pneumonia (Fernald, 1975).

Pathogenesis and Pathology

M. pneumoniae, a surface parasite, colonizes the mucosa of the respiratory tract. Its ability to attach to respiratory mucosal cells, escape phagocytosis, and modulate the immune system is essential to initiation of disease. Its gliding motility may allow it to penetrate through respiratory secretions, and its filamentous, flexible form with terminal attachment organelle may facilitate localization in crypts and folds of the host cell membrane and between microvilli and cilia, where it is protected from phagocytosis. Attachment of *M. pneumoniae* to host cells is mediated by the P1 protein, which interacts with neuraminic acid-containing glycoproteins at the surface of the host cell membrane (Chandler, 1982; Geary, 1987; Waite, 2008). Hydrogen peroxide and superoxide produced by *M. pneumoniae* may injure mucosal cells, causing ciliostasis and sloughing of superficial cells

(Almagor, 1984). Inhibition of catalase (which breaks down damaging peroxides) in host cells by bacterium-generated superoxides makes the cells more susceptible to damage (Waites, 2008). An adenosine diphosphate (ADP)-ribosylating protein (named community-acquired respiratory distress syndrome toxin: CARDS TX) produced by *M. pneumoniae* has been identified and postulated to have an exotoxin function, as the protein has been demonstrated to induce vacuolization and ciliostasis in cultured host cells (Waites, 2008). The target and exact cellular effects of the toxin remain to be elucidated.

Host-related factors also are involved in the pathogenesis of *M. pneumoniae* disease. The apparent high prevalence of *M. pneumoniae* infection in infants and young children, the mild nature of the disease in this age group, and the occurrence of more severe illness during infection at a later age suggest that severe disease may result from the host immune response to reinfection. *M. pneumoniae* has been demonstrated to induce cytokine production in vitro, suggesting that adherence of the bacterium to respiratory epithelial cells results in cytokine production, which in turn might both recruit inflammatory cells, including lymphocytes, to the site of infection and modulate the activity of the recruited cells (Waites, 2008). This cytokine production and influx of lymphocytes might be involved in fighting the infection by destroying the infecting organism or, conversely, might result in immune hypersensitivity that damages host cells. A more marked T cell immune response may result in more severe disease (Waites, 2008). Moreover, extrapulmonary manifestations of disease (discussed later) are suspected to be immune mediated. The interaction of *M. pneumoniae* with the I antigenic determinant of human red blood cells, which contains the necessary 2,3-sialylated poly-*N*-acetylglactosamine sequences, may alter the I antigen, converting it into a non-self-antigen that stimulates production of cold agglutinins. Other autoimmune antibodies produced during infection with *M. pneumoniae* (antibodies to lung, brain, smooth muscle, and lymphocytes) may have similar derivations.

Few descriptions of the pathologic findings of disease caused by *M. pneumoniae* are available, because most infections are self-limited and tissue is rarely obtained. In fatal cases, patchy areas of consolidation are found in the lungs. Histologic examination of involved foci shows bronchitis, bronchiolitis, and interstitial and alveolar pneumonitis with peribronchiolar collections of lymphocytes and plasma cells, accompanied by macrophages and neutrophils if cellular necrosis is present.

Clinical Manifestations

The most common manifestation of disease caused by *M. pneumoniae* is tracheobronchitis, which occurs in about half of infected patients. After an incubation period of several weeks, sore throat, cough, coryza, fever, headache, myalgia, and sometimes conjunctivitis and myringitis are seen. The infection may resolve or may progress to pneumonia, the frequency of which is age dependent, with children aged 5–15 most likely to develop lower respiratory involvement (Baum, 2000; Waites, 2004). Chest radiographs show unilateral lower lobe bronchopneumonia, or occasionally bilateral feathery infiltrates. The peripheral white blood cell count is normal early and rises as the disease progresses. Maculopapular or, less commonly, vesicular skin eruptions occur in about 15% of cases a few days after disease onset. Without antimicrobial therapy, fever resolves in 2–14 days, but malaise, cough, and radiographic abnormalities persist for 2–6 weeks. In a small percentage of children and adults, pneumonia is severe enough to warrant hospitalization; these patients may develop lung abscess, pleural effusions, secondary bacterial infections, bronchiectasis, or clinical relapse.

Extrathoracic manifestations such as clinically apparent hemolytic anemia (typically with very high titers of cold agglutinins); erythema multiforme, erythema nodosum, and urticaria; myocarditis and pericarditis; and arthralgias, arthritis, acute glomerulonephritis, tubulointerstitial nephritis, and IgA nephropathy may occur, but are not frequent (Ponka, 1979; Cassell, 1981; Baum, 2000; Waites, 2004). *M. pneumoniae* has become recognized, however, as having a significant association with CNS disorders, from minor to severe, including encephalitis and acute disseminated encephalomyelitis, with 6%–7% of patients hospitalized with *M. pneumoniae* infection demonstrating neurologic manifestations (Waites, 2004). Among 1988 patients referred to the California Encephalitis Project over a 9-year period, *M. pneumoniae* was implicated in 111 patients (5.6%) and was the single most common implicated infectious agent (Christie, 2007). Many cases of encephalitis associated with *M. pneumoniae* appear to be relatively mild; however, severe cases of acute disseminated encephalomyelitis that may even result in fatality can occur in association with the infection (Waites, 2004; Christie, 2007; Stamm, 2008).

GENITAL MYCOPLASMAS

Epidemiology

Ureaplasma species (*U. urealyticum* has been separated into *U. parvum*, formerly *U. urealyticum* biovar 1, and *U. urealyticum*, formerly *U. urealyticum* biovar 2) can be found colonizing the vagina and cervix in 40%–80% of adult women, and *M. hominis* can be found in 21%–53% of women (Waites, 2005). The frequency in males appears to be lower. Prevalence studies for *M. genitalium* are infrequent in the literature, but it appears to be less common as a colonizer in asymptomatic individuals and is found with a frequency of around 1% (Takahashi, 2006; Manhart, 2007). Colonization of infants with genital mycoplasmas can occur during passage through the birth canal, but colonization appears to be temporary in many cases, and a lower rate of colonization has been noted in children (Klein, 1969; Hammerschlag, 1978). The increase in colonization by mycoplasmas after puberty indicates an association with sexual activity. In addition to passage through the birth canal, neonates can acquire infections due to *Ureaplasma* spp. and *M. hominis* hematogenously through the placenta or through an ascending infection, resulting in seeding of amniotic fluid (Waites, 2005).

Clinical Manifestations

Although simple vaginal colonization with the genital mycoplasmas in pregnant women is not associated with disease, the presence of mycoplasma (primarily *Ureaplasma* spp. and to a lesser extent *M. hominis*) in the placental membranes or amniotic fluid is consistently associated with chorioamnionitis, preterm birth, and adverse perinatal outcomes associated with several neonatal disorders, including perinatal pneumonia and sepsis in preterm infants (Waites, 2005; Goldenberg, 2008). Both *Ureaplasma* spp. and *M. hominis* are associated with postpartum fever. *Ureaplasma* spp. can cause urinary calculi and are a cause of nongonococcal urethritis (NGU) (Waites, 2005). *M. hominis* has been related to both pelvic inflammatory disease (PID) and pyelonephritis and may have an association with bacterial vaginosis (Waites, 2005). *M. genitalium* has been linked to NGU in males only relatively recently, but it is now firmly established as a significant cause of the disorder and is the etiologic agent in approximately 25% of cases (Ross, 2006; Gaydos, 2009). Among women, *M. genitalium* has shown an association with cervicitis, endometritis, PID, and tubal infertility (Haggerty, 2006; Short, 2009).

LABORATORY DIAGNOSIS

Mycoplasma pneumoniae

Specimens recommended for diagnosis of infection caused by *M. pneumoniae* are throat swabs and serum, but bronchoalveolar lavage fluid, sputum, and lung tissue are acceptable. A nonspecific serologic test that may provide useful information is detection of cold agglutinins, which are IgM antibodies against the I antigen of human erythrocytes. The cold agglutinin response usually corresponds with the severity of pulmonary disease, as a titer of $\geq 1:32$ is found with severe pneumonia, whereas agglutinins are not detectable in mild disease (Waites, 2008). Cold agglutinins appear by the end of the first week or early in the second week of illness in at least half of infected persons, but their presence is not diagnostic of infection with *M. pneumoniae*, as they may also be seen with other bacterial, rickettsial, or viral infections.

Definitive diagnosis is based on detection of the organism, specific antibodies, or specific nucleic acid sequences. To isolate *M. pneumoniae*, special agar media, broth media, or a biphasic culture system is inoculated and incubated in a sealed container for 3 weeks or more in 5%–10% CO₂, or anaerobically at 37° C. Cultures are examined microscopically (40×) once or twice each week for typical spherical colonies with a dense center and thin outer layer (resembling a “fried egg”) embedded in the agar. Such colonies, consistent with *M. pneumoniae*, that demonstrate glycolysis (as demonstrated color change in the media pH indicator), β -hemolysis, and hemadsorption of guinea pig erythrocytes on further testing are presumptively *M. pneumoniae*. Definitive speciation usually requires staining with monoclonal antibodies using immunofluorescence or immunoperoxidase, immunoblotting, or PCR.

Because isolation of *M. pneumoniae* may require several weeks, rendering a culture clinically noncontributory, more rapid tests are most useful for diagnosis. Detection of specific IgM in a single serum sample is diagnostic of acute infection. If IgG is measured, acute and convalescent phase samples must be tested, and the diagnosis is based on a fourfold or greater rise in titer. A variety of tests based on particle agglutination, EIA, or

immunofluorescence are available; EIA, particularly with membrane-bound assays, is the most popular (Waites, 2004). Serologic testing is not without problems as antibody titers vary with age, with children and younger individuals having consistently higher titers than adults (Daxboeck, 2002). Nucleic acid amplification tests can also provide rapid diagnosis (Loens, 2003), but currently no commercial Food and Drug Administration–cleared amplification test for direct detection of *M. pneumoniae* is available. Although time is required for patients to develop a serologic response, hence the sensitivity of serology early in infection may be low, as time from onset of symptoms increases, the sensitivity of PCR decreases (Thurman, 2009). Many experts consider the combined use of PCR on respiratory specimens and serology the optimum approach to obtain maximum sensitivity in diagnosing infection (Christie, 2007; Waites, 2008; Thurman, 2009).

Genital Mycoplasmas

Ureaplasma spp. and *M. hominis* may be recovered from urethral, vaginal, or endocervical swab specimens, blood, urine, abscess material, prostatic secretions, semen, or tissues. Various culture systems may be used to isolate the genital mycoplasmas (Clyde, 1984; Yajko, 1984; Wood, 1985; Phillips, 1986). Traditionally, separate systems were used for each (U agar and U broth for *Ureaplasma* spp. and H agar and H broth for *M. hominis*) because the optimal pH for growth of the two organisms differs (pH 5.5–6.5 for *Ureaplasma* spp. and pH 6–8 for *M. hominis*). However, single culture systems are now available that effectively detect all of these species (Yajko, 1984; Wood, 1985; Phillips, 1986). Broth cultures are incubated aerobically in sealed test tubes. Agar cultures are incubated anaerobically or in an atmosphere of 5%–7% CO₂ and observed daily under the microscope. *M. hominis* also grows on sheep blood agar, producing nonhemolytic pinpoint colonies, and in most broth blood culture media, although no evidence of growth is visible.

Colonies of *M. hominis*, 200–300 µm in diameter with a typical fried-egg appearance, usually appear within 5 days. In broth containing phenol red and 0.1% arginine, *M. hominis* metabolizes arginine to ammonia, causing a color change from yellow to red. U agar plates are observed daily for 4 days, and on day 4 are stained with one to two drops of CaCl₂–urea

solution. Colonies of *Ureaplasma* spp. have an irregular rather than circular umbonate morphology, are 15–60 µm in diameter, and stain dark brown in 5 minutes. In U broth, *Ureaplasma* spp. produce a shift in pH, and the color changes from yellow to red. A loopful of broth then is transferred to agar plates and is streaked for isolation.

M. genitalium grows very slowly, similar to *M. pneumoniae*, with which it shares many morphologic and antigenic similarities, and is difficult to isolate in culture. For clinical purposes, nucleic acid amplification is the only practical test; although a commercial product does not exist at this time, many facilities have developed their own assays to detect the organism (Ross, 2006). No commercial serologic assays are available for *M. genitalium* or any of the genital mycoplasmas, and the use of serology for these organisms is confined to research.

TREATMENT

A tetracycline, macrolide, or fluoroquinolone is effective treatment for *M. pneumoniae*, and the macrolides, usually a newer drug such as azithromycin or clarithromycin, are the agents of choice because of dosing considerations. Macrolide resistance has been reported in *M. pneumoniae* isolates in Japan, and patients infected with these isolates suffered a prolonged course of infection relative to those infected with susceptible isolates (Waites, 2008). Generally, *Ureaplasma* spp. are sensitive to tetracyclines, quinolones, and macrolides, with tetracycline resistance seen in approximately 10% of isolates (Waites, 2005). Resistance to the fluoroquinolones appears to be unusual, and *Ureaplasma* spp. are resistant to clindamycin. *M. hominis* is susceptible to clindamycin and the newer quinolones but is resistant to the macrolides. Some isolates also are susceptible to tetracyclines, although resistance to the tetracyclines is thought to be greater than in *Ureaplasma* spp., at approximately 40% (Waites, 2005). *M. genitalium* can be problematic, in that treatment with macrolides (azithromycin), tetracyclines (doxycycline), or quinolones (ofloxacin, levofloxacin) can result in a significant number of failures; however, cases in which these less expensive agents fail appear to be effectively treated with moxifloxacin. Such a cascade treatment strategy is recommended by a number of studies (Ross, 2006; Bradshaw, 2008; Jernberg, 2008).

KEY POINTS

- Bacteria can be categorized based on the Gram stain reaction (gram-positive or gram-negative), shape (cocci, bacilli, coccobacilli, spirochete), preferred atmosphere (aerobic, microaerophilic, anaerobic), and presence or absence of spores; they can be identified on the basis of key biochemical tests, antigenic components (e.g., cell wall antigens, toxins), and/or molecular features.
- Among the gram-positive cocci, the most important human pathogens (and the infections they commonly cause) are *Staphylococcus aureus* (skin and soft tissue infections, bacteremia, toxic shock syndrome), *Streptococcus pyogenes* (pharyngitis and its nonsuppurative complications, skin and soft tissue infections), *Streptococcus agalactiae* (neonatal bacteremia and meningitis), *Streptococcus pneumoniae* (community-acquired pneumonia, meningitis), and *Enterococcus faecalis* and *Enterococcus faecium* (nosocomial urinary tract infections and bacteremia).
- Among gram-positive bacilli, the most important human pathogens (and the infections they commonly cause) are *Listeria monocytogenes* (meningitis, bacteremia), *Nocardia* species (pneumonia, soft tissue infections, brain abscess), *Bacillus anthracis* (skin and soft tissue infections, pneumonia; a bioterrorism agent), and *Corynebacterium diphtheriae* (diphtheria), which is rarely encountered in the clinical laboratory in the United States.
- Among gram-negative cocci, the most important human pathogens (and the infections they commonly cause) are *Neisseria meningitidis* (meningitis), *Neisseria gonorrhoeae* (gonorrhea), and *Moraxella catarrhalis*.

- Gram-negative bacilli include Enterobacteriaceae, many of which are normal flora in the gastrointestinal tract; nonfermentative gram-negative bacilli (e.g., *Pseudomonas aeruginosa* and *Acinetobacter baumannii*), which are found in the environment and cause human infection when host defenses are compromised; halophilic organisms (*Vibrio* species); microaerophilic bacteria (*Campylobacter*, *Helicobacter*); fastidious organisms (*Legionella* species, *Bordetella* species, *Francisella tularensis*, *Brucella* species, *Haemophilus* species); and miscellaneous infrequently encountered bacteria.
- Among the Enterobacteriaceae, the most important human pathogens (and the infections they commonly cause) are *Escherichia coli* (urinary tract infection, diarrhea, bacteremia), *Klebsiella pneumoniae* and *Klebsiella oxytoca* (urinary tract infection, pneumonia, bacteremia), *Proteus* species (urinary tract infection), *Salmonella* species (diarrhea, typhoid fever), *Shigella* species (diarrhea), *Enterobacter* species (nosocomial pneumonia, urinary tract infection, bacteremia), and *Serratia* species (nosocomial pneumonia).
- Among the anaerobes, the most important human pathogens (and the infections they commonly cause) are the *Bacteroides fragilis* group (intraabdominal infections, abscesses); *Clostridium* species, especially *Clostridium perfringens* (soft tissue infections, food poisoning), *Clostridium tetani* (tetanus), and *Clostridium difficile* (antibiotic-associated diarrhea); and non-spore-forming gram-positive anaerobes such as *Actinomyces israelii* and *Propionibacterium acnes*.

A wide variety of bacterial species may be recovered from clinical specimens. To appropriately assess the clinical significance of these organisms, an understanding of the normal bacterial flora present at different anatomic locations is essential. In some cases, the number of organisms present can be extremely high, for example, 10^6 organisms/cm² of skin, 10^9 organisms/mL of oral secretions, and 10^{11} organisms/g of colon contents. It is important to obtain samples with minimal contamination from the normal flora (Miller, 2007). This may be difficult but can be optimally achieved if proper procedures are followed. These procedures, along with processing techniques that serve to enhance recovery of pathogenic microorganisms, are discussed in Chapter 63. This chapter begins with a short discussion of laboratory procedures used to process a specimen for bacterial culture, which is followed by a more in-depth discussion of the bacterial species commonly considered to be human pathogens.

SPECIMEN PROCESSING

GRAM STAIN

Few would disagree that direct examination of a specimen with Gram stain is one of the most valuable procedures performed by the microbiology laboratory. The Gram stain result rapidly provides information that is used by the clinician for selecting appropriate antimicrobial therapy; it also helps the laboratory technologist assess the quality of the specimen and the extent to which certain organisms recovered in culture will be worked up. Organisms present in abundant quantity in specimens containing many white blood cells are given more attention than those that are present in smaller numbers in the absence of white blood cells. Multiple specimens positive for similar organisms in smears and cultures contribute to increased clinical significance of the results.

To prepare a smear for staining, an aliquot of the most purulent or bloody portion of the specimen is placed on a clean microscopic slide in a manner that provides both thick and thin areas. For sterile body fluids, a cytocentrifuge may be used to concentrate the specimen by 10–100 times (Peterson, 1988). The material on the slide is allowed to air-dry, is fixed with methanol or gentle heat, and then is stained with Gram stain reagents (crystal violet, Gram iodine, alcohol, and safranin). Organisms that have a gram-positive cell wall will resist decolorization with methanol and will retain the purple color of the crystal violet; organisms that have a gram-negative cell wall will be decolorized and will stain red with safranin counterstain.

Stained smears are initially examined using a low-power objective to look for large structures, such as nematode larvae, Curschmann's spirals, large granules, grains, bacterial microcolonies, or fungal forms. An oil immersion lens is then used to assess the type of bacteria present. Because 10^5 organisms/mL must be present to see one organism per oil immersion field (1000×), smears must be examined carefully to detect small numbers of organisms.

The organisms observed should be evaluated for size, shape, and Gram reaction, which should be reported with as much description as possible; reporting the presence of gram-positive cocci in pairs that resemble *S. pneumoniae* (Fig. 57-1) is more helpful than simply reporting

Figure 57-1 Gram stain of a sputum smear shows neutrophils, debris, and gram-positive diplococci, suggestive of pneumococcal infection (oil immersion).

gram-positive cocci in chains. White or red blood cells should be quantified and reported, along with any intracellular bacteria observed. Correlation of Gram stain observations with culture results is a good way to check on the quality of the stains and culture. Demonstration of many bacteria on Gram stain that do not grow out in culture may indicate unusual organisms that require more specialized media or the inability of laboratory personnel to recognize certain colonial types in culture, or could suggest a false-positive Gram stain result caused by contamination of reagents or collection materials, such as swabs, or incorrect interpretation of Gram stain results. Gram stain results could indicate the need to inoculate additional media for a specific specimen. For example, finding many Gram-negative coccobacilli in a respiratory specimen could indicate the need for a chocolate plate to recover *Haemophilus* spp., which would not be recovered on a blood agar plate. Other stains, such as the acridine orange stain, can be utilized for staining blood culture bottles, cerebrospinal fluid (CSF), or buffy coat preparations. This fluorescent stain provides a rapid and, at times, more sensitive stain for bacteria and fungi (Mirrett, 1982). Bacteria and fungi will produce an orange fluorescence, and mammalian cells will stain green. Some experience is required for accurate interpretation of the acridine orange stain, and correct preparation of the smears is necessary to avoid excessive cellular material, which can result in too much cellular DNA that can mask the presence of any bacterial DNA.

Many laboratories use probes for identification of specific bacteria or fungi in blood culture bottles. These are available using a fluorescent *in situ* hybridization (FISH) format (Advandx, Woburn, MA). When gram-positive cocci are seen in clusters on Gram stain of a blood culture bottle, probes can be used to differentiate *S. aureus* from coagulase-negative staphylococci, or nonstaphylococcal organisms. If gram-positive cocci are seen in pairs and chains, a probe is available that could specifically identify *E. faecalis*. The newest of these bacterial probes can be used to identify specific gram-negative bacilli when these are seen on Gram stain of the positive blood culture bottle. Yeast probes using the same format are available to differentiate among *Candida* spp.

CULTURE TECHNIQUES

Media for culture are selected to provide the optimal conditions for growth of pathogens commonly encountered at a particular site or in a particular type of specimen. Consideration is given to special growth requirements of bacteria associated with a given type of infection, or to the necessity of selecting certain pathogenic bacteria from a mixed population of indigenous flora. Therefore, the media chosen may include selective and differential media, in addition to standard enrichment agar.

Blood-supplemented agar is a good general growth medium and can be used to demonstrate the hemolytic action of colonies on the red blood cells. Antibiotics or chemicals can be added to create a selective medium such as colistin–nalidixic acid (CNA) agar or phenylethyl alcohol agar, both of which are used to inhibit the growth of gram-negative bacilli while permitting gram-positive bacteria to grow. Heating the blood to make chocolate agar and adding vitamin supplements creates an enriched medium with available hemin (X factor) and nicotinamide adenine dinucleotide (V factor) for the isolation of *Haemophilus* spp. and other fastidious bacteria. Gram-negative bacilli may be separated from gram-positive bacilli by using bile salts and dye in a medium such as MacConkey's agar, which additionally divides the colonies into lactose-positive and lactose-negative colonies, thus making it both selective and differential. Guidelines for the selection of media to be used with different types of specimens are provided in Table 57-1.

Bacterial cultures are generally incubated at 35° C and are examined initially after 18–24 hours of incubation. Addition of 5%–10% carbon dioxide (CO₂) may be essential or stimulatory to the growth of *N. gonorrhoeae*, *Haemophilus influenzae*, and *S. pneumoniae*, and should be used whenever feasible. Exceptions to this recommendation are those cultures on differential and selective media in which the pH alteration (which can be affected by added CO₂) is used to differentiate colony types (e.g., xylose-lysine-deoxycholate [XLD] agar, Hektoen enteric [HE] agar).

For recovery of anaerobes, inoculated media should be placed into an anaerobic environment as quickly as possible. Several types of anaerobic culture systems are available. One of these is the anaerobic jar, in which water is added to a CO₂ and hydrogen (H₂) generator package, and oxygen (O₂) is catalytically converted to water with palladium-coated alumina pellets contained in a lid chamber. A modification of this system is a

††If *Propionibacterium acnes* is suspected in cases of endophthalmitis, a thioglycollate broth and/or anaerobic BAP may be used.

transparent plastic bag containing its own gas generator and palladium catalyst, and designed to hold an agar plate; these are often referred to as anaerobic Bio-Bags.

Another approach to anaerobic culture is the anaerobic glove box or chamber, which consists of a large, clear plastic, air-tight chamber filled with an oxygen-free gas mixture of nitrogen, hydrogen, and carbon dioxide. Specimens, plates, and tubes are introduced into or removed from the chamber through a gas interchange lock. Anaerobiosis is maintained by palladium catalysts and the hydrogen gas in the chamber. All manipulations within the chamber are done with neoprene gloves sealed to the chamber wall or, for "gloveless" systems, through a hole with sleeves that seal tightly around the forearms. The chambers contain internal incubators that maintain the incubation temperature. Each of the anaerobe systems has its advantages and disadvantages, but all are equally effective in isolating clinically significant anaerobic bacteria from specimens. A system for

processing anaerobic specimens under a constant anaerobic environment to reduce the chance of excess exposure to oxygen is available in the Anoxamat system (Summanen, 1999).

Bacterial cultures should be examined routinely after 18–24 hours of incubation. The exception to this is the anaerobe culture, which is generally examined at 48 hours to allow these slower growing bacteria to produce visible colonies. In general, solid media are held for 48 hours, with liquid media held for an additional 24–48 hours. If this is different for specific organisms, it will be mentioned in the text.

A preliminary report is issued when the culture is first examined; this report is updated as additional information becomes available. Certain results (e.g., positive blood or CSF Gram stain, isolation of an organism requiring infection control measures) are reported to the healthcare provider as soon as the information becomes available. Final reports are issued when all work on a culture has been completed.

MEDICALLY IMPORTANT BACTERIA

GRAM-POSITIVE COCCI

Staphylococcus

Characteristics

Staphylococci are catalase-positive spherical cocci that often appear in grape-like clusters in stained smears (Fig. 57-2). They grow well on any peptone-containing nutrient medium under aerobic and anaerobic conditions, and may produce hemolysis of various species of animal blood cells and yellow or orange pigment on certain types of agar. Growth of staphylococci is readily detected on blood agar plates or in various types of nutrient broth. A selective medium for the isolation of *S. aureus* is one containing 7.5%–10% sodium chloride (NaCl) with mannitol.

Tests useful for distinguishing staphylococci from *Micrococcus* and *Kocuria* spp. (generally considered nonpathogenic) are listed in Table 57-2 (Bannerman, 2007). *S. aureus* is differentiated from other species of staphylococci principally by its production of coagulases, which are capable of clotting plasma. Two antigenically distinct forms of coagulase have been recognized: one bound to the cell wall is called clumping factor and is detected with the slide coagulase test, and the other is free from the cell wall and is detected with the tube coagulase test (often considered the definitive test for the presence of coagulase enzyme). Commercial latex agglutination products are available that detect clumping factor and protein A in *S. aureus* with good sensitivity and specificity. These assays may be appropriate in situations in which reproducibility of the test is in

Figure 57-2 Cytocentrifuge preparation of cerebrospinal fluid stained with Gram stain shows many neutrophils, smooth amorphous material, and gram-positive cocci in pairs, short chains, and clusters, suggestive of staphylococcal infection (oil immersion).

question because of the inexperience of technologists performing the assay. A FISH product (*S. aureus* peptide nucleic acid FISH) is also available for the differentiation of *S. aureus* from coagulase-negative staphylococci in a blood culture bottle found positive for gram-positive cocci in clusters. In addition, many laboratories are now utilizing polymerase chain reaction (PCR) assays for detection of *S. aureus* in nasal swabs and directly from positive blood culture bottles. Many of these assays enable detection of methicillin-resistant *S. aureus* (MRSA) versus methicillin-susceptible *S. aureus*.

Clinical Manifestations and Pathogenesis

S. aureus may be present among the indigenous flora of the skin, eye, upper respiratory tract, gastrointestinal tract, urethra, and, infrequently, vagina. Therefore, infection may arise from an endogenous or an exogenous source. Factors of importance in the development of infection due to *S. aureus* include breaks in the continuity and integrity of mucosal and cutaneous surfaces, the presence of foreign bodies or implants, prior viral diseases, antecedent antimicrobial therapy, and underlying diseases with defects in cellular or humoral immunity.

Infections caused by *S. aureus* may affect multiple organ systems. Among the most common are those involving the skin and its appendages, such as impetigo, folliculitis, mastitis, and infection of surgical wounds. *S. aureus* is among the leading causes of bacteremia in hospitalized patients, and it may cause endocarditis, particularly in persons with left-sided valvular heart disease and in intravenous drug users. *S. aureus* is the most common cause of spinal epidural abscess and suppurative intracranial phlebitis, and may be recovered from brain abscesses, typically following trauma. Meningitis caused by *S. aureus* is uncommon and generally follows head trauma or a neurosurgical procedure.

S. aureus is responsible for many cases of osteomyelitis, is the most common cause of septic arthritis in prepubertal children, and is occasionally responsible for septic arthritis in adults. *S. aureus* is an infrequent cause of community-acquired pneumonia but a common cause of nosocomial pneumonia, which usually follows aspiration of endogenous nasopharyngeal organisms. Predisposing factors include infection with measles or influenza A virus, cystic fibrosis, and immune deficiency. Urinary tract infections caused by *S. aureus* are rare, but cases of pyelonephritis and intrarenal and perirenal abscesses can be found.

Several factors play a role in the virulence of *S. aureus*. The capsule, if present, has antiphagocytic properties. Cell wall peptidoglycans have endotoxin-like activity, stimulating the release of cytokines by macrophages, activation of complement, and aggregation of platelets. Protein A, an immunologically active substance in the cell wall, has antiphagocytic properties that are based on its ability to bind the Fc fragment of immunoglobulin (Ig)G. Other surface proteins, designated as microbial surface components recognizing adhesive matrix molecules, may play an important role in the ability of staphylococci to colonize host tissues (Speziale, 2009).

S. aureus produces numerous toxins. The exotoxin TSST-1 is responsible for toxic shock syndrome, and enterotoxins A–E are responsible for staphylococcal food poisoning. The exfoliative toxins—epidermolytic toxins A and B—cause skin erythema and separation, as seen in scalded skin syndrome. Various enzymes are also produced, including protease, lipase, and hyaluronidase, all of which destroy tissue and probably function to facilitate the spread of the infection.

Toxin-mediated diseases caused by *S. aureus* include scalded skin syndrome, food poisoning, and toxic shock syndrome. Scalded skin syndrome occurs in infants infected with a strain of *S. aureus* producing exfoliative toxin. The illness begins abruptly with erythema, followed in 2–3 days by the formation of flaccid bullae, which slough, leaving denuded areas that eventually resolve completely. Staphylococcal food poisoning, characterized by nausea, vomiting, abdominal cramps, and diarrhea, occurs 1–6 hours after ingestion of foods contaminated with pre-formed staphylococcal enterotoxin.

Toxic shock syndrome is a multisystem disease affecting individuals who have no antibodies to TSST-1 and are colonized or infected with strains of *S. aureus* producing TSST-1 or rarely enterotoxin B or C. The illness is most common in women 15–25 years of age who use tampons during menstruation, but it also may occur in nonmenstruating individuals, including women in the postpartum period, persons with a surgical wound or other focal infection, and individuals who have had a surgical procedure in the nose or sinuses. Toxic shock syndrome begins abruptly with fever, myalgias, vomiting, and diarrhea, followed by hypotension, hypovolemic shock, and an erythematous rash that frequently involves the palms and soles and desquamates in 1–2 weeks. The diagnosis is clinical; isolation of

S. aureus from any site is not required. Full recovery is the rule, although repeated episodes may occur (Bannerman, 2007).

Over the past 8–10 years, cases of community-acquired infection with *S. aureus* that are oxacillin resistant (CA-MRSA) have become more common. In these isolates, a toxin referred to as Panton-Valentine leukocidin toxin (PVL), which has rarely been associated with hospital-acquired strains of *S. aureus* (Vandenesch, 2003; Klein, 2009; Lindsay, 2009), has been found. PVL has been shown to be responsible for necrotizing skin and soft tissue infections and has been infrequently demonstrated to cause a necrotizing and occasionally fatal pneumonia (Francis, 2005; Moskowitz, 2009). Individuals at risk are predominantly children involved in contact sports and those living in institutions such as prisons (MMWR, 2003; Pan, 2003). These CA-MRSA strains, unlike hospital-acquired strains of MRSA (HA-MRSA), are often susceptible to non- β -lactam classes of antibiotics. HA-MRSA strains are usually resistant to all antibiotics except the glycopeptides, such as vancomycin. The mechanism of oxacillin resistance is the same in CA-MRSA and HA-MRSA—the presence of an *mecA* gene that is responsible for production of a new penicillin-binding protein (PBP-2a or PBP-2'). However, the chromosomal cassette that houses the CA-MRSA *mecA* gene is different from and much smaller than that containing the *mecA* gene of HA-MRSA. Many experts believe that in time, blending of CA-MRSA and HA-MRSA strains will occur, and without molecular typing of any isolate, it will be difficult to distinguish them.

Infections caused by coagulase-negative species (CNS) of *Staphylococcus* usually occur in association with foreign bodies, especially implanted prosthetic valves, joints, and shunts. More than 20 species of CNS are known, of which *S. epidermidis* is the species most frequently involved in such infections. *S. saprophyticus* is an important cause of bacteriuria, particularly among sexually active young women. *S. hemolyticus*, although a relatively rare isolate in clinical specimens, can be resistant to vancomycin, an agent to which most CNS are susceptible. *S. lugdunensis* is a species of CNS that can appear morphologically similar to *S. aureus* (i.e., in production of a narrow zone of β -hemolysis on blood agar plates) and on occasion will be coagulase positive in some assays for coagulase. However, it is usually classified as a coagulase-negative staphylococcus. Clinically, it will act more aggressively than most other CNS and in this way mimics *S. aureus* infection, including its role as an agent of endocarditis, osteomyelitis, and other more severe staphylococcal infections. It is important to distinguish *S. lugdunensis* from other CNS because the breakpoints one uses (according to the Clinical Laboratory and Standards Institute [CLSI]) for the interpretation of susceptibility results versus oxacillin (or cefoxitin) should be those that are used to interpret *S. aureus* and not those used to interpret breakpoints for oxacillin (or cefoxitin) vs. CNS. (CLSI, 2010).

Laboratory Diagnosis

The observation microscopically of typical rounded, gram-positive cocci in clusters in smears of material taken from previously unopened or undrained lesions, or in smears of broth from a positive blood culture, is indicative of staphylococcal infection.

S. aureus produces coagulase, an enzyme that binds plasma fibrinogen, causing the organisms to agglutinate or plasma to clot; only rare strains of other staphylococci are coagulase positive. More than 95% of isolates of *S. aureus* are identified by the slide coagulase test, which detects cell-bound enzyme (clumping factor); nearly 100% of all isolates are identified by tube coagulase tests, which detect free coagulase (Bannerman, 2007).

The slide coagulase test is performed by mixing a dense emulsion of the organism with plasma on a glass slide. The test is positive if clumping occurs within 30 seconds. *Staphylococcus lugdunensis* and *Staphylococcus schleiferi* are two other staphylococci that may give a positive result with this slide coagulase test. A control that consists of emulsifying the suspect colony in saline should be run with each slide test to ensure that autoagglutination does not occur. If autoagglutination is present, slide test results should be considered insufficient for determination of the coagulase nature of the isolate.

For the tube coagulase test, several colonies are transferred into a tube containing plasma that is incubated at 35°C for 4 hours and then is examined for clot formation. If no clot has formed, the tube is reincubated at room temperature and reexamined after a total of 24 hours of incubation. The test should be examined after 4 hours because most isolates of *S. aureus* produce a clot within this interval, but some strains produce a fibrinolysin that can lyse the clot, thus producing a false-negative reaction if the test is observed only after 24 hours. *Staphylococcus intermedius* and *Staphylococcus hyicus* will also be positive with the tube coagulase test, but they are primarily pathogens of animals and are encountered only rarely in human specimens.

Several commercial latex agglutination assays are available for rapid identification of *S. aureus*. These assays detect protein A and clumping factor; some also detect capsular polysaccharide, which may improve the ability to detect methicillin (oxacillin)-resistant *S. aureus*. *S. saprophyticus* and *Staphylococcus sciuri* are two other staphylococcus species that may be latex agglutination positive, along with the rare *Micrococcus* spp.; however, these should all be slide coagulase negative (Bannerman, 2007).

Many species of coagulase-negative staphylococcus have been recognized; however, with the exception of *S. saprophyticus*, which is resistant to novobiocin, identification of these isolates to the species level is not practical or clinically indicated in every culture. Speciation may be needed if isolates are found repeatedly in sterile sites, if *S. lugdunensis* is being ruled out, and/or if correlation between isolates in a patient is being sought to increase the likelihood that the two isolates are the same and therefore are potentially clinically relevant. If necessary, attempts to identify these isolates to the species level may be made using commercially available identification kits, which have been found to have an accuracy of between 70% and more than 90% (Bannerman, 2007). Alternatively, isolates may be sent to a reference laboratory capable of performing standard biochemical assays or molecular assays such as 16S ribosomal RNA (rRNA) analysis (Lee, 2001). Staphylococci may be classified into strains for epidemiologic purposes in attempting to identify common sources of infection on the basis of their susceptibility to different bacteriophages, plasmid profiles, cellular fatty acids, electrophoresis of multilocus enzymes, or chromosomal molecular typing (pulsed field gel electrophoresis and repetitive PCR). These tests are generally available only through reference laboratories.

Antimicrobial Susceptibility

More than 90% of staphylococci are resistant to penicillin. Because resistance is due to an inducible plasmid-encoded β -lactamase, sensitivity to penicillin should be confirmed after a period of induction (CLSI, 2009) with a β -lactam agent.

Resistance to the penicillinase-resistant penicillins (methicillin, oxacillin, nafcillin) occurs in up to 80% of coagulase-negative staphylococci, and in more than 50% of isolates of hospital-acquired *S. aureus*. Resistance to this group of antimicrobial agents is mediated by the *mecA* gene, which encodes an altered penicillin-binding protein, PBP-2a. Resistance typically is heterogeneous, meaning that only rare cells (1 in 10^4 – 10^8) express the resistance trait. Because of this, specific guidelines must be followed to ensure detection: A 1- μ g oxacillin disk has been used traditionally for disk diffusion testing. More recently, the CLSI has suggested that if disk diffusion is used as the method of detection of MRSA, a 30- μ g cefoxitin disk test is a better indicator than oxacillin. To predict the presence of *mecA*-mediated resistance in *S. aureus* (and *S. lugdunensis*), the CLSI recommends that isolates with zone sizes ≥ 22 mm can be reported as susceptible (S), and those with zone sizes ≤ 21 mm can be reported as oxacillin resistant (R) (Velasco, 2005). For coagulase-negative staphylococci (except *S. lugdunensis*), ≥ 25 mm = S and ≤ 24 mm = R (CLSI, 2009). Oxacillin in cation-supplemented Mueller-Hinton broth containing 2% NaCl should be used for microdilution testing, and agar plates and microtiter trays should be incubated a full 24 hours at 35°C. To screen isolates of *S. aureus* for oxacillin resistance, Mueller-Hinton agar supplemented with 4% NaCl and containing 6 μ g/mL of oxacillin is spot inoculated with a cotton swab, and plates are incubated for 24 hours at 35°C. CLSI recommends that cefoxitin be considered as the antibiotic used to detect oxacillin resistance, even when broth microdilution is performed, but in all cases, reports should contain results for oxacillin, not for cefoxitin. To screen isolates of *S. aureus* for oxacillin resistance, Mueller-Hinton agar supplemented with 4% NaCl and containing 6 μ g/mL of oxacillin is spot inoculated with a cotton swab, and plates are incubated for 24 hours. Any growth on this screening medium suggests an MRSA, and further testing should be done for confirmation.

Several assays have been developed for rapid detection of oxacillin resistance. These include nucleic acid amplification, nucleic acid probe assays for *mecA*, and latex agglutination assays for PBP-2a (the MRSA Screen Test, Denka-Seiken Co., Tokyo, Japan) and PBP-2' (Oxoid Ltd., Basingstoke, UK) (Chediac-Tannoury, 2003; Chapin, 2004). For detection of MRSA on nasal swabs, two approaches can be used. Newer chromogenic media specific for the detection of MRSA require overnight incubation but allow easy detection of specific colored colonies that are (Perry, 2004). Gene-Ohm (Becton Dickinson Microbiology Systems, Sparks, Md.) has a PCR-based assay, run on the Smart Cycler instrument (Cepheid, Sacramento, Calif.), that can detect MRSA directly in clinical specimens within 90 minutes (Warren, 2004). Both Gene-Ohm and Cepheid have assays for the molecular detection of *S. aureus* and MRSA in clinical

specimens and from positive blood cultures. Other molecular assays are being developed as well. Although oxacillin-resistant staphylococci may appear to be susceptible to cephalosporins, they should be considered resistant to all β -lactam agents (penicillins and cephalosporins), including carbapenems. Hospital-acquired strains usually are resistant to many non- β -lactam antibiotics as well. The newly recognized CA-MRSA strains still remain susceptible to most non- β -lactam antibiotics (Daum, 2002).

Clindamycin may be used to treat staphylococcal infection. Inducible resistance, due to mechanisms involving a class of enzyme-inactivating genes referred to as *erm* genes, may not be detected in routine susceptibility testing. This *erm* gene also confers cross-resistance to the macrolides (e.g., erythromycin) and streptogramins (quinupristin-dalfopristin). An isolate of *S. aureus* that is resistant to erythromycin but susceptible to clindamycin in a minimum inhibitory concentration (MIC) test (broth or agar dilution or E-test) should be evaluated for inducible resistance to clindamycin by the “D-zone” test, as follows. A 15- μ g erythromycin disk and a 2- μ g clindamycin disk are placed 15mm apart on the surface of a blood agar plate inoculated with the isolate in question. After overnight incubation, if there is inducible resistance to clindamycin, blunting of the clindamycin zone of inhibition will be seen on the side near the erythromycin disk, giving the appearance of a D zone (CLSI, 2009).

Vancomycin resistance, although rarely seen in *S. aureus*, is a serious issue that laboratories need to be aware of and should screen for. Isolates of vancomycin intermediately susceptible *S. aureus* (VISA) have MICs in the intermediate range (8–16 μ g/mL) (Cosgrove, 2004). A number of cases of vancomycin-resistant *S. aureus* with vancomycin MICs as high as 1024 μ g/mL have been reported (Centers for Disease Control and Prevention [CDC], 2004b). Because the latter have not been uniformly detected in automated systems for susceptibility testing, the CDC recommends that all *S. aureus* isolates tested on an automated instrument should also be tested by a vancomycin screen assay, to ensure that the correct MIC is determined. This is usually done by inoculating 100 μ L of a 0.5 McFarland suspension of *S. aureus* to a blood agar plate containing 6 μ g/mL of vancomycin, and incubating overnight. Most automated susceptibility testing systems have been adjusted to detect vancomycin-resistant *S. aureus* (VRSA), if present; however, detection of VISA is still variable among systems—both automated and manual. Newer breakpoints have been implemented in which an MIC of 4 to vancomycin should be considered representative of a possible VISA, and further testing with microbroth dilution should be performed for confirmation. Screen-positive isolates that have elevated vancomycin MIC values (≥ 8 organisms μ g/mL) should be sent to a reference laboratory for confirmation, and confirmed cases should be referred to your state health department and the CDC. The entity of hVISA (strains of *S. aureus* that are variable within the population or colony for vancomycin nonsusceptibility) is difficult for a routine clinical microbiology laboratory to detect. If a strain with an MIC of 2 μ g/mL to vancomycin is being clinically considered nonresponsive to vancomycin, a macro E-test can be performed, employing a McFarland of 2.0 instead of the usual 0.5, and inner colonies can be looked for. Exposure of suspected isolates to increasing concentrations of vancomycin in agar plates, however, is the recommended approach for detection of hVISA, although these methods are often beyond what a routine laboratory can do (Bae, 2009).

Newer antimicrobial agents have good activity against susceptible and resistant staphylococci. These include quinupristin/dalfopristin, a streptogramin, the lipopeptide daptomycin, linezolid, and most recently telavancin. For isolates of VISA, or VRSA, or when clinicians request agents other than vancomycin for MRSA strains, laboratories should consider testing these agents or sending the isolates to reference laboratories that can test for their susceptibility.

Streptococcus and Enterococcus

Characteristics

Streptococci are catalase-negative, gram-positive, spherical, ovoid, or lancet-shaped cocci, often seen in pairs or chains. They are facultatively anaerobic. Some strains require added CO₂ for their initial isolation but may lose this requirement in subcultures. Streptococci can be broadly classified according to the hemolytic reaction on blood agar (Table 57-3). Those strains that completely hemolyze the red cells around their colonies are called β -hemolytic and can be further categorized into the Lancefield groups based on serologically reactive carbohydrates. Important members of this group include *Streptococcus pyogenes* (group A) and *Streptococcus agalactiae* (group B). Figure 57-3 is a Gram stain of *S. pyogenes* (group A streptococcus) in a specimen from abscess material on the arm of a patient

TABLE 57-3

Classification of Streptococci and Enterococci

Hemolysis	Lancefield group	Species
β	A	<i>Streptococcus pyogenes</i>
	B	<i>Streptococcus agalactiae</i>
	C	<i>Streptococcus dysgalactiae</i>
	D	<i>Enterococcus</i> spp.
α or γ	D	<i>Enterococcus</i> spp.
	D	<i>Streptococcus bovis</i> complex (reclassified into at least four new species as described in text)
	None	Viridans group*
α	None	<i>Streptococcus pneumoniae</i>

*Small colony variants of Lancefield group A, C, F, or G, or nongroupable strains, can be any hemolysis.

Figure 57-3 Gram stain of *Streptococcus pyogenes* (group A streptococcus) from a case of cellulitis.

with cellulitis. Those gram-positive cocci in chains that produce partial hemolysis (cause “greening” of the agar) are α -hemolytic. An important member of this group is *S. pneumoniae*. Streptococci that do not hemolyze blood are γ -hemolytic. An important member of this group is *Streptococcus bovis* complex. Some *S. agalactiae* may also be γ -hemolytic. Most of the remainder of the α - and γ -hemolytic streptococci are collectively called **viridans** streptococci, including *Streptococcus mutans*, *Streptococcus sanguis*, *Streptococcus mitis*, *Streptococcus salivarius*, and *Streptococcus anginosus*. The group of organisms previously referred to as nutritionally variant (pyridoxal or thiol dependent, satelliting) streptococci have now been assigned to the genus *Abiotrophia* or *Granulicatella*.

Members of the genus *Enterococcus*, previously designated as group D streptococci because their cell wall antigens reacted with group D antisera, are sufficiently different from the other members of the genus *Streptococcus* to be considered a separate genus. These organisms are gram-positive cocci that occur singly, in pairs, and in short chains. They are facultatively anaerobic. Most enterococci are α - or γ -hemolytic on blood agar, but some may exhibit β -hemolysis. The most common species are *Enterococcus faecium* and *Enterococcus faecalis*; yellow motile strains of the enterococci, usually nonpathogenic, include *Enterococcus cassiflavus* and *Enterococcus gallinarum*. These latter two species are usually intrinsically vancomycin resistant, and it is important to differentiate them from vancomycin-resistant *E. faecium* or *E. faecalis*.

Other genera of catalase-negative gram-positive cocci that may be isolated from clinical specimens include *Leuconostoc*, *Pediococcus*, *Stomatococcus* (Rothia), *Gemella*, *Aerococcus*, and *Lactococcus* spp. These organisms are considered to have low virulence potential and generally are pathogenic only in the compromised host. However, some of these isolates may be confused with viridans streptococci, in particular, and their differentiation is important because of their lower virulence and their potential for vancomycin resistance. Further differentiation should be considered if a vancomycin-resistant viridans streptococcus is thought to be clinically relevant.

Clinical Manifestations and Pathogenesis

One of the most common clinical manifestations of group A streptococci is pharyngitis. This may be accompanied by scarlet fever, a punctate exanthem overlying diffuse erythema that usually first appears on the neck or upper chest, becomes generalized, and then desquamates. Skin infections caused by group A streptococcus include cellulitis, erysipelas, and pyoderma. Acute rheumatic fever, characterized by carditis, polyarthritis, erythema marginatum, chorea, and subcutaneous nodules, may occur 1–5 weeks after group A streptococcal pharyngitis. Acute glomerulonephritis may develop 10 days–3 weeks after group A streptococcal pharyngitis or pyoderma.

Beginning in the late 1980s, serious group A streptococcal clinical syndromes, including necrotizing fasciitis, myositis, malignant scarlet fever, bacteremia, and toxic shock–like syndrome, began to be seen with increasing frequency. These have been associated with high morbidity rates and mortality rates of up to 30% or more. The reason for this increase is not completely understood but appears to be related to changes in the prevalence of organisms having an enhanced **virulence potential** (Kaplan, 2005; Vucicevic, 2008; Lappin, 2009).

S. pyogenes produces numerous virulence factors. One of the most important is the antiphagocytic cell wall M protein. Antibodies against the specific M protein confer lifelong type-specific immunity; however, because more than 60 M protein types exist, infection with a group A streptococcus possessing a different M protein may occur. Another important cell wall component is lipoteichoic acid, which permits bacterial adherence to the respiratory epithelium. *S. pyogenes* also elaborates about 20 extracellular products, including enzymes (streptolysins, hyaluronidase, streptokinase, deoxyribonucleases [DNases], and nicotinamide adenine dinucleotidase [NADase]) and erythrogenic toxins. Streptolysin O, an antigenic, oxygen-labile enzyme, produces subsurface hemolysis on blood agar plates; streptolysin S, a nonantigenic, oxygen-stable enzyme, produces surface hemolysis. Neither streptolysin has a proven role in the pathogenesis of human disease. Streptokinase promotes fibrinolytic activity by converting plasminogen to plasmin, and hyaluronidase may enhance the spread of the organism through connective tissue. The pathogenic significance of the DNases and of NADase is unknown. Pyrogenic (erythrogenic) toxins (serotypes A, B, C) are produced by isolates of *S. pyogenes* infected with a specific temperate bacteriophage. Their pyrogenicity is caused by a direct action on the hypothalamus. Streptococcus group A has also been found to possess superantigens with high mitogenic capabilities; these have been associated with cases of more severe streptococcal infection, such as necrotizing fasciitis or toxic shock syndrome (Kotb, 2002).

The pathogenesis of acute rheumatic fever is not fully understood. Certain M protein types of *S. pyogenes* may be rheumatogenic. The presence of complexes of immunoglobulin and the C3 component of complement along the sarcolemmal sheaths of cardiac myofibers from individuals with rheumatic carditis suggests that myocarditis results from the production of antibodies directed against a streptococcal cell wall M protein that cross-reacts with myocardial tissue. Moreover, a heart or tissue cross-reactive antigen of *S. pyogenes* that shares immunologic epitopes with, but is distinct from, the M protein has been identified (Barnett, 1990). Renal damage in acute glomerulonephritis is caused by deposits of circulating streptococcal–antistreptococcal immune complexes in the glomeruli and subsequent activation of complement. Cell-mediated reactions to an altered glomerular basement membrane or activation of the alternate complement pathway also may be involved. Isolates of *S. pyogenes* have been linked to toxic shock syndrome, with a clinical picture very similar to *S. aureus*; streptococcal pyrogenic exotoxins are thought to be responsible for the toxic shock–like syndrome caused by strains of *S. pyogenes* (Schlievert, 1993; Stevens, 1995).

The most common infections caused by group B streptococci are neonatal sepsis, pneumonia, and meningitis. Colonization of the maternal genital tract is associated with colonization of infants and risk of neonatal disease, with early-onset infections occurring within the first few days after delivery and late-onset infections appearing after 1 week of age. To reduce the incidence of neonatal disease, the CDC published specific guidelines to facilitate early identification and treatment of women colonized with group B streptococcus and identification and treatment of neonates at risk for developing disease (Schuchat, 1996; Centers for Disease Control, 2004a; CDC, 2009, 2010; VanDyke, 2009). All pregnant women at 35–37 weeks of gestation should have vaginal/rectal specimens collected and processed for detection of group B streptococcus. Results of this test should be available during labor, so appropriate prophylaxis can be given to the mother before delivery, to prevent infection to the newborn. Isolation of group B streptococci from the urine of a pregnant female can also

be used as a marker of group B streptococcal vaginal carriage, and this information should be used to direct prophylaxis to mothers found to be positive. If urine is positive, screening of vaginal/rectal cultures may not be necessary. Group B streptococcal infections in adults include postpartum endometritis, urinary tract infection, bacteremia, skin and soft tissue infections, pneumonia, endocarditis, meningitis, arthritis, and osteomyelitis.

Group C and G streptococci are similar to *S. pyogenes* in that they cause a wide range of infections, including bacteremia, endocarditis, meningitis, arthritis, and respiratory and skin infections. The pharyngeal infection caused by these streptococci is similar to that of group A streptococci, except that the nonsuppurative sequelae of rheumatic fever do not occur.

Infections caused by *S. pneumoniae* include pneumonia, meningitis (especially in infants and the elderly), spontaneous bacteremia (in persons who do not have a spleen), otitis, sinusitis, and spontaneous peritonitis. *S. pneumoniae* is seen in normal flora of the upper respiratory tract of 25%–50% of preschool children, 36% of primary school-aged children, and nearly 20% of adults, termed carriers (Lopez, 1999). Its spread is enhanced by upper respiratory tract infections and crowding. Pneumonia may develop when the host immune defenses are impaired. Most cases are endogenous, following aspiration of oral secretions containing normal flora that includes *S. pneumoniae*. Person-to-person transmission during epidemics occurs by droplet aerosols. The major virulence factor of *S. pneumoniae* is its antiphagocytic polysaccharide capsule, and strains with a thick, mucoid capsule are especially virulent. Vaccines designed to protect against infection by pneumococci of many of the predominant capsular polysaccharide types are available. A new vaccine is available for use in infants and children to prevent invasive pneumococcal disease.

Bacterial endocarditis is the most common infection caused by viridans streptococci; others include abscesses in the brain or liver, bacteremia, and dental caries. The milleri streptococci complex (*S. constellatus*, *S. intermedius*, and *S. anginosus*) consists of the most common viridans streptococci responsible for liver, spleen, and brain abscesses; they often are more susceptible to antibiotics than other strains of viridans streptococci, although resistance to penicillin is increasingly being recognized. *S. bovis* bacteremia has been associated with malignancies of the gastrointestinal tract. *S. bovis* is now recognized as a complex of strains and/or species. Differentiation remains difficult within the species. Presently, the two subtypes of *S. bovis* have been renamed. *S. gallolyticus* and *S. pasteurianus* are isolated from blood cultures of patients with colonic cancer more often than is *S. infantarius* or *S. lutetiensis*. In many laboratories, isolates are still reported as *S. bovis* because phenotypic identification may not be adequate for differentiation; as molecular methods of identification increase, more of these differences may be appreciated (Facklam, 2002).

Enterococci are not highly pathogenic; however, they are a common cause of urinary tract infection in hospitalized persons. They may also cause endocarditis, bacteremia, and wound infection. Vancomycin-resistant enterococci offer a greater potential for infection, especially in immunocompromised patients and patients with implanted foreign devices (Han, 2009; McBride, 2009).

More and more clinically relevant cases of *Aerococcus urinae* (and other species of aerococci) are being reported. Urinary tract infections are most common, but rare cases of more serious infection, including bacteremia, are seen (Zhang, 2000). *A. viridans* remains relatively uncommon as a pathogen, when isolated from clinical samples; *A. sanguinicola* isolation is not always associated with clinical disease, but case numbers are increasing (Ibler, 2008).

Laboratory Diagnosis

Streptococci grow well on blood or chocolate agar. Blood agar is preferred because the hemolytic properties of the organism can be assessed. When culturing vaginal/rectal swabs from pregnant women specifically for group B streptococci, specimens should first be inoculated to a selective broth, such as Lim or carrot broth, or on to selective agar, for example, Granada agar, to enrich for this organism (Spellerberg, 2007; Church, 2008; Carvalho, 2009). Tests that may be used in the clinical microbiology laboratory to presumptively name the β -hemolytic species of *Streptococcus* are shown in Figure 57-4. More than 99% of isolates of group A streptococcus are susceptible to bacitracin, but a very small percentage of isolates of group B streptococcus and 10%–20% of isolates of groups C and G streptococcus are also susceptible. Therefore results of the bacitracin susceptibility test provide a presumptive identification. An isolate may be called group A streptococcus presumptively, based on hydrolysis of the L-pyrrolidonyl- β -naphthylamide (PYRase) test (Spellerberg, 2007). All

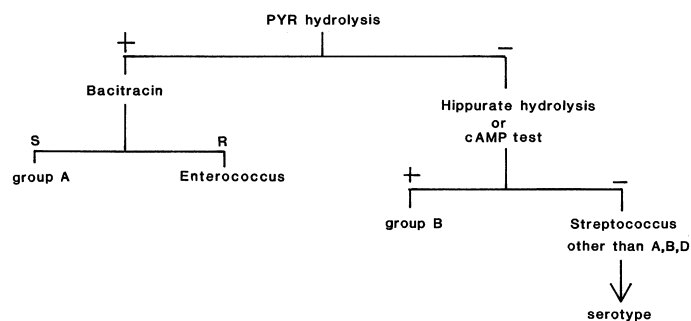

Figure 57-4 Decision tree of tests to presumptively name the β -hemolytic species of *Streptococcus*. (With permission from Woods GL, Gutierrez Y. *Diagnostic pathology of infectious diseases*. Philadelphia: Lea & Febiger; 1993.) +, Positive result; -, negative result; R, resistant; S, susceptible.

isolates of group A streptococcus and more than 99% of isolates of *Enterococcus* are PYRase-positive. Identification of group A streptococcus is confirmed by serotyping, using latex agglutination, or using a nucleic acid probe. A nucleic acid probe (Gen-Probe, San Diego) is also available for direct detection of group A streptococcus on throat swabs (Chapin, 2002).

Group A streptococcus may be detected directly in throat swab specimens by using commercial kits designed to generate a rapid result. These tests are highly specific but, given their low sensitivity, which varies among studies from 31%–95% (Wegner, 1992; Carroll, 1996), a negative direct test should be followed by culture or probe. Serologic tests to detect antibodies in acute and convalescent serum samples to streptolysin O and DNase B are used primarily to diagnose acute rheumatic fever and acute glomerulonephritis following infection with group A streptococcus.

Cultures found positive for colonies that are β -hemolytic and hippurate hydrolysis positive and/or that have a positive CAMP test (named for researchers Christie, Atkins, and Munch-Petersen) reaction presumptively can be called group B streptococcus. Isolates of presumed group B streptococcus from sterile body sites should be identified by serotyping (using latex agglutination or coagglutination tests) or by using a chemiluminescent DNA probe. The DNA probe can also be used to identify group B streptococci growing in Lim broth or other selective broth cultures (Daly, 1991; Bourbeau, 1997). This probe, however, is not sensitive enough to use directly on clinical specimens for the detection of group B streptococcus. For culture of vaginal/rectal swab specimens from pregnant women during weeks 35 through 37 of gestation, it is recommended that a broth enrichment be used along with or as a replacement for agar-based media. Selective broth media including Lim broth, selective Todd Hewitt broth, or a commercially available Trans Vag broth supplemented with 5% sheep blood (Remel, Lenexa, Kan.) can be used as enrichment media (Heelan, 2005). Chromogenic broth, including carrot broth media, can be used as enrichment broth; colonies of β -hemolytic group B streptococcus will convert the color of the tube from clear to yellow or orange. However, nonhemolytic group B streptococcus will not change the tube color, and when used, a negative broth would still need to be planted onto solid media for recovery of these strains.

In addition, a selective nonchromogenic enrichment broth can be subcultured to Granada agar, on which colonies of group B streptococcus will appear yellow to orange for ease in detection. Isolates of β -hemolytic groups C, D, F, and G *Streptococcus* are identified by serotyping with latex agglutination reagents. The Smart Cycler assay mentioned earlier can be used to detect group B streptococcus directly in vaginal-rectal specimens, or can be used to detect group B streptococcus in culture, such as Lim or carrot broth (Picard, 2004; Block, 2008), with commercial PCR kits from GeneOHM or Cepheid. The Cepheid GeneXpert GBS assay can be performed directly on clinical vaginal/rectal samples and has the potential to provide results intrapartum. There are other nucleic acid amplification assays for the detection of group B streptococcus in vaginal/rectal samples that are rapidly becoming FDA cleared for use in clinical laboratories.

Latex agglutination assays are available for direct detection of group B streptococcus (as well as *S. pneumoniae*, some serotypes of *N. meningitidis*, *E. coli*, and *H. influenzae* type b) in CSF, serum, and urine. These assays have been shown to have sensitivities equivalent to or lower than a Gram stain and may give false-positive results; hence, they do not in general provide additional useful information above that provided by the CSF Gram stain, and hence do not add clinical utility. The rapid bacterial antigen tests are much more expensive and labor intensive than Gram

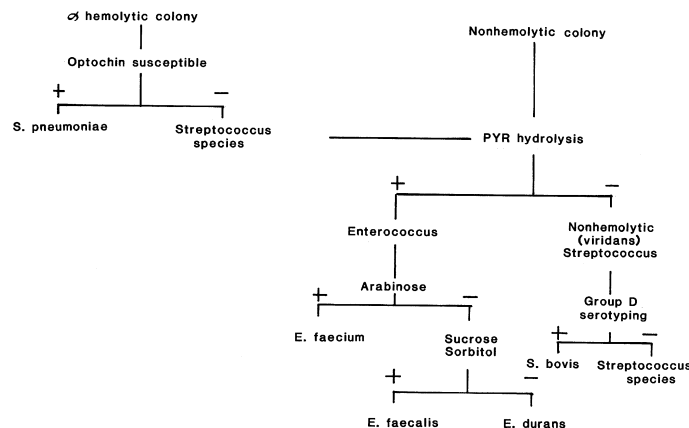

Figure 57-5 Decision tree of tests to presumptively name the α -hemolytic species of *Streptococcus* and *Enterococcus*. (With permission from Woods GL, Gutierrez Y. *Diagnostic pathology of infectious diseases*. Philadelphia: Lea & Febiger; 1993.) +, Positive result; -, negative result; R, resistant; S, susceptible.

stain; most laboratories no longer offer these tests or strictly limit their use (Maxson, 1994; Thomas, 1994; Perkins, 1995).

Tests used to presumptively identify α - and γ -hemolytic streptococci and enterococci are shown in Figure 57-5. α -Hemolytic colonies that are mucoid or flattened with a depressed center are suggestive of *S. pneumoniae*; they should be tested for susceptibility to ethylhydrocupreine hydrochloride, more commonly called optochin (P disk), and are positive for bile solubility. *S. pneumoniae* is susceptible to both; other α -hemolytic streptococci are resistant to optochin and are variable in response to bile. A urinary antigen assay for detection of *S. pneumoniae* has been shown in some studies to be the nonculture diagnostic method of choice for patients with severe pneumococcal infection, for diagnosis of pneumococcal exacerbation in chronic obstructive pulmonary disease patients, and as a tool for diagnosis of otitis media. As with any antigen assay, caution needs to be taken in interpreting results in cases where prior infection with *S. pneumoniae* may have occurred and the antigen may merely be reflecting this (Gisselsson-Solen, 2007; Andreo, 2009; Smith, 2009).

α -Hemolytic colonies that are not *S. pneumoniae* and γ -hemolytic colonies are tested for PYRase hydrolysis; enterococci are PYRase positive, and viridans streptococci are negative. Moreover, all enterococci grow in the presence of 6.5% NaCl; viridans streptococci do not. Enterococci hydrolyze esculin in the presence of bile (causing visible growth and blackening of the agar), but up to 10% of viridans streptococci are also bile-esculin positive. Additional biochemical assays are required to identify enterococci to the species level (Facklam, 2002). Most clinical isolates are *E. faecalis*. A majority of vancomycin-resistant enterococci (VRE) are *E. faecium*.

α -Hemolytic streptococci that are optochin resistant and PYRase negative and γ -hemolytic streptococci that are PYRase negative and do not grow in 6.5% NaCl are grouped as nonhemolytic (viridans) streptococci. Identification of individual species of viridans streptococci requires conventional biochemical testing. Kit systems to identify these organisms are commercially available. Full identification of species members of viridans streptococci is usually not necessary. Members of viridans streptococci belonging to the milleri streptococci, because they are usually recognized by their characteristic "caramel" odor, can be reported, if present, to alert clinicians about this group of viridans because of their propensity for abscess formation and their uniform susceptibility to penicillin. Figure 57-6 is an example of a Gram stain of a member of the milleri group of viridans streptococci from a brain abscess.

There are no vancomycin-resistant streptococci; however, occasionally a "viridans"-like isolate is reported as vancomycin resistant. Usually this is an enterococcus, but it could also be a member of some more uncommon genera such as *Leuconostoc* or *Pediococcus*. If vancomycin resistance has been demonstrated, it would be important to differentiate the intrinsically vancomycin-resistant *Leuconostoc* and *Pediococcus* from enterococci that have acquired vancomycin resistance. Characteristics that might be used to accomplish this are listed in Table 57-4 (Facklam, 1989b). Included in this table is differentiation from *Aerococcus* sp. as well, because of their morphologic similarity to *Enterococcus* sp. The clue that an isolate (especially from a urine culture) might be an *Aerococcus* sp. is the finding on Gram stain that a catalase-negative colony consists of gram-positive cocci in

TABLE 57-4

tetrads and clusters, not in pairs and chains. Some species of *Aerococcus* are l-pyrrolidonyl- β -naphthylamide (PYR) positive, which leads to further confusion with *Enterococcus* sp.

Members of the genus *Abiotrophia* will not grow in the absence of pyridoxal. Often they are first recognized as satellite colonies growing around a colony of *S. aureus*. Differential characteristics of *Abiotrophia defectiva* and *Abiotrophia adiacens* are reviewed elsewhere (Ruoff, 2007). Methods of performing susceptibility tests for strains of *Abiotrophia* and *Granulicatella* can be found in CLSI document M45-A (CLSI, 2006).

Antimicrobial Susceptibility

The antibiograms of groups A, B, C, and G streptococcus are predictable (all are susceptible to penicillin); therefore, routine antimicrobial susceptibility testing of these organisms is unnecessary unless penicillin cannot be used, as in the case of a penicillin allergy. In the latter situations, testing for resistance to macrolides, clindamycin, and the tetracyclines may be warranted. Inducible resistance to clindamycin may occur with *Streptococcus* (i.e., group B streptococcus), and a D zone test as described earlier for *S. aureus* may be warranted if the streptococcal isolate is found resistant to erythromycin. Specific guidelines for streptococcal D testing have not yet been published. Because *S. pneumoniae* organisms with intermediate- or high-level resistance to penicillin (MIC 0.12–1.0 $\mu\text{g/mL}$ or $\geq 2 \mu\text{g/mL}$, respectively) are found worldwide, isolates should be screened for susceptibility to penicillin using disk diffusion with a 1- μg oxacillin disk. Isolates that are not susceptible by this method must be further evaluated by microdilution or microdilution testing, using Mueller-Hinton broth supplemented with lysed horse blood or the E test to determine the penicillin MIC. Resistance to third-generation cephalosporins also occurs; therefore, isolates should be tested for susceptibility to these antimicrobial agents as well.

Susceptibility testing should be performed on isolates of nonhemolytic (viridans) streptococci from sterile body sites, because resistance to penicillin does occur. *Enterococcus* spp. should also be tested, primarily to identify high-level resistance to penicillin or ampicillin, high-level resistance to

streptomycin and gentamicin, and resistance to vancomycin. Enterococci are resistant to vancomycin (MIC $>32 \mu\text{g/mL}$) because of the presence of resistance genes, referred to as the *van* genes (CLSI, 2009). Although many of these genes have been described, the most common are *vanA*, *vanB*, and *vanC*. The *vanA* and *vanB* genes, conferring high-level resistance and predominantly found in *E. faecium* and much less frequently in *E. faecalis*, are acquired, plasmid-borne genes that can create infection control problems involving transmission of this resistance. This vancomycin resistance can be differentiated from intrinsic and lower level resistance (*vanC* genes) in the yellow, motile species of *Enterococcus*, and this should be done in laboratories and reported as such to the infection control team (Teixeira, 2007).

Gemella and Aerococcus

Other nonstreptococcal gram-positive, catalase-negative cocci of increasing importance are those that belong to the genera *Gemella* and *Aerococcus*. *Gemella* spp. (*Gemella haemolysans* and *Gemella morbillorum*) resemble viridans streptococci, although they usually produce smaller colonies. *G. haemolysans* has been associated with endocarditis and meningitis. Gram stain usually demonstrates diplococci with adjacent sides flattened that can be confused with a *Neisseria* sp. because cells can easily become decolorized. *G. haemolysans* is aerobic and *G. morbillorum* anaerobic. The latter usually appears as cocci in pairs or short chains. Both are PYR positive, 6% NaCl and esculin–hydrolysis negative (to differentiate them from enterococci). *G. morbillorum* is leucine-aminopeptidase (LAP) positive as well. Both are usually susceptible to penicillin. As with other gram-positive cocci, if there is doubt about the morphology of the organism (i.e., whether it is a short rod or a coccus), Gram stain performed from a broth culture will usually resolve the difficulty.

Two major species of *Aerococcus* may be clinically relevant and/or isolated from clinical specimens: *Aerococcus urinae* and *Aerococcus viridans*. Both resemble viridans streptococci or enterococci on agar plates; however, in Gram stains, they usually appear in tetrads. *A. urinae* is a recognized pathogen in urinary tract infection; in addition, it has been isolated from the blood in cases of endocarditis. *A. urinae* is PYR negative and LAP positive, in contrast to *A. viridans*, which is PYR positive and LAP negative (see Table 57-4). Both will grow in the presence of 6.5% NaCl. Neither are anaerobes, and *A. viridans* usually will not grow under anaerobic conditions. *A. urinae* is usually susceptible to penicillin and nitrofurantoin but may be resistant to sulfonamides. Variability in its response to trimethoprim has been noted (Zhang, 2000; Ruoff, 2007). A newer member of the genus *Aerococcus*, *A. sanguinicola*, which still is rarely recovered from clinical specimens, can be both LAP and PYR positive, although this is not a confirmatory identification. The significance of this isolate is still unknown in most cases (Ibler, 2008).

GRAM-POSITIVE RODS

Corynebacterium and Arcanobacterium

Characteristics

The corynebacteria, or **diphtheroids**, as they are sometimes called, appear in the Gram-stained smear as slightly curved, gram-positive rods with nonparallel sides and sometimes wider ends, giving a clubbed appearance (Fig. 57-7). These organisms are catalase positive. More than 46 species of *Corynebacterium* are known. Most are rarely pathogenic in humans; notable exceptions are *Corynebacterium diphtheriae* and its closely related

Figure 57-7 Sputum stained with Gram stain shows many neutrophils, amorphous debris, and coryneform gram-positive bacilli (oil immersion).

species or varieties *Corynebacterium ulcerans* and *Corynebacterium pseudotuberculosis*. *C. pseudodiphtheriticum* has been implicated in respiratory tract infections, including pneumonia (Chiner, 1999; Camello, 2009). Medically relevant *Arcanobacterium* spp. include *Arcanobacterium haemolyticum*, *Arcanobacterium pyogenes*, and *Arcanobacterium bernardiae*. *Arcanobacterium* species also appear as irregular gram-positive rods on Gram stain but can be easily differentiated from the corynebacteria by their negative catalase reaction.

Clinical Manifestations and Pathogenesis

At the initial site of infection on the epithelial cells of the tonsils and oropharynx, *C. diphtheriae* elaborates an exotoxin that causes local cell necrosis and subsequent inflammation. The exotoxin produced by strains of *C. diphtheriae* infected with a specific bacteriophage is absorbed into the circulation. Distribution of exotoxin through the bloodstream can produce degenerative changes in the heart, nervous system, and kidneys. The toxin molecule consists of two fragments: A, containing the enzymatically active site, and B, comprising the receptor binding site. Once in the cell, protein synthesis is disrupted. The bacteria and exotoxin produce a serum exudate and cellular infiltrate of the mucous membrane in the pharynx. Exudative lesions coalesce, forming a grayish black adherent pseudomembrane, which is characteristic of diphtheria. Although toxin production and pathogenicity are often considered to be synonymous, pseudomembranes may form in persons infected with nontoxigenic strains. Extension of the pseudomembrane superiorly into the nasopharynx or inferiorly into the larynx may be so marked as to produce respiratory obstruction. Although *C. diphtheriae* infections of other parts of the body do occur, those observed most frequently in the United States today are infections of the skin. Transmission of *C. diphtheriae* occurs by droplet nuclei from the respiratory tract or by contact from cutaneous foci of infection (Mattos-Guaraldi, 2003).

Because they are part of the normal flora of the skin and mucous membranes, it is difficult to establish the etiologic role of the other corynebacteria. Clinical significance is generally increased if the organism is observed in the Gram-stained smear in association with leukocytes, is isolated from a sterile site, and is isolated from multiple samples.

Corynebacterium jeikeium has been clearly associated with infections of implanted prosthetic materials (e.g., heart valves, CSF, joints), has caused subacute bacterial endocarditis, and has been involved in a variety of opportunistic infections. *Corynebacterium urealyticum* has been associated with urinary tract infection, as well as with bacteremia, endocarditis, and wound infection (Nebreda-Mayoral, 1994). When identified, *Corynebacterium striatum* and *Corynebacterium amycolatum* are the most common normal flora skin coryneforms. They may become pathogenic and, of note, are often resistant to β -lactam antibiotics—a characteristic usually attributed only to *C. jeikeium* (Crabtree, 2003).

A. haemolyticum has been associated with pharyngitis and wound and soft tissue infections (Gaston, 1996; Fernandez-Suarez, 2009). *A. pyogenes* and *A. bernardiae* are associated with abscess formation.

Laboratory Diagnosis

Because of the relative rarity of diphtheria in the United States today, the diagnosis may be overlooked clinically, and the laboratory may easily fail to recognize it in cultures. When the diagnosis of diphtheria is being entertained by clinicians in a patient's differential diagnosis, the laboratory should be informed so that the specimen can be handled appropriately. Specimens should be obtained with a cotton- or polyester-tipped swab from inflamed regions of the nasopharynx and, if possible, beneath the pseudomembrane. If skin lesions are suspected of being positive for *C. diphtheriae*, the most appropriate specimen would be an aspirate of the lesion. Corynebacteria will grow on routine blood-containing agar; however, cystine-tellurite (CT) blood agar or Tinsdale medium is preferred. On CT medium, colonies of *C. diphtheriae* are gray or black after 48 hours of incubation. Colonies may be large or small and flat or convex. Colonies of species other than *C. diphtheriae* may produce black colonies on CT or Tinsdale media, although these will usually be smaller. If a laboratory does not have CT or Tinsdale medium and a request for *C. diphtheriae* is made, CNA can be used, although it will be more difficult to recognize possible *C. diphtheriae* strains (Funke, 2007).

Classification of oral and skin corynebacteria or diphtheroids is difficult and confusing. The differential characteristics of some species are shown in Table 57-5. Commercial identification systems are available to identify many of the members of this group of organisms (Hudspeth, 1998). Isolates of suspected *C. diphtheriae* must be tested for production of exotoxin. The elaboration of toxin may be detected in vitro with the Elek immunodiffusion test; however, this generally is not done in a routine clinical laboratory. Isolates should be sent to a state health laboratory or a reference laboratory where this can be performed. Alternatively, PCR-based tests have been described that may be used for detection of the toxin gene (Efstratiou, 2000). *C. jeikeium* often produces a characteristic metallic sheen on the surface of blood agar plates. *C. striatum* and *C. amycolatum* are common skin flora that can be responsible for infection; whether they need to be specifically identified is controversial, and identification can be difficult; species identification of *Corynebacterium* often requires a combination of commercial kit systems, cellular fatty acid analysis, and/or sequencing (Van den Velde, 2006). *C. striatum* and *C. amycolatum* organisms are often resistant to many antibiotic agents—a characteristic that often is more typically associated with hospital-acquired strains, in particular *C. jeikeium*.

Arcanobacterium spp. are β -hemolytic on sheep blood agar. Colonies on sheep blood agar are small after 48 hours of incubation, and the hemolysis may go unnoticed. Adequate growth and noticeable hemolysis are best demonstrated in a CO_2 -enhanced environment. *Arcanobacterium* spp. are catalase negative. Biochemical reactions that are used to determine the

species of corynebacteria are also useful in identifying the *Arcanobacterium* spp. (Funke, 2007). *A. baemolyticum* produces phospholipase D, which is responsible for the reverse CAMP reaction with *S. aureus*. This organism inhibits hemolysis around the *S. aureus* streak, producing an inverted triangle of no hemolysis.

Antimicrobial Susceptibility

Although antitoxin remains the only specific method of treatment of diphtheria, antibiotics are administered to patients with disease and to asymptomatic carriers of toxigenic strains. *C. diphtheriae* is usually inhibited by penicillins and the macrolides. The antimicrobial susceptibilities of other species of corynebacteria or diphtheroids are far less predictable. *C. jeikeium* is usually resistant to the penicillins and cephalosporins, is variably susceptible to most other antibiotics, and is almost uniformly susceptible to vancomycin. Other species of *Corynebacterium*, however, may be similarly resistant to β -lactam antibiotics. Treatment of infection caused by these organisms is often complicated by the presence of compromised host defenses and implanted prosthetic materials. Arcanobacteria are sensitive to penicillin and other β -lactams, rifampin, tetracycline, and the macrolides. Growth of the organisms may be inhibited by fluoroquinolones and aminoglycosides (Funke, 2007). Methods used for performing susceptibility tests on *Corynebacterium* spp. and interpretive criteria can be found in CLSI document M45-A (CLSI, 2006).

Prevention

Methods of prevention of diphtheria are almost exclusively active and passive immunization programs with supplemental antibiotics to eliminate the carrier state of toxigenic strains during epidemics.

Listeria

Characteristics

Listeria spp. are nonbranching, non-spore-forming gram-positive rods. *Listeria monocytogenes* (Fig. 57-8) is the only species of *Listeria* that is pathogenic for humans, and *L. ivanovii* is the only species of the other five *Listeria* spp. that is pathogenic for animals but not humans. Optimal growth of *L. monocytogenes* is observed between 30°C and 37°C; however, growth may occur as low as 4°C. Colonies are small after 24 hours and exhibit a narrow zone of β -hemolysis on blood agar. A characteristic tumbling motility of saline suspensions of the colonies occurs at room temperature but rarely at 35°C. This same temperature-dependent motility is also noted in semisolid media, in which growth appears as an umbrella shape at the top of the medium (aerobic conditions), preferentially at lower temperatures.

Clinical Manifestations and Pathogenesis

L. monocytogenes is found in soil, dust, water, silage, sewage, and raw unpasteurized milk and in asymptomatic human and animal carriers. Transmission of the organism by foods such as cole slaw, pasteurized milk, and soft cheeses has resulted in several major epidemics in North America and Europe (Fleming, 1985; MacDonald, 2005). According to data from microbiological surveys of food, *L. monocytogenes* has been detected in 2%–3% of dairy products, 20% of soft cheeses and processed meats, 30% of certain vegetables (cabbages, radishes), and up to 50% of raw meat and poultry (Bille, 2007). A transient carrier state is found in 2%–20% of animals and humans.

Listeriosis is mainly a disease of industrialized countries, occurring sporadically or in epidemics. The primary mode of transmission is contaminated food products, although occasional non-food-related outbreaks have occurred in healthcare settings, primarily in nurseries, as the result of cross-infection; contaminated mineral oil for bathing was implicated in one such outbreak (McLaughlin, 1989; Schuchat, 1991).

Clinical manifestations of listeriosis differ among pregnant women, neonates, and immunocompromised individuals, which constitute the high-risk groups. Listeriosis during pregnancy, most common in the third trimester, presents as a flu-like illness. Bacteremia occurs concomitantly, during which time the uterine contents are infected. Progression to amnionitis may induce premature labor or septic abortion in 3–7 days. Infection in the mother is self-limited because the source of infection is removed with delivery of the infected fetus and uterine contents. Neonatal listeriosis may have an early or late onset. Early-onset disease, manifested at birth or a few days thereafter, results from in utero infection. Infants present with temperature instability, hemodynamic compromise, and respiratory distress; widely disseminated granulomas, particularly involving the placenta, posterior pharynx, and skin, are characteristic of the illness but are not always present. Late-onset disease, affecting full-term infants of mothers with uncomplicated pregnancies, is assumed to be acquired postpartum, but in most cases the source is unknown. Clinical manifestations of meningitis become apparent several days to weeks after birth.

Nonperinatal listeriosis usually occurs in immunosuppressed individuals, but in about one third of cases, no risk factor is identified. Tropism for *L. monocytogenes* for the central nervous system (CNS) is manifested predominantly as meningitis; other forms of CNS listeriosis include cerebritis and brainstem and spinal cord abscesses. Severe disease with high mortality rates (20%–50%) and neurologic sequelae among survivors are common. Primary bacteremia or focal infections outside the CNS are uncommon. Primary cutaneous listeriosis has occurred occupationally in veterinarians and abattoir workers after exposure to infected animal tissues. Endocarditis, osteomyelitis, arthritis, endophthalmitis, and other focal infections have been reported rarely. Febrile gastrointestinal disease due to *L. monocytogenes* has been reported in nonimmunocompromised patients; implicated foods include chocolate milk, rice salad, and delicatessen meats and cheeses (Bille, 2007). Immunocompromised patients, such as those with leukemias or bone marrow transplants and patients on immunosuppressive therapies, are cautioned against eating uncooked dairy meats for fear of infection with this organism.

The pathogenesis of listeriosis infection has been well elaborated in recent years. Host susceptibility, gastric acidity, inoculum size, and virulence properties of the organism along with specific food products are the most common factors that determine progression from infection to disease and the severity of that disease in the infected individual. *L. monocytogenes* can penetrate the epithelial cells of the gastrointestinal (GI) tract and grow within hepatic and splenic macrophages; from there, the organism can spread to the CNS or the pregnant uterus. Virulence factors such as internalin and E-cadherin, a placental receptor, interact to result in infection in the pregnant female/fetus. Immunity to listeriosis relies on T cell-mediated activation of macrophages by lymphokines (Bille, 2007).

Laboratory Diagnosis

Colonies are small and grayish blue and are surrounded by a narrow zone of β -hemolysis on blood agar. A positive catalase reaction differentiates *L. monocytogenes* from similarly appearing group B streptococci. Organisms are motile at room temperature and produce acid from glucose, trehalose, and salicin and hydrolyze esculin. Other biochemical characteristics of *L. monocytogenes* and differences between *Listeria* and *Erysipelothrix* are listed in Table 57-6.

Antimicrobial Susceptibility

L. monocytogenes is usually sensitive to penicillin, ampicillin, erythromycin, chloramphenicol, tetracycline, and gentamicin. Isolates usually are only moderately susceptible to the quinolones. Cephalosporins are ineffective against *Listeria* spp.; isolates should not be tested against cephalosporins because they are ineffective in vivo regardless of the in vitro result. Methods of performing susceptibility tests for *Listeria* and interpretive criteria can be found in CLSI document M45-A (CLSI, 2010). Resistance to chloramphenicol, macrolides, and tetracyclines has been found in several clinical isolates (Bille, 2007). Ampicillin, alone or in combination with an aminoglycoside, has been used successfully in the treatment of infections caused by *L. monocytogenes*. Trimethoprim-sulfamethoxazole may be used as alternative therapy in penicillin-allergic patients. Newer

gram-positive antibiotics such as daptomycin, linezolid, and tigecycline appear susceptible in vitro, but limited clinical data document their in vivo effectiveness.

Erysipelothrix

Characteristics

Erysipelothrix rhusiopathiae is a catalase-negative, non-spore-forming, non-motile, facultatively anaerobic gram-positive bacillus that has a worldwide distribution. Microscopically, they appear as short rods with rounded ends, occurring singly, in short chains, or in nonbranching filaments. Two species have been identified: *E. rhusiopathiae* and *E. tonsillarum*. A third species, *E. inipinata*, has been proposed recently. *E. rhusiopathiae* is a recognized pathogen in humans, occasionally causing erysipeloid, a localized cutaneous infection of hands and fingers, obtained after exposure to animals or animal products. *E. tonsillarum* has not been isolated from human specimens (Bille, 2007).

Clinical Manifestations and Pathogenesis

E. rhusiopathiae is usually transmitted to humans from animals by means of skin wounds produced by contaminated objects or in contact with blood, flesh, viscera, or feces of infected animals. *E. rhusiopathiae* is widespread in nature in wild and domestic animals, birds, fish, and decaying organic matter and causes infection in swine, sheep, rabbits, cattle, birds, and fowl. At risk of infection with this organism are butchers, abattoir workers, fishermen, fish handlers, poultry processors, and veterinarians. The most common form of erysipeloid is a local cutaneous infection manifested by pain, swelling, and a cutaneous eruption characterized by a slowly progressive, slightly elevated, violaceous zone around the site of inoculation. The swelling and erythema migrate peripherally and the lesion involutes without desquamation. Systemic disease is rare, but numerous case reports describe septicemia and endocarditis. Also rarely reported have been cases of arthritis and brain abscess.

Laboratory Diagnosis

Biopsy and tissue aspirates from erysipeloid lesions are the best specimens for culture. The organisms are located deep in the subcutaneous layer of the leading edge of the lesion; therefore, swabs of the surface of the skin are not useful. The organism will grow on blood or chocolate blood agar, but may require up to 7 days for growth. Conventional blood culture media are suitable for its isolation from blood. They are considered nonhemolytic, although greenish discoloration of the media beneath the colonies is often observed after 2 days of incubation.

E. rhusiopathiae is oxidase and catalase negative. Characteristically, it produces hydrogen sulfide (H₂S) in triple-sugar iron agar (TSIA). It is nonmotile, does not reduce nitrates to nitrites, and is negative for urease, gelatin, and esculin hydrolysis; *E. rhusiopathiae* does ferment glucose and lactose. A trait highly characteristic of *E. rhusiopathiae* is the “pipe cleaner” pattern of growth in gelatin stab cultures incubated at 22° C. This organism can be readily distinguished from *Listeria* spp. (see Table 57-6).

Antimicrobial Susceptibility

Erysipelothrix is susceptible to the penicillins, the cephalosporins, imipenem, erythromycin, clindamycin, chloramphenicol, the tetracyclines, and the fluoroquinolones but is resistant to sulfonamides, aminoglycosides, and vancomycin. Penicillin is the treatment of choice for localized and systemic infection (Bille, 2007). Methods used for performing susceptibility tests

Figure 57-9 Gram stain of *Bacillus cereus* in pleural fluid.

for *Erysipelothrix rhusiopathiae* and interpretive criteria can be found in CLSI document M45-A (CLSI, 2010).

Bacillus

Characteristics

Members of this genus are strictly aerobic or facultatively anaerobic, rod-shaped, spore-forming, gram-positive, and catalase-positive organisms. Figure 57-9 shows a Gram stain of a *Bacillus* sp. seen in pleural fluid. With the notable exception of *Bacillus anthracis*, they are usually motile by means of lateral or peritrichous flagella. Some strains stain gram-negatively and, because of their variable oxidase reactions, are confused with gram-negative bacilli. The most reliable diagnostic characteristic of the genus is spore formation, which occurs optimally and on a variety of media under aerobic conditions at 25°–30° C. In Gram-stained smears, endospores are detectable by the presence of unstained defects or holes within the cell. The spores themselves can be stained by any of several methods.

Clinical Manifestations and Pathogenesis

Of the numerous species of *Bacillus*, *B. anthracis* is the only one that is uniformly and highly pathogenic. Great care must be exercised when handling material suspected of harboring this species. Work should be performed in biological safety cabinets by gloved, gowned, masked, and immunized personnel; work surfaces must be disinfected with 5% hypochlorite or 5% phenol; all supplies, materials, and equipment must be decontaminated. Because *B. anthracis* spores have been used as a means of bioterrorism, cultures containing suspect *B. anthracis* should be handled only by reference or public health laboratories.

Three forms of anthrax are recognized: cutaneous, inhalation, and intestinal. In its cutaneous form, anthrax produces a small, red, macular lesion that progresses to a vesicle and finally to necrosis with formation of a characteristic black eschar. Regional lymphadenopathy and septicemia may occur. Mortality in untreated cases with this form of disease is approximately 20%. Inhalation of anthrax spores can lead to acute bronchopneumonia, mediastinitis, and septicemia (“wool sorter’s disease”). The mortality in recognized cases of this form of disease is nearly 100%. Intestinal anthrax follows the ingestion of contaminated food and is manifested by nausea, vomiting, and diarrhea. In some cases, gastrointestinal bleeding is followed by prostration, shock, and death. Septicemia can occur in all three forms of anthrax and may lead to a fatal, purulent meningitis.

A major factor in the organism’s pathogenic capabilities is its glutamyl polypeptide capsule, which inhibits phagocytosis; anticapsular antibodies do not protect against the disease. A complex toxin with three components (edema factor, protective antigen, and lethal factor) is responsible for the signs and symptoms of anthrax (Logan, 2007).

Humans become infected with anthrax by contact with and inhalation or ingestion of infected animals, their carcasses, or their byproducts. Cattle, sheep, horses, and goats are the animals most frequently infected and provide a ready source of vegetative organisms that sporulate and perpetuate the environmental contamination.

Although usually saprophytic, other species of *Bacillus* can cause disease. *Bacillus cereus* has been associated with ear infection, pneumonia, post-traumatic ocular wound infection, septicemia, and endocarditis. Patients with pneumonia and septicemia are often immunosuppressed. Bacteremia

Figure 57-10 Colonies of *Bacillus anthracis* on blood agar. Note the irregular edges of the colonies.

is frequently associated with intravenous drug use and with contaminated intravascular devices.

Two forms of gastroenteritis are associated with *Bacillus* species. Food poisoning caused by *Bacillus* may occur within 1–6 hours following ingestion of food contaminated by *B. cereus* that has produced a pre-formed heat-stable toxin. Major manifestations of *Bacillus* food poisoning include nausea, vomiting, cramps, and occasionally diarrhea. Typically, this form of *Bacillus* gastroenteritis results from the bulk preparation of foods that are not reheated before they are served. *B. cereus* type 1 grows particularly well in fried rice and is more heat resistant than other types, so this form of gastroenteritis is frequently seen in association with consumption of cooked rice in Chinese restaurants. The second form of gastroenteritis caused by *Bacillus* spp. results from contamination of meat and vegetable dishes and is characterized by the onset of cramps and diarrhea 8–16 hours following ingestion of contaminated food. In this instance, the major manifestations of *B. cereus* infection are caused by the production of a heat-labile enterotoxin.

The genus *Bacillus* contains more than 100 species; other than *B. anthracis* and *B. cereus*, common species include *B. subtilis*, *B. licheniformis*, *B. megaterium*, *B. pumilus*, and *B. thuringiensis*. Many species have been removed, however, and more than 25 new genera of gram-positive spore-producing aerobic bacilli have been named. One of those genera, *Paenibacillus*, contains species that have been associated with clinical disease, including meningitis and endophthalmitis. Species of *Paenibacillus* include *P. alvei*, *P. macerans*, *P. popilliae*, and *P. bongkongensis* (Logan, 2007; Ouyang, 2008). *P. macerans* has been reportedly found in contaminated blood culture bottles in a neonatal intensive care unit (Noskin, 2001).

Laboratory Diagnosis

In cases of suspected cutaneous anthrax, vesicle fluid and material under the edge of the eschar should be collected with a swab for smear and culture. For suspected inhalation anthrax, sputum should be collected for smear and culture. Cultures of stool should be considered in the intestinal form. Smears and cultures consist of CSF should be requested in suspected meningitis. In the septicemic stage, blood cultures should be performed.

Finding large, boxcar-shaped, gram-positive cells in smears of any of these specimens should raise suspicion for the diagnosis. Fluorescent microscopy, available in some state health laboratories and at the CDC, can provide a rapid presumptive diagnosis. As mentioned earlier, because of the use of *B. anthracis* in terrorist attacks, sentinel laboratories (level A) should send any suspicious isolates of this organism to their state health laboratory or the CDC.

Species of *Bacillus* grow well on sheep blood agar. Colonies of *B. anthracis* are usually flat, with an irregular margin ("Medusa head"), appear off-white with a ground glass surface, and are usually nonhemolytic. Figure 57-10 demonstrates the colonial morphology of *B. anthracis* on blood agar. When touched with an inoculating loop, the colonies are tenacious and will stand up like beaten egg white. The Medusa head colony may be seen with *B. cereus* and certain other *Bacillus* species. Anthrax bacilli are nonmotile in a hanging drop test or in semisolid media, whereas most other species of *Bacillus* are motile. Motility by the hanging drop method is a useful differential test between *B. anthracis* and *B. cereus* but must be

Figure 57-11 Sputum smear stained with Gram stain shows neutrophils, amorphous debris, and filamentous, beaded, branched gram-positive bacilli (oil immersion).

carried out with a fresh broth culture of the organism. Additional characteristics and biochemical reactions that may be used to identify isolates to the species level are summarized by Logan (2007). A commercial system has been evaluated recently for identification of aerobic endospore-formers; 93% of the strains were correctly identified to species level in the genera *Bacillus*, *Paenibacillus*, *Aneurinibacillus*, *Brevibacillus*, *Geobacillus*, and *Virgibacillus* (Halket, 2010).

The diagnosis of *B. cereus* gastroenteritis cannot be accurately made by culture of stool because the organisms may be a component of the indigenous gut flora. Diagnosis, therefore, depends on quantitative culture of the suspected contaminated food. The presence of greater than or equal to 10^5 colony-forming units (CFUs)/g in the suspected food constitutes presumptive evidence of *B. cereus* food poisoning (Logan, 2007). This testing is usually not performed in a routine Clinical Microbiology laboratory.

Antimicrobial Susceptibility

Although susceptible to a variety of agents, antibiotic therapy of anthrax has centered on the use of fluoroquinolones. These agents are highly active against *B. anthracis*, strains of which are typically susceptible to β -lactam antibiotics. However, many strains of *Bacillus* spp. elaborate β -lactamases in nature, hence these agents usually are not considered as first-line drugs of choice until the specific susceptibility of the isolate is known. Most strains of *Bacillus* spp. are inhibited by fluoroquinolones, tetracyclines, aminoglycosides, and chloramphenicol at low concentrations (Logan, 2007), and most are susceptible to vancomycin, but reports have described vancomycin resistance in *B. circulans* and *P. thiaminolyticus*. *Bacillus* strains have been demonstrated to carry genes similar to the *vanA* gene of the enterococci (Patel, 2000). Methods of performing susceptibility tests and of interpreting their results can be found in the CLSI document M45-A2 (CLSI, 2010).

Prevention

Prevention of anthrax in humans ideally depends on its control in animals. Prompt diagnosis of sick animals, their isolation and therapy, and cremation of carcasses are indicated when sporadic outbreaks occur. In enzootic areas, vaccination with nonencapsulated spore preparations is used. Occupationally exposed persons should also be immunized. Acute diarrheal disease caused by *B. cereus* may be prevented by proper cooking and refrigeration of foods prepared in bulk to prevent proliferation of vegetative forms of the bacteria and formation of the enterotoxin.

Nocardia

Characteristics

In Gram-stained smears of clinical specimens, *Nocardia* spp. appear as long, thin, beaded, branching gram-positive bacilli (Fig. 57-11). The most distinguishing quality of the nocardiae is their partial acid fastness; cells stain positively with a modified acid-fast (Ziehl-Neelsen or Kinyoun) stain, differentiating them from *Actinomyces*, which may have a similar Gram-stain appearance. Partial acid fastness may be difficult to demonstrate and can be enhanced by growing the organism for about 4 days on Middlebrook

7H10 agar, or in litmus milk broth. Most clinical infections have been caused by members of the *Nocardia asteroides* complex, most commonly *Nocardia cyraccigeorgica*, *Nocardia farcinica*, and *N. nova*, followed by *Nocardia brasiliensis* and rarely *Nocardia otitidis caviarum* (Cloud, 2004).

Clinical Manifestations and Pathogenesis

Nocardiae are found in soil and organic material worldwide and cause disease in many animals and in fish. Human infection is slightly more common in males than in females. It is usually acquired via inhalation of the organism but may occur following trauma and contact with contaminated soil, or the organism may enter the body via the GI tract when contaminated material contacts an area of mucosal ulceration.

In the lungs, *Nocardia* spp. are phagocytosed by alveolar macrophages and grow intracellularly, eliciting a mixed inflammatory response (neutrophils, lymphocytes, and macrophages), eventually resulting in abscess or, occasionally, granuloma formation. In vitro studies of the host defenses against *Nocardia* spp. suggest that neutrophils, activated macrophages, and cytotoxic T cells are involved. Although neutrophils do not kill virulent *Nocardia* spp., they inhibit their growth, possibly suppressing the infection until macrophages are fully activated. If the infection is not contained within the lung, organisms spread to other tissues by advancing growth, thus producing empyema, chest wall involvement, and draining sinuses, or by hematogenous dissemination, resulting in abscess formation, especially in the brain, subcutaneous tissues, and kidneys. The primary host factor associated with increased risk of nocardiosis is cellular immune dysfunction, although many persons infected with *Nocardia* spp. have no recognized cellular or humoral immune defect (Wilson, 1989).

Pulmonary disease, the most frequent manifestation of nocardiosis, is characterized by fever, anorexia, weight loss, cough, dyspnea, and pleuritic chest pain. Skin and subcutaneous disease may present as pyoderma, cellulitis, single or multiple abscesses, lymphocutaneous disease resembling sporotrichosis, or nodules. In Central and South America, primary infections of the skin with *N. brasiliensis* may produce an actinomycetoma (a

localized indurated granulomatous mass with sinus tracts draining pus and “sulfur” granules), typically on the lower extremities. Disseminated disease is usually caused by members of the *N. asteroides* complex. It originates in the lung in most cases and typically is manifested as single or multiple abscesses involving the CNS. The skin is the second most common site of dissemination, followed by kidney, liver, and lymph nodes (Conville, 2007).

Laboratory Diagnosis

Nocardia spp. grow aerobically on most nonselective media such as sheep blood and chocolate agars, potato dextrose agar, Sabouraud's dextrose agar, and Löwenstein-Jensen or Middlebrook media and in 7H9 broth used for mycobacterial culture. These organisms will grow on buffered charcoal-yeast extract (BCYE) used for the isolation of *Legionella* spp. as well. It is important to note that *Nocardia* spp. may not always survive the decontamination procedures used for recovery of mycobacteria. Incubation in the presence of 10% CO₂ enhances growth. *Nocardia* spp. may grow in 48 hours, but colonies typically appear in 5–10 days as waxy, bumpy, or velvety rugose forms, often with yellow to orange pigment, depending on the species. Observing branching filaments that stain only with a modified acid-fast stain distinguishes *Nocardia* spp. from mycobacteria. *Nocardia* spp. are differentiated from most other aerobic actinomycetes by testing resistance to the action of lysozyme (*Nocardia* spp. are resistant; *Streptomyces* spp., *Rhodococcus* spp., *Gordona* spp., and *Actinomyces* spp. are susceptible) and examining their morphology on tap water agar. The latter can help in differentiating the branching *Nocardia* from nonbranching *Rhodococcus* spp., for example. Because many new species of *Nocardia* have been recognized over the past several years, the use of biochemical tests (e.g., casein, hypoxanthine, tyrosine, xanthine) is not sufficient for identification. Molecular tests (e.g., 16S rDNA sequencing, PCR-restriction enzyme pattern analysis [PRA]) are required for accurate species identification (Cloud, 2004; Patel, 2004). Identification to the species level is important because of the variability in antibiotic susceptibility patterns noted among species (Table 57-7) (Brown-Elliott, 2006).

Antimicrobial Susceptibility

Sulfonamides (alone or in combination with trimethoprim [e.g., trimethoprim-sulfamethoxazole]) are usually the antimicrobial agents of choice; however, optimal antimicrobial therapy depends on the species of *Nocardia* present, the susceptibility pattern of the individual strain, and the type of infection. Other potential antimicrobial agents include amikacin, clarithromycin, imipenem, or a quinolone, depending on the species isolated. The CLSI has information about methods used for susceptibility testing and interpretation of results for *Nocardia* and other aerobic actinomycetes (NCCLS, 2003).

Other Aerobic Actinomycetes

Other genera of actinomycetes that are medically relevant to humans include *Rhodococcus*, *Gordona*, *Tsukamurella*, *Actinomadura*, and *Streptomyces*. One other member, *Tropheryma whippelii*, is nonculturable and is the putative agent of Whipple's disease.

Clinical Manifestations and Pathogenesis

Members of this group of organisms are ubiquitous in the environment and have been isolated from soil, fresh water, marine water, and organic matter.

Rhodococcus equi is the most common *Rhodococcus* sp. pathogenic to humans. It is an opportunistic pathogen in severely immunocompromised hosts, causing a slowly progressive granulomatous pneumonia. It may be isolated from the blood of infected patients. The organism is likely acquired via the respiratory route, possibly as a result of exposure to infected animals. The organism's ability to persist in and ultimately destroy macrophages probably accounts for its ability to cause disease (Weinstock, 2002). Infections caused by *Gordona* spp. and *Tsukamurella* spp. are only rarely reported. *Tsukamurella* spp. appear to be pathogenic only when certain clinical conditions are present (e.g., immunosuppression, presence of foreign body, active chronic infection such as tuberculosis) (Woo, 2003). *Actinomadura* spp. are a frequent cause of actinomycotic mycetomas, most of which are seen in tropical and subtropical countries, where walking barefoot increases the chance of exposure through repeated puncture wounds. *Streptomyces* spp. have traditionally been considered of little medical significance; however, one species, *Streptomyces somaliensis*, has been identified as an etiologic agent of actinomycotic mycetoma. Other *Streptomyces* spp. have only occasionally been reported to be of medical importance (Mossad, 1995).

Laboratory Diagnosis

Aerobic actinomycetes are slow growing and may require 2–3 weeks of incubation. These microorganisms grow on most of the nonselective media used to isolate bacteria, mycobacteria, and fungi. Species of *Rhodococcus* grow as coccobacilli in a zigzag fashion. Rudimentary branched filaments have been observed from liquid media. Colonies may be rough, smooth, or mucoid and have pigments ranging from buff to coral to orange to deep rose after several days of incubation. *R. equi* is usually pale pink, pale yellow, or coral and may appear slimy. *Gordona* spp. range from smooth, mucoid colonies that are adherent to the media to dry, raised colonies. The pigment produced may be beige to salmon-colored. *Tsukamurella* spp. are slightly acid fast by the modified Kinyoun. They appear as long rods that fragment into three parts. No aerial hyphae are produced. The colonies are circular with entire or rhizoid edges. They may be dry or creamy with a white to orange pigment. Rough colonies may be produced after 7 days of incubation. Species of *Actinomadura* form waxy, cerebriform, tough, membranous white, yellow, pink, or red colonies. Colonies of *Streptomyces* are dry to chalky, heaped or folded, gray-white to yellow, and have the odor of a musty basement. A wide variety of pigments are produced that color the substrate and hyphae. Some species do not produce aerial hyphae. As with the *Nocardia* spp., complete identification of these members of the aerobic actinomycetes often requires molecular sequencing methods (Conville, 2007).

GRAM-NEGATIVE BACTERIA—COCCI

Neisseria

Characteristics

This genus is composed of species that are nonmotile, catalase- and oxidase-positive; these aerobic, gram-negative cocci are often arranged in pairs with flattened adjacent surfaces, giving the appearance of kidney or coffee beans (Fig. 57-12). The organisms are somewhat fastidious, in some

Figure 57-12 Sputum smear stained with Gram stain shows many neutrophils and intracellular gram-negative diplococci, suggestive of *Neisseria meningitidis* infection (oil immersion).

instances requiring the addition of blood, serum, cholesterol, or oleic acid to the medium to counteract growth inhibitors, such as fatty acids. *N. gonorrhoeae* and *N. meningitidis* generally require prompt incubation in CO₂ for growth; however, this is strain dependent, varies with the phase of the organism's growth curve, and is often lost in subcultures. *N. meningitidis* and most *N. gonorrhoeae* are not inhibited by the presence of vancomycin or lincomycin, colistin, and nystatin—a characteristic that is particularly useful in their selective isolation from specimens contaminated by other bacteria. Rarely, isolates of *N. gonorrhoeae* (especially AUH strains, which require arginine, uracil, and hypoxanthine) are susceptible to vancomycin (Janda, 2007).

Clinical Manifestations and Pathogenesis

Although opportunistic infections caused by species of *Neisseria* other than *N. gonorrhoeae* and *N. meningitidis* have occasionally been reported in compromised hosts, these species are generally nonpathogenic. *N. meningitidis* may colonize the mucous membranes of the upper respiratory tract—an event that is usually followed in 7–10 days by the formation of bactericidal and hemagglutinating antibodies, which may not eliminate the carrier stage but convey group-specific immunity. In a few cases, disease results shortly after colonization, most frequently in the form of meningococcemia and meningitis. The organism also has a tendency to invade serous membranes and joint tissues, with the development of pleuritis, pericarditis, and arthritis. Carriage of *N. meningitidis* in the nasopharynx occurs in 5%–15% of healthy individuals, and this rate may be higher in confined groups such as military recruits. A direct correlation between carrier rates and incidence of disease has not been established, with the possible exception of members of large households or households with an infant or childhood case during epidemics of disease. *N. meningitidis* has also been isolated from genital sources, where its clinical significance is uncertain. When cultured from these sources, bacteria may be misidentified as *N. gonorrhoeae* unless appropriate tests for distinguishing these species are performed.

The principal virulence factor of *N. meningitidis* is a lipopolysaccharide–endotoxin complex, which in experimental animals activates the clotting cascade, depositing fibrin in small vessels, producing hemorrhage in the adrenals and other organs, altering peripheral vascular resistance, and leading to shock and death.

The pathogenesis and clinical manifestations of *N. gonorrhoeae* infections differ somewhat from those of *N. meningitidis*. Pathogenic types of *N. gonorrhoeae* adhere by means of pili, which are not produced by non-pathogenic types, to various human cells. These antigenically heterogeneous pili, which represent one of the principal virulence factors of *N. gonorrhoeae*, may inhibit phagocytosis and stimulate strain-specific antibody formation. Other possible virulence factors of *N. gonorrhoeae* are less clearly defined. Both *N. gonorrhoeae* and *N. meningitidis* produce an IgA protease, which may be important in their pathogenesis because IgA is the antibody class that predominates in secretions on mucous membranes (Janda, 2007).

Laboratory Diagnosis

The single most important element in the laboratory diagnosis of infection caused by *N. meningitidis* or *N. gonorrhoeae* is the specimen, including

proper selection, collection, and transport to the laboratory (see Chapter 63). The pathogenic species are sensitive to drying and extremes of temperature, and material must be cultured promptly to enhance recovery. They are mesophilic and grow poorly, if at all, at room temperature. Many require prompt incubation in CO₂ (2%–8%) for primary isolation. Media containing chocolate blood are commonly used for cultures and should contain antibiotics (i.e., vancomycin or lincomycin, as well as colistin, nystatin or anisomycin, and trimethoprim) if the specimen is prone to be contaminated by indigenous flora. Vancomycin-susceptible gonococci will grow on media containing lincomycin; however, because of the synergistic interaction of lincomycin and trimethoprim, the latter must be omitted from media containing lincomycin. Direct inoculation of specimens at the bedside followed by prompt incubation at 35° C in CO₂ is optimal. This can be accomplished in several ways: placing the medium into a candle jar; placing the medium in a sealed bag containing a citric acid bicarbonate tablet; or using a medium contained within a bottle having a CO₂ atmosphere. If any of these culture systems must be mailed to a reference laboratory for processing, they must first be incubated overnight to ensure growth of the organisms.

An isolate from a urogenital specimen showing the appropriate colony appearance on a selective medium presumptively may be called *N. gonorrhoeae* based on results of Gram stain and oxidase and catalase tests. Gram-stained smears prepared from colonies of *N. gonorrhoeae* should show typical gram-negative diplococci, but organisms may occur in tetrads, especially from young cultures. All species of *Neisseria* are oxidase positive, and all species except *N. elongata* are catalase positive. Because *Neisseria* other than *N. gonorrhoeae* may be recovered from urogenital sites, confirmatory testing is strongly recommended and is required for all isolates from extragenital sites, and when sexual abuse is suspected (preferably by more than one method).

Confirmation of *N. gonorrhoeae* and identification of the other *Neisseria* spp. are based on growth and biochemical characteristics (Table 57-8) (Janda, 2007). The standard method of identification consists of detection of acid production from carbohydrates in a cystine trypticase acid (CTA) base medium and other conventional biochemical tests. However, given the drawbacks of conventional methods, more rapid identification tests are used in most clinical laboratories. Tests for direct detection of *N. gonorrhoeae* and *N. meningitidis* in clinical specimens are also available. Typing of isolates of *N. gonorrhoeae* and *N. meningitidis* is done primarily for epidemiologic studies.

With the standard method of identification, acid production from glucose, maltose, lactose, sucrose, and fructose in a CTA base medium and a carbohydrate-free control are tested. Tubes are inoculated, incubated at 35°–37° C in ambient air, and examined at 24-hour intervals until reactions are interpretable, or for 72 hours. Expected results for the species of *Neisseria* are shown in Table 57-8. Occasionally, however, an isolate of

N. meningitidis yields aberrant carbohydrate reactions: glucose-negative, maltose-negative, or asaccharolytic. If *N. meningitidis* is strongly suspected in these cases, identification can be confirmed by slide agglutination, using pooled polyvalent grouping antisera or sera specific for individual serogroups. In addition to conventional carbohydrate degradation tests, reduction of nitrates and nitrites and production of DNase should be evaluated. The latter is especially useful for identification of *Moraxella catarrhalis*, which is DNase positive (*Neisseria* spp. are DNase negative). Drawbacks to conventional tests are the requirement for a heavy inoculum, the need to work with pure cultures, long turnaround time, and failure of some fastidious strains of *N. gonorrhoeae* to grow.

Several commercial systems detect acid production from carbohydrates, usually in 1–4 hours (Dillon 1988; Janda, 2007). The inoculum must be prepared from a pure culture of the isolate, so identification is generally available 24 hours after isolation. Acid reactions of some *N. gonorrhoeae* and, to a lesser extent, *N. meningitidis* may be difficult to interpret or may be aberrant with some kits, and strains of *N. gonorrhoeae* that are weak producers of acid from glucose may appear to be glucose negative. Some strains of *Neisseria cinerea*, which does not typically produce acid from glucose, can appear glucose positive in certain systems.

Enzyme substrate tests provide rapid identification (1–4 hours) only of isolates of oxidase-positive, gram-negative diplococci recovered on a selective medium (Kellogg, 1995; Janda, 2007). They are valuable for differentiating maltose-negative strains of *N. meningitidis* from *N. gonorrhoeae*, but color changes may be subtle and if misinterpreted could cause isolates of *N. meningitidis* and other *Neisseria* spp. to be incorrectly called *N. gonorrhoeae*. Moreover, strains of *N. cinerea* and *Kingella denitrificans* that grow on gonococcus-selective media could be misidentified as *N. gonorrhoeae* if not confirmed by other procedures. Commercial products that combine enzyme substrate tests with modified conventional tests provide accurate identification of species of *Neisseria* and *Haemophilus* (Janda, 1987, 2002).

Immunologic tests for *N. gonorrhoeae*, in particular coagglutination, can be used to confirm the biochemical identification of *N. gonorrhoeae*. Three tests are available for this: the Phadebact Monoclonal GC Test (Boule Diagnostics AB, Huddinge, Sweden), the GonoGen I (New Horizons Diagnostics, Columbia, MD), and the GonoGen II (New Horizons Diagnostics). Both false-positive and false-negative results have been reported with these reagents (Dillon, 1988; Kellogg, 1995). A chemiluminescent nucleic acid probe for detection of *N. gonorrhoeae* can be used for culture confirmation or direct detection of the organism in endocervical or urethral swab specimens (Limberger, 1992; Hale, 1993). Nucleic acid amplification assays (NAAT) for use on endocervical or urethral swab specimens and urine are also available and may increase sensitivity when compared with nucleic acid probe and culture techniques, largely because the problem with organism viability is not an issue.

Latex agglutination assays are available for direct detection of *N. meningitidis* antigens in CSF, serum, and urine. As discussed previously (see *Streptococcus*), the sensitivity of these assays has been found to be less than or equal to that of the Gram stain, and the results of such testing appear to have little impact on patient care (Maxson, 1994; Perkins, 1995); therefore many laboratories have stopped offering this test.

Cultural detection of *Neisseria gonorrhoeae* from urogenital sites has been largely replaced by molecular methods, including probes and/or NAAT. Many products are available for NAAT that simultaneously detect *N. gonorrhoeae* and *Chlamydia trachomatis* from cervical, urethral, and urine samples with much greater sensitivity, and for which loss of viability of *N. gonorrhoeae* in particular is not an issue. These molecular techniques are described in other sections of this text (Janda, 2007).

Antimicrobial Susceptibility

Despite the occasional recovery of *N. meningitidis* strains with decreased susceptibility to penicillin, penicillin G remains the drug of choice for treatment of meningococcal meningitis (Janda, 2007). Decreased susceptibility of *N. meningitidis* to penicillin is thought to be due to decreased binding of penicillin by altered meningococcal cell wall penicillin-binding proteins, PBP-2 and PBP-3. Other species of *Neisseria* have also demonstrated this lowered affinity to penicillin (Saez-Nieto, 1992). Other agents that have good activity against *N. meningitidis* include the extended-spectrum cephalosporins and chloramphenicol. Rifampin, minocycline, and the fluoroquinolones may be used for prophylaxis among household contacts. Standardized methods of susceptibility testing and breakpoints in the CLSI documents are now available (CLSI, 2009). The CLSI does recommend that a broth microdilution or an agar dilution MIC test with cation-supplemented Mueller-Hinton Broth (with 2%–5% laked horse blood) or Mueller-Hinton Agar (with 5% [vol/vol] sheep blood) should be used if testing is done. Enrichments such as IsoVitalX (1%) may also be needed. In laboratories where susceptibility testing for *N. meningitidis* is not available, β -lactamase testing can be performed by using the chromogenic cephalosporin test, the cefinase nitrocefin disk test, if lowered susceptibility or clinical failure on penicillin is suspected. If positive, isolates can be shipped to a reference laboratory for further testing.

Because of widespread resistance of *N. gonorrhoeae* to penicillin and tetracycline (Fox, 1997), current recommendations for treatment include extended-spectrum cephalosporins but no longer include the newer fluoroquinolones. Although no resistance to the cephalosporins is apparent, resistance to the fluoroquinolones has been documented (CDC, 2007). Therefore susceptibility testing should be performed if symptoms persist after treatment. β -Lactamase production can be detected using a chromogenic cephalosporin. Disk diffusion using GC agar with 1% growth supplement is recommended to determine the susceptibility of *N. gonorrhoeae* to the cephalosporins, quinolones, and spectinomycin. The CLSI document recommends the agar dilution method or a disk diffusion method for testing of *N. gonorrhoeae* (CLSI, 2009). In addition, an E-test can be performed. For some agents, only a susceptible breakpoint is available because no resistant strains have yet been documented. If one identifies a nonsusceptible result with a third-generation cephalosporin, for example, confirmation tests and referral to a reference laboratory should be strongly considered (CLSI, 2009).

Prevention

A polysaccharide vaccine against *N. meningitidis* serogroups A, C, Y, and W135 is licensed in the United States and is recommended for military personnel, for persons living in epidemic areas of developing countries, for individuals with a nonfunctional or absent spleen, and for college students. Antibiotic prophylaxis should be limited to household contacts and those who have had contact with patients' oral secretions. Rifampin is currently the drug of choice.

The use of preexposure antibiotics to prevent gonococcal disease is discouraged because of the potential risks of sensitization and the emergence of resistant strains. The sole exception to this rule is the application of silver nitrate solution or erythromycin ointment to the eyes of newborns to prevent gonococcal (and chlamydial) ophthalmia.

Moraxella catarrhalis

M. catarrhalis may be carried in the oropharynx of healthy children and adults. It is an encapsulated organism, and extending from its outer membrane are pili that serve as adhesins. The most common infections caused by this organism are bronchitis, otitis, sinusitis, and pneumonia (especially in persons with underlying chronic lung disease) (Schreckenberger, 2007). *M. catarrhalis* is an infrequent cause of bacteremia, endocarditis,

Figure 57-13 Gram stain of *Moraxella catarrhalis* in a sputum specimen. Note the intracellular gram-negative diplococci that resemble *Neisseria* spp.

meningitis, urogenital infection, and ophthalmia neonatorum. Figure 57-13 shows the Gram stain of sputum in which *M. catarrhalis* is seen in large quantities inside and outside the polymorphonuclear leukocytes. *Moraxella catarrhalis* was part of the *Neisseria* genera and later transferred to the *Branhamella* genus for a short time. *M. catarrhalis* is a coccus that morphologically resembles *Neisseria* spp., unlike other members of the genus *Moraxella* (e.g., *Moraxella lacunata*, *Moraxella osloensis*, *Moraxella atlantae*), which appear as rods. *M. catarrhalis* bacteria are oxidase and catalase positive but can be differentiated from *Neisseria* spp. in their ability to grow readily on blood and chocolate agar, their lack of oxidative metabolism (sugars will be negative), and their production of DNase. Nearly all isolates of *M. catarrhalis* produce β -lactamase, which can be detected using nitrocefin. Although they should be assumed to be resistant to penicillin because of this, these isolates generally remain susceptible to cephalosporins, trimethoprim-sulfamethoxazole, and β -lactamase inhibitor combinations (Schreckenberger, 2007).

GRAM-NEGATIVE BACTERIA—BACILLI

The gram-negative bacilli make up a complex group. They are broken down into the following: Enterobacteriaceae—those found normally in the GI tract or that colonize and cause infection there primarily; nonfermentative gram-negative bacilli, which usually are not found as part of the normal flora of humans but rather are environmental bacteria; non-Enterobacteriaceae that can cause GI infection, such as *Vibrio* or *Campylobacter*; agents of infections with specific epidemiologic characteristics, such as *Legionella* and *Francisella*; other gram-negative bacilli, including *Haemophilus* spp.; and miscellaneous genera.

Enterobacteriaceae

Characteristics

The Enterobacteriaceae are aerobic and facultatively anaerobic, non-spore-forming, nonmotile or peritrichously flagellated, oxidase-negative, gram-negative bacilli that produce acid fermentatively from glucose and reduce nitrates to nitrites. Figure 57-14 shows a Gram stain of *Escherichia coli*, but it could represent any member of the Enterobacteriaceae. Genera included in this group are *Budvicia*, *Buttiauxella*, *Cedecea*, *Citrobacter*, *Edwardsiella*, *Enterobacter*, *Escherichia*, *Ewingella*, *Hafnia*, *Klebsiella*, *Kluyvera*, *Leclercia*, *Leminorella*, *Moellerella*, *Morganella*, *Obesumbacterium*, *Pragia*, *Pantoea*, *Photobacterium*, *Proteus*, *Providencia*, *Rahnella*, *Salmonella*, *Serratia*, *Shigella*, *Tatumella*, *Trabulsiella*, *Xenorhabdus*, *Yersinia*, and *Yokenella*. Only a few of these are discussed here (Farmer, 2007).

Clinical Manifestations and Pathogenesis

Enterobacteriaceae are found on plants, in soil, in water, and in the intestines of humans and animals. They have been associated with many clinical infections, including abscesses, pneumonia, meningitis, septicemia, and urinary tract infections. Those commonly associated with human infection include *E. coli*, *Klebsiella* spp., *Proteus* spp., *Enterobacter* spp., *Salmonella* spp., *Shigella* spp., *Serratia* spp., *Citrobacter* spp., and *Providencia* spp. Figure 57-15 shows a Gram stain of CSF from a newborn child that was culture positive for *E. coli*. In the urinary tract, those frequently isolated are *E. coli*, *Proteus mirabilis*, and *Klebsiella pneumoniae*. Gram-negative pneumonias

Figure 57-14 Gram stain of urine positive for *Escherichia coli*. The short, plump gram-negative rods are typical of any member of the Enterobacteriaceae.

Figure 57-15 Gram stain of a cerebrospinal fluid specimen from a neonate containing gram-negative bacilli that grew *Escherichia coli*.

associated with the Enterobacteriaceae are frequently caused by *K. pneumoniae*. Gram-negative bacteremias related to the Enterobacteriaceae are frequently caused by *E. coli*, *K. pneumoniae*, and *P. mirabilis*. Infections acquired in the hospital are likely to be caused by members of antibiotic-resistant genera, such as *Citrobacter*, *Enterobacter*, and *Serratia*. Enterobacteriaceae associated with diarrhea include *Shigella* spp., *Salmonella* spp., *E. coli* (enterohemorrhagic [Shiga toxin producing], enterotoxigenic, enteroinvasive, enteropathogenic, enteroadherent), and *Yersinia* spp. *Shigellas* are rarely isolated from sources other than the GI tract, and salmonellas are more frequently isolated from other sources, such as urine or blood. *Calymmatobacterium granulomatis*, an agent of the sexually transmitted disease donovanosis, has been renamed *Klebsiella granulomatis* and is now part of the Enterobacteriaceae, even though the organism cannot be cultured on bacteriologic media (Abbott, 2007; Farmer, 2007). This topic is discussed later under a separate heading.

Endotoxins that are present within the cell walls of the Enterobacteriaceae, as well as other gram-negative bacilli, are responsible for much of the morbidity and mortality resulting from infections associated with these bacteria. Endotoxins consist of lipid and polysaccharide moieties with small quantities of amino acids and are often referred to as lipopolysaccharides. Lipopolysaccharides may elicit fever, chills, hypotension, granulocytosis, thrombocytopenia, disseminated intravascular coagulation, and activation of both classic and alternate complement pathways. Endotoxic shock is the result of gram-negative septicemia, with endotoxin reacting with macrophages, leukocytes, platelets, complement, and other serum proteins to increase the blood levels of proteolytic enzymes and vasoactive substances, resulting in pooling of blood, increased peripheral vasoconstriction, and diminution in cardiac output. It has become clear that the lethal effects of endotoxin are dependent on macrophage activation and responsiveness, and that the production of cachectin from the activated

macrophage plays a major role in causing profound shock and multiple organ injury (Tracey, 1988).

Other pathogenetic factors of the Enterobacteriaceae include the K1 antigen, which is associated with a high percentage of strains of *E. coli* causing neonatal meningitis; the capsule of *K. pneumoniae*, which, like that of the pneumococcus, inhibits phagocytosis; the Vi antigen of *Salmonella* serotype *typhi*, which may interfere with intracellular killing of this organism; and various surface antigens, such as fimbriae, that mediate adherence of the organism to mucosal surfaces.

Plasmid-mediated factors appear to play an important role in the invasive properties of *Salmonella*, *Shigella*, and enteroinvasive strains of *E. coli*. Moreover, the heat-labile enterotoxins (LT) and the heat-stable enterotoxins of *E. coli* are plasmid mediated. LT stimulates adenylate cyclase in mucosal cells of the small intestine, which, in turn, activates cyclic adenosine monophosphate (cAMP); this causes secretion of fluid and electrolytes into the intestinal lumen and produces watery diarrhea. In contrast, heat-stable (ST) enterotoxins appear to activate guanylate cyclase.

Laboratory Diagnosis

The isolation of gram-negative bacilli from contaminated specimens is greatly facilitated by the use of differential and selective media (Table 57-9). Eosin methylene blue (EMB) and MacConkey's agar can be used interchangeably as minimally selective and differential media to initially select for and differentiate lactose-fermenting from non-lactose-fermenting gram-negative bacilli. XLD and HE agars are more selective differential media that are especially useful in selecting for *Salmonella* spp. and *Shigella* spp. in heavily contaminated specimens such as stool. Bismuth sulfite is a highly selective medium that is especially useful for the detection of salmonellae in endemics or epidemics. *Salmonella* spp. produce H_2S and are easily recognized by the production of colonies with black centers on XLD, HE, and bismuth sulfite agars. An enrichment medium, such as selenite-F or gram-negative (GN) broth, may be useful for detecting low numbers of *Salmonella* spp. and *Shigella* spp. in stool. Cefsulodin-irgasan-novobiocin (CIN) agar incubated at room temperature is selective and differential for the recovery of *Yersinia enterocolitica*. Colonies will appear as bull's-eyes with red centers and transparent borders. MacConkey's agar with sorbitol as the fermentable sugar is a differential medium that is capable of differentiating the sorbitol-fermentation-negative *E. coli* 0157:H7, which is associated with hemolytic-uremic syndrome from most other *E. coli* (Abbott, 2007; Nataro, 2007).

For some of the Enterobacteriaceae, a few simple colonial characteristics or biochemical reactions can be used to presumptively identify an isolate. For example, *Proteus* spp. swarm on blood agar, *Klebsiella* spp. form lactose-positive mucoid colonies, *Serratia marcescens* may produce a red pigment, *Salmonella* spp. produce H_2S , and *E. coli* is indole positive. Definitive identification of these and other species requires additional biochemical testing and/or molecular methods. Innumerable schemes based on the use of conventional biochemical media have been described for identification of the Enterobacteriaceae. Differential characteristics of the Enterobacteriaceae most commonly encountered in the clinical laboratory are shown in Table 57-10. Commercially prepared kits and automated devices are available and offer convenience and accuracy in identifying the vast majority of isolates belonging to the Enterobacteriaceae. In some instances, identification is accurately made in a few hours. Semiautomated systems may combine identification and antimicrobial susceptibility testing in a single disposable unit. In general, accuracy of identification among these systems is very high and comparable.

Classification of the Enterobacteriaceae has undergone considerable revision in recent years as the result of DNA hybridization and relatedness studies. Because phenotypic groupings on the basis of biochemical reactions are not always consistent with their DNA relatedness, the use of tribes (e.g., Klebsielleae, Proteae) for grouping species within the Enterobacteriaceae has been discontinued.

Historically, the genus *Salmonella* has been divided into the following species: *S. typhi*, *Salmonella paratyphi* A and B, *Salmonella choleraesuis*, *Salmonella typhimurium*, and *Salmonella enteritidis*. Because all groups have been found to be genetically very closely related, current terminology now recognizes only two species: *S. enterica* and *S. bongori* (rarely isolated from humans), each of which contains multiple subspecies. Six subspecies of *S. enterica* are known, with subspecies I (*S. enterica* subsp. *enterica*) as the usual human isolate. More than 2000 serotypes of *Salmonella* have been identified, most belonging in the subspecies *enterica*. Serotyping is based on immunologic reactivity of the heat-stable somatic "O" antigens, which are predominantly lipopolysaccharide in content, and the heat-labile

flagellar “H” antigens. In the United States, *Salmonella* serotypes *typhimurium* and *enteritidis* are the most common. *Salmonella* serotype *typhi* also produces a heat-labile capsular polysaccharide Vi antigen. In practice, most clinical laboratories identify isolates as *Salmonella* spp. based on biochemical reactions and use group-specific immunologic reagents to assign isolates to a specific serogroup. Commercial slide agglutination tests to differentiate large serogroups—A, B, C, and D—are useful in differentiating typhoidal salmonella from nontyphoidal strains. *S. serotype typhi* carries the D serogroup and Vi antigen. Further identification of the specific serotype is generally performed only by State Health Departments or other reference laboratories.

Isolates biochemically resembling *Shigella* are also classified by the reactivity of the “O” antigen, as are isolates of *E. coli* that are identified as potential causes of diarrhea and hemolytic-uremic syndrome. Such *E. coli* are classified by the type of toxin produced as well. Commercial kits are available to identify *E. coli* O157 and to detect some types of toxins in culture or stool specimens; however, this type of testing is often sent out to referral laboratories or the State Health Department. The CDC has recommended that all laboratories consider testing stool samples for the presence of shiga toxins I and II produced by certain strains of hemorrhagic *E. coli* (O157:H7 and other serotypes). Shiga toxin is also produced by *Shigella*, but the species is *S. dysenteriae*, which is not often seen in the United States. Serologic antigen tests are available and are widely used in clinical laboratories for this toxin (Nataro, 2007).

Antimicrobial Susceptibility

The susceptibility of Enterobacteriaceae to various antimicrobial agents is highly variable. Susceptibility to ampicillin was common among strains of *E. coli* and *P. mirabilis*, for example (although resistance in both has increased greatly over the past 10–15 years) but was not expected among most other clinically significant members of the Enterobacteriaceae. Resistance to first-generation cephalosporins (cefazolin, cephalothin) is expected for *Enterobacter* spp., *Serratia* spp., *Citrobacter* spp., *Proteus vulgaris*, *Providencia* spp., *Morganella* spp., and *Yersinia* spp.; susceptibility to third-generation cephalosporins (e.g., ceftriaxone, cefotaxime, ceftazidime) continues for many members of the Enterobacteriaceae. However, the presence of extended-spectrum β -lactamases and *Amp-C* genes, which are recognized by resistance of the bacteria to third-generation cephalosporins and all β -lactam antibiotics, except carbapenems, is increasing in selected strains of *E. coli*, *K. pneumoniae*, *P. mirabilis*, and others. Most Enterobacteriaceae are susceptible to aminoglycosides and fluoroquinolones. It had been very unusual for a member of the Enterobacteriaceae to be resistant to carbapenems (e.g., imipenem, meropenem, ertapenem, doripenem); however, in the late 1990s in a few U.S. states, isolates of *K. pneumoniae* were first recognized that produced a *bla*_{KPC} gene, resulting in production of carbapenemases that inactivate all carbapenems. These strains are often referred to as “KPCs” or *K. pneumoniae*-producing carbapenemases. These isolates are resistant to most classes of antibiotics, except for an aminoglycoside, colistin, and tigecycline. The spread of these KPC genes has been

rare, but it is feared that these will be introduced into *E. coli*, for example, which accounts for significant nosocomial infections.

Detection of carbapenem resistance may be difficult with some strains possessing this resistance, and a newer confirmatory test, the modified Hodge test, has been introduced into clinical laboratories for this purpose. A potential KPC is inoculated near a carbapenem antibiotic disk onto an agar plate, onto which a lawn of carbapenem-susceptible *E. coli* has first been placed. Inactivation of the carbapenem will result in a reduction in the zone size of *E. coli* near the disk in close proximity to the inoculated KPC if the test is positive. Ertapenem is a better marker for carbapenem resistance than is meropenem or imipenem, but resistance to one of these leads to resistance to all carbapenems (Endimiani, 2009, 2009a; Kitchel, 2009). Infection control procedures are essential to prevent the spread of these highly resistant strains.

Because the susceptibility pattern of the Enterobacteriaceae is unpredictable, as a general rule susceptibility testing should be performed if antimicrobial therapy is being considered. No susceptibility testing need be performed if antimicrobial therapy is not instituted, as is the case for uncomplicated enteric infection due to salmonella, for which therapy may actually prolong the carrier state, or when a mixed flora infection is present and individual susceptibilities may not be appropriate. Methods for performing susceptibility tests, including the modified Hodge test and confirmatory extended-spectrum ESBL tests, and interpretive criteria can be found in CLSI documents (CLSI, 2010).

Plesiomonas

Characteristics

Plesiomonas shigelloides, the only species in the genus *Plesiomonas*, is a facultatively anaerobic, oxidase- and catalase-positive, glucose-fermenting, gram-negative rod. Recent molecular genetic evidence demonstrates that the genus *Plesiomonas* is most closely related to the genus *Proteus*. Therefore, it has been placed into the Enterobacteriaceae family (Farmer, 2007) as the only oxidase-positive member of this group of gram-negative bacilli.

Clinical Manifestations and Pathogenesis

P. shigelloides is found in aquatic environments that are limited geographically by its minimum growth temperature of 8° C. It may be found in fresh and estuarine water, usually in tropical countries. It has been implicated as a cause of gastroenteritis, especially following the ingestion of uncooked shellfish. The diarrheal stool specimen frequently contains polymorphonuclear leukocytes and red blood cells, although a cholera-like illness may occur. Gastroenteritis may occur in sporadic cases, as well as in outbreaks. Extraintestinal manifestations of infection with *P. shigelloides* include meningitis, septicemia, cellulitis, arthritis, and endophthalmitis (Ampofo, 2001).

Relatively little is known as yet about virulence factors of *P. shigelloides*. The organism appears to have invasive properties, and some data suggest enterotoxigenic activity (Brenden, 1988; Abbott, 2007).

Figure 57-16 Gram stain of *Pseudomonas aeruginosa* in a sputum specimen. Note the longer, gram-negative bacilli compared with Figure 57-13.

Figure 57-17 Extracted pyocyanin pigment from *Pseudomonas aeruginosa*.

Laboratory Diagnosis

P. shigelloides can be isolated on a variety of nonselective and enteric-selective media, including HE agar. Acid production from lactose is variable, but on enteric media the organism usually appears to be a non-lactose fermenter. It is indole positive; reduces nitrates to nitrites; produces catalase; is methyl red positive; and ferments glucose, maltose, and trehalose (Brenden, 1988; Abbott, 2007).

Antimicrobial Susceptibility

P. shigelloides is susceptible to a variety of antimicrobial agents, including cephalosporins, trimethoprim-sulfamethoxazole, imipenem, and the quinolones (Abbott, 2007). Susceptibility to the penicillins is variable against the presence of a β -lactamase similar to that of *Aeromonas* spp.

GRAM-NEGATIVE BACTERIA—NONFERMENTATIVE BACILLI

A group of gram-negative bacilli that do not ferment glucose and other sugars are often lumped together under the heading of “nonfermenters.” They account for about 15% of the gram-negative bacilli isolated from hospitalized patients. Although many genera of nonfermenters are known, 75% of the clinically relevant ones are *Pseudomonas aeruginosa*; most of the remaining 25% are *Acinetobacter* spp., *Stenotrophomonas maltophilia*, or *Burkholderia cepacia*. As a group, they are environmental bacteria and are not usually found as part of the normal flora of the human body, except as colonizers in hospitalized patients. They can be readily isolated from water, soil, vegetables, plants, and hospital surfaces. Although no uniform biochemical characteristics have been noted, they are often oxidase-positive, lactose-negative colonies on selective media such as MacConkey’s agar (although some of the species do not grow on this media), and they are frequently resistant to many of the antibiotics that are effective against members of the Enterobacteriaceae. The four main species mentioned previously, as well as a few others, are discussed in this chapter.

Pseudomonas

Characteristics

The genus *Pseudomonas* has undergone extensive revision, and now many of the species that were previously classified in this genus have been reclassified into the genera *Burkholderia*, *Stenotrophomonas*, *Comamonas*, *Shewanella*, *Ralstonia*, *Methylobacterium*, *Sphingomonas*, *Acidovorax*, and *Brevundimonas*. Of the species that remain, *P. aeruginosa* is the most significant human pathogen. Figure 57-16 shows the Gram stain of *P. aeruginosa* in a sputum specimen.

Pseudomonads are strictly aerobic, catalase-positive, oxidase-positive, gram-negative bacilli. Their metabolism is respiratory and never fermentative, with oxygen as the terminal electron acceptor. Some pseudomonads are motile by means of polar flagella.

Clinical Manifestations and Pathogenesis

Pseudomonads are found in moist environments. Some of the more unusual habitats for these organisms include cosmetics, swimming pools,

hot tubs, and the inner soles of sneakers. The latter can lead to puncture wounds that are infected with *P. aeruginosa*. The species causing the greatest morbidity and mortality today is *P. aeruginosa*. Other species of *Pseudomonas*, although often isolated from clinical specimens, are only occasionally involved in disease.

P. aeruginosa is ubiquitous in the hospital environment, existing almost anywhere there is moisture, including medical equipment and disinfectant solutions and soaps. It is only rarely found as part of the normal flora of healthy people, but in hospitalized patients, the rates of colonization increase with the length of hospitalization. *P. aeruginosa* may produce serious infection in patients with burns and traumatic and operative wounds; following urinary tract manipulation; in patients with diseases of the hematopoietic, reticuloendothelial, and lymphoid systems; and in those with impaired cellular or humoral defenses. Pulmonary infection occurs commonly in patients with cystic fibrosis. The mortality rate is highest in severely leukopenic patients.

P. aeruginosa produces a slime polysaccharide, an endotoxin, and proteases that inactivate components of complement, thereby inhibiting to some degree opsonization and the inflammatory response, and perhaps contributing to its invasiveness. Exotoxin A promotes cellular damage and tissue invasion and is toxic for macrophages.

Laboratory Diagnosis

The presence of *P. aeruginosa* in cultures can often be suspected because of its musty grape-like (or corn tortilla) odor, the rough or ground glass appearance of its colonies on sheep blood agar, and the presence of one or both of two pigments: a “blue-green” fluorescent pigment (Fig. 57-17) and/or a metallic sheen caused by pyoverdine pigment. It can be identified easily with a positive oxidase reaction, an alkaline slant/neutral butt reaction in TSIA, growth at 42° C, and the formation of sheen and/or pigment on the slants of TSIA and *Pseudomonas* P agar. Additional tests are shown in Table 57-11. Tests of carbohydrate utilization should be carried out in O-F basal medium, which contains a minimal quantity of peptone and a relatively large quantity of carbohydrate, and so can allow detection of very small quantities of acid formed by this group of bacteria. Reactions are usually complete within 48 hours but may require as long as 7 days.

Antimicrobial Susceptibility

As a general rule, susceptibility testing should be performed for all clinically significant isolates of *P. aeruginosa*. Hospital strains of *P. aeruginosa* may be resistant to many classes of antibiotic. Isolates are often susceptible to the aminoglycosides, the carboxypenicillins and ureidopenicillins, ceftazidime or cefepime, carbapenems, and the quinolones. *P. aeruginosa* is always resistant to sulfamethoxazole-trimethoprim (SXT) and tetracyclines, including the newer broad-spectrum tigecycline, ertapenem, and nitrofurantoin. Multiple resistance to drugs to which *P. aeruginosa* was once susceptible is increasing, especially in intensive care units and among patients who have long-standing *Pseudomonas* infections, such as patients with cystic fibrosis and other chronic syndromes (Friedland, 2004; Hauser, 2005). Laboratories are being asked to test additional antibiotics, especially colistin or polymyxin B, when these resistant isolates are encountered. The CLSI has recently provided breakpoints for testing of polymyxin B that can be interpreted for polymyxin B or colistin (CLSI, 2009).

Acinetobacter

Characteristics

Organisms in this genus are short, rod shaped to spherical, nonmotile, oxidase negative, strictly aerobic, and gram negative. In a Gram-stained smear, they often appear in pairs and may be difficult to decolorize.

Clinical Manifestations and Pathogenesis

Acinetobacter spp. are found commonly in soil and water and uncommonly on the skin and mucous membranes of healthy people. Little is known about virulence factors in this group of organisms, but they do appear to form small amounts of endotoxin. Although usually nonpathogenic, they have been increasingly associated with nosocomial septicemia, pneumonia, bacteriuria, and wound infection.

Laboratory Diagnosis

Acinetobacter spp. can be distinguished readily from pseudomonads on the basis of their lack of motility, inability to reduce nitrates, and negative oxidase reaction. They may produce characteristic purplish colonies on MacConkey's agar. More than 25 species are known, but their differentiation biochemically is difficult, and they are often lumped together in the *Acinetobacter calcoaceticus*–*Acinetobacter baumannii* complex. The glucose-oxidizing (saccharolytic strains), nonhemolytic clinical strains are usually referred to as *A. baumannii*; nonsaccharolytic strains (non-glucose oxidizers) may be *Acinetobacter lwoffii* if nonhemolytic, or *Acinetobacter baemolyticus* if hemolytic (Schreckenberger, 2007). The most clinically relevant species is *A. baumannii*.

Antimicrobial Susceptibility

Acinetobacter spp. are resistant to most available β -lactam and aminoglycoside antibiotics. Resistance to the aminoglycosides is caused by plasmid-mediated acetyl-, adenyl-, and phosphotransferases. *Acinetobacter* spp. may be susceptible to doxycycline, trimethoprim-sulfamethoxazole, quinolones, ureidopenicillins, imipenem, ampicillin-sulbactam, and ceftazidime. The carbapenems (imipenem, meropenem, ertapenem, and doripenem) are considered the most active, but resistance rates up to 11% have been described in nosocomial strains throughout the United States (Gales, 2001). These isolates of carbapenem-resistant *A. baumannii* are often referred to as carbapenem-resistant *A. baumannii*; they are often resistant to all classes of antibiotics, except colistin and tigecycline (Perez, 2007, 2009). Appropriate infection control procedures are necessary to prevent their transmission (Rodríguez-Baño, 2009). Susceptibility testing should be performed for clinically significant isolates, usually upon the request of the clinician.

Burkholderia

Burkholderia spp. are aerobic, non-spore-forming, gram-negative rods; except for *Burkholderia mallei*, all are motile because they have polar flagella. These organisms are catalase positive, and most are oxidase positive. On MacConkey's agar, they produce lactose-negative colonies.

Clinical Significance and Pathogenesis

These organisms are found in the environment in water, in soil, and on plants. Because of their predilection for watery environments, some can

be found in the hospital environment and have the potential to cause nosocomially acquired infection.

Two important human pathogens in the genus *Burkholderia* are *Burkholderia pseudomallei* and *Burkholderia cepacia* complex. *B. pseudomallei*, which is acquired via inhalation or contact through cut or abraded skin, causes melioidosis. The infection can be asymptomatic, can become chronic, or can cause a fulminant sepsis. Melioidosis is most prevalent in southeast Asia and Australia but may occur in other tropical and subtropical environments.

B. cepacia, a nosocomial pathogen that is associated with contaminated equipment, medications, and disinfectants, can cause bacteremia, urinary tract infection, septic arthritis, and respiratory tract infection. It is an important pathogen in patients with cystic fibrosis (CF) and in those with chronic granulomatous disease. Patients with CF who become chronically infected with this organism have a decreased rate of survival. *B. cepacia* complex comprises at least nine species, and all species have been recovered from patients with CF. In the United States, however, $\approx 85\%$ of strains are *B. multivorans* or *B. cenocepacia*; *B. cenocepacia* has been shown in many studies to possess potent virulence factors that lead to increased mortality in CF patients who are infected with it versus other strains of *Burkholderia* (LiPuma, 2007).

Laboratory Diagnosis

Burkholderia species grow well on standard laboratory media, including blood and chocolate agar. Isolation of *B. cepacia* from contaminated specimens such as sputa may be made easier through the use of selective media (e.g., *Pseudomonas cepacia*, oxidative fermentative base, polymyxin B, bacitracin lactose agar, and *B. cepacia* selective agar) (Welch, 1987). A variety of different biochemical tests are needed to differentiate these organisms from one another (Kiska, 1996). No good biochemical methods are available to differentiate among the *B. cepacia* complex, or between the complex and related species such as *B. gladioli* and *Ralstonia*, *Cupriavidus*, and *Pandora* spp. Molecular techniques are often required for confirmatory identification and should be pursued when a *B. cepacia* complex organism is suspected. The CF Foundation (<http://www.cff.org>) has established a *B. cepacia* reference laboratory to confirm the identity of possible isolates in CF patients (LiPuma, 1999, 2007; Heath 2002).

Antimicrobial Susceptibility

The susceptibility of these organisms to antimicrobial agents varies considerably. *B. cepacia* is highly resistant to many antimicrobials but is usually susceptible to piperacillin, ceftazidime, chloramphenicol, and trimethoprim-sulfamethoxazole. Strains from CF patients who have been on repeated courses of antibiotics are likely to become resistant to these agents. The CLSI recommends reporting only ceftazidime, meropenem, minocycline, and trimethoprim-sulfamethoxazole for *B. cepacia* (CLSI, 2009). All *B. cepacia* organisms are intrinsically resistant to polymyxins (colistin).

Stenotrophomonas maltophilia

Characteristics

Stenotrophomonas maltophilia is a significant nosocomial pathogen. Risk factors for colonization or infection with this organism are mechanical

ventilation, use of broad-spectrum antibiotics, catheterization, and neutropenia.

Laboratory Diagnosis

Important distinguishing biochemical reactions of *S. maltophilia* are its negative oxidase reaction and positive DNase activity. Colonies grow on blood agar (lavender green colonies) and MacConkey's agar; the bacteria are nonmotile and nonfermentative.

Antimicrobial Susceptibility

S. maltophilia is inherently resistant to many antibiotics, in particular, the carbapenems. Trimethoprim-sulfamethoxazole is the antibiotic of choice, although some strains are resistant (Gales, 2001). CLSI recommends reporting only levofloxacin, trimethoprim-sulfamethoxazole, and minocycline. Breakpoints have been put forth for interpretation of these agents for MIC and disk diffusion testing (CLSI, 2009).

Other nonfermentative gram-negative bacilli include members of the genera *Alcaligenes*, *Achromobacter*, *Flavobacterium*, *Flavimonas*, *Chryseomonas*, *Acidovorax*, *Brevundimonas*, *Comamonas*, and *Ralstonia*, among others. These are infrequently isolated from clinical specimens, often when they may represent contamination or colonization. They can be considered as significant, especially when isolated from sterile sites, on multiple occasions in immunosuppressed patients or patients with foreign devices in place.

Vibrio

Characteristics

Vibrio spp. are facultatively anaerobic, oxidase-positive, short, curved, or straight gram-negative bacilli that are usually motile by means of polar flagella; they ferment carbohydrates and reduce nitrates to nitrites. Several species are medically important (Table 57-12).

Clinical Manifestations and Pathogenesis

Among the vibrios, *Vibrio vulnificus* causes the most severe disease. Wound infections and septicemia with this organism are often fatal. Disease is usually associated with consumption of raw oysters or oyster-related injury.

Preexisting hepatic disease is almost always present in serious illness. Decreased liver function results in increased available iron and appears to facilitate the growth of the organism.

Cholera toxin-producing *Vibrio cholerae* O1 is a well-known cause of epidemic cholera, which manifests itself by massive intestinal fluid loss and dehydration. The cholera toxin mediates this effect by binding to and activating the adenylate cyclase of cells in the small intestine, resulting in hypersecretion of electrolytes and water (Kaper, 1995). Non-O1 strains of *V. cholerae* cause a self-limited gastroenteritis but are not responsible for epidemics of disease. Nearly all non-O1 strains of *V. cholerae* do not produce cholera toxin but do produce two types of hemolysins and a heat-stable enterotoxin.

Vibrio mimicus and *Vibrio parahaemolyticus* primarily cause gastroenteritis. The mechanism of pathogenicity of *V. parahaemolyticus* appears to be related to invasiveness rather than to enterotoxin production. More than 95% of isolates of *V. parahaemolyticus* isolated from patients with gastroenteritis produce a cell-free hemolysin that is lethal to mice when injected in high doses and is described as the Kanagawa phenomenon. This halophilic organism is widely distributed in marine environments and has been found to contaminate fish and shellfish. Outbreaks of acute diarrheal disease following ingestion of contaminated food have been especially common in Japan but have also occurred in the United States and other countries (Abbott, 2007a).

Laboratory Diagnosis

Although formerly of concern only to U.S. travelers to endemic areas, cases of *V. cholerae* disease have been described in the United States in association with ingestion of contaminated shellfish from the Gulf Coast. In addition, gastroenteritis caused by *V. parahaemolyticus* and by other halophilic vibrios in contaminated shellfish has been described in many parts of the country, particularly in coastal areas. Thus it is important for clinical laboratories to have the capability to culture stool for *Vibrio* spp. when indicated on the basis of travel and dietary history.

With the exception of *V. cholerae* and *V. mimicus*, growth of this group of organisms requires media containing NaCl. Most solid and liquid media used for bacterial culture contain enough sodium that the use of special media in such instances is not necessary. Selective media containing

sucrose, such as thiosulfate citrate bile salts medium, are very useful for culturing stool specimens for *Vibrio* spp. Certain species (*V. cholerae* and *Vibrio alginolyticus*) ferment the sucrose and appear as yellow colonies on this medium. An enrichment medium, such as alkaline peptone water, may be used prior to subculture to solid medium to enhance recovery of *Vibrio* spp. from stool. *Vibrio* spp. can be differentiated among themselves and from other enteric gram-negative bacilli according to the reactions listed in Table 57-12. It may be necessary to carry out biochemical testing of the halophilic vibrios in media supplemented with 1%–3% NaCl. If TSEA and lysine iron agar are inoculated for screening purposes, their reactions will be acid slant/acid butt with no gas (A/A) or H₂S and alkaline slant/alkaline butt (K/K), respectively (Abbott, 2007a). Not all commercially available gram-negative identification systems are reliable for the identification of *Vibrio* spp.; they should be used only if they have proved accurate (O'Hara, 2003).

Antimicrobial Susceptibility

Antimicrobial susceptibility testing can be performed using the disk diffusion method with Mueller-Hinton agar, and broth microdilution using cation-adjusted Mueller-Hinton broth and incubation at 35° C for 16–18 hours. CLSI has established interpretive standards for *V. cholerae* tested with ampicillin, tetracycline, doxycycline, trimethoprim-sulfamethoxazole, chloramphenicol, and sulfonamides (CLSI, 2009). Interpretive standards have been put forth for the other *Vibrio* spp. in CLSI document M45-2A (CLSI, 2010).

Aeromonas

Characteristics

Members of this genus are facultatively anaerobic, oxidase- and catalase-positive, rod-shaped, gram-negative bacilli. They are usually motile by means of polar flagella, although some species may be nonmotile. They form acids from carbohydrates by respiratory and fermentative metabolism and reduce nitrates to nitrite.

Clinical Manifestations and Pathogenesis

Aeromonas spp. are mainly found in aquatic environments. They have been isolated from tap water, rivers, soil, and various foods, and are only rarely found in marine environments. These organisms have been associated with both intestinal and extraintestinal disease. Although no definitive evidence has demonstrated the role of *Aeromonas* spp. in GI disease, the presence of *Aeromonas* spp. in stool is more often associated with diarrhea than with an asymptomatic carrier state. Its role in producing diarrheal disease is possibly related to the production of an enterotoxin by some strains. A hemolysin and a cytopathic factor have also been described. *Aeromonas* spp. may cause infection of traumatically acquired wounds or septicemia in patients who are immunocompromised (Janda, 1994, 2010).

Laboratory Diagnosis

Isolation of a fermenting, oxidase-positive, gram-negative bacillus from an appropriate specimen should suggest the possibility of *Aeromonas* spp. Organisms grow readily on conventional laboratory media and produce colonies that resemble those of *Pseudomonas* spp., have a greenish, ground glass appearance, and have a fruity odor. Most species are β -hemolytic on blood agar. Isolation of *Aeromonas* spp. from stool specimens may be enhanced by inoculation of blood agar containing ampicillin or CIN medium. More than 18 species of *Aeromonas* are now recognized; *Aeromonas hydrophila* complex, *Aeromonas caviae* complex, and *Aeromonas veronii* complex are the most common isolates from human specimens. Esculin, Voges-Proskauer, gas from glucose fermentation, and l-arabinose are four biochemicals that can be used to separate *Aeromonas* spp. into one of these three complexes, but a more definitive identification would require conventional biochemicals in conjunction with molecular sequencing methods (Horneman, 2007).

Antimicrobial Susceptibility

Aeromonas spp. are susceptible to the quinolones, aminoglycosides, carbapenems, and trimethoprim-sulfamethoxazole but produce a β -lactamase that mediates resistance to the penicillins and first-generation cephalosporins (Horneman, 2007). Carbapenemases, although rare, may be difficult to detect by conventional susceptibility testing methods, including automated systems (Rossolini, 1996; Horneman, 2007). *Aeromonas* spp. have been found to maintain resistance plasmids of both the Enterobacteriaceae and *Pseudomonas* spp.

Figure 57-18 *Campylobacter jejuni* Gram stain: Note the comma-shaped appearance of the bacilli.

Campylobacter

Characteristics

Campylobacter spp. are small (0.5–8 μ m long \times 0.2–0.5 μ m wide), motile, non-spore-forming, curved (comma-shaped) or S-shaped gram-negative bacilli that grow optimally in an atmosphere containing 5%–10% oxygen and, therefore, are considered to be microaerophilic. Figure 57-18 shows the Gram stain of *Campylobacter jejuni* from culture. *C. jejuni* is the most common cause of bacterial enteritis in the United States. Other *Campylobacter* spp. associated with enteritis are *Campylobacter coli*, *Campylobacter lari*, and *Campylobacter upsaliensis*. *Campylobacter fetus* subsp. *fetus* is a cause of septic thrombophlebitis, arthritis, peritonitis, abscess, and pericarditis (Fitzgerald, 2007), especially in persons with an underlying chronic disease. *Arcobacter* are aerotolerant, *Campylobacter*-like, spiral-shaped bacteria that are frequently isolated from bovine and porcine products of abortion and feces of animals with enteritis (Fitzgerald, 2007). *A. butzleri* has been isolated from patients with bacteremia, endocarditis, diarrhea, and peritonitis. *A. cryerophilus* has been isolated from patients with bacteremia and diarrhea (Fitzgerald, 2007).

Clinical Manifestations and Pathogenesis

C. jejuni is found worldwide as a commensal of the GI tract of wild or domesticated cattle, sheep, swine, goats, dogs, cats, and fowl, especially turkeys and chickens. It is the most common cause of bacterial enteritis in the United States, with an estimated occurrence of 1000 cases per 100,000 individuals. The incidence of infection in the United Kingdom and in other developed nations is similar to that in the United States, and the incidence in underdeveloped countries is probably even higher. Infections generally occur in the summer and fall and are commonly the result of ingestion of improperly cooked foods, usually poultry. In addition, several outbreaks of *C. jejuni* enteritis have been linked to unpasteurized milk and to defects in municipal water systems. The spectrum of illness ranges from asymptomatic to severely ill. The diarrhea produced may be with or without blood or fecal leukocytes. Symptoms can last up to 1 week and generally are self-limited. Extraintestinal infections, including bacteremia, reactive arthritis, urinary tract infection, and meningitis, may also occur. *C. jejuni* is the most recognized antecedent cause of Guillain-Barré syndrome. The pathogenesis of this organism is not completely understood; it appears to first colonize the intestinal mucous layer and then is able to translocate through the epithelial surface to the underlying tissue (Fitzgerald, 2007).

The major habitat of *C. fetus* subsp. *fetus* is the intestine of sheep and cattle; it also may be found in the genital tract of these animals, their placentas, and the gastric contents of their aborted fetuses and, less frequently, in other animals and birds. The mechanisms of transmission of infection to humans are not understood completely. Direct contact with an infected animal is possible, but less than one third of infected individuals have a history of environmental or occupational exposure. Contaminated food or water may be a vehicle for infection, or infection may originate from an endogenous source.

Laboratory Diagnosis

A single stool specimen is generally adequate to detect enteric pathogens, including *Campylobacter* spp. Examination for fecal leukocytes is not recommended because they may be present in as few as 25% of cases. An enzyme immunoassay (EIA) is available for direct detection of *Campylobacter jejuni* and *Campylobacter coli* antigens in stool specimens (Tolcin, 2000; Dediste, 2003).

Several media can be used for the selective isolation of *Campylobacter* spp., including charcoal-cefoperazone-deoxycholate agar, charcoal-based selective medium, semisolid blood-free motility medium, Skirrow's medium, and *Campylobacter* agar with 5% sheep blood and five antimicrobials (cephalothin, trimethoprim, vancomycin, polymyxin B, and amphotericin B). Most *Campylobacter* spp. require a microaerobic environment (5% O₂, 10% CO₂, and 85% N₂), which can be produced using commercially available gas generator packs. The amount of oxygen in a candle jar is too little to support the growth of *Campylobacter* spp. and should not be used. Incubation of the plates at 42° C increases selectivity for *C. jejuni*.

If *Campylobacter* spp. are suspected in a blood culture based on clinical history or appearance of an organism on Gram stain, the broth should be subcultured to a nonselective blood agar plate and incubated at 37° C in a microaerobic environment.

In general, *Campylobacter* spp. produce gray, flat, irregular, spready colonies, which may become round, convex, and glistening as the moisture content in the media is reduced. A typical Gram stain appearance and a positive oxidase reaction from a colony growing on selective media at 42° C can be reported as *Campylobacter* spp. *C. jejuni* is able to hydrolyze hippurate and is susceptible to nalidixic acid and resistant to cephalothin. *C. coli* is hippuricase negative.

Strains of *C. fetus* subsp. *fetus* are resistant to nalidixic acid, fail to hydrolyze hippurate, and do not ordinarily grow at 42° C.

Antimicrobial Susceptibility

C. jejuni is variably susceptible to antimicrobial agents. Most are not susceptible to penicillins or cephalosporins. For intestinal infection, erythromycin is the drug of choice, with quinolones used as alternative therapy. Treatment often is not warranted, however, for simple gastroenteritis with *Campylobacter* sp. in an otherwise healthy individual. Resistance to both agents has been encountered. Currently, no standardized methods are used for susceptibility testing of this group of organisms; however, a CLSI document giving guidelines for testing is available (CLSI, 2010).

Helicobacter

Characteristics

Helicobacter spp. are spiral-shaped or curved, gram-negative, non-spore-forming bacilli, measuring 0.3–1.0 µm wide and 1.5–10 µm long. They are motile by multiple bipolar or monopolar flagella, are microaerobic, and have a respiratory metabolism.

Clinical Manifestations and Pathogenesis

Helicobacter spp. are found in the GI tracts of mammals and birds. Transmission from one host to another occurs through both oral–oral and fecal–oral routes. *Helicobacter pylori* is considered to be one of the “gastric” helicobacters. In the stomach, it lives within or beneath the mucous layer adjacent to the epithelium. It is also found transiently in the duodenum, saliva, and feces.

Infection with *H. pylori* may result in acute gastritis symptoms. Most infected patients develop chronic active gastritis, which may lead to nonulcer dyspepsia or duodenal ulcers. *H. pylori* has been associated with 90% of duodenal ulcers and nearly all gastric ulcers. Infection with *H. pylori* has also been associated with gastric carcinoma and gastric lymphoma (Parsonnet, 1994). The prevalence of gastritis associated with *H. pylori* increases with age, suggesting that the organism is acquired as people become older.

The “enteric” helicobacters, such as *Helicobacter* (formerly *Campylobacter*) *cinaedi* and *Helicobacter fennelliae*, have been implicated in cases of gastroenteritis. Rarely, these organisms may invade the bloodstream and be isolated from cultures of blood (Solnick, 2003).

Laboratory Diagnosis

Typically, nonculture methods have been utilized to diagnose *H. pylori* infection. One such test is the urea breath test. This is a noninvasive test that detects urease activity of *H. pylori* by measuring ¹⁴C- and ¹³C-labeled

Figure 57-19 Gram stain of a *Haemophilus influenzae* coccobacillus in a brain abscess.

CO₂ in the patient's expelled air after ingestion of labeled urea. Serologic assays are also widely used in symptomatic patients to detect antibodies against *H. pylori*; however, because most adults will have been exposed to *H. pylori*, this can be a nonspecific test, except as an epidemiologic or surveillance tool. In some cases, biopsies of the affected tissues are obtained and are examined histologically using the hematoxylin and eosin or Giemsa stain for the presence of organisms with morphology typical of *H. pylori*. Because the organism hydrolyzes urea very rapidly, a portion of the gastric biopsy may be placed directly into urea broth or onto urea-containing agar to detect urea hydrolysis in 1–24 hours (CLO test). A commercially available EIA for detection of *H. pylori* antigen in stool is a noninvasive alternative for diagnosis of *H. pylori* infection (Premier Platinum HpSA, Meridian Bioscience, Cincinnati). Sensitivity of this assay is as high as 89%, with specificities up to 95% (Masoero, 2000; Montiero, 2001). PCR has also been reported as a sensitive method for detection of *H. pylori* (Montiero, 2009).

If culture is requested, tissue specimens should be maintained at 4° C and processed within 2 hours of collection. Transport media include *Brucella* broth with 20% glycerol, cysteine Albemi broth with 20% glycerol, isotonic saline with 4% glucose, and Stuart's transport media. Processed specimens may be inoculated to one of several media, including brain-heart infusion, *Brucella*, Columbia, or Skirrow's supplemented with horse blood, horse serum, or sheep blood. Vancomycin, amphotericin, and cefsulodin are recommended to be added as selective agents. Inoculated media should be incubated in a microaerobic atmosphere (5%–10% CO₂, 80%–90% N₂, and 5%–10% O₂) under high humidity at 35° C for 5–7 days. Addition of 5%–8% H₂ in the atmosphere enhances growth of *H. pylori*, which generally produces small, gray, translucent colonies on these media, and is oxidase, catalase, and urease positive. Feces generally are not cultured for the enteric helicobacters. *Helicobacter* spp. will grow and will be detected by the automated blood culture systems used in many laboratories, but may require incubation for longer than the standard 5 days (Fox, 2007).

Antimicrobial Susceptibility

Multidrug regimens are used to treat *H. pylori* infection. These usually include two antibiotics (metronidazole, clarithromycin, tetracycline, or amoxicillin) and an “antacid” drug. Strains resistant to metronidazole and clarithromycin have been reported. For susceptibility testing, the CLSI recommends agar dilution using Mueller-Hinton agar plus 5% sheep blood (CLSI, 2010). Interpretive breakpoints are given only for clarithromycin.

Haemophilus

Characteristics

Members of the genus are oxidase-positive, facultatively anaerobic, small, gram-negative, pleomorphic rods or coccobacilli with a potential requirement for X (hemin) and/or V (NAD) factor. **Figure 57-19** shows an *H. influenzae* bacterium in a brain abscess specimen.

Figure 57-20 Note the pleomorphic nature of the *Haemophilus influenzae* seen in this Gram stain of cerebrospinal fluid.

Clinical Manifestations and Pathogenesis

Most *Haemophilus* spp. are normal inhabitants of the upper respiratory tract. Some may reside in the gastrointestinal or urogenital tract. Person-to-person spread occurs by respiratory droplets. Infections caused by *Haemophilus* spp. range from conjunctivitis and otitis media to meningitis and endocarditis. Those that are generally considered human pathogens are *H. influenzae*, *Haemophilus parainfluenzae*, *Haemophilus ducreyi*, and *Aggregatibacter* (*Haemophilus*) *aphrophilus* (Kilian, 2007).

The major virulence factor of *H. influenzae* is the polysaccharide capsule, of which there are six serotypes (a–f). Strains that do not possess a capsule are referred to as nontypeable. Endotoxin is not produced by *H. influenzae*, and this species is rapidly killed once ingested by macrophages unless antibody, complement, or the phagocytes are deficient. The role of antibodies in immunity is also poorly understood. Antibodies develop with age, presumably following natural infection with *H. influenzae* or with cross-reacting antigenic organisms, so that most persons older than 15 years have antibodies. Which antibodies are present and what level of those antibodies is protective remain unknown.

Since the introduction of a vaccine for *H. influenzae* type b in the mid 1980s, there has been a sharp drop in the incidence of invasive infection such as meningitis and epiglottitis due to this organism. Figure 57-20 demonstrates the pleomorphic nature of the *H. influenzae* seen in this CSF specimen. Nontypeable strains of *H. influenzae* are most frequently associated with acute otitis media and acute exacerbations of chronic bronchitis. *H. parainfluenzae* is usually a commensal in the upper respiratory tract but may also cause serious illness, such as endocarditis. *Aggregatibacter* (*Haemophilus*) *aphrophilus*, another upper respiratory tract commensal, can cause endocarditis, brain abscess, pneumonia, meningitis, and bacteriuria. *H. ducreyi* is responsible for the sexually transmitted disease chancroid (Kilian, 2007).

Laboratory Diagnosis

Isolation of *Haemophilus* spp. usually requires the presence of X and/or V factor in the culture medium. The former is most frequently supplied by the incorporation of heat-lysed (“chocolatized”) blood cells in agar, although it may also be provided by whole human, horse, or rabbit blood cells. NAD is commonly supplied by the incorporation of yeast extract or other appropriate supplements in the medium or by a suspension of staphylococci, which is streaked across the agar surface and about which satellite colonies of dependent strains of *Haemophilus* spp. grow. The differential characteristics of members of this genus are listed in Table 57-13.

Requirements for X and V factors are determined by absence or presence of growth on media containing these factors. An alternative method to test for X factor dependence is the porphyrin test described by Kilian, which determines the ability of dependent species to use δ -aminolevulinic acid in the biosynthesis of porphobilinogen and porphyrins. The formation of porphobilinogen can be detected by adding Kovac's reagent to the reaction mixture and observing the development of a red color in the aqueous phase. Alternatively, the formation of porphyrins in the reaction mixture can be demonstrated by red fluorescence under a Wood's lamp. Hemolytic properties of *Haemophilus* spp. can be determined on rabbit or horse blood agar.

Aggregatibacter (*Haemophilus*) *aphrophilus* must often be distinguished from species such as *Aggregatibacter* (*Actinobacillus*) *actinomycetemcomitans*, *Cardiobacterium hominis*, and *Eikenella corrodens* (Table 57-14), all of which have been associated with subacute bacterial endocarditis.

Cultivation of *H. ducreyi* from chancroid lesions is problematic. A Gram-stained smear of material from the lesion may be helpful if gram-negative bacilli in pairs or in rows (“schools of fish”) are seen. Figure 57-21 shows a “typical” Gram stain of *H. ducreyi* from clinical material. Material may be inoculated onto GC medium base plus 1% hemoglobin, 5%–10% fetal calf serum, 1% IsoVitalX (BBL Microbiology Systems), and 3 μ g/mL of vancomycin or Mueller-Hinton agar plus 5% horse blood, 1% cofactor-vitamin-amino acid enrichment, and 3 μ g/mL vancomycin.

Antimicrobial Susceptibility

Currently, the CLSI recommends testing *H. influenzae* isolated from blood or CSF against ampicillin, chloramphenicol, a third-generation cephalosporin, and meropenem (CLSI, 2009). Resistance to ampicillin may be as high as 60% in the United States, varying geographically. Resistance to ampicillin is usually mediated by the production of β -lactamase; however, rare isolates are resistant on the basis of alterations in outer membrane permeability or affinity to penicillin-binding proteins. Resistance to second- or third-generation cephalosporins has not been documented in the United States. Susceptibility testing of *H. influenzae* requires the use of *Haemophilus* test medium (HTM). The recommended treatment for *H. ducreyi* infection is erythromycin; alternative agents include azithromycin, ciprofloxacin, ceftriaxone, amoxicillin-clavulanate, and trimethoprim-sulfamethoxazole. Although not many data are available on the susceptibility of other *Haemophilus* spp. to antibiotics, resistance is assumed higher than among *H. influenzae* strains (Kilian, 2007).

GRAM-NEGATIVE BACTERIA—THE HACEK BACTERIA

Five small gram-negative coccobacilli are part of the normal oral flora and are associated occasionally with bacterial endocarditis and rarely with other

infections. They are opportunists that enter the bloodstream, settle on damaged heart valves, and cause a relatively slowly progressive, indolent form of endocarditis. They typically require an additional 1–2 days before they are isolated from blood cultures, and they are uniformly susceptible to many antimicrobial agents. The word HACEK is an acronym for the bacteria responsible for this disease: *Haemophilus* spp. (*influenzae*, *parainfluenzae*), *Aggregatibacter (Haemophilus) aphrophilus* (most commonly, *Aggregatibacter [Actinobacillus] actinomycetemcomitans*), *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella* spp. Some taxonomic changes have been noted more recently, and some of the HACEK members have been reassigned to the genus *Aggregatibacter* (Norskov-Lauritsen, 2006). Differential characteristics of the members of this group are listed in Table 57-14.

Haemophilus

H. influenzae and *H. parainfluenzae* were discussed earlier in this chapter. *Aggregatibacter (Haemophilus) aphrophilus* is also part of the HACEK group. It does not require X or V factor, hence can easily grow on blood and chocolate agars. It does not require CO₂ for growth. Along with causing endocarditis, *A. aphrophilus* has been reported in cases of endophthalmitis (following ophthalmic procedures), bacteremia, meningitis, brain abscess, cervical lymphadenitis, empyema, and a few other infectious syndromes. In one study, 39% of patients reported undergoing prior dental procedures before developing their *A. aphrophilus* infection (Huang, 2005). It is usually susceptible to β-lactam agents; successful treatment may require combination therapy with a β-lactam and an aminoglycoside.

Aggregatibacter (Actinobacillus)

Characteristics

A. actinomycetemcomitans is a gram-negative, non-spore-forming coccobacillus or short rod. It grows both aerobically and anaerobically. The addition of 5%–10% CO₂ enhances growth. Colonies on blood agar appear slowly and remain small. A description of “star-shaped” colonies has been given to their appearance on agar media.

Clinical Manifestations and Pathogenesis

Aggregatibacter organisms are found in the mucous membranes of the respiratory and genitourinary tracts of humans and animals. They generally cause disease only in immunocompromised individuals, or when they are accidentally introduced into healthy surrounding tissue, for example, by trauma. *A. actinomycetemcomitans* has a low level of pathogenicity. It derives its species name from its frequent association with actinomycotic lesions. In recent years, however, it has most frequently been reported as a cause of subacute bacterial endocarditis, periodontitis, and brain abscess. Two virulence factors are known: a leukotoxin and a collagenase.

Laboratory Diagnosis

A. actinomycetemcomitans grows on blood and chocolate agar. After 24–72 hours, colonies are 1–3 mm in diameter with a central wrinkling. The organism is catalase positive, oxidase negative or weakly positive, and urease negative (vonGraevenitz, 2007). Additional biochemical assays must be used to differentiate it from other slowly growing, somewhat fastidious gram-negative bacilli (see Table 57-14).

Antimicrobial Susceptibility

This organism is resistant to penicillin but is usually susceptible to many other antibiotics, including the cephalosporins, β-lactam–β-lactamase inhibitor combinations, fluoroquinolones, and tetracycline.

Cardiobacterium hominis

Characteristics

C. hominis is a gram-negative, non-spore-forming bacillus that is part of the normal oral flora. It is a facultative anaerobe that does not require CO₂, although growth is enhanced in microaerophilic conditions. Growth occurs on blood and chocolate agar but not on MacConkey's agar and is better at longer than 48 hours.

Clinical Manifestations and Pathogenesis

Cardiobacterium hominis can cause subacute bacterial endocarditis, similar to other HACEK members; it may also be responsible for cases of periodontitis and peritonitis (Bhan, 2006). The usual habitat of *C. hominis* is the upper respiratory tract, but it may also be found in the gastrointestinal and genitourinary tracts (vonGraevenitz, 2007).

Laboratory Diagnosis

Colonies at 48 hours' incubation are small and may have a yellow pigment, although most are white. The organism is generally oxidase and indole positive but negative for catalase, urease, esculin, and nitrate reduction. Acid may be produced from glucose, maltose, and sucrose (vonGraevenitz, 2007).

Antimicrobial Susceptibility

Isolates are usually susceptible to penicillins and cephalosporins, aminoglycosides, and tetracyclines. Resistance to clindamycin is common. β -Lactamases have been rarely reported (Lu, 2000).

Eikenella

Characteristics

Formerly classified as *Bacteroides corrodens*, the "corroding bacilli" that are facultatively anaerobic have been assigned to the species *Eikenella corrodens*. *E. corrodens* organisms are oxidase-positive, catalase-negative, nonfermentative, gram-negative bacilli, colonies of which may corrode or pit agar. Growth is enhanced by 5%–10% CO₂ and/or the presence of hemin (X factor) in the medium.

Clinical Manifestations and Pathogenesis

Little is known about factors contributing to the organism's virulence in human disease; it has a low level of pathogenicity for animals. *E. corrodens* resides predominantly in the oral cavity and is isolated frequently from the upper respiratory tract. Similar to other HACEK bacteria, it is responsible for subacute bacterial endocarditis. It has been recovered from abscesses, cellulitis, and wound infections, often following human bites. Infections are usually mixed with other organisms (vonGraevenitz, 2007).

Laboratory Diagnosis

Growth is observed on blood or chocolate agar but not on MacConkey's agar. The most striking features of *E. corrodens* in culture are the distinctive odor of bleach and the characteristic pitting of the agar; however, pitting does not occur with all strains. Colonies appear slowly (2–4 days) and are generally small (0.5–1.0 mm in diameter). *E. corrodens* must usually be distinguished from other fastidious, slowly growing gram-negative bacilli (see Table 57-14).

Antimicrobial Susceptibility

E. corrodens is susceptible to the penicillins, quinolones, and tetracycline, variably susceptible to aminoglycosides, and resistant to clindamycin and metronidazole. β -Lactamases have been described in clinical strains, but resistance can be overcome with the use of β -lactamase inhibitors in combination with β -lactam antibiotics (vonGraevenitz, 2007).

Kingella

Characteristics

Kingella has three recognized species: *K. kingae* (the HACEK species), *Kingella oralis*, and *Kingella denitrificans*. They are gram-negative rods to coccobacilli, requiring increased CO₂ for optimum growth. Colonies will grow on blood (β -hemolytic) and chocolate, but not on MacConkey's agar, after 2 days.

Clinical Manifestations and Pathogenesis

K. kingae is the most pathogenic of the three species. It is a member of the HACEK group, causing an indolent, slowly progressive endocarditis. In addition, it is associated with septic arthritis/osteomyelitis (usually in children younger than 4 years of age) (Yagupsky, 2004; Sena, 2009) and septicemia. *K. oralis* has been isolated from patients with periodontitis, but with unclear clinical relevance. *K. denitrificans* is a rare clinical isolate that can be associated with endocarditis (vonGraevenitz, 2007).

Laboratory Diagnosis

K. kingae is oxidase positive and nonmotile and produces acid from glucose, although in delayed fashion. Indole and catalase are negative.

Antimicrobial Susceptibility

K. kingae is susceptible to penicillin and most antibiotics to which other members of the HACEK group are susceptible. β -Lactamases have been described in clinical strains, but resistance can be overcome with the use of β -lactamase inhibitors in combination with β -lactam antibiotics (vonGraevenitz, 2007).

Figure 57-23 *Legionella pneumophila* faintly staining negative with Gram stain of pulmonary infiltrate.

MISCELLANEOUS GRAM-NEGATIVE BACILLI

Legionella

Characteristics

Legionella spp. are non-spore-forming, faintly staining, thin, gram-negative bacilli. *Legionella* spp. were first recognized to cause human disease during an epidemic of pneumonia that occurred among members of the Pennsylvania American Legion who had gathered in Philadelphia to celebrate the 1976 bicentennial. There are now more than 20 named species and a number of unnamed species. Most clinical cases have been due to *Legionella pneumophila*, serogroup 1. **Figure 57-22** demonstrates excellent staining of *Legionella* spp. with a Dieterle silver stain.

Clinical Manifestations and Pathogenesis

Legionella spp. are found in the environment in association with water. Growth within environmental protozoa is thought to be an important factor for survival of the organism in the environment. Transmission to humans occurs through exposure to contaminated water (e.g., faucets, shower heads, public fountains). Human-to-human infection and laboratory-acquired infections are not known to occur.

Infections can be subclinical, pulmonary, or extrapulmonary. Infection is usually manifested as an acute, fibrinopurulent pneumonia with lobular distribution. Histologically, there is an alveolar infiltrate of neutrophils and macrophages, accompanied by fibrin and red blood cell extravasation. *Legionella* spp. may be found within alveolar macrophages. **Figure 57-23** shows the Gram stain of sputum of a patient with *L. pneumophila* pneumonia. *L. pneumophila* has also been isolated from cultures of blood.

Figure 57-24 Gram stain of culture of *Legionella pneumophila*.

Laboratory Diagnosis

Legionella spp. may be isolated on BCYE agar supplemented with growth factors, including l-cystine, ferric salt, and α -ketoglutarate. This medium may be made selective for culture of nonsterile body sites by the addition of cefamandole, polymyxin B, and anisomycin or polymyxin B, anisomycin, and vancomycin (Edelstein, 1987, 2007). Chocolate agar may also support the growth of legionellae. Treatment of sputum with a weak acid (0.2M HCl/KCl pH 2.2) for 4 minutes or with heat (60°C) for 2 minutes may help to reduce contamination from other organisms but may reduce the number of legionellas as well.

Inoculated media should be incubated for at least 5 days in a humid atmosphere containing no more than 2%–5% CO₂. Colonies often appear iridescent and have a sticky consistency. Isolates with typical Gram stain morphology should be subcultured to blood agar, where no growth will be observed. These organisms may be weakly oxidase and catalase positive, are gelatinase positive, and often are motile. Identification of this organism is most accurately achieved using type-specific antibody assays or sequencing with appropriate primers. Figure 57-24 shows a Gram stain of *L. pneumophila* from culture.

Legionella spp. may be detected or identified by direct fluorescent antibody (DFA) staining of specimens or colonies in cultures. Sensitivity of direct DFA examination of respiratory specimens has ranged from 25%–75% but is considerably higher in open lung biopsies. However, use of this test has decreased because of the availability of more sensitive tests (e.g., the urine antigen assay, direct PCR methods). Cross-reactions in DFA assays have been reported between *L. pneumophila* and other *Legionella* spp., as well as with some strains of *Bordetella pertussis*, *Pseudomonas fluorescens*, and *Bacteroides fragilis*. Sensitivity of DFA for detection of other species than *L. pneumophila* in sputum is not known.

The urine antigen test for *L. pneumophila* serogroup 1 has a reported sensitivity of 80%–90%, although it should be noted that antigenuria may persist for many months following infection. Use of the urinary antigen test within and outside of the intensive care unit has been shown to have a positive impact on patient cases (Garbino, 2004; Edelstein, 2007).

The diagnosis of legionellosis can also be established serologically by detecting a fourfold or greater rise in antibody titer to at least 1:128. A single antibody titer of 1:256 is presumptive evidence of past infection. The sensitivity of serologic diagnosis for disease caused by species other than *L. pneumophila* serogroup 1 is not known, and the specificity of antibody tests for disease caused by other species is less than that of *L. pneumophila* serogroup 1. PCR assays for direct detection of *Legionella* spp. in clinical specimens and for sequencing identification of cultured isolates have been developed. Sensitivities of 64%–100% and specificities of 88%–100% have been reported (Edelstein, 2007). Use of these assays can provide more rapid results, especially when used in direct specimen testing; in addition, identification of species other than *L. pneumophila*, which is not possible with DFA and serology, could increase the demand for such assays. PCR for *Legionella* spp. directly in clinical samples will be performed most often in the future, as assays become cleared for clinical laboratory testing to enhance recovery or in assays in which other respiratory pathogens can be simultaneously searched for (Khanna, 2005).

Antimicrobial Susceptibility

Because of the intracellular nature of *Legionella* spp. in clinical infection, in vitro susceptibility test results do not predict the clinical response of antibiotics. Susceptibility testing should not be performed. Therapy generally consists of a macrolide (clarithromycin and azithromycin are as efficacious and result in fewer side effects than erythromycin), or a fluoroquinolone alone or in combination. Other agents that have been used include trimethoprim-sulfamethoxazole, rifampin, or a tetracycline (Edelstein, 2007; Valve, 2009). No β -lactam antibiotic has acceptable intracellular activity against *L. pneumophila*. Macrolides and fluoroquinolones should always be efficacious against infection with *Legionella micdadei*, *longbeachae*, *bozemaniae*, or *dumoffi* (Muder, 2002).

Bordetella

Characteristics

Bordetella spp. are strictly aerobic, nonfermentative, catalase-positive, minute coccobacilli requiring nicotinic acid, cysteine, and usually methionine, but not X or V factor, for growth. Phase variation from smooth virulent strains to rough avirulent strains occurs after cultivation on artificial media.

Clinical Manifestations and Pathogenesis

Bordetella spp. are found in the respiratory tracts of warm-blooded animals. *Bordetella bronchiseptica* primarily causes kennel cough in dogs, although it may rarely cause pertussis-like symptoms in immunocompromised human hosts. *Bordetella parapertussis*, which infects both humans and lambs, is an uncommon human pathogen. Infection may be asymptomatic or may cause a pertussis-like illness, most frequently bronchitis. *B. pertussis*, the etiologic agent of whooping cough, causes disease only in humans.

B. pertussis, *B. parapertussis*, and *B. bronchiseptica* produce a number of virulence factors. *B. pertussis* produces toxins including pertussis toxin (PT), an exotoxin that is involved in colonization of the respiratory tract and establishment of the infection with *B. pertussis* and a virulence factor that inhibits intracellular signal transduction factors by transferring adenosine diphosphate ribose to G-proteins of cells; adenylate cyclase toxin, which inhibits immune effector and other cell functions by creating a high intracellular level of cyclic adenosine 3',5'-phosphate; and tracheal cytotoxin, which causes cell ciliostasis and cell death. *B. pertussis* virulence factors also include substances that mediate adherence to ciliated epithelial cells; these include PT, filamentous hemagglutinin (FHA), pertactin, and fimbriae.

It is thought that in a pertussis infection, the organism first attaches to the ciliated epithelium of the respiratory tract and immune effector cells by means of fimbriae, FHA, PT, and pertactin. PT and adenylate cyclase toxin work together to inhibit the host's immune system, and tracheal cytotoxin damages the respiratory epithelium. Results may include inflammation and epithelial necrosis; leukocytosis and lymphocytosis; accumulation of secretions; cough; and ultimately bronchopneumonia, hypoxic episodes, and encephalopathy (Xu, 2009).

B. pertussis contains a protective antigen that when combined with antibody abolishes its infectivity. It appears, however, that both cellular immunity and humoral immunity are needed to eradicate the organism. *B. parapertussis* and *B. bronchiseptica* can produce pertactin and FHA. They also possess promoter and structural genes for PT, but these are not expressed (Mattoo, 2005).

Laboratory Diagnosis

The rate of isolation of *B. pertussis* from patients declines with the duration of illness. The most commonly recommended specimen is the nasopharyngeal swab; however, nasopharyngeal aspirates collected with a soft rubber catheter have provided higher rates of isolation in some people's hands. A more invasive specimen such as fluid collected by bronchoalveolar lavage may also be cultured. In general, swabs or aspirates should be inoculated onto suitable media, such as Regan-Lowe agar or Bordet-Gengou medium, as quickly as possible after collection. For shipment to reference laboratories, the inoculated medium should be incubated for at least 24 hours in ambient air at 35°C prior to transport to allow some initial growth of the organism.

Direct examination of smears stained with fluorescein-conjugated *B. pertussis* monoclonal or polyclonal antiserum may provide a rapid diagnosis; however, DFA assays suffer from low sensitivity (30%–71%) and low specificity. Results of DFA should be considered presumptive only and should be used as an adjunct to culture or PCR (Loeffelholz, 2007). Direct

detection of *B. pertussis* in clinical specimens by means of PCR is quickly replacing DFA in many laboratories and is rapidly becoming the primary method for detection of *B. pertussis*. As more commercial products become available, the reproducibility of results between laboratories should improve (Khanna, 2005). PCR test results, however, may remain positive longer than results obtained with culture or DFA, even with appropriate antimicrobial therapy. PCR methods for the direct detection of *B. parapertussis* in clinical specimens are also available (Dragsted, 2004), and consideration should be given to use of a PCR, which can detect both organisms, because in some outbreaks, a significant cause of whooping cough is actually *B. parapertussis* (Loeffelholz, 2007). However, reports have described PCR misidentifying *B. bronchiseptica* as *B. pertussis* when the pertactin gene was the target of the PCR assay (Register 2007).

Culture for *B. pertussis* provides the most specific diagnosis of whooping cough and enables a laboratory to perform susceptibility testing and/or genotypic analysis if required. Cultures, however, are not the most sensitive means of recovering *B. pertussis* from respiratory specimens. Cultures, when done, should be incubated in ambient air in a humid environment at 35°C. Incubation in a CO₂ incubator may slow the growth of *B. pertussis*. Colonies may not be visible for 3–4 days, and cultures should be held for 7–12 days before they are discarded as negative (Loeffelholz, 2007). Colonies of *B. pertussis* are small, smooth, round, and shiny and may have the appearance of a drop of mercury. Organisms with typical colony morphology and Gram stain appearance should be subcultured to blood agar to verify the absence of growth on this medium. Positive catalase and oxidase reactions and negative urease can be used for presumptive identification of an organism as *B. pertussis*. *B. parapertussis* grows more rapidly and will grow on blood agar and occasionally on MacConkey's agar. Colonies are oxidase negative and catalase and urease positive. *B. bronchiseptica* grows well on both blood and MacConkey's agars and is the most biochemically active of the three. It is catalase, oxidase, urease, and nitrate reduction positive. *B. holmseii* has been described more recently in the genus, not as a cause of whooping cough, but rather in association with bacteremia, endocarditis, and respiratory illness in immunocompromised patients, especially in asplenic patients (Shepard, 2004). *B. holmseii* will grow well on blood agar, and its appearance on MacConkey's agar may be delayed. It is negative for oxidase, nitrate reduction, and urease. Other *Bordetella* spp., including *B. binzii*, *B. trematum*, and *B. avium*, grow on both blood agar and MacConkey's agar and are motile, unlike all other members of the genus (Loeffelholz, 2007).

Serologic diagnostic methods for *B. pertussis* are usually used to detect immune response; EIA is the method of choice. Demonstration of seroconversion or a significant rise in concentration of IgG against PT is thought to be the most sensitive and specific test. In a recent study comparing culture, PCR, and serology for diagnosis of pertussis, if a minimum of two antigens to *B. pertussis* (IgG, IgA, or IgM) were obtained in both acute and convalescent sera, serology was found to be as sensitive as PCR, and both were more sensitive than culture (Cengiz, 2009).

Antimicrobial Susceptibility

Antimicrobial agents probably play no role in the therapy of pertussis, but nasopharyngeal cultures become negative after 1–2 days of treatment, which may prevent bacterial complications in patients with the disease and may be effective in preventing spread of the disease to nonimmune contacts. Susceptibility testing is not indicated for *B. pertussis*, and methods are not standardized. A macrolide (erythromycin, azithromycin, or clarithromycin) is the drug of choice for treatment and prophylaxis; trimethoprim-sulfamethoxazole (SXT) is an acceptable alternative in patients with macrolide intolerance and in those in whom the isolate is resistant to the macrolides, which occurs very rarely (Loeffelholz, 2007).

Vaccination against *B. pertussis* provides a good tool in the prevention of whooping cough, although immunity to disease or vaccination is said to wane after 5–12 years. Older children and adults have thus become a reservoir of the organism (Guiso, 2009).

Brucella

Characteristics

Brucella spp. are small, gram-negative coccobacillary organisms (0.5–0.7 µm × 0.6–1.5 µm). In smears, they occur predominantly as single coccobacilli, but they may occur in pairs or in short chains. They have been described as having the appearance of sand. They are nonmotile, strictly aerobic, catalase- and usually oxidase-positive organisms. They are nonfermenters. Growth in the laboratory is often enhanced by the presence of 5%–10% CO₂ and requires complex media, which are improved by the addition of

blood or serum. Of the recognized species, *Brucella melitensis*, *Brucella abortus*, *Brucella suis*, and *Brucella canis* are human pathogens, although *B. canis* has reduced virulence for humans as compared with other species. *B. ovis* is a pathogen of sheep, and *B. neotomae* has been isolated from the desert wood rat. All species hydrolyze urea, except *B. ovis*, and this remains a significant characteristic of the genus (Lindquist, 2007).

Clinical Manifestations and Pathogenesis

Brucella spp. are intracellular bacteria that infect a wide range of animal species (including humans) and have been found in some insects and ticks. They are important veterinary and human pathogens. Preferential hosts are sheep and goats for *B. melitensis*, cattle for *B. abortus*, swine for *B. suis*, and dogs for *B. canis*; however, each species may occasionally infect other animals. Humans become infected by inhalation of the organism; by direct contact with infected material, including animal carcasses, fetal membranes, vaginal discharge, fetuses, skin, or mucous membranes; or by ingestion of unpasteurized milk or milk products from infected animals. Approximately 100 cases of human brucellosis are reported per year in the United States. A common risk factor is consumption of imported cheese made from unpasteurized goat's milk.

Local lymphadenopathy often occurs with dissemination and secondary localization in the reticuloendothelial system and formation of granulomas in the liver, spleen, bone, genitourinary tract, lungs, and soft tissues. Organisms may be seen within phagocytes. Signs and symptoms are often variable and nonspecific, with chills, fever, sweats, and anorexia occurring frequently. The fever is characteristically diurnal ("undulant").

Laboratory Diagnosis

Brucella spp. are recovered most often from blood and bone marrow and less often from material obtained from spleen and liver abscesses. The organism grows on standard laboratory media, including *Brucella*, blood, chocolate, and trypticase soy agar. Some strains will grow on MacConkey's agar. *Brucella* spp. will grow in media used for culturing blood specimens. Many references recommend incubating blood cultures for at least 21 days with blind subculture performed early and late in the incubation period; however, these recommendations may not be necessary with newer automated blood culture systems, some of which have been shown to reliably recover *Brucella* spp. in 5 days or less without blind subculture (Lindquist, 2007; Yagupsky, 1997). *Brucella* spp. are recognized as Class A bioterrorism organisms, and as such should be handled only in public health laboratories and/or by the CDC. Identification and testing of this organism are described here for completeness but should not be performed in sentinel laboratories, which include most hospital laboratories.

Solid media should be incubated in an atmosphere containing 5%–10% CO₂. These organisms grow slowly, and even after 48 hours of incubation, colonies may be difficult to see. Organisms can be presumptively identified as *Brucella* spp. based on a characteristic Gram stain appearance and may be positive for catalase, oxidase, and urease. Urease activity is manifested rapidly (about 15 minutes) by *B. suis* and more slowly (2–24 hours) by *B. melitensis* and *B. abortus*. Because brucellosis can be laboratory acquired, laboratory personnel should be notified if this organism is suspected, and all manipulations of possible *Brucella* spp. should be conducted in a biological safety cabinet (Lindquist, 2007).

Identification of *Brucella* spp. to the species level requires tests for CO₂ requirement, H₂S production, urea hydrolysis, dye sensitivity, and phage sensitivity. Most hospital laboratories refer this testing to State Health Departments or other reference laboratories. Molecular tools such as PCR will probably become more effective means of detecting cases of brucellosis in the future (Queipo-Ortuno, 2005).

The diagnosis of brucellosis can be made serologically. A minimum titer of 1:160 in a standard tube agglutination test is suggestive of the diagnosis; however, evidence of recent brucellosis can be accepted only when a fourfold or greater rise in titer occurs during the first month or two of illness. Prozone effects can occur in patients with titers as high as 1:640, so that all sera from patients with suspected disease should be diluted to at least 1:1280. Cross-reactivity with *Francisella tularensis* and with *V. cholerae*, including cholera vaccination, may occur (Lindquist, 2007).

Antimicrobial Susceptibility

Treatment consists of combinations of tetracycline, aminoglycosides, rifampin, and trimethoprim-sulfamethoxazole for prolonged periods. Although treatment failures do occur, they are not due to antimicrobial resistance, and susceptibility testing is not recommended (Lindquist, 2007).

Pasteurella

Characteristics

Pasteurellae are facultatively anaerobic, oxidase- and catalase-positive, nonmotile, gram-negative bacteria that range morphologically from coccobacilli to long filamentous rods. Of the eight species known to infect humans (*Pasteurella multocida*, *Pasteurella bettyae*, *Pasteurella canis*, *Pasteurella dagmatis*, *Pasteurella stomatis*, *Pasteurella pneumotropica*, *Pasteurella haemolytica*, *Pasteurella aerogenes*), *P. multocida* is the most important human pathogen. *Pasteurella* spp. are phenotypically similar to the *Actinobacillus* spp., and DNA–DNA hybridization studies and comparisons of 16S rRNA have shown that *P. pneumotropica*, *P. haemolytica*, and *P. aerogenes* are more closely related to the genus *Actinobacillus* than to the genus *Pasteurella*.

Clinical Manifestations and Pathogenesis

Pasteurella spp., especially *P. multocida*, may be found as commensals in the upper respiratory tracts of fowl and mammals and are frequently isolated from animal bite or scratch wounds. Cat bites more often become infected than dog bites. Local infections can become systemic, and a number of reports have described septicemia, osteomyelitis, and meningitis. Pasteurellae have been associated with respiratory tract infections, including sinusitis, peritonsillar abscess, mastoiditis, pulmonary abscess, pneumonia, empyema, bronchitis, and bronchiectasis, usually in patients with chronic pulmonary disease (vonGraevenitz, 2007).

Laboratory Diagnosis

Pasteurellae grow well on blood agar and are only rarely able to grow on gram-negative differential media, such as EMB or MacConkey's agar. The finding of a gram-negative bacillus that grows on blood agar only and is oxidase and indole positive and ortho-Nitrophenyl- β -galactoside (ONPG) negative provides strong presumptive evidence for the isolation of *P. multocida*, the most frequently encountered species. In addition, susceptibility to penicillin, as evidenced by a wide zone of inhibition around a penicillin disk on a blood agar plate, is good evidence that the isolate is *P. multocida*.

Antimicrobial Susceptibility

Resistance to antimicrobial agents is rarely seen in human isolates. Pasteurellae are usually susceptible to penicillin and tetracycline and many other antibiotics. Penicillin is the therapeutic drug of choice. Rare strains of *P. multocida* have produced β -lactamase, but the combination of a β -lactam with a β -lactamase inhibitor drug should be effective (vonGraevenitz, 2007).

Francisella

Characteristics

F. tularensis is a very small, strictly aerobic, coccoid to pleomorphic rod-shaped, gram-negative bacillus that requires cystine or cysteine for growth. Faint bipolar staining occurs with aniline dyes.

Clinical Manifestations and Pathogenesis

F. tularensis is found in both wild and domesticated animals, birds, arthropods, water, mud, and animal feces. The primary reservoir for this organism is the cottontail rabbit. Transmission to humans occurs through tick bite, direct cutaneous inoculation from an infected animal, conjunctival inoculation, inhalation, or ingestion of undercooked infected animal meat or contaminated water. Several forms of the disease occur, including ulceroglandular, glandular, oculoglandular, oropharyngeal, intestinal, pneumonic, and typhoidal. Approximately 100–200 cases of tularemia are reported each year in the United States. *F. tularensis* is considered to be one of the class A agents of bioterrorism; because of this, workup of suspected cases is limited to approved laboratories. Most clinical laboratories are considered sentinel laboratories, and if *F. tularensis* is suspected, isolates should be sent to State Health Departments or other selected laboratories (Lindquist, 2007).

Tularemia manifests in various forms after an incubation period of 1–10 days. Headache, fever, chills, vomiting, and myalgias characteristically occur at the onset. In ulceroglandular disease, lymphadenitis and lymphadenopathy occur in the region draining the primary lesion. The lesion is initially papular and is later ulcerative. Oculoglandular disease is characterized by inflammation of the conjunctiva and usually a papule of the lower lid with lymphadenitis of the preauricular, parotid, submaxillary, and anterior cervical nodes. The intestinal form of tularemia is characterized by ulcerative lesions of the mouth, throat, and upper gastrointestinal tract.

Virulence appears to be related to a smooth colonial morphology. Repeated subcultures result in alteration from smooth to rough colonies, with concomitant loss of virulence. Highly virulent strains for humans have citrulline ureidase activity and ferment glycerol, and are most often associated with tick-borne disease in rabbits. Toxins have not been recognized.

Tularemia should be suspected in anyone who has been in an endemic area, has had contact with wild animals or livestock, has a history of tick bite, has been engaged in farming operations, has drunk impure water, or has been exposed to cultures or infected animals in the laboratory. Trappers, hunters, fur and meat industry workers, agricultural workers, and laboratory personnel are at greatest risk. Because of its protean manifestations, tularemia is readily confused with many other diseases, such as brucellosis, anthrax, sporotrichosis, typhoid fever, tuberculosis, histoplasmosis, and syphilis.

Laboratory Diagnosis

Material suitable for examination includes fluid or curettings from the primary lesion, aspirates of enlarged regional nodes, sputum, pharyngeal washes, and gastric aspirates. Bacterial isolation is difficult because the organism has special growth requirements and grows slowly, allowing for overgrowth of other organisms present in the specimen. The organism grows on glucose–cysteine agar supplemented with 5% defibrinated rabbit blood, chocolate agar with IsoVitalX, or BCYE agar. Some isolates may even grow on blood agar or trypticase soy agar. If clinical material is contaminated by other organisms, penicillin, polymyxin B, and cycloheximide can be added to inhibit their growth. Special care must be exercised in handling infected material to prevent aerosolization or direct contact with the skin. Clinicians should always notify laboratory personnel if *F. tularensis* is suspected, so that proper precautions can be taken to prevent exposure to this organism (Lindquist, 2007).

Cultures are incubated at 35°C with or without added CO₂. Colonies usually appear within 2–4 days and are blue-gray to white, round, smooth, and slightly mucoid. On blood-containing agar, a small zone of α -hemolysis may be seen. Because working with the organism in the laboratory is dangerous, suspected isolates should be sent to a reference laboratory such as the CDC for confirmation with a slide agglutination or direct fluorescent antibody test.

The diagnosis of *F. tularensis* can be established serologically. Agglutination titers as low as 1:40 in the absence of previous disease are diagnostic and may rise within the first 3 weeks to a level of 1:640 or greater. *Brucella* agglutinins may also rise nonspecifically, but usually to a considerably lower level (Johansson, 2004; Lindquist, 2007).

Antimicrobial Susceptibility

Streptomycin is bactericidal, and the tetracyclines and chloramphenicol are bacteriostatic to *F. tularensis*. Because relapses may occur after treatment with bacteriostatic agents, streptomycin is the agent of choice.

Gardnerella

Characteristics

Gardnerella vaginalis is a thin, gram-variable rod or coccobacillus. Over the years, this organism, in its association with bacterial vaginosis, has been called *Haemophilus vaginalis* and *Corynebacterium vaginale*, further demonstrating its gram-variable appearance. Catalase is not produced, and cells are nonmotile. Growth is best observed after 48 hours of incubation in a 5% CO₂-enriched atmosphere. Colonies are small and exhibit β -hemolysis on media containing rabbit or human blood.

Clinical Manifestations and Pathogenesis

This organism is associated with bacterial vaginosis but is not the cause. It has been found in the blood of patients with postpartum fever and can cause infection in newborns. *G. vaginalis* is a part of the anorectal flora of healthy adults of both sexes, as well as of children. It is part of the endogenous vaginal flora of women of reproductive age.

Laboratory Diagnosis

Diagnosis of bacterial vaginosis does not require culture. The diagnosis is made by direct examination of vaginal secretions for the presence of clue cells (epithelial cells covered with bacteria on the cell margins) and small gram-negative rods and coccobacilli, the absence of lactobacilli (gram-positive thin rods), a pH greater than 4.5, and a fishy amine odor after addition of 10% potassium hydroxide (KOH) to the secretions. A scored Gram stain is the laboratory test that should be performed when vaginal discharge is submitted for the diagnosis of bacterial vaginosis (Nugent,

Figure 57-25 Blood smear positive for *Capnocytophaga canimorsus* in patient with septicemia (Wright's stain).

1991). Alternatively, a nucleic acid probe (Affirm, Becton Dickinson Microbiology Systems, Sparks, MD) is available that tests for a high concentration of *G. vaginalis* as a marker for bacterial vaginosis (Briselden, 1994). When observed in culture, the organism is presumptively identified based on hemolysis on human blood bilayer Tween agar after 48 hours of incubation (Funke, 2007).

Antimicrobial Susceptibility

Susceptibility testing of *G. vaginalis* is not recommended, and no guidelines exist for performing this testing. Metronidazole is the drug of choice for bacterial vaginosis. Systemic infection due to *G. vaginalis* may be treated with ampicillin because this organism has not been found to produce β -lactamase (Funke, 2007).

Capnocytophaga

Capnocytophaga is a genus of gram-negative, facultatively anaerobic, gram-negative rods to filamentous bacteria. Species include *Capnocytophaga ochraceus*, *Capnocytophaga canimorsus* (formerly DF-2), *Capnocytophaga gingivalis*, and *Capnocytophaga sputigena*, among others. *C. canimorsus* is part of the oral flora of dogs and cats; the others can be found as part of normal human oral flora.

Clinical Manifestations and Pathogenesis

C. ochraceus can cause transient bacteremia or endocarditis in immunocompromised and immunocompetent patients (vonGraevenitz, 2007). It also has been associated with periodontitis. *C. canimorsus* is a cause of a fatal septicemia following wound infection subsequent to the bite of dogs or cats. Patients with this fatal septicemia have predisposing factors of a prior splenectomy or alcoholism (Oehler, 2009). Meningitis, endocarditis, arthritis, and eye infection have also been documented with *C. canimorsus* (Gasch, 2009). **Figure 57-25** shows a Wright's stain of *C. canimorsus* seen on the blood film of patient with *C. canimorsus* septicemia. Note the intracellular nature of the bacilli.

Isolation of *Capnocytophaga* spp. requires inoculation of blood or chocolate agar and incubation in a 5%–10% CO₂ environment, generally for longer than 24 hours. Colonies are usually slightly pigmented yellow or orange and may spread because of a “sliding” motility. Gram stains often show long, thin, spindle-shaped cells, almost fusiform in appearance. **Figure 57-26** shows the Gram stain of *C. ochraceus*, demonstrating the fusiform bacilli. *C. ochraceus* is oxidase and catalase negative; *C. canimorsus* is oxidase and catalase positive. *Capnocytophaga* spp. are usually susceptible to many antibiotics, including β -lactams, macrolides, tetracycline, clindamycin, and quinolones. They are resistant to the aminoglycosides. Occasional β -lactamases have been described in this genus, although response to β -lactam/ β -lactamase inhibitor combinations has been good (Jolivet-Gougeon, 2000; vonGraevenitz, 2007).

Calymmatobacterium

Characteristics

Calymmatobacterium granulomatis is a gram-negative, nonmotile, encapsulated, pleomorphic rod that may be cultured in yolk sacs or on fresh egg yolk medium. The organism possesses antigenic and molecular

Figure 57-26 Gram stain of *Capnocytophaga ochraceus*. Note the fusiform bacilli.

determinants similar to those of *Klebsiella* spp., leading taxonomists to now classify it among the Enterobacteriaceae as *Klebsiella granulomatis* (Abbott, 2007).

Clinical Manifestations and Pathogenesis

The organism does not produce disease in animals. In humans, it causes granuloma inguinale (donovanosis), characterized by ulcerogranulomatous lesions of the skin and mucosa of the genital and inguinal areas (Rashid, 2006).

Laboratory Diagnosis

A fragment of tissue removed from the margin of an ulcer is pressed and rubbed against a glass slide and stained with Wright's or Giemsa stain. The finding of small, straight or curved, pleomorphic rods with rounded ends and characteristic polar granules, giving a “safety pin” appearance within mononuclear cells, is the most effective way of establishing the diagnosis. *K. granulomatis* does not grow on routine culture media (Abbott, 2007).

Antimicrobial Susceptibility

The tetracyclines, erythromycin, ampicillin, and chloramphenicol are active against *C. granulomatis*. Resistance may develop to streptomycin.

Streptobacillus

Characteristics

Streptobacillus is a facultatively anaerobic, fermentative, nonencapsulated, and nonmotile pleomorphic gram-negative rod, frequently occurring in chains or long filaments, and often with a series of oval to elongated bulbous swellings, giving a string-of-beads appearance. The microscopic morphology varies with time, being more homogeneously filamentous in young cultures and becoming fragmented into irregular coccobacilli with age. L-phase organisms having a “fried egg” appearance may occur spontaneously on agar and may become stabilized if penicillin is incorporated in the medium. **Figure 57-27** is a smear of *Streptobacillus moniliformis* from the culture of a patient with rat-bite fever.

Clinical Manifestations and Pathogenesis

S. moniliformis occurs as indigenous flora in the upper respiratory tract of wild and laboratory rodents. Infection (rat bite fever or Haverhill disease) in humans follows rodent bites, ingestion of contaminated food, or traumatic injury. Local lymphangitis and lymphadenitis may develop up to 3 weeks later, followed by fever, chills, malaise, and, later, a general morbilliform maculopapular or petechial rash. Some patients develop a migratory polyarthritis. Endocarditis has been reported, as have cases of myocarditis, pericarditis, meningitis, pneumonia, and abscess development due to *S. moniliformis*. The histopathology is nonspecific chronic inflammation (vonGraevenitz, 2007).

Laboratory Diagnosis

Specimens for recovery of *S. moniliformis* include blood, joint fluid, and abscess material. *S. moniliformis* is a facultative anaerobic, nonmotile, gram-negative bacillus with a pleomorphic appearance. The organism grows on media enriched with 15% sheep or rabbit blood, serum, or ascitic

Figure 57-27 Gram stain of *Streptobacillus moniliformis* from culture. (Courtesy Dr. Nancy Cornish.)

fluid. Inoculated media should be incubated at 35°C in a humid environment containing an atmosphere of 5%–10% CO₂. Colonies on solid media are small and slightly translucent to opaque with slightly irregular edges. Coccal forms and gram variability may occur, but usually colonies will demonstrate long filaments with granules and bulbs or banding forms on Gram stain. L-forms may be present in some cultures, along with the usual bacterial forms.

Colonies in broth form as fluff balls usually at the bottom of the tube. Cultures die out quickly unless subcultured often. Because this organism is relatively inert, identification of *S. moniliformis* is complex. Biochemical tests must be performed in heart infusion agar or broth supplemented with yeast extract and horse serum. Molecular sequencing methods or fatty acid analysis is required for complete identification (vonGraevenitz, 2007).

Antimicrobial Susceptibility

S. moniliformis is susceptible to penicillin and doxycycline. It is resistant to colistin, nalidixic acid, and SXT.

Prevention and Control

Because 10%–65% of rats are infected with the organism, their control and precautions against bites represent the only effective methods of control of the disease.

ANAEROBIC BACTERIA

It is important to reemphasize that anaerobes represent a major component of the indigenous flora of the skin and mucous membranes; therefore their isolation and identification are contingent on the proper selection and collection of specimens, as well as on their proper transport to the laboratory. Anaerobic infections are frequently mixed, consisting of several species of anaerobes, or of anaerobes mixed with facultatively anaerobic bacteria; therefore the first task in examining an anaerobic culture is to separate facultatively anaerobic from obligate anaerobic bacteria. With experience, the more commonly isolated anaerobes can often be recognized on the basis of their colonial and microscopic morphologies and presumptively identified on the basis of a few additional tests. Definitive identification is based on biochemical reactions, physiologic and molecular characteristics, and occasionally pathogenicity and toxin neutralization tests.

The extent to which anaerobes are identified varies according to the facilities and expertise available, the interest of laboratory personnel and clinical staff, and the clinical relevance of the information available from the laboratory. Anaerobes have been fairly consistent in their response, at least in vitro, to antibiotics, but as with other groups of bacteria, resistance is becoming an issue with many anaerobes; this may prompt additional identification and susceptibility testing in the future (Hecht, 2006; Roh, 2009).

Definitions and Characteristics

An anaerobe requires an atmosphere with reduced oxygen tension for its growth and fails to grow on the surface of solid media in an atmosphere

of room air with 10% CO₂. A facultatively anaerobic bacterium will grow in the presence or absence of room air. The term *microaerophile* has not been strictly defined but is commonly applied to bacteria—usually campylobacters and streptococci—that grow only or preferentially in an atmosphere with reduced O₂ and with increased CO₂.

Pathogenesis and Virulence Factors

Little is known about the factors responsible for the pathogenic and virulence properties of most anaerobes other than the clostridia. Endotoxic, proteolytic, and heparinase activities have been identified among the Bacteroidaceae. The polysaccharide capsule of *B. fragilis* promotes abscess formation. Clostridia, on the other hand, elaborate potent exotoxins, including lethal and necrotizing toxins, hemolysins, lecithinases, gelatinases, and hyaluronidases.

Although clostridial infection may be exogenous or endogenous in origin, disease caused by other anaerobes usually originates endogenously from the normal indigenous anaerobic flora of a contiguous mucous membrane, the integrity of which has been disrupted by surgery, instrumentation, trauma, or malignancy. Essential to the establishment of anaerobes in the infectious process is a decrease in the oxidation-reduction potential (*Eh*) of the area, which may result from failure of its blood supply or from the multiplication of other bacteria at the site.

Although clostridial infections and intoxications are unquestionably of major medical importance, the role of other anaerobes in causing cellulitis and myonecrosis has been recognized more recently. Most isolates of *Clostridium perfringens* are the result of simple contamination of a wound. In such instances, the clostridia may multiply in cellular debris, a hematoma, or necrotic tissue without observable clinical symptoms. Anaerobic cellulitis is a necrotizing process of the soft tissues. Its onset is gradual, but it can progress rapidly and extensively. Gas is produced; however, the process typically does not involve muscle. In addition to or instead of clostridia, the bacteriology of anaerobic cellulitis may involve anaerobic cocci and anaerobic gram-negative bacilli.

In contrast to anaerobic cellulitis, gas gangrene or clostridial myonecrosis is an acute and rapidly progressive invasive process producing marked changes in muscle. Distinguishing between anaerobic cellulitis and gas gangrene is critical to avoid performing unnecessarily aggressive and mutilating surgery in the former condition.

Histotoxic clostridia associated with gas gangrene include *C. perfringens*, *Clostridium novyi*, *Clostridium septicum*, *Clostridium histolyticum*, *Clostridium sporogenes*, and *Clostridium bifermentans*. *C. perfringens* has been the species most frequently involved in gas gangrene; the prevalence of other species in this process has varied widely.

Tetanus and botulism, caused by *C. tetani* and *C. botulinum*, respectively, are described as intoxications rather than as infections, because their manifestations are related to the elaboration of potent neurotoxins. Botulism is most frequently due to the ingestion of home-processed foods that have been improperly preserved or canned; sporadic outbreaks of the disease have been associated with commercially processed food and with wounds infected by the organism. The incubation period for botulism is short: Signs and symptoms usually occur between 18 and 36 hours following ingestion of contaminated food. Of the seven antigenic types of botulinum toxin known, type A is the most common in cases of food poisoning in North America, followed by types B, E, and F. The toxin is absorbed from the intestinal tract and, rarely, from an infected wound and ultimately attaches to motor nerve terminals, thereby preventing acetylcholine release at the nerve endings.

Tetanus typically occurs in nonimmunized persons within the first 2 weeks following a traumatically acquired puncture, laceration, or abrasion. Cases have been reported to occur postoperatively; following dental work, childbirth, and abortion; or in association with stasis and decubitus ulcers. The toxin, tetanospasmin, is transported to gangliosides in the CNS via the lymphatics and bloodstream, and by migration through the perineural spaces of peripheral nerves.

Clostridium difficile is the major cause of nosocomial diarrhea and the primary pathogen responsible for pseudomembranous colitis. It is a rare cause of abscesses, wound infections, osteomyelitis, pleuritis, peritonitis, septicemia, and urogenital tract infections. Carriage rates of *C. difficile* and its toxins are high (50% or more) in neonates, but disease is rare (Bartlett, 1997). Colonization, with or without toxin production, may be maintained for several months, but when the adult flora becomes established at 6–12 months of age, colonization rates fall, and only about 3% of normal healthy adults are colonized with the organism. *C. difficile* almost always is acquired in the hospital by persons receiving antimicrobial agents via direct or indirect exposure to human or inanimate reservoirs. Although the

penicillins and the cephalosporins are implicated most frequently, any antimicrobial agent may trigger *C. difficile*-associated disease. Disease rarely occurs without antibiotic exposure, but cases have been reported following therapy with antineoplastic agents that have antibacterial activity. Pseudomembranous colitis is a toxin-mediated illness in which microbial invasion of the mucosa is not known to occur. *C. difficile* produces two toxins. Toxin A, a weakly cytopathic toxin, is predominantly responsible for the enterotoxic activity of the organism. Toxin B, a potent cytotoxin, appears to play a minor role in human disease, although toxin-A-negative, B-positive strains have been isolated from symptomatic patients (Johnson, 1998). Use of a PCR assay in the laboratory for detection of both toxin A and toxin B will increase sensitivity (Eastwood, 2009; Kvach, 2009; Stamper, 2009).

As previously mentioned, other anaerobic bacteria, particularly anaerobic cocci and gram-negative bacilli, have been associated with anaerobic cellulitis, in addition to or instead of the histotoxic clostridial species. These organisms are part of the indigenous flora of the mucous membranes of the oral cavity and of the gastrointestinal and genitourinary tracts. As such, they are encountered in aspiration pneumonias, lung abscesses, empyemas, intraabdominal infections and abscesses, pelvic abscesses, brain abscesses, and bacteremias. Anaerobic intraabdominal infections commonly follow abdominal and especially colon surgery, and are most frequently associated with the *B. fragilis* group. Clinically significant anaerobic bacteremias are also most frequently caused by this species. *Propionibacterium acnes* have been increasing in isolation and in association with clinical disease.

Significant taxonomic changes have occurred among the anaerobes. Some of these are delineated in Tables 57-15 through 57-19.

Laboratory Diagnosis

Identifying anaerobic bacteria to the species level can be a complex task; however, the extent to which isolates of anaerobic bacteria are identified varies widely and may be limited to basic information that is of clinical relevance and/or that might be needed to predict antimicrobial susceptibilities. For example, the mixed anaerobic flora from a site such as a decubitus ulcer, perirectal fistula, or intraabdominal abscess may simply be reported as mixed fecal flora (mentioning specifically whether there are aerobes and anaerobes or only anaerobes) without specific identification of its components. Determining the species of an isolate may be limited to those present in pure culture from a normally sterile body fluid or site, and can be readily accomplished with the use of any of several commercially available biochemical assay-containing kits, by using gas-liquid chromatography (GLC), or by combining the two approaches. Many laboratories have begun to use sequencing as a means of identifying anaerobic isolates. Results are often available rapidly, and increasing numbers of databases are available for the identification of many more species than can be identified with phenotypic kit systems (Simmon, 2008). MALDI-TOF-MS (matrix-assisted laser desorption/ionization time-of-flight mass spectrometry) is a recently developed method for the identification of a wide variety of bacteria, including anaerobes (Stingu, 2008). One should understand that the clinical value of any report of the presence of anaerobic bacteria is directly related to the speed of reporting such results from the laboratory. Identification procedures that require 1–2 weeks to complete are generally of academic interest only.

Because of their rapid progression and considerable morbidity and mortality, the initial diagnosis and management of diseases caused by the

TABLE 57-15

Most Frequently Isolated Gram-Positive Non-*Clostridium* spp. Anaerobic Bacteria

Species	Gram stain	Colony	Indole	PYR
Gram-Positive Cocci				
<i>Peptostreptococcus anaerobius</i>	Large cocci, often in chains	Nonhemolytic; gray with raised center; sweet odor	Negative	Negative
<i>P. micros</i>	Clusters or short chains; <0.6 µm	Small; dull color; "halo" around colony	Negative	Positive
<i>Finegoldia marna</i>	Pairs, tetrads, and clusters; >0.6 µm	Small, white, convex	Negative	Positive
<i>Peptoniphilus asaccharolyticus</i>	"Clumps," pairs, or tetrads	Small; slight yellow pigment	Usually positive	Negative
<i>Anaerococcus tetradius</i>	Clumps and tetrads	Nonglistening; gray; convex	Negative	Weak
<i>A. prevotii</i>	Clumps and tetrads	Nonglistening; gray; convex	Negative	Positive
<i>Staphylococcus saccharolyticus</i>	Clusters and tetrads	Catalase and coagulase negative	ND	ND
Gram-positive non-spore-forming bacilli	Gram stain	Colony	Aerotolerance/ Biochemical clues	Other characteristic
<i>Actinomyces israelii</i>	Short rods; branching or beading	White; opaque; "molar tooth"	+	Most common cause of actinomycosis: genital; pulmonary; abdominal
<i>A. naeslundii</i>	Short rods; branching or beading	Gray-white; translucent	+++	Oral flora; rarely pathogenic
<i>A. odontolyticus</i>	Short rods; branching or beading	May produce pink to red colonies in ambient air	+++	Oral flora; rarely pathogenic
<i>A. turicensis</i>			++	Genital sites
<i>Propionibacterium acnes</i>	Short rods; may appear "spidery"	White round colonies	++++ Catalase positive; indole positive	Normal flora on skin; associated with endophthalmitis (post cataract surgery); ventricular shunt infections; infrequent cause of endocarditis, osteomyelitis
<i>Propionimicrobium lymphophilum</i>	Coccoid; singly, pairs, or short chains	White, glistening	Non-aerotolerant	Isolation: lymph nodes; uncertain relevance
<i>Bifidobacterium</i> spp.	Diphtheroidal; bifurcated or forked ends		Non-aerotolerant	Normal flora of GI and GU tract; rarely clinically significant
<i>Eggerthella lenta</i> (formerly <i>Eubacterium lentum</i>)	Straight rod with rounded ends		Non-aerotolerant Catalase positive; indole negative	Grow in 20% bile; saccharolytic; have been isolated in anaerobic bacteremia

+, ++, +++, +++++, Positive with increasing strength; ND, not done; PYR, l-pyrrolidonyl-β-naphthylamide.

TABLE 57-16

Most Frequently Isolated Gram-Negative Anaerobic Bacteria (all should grow in presence of 20% bile)

Species	Colony	Biochemicals	Other characteristics
<i>Bacteroides fragilis</i> complex*	White, round; requires ≈24–48 hours		
<i>B. fragilis</i>		Negative for indole Positive for catalase and indole	Most common and most pathogenic of the complex
<i>B. distasonis</i>		Negative for indole Usually positive for catalase and esculin	
<i>B. thetaiotaomicron</i>		Positive for indole, catalase, and esculin	
<i>B. vulgatus</i>		Negative for indole; usually negative for catalase and esculin	
<i>B. ovatus</i>		Positive for indole, catalase, and esculin	
<i>B. goldsteinii</i>		Negative for indole; variable for catalase and positive esculin	
<i>Bacteroides urealyticus</i>	Colonies often “pit” the agar	No growth in 20% bile; indole, esculin, and catalase usually negative; urease positive	Part of normal anaerobic oral flora
<i>Bilophila wadsworthia</i>		Will grow in 20% bile; catalase positive; negative for indole and esculin	
<i>Porphyromonas asaccharolyticus</i>	Colonies fluoresce brick red (ultraviolet light exposure); black pigment with age	Bile sensitive; indole positive and catalase negative	Normal oral flora; pulmonary disease
<i>Prevotella disiens</i> and <i>P. bivia</i>		Bile sensitive; indole and esculin negative; saccharolytic and nonpigmented	Normal genitourinary flora; can be involved in pelvic abscesses
<i>Fusobacterium nucleatum</i>	Breadcrumb-like and speckled; Gram stain: long thin, pointed bacilli	Bile sensitive; indole positive and esculin negative	Oral flora; can be involved in bacteremia, pulmonary infection
<i>F. necrophorum</i>	Umbonate colonies; greening of agar; Gram stain: round, not tapered ends; often “bizarre” forms seen	Usually sensitive to bile; indole positive, lipase positive	Associated with Lemierre’s syndrome
<i>F. mortiferum</i>	“Fried egg” appearance of colonies; nontapered rods and bizarre round “bodies” on Gram stain	Grows on 20% bile; indole negative and esculin positive	Infrequent isolate
Gram-Negative Cocci			
<i>Veillonella</i> spp.	Small white colonies; Gram stain: well staining, round cocci, singly or in pairs	Catalase variable; nitrate reduction positive	Common isolate, but rarely involved in clinical disease

*In addition to those listed, *B. fragilis* complex includes *B. caccae*, *B. eggerthii*, *B. merdae*, *B. stercoris*, and *B. uniformis*.

TABLE 57-17

Most Common Species of *Clostridium* (Spore-Former) in Clinical Samples

Species	Colony	Gram stain	Characteristics
<i>C. perfringens</i>	Large, white, with double-zone hemolysis	“Box-car” (short and fat) shaped rods; short chains may be seen; rare spores seen	Lipase negative; lecithinase positive; indole negative; reverse CAMP positive Most common isolate; skin and soft tissue infections (including gangrene); bacteremia; also found in gastrointestinal tract as part of normal flora
<i>C. ramosum</i>	Large, spready white colony	Often stain gram negative or variable; cells are more slender and longer than <i>C. perfringens</i> ; spores not commonly seen	Commonly isolated from clinical samples
<i>C. sordelii</i>	White	Large, gram-positive rods with subterminal spores seen; lecithinase positive; lipase negative; indole and urease positive	Less frequently isolated than <i>C. perfringens</i> , <i>C. ramosum</i> , and <i>C. septicum</i>
<i>C. tetani</i>		Thin bacilli with terminal spores: “snow-shoe” or “tennis racquet” appearance; lecithinase negative; lipase weak positive; indole variable and urease negative	May be part of gastrointestinal flora; cause of tetanus
<i>C. septicum</i>	White, swarming colonies	Long, filamentous bacilli with rare subterminal spores seen; lecithinase, lipase, indole, and urease negative	When isolated from blood cultures, indicates a possible gastrointestinal malignancy
<i>C. difficile</i>	White colonies with distinctive “horse-barn” odor; selective CCFA media: yellow, ground glass appearing colonies	Thin, long bacilli with spores seen	Cause of pseudomembranous colitis and antibiotic-associated diarrhea; rarely found outside of the gastrointestinal tract

clostridia must be based on their clinical presentation and manifestations. In some patients with tetanus, no primary wound is evident. When a wound is present, organisms typical of *C. tetani* are seldom seen in stained smears, even though they may be recovered from cultures. Moreover, because of this organism's widespread distribution in nature, its isolation from a wound is not necessarily indicative of the diagnosis of tetanus. Laboratory confirmation of botulism requires detection of the toxin in serum, wounds, gastric contents, feces, or the food suspected of causing the disease. Procedures for extracting the toxin and for performing mouse neutralization tests are complex; therefore it is suggested that the appropriate materials be referred to the CDC for examination. Telephone consultation should be made in such instances to ensure that the requisite specimens are properly collected and transported, and that the appropriate authorities are alerted.

In cases of suspected anaerobic cellulitis or gas gangrene, the laboratory can be helpful by examining exudate or tissue microscopically. The finding of numerous, large, "boxcar"-shaped, gram-positive bacilli (Fig. 57-28) provides presumptive confirmation of the diagnosis. Stained smears may also be diagnostic of anaerobic streptococcal myositis. Cultures of exudate, tissue, and blood should be performed. Once again, the level or extent of identification varies considerably among laboratories; however, *C. perfringens* may be easily identified by its Gram stain morphology, the production of double zones of hemolysis on blood agar, and a positive Nagler's reaction on egg yolk agar. Laboratory diagnosis of *C. difficile* diarrhea has been accomplished in most laboratories by detecting the toxin directly in stool using an EIA or cell culture assay. Culture of stool for the organism and,

Figure 57-28 Gram stain of a smear of exudate from a wound that had gas bubbles shows large, boxcar-shaped, gram-positive bacilli, suggestive of clostridial disease (oil immersion).

Figure 57-29 Gram stain of *Bacteroides fragilis* from broth culture.

when positive, determination of whether toxin is being produced is primarily reserved for epidemiologic and surveillance studies, although it is used diagnostically in a few laboratories. Many believe it is the "gold standard" for detection. Assays that detect a "common" antigen, glutamate dehydrogenase, which is found in most *C. difficile* isolates, are now being used as part of a two- or three-step procedure for laboratory diagnosis of *C. difficile* to increase sensitivity. Unfortunately, the antigen can be found in other bacteria, so that a positive antigen should be confirmed before it is reported as *C. difficile* positive. Confirmation is carried out in the two-step assay with PCR or cytotoxicity studies; in the three-step assay, a positive antigen is followed by an EIA, and any antigen-positive/EIA toxin-negative samples would have a PCR performed or a cytotoxicity test conducted for confirmation. The prevalence of *C. difficile* usually is not >20% in any single facility, and the two- or three-step approach allows rapid results to be obtained from negative samples. Some more recent studies have questioned the sensitivity of the antigen, but in most studies and laboratory validations, it appears to be highly sensitive. A PCR method for initial detection of the toxins of *C. difficile* is now commercially available, and many laboratories have started to use PCR as a replacement for EIA or cytotoxicity (Eastwood, 2009; Kvach, 2009; Stamper, 2009).

One of the most common groups of clinically relevant and frequently isolated anaerobic bacteria is the *B. fragilis* complex. Isolates from this complex will grow selectively on *Bacteroides* bile esculin medium, and they have characteristic Gram stain morphology as seen in Figure 57-29. These gram-negative bacilli are found as normal flora throughout much of the gastrointestinal and genitourinary tracts. Infections caused by the complex include abdominal abscess, pelvic abscess, bacteremia, and brain abscess. They may rarely be involved in pulmonary disease. Although most anaerobic infections are polymicrobial, *B. fragilis* alone may be responsible for infection. Members of the *B. fragilis* complex include *B. caccae*, *B. distasonis*, *B. eggerthii*, *B. fragilis*, *B. goldsteinii*, *B. merdae*, *B. nordii*, *B. ovatus*, *B.*

Figure 57-30 Gram stain of *Propionibacterium acnes* from vitreous fluid.

salyersiae, *B. stercoris*, *B. thetaiotaomicron*, *B. uniformis*, and *B. vulgatus*. With rare exception, members of the complex will grow in the presence of 20% bile and will hydrolyze esculin. Inclusion of a *Bacteroides* bile esculin agar (BBE) plate when anaerobic specimens are processed will allow more rapid detection and identification of these organisms.

An anaerobic gram-positive bacillus, *Propionibacterium acnes*, has been associated with cases of endophthalmitis that occur after cataract surgery. In addition, *P. acnes* may be associated with ventricular shunt infection in patients with hydrocephalus; rarely, *P. acnes* can cause endocarditis, septic arthritis, or other infections. Isolation of this organism may require extended incubation, often up to 10 days. **Figure 57-30** shows a Gram stain

of *P. acnes* in vitreous fluid obtained from a patient months after cataract surgery. *Actinomyces israelii* and other species of *Actinomyces* can be involved in lung abscesses, brain abscesses, skin and soft tissue infections, and mycetoma, and may be involved in genital infections involving use of an intrauterine device (IUD), although this is a controversial topic (Burkman, 1996; Westhoff, 2007).

Antimicrobial Susceptibility

Susceptibility testing of anaerobic bacteria in the past was considered unnecessary, except in the following circumstances. Major indications for testing are clinical settings in which decisions regarding the selection of agents are critical because of (1) failure of usual therapeutic regimens and persistence of infection, (2) the key role of antimicrobial agents in determining the outcome of infection, or (3) the difficulty involved in making empirical therapeutic decisions based on precedent. Infections from which isolates should be tested include brain abscess, endocarditis, osteomyelitis, joint infections, infections of prosthetic devices or vascular grafts, and refractory or recurrent bacteremia. Testing under these circumstances should include some members of the *B. fragilis* group, certain *Fusobacterium* spp., *C. perfringens*, and *Clostridium ramosum*. Agents such as metronidazole, imipenem, and ampicillin-sulbactam have almost always been reported as active against anaerobic bacteria and usually are not routinely tested for clinical purposes. Thus testing was limited to alternative agents with unpredictable activity, such as penicillin, clindamycin, ceftiofen, and cefotetan. More recently, results are not as predictable, and the need for performance of an in vitro susceptibility test is increasing (Hecht, 2006; Roh, 2009). Although an agar dilution method has been recommended for reference purposes, testing in the clinical laboratory is generally performed by the microdilution (CLSI, 2007) or Etest method. Batch testing of saved isolates on a yearly basis is recommended to develop antibiograms for empirical use by clinicians, and to monitor for possible development of resistance (Boyanova, 2007).

KEY POINTS

- The minimum inhibitory concentration (MIC), or the lowest concentration of antibiotic that inhibits the visible growth of an organism in vitro, is distinguished from the breakpoint, or the concentration of antibiotic that determines whether an isolate is categorized as susceptible, intermediate, or resistant.
- MIC values are determined by inhibitory methods, which include macrobroth dilution, microbroth dilution, agar dilution, and Epsilometer (E-test). Disk diffusion testing, which is a qualitative rather than a quantitative test, does not directly result in an MIC value, but is based on direct correlation of inhibitory zone sizes with MIC values.
- Whatever method of susceptibility testing is used, standardized conditions related to media, inoculum concentration, incubation time, atmosphere, and temperature are necessary to produce accurate and reproducible results. Standards for these variables are published by the Clinical and Laboratory Standards Institute (CLSI) and represent standard of practice for microbiology laboratories.
- Commercial automated instrument systems are available for rapid, high-volume susceptibility testing; however, despite the advantages of speed and efficiency that these systems allow, it must be remembered that the systems may have weaknesses. In addition to the expense of the systems, some are associated with problems in accurately detecting specific resistance phenotypes.
- Both the indications for susceptibility testing and the selection of which antimicrobials to test and report should be determined by individual laboratories on the basis of recommendations published by the CLSI and in close consultation with the medical and infectious disease staff of the facility served by the laboratory.
- Cumulative antimicrobial susceptibility reports (antibiograms) should be published by laboratories, based on CLSI guidelines, on at least an annual basis. These compilations are important for use by physicians in initiating empirical treatment before testing results are available, and are helpful for pharmacists in monitoring the use and need of specific antimicrobials and in attempting to control drug costs.

Selection of an antibiotic by a physician to treat an infection in a patient involves consideration of numerous factors, including but not limited to the known or most likely infecting organism(s), local patterns of drug resistance on the part of the organism(s), the site of infection, pharmacodynamic and pharmacokinetic properties of the drug, overall health of the patient, the cost of the antibiotic, and personal experiences of the physician. Although in many cases initial selection of an antimicrobial agent is empirical, in vitro laboratory testing of the susceptibility of isolated pathogen(s) to antibiotics is an important aid in subsequent management of the patient. Modification of therapy may be desirable if (1) the infecting organism(s) is resistant to current therapy, (2) the dose of antibiotic is not appropriate, or (3) an equally effective but less expensive agent can be used.

DEFINITIONS

Currently, most in vitro antibiotic susceptibility testing in clinical laboratories is still performed with the use of phenotypic methods, which are simple and inexpensive. Phenotypic methods require isolation of the pathogen being tested, followed by exposure of the pathogen to the antimicrobial and subsequent evaluation of the expression, or lack of expression, of resistance to the antibiotic. This process can be labor intensive and time consuming, which, under some circumstances, may be disadvantageous to the patient or the laboratory, or both. Despite this fact, phenotypic methods, which include broth dilution, agar dilution, disk diffusion, and gradient diffusion (E-test), are at present the most prevalent and in most cases the most cost-effective way to accomplish susceptibility testing. Commercial systems, based on phenotypic methods, have reduced the labor and the time necessary to detect the expression of antibiotic resistance and are used in many laboratories, although at increased cost to the laboratory in most cases.

Antimicrobial susceptibility tests may be categorized according to the endpoint used, that is, inhibition of growth or killing. In most cases, inhibition of growth is the parameter used in the laboratory, with only limited use of a killing endpoint for very specific circumstances.

The inhibitory parameter that forms the basis for the majority of phenotypic susceptibility tests is the MIC, which is the lowest concentration of antibiotic that inhibits the visible growth of an organism in an in vitro system. MIC results are dependent not only on the interaction between

the antimicrobial agent and the organism, but also on test conditions. These conditions include pH and ion concentrations of testing media, the temperature at which the test system is incubated, the incubation atmosphere, the amount of organism used in testing, and the length of time the system incubates. To allow intralaboratory and interlaboratory reproducibility, these test conditions have been standardized. Various standards organizations in a variety of venues throughout the world have set and published these parameters, and in the United States, the CLSI fulfills this role.

Although the MIC is a very useful and reproducible indicator of the interaction of an antibiotic with a specific organism, the information it provides to a physician in the context of the infected patient by itself is limited. The MIC is a “snapshot” assessment of the interaction of a constant concentration of drug with the organism at a specific point in time under specified conditions *in vitro*. The MIC must be correlated with the complex and changing environment of the physiology of the patient to allow the physician to predict whether therapy with a particular antibiotic will be successful. This is accomplished through the use of **breakpoints**, which allow assessment of the efficacy of killing or inhibition of growth of the organism by the antimicrobial. Several types of breakpoints, including microbiological breakpoints, pharmacokinetic/pharmacodynamic breakpoints, and clinical breakpoints, have been identified. Clinical breakpoints, which are intended to separate strains of organisms into categories that predict whether therapy in a patient will be successful, are breakpoints relevant to this short review and are the only type of breakpoint discussed here. Determining clinical breakpoints is complex, difficult, and subjective. The process can involve numerous clinical trials, and clinical breakpoints may vary with the determining standards organization and may vary over time. In the United States, clinical breakpoints for specific antibiotic-organism combinations are set and published for use by clinical laboratories by the CLSI, and they are updated yearly (Clinical and Laboratory Standards Institute, 2009). Breakpoints established by the CLSI may differ for a variety of reasons from those set by the European Committee on Antimicrobial Susceptibility Testing or other standards organizations. Excellent discussions of breakpoints and their determination, maintenance, and relevance can be obtained by referring to several review articles (Mouton, 2002; Turnidge, 2007).

Interpretive categories have been established that allow simplified and easily understood reporting of susceptibility results by laboratories. Many laboratories report these categories, in addition to reporting an MIC or, in some cases, in lieu of reporting an MIC. Based on clinical breakpoints, specific isolates can be divided into categories after susceptibility testing that is intended to assist the physician in easily interpreting the results. Although highly knowledgeable infectious disease physicians may be able to make informed management decisions with no other information aside from the MIC obtained by testing a specific isolate against an antibiotic, this is unlikely to be the case for physicians who do not specialize in this area. The basic interpretative categories include **susceptible**, **intermediate**, and **resistant**. Definitions of these categories can be found in CLSI documents (Clinical and Laboratory Standards Institute, 2009). Susceptible implies that therapy with the recommended dosage of a particular antibiotic is likely to be effective in eradicating the infection, and resistant indicates that the antibiotic in the appropriate dose has not been shown to have a high likelihood of treatment success in clinical trials.

Reporting a susceptibility category of intermediate has several implications. It suggests that the isolate tested may be less inhibited by the usual dose of the antibiotic than those isolates that are categorized as susceptible, and that therapy with higher doses of antibiotic or therapy with the antibiotic for infection in anatomic locations in which the antibiotic normally is concentrated is likely to be effective. An example of this latter situation is the use of β -lactam antibiotics in treating urinary tract infection. This category also includes a **buffer zone**, which is intended to prevent technical factors from resulting in a major interpretive error. An additional category of **nonsusceptible** has recently been added. This category is intended for cases in which intermediate and resistant isolates have not been found or categories of intermediate and resistant have not been defined. It is utilized primarily for new antibiotics. If testing of an isolate yields an MIC value that is above the cutoff concentration established for the breakpoint for a susceptible category, the laboratory can report the isolate as nonsusceptible. This does not necessarily imply that resistance to the antibiotic exists, but it means that experience with isolates that demonstrate MICs at this level is limited, so no assessment can be made.

Although reporting of antimicrobial susceptibility testing and categorization of an isolate into one of the interpretative categories are helpful to

physicians in managing patients with infection, it must be remembered that antimicrobial activity *in vivo* depends on many factors. In addition to drug dosage, route of administration, pharmacokinetic/pharmacodynamic characteristics of the drug, and site of infection, patient-specific factors such as immune status and hepatic and renal function also help determine a patient's response to therapy and must be considered in planning treatment. Antimicrobial susceptibility testing is thus an adjunct to patient management and does not in itself predict response to therapy.

INHIBITORY METHODS FOR SUSCEPTIBILITY TESTING

DILUTION TESTING

In dilution testing, a standardized amount of organism is inoculated into a series of tubes, wells, or dishes that contain a range of concentrations of antimicrobial in a vehicle, such as broth or agar, usually starting with an integral of 2 (e.g., 128 $\mu\text{g/mL}$) and decreasing on a log₂ basis to the lowest concentration tested. For the purposes of convenience and economy, it has become common to limit the range of concentrations of each antimicrobial tested to those concentrations that encompass the breakpoints that distinguish between susceptible and resistant. Some commercial systems contain only a single concentration of an antimicrobial agent.

The broth macrodilution method is performed using standard test tubes, and the tubes are viewed by the unaided eye to determine whether growth is present. The broth macrodilution system is no longer used by most laboratories because of its labor-intensive nature, but this method is the foundation of most modern susceptibility testing systems. Similarly, the agar dilution method, where the antibiotic being tested is incorporated into solid agar in Petri dishes, is an older, labor-intensive method that is little used by modern laboratories for routine testing. However, because the isolate being tested is placed on the agar as a single spot, the agar dilution method can allow the testing of multiple isolates on a single plate. Additionally, some species that do not grow well in broth, or for which the broth method has not been shown to be sufficiently reproducible, can be tested by this method. With the exception of the *Bacteroides fragilis* group, agar dilution is the only standardized method recommended by the CLSI for susceptibility testing of anaerobe species (Clinical and Laboratory Standards Institute, 2007).

Broth microdilution is the most common dilution method used in the modern microbiology laboratory, and this method is the basis for most commercial systems. Commercially prepared and disposable microtiter trays containing antibiotics exist as standalone devices, which are manually inoculated and read by visualization, or as components of automated systems that are read by spectrophotometric methods. Several systems have been in existence for a number of years, have extensive databases built over the years, and offer the advantage of computerized software that allows collection of antibiogram data and “expert” systems that assist in interpretation. Several newer systems have also come onto the market recently. Because of the labor associated with preparing microtiter trays in-house, and the extensive quality assurance testing necessary when preparing the trays, commercially prepared trays and systems are very popular. They can be expensive, however, and the antibiotics available on a given tray may not conform to local needs. Customized trays may be available but usually are associated with additional expense.

EPSILOMETER

The Epsilon meter, or E-test (AB Biodisk, Solna, Sweden), is a plastic strip with a gradient of antibiotic on one side of the strip and a continuous MIC scale on the opposite side. The strip is placed on the surface of an agar plate that has been inoculated with the isolate. Antibiotic will diffuse into the surrounding agar in a gradient that corresponds to the gradient on the strip. If the isolate is susceptible, an ellipse of inhibition will occur in growth of the bacterium on the surface of the plate, and the point on the MIC scale of the strip where the ellipse of inhibition intersects is the MIC (Fig. 58-1). The MIC obtained using the E-test has been shown to correlate well with the MIC obtained with the agar or broth dilution for many antibiotic-bacterial species combinations (Baker, 1991). This method is useful because it allows the testing of single antibiotics against isolates, which has particular utility if testing of an isolate against a drug not on the laboratory's preconstructed antibiotic panel is necessary, or if testing of one or a few drugs against fastidious species that require special media is required (e.g., *Haemophilus influenzae*).

Figure 58-1 Epsilometer, or E-test. A gradient of antibiotic (penicillin in this example) is incorporated into the plastic strip, which is placed on the agar surface on which an organism has been streaked (*Streptococcus pneumoniae*). The intersection of the zone of inhibition with the numeric scale on the strip is read as the minimum inhibitory concentration (MIC) (arrow).

Figure 58-2 Disk diffusion. The zone of inhibition around the antibiotic disk (vancomycin in this case) on the agar surface on which the organism (*Streptococcus pneumoniae*) has been streaked is measured. The result may be susceptible, intermediate, or resistant, based on the zone size.

DISK DIFFUSION

In the disk diffusion test (Kirby-Bauer), which is largely limited to rapidly growing aerobic and facultatively anaerobic bacteria, a paper disk containing a specified amount (not concentration) of antimicrobial is applied to an agar surface that has been streaked with a standardized inoculum of the isolate. Testing is done on a 150-mm-diameter agar plate that allows testing of 12 antibiotics at once. The antibiotic diffuses into the agar medium from the disk, resulting in a zone of growth inhibition at the point at which a critical concentration of the antimicrobial in the medium inhibits growth of the bacteria after a standardized time period (16–18 hours) (Fig. 58-2). The diameter of the zone of growth inhibition has been shown

to be inversely correlated with the MIC. The relationship between the two can be expressed as a linear regression line, and zone diameter equivalents of susceptible, intermediate, and resistant interpretations can be extrapolated from their intercepts on the regression line with corresponding MIC values.

Disk diffusion is a simple method that provides a qualitative susceptibility result. It allows easy modification of the panel of antibiotics being tested and is inexpensive relative to a number of other methods. It is primarily a manual method, although a video-assisted plate reader as part of a susceptibility data management system, BIOMIC System (Giles Scientific, New York), has been available for a number of years. For laboratories with a high volume of testing, dependence on manual labor may prohibit the use of disk diffusion as the routine method of susceptibility testing. Certain fastidious species may require special media or conditions for performing disk diffusion that may prohibit routine testing in less well funded laboratories, as it may not be cost-effective to keep the necessary media on hand for the times when testing is necessary. Referral of the isolate to a reference laboratory for susceptibility testing is sometimes a more cost-effective approach in these situations.

DIRECT TESTS FOR β -LACTAMASE

Direct β -lactamase tests are not inhibitory tests but are phenotypic tests that detect the presence of β -lactamase production by an organism. They are mentioned with the inhibitory tests because they, like the inhibitory tests, are commonly used in clinical laboratories. These tests are useful in detecting penicillinase enzymes in gram-positive and a few gram-negative species. Three types of β -lactamase direct test may be used: acidometric, iodometric, and chromogenic. The chromogenic test is the most sensitive, the most specific, and the easiest to use; it has replaced the other types in usual laboratory use and is the only type discussed here. The chromogenic test consists of a paper disk impregnated with a chromogenic cephalosporin (nitrocefin). A loopful of bacteria to be tested is simply smeared onto the disk, and if the organism is producing β -lactamase, hydrolysis of the chromogenic cephalosporin will occur and the disk color will change from yellow to red, usually within a minute; however, a final observation of the disk at 15 minutes is necessary for slowly developing reactions. The test can be used to detect β -lactamase production in several species, including *Haemophilus* species, *Moraxella catarrhalis*, *Staphylococcus* species, *Enterococcus* species, and gram-negative anaerobes (excluding the *B. fragilis* group). A positive test indicates that the organism will not be inhibited by a penicillinase-susceptible penicillin. A positive nitrocefin test for an isolate of *H. influenzae* or *M. catarrhalis* indicates that infection due to the isolate will not respond to ampicillin or amoxicillin. For many gram-positive species, the enzymes require induction by exposure to a β -lactam antibiotic before the enzyme is expressed and can be detected. For example, a simple and appropriate method for testing a staphylococcal isolate for β -lactamase production is accomplished by selecting growth from around the edges of a β -lactam-containing disk on a disk diffusion plate. It should be noted that β -lactam direct tests cannot be used to predict susceptibility to β -lactam antibiotics used in the treatment of infection caused by gram-negative members of aerobic or facultative anaerobes such as *Pseudomonas* spp. or Enterobacteriaceae.

TECHNICAL CONSIDERATIONS IN SUSCEPTIBILITY TESTING

Whichever method of dilution or disk diffusion testing a laboratory selects, utilization of a standardized procedure is of the utmost importance in producing accurate and reproducible results. A variety of standards organizations throughout the world have published performance standards for these procedures, and in the United States, professional organizations (e.g., the American Society for Microbiology, Infectious Disease Society of America), private industry, and governmental organizations have worked together within the Subcommittee on Antimicrobial Susceptibility Testing under the Area Committee on Microbiology of the CLSI to establish the necessary standards. The CLSI has published a series of documents that describe standardized procedures for susceptibility testing of aerobic and facultatively anaerobic bacteria (Clinical and Laboratory Standards Institute, 2009b, 2009c), anaerobic bacteria (Clinical and Laboratory Standards Institute, 2007), mycobacteria and aerobic actinomycetes (National Committee for Clinical Laboratory Standards, 2003), filamentous fungi (Clinical and Laboratory Standards Institute, 2008), and yeasts (National Committee for Clinical Laboratory Standards, 2004, 2008, 2008b). The

Subcommittee on Antimicrobial Susceptibility Testing revises the text of most documents on a 3-year cycle and reviews and revises on a yearly basis tables detailing MIC breakpoints or zone diameter breakpoints. Standardized procedures published by the CLSI represent the standard of laboratory practice in the United States, and laboratories should ensure that the most current tables and texts are on hand, and that revisions in the tables and texts are incorporated into the methods and policies of the laboratory when they become available.

Testing Media

It has been demonstrated that testing components with which susceptibility testing is carried out may have an effect on the results. With respect to testing media, the CLSI currently recommends Mueller-Hinton agar or broth because it demonstrates good batch-to-batch reproducibility; is low in sulfonamide, trimethoprim, and tetracycline inhibitors; and supports the growth of most nonfastidious bacteria (Clinical and Laboratory Standards Institute, 2009b, 2009c). Stringent quality control must be adhered to in preparation of the media when media are prepared commercially or “in-house,” as many physical properties of the media directly influence testing. Variations in ion concentrations and pH will affect testing (Clinical and Laboratory Standards Institute, 2009b, 2009c). For example, excess calcium and magnesium will cause *Pseudomonas aeruginosa* isolates to appear more resistant when tested against aminoglycosides, but decreased levels may demonstrate false susceptibility. The level of calcium will also affect daptomycin susceptibility results for those species against which the drug is tested, and zinc ion levels influence carbapenem results. As another example, the pH of the media will also directly affect testing, and it must be between 7.2 and 7.4 for accurate results. A more acidic pH will cause some drugs such as aminoglycosides, quinolones, and macrolides to lose potency, and some drugs such as penicillin to have increased activity. A higher pH can have the opposite effect.

For some fastidious species, supplements must be added to the Mueller-Hinton media, or specialized media containing required growth factors are necessary. For example, streptococci do not grow well in or on unsupplemented Mueller-Hinton media; this problem can be overcome by adding defibrinated sheep blood to a final concentration of 5% for disk diffusion or lysed horse blood to the medium at a final concentration of 2.5% to 5% for broth dilution. *Haemophilus influenzae* requires *Haemophilus* test medium when performing broth dilution, and *Neisseria gonorrhoeae* testing requires GC agar base medium with growth supplement (Clinical and Laboratory Standards Institute, 2009b, 2009c). For susceptibility testing of anaerobes, *Brucella* agar supplemented with laked sheep blood, hemin, and vitamin K₁ (Wadsworth method) is necessary to allow testing using the agar dilution method, which is the only CLSI recommended method for testing these species (Clinical and Laboratory Standards Institute, 2007). An exception is seen with the *B. fragilis* group, which can be tested using the microbroth dilution method with *Brucella* broth with hemin, vitamin K₁, and 5% lysed horse blood. The range of drugs that can be tested against *B. fragilis* group using microbroth dilution is more limited, however.

Additional medium parameters may influence testing. For example, agar depth in plates used in disk diffusion testing must measure 4 mm; otherwise, the diffusion gradient of the antibiotic will be affected. False resistance may occur if the agar is too deep, and false susceptibility may occur if the agar is not deep enough. When Mueller-Hinton is supplemented with blood, the zones of inhibition may be smaller by 2 to 3 mm than those obtained with unsupplemented agar.

Inoculum

Intuitively, it is evident that the quantity of bacteria present will influence results in susceptibility testing when a finite amount of antibiotic is used in the testing process. To ensure consistency in the quantity of organisms inoculated into the test system, the CLSI has mandated that the prepared inoculum suspension must have a turbidity equivalent to a 0.5 McFarland turbidity standard. These standards can be purchased commercially, or a BaSO₄ suspension can be prepared in the laboratory; the instructions for which are detailed in CLSI documents (Clinical and Laboratory Standards Institute, 2009c).

Inoculum preparations can be made by several methods by directly suspending 18–24-hour-old colonies from nonselective media in broth or saline until turbidity of 0.5 McFarland is achieved, or by suspending several colonies of the organism to be tested into nutrient broth and incubating for several hours until growth results in turbidity equivalent to 0.5 McFarland. The direct colony suspension method is necessary for very fastidious species that require special supplements or media for growth, although the growth method is preferable for species that are difficult to suspend

uniformly and when 18–24-hour plates are not immediately available. For most commonly isolated species, the two methods are equivalent.

Incubation Conditions

Test systems must be incubated under standardized temperature and atmospheric conditions to ensure uniform results. These conditions have been described and published by the CLSI for U.S. laboratories. General conditions for disk diffusion and broth dilution of bacteria include a temperature of 35° C ± 2° C with an atmosphere of ambient air for a period of 16–20 hours (Clinical and Laboratory Standards Institute, 2009b, 2009c). Many exceptions to this have been noted, however. For example, for disk diffusion, *Streptococcus* spp. and *Haemophilus* spp. require incubation in an atmosphere of 5% carbon dioxide, and although zones of inhibition of *Haemophilus* spp. are measured after 16–18 hours of incubation, those for *Streptococcus* spp. should not be determined until after 20–24 hours. Similarly, although susceptibility testing for most antibiotics against *Staphylococcus* spp. and *Enterococcus* spp. requires 16–18 hours, when oxacillin and vancomycin against *Staphylococcus* spp. and vancomycin against *Enterococcus* spp., respectively, are tested, a full 24 hours of incubation is necessary. Differences in testing and incubation parameters among aerobic, facultative anaerobic, anaerobic, mycobacterial, filamentous fungi, and yeast species require that the relevant CLSI documents be studied carefully prior to testing.

COMMERCIAL AUTOMATED INSTRUMENT SYSTEMS

Over the past several decades, many microbiology laboratories in the United States have shifted from using disk diffusion or manual broth susceptibility testing methods to use of automated commercial microbroth dilution systems as their predominant testing systems. Most laboratories now use these systems (Jones, 2001). Reasons for the shift include the efficiency gained from replicate inoculation of combined systems for identification and susceptibility testing, as well as the benefits of data management software that is an integral component of most of these systems. Additionally, it has sometimes been stated that these systems allow reporting of the MIC value, which is more accurate than simply reporting the interpretive categories generated by disk diffusion testing, and that physicians prefer the reporting of MIC values. However, these statements are not supportable. Inhibitory zone measurements have been accurately correlated with MIC values statistically, and although physicians whose specialty is infectious diseases can utilize an MIC value for dosing strategies in complex or difficult cases, the average physician often has neither the knowledge nor the need to utilize the MIC. Selection of the method to be used for antibiotic susceptibility testing, that is, automated microbroth dilution testing or manual disk diffusion, can be done based on workflow, convenience, economic reasons, or preferences of the medical staff without regard for any differences in accuracy.

A variety of systems are available for selection. Before deciding to purchase a system, the laboratory director should consider whether the advantages of replicate inoculation and of data management systems outweigh the costs of the commercial system, which involves both an up-front outlay of cash and an ongoing expense related to consumable components of the system, compared with the economy and simplicity offered by the disk diffusion test. The tendency is to consider the disk diffusion test archaic and too unsophisticated for modern laboratory practice; however, this method can provide accurate results that are easily understood by health care providers and that suffice in many clinical situations, and it is economical and flexible. The labor-intensive nature of the test compared with automated systems may be limiting in high-volume laboratories, however.

Selection of a particular automated system is based on a list of considerations. Systems differ somewhat in terms of some of these parameters, and it is incumbent on the laboratory director to find the best fit for his/her laboratory. The list of parameters for evaluation includes the volume the system can handle, the technical expertise required to operate the system, the utility and usability of the data management system, the cost of the hardware, the cost of disposable supplies, reagents, and service contracts, and the space occupied by the system. With the Vitek System (BioMerieux, Hazelwood, Mo.), antimicrobial agents are contained in wells within a plastic card, which are inoculated with the isolate in a filler-sealer module, placed in an incubator-reader, and read after incubation, with data managed by the computer module and displayed on the data terminal or printed, or both. The original system (Legacy system) was very

popular in clinical laboratories but now has been superseded by the Vitek 2 system. The updated system has automated some of the procedures in the original system that required manual performance, and combines a multichannel fluorometer and photometer to monitor organism growth at 15-minute intervals, allowing results to be generated in hours.

Microscan (Dade Microscan, West Sacramento, Calif.) is a suite of systems that may be utilized in manual mode when frozen or lyophilized panels are inoculated, and then may be read manually after overnight incubation. The semiautomated version, the Microscan Walkaway, can perform traditional overnight MIC testing in which the results are read with a spectrophotometer, or a more rapid method can be used that is based on the generation of fluorescence from the utilization of substrates by inoculated organisms. Fluorometric panels can provide results in hours, similar to the Vitek 2 system.

The Phoenix system (Becton-Dickinson, Sparks, Md.) is relatively new compared with the previously described systems, and it uses a redox indicator to assess bacterial growth in inoculated wells. Similar to Vitek 2 and Microscan Walkaway, this system has the capability to provide results within a usual 8-hour laboratory working shift, if the clinical situation warrants, and if laboratory staffing and workflow are compatible with this goal.

The ability to report antimicrobial susceptibility results faster is heavily promoted by manufacturers as a benefit of automated susceptibility systems. The concept behind this is that switching a patient to an antibiotic that has been demonstrated to be susceptible by in vitro susceptibility testing sooner rather than later will improve the outcome of treatment. For a variety of reasons, including the fact that difficult methodologic and ethical problems are related to designing such studies, and the fact that for some pathogens and infections, it has not been unequivocally proven that antimicrobial therapy in itself is beneficial, this claim on the part of the manufacturers has been difficult to prove.

It has been demonstrated in some studies that physicians will alter antibiotic therapy based on more rapid reporting of susceptibility results. In a nonrandomized study, Matsen (1985) gave physicians the results of rapid (2–5-hour) susceptibility system and disk diffusion testing, and then questioned physicians as to whether the rapid result influenced their choice of therapy. In 32% of cases, the physicians indicated that based on the rapid results, they chose a different antibiotic for initial therapy than they otherwise would have chosen and another 17% “probably” would have chosen. In a prospective, randomized study of 794 general surgical patients, Vincent (1985) provided rapid results for half of the patients and conventional results for the other half. It was found that antimicrobial therapy was modified in a larger percentage of the rapid-reporting group (14.5%) as opposed to the conventional group (8.8%; $P < .0005$). No statistical difference in length of hospital stay was noted between the two groups, however. A recent study involving 1498 inpatients with infection of sterile body fluids (70% bloodstream infections) demonstrated similar findings. Kerremans (2008) showed that reporting rapid results using the Vitek 2 (a mean of 20 hours sooner than the conventional group) resulted in faster alterations in therapy when compared with conventional results reported with the Vitek Legacy, including a reduction in the number of doses of antibiotics (defined daily doses). Similar to the previous study, a reduction in mortality between the two groups was not seen.

Although Barenfanger (1999) was not able to demonstrate a reduction in mortality when comparing outcomes of patients for whom rapid identification and susceptibility results were reported compared with those for whom conventional results were reported, this meaningful study demonstrated that there can be a significant contribution with respect to outcomes aside from mortality, in that it was demonstrated that rapid reporting of identification and antibiotic susceptibility testing can result in a significant decrease in length of hospital stay. A mean decrease in length of stay of 2 hospital days ($P < .0006$) was noted for those patients for whom rapid testing results were available, with a concomitant significant resultant decrease in total cost of hospital stay ($P < .04$); this is a not insignificant contribution in the current medical environment in the United States. In an earlier study involving demographically equivalent inpatients who were randomly assigned to a group in which rapid identification and antibiotic susceptibility testing were performed and a control group in which conventional testing was done, Doern and colleagues (1994) did not demonstrate a decrease in hospital stay, but did show a statistically significant decrease in costs related to laboratory, pharmacy, and other expenses, such that the mean overall cost of hospitalization was significantly decreased. Additionally, this is the only study on the clinical impact of rapid identification and antibiotic susceptibility testing to date that has demonstrated a decrease in mortality in the rapid testing group.

In theory, the faster that antibiotic susceptibility results are available, the greater is the potential for effective therapy, and hence the greater is the likelihood of improving outcome. This potential will vary with the disorder in question, the specific pathogen, the patient population, and the environment. In a retrospective cohort study of 2731 patients with septic shock in medical and surgical intensive care units, Kumar (2006) found that time from presentation to the institution of appropriate antimicrobial therapy was the major factor that influenced outcome. After initial presentation of hypotension, for every hour over the next 6 hours that appropriate antimicrobial therapy was delayed, survival decreased by 7.6%. Despite the demonstration of the importance of antibiotic therapy in helping to determine outcome with respect to mortality in some infections, and the intuitive conclusion that the faster antibiotic susceptibility results are available, the more likely it is that effective therapy can be administered and can improve outcome, the potential contribution of rapid (within hours) susceptibility testing offered by commercial automated systems has been difficult to document. As described previously, few studies have addressed this issue, and of those, only one has demonstrated an effect on outcome as measured by mortality. Given the methodologic and ethical issues involved in completing such a prospective study, the contribution of rapid susceptibility testing to outcomes as measured by mortality or morbidity may have to be accepted by inference. As noted in the studies cited here, however, the potential contribution of faster susceptibility testing in certain environments using other types of outcomes measures has been well demonstrated (e.g., reducing the cost of hospitalization), facilitating faster switching or focusing of antibiotic therapy as the most effective and/or least expensive alternative antimicrobial. The former is of great importance in the current cost-conscious health care environment in this country, and the latter not only contributes to cost savings but also can play a role in reducing the prevalence of resistant isolates in a facility and preventing the emergence of specific nosocomial pathogens, such as vancomycin-resistant enterococci (VRE) or *Clostridium difficile*.

Although there appears to be a valid case for the benefit of automated susceptibility systems in certain environments, as determined by the laboratory director in cooperation with the medical staff, it should be remembered that these systems, similar to all systems, are not infallible and do have weaknesses. In addition to the expense associated with purchase of the systems and their supplies, the automated systems may have difficulty in producing accurate results for specific antimicrobial–pathogen combinations. Difficulties may be specific to a given system or, more frequently, common to many of the automated systems. Tenover (2006) reported that the Phoenix system, the Microscan system, and Vitek 2 all had difficulty in detecting carbapenem resistance in *Klebsiella pneumoniae* isolates, although the Phoenix and Microscan performed better than the Vitek 2 in this study. Similarly, Wiegand and colleagues (2007) compared the ability of these systems to detect extended-spectrum β -lactamase (ESBL) production in species of Enterobacteriaceae and found that issues existed for all systems, but of a slightly different nature. The Phoenix system had a high sensitivity (99%) but with lower specificity (52%), while the systems with a higher specificity of 78% (Vitek 2) had a lower sensitivity (86%). All systems showed variability in performance depending on the species of Enterobacteriaceae being tested. Despite shortcomings, these systems may have an important role in antimicrobial susceptibility testing in some laboratories, especially those with high volume, as long as the laboratory director is familiar with the weaknesses of a given system and compensates for them through additional testing methods.

MOLECULAR-BASED TESTING FOR ANTIMICROBIAL SUSCEPTIBILITY

Molecular-based methods (e.g., nucleic-acid amplification [NAA]) have been found to have applicability in the detection and identification of a number of pathogens in the clinical laboratory. Low detection limits, quick speed of performance of the test (hours in many cases), and the ease with which the tests are adapted to high-volume testing have made them particularly useful in situations where the pathogen in question is a slow grower, like *Mycobacterium tuberculosis* complex (MTBC), or where speed of detection is of great help in managing the patient, as when enterovirus is identified in the cerebrospinal fluid (CSF) of a child who presents with meningoencephalitis. It is not difficult to see how the ability to identify a pathogen and to determine the antimicrobials to which the organism is resistant in a matter of hours using molecular-based methods could be helpful in patient management.

The use of NAA and other molecular-based methods in attempting to detect the presence of antimicrobial resistance in an organism is rather more complicated than identification, for a number of reasons. First, although identification can be accomplished by amplifying and detecting a particular species-specific segment of genome, resistance to a particular antimicrobial may be due to a variety of mechanisms; therefore testing for a number of genes may be required to exclude the potential for resistance. Second, the presence of the target segment of nucleic acid, which may be a gene, a segment near a particular gene, or a portion of the gene, does not necessarily imply that the gene is being expressed and is manifesting as the phenotypic expression of drug resistance.

Fewer mechanisms for antimicrobial resistance exist in gram-positive organisms, and in some cases, resistance to a particular drug is almost wholly due to the expression of a single gene. This has made the group more amenable for the initial development and deployment of molecular tests to detect antimicrobial resistance. Molecular tests to detect oxacillin resistance in *Staphylococcus aureus* that are commercially available are the best example. In the United States, two assays using the real-time polymerase chain reaction (PCR) method—the StaphSR (BD GeneOhm, San Diego) and the Xpert MRSA (Cepheid, Sunnyvale, Calif.)—have been in use for a number of years to screen patients for colonization with methicillin-resistant *Staphylococcus aureus* (MRSA). Both assays have been evaluated recently in the literature for the detection of MRSA in blood cultures, the rapid identification of which directly from blood culture bottles would allow more appropriate utilization of antibiotics up to 48 hours sooner than without the molecular test; both performed well. The StaphSR showed sensitivity and specificity of 95.6% and 95.3%, respectively, in detecting MRSA from spiked blood culture bottles in one study, and sensitivity and specificity of 100% and 98.4%, respectively, in a second study using positive blood cultures from patients (Stamper, 2007a; Grobner, 2009). The Xpert MRSA showed sensitivity and specificity of 98.3% and 99.4%, respectively, from blood cultures (Wolk, 2009). These studies illustrated some of the issues associated with molecular testing for antibiotic resistance (e.g., whether identification of a specific but very focused genomic segment correlates with a particular species or resistance phenotype). In particular, false-positive results were noted from revertant MRSA isolates that had residual SCCmec extremity fragments but without functional *mecA* genes (Grobner, 2009), as well as from a specimen with a mixture of a methicillin-resistant coagulase-negative *Staphylococcus* and an SCCmec empty cassette variant (Wolk, 2009). The issue of specificity for a particular gene has been particularly well illustrated with the VanR assay (BD GeneOhm), an amplification test that detects the presence of the *Van A* and *Van B* genes associated with glycopeptide resistance in *Enterococcus* species. This assay is intended to allow screening of patients for VRE colonization. It is very effective for its intended purpose when screening in facilities with a high prevalence of VRE due to isolates with the *Van A* gene, but it suffers from specificity issues in situations where *Van B* is highly prevalent because of the apparent ability of other species, such as *Clostridium* spp., to acquire the gene (Stamper, 2007b).

Development of the multiplex-PCR method, an innovation allowing concurrent amplification of multiple nucleic acid segments using multiple primers, is central to the performance of assays like the StaphSR, which targets several nucleic acid segments, and is particularly necessary for any attempt to assess resistance in gram-negative organisms. Relative to gram-positive bacteria, antimicrobial resistance in gram-negative bacteria is complex, as resistance to a given drug may be due to alterations in the structure or quantity of porins that allow drug entry into the cell, efflux pumps, or enzymes that inactivate the drug, or it may be due to modifications of the target of the drug. This variety in drug resistance mechanisms had impaired the development of rapid tests based on molecular methods that detect antimicrobial resistance in gram-negative organisms, and it limited widespread availability of these tests to laboratories. However, by using multiplex PCR to target multiple sites, by focusing on specific resistance mechanisms that can be difficult to assess by classical phenotypic methods, and by analyzing using a convenient DNA microarray detection system, some investigators have shown that molecular diagnostic methods have the potential to improve resistance detection for gram-negative organisms. Zhu and colleagues (2007) used these techniques to determine whether any of 10 different ESBL and *AmpC* β -lactamase genes were present in clinical isolates of Enterobacteriaceae. Their assay showed “complete agreement with complementary sequencing results” and >95% correlation with phenotypic susceptibility testing for isolates of *K. pneumoniae* and *Escherichia coli*, although the authors noted that correlation of the phenotypic assays and the molecular assay was not as good for *Enterobacter cloacae* isolates that possessed the chromosomal *AmpC* gene.

Additionally, four *K. pneumoniae* isolates that demonstrated ESBL genes through the assay were “susceptible to all the antibiotics tested,” again illustrating occasional disagreement between detection of a gene for a resistance mechanism and results obtained by phenotypic testing.

Along with variability in mechanisms of resistance, geographic variation in prevalence may affect the performance of a molecular-based test for susceptibility testing. The ESBL screen described by Zhu (2007) may well perform more poorly in another locale if ESBL enzymes that exist in that locale are different. An analogous situation has been suggested in some studies on commercially available molecular tests for resistance in MTBC. A few such commercial, standardized tests exist, including the Genotype MTBDRplus assay (Hain LifeScience, Nehren, Germany), an assay based on multiplex PCR with detection by reverse hybridization on nitrocellulose strips. The assay predicts resistance to rifampin by detecting mutations in the *rpoB* gene, and resistance to isoniazid by detecting mutations in regions of *katG* and *inhA* genes. Sensitivity for detecting resistance to rifampin has been uniformly high in published studies (range, 95%–98%), and sensitivity for detecting resistance to isoniazid has had a wider range (range, 73%–97%) (Hillemann, 2007; Lacombe, 2008; Huang, 2009; Nikolayevskyy, 2009). Although most (approximately 95%) rifampin resistance is due to mutations in a few codons of the *rpoB* gene, greater variability in possible sites for mutation have led to isoniazid resistance. Although the most common mutation imparting isoniazid resistance is found at codon 315 of the *katG* gene, mutations in the *inhA*, *aphC-oxvR* intergenic region and others may be responsible (Hillemann, 2007). Several authors have pointed out that the wide variation in sensitivity for detection of isoniazid resistance by this assay is attributable to geographic variation in the incidence of specific genetic mutations (Huang, 2009; Nikolayevskyy, 2009).

The use of molecular techniques to detect the presence of possible antimicrobial resistance is an important innovation that has begun to be investigated in the past several years, in some cases leading to standardized, commercially available tests for use by clinical laboratories. This innovation is still in its formative stages, as clinical microbiologists are learning the abilities and limitations of the highly specific but as yet incompletely understood techniques. Additionally, use of these tests may require reorientation in thinking on the part of some physicians, in that test results show detection of resistance rather than an indication of susceptibility. The rapidity of the tests may provide useful epidemiologic infection control and, in some specific cases, patients, or locales, may reveal information that will aid in patient management; however, until the full implications of detecting or not detecting a specific gene using a particular molecular technique are fully understood, these tests will serve in a supporting role to phenotypic antimicrobial susceptibility testing in most clinical laboratories.

INDICATIONS FOR SUSCEPTIBILITY TESTING

Whether antimicrobial susceptibility testing on a particular isolate is necessary varies with the infecting species. If the susceptibility of an aerobic or facultatively anaerobic bacterial species to a particular antimicrobial is unpredictable, then testing is necessary. If the susceptibility profile is predictable, it is not necessary, in most cases, to do testing on an isolate. For example, resistance to penicillin in *Streptococcus pyogenes* has not been reported in the United States, so it is appropriate to treat a patient with *S. pyogenes* pharyngitis without susceptibility testing. However, if a patient is allergic to, or cannot take, the primary choice of antibiotic to treat an infection that caused a particular pathogen, or if, for another reason, the susceptibility profile of the alternative choice antibiotic is unpredictable, testing must be done. If the patient in the previous example were allergic to penicillin, and the physician wished to treat the patient with a macrolide, such as azithromycin, susceptibility testing of the isolate against macrolides should be done because a high proportion of *S. pyogenes* isolates have tested resistant to macrolides for a number of years (Jacobs, 2003). It must also be remembered that testing should be limited to those isolates that are definite pathogens, because testing of isolates that are “contaminants” or “normal flora” is expensive and time consuming and may lead to unnecessary administration of antibiotics (Bates, 1991); therefore it should be avoided. With increasing numbers of severely immunocompromised patients, however, species generally considered to be normal flora or contaminants may be pathogenic, and in these patients susceptibility testing against these species may be warranted. Close consultation with infectious disease physicians is necessary in these cases.

Several years ago, antibiotic therapy for infection caused by anaerobes was often empirical, because the susceptibility profiles of these pathogens were thought to be relatively predictable, susceptibility testing was not standardized, and only limited proof suggested that susceptibility testing correlated with outcome. In recent years, however, it has been demonstrated that the susceptibility patterns of many anaerobic pathogens are changing, and that at least for some species, in vitro antibiotic susceptibility testing correlates with clinical outcome. This is particularly true of *Bacteroides fragilis* and closely related species (Nguyen, 2000; Snyderman, 2002). *B. fragilis*, the most frequently isolated species from infections, has the greatest number of antimicrobial resistance mechanisms, as well as the highest rates of antimicrobial resistance, among anaerobic bacterial pathogens (Wexler, 2007). The CLSI recommends testing of anaerobic isolates from specific types of infections, including brain abscess, endocarditis, osteomyelitis, joint infection, infection of prosthetic or vascular devices, and bacteremia (Clinical and Laboratory Standards Institute, 2007). Additionally, certain species that have a high incidence of resistance or are highly virulent warrant testing, including species of *Bacteroides*, *Prevotella*, *Fusobacterium*, *Clostridium*, *Bifidobacteria*, and *Sutterella*. Currently, the only CLSI-recommended susceptibility testing method for anaerobes is the agar dilution method (Clinical and Laboratory Standards Institute, 2007). The exception is the *B. fragilis* group, for which broth microdilution can be performed (Clinical and Laboratory Standards Institute, 2007). Laboratories that do not have the capability to perform agar dilution testing may wish to perform broth microdilution testing on *B. fragilis* isolates that require testing, and may refer other species to a reference laboratory with agar dilution testing capabilities. For other isolates not already discussed, batch susceptibility testing of archived isolates of anaerobes can be performed, either locally or by a reference laboratory, on a periodic basis (recommended annually by the CLSI) in a surveillance protocol to detect local changes in resistance patterns.

Unlike anaerobes, all initial isolates from newly diagnosed cases of tuberculosis should be tested for susceptibility to primary antituberculous drugs; if clinical evidence reveals therapeutic failure or failure of cultures to convert to negative after 3 months, testing should be repeated (National Committee for Clinical Laboratory Standards, 2003). Testing of initial isolates is crucial, because it has been demonstrated that treatment of a patient with a regimen of antitubercular medications without initial susceptibility can lead to significant consequences if the initial isolate is drug resistant. The incidence of treatment failure and relapse and the development of further drug resistance increase significantly if the treatment regimen in these patients is not based on susceptibility testing results of the initial isolate (Lew, 2008). Guidelines exist for testing of some slow-growing nontuberculous mycobacteria (*Mycobacterium avium* complex, *Mycobacterium kansasii*, *Mycobacterium marinum*) and rapidly growing mycobacteria (*Mycobacterium fortuitum* group, *Mycobacterium chelonae*, *Mycobacterium abscessus*, *Mycobacterium mucogenicum*, *Mycobacterium smegmatis* group). Similarly, recommendations have been put forth for susceptibility testing of the aerobic actinomycetes (*Nocardia* spp., *Actinomyces* spp., *Rhodococcus* spp., *Gordonia* spp., *Tsukamurella* spp., *Streptomyces* spp.). In general, testing of nontuberculous mycobacteria and of aerobic actinomycetes involves variations in the broth dilution method, and commercial systems can be used for a few species. Because the drugs tested and the methods of testing vary with the species, CLSI document M24-A (National Committee for Clinical Laboratory Standards, 2003) should be consulted for details. It should be emphasized that some of these species can exist as transient colonizers of the respiratory tract, or they may be recovered as contaminants, so adherence to criteria to assess clinical significance prior to susceptibility testing, as outlined in CLSI document M24-A, is strongly recommended.

Similarly, both yeasts and moulds may exist as transient colonizers or contaminants; however, with the increase in the number of immunocompromised patients over the past several decades, the prevalence of fungal infection has increased. Additionally, many new antifungal agents have become available, and resistance to these as well as to the older agents has been described. For *Candida* spp., good correlation between in vitro antifungal resistance and treatment failure has been demonstrated in patients with acquired immunodeficiency syndrome who have oropharyngeal and esophageal candidiasis (Kanafani, 2008). Susceptibility testing by both broth dilution and disk diffusion methods has been standardized for yeasts, excluding the yeast phases of dimorphic fungi such as *Blastomyces dermatitidis*, and breakpoints against a variety of antifungals for *Candida* spp. have been established (National Committee for Clinical Laboratory Standards, 2004; Clinical and Laboratory Standards Institute, 2008, 2008b, 2008c). In recent updates, interpretive guidelines for additional antifungal agents

have been added, and the relevant CLSI documents should be consulted (Clinical and Laboratory Standards Institute 2008b). With moulds, the situation involving susceptibility testing is more complex; although procedures for both broth dilution and disk diffusion have been standardized and published by the CLSI (Clinical and Laboratory Standards Institute, 2008d, 2009d), in vitro susceptibility alone has not been shown to predict therapeutic success or failure in clinical trials (Kanafani, 2008).

Many factors, including whether the patient is immunosuppressed, the burden of fungal organisms when treatment is started, the site of infection, and the patient's underlying disease, to name several, are involved in determining whether antifungal therapy will be successful in a patient with a systemic mould infection (Kanafani, 2008). Further, clinical breakpoints have not been established for antifungals and moulds. However, by using epidemiologic cutoff values (ECVs), which have been established for some antifungals, laboratories can detect isolates that show reduced susceptibility to an antifungal relative to "wild-type" isolates, or isolates with no acquired phenotypically detectable resistance. It is important to consider, however, that ECVs are not clinical breakpoints, and an isolate may respond to therapy despite having an MIC above the ECV. An infectious disease specialist may consider this information helpful in his/her management of a patient with systemic mould infection, however, particularly if he or she is able to compare susceptibility results versus a cohort of the same species tested at the same institution as the patient (i.e., if there is a local antibiogram of the particular species). Currently, the CLSI recommends determining MIC values on mould species to use as an aid in managing invasive infection when the utility of antifungal therapy is uncertain, or to establish antibiograms at a particular institution (Clinical and Laboratory Standards Institute, 2009d).

SELECTION OF ANTIBIOTICS FOR TESTING AND IMPORTANT RESISTANCE PHENOTYPES

Selection of antimicrobial agents for testing is complicated by the expanding spectrum and number of antibiotics available and by the growing list of resistance phenotypes that are being identified in pathogenic bacteria. Testing of all agents available in an institution's formulary is neither practical nor warranted. The antimicrobial testing menu should be established in consultation with the medical staff, infectious disease specialists at the institution, and the Pharmacy and Therapeutics Committee, so that the therapeutic needs of the patient population can be best coordinated with the practical limitations of the institution, the pharmacy, and the clinical laboratory. This coordination is important for a variety of reasons. First, many laboratories utilize commercial automated testing systems for susceptibility testing. Manufacturers offer a variety of preconfigured antibiotic testing panels in systems designed to correspond to hospital formularies; however, disparities between the preconfigured panel and the hospital formulary often exist. The laboratory may be faced with an added expense of modifying a preconfigured panel, or of adding testing methods to the laboratory to accommodate testing of additional agents. Second, it is not usually necessary to report susceptibility testing results for multiple representatives of the same spectrum class (e.g., cefotaxime, ceftizoxime, ceftriaxone), in that results derived by testing a representative drug of the class can sometimes be generalized to all representatives of the class. Discussion and coordination with medical staff and infectious disease specialists relative to which antibiotics are necessary to allow caregivers at the institution to manage their patients may save the laboratory these added expenses.

The yearly CLSI informational supplement (Clinical and Laboratory Standards Institute, 2009) lists in a table antimicrobial agents that are recommended for testing for high prevalence and important nonfastidious pathogens, including Enterobacteriaceae, *Pseudomonas aeruginosa*, *Staphylococcus* spp., *Enterococcus* spp., *Acinetobacter* spp., *Burkholderia cepacia*, and *Stenotrophomonas maltophilia*. A separate table lists recommended antibiotics for more fastidious pathogens such as *Haemophilus* spp., *Neisseria gonorrhoeae*, *Streptococcus pneumoniae*, *Streptococcus* β -hemolytic spp., and *Streptococcus viridans* group spp. The antibiotics are listed in four groups, with group A containing drugs recommended for testing and reporting on all isolates, and with group B containing agents suggested for testing against all isolates but reported only under certain circumstances (e.g., when the isolate is resistant to drugs in Group A). Group C lists antibiotics that are considered supplemental and could be used in facilities that have a high prevalence of highly resistant isolates, when unusual pathogens are

isolated, or by infection control practitioners as epidemiologic tools. Finally, group U lists antimicrobials that should be tested and reported only on isolates from urine.

Within each group—A, B, C, or U—more antibiotics are listed than need be tested or reported. Within boxes in the tables, drugs that usually have similar interpretive results and clinical efficacy are grouped together, and if an agent is listed with another agent separated by “or,” this implies almost identical cross-resistance or susceptibility between drugs; the results of testing one drug will predict the susceptibility result for the other. In the absence of the “or,” even though the antibiotics listed in the same box have similar clinical efficiency and similar interpretive results, stringent statistical criteria for comparable testing results were not met when a large number of isolates were tested with the antibiotics in question, or the data were not available, so equivalence for testing results cannot be confidently inferred. For example, for Enterobacteriaceae in Table 1 (Clinical and Laboratory Standards Institute, 2009), the two cephalosporins, cephalothin and cefazolin, are listed in group A in the same box but are not separated by an “or.” A footnote to the table notes that testing of cephalothin will predict the susceptibility profile of many other first-generation cephalosporins. Some first-generation cephalosporins must be tested separately, however, because an isolate may be susceptible to the drug despite being resistant to cephalothin. In contrast, in group B, the third-generation cephalosporins cefotaxime and ceftriaxone are separated by an “or,” indicating that their susceptibility profiles are virtually interchangeable, and that only one of the two needs to be tested if the isolate is a member of Enterobacteriaceae.

The cephalosporins have been an important mainstay of therapy for gram-negative and gram-positive organisms; therefore, resistance mechanisms developed by these groups have been of great interest, and developments in or discovery of resistance phenotypes to the β -lactams have stimulated many changes in susceptibility testing in recent years. Although this is not the only method by which bacteria become resistant to β -lactams, particularly gram-positive bacteria, β -lactamases have been a topic of high interest in recent years because of the development of new resistance phenotypes mediated by these enzymes. *Staphylococcus* spp. and *Enterococcus* spp. are two major gram-positive pathogens for which β -lactamase testing is a matter of interest, and the CLSI recommends that penicillin should be tested against isolates. Among *Staphylococcus* spp., these enzymes are highly prevalent and are inducible rather than constitutive, that is, the isolate must be exposed to a β -lactam drug before it can phenotypically demonstrate its production. Penicillin therapy may be considered for members of this genus (for some species, this depends on the results of testing for methicillin-resistance [see later]); the CLSI M-100 document details a procedure for testing of inducible β -lactamase using a nitrocefin-based test. Use of the nitrocefin-based test is also recommended for *Enterococcus* spp., as MIC methods will not reliably detect production of the enzyme in these isolates. Although the enzyme is produced constitutively in enterococci, its expression shows an inoculum effect, and greater quantities of bacteria are needed to demonstrate its expression in disk diffusion or broth dilution (Murray, 1990).

Note that testing of ampicillin is also recommended for testing against *Enterococcus* spp., and that although the ampicillin susceptibility profile will predict the profile of penicillin, the reverse is not true (Clinical and Laboratory Standards Institute, 2009). Resistance to ampicillin in *Enterococcus* spp. is mediated by alterations in the enzymes involved in peptidoglycan synthesis, the penicillin-binding proteins (PBPs), so testing for β -lactamase production in this genus will not predict ampicillin susceptibility. The same is true for methicillin (or oxacillin) resistance in *Staphylococcus aureus* (MRSA) and coagulase-negative *Staphylococcus* spp. (CNS). These isolates are resistant to all currently available β -lactam antimicrobials (and β -lactam- β -lactamase inhibitor combinations), hence their detection is crucial for therapeutic management. Most commonly, oxacillin resistance in *Staphylococcus* spp. is due to production of an altered PBP (PBP 2a) product of the *mecA* gene, which may be expressed homogeneously or heterogeneously. Although isolates that express the gene homogeneously can be relatively easily detected, those that express it heterogeneously may be more problematic, and they may appear phenotypically sensitive by dilution testing using oxacillin (Sakoulas, 2001; Swenson, 2001; Felten, 2002).

When a dilution technique is used, sensitivity for detecting these heteroresistant strains can be improved by adding NaCL (2% weight/volume) to the medium (Clinical and Laboratory Standards Institute, 2009c). Cefoxitin, in dilution tests or in the disk diffusion test, can be used to screen staphylococci for *mecA*-mediated resistance, and has been shown to be equivalent in sensitivity and specificity to dilution methods using

oxacillin for *S. aureus* and superior to dilution testing for CNS (Clinical and Laboratory Standards Institute, 2009c). This high performance level extends to the automated susceptibility systems, which have incorporated cefoxitin MIC testing for *Staphylococcus aureus* into their testing and expert systems, with studies showing close to 100% agreement on detection of MRSA compared with reference methods such as *mecA* gene detection (Junkins, 2009; Kaase, 2009). Additionally, because no disk diffusion zone diameters are known for oxacillin for CNS, the cefoxitin disk test provides a convenient and simple method of screening for oxacillin resistance in this group. Cefoxitin dilution testing can be used for *S. aureus*, but not for CNS, to predict *mecA*-mediated β -lactam resistance. However, tests that detect the *mecA* gene or PBP 2a itself are considered the most accurate of the available tests (Clinical and Laboratory Standards Institute, 2009c). Tests used to detect the *mecA* gene were discussed in the section on molecular-based tests and will not be discussed further here. With respect to detection of PBP 2a, several tests based on a latex agglutination format (MRSA-Screen, Denka Seiken Co., Tokyo, Japan; Oxoid PBP2' latex agglutination test, Oxoid, Basingstoke, United Kingdom) have been approved for use in *S. aureus* colonies growing on agar and can be used to separate MRSA from methicillin-sensitive isolates. Studies have shown sensitivities of 98.5%–100% with specificity of 100% for detecting MRSA (Louie, 2000; Arbiq, 2001; Sakoulas, 2001). The MRSA-Screen is not approved for detection of methicillin resistance in CNS; the Oxoid PBP2' latex agglutination test can be used for this purpose, although literature is not available to assess its performance in this role.

MRSA and methicillin-resistant CNS have become significant problems in hospital environments, with MRSA accounting for 59.5% of *S. aureus* and methicillin-resistant CNS 89.1% of CNS isolates in intensive care environments (NNIS, 2004); the increased prevalence of community-acquired MRSA has further increased the importance of detection of methicillin resistance in these species. The situation with *Streptococcus pneumoniae* is similar, with alterations in PBPs leading to resistance to penicillin and cephalosporins. The longitudinal PROTEKT surveillance study showed that although the incidence of high-level (MIC ≥ 2 $\mu\text{g/mL}$) penicillin resistance decreased from 26.5% to 16.5%, the level of intermediate resistance (MIC 0.12–1 $\mu\text{g/mL}$) increased from 12.5% to 20% over the period of the report (2001–2004) (Jenkins, 2008). The incidence of multidrug resistance (resistance to penicillin and two other antibiotics) remained at about 30% over this period.

Susceptibility testing of this pathogen is mandatory when isolated from sterile sites. The oxacillin screen disk diffusion method can be used, with isolates having a zone of inhibition ≥ 20 mm, indicating that the isolate is susceptible to penicillin and to other β -lactams listed in M100 (Clinical and Laboratory Standards Institute, 2009). This applies only to nonmeningitis isolates, as MIC testing is recommended for isolates from this source. Further, zone sizes <19 mm on the oxacillin screen require additional testing using an MIC method because a zone of inhibition of this size may be seen with isolates that are resistant, susceptible, or intermediate to penicillin; therefore, it may be most effective to proceed directly to MIC testing when an isolate is obtained from a source (meningitis, blood) for which a delay in susceptibility testing may be potentially dangerous. It should be noted that interpretive standards for penicillin and the third-generation cephalosporins differ, depending on whether the isolate is a CSF isolate or not; the CLSI recommends that both interpretations be reported unless the isolate is obtained from the CSF, in which case only the meningitis interpretive category is reported. Testing methods are determined by the antibiotics tested for *S. pneumoniae*, as disk diffusion cannot be performed for drugs such as ampicillin, cefotaxime, ceftriaxone, imipenem, and meropenem, to name several (Clinical and Laboratory Standards Institute, 2009c). The commercial automated systems—Phoenix (Becton Dickinson Diagnostic Systems, Sparks, Md.) and Vitek 2 (bioMérieux)—offer antibiotic testing panels for *S. pneumoniae*; their performance has been favorable in published studies (Ligozzi 2002; Richter, 2007).

Most penicillin resistance in enterococci, usually seen in *Enterococcus faecium*, is due to the production of low-affinity PBPs (Clinical and Laboratory Standards Institute, 2009c), although in some cases, β -lactamase production is the cause of the resistance. This is important to note, in that dilution procedures will not detect β -lactamase production, which is the reason why the CLSI recommends testing isolates, particularly those from blood or CSF, with the nitrocefin β -lactamase test (Clinical and Laboratory Standards Institute, 2009c). Penicillin or ampicillin resistance is of importance in enterococci, as a synergistic action of penicillin or ampicillin with aminoglycosides is often effective therapy for serious infection. This synergistic effect can occur even when the penicillin or ampicillin MIC is at

a high level, above the resistant interpretive category (Clinical and Laboratory Standards Institute, 2009c). Aminoglycosides are clinically ineffective against enterococci by themselves, and susceptibility testing is performed only for the possible synergistic effect when combined with penicillin, ampicillin, or a glycopeptide. Testing is performed only with high concentrations of the aminoglycoside, 500 µg/mL gentamicin, or 1000 µg/mL of streptomycin, using broth dilution. Enterococci causing serious infection require testing against penicillin or ampicillin, high-level aminoglycoside screening, and testing for susceptibility to a glycopeptide, which is usually vancomycin in the United States.

Glycopeptide resistance in enterococci is produced by the production of altered pentapeptide peptidoglycan precursors, which results in a greatly reduced affinity for binding of vancomycin by 1000-fold. Binding of vancomycin to the pentapeptide prevents cross-linking with other precursors, resulting in prevention of the production of a stable cell wall. Altered precursors are the result of specific genes, of which the two most relevant are *Van A* and *Van B*, and isolates that demonstrate resistance to vancomycin are VRE, of which most are *E. faecium*, although *E. faecalis* may also be included as VRE. Isolates with *Van A* or *Van B* will demonstrate high-level vancomycin resistance, and a third gene, *Van C*, which is usually found in *E. casseliflavus* or *E. gallinarum*, will cause a low level of vancomycin resistance, the clinical significance of which is unknown. Screening for VRE can be done using agar or broth dilution or a screening agar consisting of brain heart infusion with 6 µg/mL of vancomycin. During testing, it is important that the previously mentioned testing systems be incubated for a full 24 hours, because reading at 16–20 hours may produce an erroneous result (Clinical and Laboratory Standards Institute, 2009c). Modern commercial test systems have performed well in detecting VRE, with all isolates with the VRE phenotype detected by the Phoenix (BD Diagnostic Systems) and the Vitek 2 (bioMérieux) in published studies (Ligozzi, 2002; Fahr, 2003; Abele-Horn, 2006; Carroll, 2006).

Vancomycin susceptibility testing of *S. aureus* has become an important concern for clinical microbiology laboratories since the detection of isolates with reduced susceptibility to the drug (i.e., vancomycin-intermediate *Staphylococcus aureus* [VISA] with MIC values of 4–16 µg/mL, and vancomycin-resistant *Staphylococcus aureus* [VRSA] with MIC >32 µg/mL). Although the mechanism of resistance in VRSA isolates appears to be linked to acquired *Van A* (Centers for Disease Control and Prevention, 2002, 2004), the mechanism associated with elevated MIC values in VISA is not completely understood, but appears to be linked to increased cell wall thickness and vancomycin-binding peptides (Cui, 2000). Detection of these isolates is important because most are also MRSA, and vancomycin is often used to treat these β-lactam-resistant organisms. VRSA isolates, which are very rare, can be reliably identified by microbroth dilution, disk diffusion, or vancomycin screening agar Brain-heart infusion agar with 6 µg/mL vancomycin, as long as the test systems are incubated a full 24 hours at 35° C ± 2° C (Clinical and Laboratory Standards Institute, 2009c). For VISA, however, the issue is more problematic because disk diffusion is not an effective screening method, and the vancomycin screening agar is not reliable for isolates that have MIC values on the lower end of the spectrum (e.g., 4–8 µg/mL) (Clinical and Laboratory Standards Institute, 2009c; Swenson, 2009).

Commercial automated and nonautomated systems similarly have difficulty detecting VISA with MIC values near the low end of the intermediate resistance spectrum, and these systems all have their own peculiarities with respect to testing of these isolates; laboratories should be aware of these peculiarities if consideration is given to using a given system (Swenson, 2009). It is interesting to note that in the study by Swenson (2009), the testing method that was most reliable for detecting VISA, that is, manual microbroth dilution, had difficulty with VISA isolates with MIC values on the low end of the intermediate resistance spectrum. The issue of VISA is further complicated by the existence of so-called vancomycin heteroresistant *S. aureus* (hVISA) isolates, which are isolates that contain subpopulations of organisms with MIC values of 8–16 µg/mL. Much like VRSA and VISA, hVISA appears to be associated with treatment failure when vancomycin is used (Tenover, 2007). Additionally, although VRSA and VISA isolates are infrequent, studies have suggested that hVISA isolates are not rare and may account for up to 18% of isolates in some geographic locations (Tenover, 2007). Unfortunately, no current susceptibility testing method is reliable for detecting hVISA. In an effort to aid in detecting hVISA, particularly among strains with MIC values >2 µg/mL, when data indicating that some hVISA strains will have MIC values in the 0.5–4 µg/mL range were used, the CLSI lowered the interpretive breakpoints for *S. aureus* and vancomycin, with susceptibility decreasing to

≤2 µg/mL; intermediate decreased to 4–8 µg/mL, and resistant decreased to ≥16 µg/mL (Tenover, 2007). Not all hVISA strains will be detected using this strategy, however, and additional advancements in susceptibility testing methods are needed to address this issue.

For streptococci other than *S. pneumoniae* or enterococci, antimicrobials to be tested and reported depend on the species. For example, for *Streptococcus pyogenes* (Lancefield group A), susceptibility testing for penicillin and other β-lactams and vancomycin is not necessary because resistant strains have not been reported (Clinical and Laboratory Standards Institute, 2009). If the patient is penicillin allergic and consideration is given to treatment with a macrolide, testing is necessary, and results obtained with erythromycin may be generalized to azithromycin, clarithromycin, and dirithromycin (Clinical and Laboratory Standards Institute, 2009). Similarly, current recommendations are that β-lactam susceptibility testing for *S. agalactiae* (Lancefield group B) is not necessary; however, recent literature has reported the occurrence of isolates with MIC values above the breakpoints for susceptibility for penicillin and cephalosporins from the Far East and from the United States (Dahesh, 2008; Kimura, 2008). Altered PBPs, similar to those found in *S. pneumoniae*, were identified by molecular studies. Additional studies are necessary to determine the implications, both clinically and with respect to laboratory testing, before the clinical relevance of these reports is known.

It is also recommended that for pregnant women who are colonized with group B streptococci and who are allergic to penicillin, testing for clindamycin and erythromycin should be carried out (Clinical and Laboratory Standards Institute, 2009). Isolates that are resistant to erythromycin but susceptible to clindamycin should be tested for “inducible” resistance to clindamycin mediated by the *erm* gene (MLS_B resistance: macrolide, lincosamide, streptogramin B) using the **D-zone approximation test**, with closely approximated diffusion disks of both clindamycin and erythromycin (Clinical and Laboratory Standards Institute, 2009) (Fig. 58-3). For staphylococci, a single-well broth microdilution test may also be used (Clinical and Laboratory Standards Institute, 2009c). “Inducible” clindamycin resistance can occur in staphylococci and β-hemolytic streptococci, and prevalence may vary from geographic area to geographic area, as noted in studies determining prevalence in group B streptococci and group A streptococci (Desjardins, 2004; Richter, 2005; Tazi, 2007), or may vary with the origin of the isolate in a given geographic area, such as whether or not a *S. aureus* isolate is hospital or community acquired (Patel, 2006). Some institutions test for inducible clindamycin resistance routinely or in certain situations (Feibelkorn, 2003; Jorgensen, 2004). A possible strategy that can be used to determine and implement the most cost-effective testing strategy for inducible clindamycin resistance in relevant species would be to survey for the prevalence of this type of resistance and, in consultation with infectious disease and/or medical staff, set new testing policies based on these results (Schreckenberger, 2004).

For the viridans streptococci, any isolate derived from a sterile body site and implicated in a serious infection, such as endocarditis or sepsis, should be tested for penicillin or ampicillin susceptibility (Quinn, 1988; Clinical and Laboratory Standards Institute, 2009). Diffusion testing

Figure 58-3 Disk induction or “D” test. The *Staphylococcus aureus* isolate on the left demonstrates erythromycin (E) resistance but susceptibility to clindamycin (CC). The *S. aureus* isolate demonstrates inducible clindamycin resistance with blunting of the zone of inhibition around the clindamycin disk adjacent to the erythromycin disk.

interpretive standards for penicillin and ampicillin do not exist for viridans streptococci, as the method is unreliable for this pathogen–antimicrobial combination, so testing is accomplished using an MIC method (Clinical and Laboratory Standards Institute, 2009). Viridans streptococci are important pathogens causing sepsis in patients with neutropenia and native valve endocarditis, and studies have demonstrated increasing rates of resistance to penicillin especially, and also to the cephalosporins (Prabhu, 2004; Gordon, 2002; Han, 2006; Yap, 2006). Fluoroquinolones are often used prophylactically in neutropenic patients, and since the development of fluoroquinolone resistance in viridans streptococci colonizing these patients (Prabhu, 2005) and bloodstream isolates (Han, 2006) was reported, testing of fluoroquinolones in this patient population is indicated despite an overall low prevalence of fluoroquinolone resistance in viridans streptococci in general (Gordon, 2002). This illustrates a situation wherein a specific patient population served by a facility dictates testing and reporting of specific antimicrobials.

Although resistance to the β -lactam antibiotics in gram-positive organisms in many cases involves altered PBPs, in gram-negative organisms, resistance is mediated primarily by the production of β -lactamases. For some gram-negative species, it may be possible to test for β -lactamase production using the chromogenic cephalosporin test. The prevalence of β -lactamase-positive *Haemophilus influenzae* in the United States is approximately 30%, while the prevalence of β -lactamase-negative, ampicillin-resistant (BLNAR) strains, which are not detected by the β -lactamase test, is low (Jacobs, 2003). Geographic variation has been noted, however, and in some areas outside of the United States up to this point, BLNAR strains make up a significant portion of all isolates (Tristram, 2007). For non-life-threatening infection with *H. influenzae*, the nitrocefin test will predict susceptibility to ampicillin and amoxicillin. It may be possible for a laboratory to utilize the nitrocefin test alone in this situation, saving time and money, because susceptibility testing of *Haemophilus* spp. requires specialized media (*Haemophilus* test medium), which have a short shelf life. In areas with a high prevalence of BLNAR, this strategy would not be effective. In the case of life-threatening infection, such as meningitis, the CLSI recommends that susceptibility testing be performed, and that only ampicillin, a third-generation cephalosporin, chloramphenicol, and meropenem should be reported (Clinical and Laboratory Standards Institute, 2009).

In contrast to *H. influenzae*, penicillin resistance in *Neisseria meningitidis* is due primarily to altered PBPs, although occasional isolates with β -lactamase production do occur (Jorgensen, 2005). Both MIC interpretive standards and disk diffusion breakpoints for susceptibility testing of *N. meningitidis* have been published in CLSI documents (Clinical and Laboratory Standards Institute, 2009), and the testing method has been standardized and validated (Clinical and Laboratory Standards Institute, 2009c). Although resistance to penicillin has been reported in the United States, resistance to cefotaxime and ceftriaxone, used in the treatment of meningitis or sepsis due to this species, or to sulfonamides and rifampin, which are used for prophylaxis, has not been reported (Jorgensen, 2005), so testing protocols for this particular species may be determined with input from local medical staff or infectious disease specialists. It is important to remember that if testing is undertaken, because of the occurrence of laboratory-acquired meningococcal infection, which has a high fatality rate, appropriate safety precautions, including the use of a biological safety cabinet, must be utilized by testing personnel (Clinical and Laboratory Standards Institute, 2009).

β -Lactam antibiotics are used in high frequency for treatment of infection due to the gram-negative Enterobacteriaceae; this group of bacteria has developed the capacity to produce a wide array of β -lactamase enzymes. One group of high interest consists of the so-called ESBLs, which are plasmid-derived and hence highly transferable enzymes that have evolved through the mutation of older Temoniera (TEM) and sulphydryl reagent variable (SHV) enzymes. Paterson and Bonomo (2005) provide a concise definition of these enzymes as enzymes that produce resistance to penicillins, the first- through third-generation cephalosporins, and aztreonam, but that are susceptible to inhibition by β -lactamase inhibitors and do not hydrolyze the cephamycins. The importance of these enzymes is twofold: First, isolates that have them may appear susceptible by *in vitro* testing to antimicrobials that they are capable of hydrolyzing; second, there may be a good chance of clinical failure when therapy using one of these antimicrobials is provided, even when MIC values are in the susceptible range (Paterson, 2005). Isolates with ESBLs accounted for approximately 5% of Enterobacteriaceae isolates in one survey study in the United States, with a high predilection for intensive care unit environments and association with prolonged hospital stays, indwelling medical devices, and therapy

with antimicrobials of a variety of types (Paterson, 2005; Moland, 2006). In the United States, they are found primarily in *Klebsiella pneumoniae*, *K. oxytoca*, *Escherichia coli*, and *Proteus mirabilis*—species recommended for screening by the CLSI—but they may be found in other species as well, including *Enterobacter* spp., *Citrobacter* spp., *Serratia* spp., and *Salmonella* spp. (Bradford, 2001; Paterson, 2005; Moland, 2006).

CLSI documents provide procedures for screening using disk diffusion or broth microdilution, as well as confirmation utilizing the characteristic that these enzymes are inhibited by β -lactamase inhibitors and by testing susceptibility with and without an inhibitor (Clinical and Laboratory Standards Institute, 2009). It should be remembered that for screening, using the results obtained with more than one antimicrobial improves sensitivity, and confirmation with both cefotaxime and ceftazidime, with and without clavulanic acid, improves specificity (Paterson, 2005; Clinical and Laboratory Standards Institute, 2009). Automated susceptibility systems include tests that can be used to detect ESBLs; however, sensitivity issues for some systems and issues with expert software systems have suggested that manual methods should remain an important part of testing for ESBLs in the clinical microbiology laboratory (Thomson, 2007; Snyder, 2008).

A false-negative on the ESBL phenotypic confirmation test as described by the CLSI may be produced by an organism that is producing another type of β -lactamase that is of high interest—AmpC β -lactamase—in addition to an ESBL. AmpC enzymes exist in two forms, with the first type having the gene located on a chromosome. Among the Enterobacteriaceae, chromosomally mediated AmpC can be found in *Enterobacter* spp., *Citrobacter freundii*, *Serratia marcescens*, and *Escherichia coli*, to name a few; it may also be found in *Pseudomonas* spp. and *Acinetobacter* spp. (Coudron, 2000). Under these conditions, this enzyme is usually inducible, except in *E. coli*, where it is constitutive but is often produced in small amounts. AmpC may be plasmid derived, and in the United States, it is most often found in *K. pneumoniae* and *E. coli*, is usually constitutive, and is of importance, because isolates that produce this enzyme will be resistant to broad-spectrum penicillins, extended-spectrum cephalosporins, monobactams, and, in contrast to ESBLs, the cephamycins such as cefoxitin. Also in contrast to ESBLs, they are not inhibited by commercially available β -lactamase inhibitors (hence the production of a false-negative ESBL confirmation test) (Coudron, 2000).

Similar to ESBL-producing isolates, an AmpC isolate may appear susceptible to one of the aforementioned antimicrobials on testing, but treatment with the antimicrobial may result in treatment failure and, in some cases, mortality (Pai, 2004). Possible screens for the presence of an AmpC β -lactamase-producing isolate include the presence of cefoxitin resistance or a positive ESBL screen but a negative ESBL confirmatory test (Black, 2005). Unfortunately, the screens are nonspecific, cefoxitin resistance may be due to porin loss, and confirmatory tests for the presence of AmpC are problematic. Cefoxitin-resistant non-AmpC β -lactamase-producing isolates can be separated from those producing AmpC β -lactamase by a three-dimensional extract test or an AmpC disk test; however, neither is standardized and both are complex to perform and are not really suitable for routine laboratory use (Coudron, 2000; Hanson, 2003; Black, 2005). A negative ESBL confirmatory test will provide indirect evidence of AmpC β -lactamase (Thomson, 2001), especially if the isolate is resistant to cefoxitin and sensitive to carbapenems and ceftipime. However, this is still non-specific, and a limitation of both the utilization of phenotypic confirmatory tests and inductive reasoning using susceptibility patterns is the increasing number of isolates that have multiple β -lactamases or other resistance mechanisms such as porin loss that can result in similar phenotypic resistance patterns. Currently, no CLSI-approved test is known to detect or confirm AmpC β -lactamase production in an isolate. It has been suggested that revision of interpretive breakpoints for the antimicrobials affected by both ESBLs and AmpC β -lactamases will be necessary and would be the most effective way to deal with these problematic resistance mechanisms (Clinical and Laboratory Standards Institute, 2009c).

Enterobacteriaceae that produce an ESBL or AmpC β -lactamase (or both) may often be treated with a carbapenem, as resistance to this class is not a consequence of the production of either β -lactamase. Unfortunately, several groups of carbapenemase β -lactamases may be acquired by gram-negative bacteria, and the type that is of current interest and importance in the United States with respect to Enterobacteriaceae is a group of serine carbapenemases, the *Klebsiella pneumoniae* carbapenemase (KPC) enzymes. These β -lactamases produce resistance to all β -lactams, including extended-spectrum cephalosporins and carbapenems, although on phenotypic susceptibility testing, the carbapenem MIC may be only elevated and still in the susceptible range, yet treatment of an infection with a

carbapenem can result in treatment failure (Weisenberg, 2009). KPC enzymes may be found in a variety of species of Enterobacteriaceae, but in the United States, they currently are most often found in *K. pneumoniae*, and although the overall percentage relative to a large group of tested isolates is not high nationally—less than 1% in one national survey (Deshpande, 2006)—the genes for production of the enzymes are plasmid-borne, and clonal expansion can occur easily. KPC enzymes first appeared in the United States in New York City, and a survey of four hospitals in Brooklyn, N.Y., over 2 months in 2004 demonstrated that 24% of *K. pneumoniae* isolates had one of two KPC genes (Walther-Rasmussen, 2007). A standardized procedure for screening and confirmation of KPC-type carbapenemases in Enterobacteriaceae has been published by the CLSI (Clinical and Laboratory Standards Institute, 2009).

For isolates that are resistant to one or more third-generation cephalosporins, screening with an ertapenem or meropenem disk, or with ertapenem, meropenem, or imipenem broth microdilution, can be done; if the screen is positive, a confirmatory test, the modified Hodge test, can be performed. The modified Hodge test involves streaking an isolate of interest perpendicularly to a centrally placed carbapenem disk (ertapenem or meropenem) on a Mueller-Hinton agar plate that has been streaked with *E. coli* ATCC 25922 in the same manner as a Kirby-Bauer disk diffusion plate (i.e., to produce confluent growth). Enhanced growth of the *E. coli* ATCC 25922 in the zone of inhibition along the streaked test isolate of Enterobacteriaceae indicates that it is producing a carbapenemase that has inhibited the carbapenem along the streak and has allowed the *E. coli* ATCC 25922 indicator organism to grow where it normally would not. It is possible to have false-positive results with the modified Hodge test, for example, if a *K. pneumoniae* isolate is producing an ESBL and has carbapenem resistance due to porin loss, the modified Hodge test may be interpreted as positive. Testing of the isolate with a carbapenem disk with and without boronic acid can differentiate those isolates producing carbapenemases from those with resistance to carbapenems due to other mechanisms (Doi, 2008; Tsakris, 2009). Boronic acid inhibits KPC-carbapenemases, resulting in an increase in the zone of inhibition diameter around the carbapenem-boronic acid disk relative to the carbapenem-only disk.

Detection of carbapenem resistance mediated by carbapenemases by automated systems is problematic, and if one of these systems is used, careful monitoring and repeat testing with careful attention to inoculum size or utilization of a different method is warranted if incongruent or discrepant results are obtained (Tenover, 2006). It is important to remember that if an isolate tests resistant to a carbapenem on routine susceptibility testing, current CLSI guidelines are that the interpretation should be reported, irrespective of whether or not a carbapenemase is subsequently identified, because there are other mechanisms of resistance; the CLSI recommends that in those cases in which a carbapenemase is identified, and some carbapenems test susceptible by current breakpoints, the MIC values should be reported without an interpretation (Clinical and Laboratory Standards Institute, 2009). Some laboratories may wish to report all carbapenems as resistant in this case, and local policy may be established in concert with infectious disease specialist and medical staff consultation.

Carbapenems are an important group of drugs used in the treatment of anaerobic infection, and susceptibility data related to this drug, and the most common anaerobic cause of sepsis, *Bacteroides fragilis* group, are illustrative of one of the important points related to anaerobic bacteria, that is, that their susceptibility profile can vary greatly with geographic area. Survey studies in Europe and the United States demonstrated very low rates of resistance in *B. fragilis* to imipenem and meropenem ($\leq 0.8\%$ and $\leq 1.3\%$, respectively), and a survey in Taiwan showed rates of 7% and 12% resistance to imipenem and meropenem, respectively (Soki, 2006; Snyderman, 2007; Liu, 2008). Similarly, closely related species or even the same species may have great variance in resistance rates; the CLSI notes ranges for the *B. fragilis* group of 15%–44% for clindamycin, 13%–94% for cefotetan, and 3.5%–41.5% for cefoxitin (Clinical and Laboratory Standards Institute, 2007). Antibiotic resistance is predictable in some species, such as *Bilophila wadsworthia*, and is common in many species, for example, *Prevotella* spp., with 50%–72% of isolates resistant to penicillin, but in general, the antibiotic susceptibility profiles of many anaerobes are unpredictable, variable, and increasing (Clinical and Laboratory Standards Institute, 2007; Wybo, 2007). This fact, in addition to findings of recent studies demonstrating that in vitro susceptibility testing results for anaerobes can have a direct correlation with favorable outcome, as in a study correlating antimicrobial treatment of *Bacteroides* bacteremia with susceptibility results and outcome (Nguyen, 2000), has pointed out the importance of antimicrobial susceptibility testing for anaerobes.

Several caveats must be borne in mind with respect to testing of anaerobic species: First, anaerobic infections can often be polymicrobial, making susceptibility testing difficult and in some cases impractical. Second, agar dilution is the CLSI-approved method for susceptibility testing of anaerobic species, with the exception of the *B. fragilis* group, for which microbroth dilution is also standardized; this is a demanding technique that may be beyond the capabilities of many laboratories. CLSI recommendations are that susceptibility testing should be performed with specific infections caused by anaerobes, and suggested groupings of antibiotics to be tested are recommended (Clinical and Laboratory Standards Institute, 2007). Given that this may be difficult for some laboratories because of the method required, referral to a reference laboratory in specific cases is an option; surveillance testing of collected isolates in a given geographic area or institution to generate an antibiogram on which physicians can base empirical therapy is another option that is within CLSI guidelines and is recommended by a number of authors (Clinical and Laboratory Standards Institute, 2007; Wybo, 2007; Liu, 2008).

For MTBC, all new isolates should be tested for susceptibility to primary antituberculosis drugs (isoniazid at two concentrations [critical and high concentrations], rifampin, ethambutol, and pyrazinamide) (National Committee for Clinical Laboratory Standards, 2003). Additionally, if the patient fails to respond to therapy, or cultures fail to become negative by 3 months after initiation of therapy, testing should be repeated. Testing results must be available as soon as possible, and it is recommended that laboratories provide results within 28 days of receiving the initial specimen (Bird, 1996). Until relatively recently, drug susceptibility to MTBC was determined primarily by the agar proportion method using solid agar, a modified agar dilution method, or with the use of liquid media with the BACTEC 460TB (Becton Dickinson, Sparks, Md). The BACTEC 460 allowed a faster turnaround time over the manual agar proportion method, but the system was only semiautomated and required disposal of radioactive waste from the indicator system. Liquid-based systems that are automated and use nonradioactive indicator systems have been developed, two examples of which are the MB/BacT (Organon-Teknika, Durham, N.C.) and Mycobacteria Growth Indicator Tube 960 (Becton Dickinson). Comparison studies between the proportion method and BACTEC 460 and the new automated systems have demonstrated generally good correlation, and the automated systems have become popular in laboratories in the United States where the cost of the systems is not prohibitive (Bemer, 2002, 2004; Tortoli, 2002; Garrigó, 2007).

Susceptibility testing with antifungal agents is predominantly performed on yeasts in those institutions that perform testing, with CLSI breakpoints available for *Candida* spp. with itraconazole, fluconazole, voriconazole, flucytosine, and the echinocandins (anidulafungin, caspofungin, and micafungin) when using microbroth dilution, and with fluconazole and voriconazole when using disk diffusion (National Committee for Clinical Laboratory Standards, 2004; Clinical and Laboratory Standards Institute, 2008c). Testing options are very limited with disk diffusion, and the reference microbroth dilution method is labor intensive, so many have turned to commercial testing systems such as the Sensititre YeastOne (Trek Diagnostic Systems, Westlake, Ohio), a manual microbroth dilution system with a chromogenic indicator; the Etest (AB Biodisk), or the automated VITEK 2 (bioMérieux), which offers a yeast susceptibility testing card. The Sensititre YeastOne is a comprehensive manual system that offers all drugs for which CLSI breakpoints exist, including the echinocandins. Performance in published evaluation studies has been good, although Alexander (2007) pointed out that both the Sensititre and the Etest had a tendency toward slightly higher MIC values than the reference broth microdilution method. Categorical agreement was good for all *Candida* spp.–antifungal combinations, although it was lower for *C. glabrata* and *C. tropicalis* tested against some of the azoles. Most errors caused by the two systems in the study were of a minor nature. The authors pointed out that incubation times significantly influenced results.

In CLSI document M27-A3 (2008b), specific reading times for individual drugs are given for use in the reference microbroth dilution method. In another study evaluating only the echinocandins against *Candida* spp., the Sensititre was essentially equivalent to the reference microbroth dilution method (Pfaller, 2008). The VITEK 2 yeast susceptibility test has the advantages of being fully automated and giving spectrophotometric readings in 12–15 hours, although the menu of drugs that can be tested is more limited. In published studies, performance of the system using a panel of *Candida* spp. against fluconazole, flucytosine, voriconazole, and amphotericin B was good, with findings similar to those seen in studies evaluating the Sensititre and Etest related to *C. glabrata* (Pfaller, 2007, 2007b).

SELECTING ANTIBIOTICS TO BE REPORTED

Policies for reporting of antibiotics for isolates should take into account not only the results of testing, but a variety of factors. For example, as outlined in CLSI document M100 (2009), antimicrobials that are not effective for treating CSF infection for a variety of reasons, such as first- or second-generation cephalosporins, macrolides, clindamycin, fluoroquinolones, tetracyclines, or orally administered drugs, should not be reported for isolates from the central nervous system. Similarly, drugs that may test susceptible *in vitro* but have been shown to be ineffective *in vivo* for particular species, such as cephalosporins or trimethoprim-sulfamethoxazole for *Enterococcus* spp., also should not be reported (Clinical and Laboratory Standards Institute, 2009). Drugs that are effective only for urinary tract infection (e.g., nitrofurantoin) should not be reported on isolates from any site other than the urinary tract. Many institutions utilize **cascade** reporting to encourage the use of antimicrobials that are effective based on *in vivo* susceptibility testing but are less expensive than the “newest” or most heavily commercially promoted drug, to try to lower pharmacy costs. For example, third-generation cephalosporins will be reported, barring other considerations such as isolate source, only if first- or second-generation cephalosporins are resistant on testing.

A close working relationship between the clinical microbiology laboratory and the infectious disease service is important in effective **antibiotic stewardship** programs that guide an institution’s caregivers in the most appropriate use of antibiotics. These programs are instituted to save money or, more important, to combat the increasing problem of antibiotic resistance; they may involve the use of mandatory prescribing and treatment guidelines, reporting or nonreporting of specific antibiotics on susceptibility profiles, and **gatekeeper** providers such as infectious disease physicians, whose approval is required before specific antibiotics can be used. As an example, it has been demonstrated in prospective studies (Project ICARE: Intensive Care Antimicrobial Resistance Epidemiology) that the frequent use of vancomycin and third-generation cephalosporins is associated with increased prevalence of VRE in ICUs, and that by limiting the use of vancomycin, the prevalence can be decreased (Fridkin, 2001, 2002). Similarly, in a multicenter retrospective analysis, Pakyz and colleagues (2009) showed that restricting the use of carbapenems resulted in lower incidences of carbapenem-resistant *Pseudomonas aeruginosa* than were seen in hospitals that did not restrict carbapenem use.

Finally, reports from several centers in different parts of the world have detailed outbreaks of a highly virulent strain of *Clostridium difficile* that produced high morbidity and mortality. These outbreaks have been determined to be associated with the use of specific antibiotics in the facility, particularly fluoroquinolones, to which this particular strain is highly resistant; containment of the outbreaks has required a number of measures, including strict antibiotic stewardship programs that in some cases required the complete prohibition of fluoroquinolone use (Valiquette, 2007; Labbé 2008; Debast, 2009). These examples demonstrate the importance of knowing how and what antibiotics are reported by the laboratory, as well as the importance of the clinical laboratory working closely with the infectious disease service in addressing issues created by patterns of antibiotic use. A multicenter survey of U.S. hospitals showed that the most frequently prescribed antibiotic class from 2002–2006 was the fluoroquinolones, and that carbapenem use was increasing significantly (Pakyz, 2008); these issues are directly relevant to the examples given here and show that the management of antibiotic use in hospitals, including what antibiotics the clinical laboratory is to report, will be a continuing and increasingly complex issue in the coming years.

CUMULATIVE ANTIMICROBIAL SUSCEPTIBILITY REPORTS

Susceptibility patterns for specific species against antimicrobials can vary with geographic locale, type of medical facility, and antibiotic usage patterns, and it is the responsibility of the clinical microbiology laboratory to monitor susceptibility patterns and keep the medical staff informed of current patterns. This is usually accomplished by monitoring susceptibility data on isolates over time, compiling these data for a specific time period, calculating the percentage of a specific species that is susceptible to a given drug, putting all the data into an easily accessible format, and making it available to the medical staff. These reports, usually referred to as antibiograms, can be used by the medical staff to treat infections empirically while

awaiting specific culture and susceptibility results, or they can be used by hospital epidemiology and infection control to monitor resistance trends, identify outbreaks, and formulate infection control policy; they may also be referred to by the pharmacy and therapeutics committee of the facility when making policy or formulary decisions (Zapantis, 2005). By including antibiotic cost data in the antibiogram, institutions may encourage providers to utilize less expensive but still effective drugs.

The CLSI provides guidance to facilities on the preparation of antibiograms in CLSI document M39-A3 (2009e) and includes suggestions on use of terminology, obtaining data, analysis of the data, presentation of data, statistical considerations, and specific limitations of the antibiogram. Examples and templates are included in the document. Hindler and Stelling (2007) summarized many of the essential considerations discussed in the CLSI document, and they discussed issues that must be considered and decided upon when compiling an institution’s antibiogram. For example, how multiple isolates from a single patient are counted in compiling the data can have a marked effect on the percentage of a specific species that appears susceptible to a given antibiotic. If all isolates are counted, this will bias the result toward isolates that are submitted from patients who have multiple cultures submitted over time (e.g., those patients with infection due to resistant organisms, who remain hospitalized for long periods, or who do not respond to therapy) (Hindler, 2007). Whether duplicate isolates from the same patient are all counted (isolate-based algorithm), are excluded and only the first one counted (patient-based algorithm), are counted only if they represent a new clinical episode (episode-based algorithm), or are counted only if they show a new resistance phenotype (phenotype-based algorithm) directly affects the percentages of susceptibility for an antimicrobial; which algorithm is best for a given institution should be decided upon in consultation with the medical staff and/or the pharmacy and therapeutics committee, then adhered to during subsequent compilations, so comparisons between individual time periods are valid.

The data management associated with antibiograms and the information that can be obtained from these data may be complex and difficult to manage and manipulate. The World Health Organization (WHO) Collaborating Centre for Surveillance of Antimicrobial Resistance has made available a software program that can be downloaded and utilized at no charge to accomplish useful data management (WHO, 2006). The software program (WHONET) has a module that allows a laboratory to input which antimicrobials are reported and what patient care areas are served by the laboratory, and allows alerts for important organisms or phenotypes. A second module permits the entry, retrieval, correction, and printing of clinical reports. Finally, a third module allows a variety of analyses to be generated from the facility data, including but not limited to organism frequencies over time, antimicrobial susceptibility statistics, disk diffusion zone diameter or MIC histograms, antimicrobial scatterplots, and regression curves. Additionally, a software component, BacLink, can be obtained that can upload data from a facility’s current system directly into WHONET, avoiding manual entry of data. Both WHONET and BacLink software can be downloaded directly from the Internet at no cost (WHO, 2006). The WHONET software is currently on version 5.6, is being used by laboratories in more than 90 countries worldwide, and is available in 17 languages.

BACTERICIDAL TESTING

Bactericidal testing of antimicrobial agents is infrequently performed in the current clinical laboratory environment. Many tests are labor intensive and complicated, and until relatively recently, the procedures were not standardized. The three major categories of bactericidal antimicrobial testing are (1) determination of the minimum concentration of an antimicrobial necessary to kill 99.9% of an inoculum of the isolate, that is, the minimum bactericidal or lethal concentration (MBC or MLC); (2) determination of the killing rate (time-kill curve or killing curve) at which an antibiotic kills an inoculum of the isolate; and (3) determination of the highest dilution of the serum of a patient receiving antibiotic(s) necessary to kill 99.9% of an inoculum of isolate, otherwise known as the serum bactericidal titer (SBT) or serum lethal titer.

Publication of an approved guideline by the CLSI for performance of the MBC has addressed one of the criticisms leveled at the performance of this test—that it is not standardized (NCCLS, 1999). To determine the MBC, serially diluted (on a log₂ basis) antimicrobial in broth is inoculated with a standardized suspension of the isolate of interest, in the same way as when determining the MIC. After incubation at 35° C for 24 hours, those dilutions demonstrating no visible growth are subcultured onto

antimicrobial-free agar medium. After incubation, the number of colonies on the agar medium is counted, and the number of viable organisms per milliliter of antimicrobial dilution is calculated. The MBC or MLC is the lowest concentration of the antimicrobial agent that is lethal or bactericidal to the original inoculum, with the endpoint defined as a 99.9% decrease in viable organisms relative to the original inoculum.

Although in theory, one could see how the MBC could be very useful for certain types of infection, determination of the MBC often is not straightforward and can be confounded by several factors. One such factor is the persistence of a small number of organisms of the inoculum ("persisters") that survive the antimicrobial exposure but remain susceptible if retested against the antimicrobial. In the case of cell wall-active agents, such as the β -lactams and vancomycin, at least some may represent cells that are in a dormant or nongrowing phase of the cell cycle. These cells have been termed "indifferent" to the effects of the antibiotic by some authors, rather than "resistant" (Jayaraman, 2008). Second is the paradoxical effect (Eagle phenomenon), which is an unexplained increase in the number of surviving organisms as the concentration of the antimicrobial increases above the MBC. Third is tolerance, a phenomenon in which bactericidal agents have reduced bactericidal activity against a particular strain of a bacterial species. The mechanism behind tolerance currently is not understood, but as pointed out by Jayaraman (2008), "tolerance" on the part of an isolate is clearly different from "indifference," or dormancy. Some authors have given a more practical (at least for the laboratory) definition of "tolerance" on the part of an isolate, that is, if the MBC/MIC ratio is ≥ 32 , the isolate is defined as tolerant to the test antimicrobial (Sheris, 1986).

In determining the time-kill curve, a single dilution of the test antimicrobial, usually at a concentration at or near what can maximally be achieved in a patient, is inoculated with a standardized inoculum of the isolate in question; then quantitative cultures are performed at regular intervals over a 24-hour period. The amount of bacterial growth evident on quantitative culture at each time period over 24 hours is graphed to generate the time-kill curve. The test essentially determines the rate and duration of killing by the antimicrobial at a specified concentration. This test is very useful in animal models of specific infections and in pharmacologic research, but its labor-intensive nature is one of the factors that make it difficult for laboratories to offer it as a clinical test.

The basic premise of the MBC and the time-kill study can be applied to the serum bactericidal titer, with the addition of serum from the patient receiving antibiotics to the test system. As with the MBC, serum bactericidal tests have been standardized by the CLSI (NCCLS, 1999b). The modification involves obtaining two serum specimens from the patient—a specimen when the antibiotic is at its lowest concentration in the body ("trough" specimen), usually just before the patient receives a dose of the antimicrobial, and a specimen when the antibiotic is at its highest ("peak specimen"), a specified time after a dose of the antimicrobial is given, with

the time depending on the route of administration. Serial \log_2 dilutions are made of each specimen and are inoculated with a standardized inoculum of the isolate of interest; the dilutions are incubated at 35° C for 24 hours. Similar to the MBC, those dilutions in which no visible growth is seen are subcultured to agar medium for quantitative culture and are reincubated. The **serum bactericidal titer** is the lowest concentration of antimicrobial that results in a 99.9% decrease in viable organisms relative to the original inoculum. The theory behind the SBT is that it takes into account factors such as the effects of absorption and metabolism of the antimicrobial, effects of metabolites or breakdown products of the antimicrobial on the isolate, protein binding of the antimicrobial, and the effects of interaction with any other medications the patient is taking (NCCLS, 1999b). The SBT can provide an assessment of bactericidal activity by determining the antibiotic concentration relative to the MBC, and can allow an assessment of how many half-lives of the antimicrobial bactericidal activity will persist in the patient's serum (NCCLS, 1999b). Finally, if a time-kill study is performed using the patient's serum, the serum bactericidal rate or the rate of killing over time can be determined, or, if the area under the curve is examined, the magnitude and duration of bactericidal activity can be ascertained (NCCLS, 1999b).

In addition to the labor-intensive nature of the bactericidal tests, which a laboratory must address if it is decided that these tests will be performed, another consideration is the clinical relevance of the tests. At various times in the past, bactericidal tests have been recommended as contributory in the prediction of therapeutic success or failure in bacterial endocarditis, osteomyelitis, sepsis in immunocompromised patients, infected prosthetic implants, and infections for which therapeutic guidelines are poorly described (Petersen, 1992). Many of the studies supporting these recommendations were performed before standardization of the procedure, and subsequent studies have failed to support the claim that the tests are directly predictive of therapeutic success or failure (Petersen, 1992). Despite this, studies that suggest that bactericidal tests have a role in predicting prognosis in specific infections or in infections in special patient populations continue to appear. Liao and colleagues (2007) suggest that for nosocomial infections with multidrug resistant *Acinetobacter baumannii*, the SBT is useful in determining prognosis and the need for therapeutic alterations. Cahen and colleagues (1993) state that they demonstrated that the SBT is directly predictive of cure or failure in acute pulmonary exacerbation in cystic fibrosis patients. The clinical utility of the tests remains controversial; however, what is not controversial is the resources that the clinical microbiology laboratory must invest to accurately perform these tests. Based on this, the recommendation put forth by both Petersen and Shanholtzer (1992) and the CLSI (NCCLS, 1999, 1999b) indicates that if consideration is given to requesting this test on the part of the clinical staff, the clinical microbiology laboratory director should be consulted to determine whether the test can be contributory to patient care, what method should be used, and how to the results should be interpreted.

KEY POINTS

- With few exceptions, human disease caused by spirochetes typically follows a clinical course that reflects three sequential phenomena: (1) early, local proliferation of the organisms at the site of inoculation, (2) spirochetemia with systemic dissemination, and (3) persistence of small numbers of microbes at various, often immune, "privileged" sites.
- Although direct detection of spirochetes causing human disease is sometimes possible by microbiological culture, microscopy, and genomic amplification, diagnosis often relies upon the demonstration of a patient's serologic response to the offending agent.
- Venereal syphilis is a historic sexually transmitted disease caused by *Treponema pallidum* subspecies *pallidum*.
- In the early stages of disease, venereal syphilis may be diagnosed using direct microscopic visualization.
- Serologic detection of syphilis, by far the most common mode of diagnosis, comprises methods that semiquantitatively measure antibody to various lipoproteins, as well as methods that qualitatively measure antibody to treponeme-specific antigens.
- Yaws, endemic syphilis (bejel), and pinta are not sexually transmitted, are endemic to various tropical and Middle Eastern regions, and are caused by *T. pallidum* subsp. *pertenue*, *T. pallidum* subsp. *endemicum*, and *T. carateum*, respectively.
- Presumptive diagnosis of the endemic trepanematoses can sometimes be made on the basis of clinical and epidemiologic data; however, as with venereal syphilis, serologic and direct microscopic techniques may prove useful.
- The most common tick-borne disease in North America and Europe, Lyme disease is caused chiefly by *Borrelia burgdorferi* sensu stricto, *Borrelia garinii*, and *Borrelia afzelii*.
- Typical clinical manifestations of Lyme disease include erythema migrans (early localized disease), neuroborreliosis (early disseminated or late-stage disease), and/or Lyme arthritis (late-stage disease).

- Because no single laboratory test performs sufficiently in all clinical scenarios, a diagnosis of Lyme disease must be based on a combination of (1) clinicoepidemiologic characteristics, (2) host serologic response (as measured by enzyme-linked immunosorbent assay/immunofluorescence assay and immunoblot), (3) molecular evidence, and/or (4) culture results.
- Epidemic, louse-borne relapsing fever has a worldwide distribution and is caused by *Borrelia recurrentis*.
- Endemic, tick-borne relapsing fever has a limited geographic distribution and is caused by several *Borrelia* species, including *Borrelia hermsi* and *Borrelia turicata*.
- Acute onset of high fever and constitutional symptoms followed by cycles of evanescence and recrudescence is frequently recognized in both forms of relapsing fever.
- Diagnosis of relapsing fever is most often established through the demonstration of spirochetes in peripheral blood smears stained by a Giemsa technique.
- One of the most common zoonotic diseases throughout the world, leptospirosis is caused by various serovars of different species within the genus *Leptospira*.
- Although leptospirosis is usually subclinical or mild and flu-like, a small proportion of patients develop severe constitutional symptoms, in addition to gastrointestinal/hepatic disease, meningitis, renal failure, and/or myocarditis (also referred to as Weil's disease).
- Although *Leptospira* spp. can be cultivated in vitro, diagnosis is usually made by demonstrating seroconversion.
- *Brachyspira aalborgi* and *Brachyspira pilosicoli* have been demonstrated in and isolated from the colon of humans with diarrheal disease, but their pathogenicity has not been firmly established.
- Demonstration of spirochetes along the colonic epithelial cell borders using routine, immunohistochemical, or in situ hybridization microscopy from biopsy material is more commonly performed than cultivation or genomic amplification assays.

Spirochetes (“spiro” means “coiled,” and “chaete” means “hair”) are slender, spiral-shaped bacteria containing one or more complete rotations that form a helix. They are gram-negative but can be visualized only by darkfield or phase microscopy, silver impregnation, and immunohistochemical stains in tissue sections. Flagella-like organelles called periplasmic fibrils or axial filaments are attached near the poles of the bacteria and permit a corkscrew-like motility. Many commensal and nonpathogenic species of spirochetes exist, and human disease is limited primarily to infection by members of three genera: *Treponema*, *Borrelia*, and *Leptospira*. Widely diverse from an epidemiologic standpoint, spirochetes within these genera demonstrate a number of pathogenic, and hence clinical, similarities upon acquisition by humans (Schmid, 1989). Several other spirochete-like bacteria, including *Spirillum minor* and *Anaerobiospirillum succiniciproducens*, have been implicated in human disease and are discussed briefly here. Although *Brachyspira* species have been associated with gastrointestinal syndromes, definitive causation of disease by these bacteria has not been universally accepted.

TREPONEMA

The genus *Treponema* contains two species responsible for disease in humans. *Treponema pallidum* is divided into three subspecies, each of which is the etiologic agent of a distinct clinical entity: subspecies *pallidum*, *pertenue*, and *endemicum* are the etiologic agents of venereal syphilis, yaws, and endemic syphilis (bejel), respectively. Pinta is caused by the second closely related species, *Treponema carateum*. Controversy exists even to this day concerning the origins of the sexually transmitted form of infection. Previously, the debate focused largely on deducing geographic regions of disease occurrence (e.g., Old World vs. New World) based on morphologic skeletal abnormalities of excavated remains that were presumably a result of *T. pallidum* subsp. *pallidum* infection. More recent work utilizing phylogenetic molecular methods seems to support the “Columbian” theory, that is, that a form of venereal infection was acquired during exploration of the New World and was subsequently introduced into Europe (Harper, 2008b).

CLASSIC TREPONEMAL DISEASE

Syphilis

Description

T. pallidum subsp. *pallidum*, the etiologic agent of venereal syphilis, is a thin (0.2 μm) spirochete, 6–20 μm in length with 10–13 coils (Fig. 59-1). The disease appears to have spread rapidly throughout Europe during the 16th century, and its absence in the medical literature prior to this period suggests that the organism was brought from the New World. The term **syphilis**, in common use during the last ≈ 200 years to describe the disease process, is derived from the fictional character Syphilus, the protagonist of a 1530 poem by Girolamo Fracastoro. The work’s title, *Syphilis sive morbus gallicus* (“Syphilis or the French disease”), underscores the popular notion of that era as to the point of disease origination (no doubt promulgated chiefly by Italians). For a thorough and entertaining review of the

Figure 59-1 An electron photomicrograph of two spiral-shaped *Treponema pallidum* bacteria ($\times 36,000$). (CDC/PHIL file photo.)

historical literature, particularly as it relates to the United States, the reader is referred to a recent work by Parascandola (2008).

Epidemiology

Man is the only natural reservoir for *T. pallidum* subsp. *pallidum*. Transmission occurs by direct contact with active lesions, largely through sexual contact. Vertical transmission across the placenta, the second most common mode of infection, may result when a latently infected female becomes pregnant, or when a pregnant woman becomes infected (Wicher, 2001). Infection may also rarely be transmitted by nonsexual contact with an active lesion, by transfusion of fresh blood products from an infected person (although organisms do not survive >48 hours under typical blood bank storage conditions), by accidental needle stick, or when infectious specimens are handled in the laboratory.

The incidence of venereal syphilis in the United States declined dramatically with the advent of penicillin following World War II and remained stable until the mid 1980s, when the incidence began to increase once again (Fig. 59-2), presumably as the result of increased intravenous drug use and sexual promiscuity. Although the global prevalence of syphilis remains strikingly variable (Gerbase, 1998; Peeling, 2004), the United States experienced a continuous decline in infection rates among women of childbearing age throughout the 1990s; this was paralleled by a comparable decrease in the incidence of congenital syphilis (Centers for Disease Control and Prevention, 2003, 2004a). Following a nadir in disease incidence in 2000 that marked the lowest rate of syphilis in the United States during recorded history, numbers of cases have been steadily increasing, predominantly among men who have sex with men (Fig. 59-3). In 2006, the National Plan to Eliminate Syphilis from the United States was updated to reflect a new target of reducing the incidence of primary and secondary syphilis to $<2.2/100,000$ persons, and of congenital syphilis to $<3.9/100,000$ live births by 2010 (Centers for Disease Control and Prevention, 2006a). As of 2009, however, the goals remained elusive (4.6 cases/100,000 persons for primary and secondary syphilis and 10 cases/100,000 live births for congenital disease).

Pathogenesis and Pathology

T. pallidum subsp. *pallidum* penetrates an intact mucous membrane or gains access to tissue through abraded skin, multiplies at the inoculation site, and then enters the lymphatic and circulatory system and spreads throughout the body. In laboratory animals, infections have been produced with

Figure 59-2 Reported cases of syphilis by stage of infection: United States, 1941–2004. (CDC, 2005.)

Figure 59-3 Primary and secondary syphilis—rates by sex: United States, 1981–2004. (CDC, 2005.)

as few as four spirochetes (Cumberland, 1949). Clinical lesions appear when a critical mass of organisms is reached locally ($\approx 10^7$ spirochetes); therefore, the incubation period is directly related to the size of the initial inoculum and varies from 3 days to 3 months (Magnuson, 1956).

The host immunologic response to *T. pallidum* subsp. *pallidum* is influenced by the structure of the bacterium. The outer membrane is a phospholipid bilayer with few demonstrable protein antigens. The most important antigens for the host immune response appear to be lipoproteins within the periplasmic space (Chamberlain, 1989; Cox, 1992; Salazar, 2002). Additionally, the bacterium appears to be able to coat itself with host proteins. The net effect is to delay the humoral response, reducing its effectiveness because the spirochetes are in extravascular locations by the time antibodies are produced. Furthermore, it has been demonstrated in animal models that the cellular immune response is downregulated in syphilis, despite the ineffective humoral response (Fitzgerald, 1992).

This delayed and attenuated immune response allows *T. pallidum* subsp. *pallidum* to disseminate and to produce a chronic infection. The course of syphilis can be divided into predictable stages. Its primary stage, the development of a chancre, occurs at a median of 3 weeks post inoculation, although a primary lesion may not develop in all patients. Additionally, because of its painless nature, the lesion may go unnoticed in a proportion of cases. Upon healing within 2–8 weeks, the chancre gives rise to the secondary stage. Typically manifesting about 6 weeks after inoculation (range, 2–12 weeks), this stage is characterized by widespread dissemination of spirochetes via the bloodstream and the development of mucocutaneous and organ involvement with the presence of constitutional symptoms. Upon resolution of the secondary stage, the infection enters a period of latency, during which time the patient exhibits minimal manifestations of infection. The first year of this stage, termed the early latent period, may be characterized by occasional relapses, whereas relapse is not common during the late latent period. Following a period of 10–25 years, approximately one third of untreated patients develop tertiary syphilis, the most serious manifestations of which involve the cardiovascular system or the central nervous system (CNS).

Whatever organ is involved or whatever stage of the disease is reached, the histologic hallmark of syphilis is obliterative endarteritis, demonstrating concentric endothelial and fibroblastic proliferations with an associated mononuclear cell infiltrate rich in plasma cells (Fig. 59-4, A). Endarteritis results from the binding of spirochetes to endothelial cells via fibronectin molecules that have attached to the surface of the bacteria (Thomas, 1986). Treponemes may be demonstrable in tissues with silver impregnation (Fig. 59-4, B) and immunohistochemical stains, particularly during the first and second stages of disease (Martin-Ezqueria, 2009). With progression, both the plasma cell infiltrate and the concentration of treponemes lessen in intensity. Although commonplace in the pretreatment era, syphilitic gummas, or large visceral necrotizing granulomas, develop as tertiary-stage manifestations but are rare today (Fargen, 2009).

Elucidation of the complete genomic sequence of *T. pallidum* subsp. *pallidum* may provide insight into the pathogenesis of this organism

(Fraser, 1998). For example, researchers have verified the absence of many enzymatic pathways typically found in other cultivable bacterial pathogens. One interesting finding was a series of duplicated genes, termed *T. pallidum* repeats (tprA–tprL), which encode homologous membrane proteins that may impart the means of antigenic variability and immunologic escape (Centurion-Lara, 1999). Their roles in such, as well as their putative cellular location, however, remain vague (Hazlett, 2001).

Clinical Manifestations

Syphilis is a chronic infection with a multiplicity of expressions, primarily related to the stage at which it presents. The primary chancre is characteristically ulcerated with raised, firm edges and a smooth base and is notable for absence of an exudate or pain (Fig. 59-5, A). Although these are typically solitary, multiple chancres can occur in up to one third of patients. Patients with previous infection can present with atypical lesions, such as a small papule, or may not develop a lesion at all. Regional lymphadenopathy, with moderately enlarged, rubbery, nonsuppurative lymph nodes, is seen in some patients.

Dissemination marks the secondary stage, and patients present with signs and symptoms of a systemic illness. More than 90% develop a rash that begins on the trunk and extremities (although any body surface can be involved) as small macules that progress to papules, and in some patients to pustules, over a period of weeks. The appearance of the rash on the palms and soles is characteristic (Fig. 59-5, B), and enlargement and coalescence of papules produce the pale plaques of condyloma lata (Fig. 59-5, C). Approximately 90% of patients also exhibit generalized lymphadenopathy, and as many as three fourths may suffer fever, malaise, anorexia, arthralgia, pharyngitis, and weight loss. Mucous patches are seen in up to one third of cases. About 40% of persons develop CNS symptoms during this stage, particularly among those coinfecting with human immunodeficiency virus (HIV), although only 1%–2% present with acute meningitis (Lukehart, 1988; Centers for Disease Control and Prevention, 2007). The remainder may experience headache and meningismus, uveitis, sensorineural hearing loss, and cranial nerve involvement.

The tissue destruction of tertiary syphilis usually becomes evident decades after the primary infection. Cardiovascular syphilis occurs as a result of weakening of the tunica media and results in an aneurysm of the ascending aorta with aortic valve insufficiency and narrowing of the coronary artery ostia. Syphilitic gummas may involve the skin, brain, skeletal system, or mucocutaneous tissues, although any organ can be affected. Both cardiovascular syphilis and syphilitic gummas became much less frequent after the advent of antibiotic treatment. Meningovascular syphilis occurs 5–10 years after initial infection and clinically presents as seizures, stroke, and aphasia. Multiple small infarcts due to endarteritis in the CNS are the cause of this form. Parenchymatous neurosyphilis, which presents 15–30 years after initial infection, is a degenerative process with loss of neurons and myelinated tracts resulting in a complex of neurologic and psychiatric manifestations, including general paresis, tabes dorsalis, and pupillary abnormalities. Some patients lack clinical signs or symptoms

altogether but demonstrate cerebrospinal fluid (CSF) abnormalities such as pleocytosis, increased protein, a reactive Venereal Disease Research Laboratory (VDRL) test, or antibody against *T. pallidum* indicating CNS infection. Such patients have been described as having “asymptomatic neurosyphilis” (Tramont, 2000).

Congenital syphilis occurs clinically as two forms: an early or infantile form (<2 years of age) and a late form following a period of latency (few years to several decades). Although transplacental passage of spirochetes can occur during any trimester, congenital acquisition during early gestational age results in stillbirth more often than does acquisition during late gestation or parturition (Harter, 1976; Blanc, 1981). As may be expected, congenital transmission is more frequent during the primary, secondary, and early latent periods of maternal infection (Woods, 2009). Necrotizing funisitis, or inflammation of the umbilical cord, is characteristic of congenital syphilis, although it is typically present in only the most severe cases. In the infantile form, a diffuse rash with sloughing of the skin, osteochondritis, and periostitis are characteristic; however, affected newborns may be asymptomatic (Dorfman, 1990; Ikeda, 1990). Diffuse fibrosis of the liver (hepar lobatum) and lung (pneumonia alba) is also seen. After a latent period, the late form presents in childhood or adulthood with a wide variety of signs and symptoms; however, the triad of interstitial keratitis, Hutchinson’s teeth, and eighth nerve deafness is classic. Periostitis, saber shins, and saddle deformity of the nose are also seen frequently.

Syphilis and HIV infection are increasingly seen as coinfections because these diseases share common risk factors and may even potentiate one another. Studies that have examined the association have demonstrated no difference in stage at clinical presentation between patients with concomitant syphilis and acquired immunodeficiency syndrome (AIDS) and those without AIDS (Hutchinson, 1991; Gourevitch, 1993). Whether AIDS has an effect on the clinical course of primary and secondary syphilis is controversial. Some experts cite a predilection for the infection to present with an atypical and more severe rash, exaggerated constitutional symptoms,

and a more malignant course in AIDS patients (Tramont, 2000; Collis, 2001). Others suggest little difference in disease manifestations between AIDS and non-AIDS patients (Musher, 1990; Hutchinson, 1991; Rolfs, 1997). Although it has been proposed that AIDS patients with syphilis show an increased propensity to develop neurosyphilis, and to develop it more rapidly, than non-AIDS patients (Johns, 1987; Musher, 1990), this remains a contested issue given (1) the shortcomings of current neurosyphilis diagnostic criteria (Collis, 2001), and (2) an apparent lack of correlation between early CNS treponemal invasion and HIV status (Lukehart, 1988; González-López, 2009). One multicenter prospective study showed that CSF nontreponemal tests were more likely to remain positive following syphilis therapy in HIV-infected individuals than in HIV-uninfected patients (Marra, 2004a). It remains to be seen, however, if such laboratory evidence of treatment failure is a true reflection of potential clinical relapse. What does seem clear, as evidenced by multiple studies, is that anti-HIV therapy itself improves the likelihood of serologic response following syphilis treatment in HIV-positive patients (Ghanem, 2008; Marra, 2008; González-López, 2009). The high incidence of eye involvement among patients with AIDS is also unquestionable, with anterior uveitis being the most common manifestation of *T. pallidum* infection in this setting (Tramont, 2000).

Yaws

Yaws (also called frambesia tropica, pian, parangi, paru, buba, or bouba) is a chronic disease caused by *T. pallidum* subsp. *pertenue* and is the most prevalent of the nonvenereal treponematoses. This disease, which has afflicted residents of the tropics since antiquity, is common in rural areas of tropical countries with heavy rainfall. After a decline in the 1950s due to large campaigns to control the treponematoses, the incidence of yaws has increased in some areas (Engelkens, 1991a; Antal, 2002).

Yaws is contracted chiefly during childhood by direct contact, with breaks in the skin allowing entry of treponemes. Early lesions generally

Figure 59-6 In vitro diagnostic modalities for venereal syphilis detection. **A**, Darkfield microscopy technique ($\times 400$) reveals the presence of motile spirochetes. **B**, Positive fluorescent treponemal antibody absorption (FTA-ABS) test for antibody response in patient with syphilis. (CDC/PHIL file photo.)

appear about 3 weeks later but may not develop for months. One or several papules appear, most frequently on the lower extremities, and then ulcerate or progress to papillomatous lesions. Numerous treponemes are found in these lesions. Spontaneous resolution is usual; however, relapses preceded by malaise, fever, and generalized lymphadenopathy followed by disseminated skin lesions are common. Most patients enter a period of latency during which no clinical signs or symptoms are evident. For most, the disease shows no additional manifestations; however, approximately 10% develop late yaws, which shows irreversible, destructive lesions of bone, cartilage, soft tissue, and the skin (Engelkens, 1991a; Antal, 2002). Cardiovascular and CNS lesions similar to those seen in syphilis have been reported to occur (Roman, 1986).

Endemic Syphilis

Endemic syphilis (bejel) is a nonvenereal chronic infection caused by infection with *T. pallidum* subsp. *endemicum*. The disease is ancient and, although it is no longer as widespread as it once was, still occurs in the Middle East and Africa in hot, dry climates. In Sahelian Africa, the disease has been increasing in prevalence (Engelkens, 1991b). Endemic syphilis is transmitted by direct contact with active lesions, contaminated fingers, and eating or drinking utensils. Crowded living conditions and poor hygiene are common associated factors. Children aged 2–15 years are primarily infected, although the disease can be found in adults in the same family, and those adults who did not suffer from the disease in childhood can be infected by their children. The inoculum is small and the primary lesions of early endemic syphilis, most frequent on the oropharyngeal mucosa, often are not apparent. Initial clinical manifestations of the disease are usually seen in a secondary stage, with mucous patches, condyloma lata, angular stomatitis, generalized lymphadenopathy, and painful osteoperiostitis. This is followed by a latent period of variable length. The late stage is characterized by tissue destruction of the skin, bones, and cartilage, with a predilection for the nose and palate (so-called gangosa), and sometimes laryngeal involvement.

Pinta

Pinta (carate, mal de pinto, azul) is caused by infection with *T. carateum*. The disease is endemic in rural tropical Central and South America and recently has reappeared in Mexico and Colombia, two countries from which it was eradicated in the 1950s (Engelkens, 1991b). Children younger than 5 years of age are primarily infected. Inoculation is thought to occur via nonvenereal skin or mucous membrane contact. Characterization of the pathogenesis of the disease is difficult because, unlike other treponematoses that are pathogenic in humans, an animal model is unavailable and the treponeme cannot be cultured continuously. Although similar to other treponemal infections that have early and late stages, frequent overlap of stages occurs in pinta. A primary papule or plaque develops at the site of inoculation after weeks to months, with or without localized lymphadenopathy. The primary lesion resolves, and several months to years later, disseminated secondary lesions, or pintids, which resemble scaly psoriasisiform plaques, appear and remain for long periods or resolve and recur. In late pinta, lesions demonstrate hypopigmentation and skin atrophy or

hyperkeratosis, which can persist for life. The skin appears to be the only organ affected in this disease (Antal, 2002).

LABORATORY DIAGNOSIS OF TREPONEMATOSES

Because the etiologic agents of the human treponematoses cannot be isolated easily by routine culture methods, testing for disease generally is completed directly by visualization of the organisms in material from lesions or indirectly by immunologic methods. Consequently, different stages of the treponematoses often require a particular testing modality. In the early stages when lesions are present, highly specific microscopic techniques are used. Upon resolution of lesions, a variety of serologic tests are employed for diagnosis. It is important to remember that none of these laboratory tests is capable of distinguishing between the closely related species and subspecies of pathogenic treponemes, so differentiating between them requires clinical, epidemiologic, and, when possible, genomic information (Harper, 2008a).

Darkfield Microscopy

When direct sampling of lesions is possible, such as in primary, secondary, or early congenital syphilis (chancres, mucous patches, or condyloma lata), the lesion should be cleansed with sterile water (no soap or antiseptic) and gently abraded. Pressure is applied, causing serous exudate to collect in the lesion. A drop of the fluid is placed on a slide and a coverslip is placed over the fluid. The specimen must be examined immediately, as visualization of motility is necessary for definitive identification. Because of their narrow width, treponemes cannot be visualized by conventional light microscopy. Instead, darkfield microscopy is necessary. This technique makes use of a patch stop, which creates the microscopist's "dark field," and a condenser lens that targets the spirochetes with light waves at an oblique angle, some of which are scattered into the objective, giving the appearance of bright organisms in a dark background (Fig. 59-6, A). The darkfield examination can be positive several weeks before a positive serologic test and has a sensitivity of 80% in diagnosing syphilis (Larsen, 1995). Because of possible confusion with commensal treponemes in the mouth, however, it is not recommended that this technique be utilized for oral lesions. Additionally, three *Treponema* spp. that are normal inhabitants of the genital region (*T. phagedensis*, *T. refringens*, and *T. minutum*) could potentially be confused with *T. pallidum* on darkfield examination. Careful cleaning of the area is important in reducing the likelihood of this occurrence. A more recent adaptation of in vivo reflectance confocal microscopy has also been explored as a potential method of spirochete visualization within cutaneous lesions (Venturini, 2009).

Fluorescence Microscopy

Fluorescein isothiocyanate (FITC)-labeled antibodies specific for *T. pallidum* can be used for direct detection of treponemes in lesions, obviating the need to observe motility of the bacteria. The test can be applied to tissue fluid that has been dried and fixed to the slide (direct fluorescent

Figure 59-7 Rapid plasmin reagin test card showing nonreactive, weakly reactive, and strongly reactive serum samples (wells 1–3) with their respective agglutination patterns.

antibody [DFA-TP]) or paraffin-embedded tissue sections (direct fluorescent antibody tissue test [DFAT-TP]). Monoclonal antibodies are commercially available and can be used in these tests in place of the older and less specific Reiter treponeme adsorbed polyclonal antibodies obtained from syphilitic rabbits and humans. When used on fluid from fresh lesions, both DFA-TP and DFAT-TP have a sensitivity of approximately 100% (Larsen, 1995). Because these tests are specific for the pathogenic treponemes, they are preferred for examination of oral lesions.

Immunohistochemical Microscopy

In a manner similar in principle to fluorescence microscopy, monoclonal and polyclonal antibodies with specificities for spirochetes, treponemes, or *T. pallidum* have been used by pathologists for detection in paraffin-embedded tissues (Guarner, 2000; Hoang, 2004; Martin-Ezquere, 2009). In contrast to immunofluorescence, immunohistochemistry does not require the use of expensive fluorescent microscopes. With this technique, antitreponemal antibodies bound to spirochetes in tissue sections are detected after a series of immunologic reactions typically consisting of a primary, biotinylated antibody conjugate with organism specificity followed by an enzyme-conjugated streptavidin complex. After development of the enzyme with an appropriate chromogenic substrate, organisms are highlighted against a pale counterstained background. This allows for easy detection of rare bacteria and affords the capability for histologic localization. The procedure reportedly offers improvement in sensitivity and specificity over silver impregnation stains for the detection of treponemes, but this is largely dependent upon the source of primary antibody.

Nontreponemal Serologic Tests

The nontreponemal assays detect antibodies to lipoprotein material and cardiolipin released from cells damaged by treponemes. As a consequence, they are not specific for *Treponema*. These tests have been used traditionally to screen for disease and to monitor the course of the disease after treatment. Standard tests include the VDRL, rapid plasma reagin (RPR), unheated serum reagin (USR), and toluidine red unheated serum (TRUST) tests. Several nontreponemal enzyme-linked immunosorbent assays (ELISAs) have also been approved by the U.S. Food and Drug Administration (FDA) and are used by some high-volume laboratories (e.g., blood donation testing centers). All these tests use a phospholipid antigen, some fortified with lecithin and cholesterol. Flocculation is the end point for the manual standard tests, whereas absorbance values are calculated spectrophotometrically in the ELISA. Serum is the preferred specimen for each. Heating of the serum to eliminate nonspecific reactions is required in the VDRL, whereas the addition of choline chloride to the RPR and USR eliminates the need for heating, making these popular choices among diagnostic laboratories. Antibody-antigen reactions in the VDRL and USR are assessed using a microscope at 100 \times , and the addition of charcoal to the RPR and dye to the TRUST makes the reactions macroscopically visible (Fig. 59-7).

Antibodies detected by these tests generally develop 1–4 weeks after the appearance of the primary chancre. The time at which the specimen is taken during the primary stage, therefore, will affect assay sensitivity. The titer rises, remains high during the first year of infection, and then gradually declines. The tests will ultimately revert to negative in most patients in the absence of therapy, particularly during the late latent stage. Thus, these tests are general markers of disease activity. False-negative nontreponemal tests may also be associated with very high titers of antibody (prozone phenomenon), which are seen most commonly in secondary syphilis. This condition is easily resolved by diluting the specimen prior

to testing. False-positive results occur temporarily with acute illnesses such as hepatitis, other viral infections, and pregnancy; or chronically with the connective tissue diseases (Larsen, 1995).

Standard nontreponemal tests afford the capability of semiquantitative reporting by testing serial twofold specimen dilutions (i.e., titers). Follow-up titers are used to determine the efficacy of treatment, with a fourfold decrease in titer at 6 months for early syphilis or at 12–24 months for late syphilis considered an adequate response (Centers for Disease Control and Prevention, 2006b). As with any paired acute/convalescent serum analysis, testing by the same method and, when possible, in the same laboratory is preferred. Patients treated in early syphilis are more likely to revert to negative than those treated in late syphilis (Fiumara, 1980; Brown, 1985). In a small minority of patients, nontreponemal tests will remain positive despite adequate therapy—a situation known as the “serofast” response. Although useful for high sample throughput, the ELISA is not easily amenable to semiquantitative analysis, so follow-up testing using standard assays is often necessary for therapeutic monitoring of confirmed cases.

Reports have documented various aberrant nontreponemal test results with patients coinfecting with HIV and syphilis, including delayed seroconversion; however, seronegative syphilis does not appear to be prevalent in AIDS patients (Flores, 1995). The false-positive rate is reportedly increased in AIDS patients (4% vs. 1% in non-AIDS); however, the increased rate of positivity may be associated with intravenous drug abuse rather than HIV infection itself (Flores, 1995; Larsen, 1995; Hernandez-Aguado, 1998). False-negative results also occur in AIDS patients with syphilis because of an exaggerated nontreponemal antibody response that occurs in some patients, with the resultant prozone effect (Gourevitch, 1993). Furthermore, as mentioned previously, a small number of AIDS patients may experience minimal to no decline in nontreponemal antibody titers despite presumably adequate therapy, although this may be related to the stage at which treatment was initiated rather than HIV coinfection (Larsen, 1995).

Treponemal Serologic Tests

These tests detect the presence of antibodies to treponemal antigens and are used to confirm a positive nontreponemal screening test, or to confirm infection in the face of a negative nontreponemal test in late or latent disease stages, which can occur in up to 30% of patients with tertiary syphilis (Larsen, 1995). The fluorescent treponemal antibody absorption test (FTA-ABS), one of the two standard treponemal tests, is an indirect fluorescent antibody test. It involves the addition of heated patient serum, which has been absorbed with antigen of the nonpathogenic Reiter treponeme for removal of cross-reactive antibodies to a slide on which *T. pallidum* subsp. *pallidum* (Nichols strain) has been fixed, followed by the addition of FITC-labeled anti-human globulin. Visible treponemes on fluorescent microscopy indicate the presence of antibody to the pathogenic treponemal species in the patient's serum (see Fig. 59-6, B). The second test, which is preferred by many laboratories because of its relative simplicity, is the microhemagglutination-*T. pallidum* test (MHA-TP). Absorbed serum is added to sheep red blood cells sensitized with *T. pallidum* (Nichols strain) sonicate in a microtiter tray. Agglutination of red cells is produced by syphilis-specific antibody. Generally, the MHA-TP and FTA-ABS are equivalent, except in the primary stage of syphilis, where the FTA-ABS may be slightly more sensitive (Hart, 1980; Augenbraun, 1998). Sensitivities and specificities of the various nontreponemal and treponemal serologic tests are summarized in Table 59-1 (Larsen, 1995).

Treponemal-specific antibody develops in primary syphilis and persists indefinitely in most patients, although as many as 20% may eventually serorevert (Romanowski, 1991). AIDS patients have shown a greater tendency to revert to seronegativity following treatment (Haas, 1990). The FTA-ABS usually is the first test to become positive, followed by the MHA-TP, and then the nontreponemal tests shortly thereafter. False-positive FTA-ABS results occur in \approx 1% of patients, most often in the elderly, in persons with connective tissue disease, and in those infected with related organisms, such as *Borrelia* spp. (Larsen, 1995). The frequency of false-positive results with the MHA-TP is reportedly lower than with the FTA-ABS (Larsen, 1995).

As with the nontreponemal tests, ELISA and chemiluminescent test formats utilizing treponeme-specific antigens (e.g., sonicated lysates, recombinant proteins) have become available for use in clinical laboratories. Again, these offer the advantages of automation for high-volume testing and an objective, numeric interpretation. Sensitivity and specificity of various commercially available products are comparable with those of the FTA-ABS and MHA-TP (Lefevre, 1990; Norgard, 1993). Of interest,

TABLE 59-1

Sensitivities of Serologic Tests for Syphilis in Different Stages of Disease

Test	STAGE OF SYPHILIS (% SENSITIVITY)*			
	Primary	Secondary	Latent	Late
VDRL	78 (74–87)	100	95 (88–100)	71 (37–94)
RPR	86 (77–100)	100	98 (95–100)	73
FTA-ABS	84 (70–100)	100	100	96
MHA-TP	76 (69–90)	100	97 (97–100)	94

versions of these tests have recently been implemented as primary screening assays in some laboratories in the United States (Centers for Disease Control and Prevention, 2008) and Europe (Marangoni, 2009; Sokolovskiy, 2009). Because this testing algorithm does not distinguish past from active infection, follow-up testing for positive results typically includes semiquantitative nontreponemal tests and, when these are negative, repeat analysis using an alternative treponemal specific assay. Immunoassays with immunoglobulin (Ig)M-specific detection capability are also available and may have some utility in the diagnosis of congenital syphilis (Stoll, 1993; Larsen, 1998). Finally, several rapid, point-of-care assays that incorporate treponemal or nontreponemal antigens have been described (Greer, 2008). Their utility lies chiefly in areas with high prevalence rates and low likelihood of patient follow-up, where patients with positive results can be treated presumptively at the time of testing.

More highly complex tests, such as the immunoblot and the polymerase chain reaction (PCR), are available in some reference laboratories. The immunoblot has been integrated into the diagnosis of congenital syphilis or as confirmation for treponemal-specific antibody screening by some laboratories (Larsen, 1995; Wang, 2009). PCR has been advocated for the diagnosis of neurosyphilis, particularly in AIDS patients, although some studies have not demonstrated advantages over currently used methods (Marra, 1996). Neither immunoblot nor PCR is used extensively in the diagnostic setting, as standardization remains poor (Wicher, 1999).

Serologic screening for syphilis requires the use of particular specimens and/or tests, depending on the population and/or disease manifestation. For example, in congenital syphilis screening, antepartum maternal serum is the ideal specimen, and all women should be tested at least once during pregnancy (U.S. Preventative Services Task Force, 2009). In high prevalence areas or among women with potential risk factors, repeat testing may be indicated in later trimesters. Confirmation of congenital syphilis, however, may require a combination of clinical and radiologic examinations, placental analysis, and testing of neonatal serum. The latter is typically performed semiquantitatively using nontreponemal tests, and is compared with maternal serologic titer to determine the source of the antibody (i.e., to exclude transplacentally derived maternal antibody). Another example is the diagnosis of neurosyphilis, which requires a positive serum treponemal test in addition to a positive VDRL on CSF or some other CSF abnormality (e.g., pleocytosis, elevated protein level) (Centers for Disease Control and Prevention, 2002). The VDRL applied to CSF is highly specific for the diagnosis of neurosyphilis but is also insensitive. It is negative in 22%–69% of patients with active neurosyphilis, and its sensitivity in inactive neurosyphilis may be as low as 10% (MacLean, 1996). By contrast, the CSF FTA-ABS is reported to have high sensitivity and negative predictive value for neurosyphilis, so some experts advocate using this as a means of excluding the diagnosis (Marra, 2004b). Its low specificity limits its positive predictive value, however. Finally, one study suggests that the RPR may be used in place of VDRL on CSF samples (Castro, 2008), although this remains an uncommon practice in general.

TREATMENT OF TREPONEMATOSES

T. pallidum subspecies and *T. carateum* are uniformly susceptible to penicillin and other β -lactam antibiotics. Treatment for primary, secondary, and early latent syphilis is a single intramuscular injection of benzathine penicillin G. Yaws, pinta, and endemic syphilis are treated with the same

antibiotic, although often at a lower dose (Engelkens, 1991a, 1991b). Household contacts of patients with the latter three diseases usually are also treated. For patients who are allergic to penicillin, doxycycline or tetracycline may be used. Macrolide antibiotics are no longer recommended, as efficacy has been shown to be less than 90% (Schroeter, 1972). A pronounced worsening in clinical course, termed the Jarisch-Herxheimer reaction, may be seen upon treatment of venereal syphilis patients, although symptoms frequently are not as severe as in treatment of relapsing fever spirochetes (Griffin, 1998). For late latent syphilis or syphilis of unknown duration, benzathine penicillin G is given in multiple doses in a course of several weeks. Stage of disease does not affect treatment for yaws, pinta, or endemic syphilis (Engelkens, 1991a, 1991b). A 10–14-day course of high-dose intravenous aqueous penicillin G is indicated for neurosyphilis and congenital syphilis. For patients coinfecting with HIV and *T. pallidum*, current Centers for Disease Control and Prevention (CDC) guidelines do not recommend any significant deviation in therapy (Centers for Disease Control and Prevention, 2006). Indeed, prospective studies have failed to show any benefit of “enhanced” or alternative therapies for early syphilis and neurosyphilis, respectively, among HIV-infected persons (Rofis, 1997; Marra, 2000). On the other hand, some authorities suggest that, given a propensity to develop neurosyphilis even in the face of treatment for primary syphilis, AIDS patients should be treated with higher doses of penicillin (Musher, 1991; Tramont, 2000).

OTHER TREPONEMAL DISEASES

Description

A number of spirochetes belonging to the treponeme molecular group-1, previously referred to as pathogen-related oral spirochetes, and various species of *Treponema* (e.g., *Treponema denticola*, *Treponema socranski*) have been recovered with increased frequency and in higher numbers from the gingiva of patients with ulcerative gingivitis and chronic periodontitis compared with patients with healthy gingiva (Riviere, 1995, 1996; Loesche, 2001). Although originally thought to resemble *T. pallidum* on the basis of immuno-cross-reactivity and in vitro invasive properties, these putative pathogens are rather genetically heterogeneous—only distantly related to *T. pallidum*—and can be induced to express cross-reactive surface antigens (Choi, 1996; Riviere, 1999).

Pathogenesis

A definitive causal relationship between the spirochetes and these diseases has not been firmly established; however, their presence in significant numbers, more commonly in diseased than in healthy tissue, suggests at least an association with gingivitis/periodontitis. Because of the fact that a number of other nontreponemal bacterial genera (e.g., *Prevotella*, *Actinobacillus*, *Porphyromonas*) have also been associated with these clinical manifestations, the current debate seems primarily to involve determining whether culpability belongs to specific virulent organisms among them or rather to the overall diversity of organisms contained within the plaque biofilm (Loesche, 2001).

Diagnosis

As with the commensal species of *Treponema* found in the genital area, some oral *Treponema* species can be cultured under strict anaerobic conditions using a variety of specialized, enriched broth media (Choi, 1996; Riviere, 1999). Other species, including most of those associated with periodontal disease, have not been cultured in vitro (Loesche, 2001). These organisms have been detected with monoclonal antibodies against *T. pallidum*, with which they cross-react. Other investigators have employed a variety of genetic amplification tools in an effort to identify and characterize them (Paster, 2001; Hutter, 2003). These “molecular expeditions” are conducted by using primers that target conserved bacterial sequences and either PCR to amplify ribosomal (rRNA) genes or reverse-transcriptase PCR to amplify the rRNA itself. Resultant products can then be cloned in *Escherichia coli* and sequenced to determine phylogenetic relationships.

Treatment

For years, treatment has been aimed primarily at reducing the overall bacterial burden by removing the plaque biofilm, both above and below the gumline, through physical manipulation (e.g., surgical debridement). Recently, the addition of various antimicrobial regimens, including systemic antibiotics and locally applied agents, has been shown to be a potentially beneficial adjunct (Loesche, 2001).

LEPTOSPIRA

DESCRIPTION

The genus *Leptospira* is composed of 18 genomic species, many containing both pathogenic and nonpathogenic strains, and more than 260 serovars (Perolat, 1998; Brenner, 1999). Previously, *Leptospira* was divided into three species, *L. interrogans* (pathogenic), *L. biflexa* (nonpathogenic), and *L. parva* (nonpathogenic), based on biochemical properties. However, it has become evident that such properties, in addition to pathogenicity and antigenicity, are not consistently predictive of genetic relatedness (Levett, 2001). Leptospirae are tightly coiled with hooked ends, 0.1 μm in width by 6–20 μm in length, and demonstrate a spinning motility. They survive in alkaline fresh water but are killed by acid pH, salt water, and drying.

EPIDEMIOLOGY

Leptospirosis is perhaps the most widespread global zoonosis; although it was identified nearly 100 years ago, it is still considered an important emerging disease. Individual serovars show geographic preferences, as well as particular ecologic niches. The organism is carried by many rodents and feral and domestic animals; however, the rat is one of the most frequent reservoirs and an important source of infection in man. Contact with urine-contaminated water along with entry of the bacteria through cuts or mucosal surfaces is a frequent mode of infection. Those with occupational exposure (e.g., miners, farmers and field workers, veterinarians, fish farmers, sewage workers) or recreational exposure (e.g., camping near or swimming in infected waterways) are at particular risk. The incidence in the United States is 40–120 cases per year; however, the disease is probably significantly underreported (Farr, 1995).

PATHOLOGY AND PATHOGENESIS

After entry into the circulation, the organisms disseminate widely, including into the CNS and eye. Damage to endothelium in infected tissues results in local ischemia and hemorrhage. Hepatocellular damage and renal tubular damage also occur. The liver may have a characteristic yellow-green color, but histologic changes are nonspecific and include ballooning degeneration, acidophilic bodies, regeneration, and cholestasis; leptospirae can be found in around 25% of cases (Dooley, 1976). The kidney shows a chronic interstitial nephritis, necrosis of proximal tubules, and granular or hyaline casts, with intratubular leptospirae in around 65% (Arean, 1962). Pulmonary manifestations include congestion and edema, alveolar hemorrhage, pleural effusion, and occasional hyaline membrane formation (Arean, 1962; Ramachandran, 1977). Myocarditis, meningitis/encephalitis, and myositis may also be seen (Arean, 1962). The mechanisms for endothelial, hepatic, and renal damage are unknown but may be immune mediated.

CLINICAL MANIFESTATIONS

Typically, infection with leptospirae presents as a mild, influenza-like illness (anicteric form) or is subclinical and never recognized; in the minority of patients, a more severe form characterized by jaundice is reported and has a 5%–10% fatality rate (icteric form or Weil's disease). Leptospirosis is biphasic, beginning, after an incubation period of 2–20 days, with the abrupt appearance of chills, fever, headache, myalgia, back pain, abdominal pain, anorexia, and nausea and vomiting. During this phase, termed the bacteremic phase, wide dissemination of bacteria occurs. The bacteremic phase lasts 4–7 days and is followed by a short remission of several days, after which the immune phase, characterized by the appearance of antibodies to the organism, meningitis, uveitis, rash, and hepatic and renal damage, occurs. A pretibial rash has been associated with infection by serovar autumnalis (Fort Bragg fever). In many, the immune phase is mild and lasts only 1–3 days. About half of patients have clinical signs of meningitis and a CSF pleocytosis during the second week of illness. In the small percentage of patients who suffer from Weil's disease, the two phases merge with persistent high fever, jaundice, and bleeding, followed by oliguric renal failure, shock, and myocarditis. Mortality has been reported to be 5%–10% in Weil's disease (Edwards, 1960; Arean, 1962; Levett, 2001).

LABORATORY DIAGNOSIS

Leptospirae can be isolated from CSF, blood, and tissues early in the bacteremic phase (first 10 days), and from urine during the immune phase

(second week to up to 30 days). Culture requires a semisolid medium (Fletcher's or Ellinghausen-McCullough-Johnson-Harris), which is incubated in the dark for 4–6 weeks at 25°–30° C. Urine requires alkalization unless cultured immediately. Leptospirae grow 1–3 cm below the surface of the medium and may form a linear disk of growth. Material from this location should be examined by darkfield microscopy weekly for the characteristic spinning leptospirae with hooked ends. Leptospiral antigens, detected directly in clinical specimens (e.g., ELISA, radioimmunoassay, immunomagnetic capture) or in processed tissue samples (e.g., immunofluorescence, immunohistochemistry), have been used with variable success in the diagnosis of leptospirosis.

A majority of cases, by contrast, are diagnosed serologically. Agglutinating antibodies appear during the first week of illness, peak at around 3–4 weeks, and may persist for years. Antibodies can be detected using bacterial antigens by a macroscopic or microscopic agglutination test, a hemagglutination test, or enzyme immunoassay (EIA) testing. The microscopic agglutination test, which employs antigen from live bacteria, is the established serologic reference method but is used primarily in a research setting. Recently, a modified EIA dipstick test that detects *Leptospira*-specific antibodies has been used with success in settings with minimal laboratory facilities (Gussenhoven, 1997; Yersin, 1999). Molecular methods, including hybridization techniques and PCR, have been used to detect leptospiral DNA in infected patients (Vinetz, 1996; Levett, 2001).

TREATMENT

Severe disease requires aqueous penicillin G or ampicillin given intravenously, and less severe disease can be treated with oral ampicillin, amoxicillin, or doxycycline. Prophylaxis with doxycycline provides protection for individuals in high-exposure environments (Farr, 1995). Immunization of domestic livestock and pets has reduced the danger of infection from these animals to high-risk populations such as veterinarians and farmers. Risk is not completely eliminated, as infection has been shown to occur in immunized animals with transmission of the disease to humans (Feigin, 1973).

BORRELIA

The genus *Borrelia* contains several pathogenic and nonpathogenic species that form two clades: the Lyme borreliosis group (or *Borrelia burgdorferi* sensu lato [s.l.]) and the relapsing fever group. The former has been divided into several genospecies by molecular analyses, three of which cause most human disease: *B. burgdorferi* sensu stricto (s.s.), *Borrelia garinii*, and *Borrelia afzelii*. The relapsing fever group contains a variety of species that can be isolated from argasid (soft) ticks (e.g., *Borrelia hermsii*, *Borrelia turicatae*), ixodid (hard) ticks (e.g., *Borrelia lonestari*, *Borrelia miyamotoi*), and the human body louse (*Borrelia recurrentis*). Morphologically similar to the treponemes, members of the *Borrelia* genus are helical bacteria ranging in size from 5–30 μm long by 0.2–0.5 μm wide. They are actively motile, contain 7–22 periplasmic flagella, and multiply by binary fission. Unlike *Treponema* spp., however, *Borrelia* exhibit a multitude of immunogenic proteins on their outer membrane surfaces, and many species can be cultivated in/on artificial media. Moreover, the intricacies of the *Borrelia* genome, with its 910-kB linear chromosome and 21 linear and circular plasmids, render it a more genetically complex genus than *Treponema* (Porcella, 2001).

What follows is a description of the two major clinical disease forms of human borreliosis, each of which is vector-borne. As such, these entities must often be considered, both from an epidemiologic and from a clinical standpoint, in conjunction with other infectious agents transmitted by identical tick vectors. Examples include the flaviviral agents of tick-borne encephalitis and various bacteria of the Rickettsiaceae, Ehrlichiaeae, and Francisellaceae families, as well as the protist *Babesia microti*. Clinical and diagnostic information related to these and other vector-borne diseases may be found elsewhere in this volume.

LYME DISEASE

The most common tick-borne illness in North America and Europe today (Wang, 1999), Lyme disease (Lyme borreliosis) was so named during the 1970s following an epidemic of oligoarticular arthritis encompassing several communities in eastern Connecticut, chief among them the town of Old Lyme (Steere, 1977a, 1977b). Epidemiologic inquiry soon established an association between Lyme disease (then referred to as Lyme

arthritis) and the hard tick *Ixodes scapularis* (previously *Ixodes dammini*) (Steere, 1978). Within 4 years, Burgdorfer and colleagues had (1) isolated a novel spirochete species from an ixodid tick collected in New York, (2) reproduced the characteristic primary dermal lesions of Lyme disease in tick-fed rabbit models, and (3) demonstrated seroreactivity to antigens of this novel spirochete both in the rabbit model and in convalescent sera from human cases (Burgdorfer, 1982). The contemporary “immunologic” variation of Koch’s postulates were thereby fulfilled (Fredricks, 1996). The implicated organism was subsequently recognized as a member of the genus *Borrelia* and named *B. burgdorferi* in recognition of its discoverer. In retrospect, different aspects of the multisystem inflammatory ailment now commonly known as Lyme disease had been recognized and described both in Europe (Afzelius, 1910; Bannwarth, 1941) and in the United States (Scrimanti, 1970) prior to the epidemic in Connecticut. Yet the present body of knowledge pertaining to Lyme borreliosis can be attributed in large part to the establishment and identification of its infectious origin spawned by the New England outbreak.

Epidemiology and Pathogenesis

A total of 15 different genospecies of *Borrelia* from the Lyme borreliosis group have been phylogenetically characterized (Rudenko, 2009). The three well-established human pathogens include *B. burgdorferi* s.s., which causes Lyme disease in North America, Europe, and Asia, and *B. garinii* and *B. afzelii*, which cause similar but subtly different illnesses in Europe and Asia (van Dam, 2002). The remaining 12 *Borrelia* species have been isolated from a variety of geographic locations, vertebrate hosts, and/or invertebrate vectors. Their roles as etiologic agents of human disease remain in various stages of elucidation at present.

Geographic distributions of *B. burgdorferi* s.l. and consequent regional prevalence of Lyme disease are the result of complex enzootic cycles involving one or several tick vectors of the *Ixodes ricinus* complex, various animal reservoirs, and incidental hosts. Seasonal variability in disease onset parallels the life cycle and questing periods of ixodid ticks (Falco, 1999). In the United States, *B. burgdorferi* s.s. is endemic in the Northeast, Upper Midwest, and Northwest regions, where the annual incidence of Lyme disease regionally averages 10–100 cases/100,000 population (Fig. 59-8). The overall number of reported cases, however, is considerably lower in the Northwest than in the other two endemic foci (Centers for Disease Control and Prevention, 2004b). This discrepancy may be attributable in part to differences in *Borrelia* populations (Girard, 2009) but also likely reflects the distinct enzootic cycles maintained in these regions. In the Northwest, perpetuation of *B. burgdorferi* s.s. involves *Ixodes spinipalpis* ticks, which feed on dusky-footed woodrats but not on humans. The ticks acquire and transmit infection between susceptible and infected reservoir hosts in an endemic cycle. However, the Western black-legged tick (*Ixodes pacificus*) (Fig. 59-9, A), which feeds primarily on reptiles and humans, occasionally becomes infected after conceding its preferences and feeding on the woodrat. A potential consequence of this event is human infection. Yet because of the infrequency of such a concession on the part of *I. pacificus*, the overall incidence of Lyme disease remains fairly low in the

region. By contrast, the chief vector in the Midwest and Northeast, *I. scapularis* (black-legged or deer tick) (Fig. 59-9, B), promiscuously feeds on humans and on the spirochete’s principal animal reservoir, the white-footed mouse. This results in proficient transmission to humans and an extremely high disease incidence, exceeding 1000 cases/100,000 population in certain communities (Shapiro, 2000; Steere, 2001). The most important tick vectors in Europe and Asia include *I. ricinus* (sheep tick) and *Ixodes persulcatus*, respectively, whereas primary animal reservoirs for *B. afzelii* and *B. garinii* are small rodents, voles, and/or various avian species (Fukunaga, 1995; Wang, 1999; Parola, 2001).

Many other epidemiologic factors contribute to the transmission dynamics of *B. burgdorferi* s.l. High vector densities and infection rates, abundance and infectivity of reservoir hosts, and increased likelihood of human exposure all enhance the risk of Lyme disease (Parola, 2001). Furthermore, amplification of *Borrelia* in nonreservoir hosts may also influence regional disease incidence. Such has been postulated as the case in the Northeastern United States, where high population densities of white-tailed deer are thought to contribute to extremely high human infection rates (Steere, 2000). Another important transmission variable is related to the nature and duration of vector attachment during feeding. Hard-tick life cycles consist of three developmental stages, each of which secures only a single blood meal before transition to the next stage (or oviposition, in the case of an adult female). Because *B. burgdorferi* s.l. is not efficiently transmitted vertically in *Ixodes* spp., larvae acquire the spirochete while feeding upon an infected host (Shapiro, 2000; Scoles, 2001). The larval form, consequently, is not a direct vector for human infection (Patterson, 2003). Upon taking a blood meal, the larvae molt to the nymphal stage. Both nymphal and adult forms are capable of feeding on and transmitting organisms to humans, but the former are considerably smaller and are much more likely to go unrecognized while attached. Because efficient transmission of *Borrelia* to a susceptible host requires prolonged feeding durations (Piesman, 1987; Sood, 1997), the nymph is probably the principal vector for human transmission (Falco, 1999; Nadelman, 2001).

As with *T. pallidum*, the genomic sequence of *B. burgdorferi* s.s. has been completely characterized (Fraser, 1997), revealing a number of biosynthetic “gaps,” in addition to a few seemingly important lipoproteins. The latter include a group of outer surface proteins (Osp), A–F, which are encoded by plasmids, differentially expressed in vector and mammal environments, and highly immunostimulatory (de Silva, 1997; Porcella, 2001). A lipoprotein, VlsE (for “variable major protein-like sequence expressed”), with the capability to undergo extensive antigenic variation has also been described in *B. burgdorferi* (Zhang, 1998; Porcella, 2001). The diversity of symptoms observed in Lyme borreliosis is probably due to the direct effects of spirochete dissemination, as well as to the extent of the host immune response (Sigal, 1997; Whooten, 2001). Many animal models of Lyme borreliosis have been developed, some of which have been useful for investigating the dynamics of *Borrelia* dissemination (e.g., tissue localization within heart, skin, and joints), in addition to specific cellular interactions (e.g., with host glycosaminoglycans and plasminogen) (Sigal, 1997; Steere, 2000). The mouse model has been particularly valuable in uncovering details of immunologic responses in Lyme disease (Whooten, 2001). A paucity of cultivable organisms or detectable genomic material within lesions of long-standing, treatment-resistant disease, such as occurs in Lyme arthritis, suggest autoimmune event(s) rather than direct spirochete injury as a pathogenic mechanism. Reported associations between Lyme arthritis and HLA-DR4 as well as an autoantigen candidate, leukocyte function antigen-1, further substantiate this hypothesis (Gross, 1998; Steere, 2004).

Clinical Manifestations

Analogous to syphilis, the clinical progression of Lyme borreliosis has been divided into three general stages: (1) an early localized phase in which a primary lesion develops in the vicinity of the inoculation site, (2) an early disseminated phase wherein the spirochetes spread systemically, causing a variety of cardiac, neurologic, and/or dermatologic manifestations, and (3) a late phase, which may be heralded by other neurologic and/or dermatologic phenomena, in addition to rheumatologic disease. Because symptom overlap occurs during early disseminated and late persistent infection, some investigators abstain from using this clinical staging system, preferring instead simply to incorporate duration of illness into diagnostic and therapeutic considerations (Kaiser, 1998; Nadelman, 1998). Asymptomatic seroconversion or subclinical disease has also been reported to occur in as many as 7% of persons within endemic areas (Steere, 2003). Given the wide diversity of symptoms, Lyme borreliosis, similar to syphilis, has been aptly labeled “the great imitator.”

Figure 59-8 Average rate (per 100,000 population) of Lyme disease by county of residence—United States, 1998–2006. (From Bacon RM, Kugeler KJ, Mead PS. Surveillance for Lyme disease—United States, 1992–2006. *MMWR* 2008;57[SS10]:1–9.)

The earliest clinical stage begins ≈1 week following the bite of an infected tick, at which time a characteristic rash, descriptively termed erythema migrans, develops near the inoculation site in a majority of patients (the exact proportion depends upon case definition or study inclusion criteria). The lesion begins as a painless red macule or papule and subsequently expands to become an erythematous patch measuring up to 70 cm (Nadelman, 1996). Erythema migrans is typically painless, characteristically demonstrates central pallor, imparting a “target-like” or “bull’s-eye” appearance (Fig. 59-10), and may be accompanied by nonspecific symptoms such as fever, fatigue, headache, and myalgia, as well as regional lymphadenopathy (Nadelman, 1996; Smith, 2002). Histologic analysis reveals superficial, perivascular dermatitis comprising lymphocytes, macrophages, and abundant plasma cells; these organisms can sometimes be visualized in tissue sections treated with silver impregnation stains or by immunohistochemical techniques (Duray, 1997). Unlike the lesions of syphilis, vasculitis is not a typical histologic feature of erythema migrans.

Dissemination of *Borrelia* portends the second stage of clinical illness, in which many organ systems may be affected. Smaller, secondary erythema migrans lesions arising in multiple sites are one of the more common signs of early dissemination (Shapiro, 2000). Neurologic manifestations

(neuroborreliosis) affect up to 15% of U.S. patients, with symptoms including cranial nerve palsy (commonly cranial nerve VII), lymphocytic meningitis, and a variety of peripheral neuropathies (e.g., painful radiculitis) (Steere, 2001; Halperin, 2002). These manifestations are collectively referred to as **Bannwarth syndrome** in some European countries (Kaiser, 1998). Somewhat rarer, cardiac involvement in the form of transient atrio-ventricular block or myocarditis has also been reported in approximately 5% of patients with Lyme disease (Steere, 2001). Other sites potentially affected include the musculoskeletal system (e.g., fatigue, malaise), liver (e.g., mild, transient hepatitis), and eyes (e.g., conjunctivitis, neuroretinitis) (Lesser, 1995; Steere, 2000).

In the United States, the most common manifestation of untreated, late-stage Lyme disease is arthritis, which develops in well over half of untreated patients (Steere, 2000). Typically monoarticular or oligoarticular in extent, large joints such as the knee are frequently involved (Steere, 1977a, 2001). Symptoms of pain and swelling begin acutely several weeks to months following spirochete inoculation and last for several days to months (median, 1 week) (Steere, 1977b). Whether the result of autoimmunity or persistent infection, many patients continue to experience intermittent recurrences of migratory arthritis followed by prolonged disease-free periods (Nadelman, 1998). Conversely, late-stage

Figure 59-10 Characteristic “bull’s-eye” lesion, erythema migrans, observed at the site of spirochete inoculation in ≈80% of patients with Lyme disease. (Courtesy James Gathany, CDC/PHIL file photo.)

manifestations of persistent Lyme borreliosis in European patients often involve neurologic or cutaneous organs. The former may overlap clinically with early disseminated neuroborreliosis and may include lymphocytic meningitis and peripheral neuropathies (e.g., sensory polyneuropathy, pareses). In addition, CNS manifestations such as myelitis and spastic-ataxic gait disturbances, as well as short-term cognitive dysfunction, have been noted (Kaiser, 1998; Halperin, 2002). A dermatologic phenomenon known as acrodermatitis chronica atrophica has also been associated with late Lyme borreliosis in Europe. As the name implies, lesions are present on hands, wrists, elbows, and feet. They are often symmetrical and are characterized histologically by a lymphomononuclear and, to a lesser extent, granulocytic infiltrate with progressive epidermal thinning, hyperkeratosis, and dermal atrophy (Aberer, 1991; Duray, 1997). Other well-established or controversial long-term dermatologic manifestations include *Borrelia* lymphocytoma, cutaneous B cell lymphoma, morphea, and lichen sclerosis et atrophica (Duray, 1997; McGinley-Smith, 2003).

Variations in clinical manifestations, particularly during the late stages of Lyme disease, have been ascribed in part to inherent traits of the organisms themselves, whether genospecies or strain specific. For instance, *B. afzelii* (previously group VS461) has been disproportionately isolated from lesions of erythema migrans and acrodermatitis chronica atrophica in Europe as compared with other genospecies of *Borrelia* (van Dam, 1993; Balmelli, 1995; Wang, 1999). By contrast, *B. garinii* is more frequently implicated in European cases of neuroborreliosis (Balmelli, 1995; Wang, 1999). Other studies demonstrate that particular molecular subtypes of *B. burgdorferi* s.s. are more frequently associated with invasive properties and spirochetemia (Dykhuizen, 2008; Wormser, 2008). Additional observations corroborating the notion that disease course is influenced by inherent properties of the infecting *Borrelia* strain include the following: (1) Serologic responses among patients with particular clinical symptoms may be preferential toward antigens from specific *Borrelia* sources; and (2) certain genospecies appear to have different properties in vitro (Dressler, 1994; Norman, 1996; Wang, 1999).

In the vast majority of patients, clinical manifestations of Lyme disease respond to appropriate antibiotic therapy (Shadick, 1999; Seltzer, 2000; Wormser, 2006). Yet a small subset may continue to experience persistent symptoms such as musculoskeletal pain, fatigue, and neurocognitive deficits despite treatment—a condition that has variably been termed

“post-Lyme disease syndrome,” “chronic Lyme disease” or “treatment-resistant borreliosis” (Klempner, 2002). With few exceptions to date, prospective studies have shown little benefit of prolonged antibiotic therapy over placebo in reducing the symptoms of this syndrome. Further, isolation of *Borrelia* or amplification of *Borrelia* genes is often unsuccessful among patients with this disorder (Klempner, 2002). Retrospective case-controlled studies illustrate that the frequency of objective signs among “chronic Lyme disease” patients is similar to that among age-matched controls without a history of Lyme disease (Shadick, 1999; Seltzer, 2000). A recent review summarizes the evidence, or lack thereof, to support a link between *B. burgdorferi* and this chronic syndrome (Feder, 2007). It should be noted that despite the existence of only one body of medical literature, strong opposition to this viewpoint exists. Adamant dissent is evidenced not only by the many correspondence letters referencing the report by Feder et al. (2007), but also by an advocacy group, the International Lyme and Associated Diseases Society, which has issued its own management recommendations distinct from those of the Infectious Disease Society of America (IDSA), and which has contributed significant testimony to an antitrust investigation brought against IDSA by the state of Connecticut. The investigation culminated in an agreement by IDSA to allow review of the guidelines by an independent arbiter, which ultimately upheld essentially all of the prior recommendations (though not without controversy).

Several reports have documented erythema migrans-like lesions in patients residing in Southern United States. Occasionally referred to as Southern tick-associated rash illness, the lesions are preceded by the bite of the lone star tick, *Amblyomma americanum* (see Fig. 59-9, C), and have not yielded any *B. burgdorferi* s.s. isolates to date (Kirkland, 1997; James, 2001). Instead, a novel agent, *B. lonestari* sp. nov., of the relapsing-fever group, has been tentatively implicated (Varela, 2004). Because *B. burgdorferi* s.s. does occur naturally within this geographic area (Oliver, 2003), future epidemiologic work will be required to determine the details and extent of disease caused by each of these organisms in the region.

Laboratory Diagnosis

Issued for surveillance purposes, the CDC case definition of Lyme disease emphasizes clinical findings and physical examination; the development of physician-diagnosed erythema migrans in a patient with possible tick exposure is considered diagnostic (Centers for Disease Control and Prevention, 1997). Laboratory confirmation is required only for less specific, objective signs that would be expected to develop later in the disease course (e.g., arthritis, cranial neuritis, cardiac conduction defects). Other experts agree that laboratory testing, particularly using indirect methods such as serologic tests, should not be performed as standalone diagnostic modalities, but rather should serve as tools to assist in confirming or refuting clinical suspicions (Luger, 1990; Tugwell, 1997; Brown, 1999). Reports highlighting the concepts of pretest probability based on epidemiologic and clinical factors, as well as likelihood ratios and test predictive values, thoroughly demonstrate the futility and high cost of such a standalone approach (Seltzer, 1996; Tugwell, 1997; Nichol, 1998). In fact, Lyme disease testing for patients with only nonspecific symptoms like fatigue, headache, or myalgia (i.e., when pretest probability is = 0.2), even in endemic areas using accurate laboratory assays, can lead to more false-positive than true-positive results (Tugwell, 1997). Exacerbated by widespread anxiety on the part of the public and a general misunderstanding by many healthcare providers, the current diagnostic confusion surrounding Lyme borreliosis can perhaps be best dealt with by taking a thorough look at the indications for and limitations of laboratory testing.

Culture

Culture usually serves as the “gold standard” in diagnostic testing for infectious diseases in which the causative agent does not also asymptotically colonize humans. Yet, despite the fact that cultivation of *Borrelia* spp. is readily achievable and often is not as time-consuming as for other pathogenic microorganisms (Reed, 2002), most clinical and commercial diagnostic laboratories do not offer this testing alternative. Several modifications of the broth-based Barber-Stoenner-Kelly medium have been shown not only to support the growth of *Borrelia* spp. but to be useful in their recovery from biopsy tissue of erythema migrans lesions and large-volume plasma collections during the early, acute phase of disease (Nadelman, 1996; Steere, 1998; Wormser, 2001). Given the specificity of organism isolation and the absence of measurable antibody in most patients with *B. burgdorferi* s.l. infection during the early phase of clinical illness, culture would seem to be a very practical diagnostic modality. However, reliance on darkfield microscopy or fluorescent antibodies for the

detection and identification of positive cultures, high media and reagent costs, wide reported sensitivity ranges (doubtless the result of variability in quantity of tissue/blood cultured and timing of specimen collection), and the requirement that invasive procedures be performed on the patient (e.g., tissue biopsy) have probably all contributed to the test's general unpopularity outside the research arena. It is important to note that recovery of *Borrelia* from CSF, synovial fluid, or other samples collected beyond the early phases of disease is so frequently unsuccessful as to be of little diagnostic utility. For this reason, other laboratory testing modalities for Lyme borreliosis are important adjuncts.

Serologic Tests

Detection of *Borrelia*-specific antibody production during Lyme disease may be accomplished using a variety of methods that express results in terms of total Ig or class-specific IgG or IgM. Immunofluorescent antibody (IFA) assays, which typically contain antigen in the form of whole cell *B. burgdorferi* s.s. fixed to glass slides, were popular in the 1980s but have been largely superseded by the more automated and less subjective ELISA, which incorporates select antigens that are recombinantly produced or derived from partially purified extracts of *Borrelia*.

As with all serologic responses to infectious causes, a multitude of variables potentially affect the performance of assays developed to detect them. False-negative and false-positive results may consequently serve only to confound clinical impressions. Early in the course of Lyme disease, absence of antibody (or levels below the limit of detection) leads to false-negative results. This is circumvented in part with assays that detect IgM specifically, because IgM production precedes the development of an IgG response (Shapiro, 2000; Reed, 2002). As the disease progresses, test sensitivity increases (Engstrom, 1995; Brown, 1999; Liang, 1999). In fact, a recent study demonstrates that the duration of illness itself is of greater importance for serologic detection than is test method or format (Wormser, 2008). Specificity of the IFA and ELISA may also be adversely affected by cross-reacting antibodies to a variety of microorganism- and host-derived proteins. Some of these include pathogenic spirochetes (e.g., relapsing fever group of *Borrelia* and treponemes) and other bacteria (e.g., *Helicobacter pylori*) and viruses (e.g., Epstein-Barr), as well as antinuclear antigens present in autoimmune disorders such as systemic lupus erythematosus (Brown, 1999; Reed, 2002). Previous immunization with the OspA subunit Lyme disease vaccine may lead to false-positive ELISA and IFA results as well, given that this lipoprotein is typically an integral antigenic component of these tests (Steere, 1998). Other factors that may contribute to test limitations include the composition of antigen contained in the particular assay, the level of quality control within the testing facility, the interpretive levels at which positive and negative (and indeterminate) optical density or index values are set, the particular bacterial strain responsible for infection, and the patient's individual immune response.

In an effort to increase the accuracy of serologic testing as a whole, the CDC proposed the use of a two-tiered algorithm, in which all positive and indeterminate results obtained by ELISA or IFA are subsequently tested by another method, the immunoblot (Centers for Disease Control and Prevention, 1995). In this assay, proteins extracted from low-passaged *B. burgdorferi* s.s. are quantitatively standardized and then separated by electrophoresis on the basis of size and charge. Following transfer to a membrane substrate, control and test sera (in addition to a panel of monoclonal antibodies for reference and calibration) are incubated with the *Borrelia* proteins. Nonspecific immunoglobulin is removed by washing, while *Borrelia*-specific antibody is bound and visualized using an enzyme-linked conjugate. This technique provides the capability to discern antibodies against particular proteins. Interpretation is somewhat subjective, and criteria defining positive results vary somewhat. Band patterns defining a positive result as outlined by CDC (Centers for Disease Control and Prevention, 1995) are depicted in Figure 59-11.

This tiered approach theoretically consists of a highly sensitive first-round test that detects most cases of Lyme disease, followed by a highly specific assay that excludes any false-positive results from the first round (Dressler, 1993; Ledue, 1996). Clinical practice is not theoretical, however, and the high degree of interlaboratory and intralaboratory variability, less than ideal sensitivity of ELISA and IFA, and wide ranges of reported performance for the immunoblot suggest that this approach may also be imperfect (Engstrom, 1995; Aguero-Rosenfeld, 1996; Ledue, 1996; Bakken, 1997). Even so, improvement in overall testing performance using the algorithm has been described, with the single major caveat that immunoblot results may be significantly influenced by the stage of disease during which testing is performed (Engstrom, 1995; Johnson, 1996). Incorporation into the algorithm of newer ELISAs that utilize

Figure 59-11 Ten major bands and respective molecular weights of antigens identified in *Borrelia burgdorferi* immunoblot assays. For positivity according to Centers for Disease Control and Prevention (CDC) recommendations, immunoglobulin (Ig)G-specific blots require the presence of 7 of 10 bands, whereas IgM-specific assays require 2 of 3 (red arrow) bands. BmpA, Basic membrane protein A; FlaB, flagellin; kDa, kilodaltons; OspC, outer surface protein C.

recombinant, highly conserved, and immunodominant antigens (e.g., VlsE) or portions thereof (26-mer peptide from the sixth invariable region [C6 peptide]) may ultimately serve to increase accuracy even further, particularly during early stages of disease (Gomes-Solecki, 2000; Bacon, 2003; Branda, 2009).

Peak antibody titers generally plateau between 7 and 30 days following the development of erythema migrans; the degree of reactivity (e.g., number of bands by Western blot or optical density reading by ELISA) is typically higher in patients with early dissemination (Aguero-Rosenfeld, 1996). Beyond 30 days, most (but not all) patients with Lyme disease will have developed an IgG response, so diagnostic reliance upon IgM assays alone is not recommended (Centers for Disease Control and Prevention, 1995). Several reports have suggested that therapeutic intervention early in the course of disease may abrogate the antibody response and lead to "seronegative" Lyme disease (Dattwyler, 1988; Aguero-Rosenfeld, 1996; Ledue, 1996). Although one retrospective European study demonstrated that treatment had no statistically significant effect on ultimate seroreactivity, the authors did note a trend toward higher seropositivity incidence and titer among patients who did not receive antibiotics (Plorer, 1993). Finally, because IgG and IgM detection may last many years after successful eradication of the spirochete, there appears to be no role in monitoring antibody levels during convalescence for determination of disease activity and response to therapy or in assessing IgM positivity as a means of establishing the timing of infection (Hilton, 1997; Kalish, 2001).

Several other laboratory-based immunologic techniques have been evaluated for potential use in the diagnosis of Lyme disease. Reports have indicated that *Borrelia*-specific antibodies detected by IFA, ELISA, and/or immunoblot in CSF and synovial fluid samples may be useful in confirming neuroborreliosis and Lyme arthritis, respectively, particularly when compared with serum levels (Cruz, 1991; Hansen, 1991). To our knowledge, no commercially available kits had been cleared for such use by the FDA, although some laboratories have validated this specimen source. Another method that showed promise in the identification of "seronegative" Lyme disease cases, the T cell proliferative assay, was probably too complex and insensitive to gain widespread appeal among diagnostic laboratories (Dressler, 1991). A recent strategy employing

precipitation and dissociation of *Borrelia*-specific IgM from circulating immune complexes prior to capture on solid phase and quantitation shows promise (Brunner, 2001). Last, an antigen capture assay used on CSF or urine has been reported (Coyle, 1995; Klempner, 2001) but is not presently recommended for diagnostic purposes without additional validation studies (Tugwell, 1997).

Molecular Tests

Alternative testing methods for Lyme borreliosis have been strongly sought after, given the overall low sensitivity of culture and serologic assays. In the early 1990s, researchers set their sights on genomic amplification techniques, which were relatively new to the diagnostic armamentarium at that time. Since then, several modifications of the PCR using various genetic targets and amplicon detection methods have been applied to a variety of specimen types in search of *Borrelia* nucleic acids.

Samples from which *B. burgdorferi* s.l. could not be readily isolated were the primary focus of initial investigations on PCR utility. Studies of PCR analyses on joint aspirate samples from patients with Lyme arthritis demonstrated excellent sensitivity and specificity rates when several primer sets were used (Nocton, 1994; Dumler, 2001). After the results were compared with clinical information, it became apparent that (1) detection of *Borrelia* nucleic acids was more frequently associated with a history of absent or inadequate antimicrobial therapy, and (2) PCR positivity disappeared following appropriate treatment (Nocton, 1994). Further inquiry into a performance discrepancy of primer sets targeting genomic (e.g., rRNA genes) versus plasmid-derived (e.g., *OspA*, *OspB* genes) DNA revealed that the latter is present in higher quantities within joint spaces in Lyme arthritis (Persing, 1994). This phenomenon, termed **target imbalance**, seems to be unique to the inflammatory spirochete milieu of synovial fluid in Lyme arthritis and probably accounts for the higher sensitivity observed in tests that target the *OspA* gene (Lebech, 2002). By contrast, studies of amplification assays on CSF from patients with acute or chronic neuroborreliosis have demonstrated only minimal to moderate improvement in sensitivity over culture (Nocton, 1996; Dumler, 2001). In part the result of study inclusion criteria, the extremely wide reported sensitivity ranges are probably also due to the extremely low numbers of *Borrelia* genomic copies (i.e., levels near lower detection limits) in the CSF of affected patients (Schmidt, 1997). As a general rule, successful amplification occurs more frequently during the early stages of neurologic disease (Lebech, 2002).

PCR likewise has been applied to specimens collected during the primary and early disseminated stages of Lyme borreliosis. Nucleic acid detection in tissue from erythema migrans lesions has been successful; such an approach may offer improvement in both sensitivity and turnaround time over culture (Dumler, 2001). Testing of blood and plasma has also been attempted but is limited by the timing of sample collection (Schmidt, 1997). Initial reports of urine testing by PCR were encouraging because of the ease of specimen collection and the high sensitivity, but these findings have not been consistently reproduced (Brettschneider, 1998; Lebech, 2002). Additionally, detection of *Borrelia* genetic material extracted directly from ixodid tick vectors may be useful from an epidemiologic standpoint but should not be relied upon for diagnosis or management of patients from whom the ticks were removed (Sood, 1997; Dumler, 2001; Wormser, 2006).

In time, developments in technology and improvements in understanding will continue to lend themselves to new, creative uses for the PCR beyond simply diagnosis. For instance, the technique has been readily used alongside restriction fragment length polymorphism (RFLP) and DNA sequencing for subcategorization of *Borrelia* isolates for taxonomic purposes (Wang, 1999; Hoen, 2009). The use of labeled, internal hybridization probes within the reaction vessel has afforded the ability to detect and quantify amplification products in real time, which has provided clues about *Borrelia* transmission dynamics and pathogenesis (Pahl, 1999; Wang, 2002). In contrast to cases of HIV or hepatitis C virus, monitoring therapeutic responses by PCR has not been firmly established as beneficial in Lyme disease (Schmidt, 1997). However, the relationships between *Borrelia* genetic material in joints affected by Lyme arthritis, antibiotic therapy, and symptomatic outcome suggest that it may be established in the future (Nocton, 1994; Steere, 2004).

As with most amplification techniques, use of PCR for diagnosis of Lyme disease is limited by many factors, including polymerase inhibitors, low target levels, potential for contamination, primer choices, and method of amplicon detection. Whatever the application, the sensitivity and specificity of molecular tests are imperfect. Accordingly, negative results alone should never be used to exclude a diagnosis, and positive results out of context should not confirm a diagnosis. Misinterpretations such as these

may lead to dismal consequences if not resolved early (Patel, 2000; Molloy, 2001). It is important to note that because most patients with late manifestations of Lyme disease will have evidence of seroreactivity by the time of presentation (thereby fulfilling the CDC case definition), PCR studies probably are best used during early Lyme disease prior to a serologic response. Of utmost importance is the correlation of laboratory data with clinical impression, irrespective of whether such data are derived through serologic or molecular means.

Treatment and Prevention

The IDSA has recently updated its guidelines for the management of patients with suspected or proven Lyme borreliosis (Wormser, 2006). To summarize, a large body of evidence in the form of randomized, prospective, double-blind studies has consistently demonstrated that a 2–3-week course of oral doxycycline or ampicillin is highly effective in the treatment of early, uncomplicated Lyme disease. Cefuroxime is also effective but is not recommended as first-line therapy because of cost. In patients unable to tolerate any of these regimens, or for whom such regimens would be contraindicated, macrolide therapy may be an acceptable alternative. Extended treatment courses of this standard oral regimen are also considered to be effective in most patients with Lyme arthritis in the absence of neurologic manifestations. However, parenteral therapy with ceftriaxone (or penicillin as an alternative) may be used in cases of arthritis relapse. This same intravenous regimen is recommended for patients with third-degree heart block and/or neuroborreliosis. Of note, most of the prospective therapeutic trials upon which IDSA recommendations are based have endpoints defined in terms of clinical responses (i.e., disappearance of symptoms) rather than the eradication of *Borrelia*.

A somewhat more contested issue surrounds the use of prophylactic antibiotic therapy following recognition and removal of a feeding tick. Early prospective studies employing 10-day oral regimens of antimicrobial prophylaxis failed to establish any benefit over placebo (Warshafsky, 1996). Factors that further confound the matter include (1) the extremely low success rate of *Borrelia* transmission to humans (1%–3%), even in hyperendemic areas where tick infection rates may exceed 50% (Shapiro, 1992; Nadelman, 2001); (2) the frequency with which tick bites are not recognized among patients with Lyme disease (up to 75% of patients) (Nadelman, 1996); (3) the inaccuracy of tick species identification and estimates of feeding duration by nonentomologists (Falco, 1998); and (4) the potential costs of widespread antibiotic use (e.g., financial, unanticipated side effects, bacterial resistance). One investigation demonstrated that a single 200-mg dose of doxycycline administered after removal of an *I. scapularis* tick significantly reduced the incidence of subsequent development of erythema migrans (Nadelman, 2001). Although interpretations of the study were mixed (Bellovin, 2001; Leenders, 2001; Shapiro, 2001), the latest IDSA guidelines state that prophylaxis “may be offered” if the epidemiologic findings (e.g., tick species, stage and duration of feeding, confirmed area of acquisition) are compelling.

Primary Lyme disease prevention strategies that are generally agreed upon include interventions that decrease both the likelihood and the duration of vector attachment and feeding. Use of insect repellents, acaricides, and barrier clothing such as long pants and long-sleeved shirts and the performance of daily “tick checks” have a theoretical if not proven value in reducing human cases of ixodid tick-borne disease (Poland, 2001; Hayes, 2003). The single most widely accepted and thoroughly tested prevention strategy, human vaccination, is no longer commercially available, however (Hitt, 2002). This subunit vaccine containing a lipidized, recombinant *OspA* antigen was shown to significantly reduce the incidence of Lyme borreliosis following a three-step immunization schedule (Steere, 1998). Because of low sales and perhaps an unfounded fear of complications, the product was withdrawn from the market in 2002.

RELAPSING FEVER

Relapsing fever can be divided into two distinctive entities based on microbiological and epidemiologic features. Epidemic louse-borne relapsing fever (LBRF) occurs worldwide, reflecting the ubiquitous distribution of its transmission vector, *Pediculus humanus* (Johnson, 2000). Although the disease has been largely eradicated from most developed nations, documented occurrences persist in parts of east Africa and South America (Sundnes, 1993; Raoult, 1999). Humans are the only known reservoir for the causative agent, *B. recurrentis*. Successful transmission between them does not require that the vector actually feed upon a human host. Rather, when an infected louse is crushed, susceptible persons are exposed and infected via contaminated hemolymph (Johnson, 2000).

Figure 59-12 Example of a member of the Argasidae family of “soft ticks,” which are responsible for transmission of endemic relapsing fever *Borrelia*. (Courtesy James Gathany, CDC/PHIL file photo.)

Endemic tick-borne relapsing fever (TBRF) has a narrower geographic distribution, paralleling that of its primary transmission vectors, argasid ticks of the genus *Ornithodoros* (Fig. 59-12). North American areas of disease endemicity include the Pacific Northwest, the Northern and Central Rocky Mountains, and parts of the Sierra range of California (*Ornithodoros bermsi* habitats), as well as the arid flatlands of Mexico, Texas, and New Mexico (*Ornithodoros turicata* habitats) (Dworkin, 2002). The disease is also well documented in parts of Africa and Europe (Parola, 2001). In the past, *Borrelia* spp. causing TBRF were considered to have a high degree of tick-vector specificity and were named after the *Ornithodoros* species from which they were isolated (Davis, 1942). Thus, *B. bermsi* and *B. turicatae* are associated with *O. bermsi* and *O. turicata*, respectively. However, recent reports demonstrating the presence of relapsing fever group *Borrelia* nucleic acids in several *Ixodes* tick species, many captured in regions of Lyme endemicity, may challenge this assumption (Fukunaga, 1995; Scoles, 2001; Fraenkel, 2002). Furthermore, because (1) serologic cross-reactivity between organisms from the two borreliosis clades is predictable (Schwan, 1996), and (2) relapsing fever-like spirochetes have been shown to produce disease in localities heretofore considered nonendemic for TBRF (Breitschwerdt, 1994), the clinical and diagnostic implications of these reports will undoubtedly spark renewed research on relapsing fever agents.

Transmission dynamics and, therefore, epidemiologic factors associated with TBRF are considerably different from those of Lyme disease. Argasid ticks feed nocturnally and for much shorter durations than ixodid ticks (Parola, 2001). Yet, because they harbor *Borrelia* in their salivary secretions, soft ticks can successfully inoculate spirochetes within minutes of feeding (Dworkin, 2002). Although *Ornithodoros* ticks can transmit *Borrelia* vertically (transovarial) and can maintain the bacteria in nature for extended periods, several mammalian hosts also contribute to spirochete persistence (Dworkin, 2002). Human cases often occur in small clusters following exposure to the vector while sleeping in rustic cabins or in seldom occupied rural dwellings (*O. bermsi*) or in caves (*O. turicata*) (Rawlings, 1995; Dworkin, 1998).

Clinical features of LBRF and TBRF are somewhat similar. Following an approximately 7-day incubation period, infected patients experience the acute onset of high fever (38.9°–40.0° C) accompanied by nonspecific symptoms such as headache, malaise, arthralgia, and fatigue (Southern, 1969; Dworkin, 1998). Minor hemorrhagic manifestations are not uncommon and may be related to transient thrombocytopenia. Hepatosplenomegaly is identified more frequently in patients with LBRF (Southern, 1969). Neurologic involvement in the form of meningitis, seventh nerve palsy, myelitis, and encephalitis has been reported (Cadavid, 1998). Almost as suddenly as they begin, symptoms subside after 3–6 days in most patients, only to relapse roughly 1 week later (Johnson, 2000). Similar episodes of symptomatic recurrence may continue up to as many as 13 times but more typically resolve after two or three relapses (Southern, 1969). These waves of recrudescence are believed to be due to the organism's extraordinary ability to quickly vary its surface protein antigenic makeup under immune (i.e. antibody) selective pressures, thus resulting in

cycles of epitope variation and immune escape followed by new antibody production and organism suppression (Rich, 2001; Dworkin, 2002). Left untreated, LBRF appears to have a higher mortality rate than its tick-borne counterpart, but the contributive effects of other factors (e.g., famine, war) often accompanying LBRF may obscure direct comparisons (Dworkin, 2002). Nevertheless, self-limited cases of probable TBRF have been reported (Rawlings, 1995; Dworkin, 1998).

Microscopic examination of peripheral blood samples obtained during febrile episodes has been the traditional laboratory approach to diagnosis of relapsing fever. *Borrelia* organisms may be visualized in wet mounts using a darkfield technique or in fixed smears stained with Wright-Giemsa, acridine orange, or specific fluorescent antibodies. Drawbacks to microscopy include (1) the requirement of a fairly high spirochetemic burden, although this may be obviated by collection of samples during febrile periods; (2) observer inexperience or unfamiliarity with clinical differential; and (3) the inability to identify causative *Borrelia* to the species level. Cultivation of the spirochetes is possible, although difficult, and is rarely performed in clinical settings. Demonstration of serologic response using techniques such as IFA, ELISA, and Western blot has met with variable success. The degree of *Borrelia* antigenic variability may limit serologic assay sensitivity, whereas cross-reactivity with other spirochetes, in particular those of the Lyme borreliosis group, may affect specificity. Newer tests utilizing a 34-kDa recombinant protein, GlpQ, appear to be more specific for the relapsing fever spirochetes (Schwan, 1996; Porcella, 2000). At present, molecular methods such as PCR play little, if any, role in the routine diagnosis of relapsing fever. However, given their extreme power of strain and/or species discrimination (Wormser, 1999; Bunikis, 2004), these techniques may one day play a vital part in the elucidation of borreliosis etiology in regions where both relapsing fever and Lyme disease spirochetes are found.

Successful treatment of LBRF may be accomplished using a single oral dose of tetracycline or erythromycin, whereas 5–10 days of therapy with either of these agents is recommended for TBRF (Johnson, 2000). Parenteral administration of a β -lactam may be considered in the case of meningitis or encephalitis (Cadavid, 1998). Whatever the antibiotic, symptoms of the Jarisch-Herxheimer reaction are not uncommon and may be particularly severe in the louse-borne form of disease. This reaction usually occurs within a few hours of antibiotic initiation and is typified by an increase in temperature (0.5°–1° C) with rigors, systemic hypotension, and leukopenia. As with other shock-like syndromes, the proposed mechanism of Jarisch-Herxheimer reaction involves a cytokine “storm,” with tumor necrosis factor- α , interleukin-6, and interleukin-8 as major orchestrating components (Griffin, 1998).

Prevention strategies for TBRF include rodent-proofing rural cottages or cabins to avoid immigration and colonization by soft ticks, use of insecticides around such dwellings, use of topical repellents while sleeping, and altogether avoiding overnight excursions into known *Ornithodoros* habitats. Prevention of LBRF may be effected through good personal hygiene and delousing procedures (Johnson, 2000). No vaccine is currently available.

RAT-BITE FEVER

DESCRIPTION

Spirillum minus is a gram-negative, tightly coiled bacterium 2–5 μ m long by 0.5 μ m wide, with bipolar tufts of flagella, more closely related to *Neisseria* species than to members of the family Spirochaetaceae.

EPIDEMIOLOGY

Infection with *S. minus* in humans results in a relapsing fever called sodoku, most cases of which have been described in Japan, although cases have occurred worldwide. This bacterium is part of the respiratory flora of rats and is transmitted by a bite. Oral ingestion is not reported to be a source of infection for humans. The disease is very rare in the United States, though it does occur as a result of infection by *Streptobacillus moniliformis*. Research laboratory workers and world travelers are the groups at risk for infection (Anderson, 1983; Signorini, 2002).

PATHOGENESIS AND PATHOLOGY

The pathogenesis of *S. minus* is poorly understood. Dissemination from the original bite occurs soon after inoculation. In the few postmortem descriptions of fatal cases, epithelial necrosis and a mononuclear infiltrate

in the dermis at the original bite site; a perivascular mononuclear infiltrate in the dermis from the site of the rash; hyperplasia of lymph nodes; and hemorrhage and necrosis in the liver, spleen, kidney, myocardium, and meninges have been described (Washburn, 1995).

CLINICAL MANIFESTATIONS

The bite wound initially heals, but 1–4 weeks later, an indurated lesion, which may ulcerate, appears at the bite site. Febrile periods recur, separated by afebrile periods of 3–7 days. Fever can be accompanied by myalgia, headache, and vomiting. Half of patients have a macular rash that may form large plaques (Taber, 1979). Resolution usually occurs in 3–8 weeks, but relapses and complications such as endocarditis, meningitis, myocarditis, and nephritis can also occur (Washburn, 1995). The mortality for untreated cases in the preantibiotic era was 6%–10% (Washburn, 1995).

LABORATORY DIAGNOSIS

S. minus can be propagated only in mice or guinea pigs by intraperitoneal inoculation. Demonstration of the organisms can be accomplished by staining exudate from the lesion or lymph nodes with a Wright-Giemsa stain or visualization by darkfield microscopy. Serologic tests are not available; however, up to 50% of patients can have a false-positive nontreponemal test for syphilis (Taber, 1979).

TREATMENT

Intravenous aqueous penicillin G is the therapy of choice, with tetracycline used in penicillin-allergic patients.

ANAEROBIOSPIRILLUM SUCCINICIPRODUCENS

DESCRIPTION

Anaerobiospirillum succiniciproducens is a gram-negative, spiral-shaped bacterium measuring 0.6–0.8 μm wide by 4–8 μm long. It shows a corkscrew-like motility and possesses bipolar multitrichous flagella. Similar to *Spirillum* spp., members of the genus *Anaerobiospirillum* are not true spirochetes. Rather, they are more closely related to the genus *Aeromonas* than to the *Treponema* or *Borrelia* genus.

EPIDEMIOLOGY

This anaerobic bacterium can be part of the normal flora of healthy cats and dogs but has also been demonstrated in association with severe feline ileocolitis (De Cock, 2004). An association of similar illness in humans with exposure to these pets has been suggested but not definitively established (Malnick, 1990; Goddard, 1998). *A. succiniciproducens* has been associated with diarrheal illness in normal patients and with sepsis in patients with predisposing illness. The gastrointestinal tract in these patients has been postulated as the source for entry into the circulatory system (McNeil, 1987; Tee, 1998). The incidence of infection is low but has been increasing; this is thought to be due primarily to better detection by improved culture technique (Goddard, 1998).

CLINICAL MANIFESTATIONS

Patients with gastroenteritis suffer from abdominal pain, vomiting, and diarrhea for 3–7 days; those without underlying illness recover uneventfully (Malnick, 1990). Sepsis has occurred in patients with underlying illnesses, including alcoholism, atherosclerosis, malignancy, diabetes mellitus, and gingivitis (Goddard, 1998; Pienaar, 2003). Fatalities have occurred in about one third of cases of sepsis.

LABORATORY DIAGNOSIS

A. succiniciproducens grows well in automated blood culture systems (Tee, 1998). After subculture on chocolate or blood agar, moist and spreading colonies 1–2 mm in diameter appear after 2–3 days. Useful identifying biochemical reactions include a negative catalase, indole, and oxidase; production of succinic acid and acetic acid from glucose as demonstrated by gas-liquid chromatography; and no growth at 25° C or 42° C. A selective medium has been developed by Malnick (1990).

TREATMENT

Because of the uncommon nature of this infection, optimal therapy for sepsis has not been established. In vitro, most isolates tested have been susceptible to carbenicillin, cefoxitin, chloramphenicol, and metronidazole and resistant to vancomycin and clindamycin; however, testing has been limited and is not standardized (Shlaes, 1982; McNeil, 1987).

AGENTS OF INTESTINAL SPIROCHETOSIS

DESCRIPTION

Two species of spirochete, *Brachyspira aalborgi* and *Brachyspira pilosicoli* (formerly designated as a member of the genus *Serpulina*), have been found in the colon of humans. These organisms are gram-negative, 0.2–0.4 μm in diameter, and 4–8 μm in length. Four to six flagella are present subterminally at each end near the pointed ends of the bacteria.

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

B. pilosicoli, along with *B. hyodysenteriae*, causes porcine intestinal spirochetosis, a diarrheal disease in young pigs, although strains related to these species have been recovered from dogs, birds, and other animals (Korner, 2003). It is unknown whether animals act as reservoirs for human infection. In contrast, *B. aalborgi* was named after its isolation from the colon of a human patient (Hovind-Hougen, 1982), but it is less well characterized overall. The association of intestinal spirochetes with disease is not firmly established, as the bacteria have been identified in both symptomatic and asymptomatic individuals. Homosexual men have shown a higher prevalence than other populations (Teglbjaerg, 1990). Diarrhea, abdominal pain, rectal bleeding, and discharge have been attributed to intestinal spirochetosis (Teglbjaerg, 1990). Additionally, *B. pilosicoli* has been isolated from the blood of critically ill and immunocompromised patients, the clinical significance of which is uncertain (Trott, 1997; Kanavaki, 2002).

PATHOLOGY AND PATHOGENESIS

The spirochetes are easily seen on biopsy specimens as a dark blue “fringe” on the surface of colonic epithelial cells with sparing of the goblet cells (Fig. 59-13, A). Silver impregnation stains demonstrate the organisms well (Fig. 59-13, B). The epithelial cells appear normal, and no increased inflammation is noted in the lamina propria. Electron microscopy demonstrates that the bacteria attach to the surface of colonic epithelial cells end-on and are oriented perpendicular to the lumen (Teglbjaerg, 1990). Invasion into epithelial and mucosal macrophages has been demonstrated in both symptomatic and asymptomatic patients (Teglbjaerg, 1990). Pathogenesis has not been established.

LABORATORY DIAGNOSIS

Spirochetes can be detected in stool by darkfield microscopy and cultured from stool or biopsy specimens on trypticase soy agar with 5%–10% horse or calf blood. The addition of spectinomycin and polymyxin B makes the media selective (Teglbjaerg, 1990). On media incubated anaerobically, pinpoint, weakly β -hemolytic colonies develop in 3 days to 4 weeks, depending on the strain. Fluorescent in situ hybridization assays and amplification techniques followed by RFLP analysis have been used for the detection and/or identification of spirochetes from tissue biopsy samples (Calderaro, 2003; Jensen, 2004). Moreover, amplification of *Brachyspira* genes from DNA extracted directly from feces of infected animals has also been successful (Atyeo, 1998).

TREATMENT

Although antimicrobial susceptibilities of *Brachyspira* spp. have been published, standardized testing of a large number of isolates has not been described (Karlsson, 2003). Patients suffering from symptoms and intestinal spirochetosis have reportedly responded to metronidazole (Teglbjaerg, 1990).

Figure 59-13 Colonic epithelium demonstrating (A) basophilic discoloration along the bowel luminal surface (hematoxylin & eosin [H&E], $\approx \times 400$), which is confirmed in (B) to be numerous argyrophilic spirochetes, consistent with intestinal spirochetosis (Steiner silver impregnation technique, $\times 400$). KEY POINTS

- *Mycobacterium tuberculosis* complex is the only mycobacterium that is transmitted from person to person and, therefore, is of public health importance.
- The Mantoux skin test and interferon- γ release assays are useful for identifying persons with latent tuberculosis infection.
- For optimal detection of mycobacteria in clinical specimens, laboratories should use a fluorochrome stain and a liquid system with or without a concomitant solid medium for culture.
- Nucleic acid amplification testing for direct detection of *M. tuberculosis* complex should be performed on respiratory specimens from patients with suspected tuberculosis.
- Susceptibility testing to the primary antituberculous agents (isoniazid, rifampin, ethambutol, and pyrazinamide) should be performed on all initial isolates of *M. tuberculosis* complex.
- Infections caused by nontuberculous mycobacteria are acquired from the environment (e.g., water).
- The nontuberculous mycobacteria most commonly encountered in the clinical laboratory are *Mycobacterium avium* complex, which causes pulmonary disease and, in immunocompromised patients, disseminated disease; the rapidly growing mycobacteria *Mycobacterium abscessus*, *Mycobacterium chelonae*, and *Mycobacterium fortuitum* group, which most often cause skin and soft tissue infections; *Mycobacterium kansasii*, which causes pulmonary infection; and *Mycobacterium marinum*, which causes skin and soft tissue infections.

MYCOBACTERIUM TUBERCULOSIS COMPLEX

The tubercle bacilli that make up the *M. tuberculosis* complex (MTBC; *Mycobacterium tuberculosis*, *Mycobacterium bovis*, *M. bovis* Bacille Calmette-Guérin strain [BCG], *Mycobacterium caprae*, *Mycobacterium pinnipedii*, *Mycobacterium africanum*, *Mycobacterium microti*, and *Mycobacterium canettii* [Castets, 1968; van Soolingen, 1997; Pfyffer, 1998]) are the etiologic agents of human tuberculosis (TB). Worldwide, TB is the second greatest contributor among infectious diseases to adult mortality. The World Health Organization estimates that in 2007, about 10 million cases of TB and nearly 2 million deaths from TB were reported (www.who.int/topics/tuberculosis/en). That year, India ranked first in the number of incident cases, followed by China, Indonesia, Nigeria, and South Africa. Among new cases of TB, approximately 5% (or 500,000) worldwide are due to multidrug-resistant organisms (MDR-TB), defined as tubercle bacilli that are resistant to rifampin and isoniazid. MDR-TB does not respond to the standard 6-month treatment regimen and may require up to 2 years of treatment with drugs that are more toxic than first-line agents and about 100 times more costly. Mismanagement of drugs used to treat MDR-TB can result in extensively drug-resistant tuberculosis (XDR-TB), defined as MDR-TB plus resistance to any fluoroquinolone and any second-line injectable antituberculosis agent (e.g., amikacin, kanamycin, capreomycin).

In the United States, TB was the leading cause of death at the turn of the 20th century. Mortality then decreased, initially because of public health efforts and later because of antituberculous drugs. Between 1953, when TB became notifiable on a national basis, and 1984, the incidence of TB steadily decreased (Rieder, 1989). From 1985 to 1992, a resurgence of TB cases was seen, in large part because of the epidemic spread of human immunodeficiency virus (HIV), deterioration of the health care infrastructure, and an increase in the number of cases reported among foreign-born persons. In addition to the resurgence, MDR-TB emerged and remains a concern, although to a much lesser degree than in developing countries.

Since 1992, the incidence of TB in the United States has declined each year, and MDR-TB has become uncommon. TB rates are highest among foreign-born persons and those in racial/ethnic minorities. In 2008, the TB rate in the United States was ten times higher in foreign-born persons than in those born in the United States, and compared with non-Hispanic whites, TB rates were about eight times higher among Hispanics and blacks and nearly 23 times higher among Asians (Centers for Disease Control and Prevention, 2009c).

Mycobacteria are aerobic, nonmotile, acid alcohol-fast, slightly curved or straight bacilli. The organisms contain high molecular weight (60–90 carbons) mycolic acids in their cell walls that on pyrolysis release C22 to C26 straight-chain saturated long-chain acids. Their guanine plus cytosine DNA-base content ratios are in the range of 62–70 mol%. Mycobacteria can be divided into two groups: those in the *Mycobacterium tuberculosis* complex and nontuberculous mycobacteria.

Tubercle bacilli are transmitted primarily via inhalation of dried residues of small infected droplets (1–10 µm in diameter). Infection also may be acquired by direct inoculation of abraded skin—an event most likely to occur when pathologists or other laboratory personnel handle infected tissues. In addition, *M. bovis* may be transmitted from cattle to humans by drinking contaminated raw milk or by respiratory exposure to live infected cattle or their carcasses, from humans to cattle via exposure to urine from persons with urinary tract infections due to *M. bovis*, and from cattle and wild reservoirs to cattle probably by respiratory secretions.

The most important source of infection is an undiagnosed person with cavitory (and sputum smear–positive) pulmonary disease. The risk of active pulmonary disease is low after one exposure to the organism but increases under conditions of stress or in a confined environment where repeated exposures to the organism occur. Most persons who become infected with *M. tuberculosis* do not develop active disease. The lifetime risk of active disease is 5%–10% for immunocompetent persons. For persons infected with both *M. tuberculosis* and HIV, in contrast, the risk of developing tuberculosis is 7%–10% per year.

Based on analysis of its genomic sequence, *M. tuberculosis* does not appear to encode typical bacterial virulence factors (e.g., toxins). However, certain genes and gene products have been identified as key factors enabling *M. tuberculosis* to cause disease. PhoP has been shown to have an important role in virulence, because *phoP* mutants grow very poorly in macrophages and in mice (Ryndak, 2008). Lipids called phthiocerol dimycocerosates, which are found at the outermost layers of the cell envelope, are required for optimal multiplication and persistence of *M. tuberculosis* in mice lungs, and phenolic glycolipids are thought to be involved in the hypervirulence of certain *M. tuberculosis* strains (Gordon, 2009). In addition, the ESX secretion systems, which are specialized secretion systems present in many gram-positive bacteria, are important in pathogenesis, because mutants lacking the system or its substrates are attenuated in cultured macrophages and animal models of infection. Mutants with a deletion spanning much of the ESX-1 locus demonstrate defective cell-to-cell spread, altered cytokine profiles, and failure to inhibit phagolysosome fusion in cultured cells (Tobin, 2008).

The usual host response to infection with MTBC is activation of the cell-mediated immune system. During primary (initial) infection, inhaled bacilli travel to the alveolar spaces, where they are ingested by resident macrophages. These macrophages are unable to kill the tubercle bacilli, which multiply intracellularly during the first several days after infection. Macrophages infected with mycobacteria migrate to regional tracheobronchial lymph nodes and present sensitizing antigen(s) to immunocompetent T cells, or they enter the lymphatics and blood and travel back to the lungs (primarily the apices) and to distant organs such as lymph nodes, kidneys, epiphyseal areas of the long bones, vertebral bodies, and meninges, where bacilli continue to multiply until the cellular immune response is activated.

Immunocompetent T cells migrate from regional lymph nodes to the site of infection in the lung. There they release chemotactic, migration-inhibitory, and mitogenic cytokines, which stimulate recruitment of blood-derived monocytes and lymphocytes, macrophage and lymphocyte division, and macrophage activation. Activated macrophages have enhanced microbicidal activity, and they produce cytokines such as interleukin-1, interferon-γ, and tumor necrosis factor, which stimulate or regulate other components of the immune system, properties that help control infection. The cytokines and lytic enzymes released by the macrophages also contribute to concomitant local tissue destruction. Over time, the activated T cell population declines and is replaced by long-lived memory immune T cells, which protect against reinfection with MTBC and provide some cross-protection against infection with other mycobacteria. Despite the limitation of further mycobacterial multiplication in primary and metastatic foci by the activated macrophages and memory T cells, a residual nidus of infection remains indefinitely in the lung (most frequently in the apex, where the oxygen tension is high) and less often in distant sites. Therefore, the potential for reactivation of disease in these quiescent foci exists during periods of immunosuppression.

The primary focus of pulmonary infection, called the Gohn lesion, is usually subjacent to the pleura in the lower part of the upper lobes or in the upper part of the lower lobes of one lung, corresponding to areas of the lung that receive the greatest volume flow of inspired air. Lesions (tubercles) are well-circumscribed, 1–2-cm-diameter areas of grayish white consolidation with soft to necrotic centers. Similar-appearing tubercles typically are found in the regional tracheobronchial lymph nodes, and these plus the primary lung lesion are termed the Gohn complex. Microscopically, tubercles are composed of well-circumscribed caseating or

noncaseating granulomas; organisms may be seen in sections stained with an acid-fast stain. Over time, these lesions are replaced by hyalinized fibrous tissue and eventually calcify. Lesions of miliary tuberculosis are small (one to several millimeters in diameter), distinct, yellow-white areas of consolidation without gross caseation that histologically resemble tubercles. The ability to form granulomas depends on the immunocompetence of the host. Individuals infected with HIV, for example, may have extensive necrosis, many neutrophils, microabscesses, and numerous acid-fast bacilli (AFB), without granulomas.

In the United States, pulmonary TB accounts for about 85% of cases of active disease. Manifestations of pulmonary disease vary. The clinical presentation may be insidious with gradual onset of constitutional symptoms over months; catarrhal, with productive cough often attributed to a bad cold or lingering bronchitis; pneumonia- or flu-like, with high fever, aches and pains, and cough; hemoptoic with acute onset of blood-streaked sputum; or pleuritic. Extrapulmonary TB may be localized but more commonly involves multiple organs with or without concurrent lung infection. Multiorgan TB occurs predominantly in infants and young children, the elderly, and immunocompromised individuals, especially those infected with both HIV and MTBC. Additionally, most infections with *M. bovis* in the United States are extrapulmonary, involving lymph nodes, the gastrointestinal tract, bones, and kidneys, and most commonly occur in children of Hispanic ethnicity (Hlavsa, 2008; Rodwell, 2008). Infrequently, infection follows intravesical instillation of *M. bovis* BCG for treatment of superficial bladder carcinoma (Lamm, 1992; Kristjansson, 1993).

NONTUBERCULOUS MYCOBACTERIA

The nontuberculous mycobacteria (NTM; also called mycobacteria other than tubercle bacilli) may be categorized on the basis of colony pigmentation before and after exposure to light and growth rate on a solid medium as described by Runyon in 1957 (Table 60-1) (Runyon, 1959). This classification system, however, has limits. For example, *M. kansasii* is usually a photochromogen but rarely is nonchromogenic or scotochromogenic. Members of the *M. avium* complex are nonchromogenic in Runyon's scheme, but some isolates produce slightly pigmented colonies after prolonged incubation, potentially causing incorrect classification as a scotochromogen. *Mycobacterium szulgai* is a scotochromogen at 37° C and a photochromogen at 25° C. Moreover, when a liquid medium is used for mycobacterial culture, as is currently recommended (discussed in the section regarding culture methods), growth rates used by Runyon for classification do not apply. *Mycobacterium leprae* is unique among mycobacteria by virtue of the fact that it has not yet been cultivated in vitro.

In general, little is known about the antigens associated with virulence of the NTM, and the immune response to infection with these mycobacteria is poorly understood. With current molecular techniques, more than 100 species of NTM have been identified. Select potential pathogens are reviewed in the following sections. An extensive description of the more recently described and infrequently isolated mycobacteria is found in the excellent review by Tortoli (2003). *Mycobacterium gordonae*, often referred to as the “tap water bacillus,” is a common laboratory contaminant and rarely causes disease in humans.

MYCOBACTERIUM AVIUM COMPLEX

The primary pathogens in the *M. avium* complex (MAC) are *M. avium* and *Mycobacterium intracellulare*. These species have such similar growth characteristics and biochemical reactions that they often are not distinguished in the clinical microbiology laboratory; isolates of both species are reported as MAC. MAC bacilli are ubiquitous in the environment. They have been isolated from water, soil, food, house dust, and several animals, but the specific environmental sources responsible for human infection are

TABLE 60-1

Runyon's Classification of the Nontuberculous Mycobacteria

Classification	Description of colonies
Photochromogen	Not pigmented unless exposed to light (optimally during their early growth and with good aeration of the surface)
Scotochromogen	Pigmented when grown in the dark and in light
Nonchromogen	Not pigmented when grown in the dark or in light
Rapid grower	Growth on solid media in ≤7 days

not known (Inderlied, 1993; Falkinham, 1996). The most likely portal of entry is the gastrointestinal tract, but transmission via the respiratory tract is also possible. From sites of colonization, organisms enter the blood and infect many organs, especially those of the monocyte-macrophage system. In many clinical microbiology laboratories in the United States today, MAC is the most frequently isolated mycobacterium.

For many years, pulmonary disease caused by MAC occurred most often in elderly white men who had underlying chronic lung disease or who had undergone gastrectomy; however, since the mid to late 1980s, it has become more common in persons without predisposing factors, especially older women (Prince, 1989; Dhillon, 2000; Griffith, 2007). Disseminated MAC occurs almost exclusively in immunosuppressed individuals, especially persons with advanced acquired immunodeficiency syndrome (AIDS). In the United States, MAC was the most common cause of systemic bacterial infection in patients with AIDS in the late 1980s and early 1990s (Horsburg, 1991a). The numbers of such cases, however, decreased since highly active antiretroviral therapy became widely available (Centers for Disease Control and Prevention, 2009a). The major risk factor for disseminated MAC in AIDS patients is the degree of immune dysfunction, indicated by the CD4⁺ lymphocyte count, as the disease is rare in individuals whose CD4⁺ lymphocyte count is over 50/μL.

Manifestations of disease caused by MAC depend on the site and the extent of infection. Pulmonary disease may present as bronchiectasis or may mimic TB. Disseminated disease in persons without AIDS is manifested by fever, weight loss, bone pain, lymphadenopathy, hepatosplenomegaly, and skin lesions. In those with AIDS, persistent fever, weight loss, and diarrhea are most common; anorexia, weakness, lymphadenopathy, or hepatomegaly also may occur (Inderlied, 1993; Griffith, 2007; Centers for Disease Control and Prevention, 2009a). Significant laboratory abnormalities include anemia and elevated alkaline phosphatase. Cervical lymphadenitis caused by MAC most often affects children but also occurs in adults. Other manifestations of infection with MAC are synovitis, genitourinary tract disease, cutaneous lesions, deep infection of the hand, osteomyelitis, meningitis, ulcer of the colon, and pericarditis (Wolinsky, 1979; Woods, 1987; Inderlied, 1993).

The histologic findings of lesions caused by MAC vary. Caseating granulomas with AFB, indistinguishable from TB; pulmonary interstitial fibrosis with organizing pneumonia; necrotizing granulomatous vasculitis resembling Wegener's granulomatosis; and, especially in persons with AIDS, aggregates of foamy macrophages containing many intracellular AFB may be seen.

MYCOBACTERIUM KANSASII

M. kansasii, first described as the "yellow bacillus," accounted for 3% of mycobacterial isolates in the United States in 1979 and 1980; the highest numbers of cases were reported from California, Texas, Louisiana, Illinois, and Florida (Buhler, 1953; Good, 1982). The natural reservoir of *M. kansasii* is unknown; however, it has been recovered from water samples (Falkinham, 1996). Pulmonary disease is most common in males 50–60 years of age living in urban areas, among certain occupational groups (miners, welders, sandblasters, and painters), and among individuals with pneumoconioses and chronic obstructive pulmonary disease. Disseminated disease generally affects persons with impaired cellular immunity.

The most common manifestation of disease caused by *M. kansasii* is chronic cavitary pulmonary lesions, usually involving the upper lobes (Griffith, 2007). Extrapulmonary manifestations include cervical lymphadenitis in children, cutaneous disease, musculoskeletal involvement (carpal tunnel syndrome, synovitis, arthritis, tendinitis and fasciitis, or osteomyelitis), disseminated disease, isolated genitourinary tract disease, and pericarditis. Histologic findings of lesions caused by *M. kansasii* vary and include caseating or noncaseating granulomas and, especially in skin lesions, necrosis or foci of acute and chronic inflammation without well-formed granulomas. AFB are common in lung and lymph node tissue but are seen less frequently in tissue from other sites.

MYCOBACTERIUM XENOPI

M. xenopi was first isolated from a toad in 1957 and was recognized as a human pathogen in 1965 (Costrini, 1981). It has been cultured from hot and cold water taps, hospital hot water generators and storage tanks, and other environmental sources. Birds are a possible natural reservoir. Most pulmonary infections caused by *M. xenopi* have been reported from Canada, Europe, and Great Britain; it is an uncommon cause of mycobacterial disease in the United States. Disease has occurred only in adults, more

frequently in males than in females. Most persons have preexisting lung damage or another predisposing condition, such as an extrapulmonary malignancy, alcoholism, diabetes mellitus, or immunosuppressive therapy. Pulmonary disease may be chronic, subacute, or acute; symptoms are indistinguishable from those associated with disease caused by *M. kansasii*. Focal extrapulmonary infections (osteomyelitis, arthritis, lymphadenitis) and disseminated disease are uncommon, but the latter has been reported in persons with AIDS (Tecson-Tumang, 1984).

MYCOBACTERIUM GENAVENSE

M. genavense was first isolated in 1991 in Switzerland from the blood of a patient with AIDS (Bootger, 1991). Conditions for detection in the laboratory were described shortly thereafter (Coyle, 1992). Disease occurs predominantly in immunocompromised patients. The most common presentation is disseminated disease in HIV-infected patients, which clinically is very similar to disseminated MAC (Maschek, 1994; Tortoli, 1998; Griffith, 2007). Other manifestations include enteritis, genital and soft tissue infections, and lymphadenitis.

MYCOBACTERIUM MARINUM

M. marinum was recognized as a human pathogen in 1951 (Norden, 1951). It causes chronic granulomatous infections involving skin and soft tissue, often called "swimming pool granuloma" or "fish tank granuloma," and occasionally bone (Lewis, 2003; Aubry, 2002; Griffith, 2007). Human infection is typically acquired via trauma to the skin during contact with contaminated nonchlorinated fresh or salt water, but it may be acquired via trauma unassociated with water contact or contact with water in the absence of preceding trauma. A single papulonodular lesion usually appears 2–3 weeks after inoculation, most commonly on the elbow, knee, foot, toe, or finger, and often becomes verrucous or ulcerated (Ang, 2000). Occasionally, an abscess forms at the site of inoculation, and several secondary nodules develop and progress centrally along the lymphatics, resembling sporotrichosis. In immunocompromised persons, cutaneous lesions may become disseminated. Extracutaneous manifestations are uncommon: Synovitis, osteomyelitis, and ocular and laryngeal lesions have been reported (Woods, 1987).

The histology of skin lesions varies with the stage of infection. Early on, neutrophil aggregates are surrounded by histiocytes. Later, lymphocytes, epithelioid histiocytes, occasional Langhans giant cells, and foci of fibrinoid necrosis are seen. In lesions present for longer than 6 months, aggregates of lymphocytes are found in the dermis. Stains for AFB are usually negative, but organisms may be seen within histiocytes.

MYCOBACTERIUM HAEMOPHILUM

M. haemophilum was first described in 1978 but very probably was the nonculturable AFB recognized in skin ulcers in 1972 and 1974 (Lomwardias, 1972; Feldman, 1974; Sompolinsky, 1978). The organism is unique among mycobacteria in its growth requirement for hemoglobin or hemin. Human infections caused by *M. haemophilum* are uncommon, usually seen in persons who have an underlying immunodeficiency such as lymphoma, exogenous immunosuppression after organ transplantation, or AIDS, but lymphadenitis in otherwise healthy children has been reported (Centers for Disease Control and Prevention, 1991; Lindeboom, 2005). Disease most commonly is manifested by multiple cutaneous nodules, ulcers, or painful swellings, typically involving the extremities, which occasionally become abscesses and open fistulas draining purulent material. Microscopically, lesions show foci of necrosis without caseation surrounded by a polymorphous inflammatory infiltrate with occasional Langhans giant cells in the lower dermis. AFB are seen singly or in small clusters, often within cells.

MYCOBACTERIUM ULCERANS

M. ulcerans is endemic in areas of Zaire, Uganda, Nigeria, Ghana, Cameroon, Malaysia, New Guinea, Guyana, Mexico, and Australia located between latitudes 25° N and 38° S. In all endemic areas, disease is more frequent among children younger than 15 years and is slightly more common in males (Debacker, 2004; Piersimoni, 2009). The natural reservoir of *M. ulcerans* and the usual route of its transmission to humans remain unknown.

Eponyms for disease caused by *M. ulcerans* include Bairnsdale ulcer, for the area in Australia where it was first recognized, and Buruli ulcer or

Buruli disease, after the area of Uganda reporting the greatest number of cases (Amofah, 2002). The disease begins as one or, rarely, multiple painless boils or subcutaneous lumps on an exposed area, most often the leg, which possibly was a site of previous trauma. After several weeks, the lump ulcerates, and satellite nodules and ulcers may appear. Lymph nodes typically are not enlarged, and affected individuals are afebrile and without systemic symptoms unless lesions become secondarily infected with bacteria.

RAPIDLY GROWING MYCOBACTERIA

Rapidly growing mycobacteria have been cultured from soil, freshwater lakes and rivers, seawater, waste water from hospitals, drinking water, raw milk, and dust. Of the many species of rapidly growing mycobacteria, the most common human pathogens are *M. abscessus*, *M. chelonae*, and the *M. fortuitum* group; other species associated with human disease are *Mycobacterium mucogenicum*, *Mycobacterium immunogenum*, *Mycobacterium goodii*, *Mycobacterium mageritense*, *Mycobacterium neoaurum*, *Mycobacterium peregrinum*, *Mycobacterium wolinskyi*, and, rarely, *Mycobacterium smegmatis* (Brown-Elliott, 2002; Griffith, 2007).

The most common manifestation of disease due to rapidly growing mycobacteria is skin and soft tissue infection, typically following a penetrating injury (trauma or surgical procedure) with possible soil or water contamination, although outbreaks have been associated with administration of diphtheria-pertussis-tetanus-polio vaccines, histamine injections, lidocaine administration using a jet injector, use of foot baths in nail salons, and liposuction (Wallace, 1983; Brown-Elliott, 2002; Piersimoni, 2009). Primary cutaneous/subcutaneous disease may present as localized cellulitis, draining abscesses, or minimally tender nodules, generally appearing 3 weeks to 12 months (most often 4–6 weeks) after the penetrating injury in persons with an intact immune system. Osteomyelitis is an occasional complication, especially following puncture wounds to the feet. Postoperative infections are characterized by a nonhealing wound or breakdown of a healed wound with serous drainage in a person with minimal systemic symptoms. They generally develop 3 weeks to 3 months after the procedure, especially median sternotomy, augmentation mammoplasty, or insertion of a percutaneous catheter. Disseminated skin and soft tissue abscesses in which no primary source of infection is evident typically occur in immunocompromised adults, especially those receiving corticosteroid therapy.

A less common manifestation of infection with rapidly growing mycobacteria is chronic pulmonary disease. It is most often seen in patients with underlying cystic fibrosis or bronchiectasis, is usually caused by *M. abscessus*, and typically resembles disease due to *M. kansasii* or MAC, except that cavitation is uncommon. Endocarditis involving a prosthetic valve has been reported, usually becoming manifest 4–12 weeks after surgery. Rarely, rapidly growing mycobacteria cause keratitis and corneal ulceration after trauma, or cervical lymphadenitis. A very thorough description of disease caused by rapidly growing mycobacteria is found in the excellent review by Brown-Elliott and Wallace (2002).

Lesions caused by rapidly growing mycobacteria are characterized histologically by necrosis with minimal caseation and a mixed inflammatory infiltrate composed of neutrophils and granulomas with foreign body or Langhans giant cells; lipid-laden macrophages are seen occasionally. Clumps of extracellular AFB are found within aggregates of neutrophils in less than a third of cases. In lung tissue, foamy macrophages may be seen in a pattern resembling lipid pneumonia.

MYCOBACTERIUM LEPRAE

M. leprae is the etiologic agent of leprosy, also called Hansen's disease (Scollard, 2006). It is unique among the mycobacteria by virtue of the fact that it has not been cultivated. Useful animal models of infection are the mouse footpad model and the nine-banded armadillo. *M. leprae* has been recognized in nearly every part of the world at some time. The reported number of new cases registered each year remains between 500,000 and 700,000 (Lockwood, 2005).

Leprosy predominantly affects humans but is also a natural infection of wild armadillos in Louisiana, Arkansas, and Texas, and spontaneous cases have been described in mangabey monkeys (Hastings, 1988). The mechanism of transmission of *M. leprae* is unknown, but person-to-person spread via aerosolization of organisms from the nose of a person with active lepromatous disease (see later), which then contacts the nasal mucosa of another individual, is the favored theory. Transmission also may occur through intact skin or via penetrating wounds, such as thorns or the bite of an arthropod. Breast milk from lactating women with lepromatous

disease contains bacilli that may be transmitted to infants, and transplacental transmission of *M. leprae* is possible. Cases of human leprosy following contact with armadillos have been reported (Lumpkin, 1983). Moreover, the discovery of a naturally occurring leprosy-like disease among armadillos and the fact that sporadic cases of leprosy occur in persons who have no known contact with human leprosy suggest that nonhuman sources of *M. leprae* may exist (Blake, 1987).

Most persons effectively resist infection with *M. leprae*. Resistance depends on an effective cell-mediated immune response to *M. leprae* antigens, as occurs in tuberculoid leprosy. In persons who lack specific cell-mediated immunity to these antigens, bacilli multiply within macrophages, eventually resulting in widely disseminated lepromatous leprosy. The defect in cellular immunity, which may involve T lymphocyte function or interaction of T lymphocytes with macrophages, is apparently specific for antigens to *M. leprae* rather than a generalized defect. The lesions of leprosy develop after a 2–5-year incubation period, varying in appearance depending on the host's immune response. Leprosy always involves peripheral nerves, almost always involves the skin, and frequently involves mucous membranes. The three cardinal signs of the disease are skin lesions, areas of cutaneous anesthesia, and enlarged peripheral nerves.

The system outlined by Ridley and Jopling (presented in the following section) is still used to classify the spectrum of clinical and histopathologic forms of leprosy (Ridley, 1964). Indeterminate leprosy, the earliest sign of disease, is characterized by one or a few hypopigmented skin macules with minimal local sensory loss. In about 75% of cases, the disease heals spontaneously; in the rest, it progresses, often after a prolonged period.

The polar types of leprosy—lepromatous leprosy, the widespread anergic form of the disease, and tuberculoid leprosy, the localized form—are stable clinically. Lepromatous leprosy is characterized by cutaneous lesions ranging from diffuse generalized skin involvement to widespread, symmetrically distributed nodules (called lepromas) filled with organisms. Lesions generally involve the cooler parts of the body surface, that is, the anterior third of the eye, the nasal mucosa, and the superficial peripheral nerve trunks. In advanced disease, lesions are accompanied by sensory loss from involvement of dermal nerve fibers. Microscopically, lesions show foamy histiocytes containing many AFB; few or no lymphocytes; minimal intraneural inflammation; and many AFB in nerves, the perineurium, blood vessel walls, and arrector muscles. In tuberculoid leprosy, one or a few well-circumscribed anesthetic macules or plaques develop, often accompanied by an enlarged peripheral nerve near the skin lesions. Histologically, lesions demonstrate noncaseating granulomas in the nerves and dermis, extending to involve the basal layer of the epidermis; few, if any, AFB are present. Borderline leprosy, a clinically unstable condition, encompasses the types of disease between the polar forms. It may develop features more closely resembling tuberculoid disease through a process termed upgrading, or features more like those of lepromatous disease, called downgrading.

TESTING FOR LATENT M. TUBERCULOSIS INFECTION

The tuberculin skin test is useful for identifying persons infected with MTBC but does not differentiate active disease from infection. Persons infected with MTBC develop a hypersensitivity reaction to proteins of the bacilli, which make up the skin test reagent purified protein derivative (PPD). The preferred method of skin testing is the Mantoux test, performed by intracutaneous injection of 0.1 mL of intermediate-strength (5 tuberculin units) PPD-S. The reaction is interpreted after 48–72 hours by measuring the diameter of induration in millimeters (Huebner, 1993). Induration of 5 mm or greater is considered positive in persons infected with HIV, those who have had recent close contact with someone who has infectious TB, and those who have chest radiograph findings consistent with old healed TB. A reaction of 10 mm or greater is positive in persons who do not meet the previous criteria but who have other risk factors for TB. Included in this group are foreign-born persons from countries where the prevalence of TB is high (such as Asia, Africa, or Latin America); injection drug users; medically underserved, low-income populations, especially racial or ethnic minorities; residents of long-term care facilities; and persons who have a medical condition associated with increased risk of TB (e.g., silicosis, gastrectomy, jejunoileal bypass, 10% or more below ideal body weight, chronic renal failure, diabetes mellitus, treatment with high-dose corticosteroids or with other immunosuppressive drugs, malignancies). A reaction of 15 mm or greater is positive in all other persons. Interpretation is difficult in those immunized with BCG.

False-positive PPD reactions may occur in persons with NTM infection and in those immunized with BCG. False-negative reactions may be due to poor technique or improper storage of the reagent. If the test is administered appropriately, false-negative reactions are uncommon in relatively healthy people but occur in up to 20% of individuals with known TB when they are first tested. Most of these false-negative reactions are attributed to the general illness and revert to positive after 2–3 weeks of therapy when health is restored. Factors causing a state of general anergy, such as protein malnutrition, concurrent viral infection, sarcoidosis, malignancy (especially lymphoma), immunosuppressive or corticosteroid therapy, and infection with HIV, also may cause a false-negative tuberculin reaction.

The Mantoux test generally remains positive as long as viable bacilli persist in quiescent foci. However, the reaction may wane below positive with increasing age, a phenomenon that occurs most frequently in those over age 55 years. In these individuals, the reaction will be boosted (or become positive) if retesting is performed as early as 1 week after the first test, a reaction termed the booster effect.

Interferon- γ release assays (IGRAs) became commercially available in the early 21st century (Madkumar, 2008; Lalvani, 2009). These are in vitro tests that are based on the detection of interferon- γ released by T cells in response to *M. tuberculosis* proteins (ESAT-6, CFP-10, TB7.7) not present in *M. bovis* BCG or most NTM (except *M. kansasii*, *M. szulgai*, and *M. marinum*). Performance of IGRAs requires collection of blood during a single visit, and results are available within 24 hours. According to experts at the Centers for Disease Control and Prevention (CDC), IGRAs can be used in all circumstances in which the skin test is used, including contact investigations, evaluation of recent immigrants, and screening health care workers for latent MTBC infection (Centers for Disease Control and Prevention, 2005). Advantages of IGRAs over the tuberculin skin test include improved sensitivity in immunosuppressed persons (although false-negative results occur) and children, and much better specificity in persons who have been vaccinated with BCG (Mori, 2009; Ruhwald, 2009).

LABORATORY DIAGNOSIS

SPECIMENS

Specimens recommended for diagnosis of mycobacterial infection are listed in Table 60-2. Samples from contaminated sites such as sputum and other respiratory secretions, gastric secretions, urine, and feces must be decontaminated prior to inoculation of media to prevent normal flora from overgrowing and thus masking the presence of mycobacteria, which grow more slowly. Concentrating the specimen after decontamination increases

the sensitivity of smear and culture. Specimens from normally sterile body sites such as blood, cerebrospinal fluid (CSF), pleural and peritoneal fluid, and tissues may be inoculated directly without decontamination.

Processing and inoculation of specimens for mycobacterial culture should be performed in a biological safety cabinet. The *N*-acetyl-L-cysteine (NALC)–sodium hydroxide procedure (Fig. 60-1) is the most common method used in the clinical laboratory to liquefy, decontaminate, and concentrate specimens for detection of mycobacteria. Potentially contaminated specimens should be refrigerated if they cannot be processed immediately. Before proceeding to the steps outlined in Figure 60-1, additional handling is necessary for some specimens. Gastric lavage specimens should be processed immediately, but if a delay cannot be avoided, 10% sodium hydroxide should be added until the pH of the sample is neutral. If more than 10 mL of gastric secretions is collected, the sample is centrifuged at 3000 to 3600 *g* for 20–30 minutes, the supernatant is decanted, and the sediment is processed as shown in Figure 60-1. For feces, 1–2 g of a formed sample or 5 mL of a liquid specimen is placed in a 50-mL centrifuge tube, and sterile filtered distilled water is added to obtain a volume of 10 mL. The suspension is agitated on a vortex mixer, filtered through gauze, and then processed as outlined. Urine specimens are divided into two to four 50-mL centrifuge tubes and are centrifuged at 3000 to 3600 *g* for 30 minutes. The supernatant is decanted, leaving about 2 mL of sediment in each tube. Tubes are mixed on a vortex mixer, sediments are combined, and, if necessary, distilled water is added to obtain a volume of 10 mL, which then is decontaminated as shown in Figure 60-1.

MICROBIAL STAINS

In smears stained with the Gram stain, most mycobacteria appear as slender, poorly stained, beaded gram-positive bacilli, but sometimes the bacilli do not take up the crystal violet or safranin and appear “gram neutral” or as “Gram ghosts” (Fig. 60-2). Similar ghost images of bacilli may be found in macrophages in smears stained with the Wright or Papanicolaou stain. In general, specimens (except blood) collected from persons with suspected mycobacterial infection should be examined microscopically for organisms. However, to improve cost efficiency, many laboratories do not prepare smears of specimens in which AFB rarely are seen, such as CSF, urine, and bone marrow. To prepare a smear, two to three drops of the concentrated sediment are spread uniformly on a microscope slide, which then is fixed for 15 minutes at 80° C or for 1–2 hours at 65°–70° C on an electric hot plate.

Two types of stain detect AFB: carbol fuchsin (the classic Ziehl-Neelsen stain, which requires heating, and the cold Kinyoun stain) and the preferred fluorochrome stains (auramine-rhodamine and auramine-O), which

TABLE 60-2

Mycobacterial Diseases and Specimens for Diagnosis

Disease	Common <i>Mycobacterium</i> species	Specimens
Pneumonia	MTBC, <i>M. kansasii</i> , MAC, <i>M. abscessus</i>	Sputum (early morning, deep cough on 3 consecutive days), BAL fluid, lung tissue, pleural fluid, gastric contents
Disseminated	MTBC, MAC	Blood, bone marrow, involved tissue
Lymphadenitis	MTBC, MAC	Lymph node aspirate or biopsy
Skin, soft tissue	<i>M. fortuitum</i> , <i>M. abscessus</i> , <i>M. chelonae</i> , <i>M. marinum</i> , <i>M. haemophilum</i> , <i>M. ulcerans</i> <i>M. leprae</i>	Aspirate or biopsy of lesion
Musculoskeletal	MTBC, <i>M. fortuitum</i> , <i>M. abscessus</i> , <i>M. chelonae</i> , <i>M. marinum</i> , <i>M. kansasii</i>	Smears of nasal secretions and skin slits, biopsy of lesion Joint fluid, synovium, bone
Meningitis	MTBC	Cerebrospinal fluid
Brain abscess	MTBC	Abscess material
Genitourinary	<i>M. tuberculosis</i> , <i>M. bovis</i> BCG	Urine (early morning), involved tissue—kidney, bladder (<i>M. bovis</i> BCG), endometrium, fallopian tube, prostate, seminal vesicles, epididymis
Gastrointestinal	<i>M. tuberculosis</i> , <i>M. bovis</i> , MAC	Tissue, feces
Peritonitis	MTBC	Peritoneal biopsy, peritoneal fluid
Hepatitis	MTBC, MAC, <i>M. genavense</i>	Liver tissue
Pericarditis	MTBC	Pericardium, pericardial tissue
Catheter-related infection	Rapidly growing mycobacteria	Blood

are more sensitive. Smears stained with a carbol fuchsin stain are examined at 800–1000× magnification (oil immersion). Smears stained with a fluoro-chrome stain are examined at lower magnifications (250× and 400×); this allows visualization of more fields in less time. Cells of some rapidly growing mycobacteria stain poorly with fluoro-chromic stains and may not be detected; therefore, when the latter organisms are suspected pathogens (e.g., in postsurgical wound infection), restaining negative fluorescent smears with a carbol fuchsin stain is reasonable. Results are reported after 100 fields are viewed and should include a statement indicating whether the smear was prepared directly from the specimen or after decontamination and concentration. Guidelines for reporting results of smears stained for AFB are shown in Table 60-3 (Kent, 1985).

In smears stained with carbol fuchsin, AFB typically appear as purple to red, slightly curved rods (1–10 μm long and 0.2–0.6 μm wide), which

AFB, Acid-fast bacilli; F, field; sweep, scanning full length of a smear.

Figure 60-3 Smear of a sputum specimen shows acid-fast bacilli (*Mycobacterium tuberculosis*; Kinyoun, ×400).

Figure 60-4 Smear of an aspirate from an enlarged cervical lymph node shows a large, cross-barred, acid-fast bacillus (*Mycobacterium kansasii*; Kinyoun, ×400). (Courtesy Vicki J. Schnadig, MD, Department of Pathology, University of Texas Medical Branch, Galveston, Tex.)

often are beaded or banded (Fig. 60-3) but may also appear coccoid or filamentous. In general, the appearance of AFB does not provide species identification; however, cells of certain species have features that may be useful diagnostically. The formation of “cords” in smears of broth cultures is typical (but not diagnostic) of MTBC. Cells of *M. kansasii* often appear as cross-barred bacilli (Fig. 60-4), larger than *M. tuberculosis* and resembling a “shepherd’s crook.” Cells of MAC are typically pleomorphic and occasionally coccobacillary and stain positively with the periodic acid–Schiff stain. Cells of *M. marinum* are typically longer and broader than those of *M. tuberculosis* and often show cross-banding. Cells of *M. leprae* stain weaker than those of most other mycobacteria.

TABLE 60-4

Colony Morphology and Growth Characteristics of Mycobacteria Commonly Isolated in the Clinical Laboratory

<i>Mycobacterium</i> species	Colony morphology	Pigment	Growth rate, weeks	Comments
Slowly Growing Mycobacteria				
<i>M. tuberculosis</i>	Rough	N (buff)	3–6	Generally niacin and nitrate positive
<i>M. bovis</i>	Rough; thin or transparent on LJ	N (colorless to buff)	4–6	Generally niacin and nitrate negative; resistant to pyrazinamide
MAC	Smooth; small, thin, transparent or large, opaque, domed; \pm rough	N	3–6	Colonies of some isolates become lightly pigmented with prolonged incubation; grows at 42° C
<i>M. kansasii</i>	Rough, \pm smooth, β -carotene crystals	P	3–6	Rare strains are N or S
<i>M. goodii</i>	Smooth	S	3–6	Common laboratory contaminant; rare strains are N
<i>M. marinum</i>	Wrinkled, shiny; smooth, hemispherical; (rarely) rough, dry	P	2	Optimal growth, 30°–33° C
<i>M. xenopi</i>	Smooth, filamentous extensions (“bird’s nest”)	S	3–6	Growth at 42° C
<i>M. haemophilum</i>	Rough, \pm smooth	N	3–6	Optimal growth, 20°–32° C; requires hemin for growth
<i>M. szulgai</i>	Smooth or rough	S, 37° C; P, 25° C	3–6	
Rapidly Growing Mycobacteria				
<i>M. abscessus</i>	Smooth; \pm rough, wrinkled	N	<1	Branching filaments often are present on periphery of colonies
<i>M. fortuitum</i> group	Wrinkled	N	<1	
<i>M. chelonae</i>	Smooth	N	<1	

MAC, *M. avium* complex; N, nonchromogenic; P, photochromogenic; S, scotochromogenic.

The specificity of stains for AFB typically is 99% or more, and the sensitivity is about 25% to about 75% (Strumpf, 1979; Murray, 1980; Rickman, 1980). False-positive results (positive stain, negative culture) may be caused by nonviable organisms, such as might occur in patients receiving antituberculosis therapy; prolonged decontamination, killing mycobacteria as well as contaminating bacteria; or cross-contamination during the staining procedure. Factors that influence the sensitivity of smear results include (1) patient population (persons with cavitory lesions are more likely than those without cavities to have a smear-positive sputum), (2) specimen type (respiratory specimens are more likely than other specimen types to be positive), (3) the number of specimens examined, (4) the number of AFB present in the sample (5000–10,000 organisms/mL of specimen are needed for a positive result), (5) the species present (specimens containing *M. tuberculosis* or *M. kansasii* are more likely to be positive than are those that contain other mycobacteria), (6) observer experience, and (7) the stain used. Fluorochromic stains are more sensitive and are easier to read than carbol fuchsin stains, and they are recommended by experts at the CDC (Tenover, 1993). The CDC also suggests that for respiratory specimens, results of stained smears should be reported within 24 hours of specimen receipt, which means processing 7 days a week.

CULTURE METHODS

For optimal recovery of mycobacteria from clinical specimens, inoculation of both a broth and a solid medium is recommended (Tenover, 1993), because broth is more sensitive than solid media and provides more rapid detection of mycobacterial growth (Anargyros, 1990; Stager, 1991; Abe, 1992). However, use of a broth system alone may be considered if data show that adding a solid medium does not enhance recovery of mycobacterial pathogens. Broth systems currently available are the BACTEC 460TB radiometric system (BD Biosciences, Franklin Lakes, N.J.), BBL Mycobacteria Growth Indicator Tubes (MGIT; BD Biosciences), VersaTrek (previously called ESP Culture System II; Trek Diagnostic Systems, Cleveland), and BacT/Alert MB (bioMérieux, Marcy l’Etoile, France).

Two types of solid medium are used for mycobacterial culture: egg-based (Löwenstein-Jensen) and agar-based (Middlebrook 7H10, 7H11, and selective 7H11). These media are available in screw-cap tubes and flasks; agar-based media also are available in Petri dishes. Flasks are preferred to screw-cap tubes for safety reasons and because they provide a larger surface area for mycobacterial growth. Specimens from cutaneous lesions should be inoculated to one egg- or agar-based medium, and to ensure recovery of *M. haemophilum* (see later), they also should be plated on chocolate agar, 5% sheep blood Columbia agar, Mueller-Hinton agar

with Fildes supplement, or Löwenstein-Jensen containing 2% ferric ammonium citrate. To recover *M. genavense* (from specimens or subcultures of liquid to solid media), solid media must be supplemented with mycobactin J. All cultures should be incubated at 37° C in an atmosphere of 5%–10% carbon dioxide (CO₂), and tubed media should be incubated in a slanted position with caps loose for at least 1 week to ensure even distribution of the inoculum over the surface. For specimens from cutaneous sites, a second set of cultures should be inoculated and incubated at 30° C, because some mycobacteria that cause skin lesions—*M. marinum*, *M. haemophilum*, *M. chelonae*, and *M. ulcerans*—grow optimally at the lower temperature. All cultures should be examined weekly for at least 6 weeks.

The major advantage of culture on solid media is that it allows visualization of colony morphology and pigmentation, which is useful diagnostically, especially for distinguishing colonies of *M. tuberculosis* from those of some NTM. The colony appearance and growth characteristics of commonly encountered mycobacteria are outlined in Table 60-4. Disadvantages of conventional solid media include prolonged time to growth of mycobacteria (colonies often are not visible on tubed solid media for 3–4 weeks or longer) and low sensitivity. Inoculation of Middlebrook agar plates, which then are examined under the microscope, allows more rapid detection of colonies (Welch, 1993), but this procedure is labor intensive, thus prohibiting its use in many clinical laboratories.

The semiautomated radiometric BACTEC TB460 was the first commercial broth-based method for growth and detection of mycobacteria, but in most laboratories has been replaced by one of the fully automated, nonradiometric broth systems. The BACTEC TB460 uses broth media (13A for blood, 12B for all other specimen types) that contain ¹⁴C-labeled palmitic acid substrate. Each specimen is inoculated into one vial, and an antibiotic mixture is added to specimens other than blood. Vials are incubated in ambient air at 37° C for 5–6 weeks. To ensure recovery of *M. genavense*, blood cultures (especially those collected from patients with AIDS) should be incubated for 8–10 weeks. Bacilli multiply in the broth and utilize the labeled substrate, releasing ¹⁴CO₂ into the head space above the broth. Bottles are manually loaded onto the BACTEC TB460, which measures the amount of ¹⁴CO₂ and calculates a growth index (GI). A GI greater than 10 suggests that mycobacteria are present, and when the GI reaches 50–100, a smear of the broth is stained for AFB. Vials containing AFB are subcultured to a solid medium, and direct tests for identification (discussed in the following section) may be performed. For positive mycobacterial blood cultures from patients with AIDS, subculture to Middlebrook 7H11 agar containing mycobactin J should be done to allow recovery of *M. genavense* if initial subcultures from the broth show no growth, or

the positive broth should be sent to a reference laboratory prepared to do the appropriate tests.

The MGIT consists of 4 mL of modified 7H9 broth and a fluorescent indicator embedded in silicone in the bottom of a 16 × 100-mm glass tube. Tubes are inoculated with the specimen, an antibiotic mixture to inhibit growth of contaminating bacteria and a mycobacterial growth enrichment are added, and the tubes are capped and incubated at 37° C for up to 8 weeks. To detect mycobacterial growth, tubes are manually placed on top of a 365-nm ultraviolet transilluminator or in front of a Wood's lamp. The appearance of strong fluorescence in the sensor (a bright orange color on the bottom of the tube and meniscus) indicates growth. Alternatively, tubes may be incubated in the totally automated BACTEC 960 instrument, which continuously monitors tubes for fluorescence and signals those that are positive. MGIT is as sensitive as the BACTEC TB460 for recovery of mycobacteria, but the mean time to detection of growth is a few days longer with MGIT (Cornfield, 1997; Pfyffer, 1997b; Hanna, 1999).

In addition to the BACTEC MGIT 960, three other fully automated continuously monitoring systems for growth and detection of mycobacteria are commercially available: the BACTEC 9000MB system (BD Biosciences) (Pfyffer, 1997a; Zanetti, 1997), the MB/BacT system (Organon Teknika, Durham, N.C.) (Rohner, 1997; Brunello, 1999), and the Versa-Trek (Trek Diagnostic Systems) (Tholcken, 1997; Woods, 1997). With each system, bottles are incubated in the respective instrument, where they are monitored for changes in production or production and consumption of various gases, indicating growth of mycobacteria or other organisms. In general, these systems perform comparably with the BACTEC TB460 and offer the advantages of being fully automated, and thus less labor intensive, and nonradiometric.

TESTS FOR IDENTIFICATION OF MYCOBACTERIA

Identification of mycobacteria has traditionally been based on rate of growth on solid media, colony morphology, colony pigmentation with and without exposure to light, and results of biochemical tests (described in detail elsewhere [Kent, 1985]). Biochemical test results, however, are not usually available for several weeks to months after colonies appear on solid media, and for identification of MTBC especially, more rapid methods are recommended (Tenover, 1993). Additionally, biochemical testing frequently does not provide unequivocal identification at the species level.

Currently, the most rapid method for diagnosis of pulmonary tuberculosis is the use of a nucleic acid amplification test for direct detection of MTBC in clinical specimens (Piersimoni, 2003). These tests, however, do not differentiate the species in the MTBC. Two nucleic acid amplification tests are available worldwide for testing respiratory specimens: amplified *Mycobacterium tuberculosis* Direct Test (Gen-Probe, Inc., San Diego) and AMPLICOR *Mycobacterium tuberculosis* Test (Roche Diagnostic Systems, Inc., Branchburg, N.J.). The BDProbeTec ET System (BD Biosciences) is available outside the United States only. The AMPLICOR assay has been cleared by the Food and Drug Administration (FDA) for testing AFB smear-positive respiratory specimens only. The Gen-Probe test is approved for testing smear-positive and smear-negative respiratory specimens. Data

suggest that nucleic acid amplification tests may be useful in AFB smear-negative patients at high risk for tuberculosis (e.g., persons infected with HIV, incarcerated persons in correctional facilities), allowing more rapid diagnosis and earlier initiation of treatment (Gamboa, 1998; Bergmann, 1999). The sensitivity of nucleic acid amplification tests is generally slightly lower for nonrespiratory specimens, but they may be useful for diagnosis of some cases of extrapulmonary tuberculosis, especially when the AFB smear is positive. In 2009, the CDC updated its guidelines for use of nucleic acid amplification tests for diagnosis of pulmonary TB, recommending that it should be performed on at least one respiratory specimen from each patient with consistent signs and symptoms for whom a diagnosis of TB is being considered but has not yet been established, and for whom the test result would alter management or TB control activities (CDC, 2009b).

Chemiluminescent DNA probes allow identification of a few species or a species complex of mycobacteria within 1–2 hours after sufficient growth is present (on solid or in a liquid medium) (Evans, 1992; Goto, 1992; Lebrun, 1992; Reisner, 1994). Commercial probes specific for MTBC, MAC, *M. avium*, *M. intracellulare*, *M. goodii*, and *M. kansasii* are currently available. Testing requires minimal equipment (i.e., luminometer, sonicator, and heating block). Disadvantages of the probes include failure to identify some isolates of MAC, especially when testing growth from a liquid medium; false-positive results with the MAC probe when testing aliquots of broth cultures (Cloud, 2005); and rare false-positive results with the MTBC probe (Bull, 1992; Lebrun, 1992; Butler, 1994).

High-performance liquid chromatography allows identification of mycobacterial colonies on a solid medium or growth in a liquid medium in 2–4 hours. The most accurate identification method is sequencing, most commonly of the hypervariable regions of the 16S ribosomal RNA gene (Patel, 2000; Cloud, 2002; Hall, 2003). Molecular typing methods, such as spoligotyping (spacer oligotyping), are useful for identifying members of the MTBC to the species level (Mostowy, 2004). These techniques, which are technically complex and require expensive equipment, are performed predominantly in research and large reference laboratories.

SUSCEPTIBILITY TESTING

Susceptibility testing of mycobacteria should be performed according to guidelines of the Clinical and Laboratory Standards Institute (CLSI; in press). Primary and secondary drugs that should be tested are listed in Table 60-5.

For MTBC, the initial isolate from every patient should be tested to all primary drugs. Testing should be repeated if specimens remain culture positive after 3 months of appropriate therapy, or earlier if there is clinical evidence of treatment failure. Testing may be performed on isolated colonies or a positive broth culture (indirect test) or on sputum specimens that are AFB smear positive (direct test). Agar proportion is the standard method of testing susceptibility of MTBC to antituberculosis agents. With this method, isolates showing greater than 1% resistance to a single concentration of drug are considered resistant to that drug. However, because the target turnaround time for results is an average of 28 days after specimens are received in the laboratory, use of an FDA-approved liquid-based

TABLE 60-5

Drugs Recommended for Susceptibility Testing of *Mycobacteria*

<i>Mycobacterium</i> species	Indication	Drugs
MTBC	Primary	Isoniazid, rifampin, ethambutol, pyrazinamide
	Secondary	Capreomycin, ethionamide, ethambutol (higher concentration), amikacin, kanamycin, levofloxacin, ofloxacin, isoniazid (higher concentration), <i>p</i> -aminosalicylic acid, rifabutin, streptomycin
MAC	Primary	Clarithromycin
	Secondary	Moxifloxacin, linezolid
<i>M. kansasii</i>	Primary	Rifampin
	Secondary	Amikacin, ciprofloxacin, clarithromycin, ethambutol, isoniazid, moxifloxacin, rifabutin, streptomycin, trimethoprim-sulfamethoxazole
<i>M. marinum</i>	Primary	Amikacin, ciprofloxacin, clarithromycin, doxycycline, moxifloxacin, rifabutin, trimethoprim-sulfamethoxazole
Rapidly growing mycobacteria	Primary	Amikacin, cefoxitin, ciprofloxacin, clarithromycin, doxycycline, imipenem, linezolid, meropenem, moxifloxacin, tobramycin, trimethoprim-sulfamethoxazole

MAC, *M. avium* complex; MTBC, *M. tuberculosis* complex.

system that provides results equivalent to those of agar proportion is recommended (Tenover, 1993; CLSI, in press). With currently available liquid-based systems, results are generally available 5–7 days after bottles are inoculated with the MTBC isolate (Bergmann 1998, 2000; Scarparo, 2004). Susceptibility to all secondary drugs should be tested when an isolate is resistant to rifampin alone or any two of the primary agents. Isolates resistant only to the critical concentration of isoniazid also should be tested for susceptibility to secondary agents if the planned treatment regimen will include a fluoroquinolone.

Because early detection and appropriate treatment of MDR- and XDR-TB are so important to cure of the disease and prevention of transmission, various molecular methods for rapid detection of mutations known to be associated with drug resistance have been developed, including real-time polymerase chain reaction (PCR) and commercial PCR/line probe assays (Lin, 2004; Morgan, 2005; Bang, 2006). Use of a molecular test to detect drug resistance directly in an AFB smear-positive specimen may be considered in a patient who meets one or more of the following criteria: history of prior treatment for TB, coming from a country or ethnic group known to have increased drug resistance, failure to respond to standard therapy, and known exposure to MDR-TB.

Susceptibility testing of NTM may be performed on clinically significant isolates (Griffith, 2007); however, for some species, little correlation may be noted between susceptibility test results and clinical response to drug therapy. The method recommended by CLSI for susceptibility testing of rapidly and slowly growing NTM is broth microdilution (Woods, 1999; CLSI, in press). Media, incubation times and temperatures, and guidelines for interpretation of results are beyond the scope of this chapter but are described in detail in the most recent edition of CLSI M24 (CLSI, in press). In general, both the minimum inhibitory concentration (MIC) and the interpretation (susceptible, intermediate, resistant) should be reported.

TREATMENT

The chemotherapeutic regimen currently recommended for treatment of TB (Table 60-6) should be initiated before susceptibility test results are available, but treatment should be altered based on those results if an isolate is found to be resistant. Medications should be administered by directly observed therapy. Regimens commonly used to treat infections caused by the most frequently encountered NTM also are listed in Table 60-6 (Griffith, 2007). For many NTM, however, neither the optimal regimen nor the duration of therapy is known.

TABLE 60-6

Antimicrobial Agents Recommended for Primary Treatment of Common Mycobacterial Infections

Mycobacterium species	Site of infection	Antimicrobial agents
MTBC	Any	Isoniazid, rifampin, ethambutol, pyrazinamide
MAC	Pulmonary	Clarithromycin,* rifampin, and ethambutol
	Disseminated	Clarithromycin* and ethambutol ± rifabutin
	Lymphadenitis†	None
<i>M. kansasii</i>	Pulmonary	Isoniazid, rifampin, ethambutol
<i>M. abscessus</i> , <i>chelonae</i> , <i>fortuitum</i> ‡	Nonpulmonary	Clarithromycin (if susceptible) and one or more additional agents§
<i>M. abscessus</i> ¶	Pulmonary	Multidrug regimen,§ including clarithromycin
<i>M. marinum</i>	Skin/soft tissue	Clarithromycin, doxycycline/minocycline, trimethoprim-sulfamethoxazole, or rifampin and ethambutol

MAC, *M. avium* complex; MTBC, *M. tuberculosis* complex.

*Or azithromycin.

†Recommended management is surgery.

‡Surgical debridement often is necessary.

§Agent(s) selected should be based on results of susceptibility testing.

¶Currently, there are no drug regimens with proven efficacy, although antimicrobial therapy may provide symptomatic improvement and disease regression. If disease is limited, surgical resection plus multidrug therapy is optimal.

PREVENTION

MYCOBACTERIUM TUBERCULOSIS COMPLEX

Four general strategies for controlling TB are described. The most important is early identification and adequate treatment of persons with infectious TB. This measure renders the infected person noncontagious within a few weeks and eventually results in cure. The second strategy entails identification and treatment of individuals with noncontagious TB: extrapulmonary disease, primary pulmonary disease in children, bacteriologically unconfirmed pulmonary disease, and infection with *M. tuberculosis* not yet causing disease (i.e., positive skin test or interferon- γ release assay, normal chest radiograph, no symptoms).

The third strategy involves creation of a safe environment in situations where the risk of transmitting infection is high: autopsy suites, sputum induction cubicles, chest clinic waiting areas, correctional facilities, some shelters for the homeless, and mycobacteriology laboratories. To accomplish this, several issues must be addressed (Segal-Maurer, 1994). Rooms housing infectious patients or in which potentially infectious specimens are handled should be under negative pressure, and air likely to be contaminated with infectious droplet nuclei should be exhausted to the outside. A single-pass ventilation system (best accomplished by locating air supply outlets at the ceiling level and exhaust inlets near the floor) and a minimum of six air changes per hour (12 exchanges per hour for autopsy suites) are recommended. Universal precautions must be followed when handling all specimens, and both specimens and cultures must be handled in a certified, class II biological safety cabinet. Moreover, a particulate respirator that filters out particles 1–5 μ m in diameter should be worn, and personnel should be trained in a respiratory program; the standard surgical mask is not adequate.

The fourth strategy is vaccination with the BCG vaccine, an attenuated vaccine derived from a strain of *M. bovis* by Calmette and Guérin in France. This vaccine is used in many foreign countries where the prevalence of TB is high, to prevent TB meningitis and miliary TB in children, but generally is not recommended in the United States, because the risk of infection with MTBC is low and the effectiveness of the vaccine in adults is variable. In the United States, the BCG vaccine should be considered after consulting with a TB expert only for infants and children who have a negative tuberculin skin test and who are continuously exposed and cannot be separated from adults who are untreated or ineffectively treated for TB or have MDR-TB (www.cdc.gov/tb). The BCG vaccine is not routinely recommended for health care workers in the United States but should be considered on an individual basis in the following settings: a high percentage of TB patients have MDR-TB, transmission of MDR-TB to health care workers and subsequent infection is likely, and comprehensive TB control measures have been implemented but have not been successful.

The BCG vaccine should not be given to immunocompromised persons, persons likely to become immunocompromised, or pregnant women. Disseminated *M. bovis* in patients with AIDS and *M. bovis* lymphadenitis in symptomatic HIV-infected infants have occurred following BCG vaccination (Centers for Disease Control and Prevention, 1985; Blanche, 1986). However, disseminated *M. bovis* has not been reported in asymptomatic persons infected with HIV. In populations where the risk of tuberculosis is high, the World Health Organization recommends that the BCG vaccine be given to HIV-infected children at birth or soon thereafter. It should not be given to children with symptomatic HIV infection, to populations in which the risk of tuberculosis is low, or to persons known or suspected to be infected with HIV (World Health Organization, 1987).

MYCOBACTERIUM AVIUM COMPLEX

Disseminated MAC in patients with AIDS is associated with considerable morbidity and a shortened duration of survival (Horsburgh, 1991b; Nightingale, 1992); therefore, prevention of the disease is desirable. Because MAC is ubiquitous in the environment, the most reasonable approach to prevention is chemoprophylaxis. Currently, the U.S. Public Health Service and the Infectious Diseases Society of America recommend clarithromycin or azithromycin prophylaxis in AIDS patients with CD4⁺ cell counts lower than 50/ μ L (Centers for Disease Control and Prevention, 2009a). If neither of these drugs can be tolerated, rifabutin is an alternative prophylactic agent. Primary prophylaxis should be discontinued in patients who have responded to antiretroviral therapy with an increase in CD4⁺ count of >100 cells/ μ L for at least 3 months.

PROTOTHECOSIS, 1186**SELECTED REFERENCES, 1187****KEY POINTS**

- Opportunistic fungal pathogens have emerged as common causes of invasive disease in the compromised host.
- Histopathologic examination of deep tissue is a major means used for the rapid detection and recognition of fungal pathogens causing invasive infection.
- Micromorphologic and phenotypic methods continue to be the general processes used in the clinical laboratory for the identification of fungal pathogens in culture.
- Molecular methods have advanced as techniques used for the confirmed identification of fungal pathogens from culture and are evolving as future methods for the rapid identification of fungal pathogens directly in clinical material.

- Candida albicans* continues to be the most common fungal species associated with human disease; however, non-*albicans* *Candida* species are becoming more widespread in causing invasive disease with increased resistance to standard antifungal treatments.
- Dimorphic fungal pathogens are frequent causes of mild infection in people living in endemic areas; however, invasive disease, whether recurrent or primary, is becoming more common owing to the increase in immunocompromised hosts.
- Recent introduction of new antifungal agents and progression of resistance among moulds and yeast have added importance to the development and standardization of antifungal susceptibility testing.

Medical mycology is the science devoted to the study of fungi and their relationship to human disease. This scientific discipline encompasses single-celled yeasts and filamentous moulds as agents of disease ranging from superficial skin infection (cutaneous mycosis) to disseminated deep-seated visceral disease (systemic mycosis). Fungal agents include the historically pathogenic fungi (true pathogens), as well as the saprophytic fungi elevated to the status of pathogen by modern therapies and diseases (opportunistic pathogens). Modern therapies such as high-dose chemotherapy to treat cancer and solid organ transplantation, as well as immunosuppressive infection such as acquired immunodeficiency syndrome (AIDS), have served as the impetus to allow fungi to emerge as major causes of human disease (Chayakulkeeree, 2006; Pfaller, 2007; Sanchez, 2007; Chang, 2008; Marr, 2008; Richardson, 2008; Varkey, 2008).

Although medical mycology education for the medical profession in general has been lacking, pathologists who have been nurtured in the surgical pathology suite have acquired a general understanding of the recognition of fungal pathogens (Steinbach, 2003a). Overall, the general lack of education in this area is troublesome because most fungi are identified by skilled human observation rather than by machines.

The goal of this chapter is to present the fundamentals of medical mycology with an emphasis on practical issues and a description of those fungal pathogens encountered regularly in the laboratory. For a comprehensive atlas of the histopathology of fungal infections, refer to the book by Chandler and Watts (1987a). Additionally, although not included in the fungal kingdom, infections caused by achlorophyllous algae are also discussed in this chapter because the characteristics of the algae and the diseases they produce resemble fungi more than other infectious agents.

Because this chapter reports specifically on fungal mycoses, other types of fungal diseases are not discussed. Reviews of these other diseases are available and include the topics of noninvasive allergic responses to fungi (Thakar, 2004; Schubert, 2009), poisoning by the ingestion of poisonous fungi (mushroom poisoning or mycetismus) (Diaz, 2005a, 2005b), and intoxication by ingestion of fungal toxins (mycotoxicosis) (Etelz, 2002).

NOMENCLATURE, TAXONOMY, AND FUNGAL MORPHOLOGY

OVERVIEW

The first hurdle for the beginning mycologist consists of nomenclature and its handmaiden, taxonomy. Members of the fungal kingdom (Eumycota) are eukaryotic cells that have the capability to reproduce by both sexual and asexual methods. They are classified into phyla by the nature of their sexual reproductive structures or lack thereof (Hibbett, 2007). Fungi that have recognized sexual reproductive structures (perfect fungi) are classified into the phylum Zygomycota, Ascomycota, or Basidiomycota based on the type of sexual reproductive structure produced. Fungi that lack recognized sexual reproductive structures are classified in the phylum Deuteromycota, also called the imperfect fungi, on the basis of their asexual reproductive structures. The application of new molecular techniques in fungal identification has caused changes within the classification of fungi. For example, genomic studies now suggest that the phylum Zygomycota is polyphyletic, and that a new classification for this group should be considered (James, 2006). Much work is ongoing in the area of fungal taxonomics, and changes in fungal nomenclature will continue to occur.

To complicate the naming and taxonomic positioning of fungi, many species have both asexual (anamorphic) and sexual (teleomorphic) phases. Within the Deuteromycota, once the sexual phase becomes recognized, the organism is reclassified into one of the other phyla and now becomes a named teleomorph. In practice, however, the old familiar name of the anamorph is usually retained. For example, few people know *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Cryptococcus neoformans* by their respective teleomorphic names *Ajellomyces capsulatus*, *Ajellomyces dermatitidis*, and *Filobasidiella neoformans*, respectively. In contrast, the sexual phase *Pseudallescheria boydii* and the corresponding asexual phase *Scedosporium apiospermum* are both recognized species names used in common practice. Generally, the anamorphic name, as in this case *S. apiospermum*, is used to describe a fungal species in the laboratory, although many exceptions to this rule exist.

Much of fungal taxonomy is related to structural details because both classification and laboratory identification are heavily dependent on morphology. A glossary of important terms used in medical mycology is displayed in Table 61-1 on the next page. In this chapter, a simplified

Figure 61-1 Filamentous extensions from the periphery of colonies of *Candida albicans* are known colloquially as “feet.”

Figure 61-2 Powdery surface of the colonies of *Aspergillus fumigatus* overlies white masses of mycelium. Adjacent bacterial colonies contrast with the filamentous fungus. (Sheep blood agar.)

conceptual approach will be used to recognize the pathogens most commonly encountered in the clinical laboratory. For practical purposes, a few general characteristics shown in Table 61-2 serve as the basis for identification of fungi in the laboratory.

THE FUNGAL COLONY

Two morphologic forms of fungi are recognized and include yeasts and moulds. Yeasts are unicellular organisms that usually reproduce asexually by blastoconidia (also called budding) to produce a daughter cell. The colonial mass of yeast is a collection of distinct individual organisms that macroscopically resemble bacterial colonies on the surface of the agar. Yeast colonies usually are smooth with a regular edge. When the colonies become heaped and dull, they may resemble those of staphylococci. Yeast produces catalase, so the incautious microbiologist who does not perform a Gram stain or a wet preparation may mistake a yeast colony for a bacterium and provide a misleading report. The microscopic presence of “budding yeast” with or without pseudohyphae would be adequate to identify the colony as yeast. Furthermore, the pseudohyphae of yeast are often visible macroscopically as filamentous extensions from the edges of the colony, known colloquially as “feet” (Fig. 61-1).

In contrast to yeasts, moulds are described as filamentous fungi that are multicellular in structure. Although the term **mold** is used to describe this morphologic type, the term **mould** is historically recognized and more commonly used by mycologists to describe this morphologic form. The filamentous nature of the mould gives colonies a woolly, fluffy, or velvety appearance, sometimes punctuated with a granular or powdery aspect that is produced by the formation of asexual reproductive structures (Fig. 61-2). At other times, the colony may have a glabrous (smooth) appearance.

TABLE 61-1

Glossary of Terms Commonly Used in Medical Mycology

Term	Definition
Aerial mycelium	Hyphae produced above the surface of the agar media
Anamorph	Asexual form of fungal sporulation (imperfect state)
Arthroconidium	Conidium derived from the fragmentation of specialized hyphae
Ascocarp (ascoma)	Fruiting structure that contains asci (several types exist)
Ascospore	Sexual spore formed within an ascus following meiosis
Ascus (pl., asci)	Sac-like structure that contains ascospores, characteristic of Ascomycetes
Basidiospore	Sexual spore formed as on an outgrowth of a basidium
Basidium	Structure that contains basidiospores (e.g., mushroom)
Blastoconidium	Asexual spore formed by budding of the yeast cell
Chlamydospore	Thick-walled resting or survival structure (also called chlamydoconidia)
Cleistothecium (pl., cleistothecia)	Enclosed ascocarp, composed of layers of hyphae that contain randomly dispersed asci
Collarette	Funnel-shaped structure at the apex of a phialide
Columella	An extension of the sporangiophore into the base of the sporangium
Conidiogenous cell	Cell that produces conidia
Conidiophore	Specialized hyphal structure that carries the conidia
Conidium (pl., conidia)	Asexual reproductive structure formed in any manner that does not involve cleavage
Dematiaceae	Pigmented in dark color
Dimorphic	Displaying two morphologic types, one environmental (mould) and one in vivo (yeast)
Glabrous	Smooth, referring to colonial morphology
Heterothallic	Sexual reproduction requiring the interaction of two different thalli (mating strains)
Holomorph	Whole fungus; the anamorphic plus the teleomorphic state of the fungus
Homothallic	Sexual reproduction can take place within one thallus
Hyaline	Colorless or transparent
Hypha (pl., hyphae)	Vegetative unit of a mould
Intercalary	Borne within a hypha
Macroconidium	Larger of two types of conidia produced by a mould
Microconidium	Smaller of two types of conidia produced by a mould
Mould	Filamentous fungus that reproduces by sexual or asexual means
Mycelium	Mass of hyphae that make up the thallus of a mould
Perithecium	Enclosed ascocarp with a pore at the top through which the ascospores are discharged
Phialide	Cell with opening through which conidia are produced
Pseudohyphae	Connected yeast cells (blastoconidia) that resemble a hypha but contain areas of constriction between adjacent cells
Sclerotium (pl., sclerotia)	Multi-cellular clump of cells that does not produce any spores or conidia (also called sclerotic body)
Septum (pl., septa)	Cross-wall in a hypha
Sporangiophore	Stalk bearing the sporangium
Sporangiospore	Asexual spore produced within a sporangium
Sporangium	Sac-like structure in which the asexual sporangiospores develop
Sterigmata	Slender outgrowth of a cell bearing conidia
Teleomorph	Sexual form of a fungal sporulation (perfect state)
Terminal	Borne at the end of a hypha
Thallus (pl., thalli)	Vegetative growth of a fungus; includes an interwoven mass of hyphae
Thermophilic	Fungi that grow at a high temperature
Vegetative mycelium	Hyphae produced on the surface or extending into the agar media
Vesicle	Enlarged or swollen cell, often at the end of a conidiophore or sporangiophore, which may also be within hyphae
Yeast	Single-cell fungus that reproduces by budding or by fission

The distinction between moulds and yeasts is not firmly established. Some yeasts also develop a visually macroscopic filamentous component. For instance, *Trichosporon* spp. are yeasts that develop such filamentous extensions, whereas *Exophiala jeanselmei* is a dematiaceous yeast that develops a mycelium as it matures. The ultimate in fence-sitting is exemplified by the dimorphic fungi, which exhibit a mould form under some conditions and a yeast or yeast-like form in other circumstances. Clinically important dimorphic fungi are systemic pathogens that behave as moulds in the environment and on agar media at 25°–30° C. In contrast, the tissue form may be a yeast (such as *Blastomyces dermatitidis*, *Histoplasma capsulatum*, and *Sporothrix schenckii*) or, in the cases of *Coccidioides immitis* and *Coccidioides posadasii*, a yeast-like structure called a spherule. When cultivated in vitro at 37° C on appropriate media, the tissue form is reproduced by these fungi. Other agents also exhibit dimorphism but are less common in the clinical laboratory. For instance, black moulds such as *Fonsecaea pedrosi* and *Phialophora verrucosa* produce nonhyphal cells in tissue called

sclerotic bodies but appear as moulds when grown on solid media at room temperature. Reverse dimorphism is exemplified by *Malassezia furfur*, which produces both yeast cells and hyphae in the cutaneous lesions of patients with pityriasis versicolor.

STRUCTURE OF YEASTS AND HYPHAE

The morphology of the fungus is an important characteristic for the identification of both yeasts and moulds. The filamentous structure of a mould is referred to as hyphae (singular, *hypha*), and a mass of hyphae is known as a mycelium. The mycelium growing on the surface of or within the agar is known as the vegetative mycelium, whereas filamentous extensions above the colony are called aerial mycelium. True hyphae may have cross-walls that contain pores for communication through the hyphae or cross-walls that are complete, dividing the hyphae into multiple cells. Hyphae that have cross-walls are called septate, whereas those without cross-walls

TABLE 61-2
Characteristics Useful for the Identification of Fungi

Characteristic	Examples
Type of macroscopic growth	Colonies of unicellular organisms (yeast) Colonies of filamentous organisms (moulds)
Morphology of yeast	Budding Budding with pseudohyphae Round yeast with capsules Budding yeast with collarettes
Morphology of filamentous structures	True septate hyphae True nonseptate hyphae (or sparsely septate)
Pigment of hyphae	Hyaline (lightly pigmented or nonpigmented) Dematiaceous (darkly pigmented)
Morphology of asexual reproductive structures	Conidia Spores
Morphology of sexual reproductive structures	Ascospores Cleistothecia Perithecia
Growth rate	Slow (>10 days) Medium (4–10 days) Fast (<4 days)
Inhibition by cycloheximide	Many saprophytic fungi
Optimal growth temperature	25°–30° C 35°–37° C 40°–42° C 50°–58° C
Biochemical tests	Assimilation Fermentation Enzymatic degradation (e.g., urease) Growth enhancement
Conversion from mould to yeast phase	Supplanted by DNA probe tests in most laboratories
Immunologic detection of antigens or antibodies	<i>Cryptococcus</i> , <i>Histoplasma</i> , <i>Coccidioides</i> , <i>Blastomyces</i> , <i>Aspergillus</i>
DNA probe	<i>Histoplasma</i> , <i>Coccidioides</i> , <i>Blastomyces</i>

DNA, Deoxyribonucleic acid.

are referred to as aseptate. Some fungi that have septate hyphae also have aseptate or septate specialized hyphae (conidiophores) that bear asexual reproductive structures. Conversely, some so-called nonseptate fungi have occasional cross-walls and perhaps would be better designated as sparsely septate.

The width of the hyphae and the angle of branching are important clues to fungal identity. Zygomycetes, such as *Rhizopus* spp., have broad, ribbon-like hyphae that branch predominantly at right angles (Fig. 61-3), whereas hyaline moulds such as *Aspergillus* spp. have narrow hyphae that branch at acute angles (dichotomous branching) (Fig. 61-4). The designation of a fungus as *Aspergillus* on the basis of hyphal morphology in a smear or tissue section is, in truth, only a statement of the a priori odds for this pathogen group. Describing the characteristics of the hyphae is a better approach to reporting this observation.

Yeasts reproduce asexually by the formation of blastoconidia, where the daughter cell usually appears at one end of a yeast cell and eventually enlarges to form a new yeast cell. This process is also referred to in a more generic sense as **budding**. If a series of daughter cells do not detach fully from the originating cells, a pseudohypha (plural, *pseudohyphae*) is produced. Pseudohyphae are distinguished from true hyphae by the presence of a constriction at the junction of adjacent cells and by the restriction in size of the daughter cell to that of the parent (Fig. 61-5). In contrast, the walls of true hyphae are parallel without constrictions. *C. albicans* and some strains of *Candida tropicalis* may produce pseudohyphae that have the appearance of true hyphae, depending on growth conditions, and differentiation of *Candida* from hyaline moulds such as *Aspergillus* in tissue sections on occasion may be problematic. In contradistinction, *Cryptococcus*

Figure 61-3 Characteristic wide, nonseptate hypha of a Zygomycete in lung tissue. (Gomori's methenamine silver stain, ×400.)

Figure 61-4 Characteristic narrow branching, septate hyphae of a hyaline mould in tissue. (Gomori's methenamine silver stain, ×400.)

Figure 61-5 Chains of elongated budding yeasts of *Candida albicans* producing pseudohyphae observed in sputum. (Gram stain, ×1000.)

spp. produce only budding yeast and rarely rudimentary or primitive pseudohyphae, but true hyphae are not formed.

HYPHAL PIGMENT

Some mould hyphae can be characterized by the production of a dark pigment. The hyphae of dematiaceous fungi contain a melanin pigment that imparts a brown coloration to the hyphae in microscopic preparations and causes colonies of the fungi to appear dark green, brown, or black.

Figure 61-6 Sporangiophores of *Rhizopus* spp. supporting sporangia that contain sporangiospores. Rhizoids arise from the hyphae near the origin of the sporangiophores. (Lactophenol cotton blue stain, $\times 100$.)

Superimposed dyes in stained smears, wet preps, or histologic sections may partially obscure the color, which can be more obvious in unstained preparations. Those fungi that lack dark hyphal pigmentation are referred to as hyaline (clear or colorless). This term may not fully reflect the fungal species appearance, because in some cases a light pigmentation may produce colored colonies and asexual reproductive structures of some hyaline moulds may have green, brown, or black pigments that impart a color to the surface of the colony once the reproductive structures have formed. The true appearance of these moulds usually can be discerned by observing the back of the colony, which maintains a light coloration. In contrast, both the front (obverse) and the back (reverse) of dematiaceous colonies usually demonstrate the dark pigment.

REPRODUCTIVE STRUCTURES

The primary means for identification of mould fungi is by characterization of asexual reproductive structures. For yeast, phenotypic studies are the mainstay in identification, with asexual reproductive structures serving as ancillary clues in the identification process. The two principal asexual structures are spores (which may also be present as sexual structures) and conidia. Asexual spores (called sporangiospores) are produced by cleavage within an encompassing structure called a sporangium (Fig. 61-6). Conidia (singular, *conidium*) are much more diverse and form by differentiation from the tip or side of a fertile hypha, such as a conidiophore, or by hyphal differentiation. Unfortunately, interchangeable use of the terms conidium and spore in the literature has led to confusion. Sporulation and spores often are used as general terms for asexual reproduction, and the term spore is sometimes used when conidium would have been more accurate.

The principal means of asexual reproduction in yeast is by the formation of blastoconidia (i.e., budding). A bud starts as a softening of the cell wall of the mother cell, followed by expansion of the cell wall (blown out) and migration of nucleus and cytoplasm to the swollen area. A septum seals the boundary between daughter and parent cells (Fig. 61-7). If separation does not occur, a pseudohypha results.

The portions of the vegetative mycelium that differentiate into conidia are referred to as conidiogenous cells. Specialized hyphae that support the conidia are termed conidiophores, which may be the conidiogenous cell itself arising from the vegetative mycelium or may be a supporting hypha. In *Aspergillus* spp., the conidiophore, which is aseptate, enlarges at the tip to form a swollen vesicle (Fig. 61-8). Conidiogenous cells, now termed phialides, arise from the vesicle to support chains of conidia. Some species of *Aspergillus* produce a row of phialides, which occur on a row of sterile cells called metulae, with the conidia arising from the distal phialides. The Zygomycetes produce structures called sporangiophores, which support the sporangium with enclosed sporangiospores (see Fig. 61-6). An extension of the apex of the sporangiophore into the sporangium is termed the columella.

Thallic conidiogenesis is a process in which the conidium does not develop until a septum is formed between the conidium and the parent cell. The conidium originates from the whole of the parent cell. The most important human pathogens that exhibit thallic conidiogenesis are the dermatophytes and the dimorphic fungi in the *Coccidioides* spp. As

Figure 61-7 Budding and nonbudding yeast cells detected in a blood culture bottle sample. (Gram stain, $\times 1000$.)

Figure 61-8 Fruiting head of *Aspergillus fumigatus*. The conidiophore is swollen at the tip to form a vesicle, and phialides arise from the upper half of the vesicle with chains of conidia present that align parallel to the long axis of the conidiophore. (Lactophenol cotton blue stain, $\times 400$.)

Figure 61-9 Arthroconidia of *Coccidioides* species. Alternating barrel-shaped arthroconidia are separated by thin-walled, empty disjunct cells within portions of the hyphae. (Lactophenol cotton blue stain, $\times 400$.)

conidiogenesis progresses in these species, barrel-shaped conidia called arthroconidia are produced; these fragment easily and are disseminated with little difficulty, resulting in the high degree of infectivity demonstrated by these important human pathogens (Fig. 61-9). The thallic conidia of the dermatophytes are separated by size into two types: large septate macroconidia (Fig. 61-10) and small, one-celled microconidia that are simpler structures (Fig. 61-11).

Figure 61-10 Macroconidia of *Epidermophyton floccosum*. Typical blunt-ended macroconidia occur in aggregates along the hyphae with the absence of microconidia. (Lactophenol cotton blue stain, $\times 400$.)

Figure 61-11 Elongated macroconidia of *Trichophyton mentagrophytes* along with microconidia are lined up along the surface of the hypha. (Lactophenol cotton blue stain, $\times 400$.)

The other type of conidiogenesis is called blastic conidiogenesis, whereby the protoplasm of the conidiogenous cell is blown out or blasted to form the conidium. The simplest form of blastic conidiogenesis is the budding process by which many yeasts, including *Candida* spp., develop. As with thallic conidia, blastoconidia are divided into two types: one where the cell wall is involved in the process and the other where it is not. Further division of blastic conidiogenesis is made among those species in which the outer cell wall does not participate in the process (called enteroblastic conidiogenesis). In enteroblastic fungi, phialidic and annellidic conidiogenous cells have been recognized. Phialides are conidiogenous cells that often have a collarette at the apices, produced when the tip releases the first conidium. The collarette may be a conspicuous flask-shaped structure, as observed in *Phialophora* spp., or an inconspicuous structure, as seen in *Aspergillus* spp. In contrast, annellides are conidiogenous cells that rupture to leave a distinct ring of cellular material at the base of the conidium when it separates from the annellide. Formation of sequential conidia at the base pushes the oldest cell to the tip of the chain and leaves a series of rings or annellations at the apex of the annellide, providing a record of past events, like rings on a tree. Although important for the microscopic identification of some mould fungi, the fine details of these structures may be difficult to visualize using the light microscope.

Differentiation of the various conidial structures is the key to correct identification of many fungal isolates. In some cases, the pertinent morphologic features are easily discerned; however, as in surgical pathology, pattern recognition is an essential tool for identification of the most common pathogens and saprobes. The pathologist should always appreciate the salient features of the entire morphologic preparation without primarily focusing on outliers or aberrant structures. Developing conidial structures of *Aspergillus* or *Paecilomyces*, for instance, may resemble the

TABLE 61-3

Media for the Identification and Isolation of Fungi

Medium	Main function
Ascospore medium, V-8 agar	Ascospore development
Birdseed (niger) agar	Demonstration of melanin in <i>Cryptococcus neoformans</i>
Brain-heart infusion agar with blood	Enhanced recovery of dimorphic fungi
Christensen urea agar	Differentiation of <i>Trichophyton rubrum</i> and <i>T. mentagrophytes</i>
CHROMagar <i>Candida</i>	Chromogenic mixture to identify yeast species
Cornmeal agar with Tween 80	Visualization of yeast morphology
Czapek-Dox agar	Identification of <i>Aspergillus</i> species
Potato dextrose agar	Pigment development of <i>Trichophyton rubrum</i> and mould morphology
Sabouraud dextrose (SAB) agar	General purpose fungal growth medium (traditional formulation or Emmon's modification)
SAB agar with cycloheximide	Selective medium to inhibit saprophytic fungi (antibacterials such as chloramphenicol or gentamicin also included)
Slide culture (various agars)	Study of microscopic structure
<i>Trichophyton</i> agars	Differentiation of <i>Trichophyton</i> species

structures of *Penicillium*, and the observer must not be misled into thinking that two moulds are present. At the same time, the possibility of a mixed culture must be remembered. Mycologists must use a low-powered objective for initial observation from fungal culture; however, the details of cellular subsets in that low-powered picture must be appreciated for study at a higher magnification.

The fine art of mycologic diagnosis rests in the appreciation and differentiation of cellular details, and in some instances, the task requires great subtlety and considerable experience. Sometimes, the isolate must be coaxed to produce the necessary diagnostic structures by selection of appropriate media (Table 61-3). In general, enriched media favor the propagation of vegetative mycelium, whereas asexual reproductive structures are encouraged by basal (starving) media. Subculture onto water agar or potato flake agar is a general technique for encouraging the development of conidial structures. The colors of *Aspergillus* colonies are best studied on Czapek-Dox agar, whereas *Trichophyton rubrum* is encouraged to produce red pigment on potato dextrose agar or cornmeal agar with 1% glucose.

Experience also is important in determining whether a subculture has been incubated sufficiently long for diagnostic structures to form. Root-like structures (rhizoids) that develop from the hyphae of some Zygomycetes are important differentiating features, but they may not be detected if observation is terminated prematurely. Some of the techniques necessary for complete differentiation are difficult or even beyond the reach of most clinical laboratories. For instance, the dematiaceous pathogen *Exophiala (Wangiella) dermatitidis* produces blastic conidia with phialides and annellides. The presence of annellides was not recognized when the mould was studied with the light microscope, however, and this organism was once classified as *Phialophora dermatitidis*. Recognition that annellides were formed by the isolate led to a reassignment to a new genus, *Exophiala*, which contained both phialides and annellides. To add to the confusion, the genus *Wangiella* continues to be suggested for this species because the phialides do not reproduce obvious collarettes, which is the predominant feature of this genus. Subsequently, disagreement continues as to whether this species belongs in the genus *Exophiala* or in the genus *Wangiella* (McGinnis, 1999).

Sexual reproductive structures are of occasional value for fungal identification in the general mycology laboratory. Although they are infrequently encountered in vitro, recognition of sexual structures for heterothallic fungi requires that a compatible mating strain be available for testing. Homothallic fungi on the other hand, can produce sexual structures in culture without this mating process. The two structures most likely to be demonstrated in the laboratory from heterothallic species are the naked asci of *Saccharomyces cerevisiae* and the cleistothecium of *P. boydii*

Figure 61-12 Ascospores with asci (pale staining) along with budding yeast cells of *Saccharomyces cerevisiae*. (Gram stain, $\times 1000$.)

Figure 61-13 Cleistothecium of *Pseudallescheria boydii*. This sexual reproductive structure is specifically referred to as an ascus containing ascospores. (Lactophenol cotton blue stain, $\times 400$.)

(the sexual phase of *S. apiospermum*), *Aspergillus nidulans*, or the *Aspergillus glaucus* group of fungi. The naked asci of *Saccharomyces* resemble oval yeast cells in which one to four individual haploid ascospores are enclosed (Fig. 61-12). The ascospores in this species may be visualized in wet preparations but are detected more reliably using a Gram stain or an acid-fast stain. A cleistothecium is a sexual fruiting body (ascocarp) in which the ascospores are entirely enclosed and can be released only by rupture of the cleistothecial wall (Fig. 61-13). The wall is composed of single or multiple layers of specialized hyphae. A perithecium is a sexual structure similar to a cleistothecium, but it contains an opening at the apex of the pear-shaped structure.

Although asexual and rarely sexual reproductive structures are necessary for the identification of fungi, especially moulds, some isolates refuse to produce either of these structures for diagnosis. The colonies consist only of vegetative and aerial hyphae morphologically and subsequently are described as sterile hyphae or mycelia sterilia. Identification under this circumstance requires specialized molecular methods that are not available in most routine diagnostic laboratories (Iwen, 2003; Balajee, 2007b; Borman, 2008).

DIMORPHISM

Demonstration of dimorphism is the traditional approach to definitive identification of endemic fungal pathogens. In most laboratories, the initial isolate is the mould phase because culture plates usually are incubated at 25°–30° C. Conversion to the tissue phase (yeast or yeast-like structure) is accomplished by incubating a subculture at 37° C. The transition from

mould to yeast morphology may occur grudgingly, and hyphal forms are often intermixed with yeast cells. Some isolates may never be successfully converted. A rich medium, such as brain-heart infusion agar with a blood supplement, should be included with the primary isolation medium, particularly when *H. capsulatum* is suspected. Cysteine hemoglobin agar is a common medium used for the conversion of *B. dermatitidis*. Media for conversion of coccidioidal species have been described but are not often used. Similarly, inoculation of animals is infrequently employed in clinical laboratories, although this method is effective when used for conversion to the in vivo phase. The recent introduction of molecular probes has considerably simplified the task of definitive identification for these endemic fungi and has eliminated the need to demonstrate both phases of the dimorphic fungi in the laboratory (Reiss, 2000). Rapid deoxyribonucleic acid (DNA) probe tests, which utilize the technique of nucleic acid hybridization, are available for the identification of the three major dimorphic pathogens from culture (e.g., AccuProbe, GenProbe, Inc., San Diego). Although demonstration of the characteristic yeast or yeast-like phase in tissue strongly supports the diagnosis of a dimorphic fungus, identification of the pathogen in culture is still necessary for disease confirmation.

DIAGNOSTIC TECHNIQUES

With the increased number of patients undergoing transplantation procedures or receiving aggressive immunosuppression and chemotherapy, the growing population of immunosuppressed hosts has dramatically increased, leading to a subsequent rise in the prevalence of invasive fungal infection (Chandrasekar, 2009). Early recognition of a fungal infection to optimize patient management is becoming more realistic with advances in diagnostic applications for the identification of fungal etiologic agents.

LABORATORY SAFETY

Biosafety considerations from specimen collection through culture conformation in the mycology laboratory are critical (Sutton, 2007). Inoculation of specimens and manipulation of mould colonies should always be performed in a biological safety cabinet to prevent dissemination of the highly mobile fungal conidia. Scrupulous attention to cleaning the surfaces of both the biological safety cabinet and the incubator should be maintained. Separate safety cabinets for the study of isolated moulds may minimize contamination of other clinical samples.

The greatest hazard for laboratory personnel comes from handling mould cultures of the dimorphic pathogens, *Coccidioides* spp. and *H. capsulatum*. These isolates are classified as risk group 3 pathogens, requiring biosafety level 3 practices and facilities for propagating and manipulating cultures, as well as for processing soil or other environmental materials known or likely to contain infectious conidia from these agents (Department of Health and Human Services, 2007). Screw-capped tubes of culture media should be used for culture if these pathogens are suspected. Unfortunately, in most areas of the country, the diagnosis may not be appreciated before the pathogen is isolated (Kwon-Chung, 1992). Culture plates if used can be flooded with 4% formaldehyde solution (10% formalin) and left at room temperature for several hours or overnight to sterilize the culture before microscopic examination is performed. As expected, such a treatment is irreversible, so viable colonies growing on other fungal media should be available as a reserve.

Of special note is that the tissue phase of dimorphic pathogens is not infectious by the airborne route, thus little or no biohazard is involved in handling tissue specimens from patients with blastomycosis, histoplasmosis, or coccidioidomycosis. A possible exception to this rule might occur if a *Coccidioides* spp. grew as a mould within a lung cavity that connected with the bronchial tree, which would allow for in vivo sporulation.

SPECIMEN COLLECTION AND TRANSPORT

The correct specimen for submission to the mycology laboratory depends on the clinical presentation and the organ system affected. A summary of the major categories of diseases produced by fungi along with suggested specimens is presented in Table 61-4.

Yeast, particularly *Candida* spp., may be recovered on occasion from swab specimens, especially from purulent lesions. Swabs may be used for sampling oral or vaginal lesions suggestive of candidiasis and may be adequate for collecting specimens from patients with chronic external otitis, in which large numbers of *Aspergillus* conidia are usually present. However, swabs are decidedly inferior for collecting specimens in most areas of the infectious process. Particularly problematic is that swab fibers

TABLE 61-4

Major Clinical Syndromes and Commonly Associated Fungal Pathogens

Clinical presentation/ organ system	Patient group	Likely pathogens	Specimen(s)
Skin, hair, or nail infection	All	Dermatophytes <i>Candida</i> <i>Malassezia</i>	Skin scraping Hair Nail clipping
Subcutaneous tissue infection	All	<i>Coccidioides</i> <i>Blastomyces dermatitidis</i> <i>Sporothrix schenckii</i>	Lesion biopsy
	Patient with mycetoma	<i>Scedosporium apiospermum</i> <i>Madurella</i> <i>Actinomyces</i>	
Primary pneumonia	All	<i>Histoplasma capsulatum</i> <i>Blastomyces dermatitidis</i> <i>Cryptococcus neoformans</i> <i>Coccidioides</i>	Sputum Bronchoalveolar lavage Transbronchial biopsy Surgical lung biopsy
	Immunodeficient	<i>Aspergillus</i> <i>Fusarium</i> Zygomycetes <i>Scedosporium apiospermum</i> <i>Pneumocystis jiroveci</i>	
Gastrointestinal infection	Immunodeficient	<i>Candida</i> <i>Aspergillus</i> Zygomycetes	Scrapings Curettings Biopsy
Urinary tract infection	All	<i>Candida</i>	Urine
Endocarditis	All	<i>Candida</i> <i>Fusarium</i>	Blood
Meningitis	Immunodeficient	<i>Cryptococcus neoformans</i> <i>Candida</i> <i>Coccidioides</i>	Cerebrospinal fluid
Encephalitis and brain abscess	Immunodeficient	Zygomycetes <i>Aspergillus</i> <i>Cladophialophora bantiana</i>	Brain biopsy
Osteomyelitis	All	<i>Coccidioides</i> <i>Blastomyces dermatitidis</i> <i>Cryptococcus neoformans</i>	Biopsy
Keratitis	All	<i>Aspergillus</i> <i>Fusarium</i>	Scraping
External otitis	All	<i>Aspergillus</i>	Scraping Swab
Sinusitis	All	<i>Aspergillus</i> <i>Fusarium</i>	Biopsy Curettings Dematiaceous moulds
Burn wounds	All	<i>Aspergillus</i> Zygomycetes <i>Fusarium</i> <i>Scedosporium apiospermum</i>	Biopsy
Vaginitis	All	<i>Candida</i>	Vaginal secretions
Intravenous catheter infection	Indwelling catheter	<i>Candida</i> <i>Malassezia</i> (newborns)	Catheter tip Blood
Disseminated infection	All	<i>Histoplasma capsulatum</i> <i>Blastomyces dermatitidis</i> <i>Coccidioides</i>	Blood Tissue biopsy
	Immunodeficient	<i>Candida</i> Zygomycetes <i>Aspergillus</i> <i>Fusarium</i> <i>Scedosporium apiospermum</i> <i>Cryptococcus neoformans</i> Potentially any fungus	Blood Tissue biopsy

TABLE 61-5

KOH Preparation

1. Place one drop of 10% potassium hydroxide (KOH) on a clean glass slide.
2. Immerse an aliquot of the specimen in the drop of KOH on the slide.
3. Gently heat the mixture by passing the slide through a Bunsen burner flame several times. Do not allow the mixture to boil.
4. Coverslip the slide and examine at 100× and 400× magnification using reduced light. Excessively tenacious specimens may require additional heating.
5. KOH may also be used as a simple mounting medium without heating (the addition of lacto phenol [aniline] blue or Calcofluor white stain with the KOH will enhance the visibility of fungal elements).

may be mistaken for hyphal elements upon direct examination of clinical specimens. A policy of rejecting swabs for fungal culture should be accompanied in most cases by assiduous and persistent educational efforts.

The best specimens for mycologic diagnosis are scrapings, curettings, aspirates, and lesion biopsies. Hairs infected with a dermatophytic fungus (e.g., *Microsporum canis*) fluoresce under a long-wavelength ultraviolet light (Wood's lamp) and can be specifically selected for examination. Cutaneous lesions of dermatophytosis (ringworm) are characterized by an active advancing edge with central healing, so that scrapings can be collected from the edge of the process. Hair, nails, and skin scrapings should be sent to the laboratory in a clean dry container. Biopsy samples should be sent in a sterile container with sterile saline or a transport medium to prevent drying of the sample. Most samples can be handled as one would any other samples submitted for bacterial observation and culture.

DIRECT EXAMINATION

Most clinical specimens can be examined directly for the presence of a fungal pathogen, although negative results are not sensitive enough to rule out the presence of a fungus. Multiple techniques are employed for the direct examination of clinical material. As a reminder, multiple manipulations of specimen material in the laboratory may render the material not acceptable for culture, so in those cases where culture is warranted, specimens must be separated before this type of examination is performed.

Wet Preparation

The simplest method for direct examination of a specimen is to observe a suspension placed on a slide and coverslip under reduced light. For those specimens that are dry or viscous, the addition of a wetting agent such as saline is necessary prior to observation. For specimens that contain distracting tissue debris and cells, such as vaginal secretions, nails, and skin scrapings, a solution of potassium hydroxide (KOH) may be used as a means to dissolve the tissue material, so that fungal elements are more visible (Table 61-5).

Gram Stain

This commonly used microbiological stain is particularly useful for the detection of yeast. Most yeasts stain partially or completely gram-positive and are generally differentiated from bacteria by their larger size and by the presence of budding cells (see Fig. 61-5). The hyphae of moulds may appear gram-positive or gram-negative by this stain but may stain less reliably than yeast cells and are easily missed in clinical specimens using this method.

Giemsa or Wright Stain

In cases where histoplasmosis is suspected, these hematologic stains are useful for demonstrating yeast cells within macrophages.

India Ink Preparation

The polysaccharide capsule of *C. neoformans* can be demonstrated by negative staining using India ink particles; it is especially evident when infected cerebrospinal fluid is examined. When examined with the light microscope, the capsule stands out as a clear space around the fungal cell, with ink particles bouncing off the edge as brownian motion occurs (Fig. 61-14). When budding yeast cells are demonstrated along with the capsule in the cerebrospinal fluid of an infected patient, the specificity of the diagnosis of cryptococcal meningitis is ensured. Other potentially encapsulated fungi such as *Rhodotorula* spp. or other cryptococcal species are infrequent pathogens and can be eliminated from practical consideration under this

Figure 61-14 India ink preparation of cerebrospinal fluid containing *Cryptococcus neoformans*. This yeast produces a characteristic polysaccharide capsule around the budding yeast cells. (×400.)

circumstance. Although the capsules usually are large in direct examination of specimens, isolation of the pathogen on agar media is usually characterized by the production of a much diminished capsule, which is not as obvious. Unfortunately, some *C. neoformans* strains are poorly encapsulated; thus, the sensitivity of the India ink test is generally less than 50%, and the organism is especially evident in patients who are not infected with the human immunodeficiency virus (HIV). However, direct detection of antigen in cerebrospinal fluid or serum using a latex agglutination or enzyme immunoassay technique has increased the sensitivity to close to 100%. These techniques basically have replaced the use of India ink as a direct diagnostic technique, although the India ink technique is still useful when the antigen test is not immediately available and for examination of capsules in cells from isolated colonies that suggest *C. neoformans*.

Histopathologic Stains

Surgical pathologic examination of biopsy material is a common practice for the identification of suspected fungal infection. A number of stains have proved useful in recognizing fungal elements in tissue and in showing the immunologic response to infection. The periodic acid-Schiff (PAS) method is useful for demonstrating internal details. Gomori's methenamine silver (GMS) technique is considered one of the better stains for demonstrating fungi because it provides high contrast with minimal background staining, thus allowing for the demonstration of sparsely present fungal elements in the sample. The hematoxylin and eosin (H&E) stain is best used for studying the host reaction and for determining whether a fungus is hyaline (colorless) or dematiaceous (naturally pigmented). Other more specialized stains include Mayer's mucicarmine stain for demonstration of the mucoid capsule of *C. neoformans* and the Fontana-Masson stain for demonstration of melanin or melanin-like substances in the lightly pigmented agents of phaeohyphomycosis. A book by Chandler and Kaplan provides greater detail on the utilization of stains to detect fungi in tissue (Chandler, 1987a).

Calcofluor White Stain

This fluorochrome compound, a whitener used in the textile and paper industries, binds to the chitin in the walls of fungal cells and fluoresces white (Fig. 61-15) or apple green (depending on the filter combination used) when exposed to short-wavelength ultraviolet light from a fluorescence microscope (Table 61-6) (Hageage, 1984). Calcofluor white can also be mixed with potassium hydroxide to clear the specimen for easier observation of fungi. As is true with all fluorescent staining, care must be used in interpreting the results because nonspecific staining of substances that resemble fungal elements may also occur.

Immunohistochemical Stains

Immunohistochemistry has been used to identify a wide variety of infectious agents, including the fungi, in formalin-fixed tissues (Eyzaguirre, 2008). Although many fungi can be readily identified by standard histologic staining, some fungal elements appear atypical in tissue sections and in some cases cannot be distinguished morphologically. Commercial antibodies used in the immunohistochemical diagnosis of fungal infections are available for *Aspergillus* spp., *Candida albicans*, and *Pneumocystis jirovecii*.

Figure 61-15 Calcofluor white stain of *Candida albicans* in culture. When viewed with a fluorescence microscope, the chitinous walls of the fungus will fluoresce. Germ tubes shown are produced following incubation of the yeast in serum. (Courtesy Dr. Brian Harrington, CDC Public Health Image Library.)

TABLE 61-6

Calcofluor White Stain

1. Place specimen on a clean glass slide.
2. Mix with Calcofluor white reagent.
3. Using a fluorescent microscope, examine the preparation for fungal elements at 100× to 400× magnification (will typically appear bluish white against a dark background). (Calcofluor white may be substituted for lacto phenol [aniline] blue stain when microscopic morphology of culture isolates is studied.)

ISOLATION IN CULTURE

Selection of Media

All specimens should be inoculated onto a general purpose fungal growth medium (see Table 61-3). The medium used traditionally is Sabouraud dextrose agar, which has a pH of 5.5–5.6 and was designed for the isolation of dermatophytic fungi. Emmons' modification of Sabouraud dextrose agar, which contains less glucose with a pH of 6.8–7.0, is more widely used in the clinical mycology laboratory as a general growth medium because of its wide application for the culture of fungi. Inhibitory mould agar and potato dextrose agar are also utilized as general isolation media in the laboratory.

For specimens from nonsterile sites or from sites that are likely to be contaminated with other microbial flora, inoculation of a nonselective agar and a selective agar in tandem is recommended. The most commonly used selective agar employs cycloheximide to inhibit saprophytic fungi and an antibacterial agent (usually chloramphenicol or gentamicin) to inhibit bacteria. For tissue specimens, especially when dimorphic fungi might be the etiologic agent, an enriched agar, such as brain-heart infusion agar with blood and supplemented with antibiotics may be added.
